Volume 1 – Table of Contents xxv
Volume 2 – Table of Contents xxix
Abbreviations xxxiii

Section 1 Head and Neck

1: History 3
Patrick J. Bradley

2: Aetiology of head and neck cancer 17
Pablo H. Montero, Snehal G. Patel and Ian Ganly

3: Epidemiology of head and neck carcinoma 27
Kristen B. Pytynia, Kristina R. Dahlstrom and Erich M. Sturgis

4: Staging of head and neck cancer 35
Nicholas J. Roland

5: The changing face of cancer information 49
Richard Wight

6: Introducing molecular biology of head and neck cancer 55
Nikolina Vlatković and Mark T. Boyd

7: Nasal cavity and paranasal sinus malignancy 73
Cyrus Kerawala, Peter Clarke and Kate Newbold

8: Nasopharyngeal carcinoma 93
Raymond King-Yin Tsang and Dora Lai-Wan Kwong

9: Benign salivary gland tumours 115
Jarrod Homer and Andrew Robson

10: Malignant tumours of the salivary glands 131
Vincent Vander Poorten and Patrick J. Bradley

11: Tumours of the parapharyngeal space 157
Suren Krishnan

12: Oral cavity tumours including lip reconstruction 171
Tim Martin and Omar A. Ahmed

13: Oropharyngeal tumours 207
Terry M. Jones and Mererid Evans

14: Tumours of the larynx 237
Vinidh Paleri, Stuart Winter, Hannah Fox and Nachi Palaniappan

15: Rehabilitation after total laryngectomy 263
Yvonne Edels and Peter Clarke

16: Management of hypopharyngeal cancer 273
Prathamesh S. Pai, Deepa Nair, Sarbani Ghosh Laskar and Kumar Prabhash

17: Neck metastases from an unknown primary 295
Ricard Simo, Jean-Pierre Jeannon and Maria Teresa Guerrero Urbano

18: Metastatic neck disease 305
Vinidh Paleri and James O'Hara

19: Principles and practice of radiotherapy in head and neck cancer 335
Sara Meade and Andrew Hartley

20: Quality of life and survivorship in head and neck cancer 343
Simon Rogers and Steven Thomas

21: Palliative care for head and neck cancer 361
Catriona R. Mayland and John E. Ellershaw

22: Transoral laser microsurgery 369
Mark Sayles, Stephanie L. Koonce, Michael L. Hinni and David G. Grant

23: Anatomy as applied to transoral surgery 383
Mark Puvanendran and Andrew Harris

24: Principles of chemotherapy 393
Charles G. Kelly

25: Cysts and tumours of the bony facial skeleton 399
Julia A. Woolgar and Gillian L. Hall

26: Head and neck pathology 423
Ram Moorthy, Adrian T. Warfield and Max Robinson

27: Open conservation surgery for laryngeal cancer 449
Volkert Wreesmann, Jatin Shah and Ian Ganly

28: Measures of treatment outcomes 461
Helen Cocks, Raghav C. Dwivedi and Aoife M.I. Waters

29: Applications of robotics in head and neck practice 473
Chris Holsinger, Chafeek Tomeh and Eric M. Genden

30: Biologically targeted agents in head and neck cancers 483
Kevin J. Harrington and Magnus T. Dillon

31: Prosthetic management of surgically acquired oral and facial defects 499
Chris Butterworth

32: Multidisciplinary team working 509
Andrew Davies, Nigel Beasley and David Hamilton

33: Nutritional considerations 517
Rachael Donnelly, Susannah E. Penney, Siân Lewis, Lesley Freeman and Pippa Mather

34: Speech voice and swallow rehabilitation after chemoradiation 531
Justin W.G. Roe and Katherine A. Hutcheson

35: Surgical anatomy of the neck 541
Laura Warner, Christopher Jennings and John C. Watkinson

36: Clinical examination of the neck 565
James O'Hara

37: Imaging of the neck 569
Ivan Zammit-Maempel

38: Neck trauma 597
Andrew J. Nicol and Johannes J. Fagan

39: Benign neck disease 607
Ricard Simo, Jean-Pierre Jeannon and Enyinnaya Ofo

40: Neck space infections 623
James W. Moor

41: Anatomy and embryology of the mouth and dentition 633
Barry K.B. Berkovitz

42: Benign oral and dental disease 657
Konrad S. Staines and Alexander Crighton

43: Salivary gland anatomy 677
Stuart Winter and Brian Fish

44: Physiology of the salivary glands 683
Mriganke De and T. Singh

45: Imaging of the salivary glands 691
Daren Gibson and Steve Colley

46: Non-neoplastic salivary gland diseases 709
Stephen R. Porter, Stefano Fedele and Valeria Mercadante

47: Anatomy of the pharynx and oesophagus 737
Joanna Matthan and Vinidh Paleri

48: Physiology of swallowing 757
Joanne M. Patterson and Stephen McHanwell

49: Causes and assessment of dysphagia and aspiration 769
Helen Cocks and Jemy Jose

50: Functional investigations of the upper gastrointestinal tract 781
Joanne M. Patterson and Jason Powell

51: Pharyngitis 791
Sharan Jayaram and Conor Marnane

52: Cricopharyngeal dysphagia 811
Nimesh N. Patel and T. Singh

53: Oesophageal diseases 829
Shajahan Wahed and S. Michael Griffin

54: Neurological disease of the pharynx 845
Kim Ah-See and Miles Bannister

55: Rehabilitation of swallowing disorders 851
Maggie-Lee Huckabee and Sebastian Doeltgen

56: Chronic aspiration 859
Guri S. Sandhu and Khalid Ghufoor

57: Temporomandibular joint disorders 871
Andrew J. Sidebottom

58: Anatomy of the larynx and tracheobronchial tree 883
Nimesh N. Patel and Shane Lester

59: Physiology of the larynx 897
Lesley Mathieson and Paul Carding

60: Voice and speech production 905
Paul Carding and Lesley Mathieson

61: Assessment and examination of the larynx 911
Jean-Pierre Jeannon and Enyinnaya Ofo

62: Evaluation of the voice 925
Julian A. McGlashan

63: Structural disorders of the vocal cords 943
Yakubu Gadzama Karagama and Julian A. McGlashan

64: Functional disorders of the voice 963
Paul Carding

65: The professional voice 969
Declan Costello and Meredydd Harries

66: Speech and language therapy for voice disorders 973
Marianne E. Bos-Clark and Paul Carding

67: Phonosurgery 981
Abie Mendelsohn and Marc Remacle

68: Movement disorders of the larynx 995
Declan Costello and John S. Rubin

69: Acute infections of the larynx 1003
Sanjai Sood, Karan Kapoor and Richard Oakley

70: Chronic laryngitis 1011
Kenneth MacKenzie

71: Contemporary management of laryngotracheal trauma 1023
Carsten E. Palme, Malcolm A. Buchanan, Shruti Jyothi, Faruque Riffat, Ralph W. Gilbert and Patrick Gullane

72: Upper airway obstruction and tracheostomy 1037
Paul Pracy and Peter Conboy

73: Physiology of sleep and sleep disorders 1049
John O'Reilly

74: Obstructive sleep apnoea: Medical management 1061
Dev Banerjee

75: The surgical management of snoring and obstructive sleep apnoea..... 1071
Bhik Kotecha and Mohamed Reda Elbadawey

76: Laryngotracheal stenosis in adults 1081
Guri S. Sandhu and Reza Nouraei

77: Reflux disease..... 1093
Mark G. Watson and Kim Ah-See

78: Paralysis of the larynx..... 1101
Lucian Sulica and Babak Sadoughi

79: Outpatient laryngeal procedures..... 1111
Matthew Stephen Broadhurst

Section 2 Plastic Surgery

80: Rhinoplasty following nasal trauma..... 1127
Charles East

81: Pre-operative assessment for rhinoplasty 1133
Hesham Saleh and Catherine Rennie

82: External rhinoplasty 1143
Santdeep Paun

83: Revision rhinoplasty..... 1161
Claudia Rudack and Gerhard Rettinger

84: Aesthetic dorsal reduction rhinoplasty 1169
Julian M. Rowe-Jones

85: Nasal reconstruction..... 1177
Ullas Raghavan

86: Pinnaplasty 1193
Victoria Harries and Simon Watts

87: Blepharoplasty..... 1199
Brian Leatherbarrow

88: Surgical rejuvenation of the ageing face..... 1235
Gregory S. Dibelius, John M. Hilinski and Dean M. Toriumi

89: Non-surgical rejuvenation of the ageing face 1247
Lydia Badia, Peter Andrews and Sajjad Rajpar

90: History of reconstructive surgery..... 1255
Ralph W. Gilbert and John C. Watkinson

91: Grafts and local flaps in head and neck cancer 1261
Kenneth Kok and Nicholas White

92: Pedicled flaps in head and neck reconstruction..... 1283
Ralph W. Gilbert and John C. Watkinson

93: Reconstructive microsurgery in head and neck surgery 1299
John C. Watkinson and Ralph W. Gilbert

94: Benign and malignant conditions of the skin..... 1321
Murtaza Khan and Agustin Martin-Clavijo

95: Facial reanimation surgery..... 1337
Demetrius Evriviades and Nicholas White

96: Partial and total ear reconstruction..... 1345
Cher Bing Chuo

97: A combined prosthetic and surgical approach 1357
Hitesh Koria, M. Stephen Dover and Steve Worrollo

Index 1373

Contributors

Kim W Ah-See MD FRCS FRCS(ORL–HNS)
Professor and Consultant ENT Head and Neck Surgeon
Department of Otolaryngology Head and Neck Surgery
Aberdeen Royal Infirmary
Aberdeen, UK.

Omar A Ahmed FRCSEd(Plast)
Consultant Plastic, Reconstructive, and Head & Neck Surgeon
Newcastle-upon-Tyne Hospitals NHS Trust
Newcastle-upon-Tyne, UK.

Peter Andrews FRCS(ORL–HNS)
Consultant ENT Surgeon
Royal National Throat, Nose and Ear Hospital
London, UK.

Miles Bannister BSc(Hons) MBChB(Hons) DOHNS FRCS(ORL-HNS)
Specialist Registrar
Aberdeen Royal Infirmary
Aberdeen, UK.

Lydia Badia FRCS(ORL–HNS)
Consultant ENT Surgeon
Harley Street
London, UK.

Dev Banerjee MBChB BSc(Hons) MD FRCP FRACP
Consultant Sleep Physician
Woolcock Institute of Medical Research
University of Sydney; and

Central Manchester University Hospitals NHS Foundation Trust
Manchester Royal Infirmary
Manchester, UK.

David Hamilton FRCS(ORL-HNS)
Consultant Otorhinolaryngologist, Head and Neck Surgeon
Freeman Hospital
Newcastle-upon-Tyne, UK.

Meredydd Harries FRCS MSc
Consultant Laryngologist
Brighton NHS Trust
Brighton, UK.

Victoria Harries MBBS MRCS(ENT)
Specialist ENT Registrar
Bristol Royal Infirmary
Severn Deanery
Bristol, UK.

Kevin J Harrington PhD FRCP FRCR
Professor of Biological Cancer Therapies
Team Leader, Targeted Therapy Team
The Institute of Cancer Research
London, UK.

Andrew Harris PhD FRCS(ORL-HNS)
ENT/Head and Neck & Reconstructive Surgeon
Bradford Teaching Hospitals NHS Foundation Trust
Bradford, UK.

Andrew Hartley MRCP FRCR
Consultant Clinical Oncologist
Queen Elizabeth Hospital
Birmingham, UK.

John M Hilinski MD
Consultant Facial Plastic Surgeon
San Diego, California, USA.

Michael L Hinni MD
Department of Otolaryngology–Head & Neck Surgery
Mayo Clinic
Phoenix, Arizona, USA.

Chris Holsinger MD
Professor and Chief of Head and Neck Surgery
Stanford University Medical Center
Stanford, USA.

Jarrod Homer BMedSci(Hons) BMBS FRCS FRCS(ORL-HNS) MD
Consultant Head and Neck Surgeon/Otolaryngologist
Manchester Head and Neck Centre
Manchester Royal Infirmary
Manchester University NHS Foundation Trust
Manchester, UK.

Maggie-Lee Huckabee PhD
Professor, Department of Communication Disorders
The University of Canterbury; and
Director, the Rose Centre for Stroke Recovery
and Research at St Georges Medical Centre
Christchurch, New Zealand.

Katherine A Hutcheson PhD
Associate Professor
Department of Head & Neck Surgery
Section of Speech Pathology and Audiology
The University of Texas MD Anderson Cancer Center
Houston, Texas, USA.

Sharan Jayaram FRCS(ORL–HNS) MS DNB
Consultant Otolaryngologist Head & Neck Surgeon
North Manchester General Hospital
Pennine Acute Hospitals NHS Trust; and
Honorary Senior Lecturer
Edge Hill University
Lancashire, UK.

Jean-Pierre Jeannon FRCS(ORL-HNS)
Consultant Otolaryngologist Head & Neck Surgeon
Clinical Director of Surgical Oncology
Guy's & St Thomas NHS Hospital; and
Associate Professor/Reader
Guy's, King's and St Thomas' Medical and Dental School
London, UK.

Christopher Jennings FRCS
Consultant ENT Surgeon
University Hospitals Birmingham
Birmingham, UK.

Terry M Jones BSc FRCS(Ed) FRCS(ORL-HNS) MD SFHEA FASE(RCS) FAcadTM
Professor of Head and Neck Surgery
Department of Molecular and Clinical Cancer Medicine,
University of Liverpool, UK; and
Honorary Consultant Otolaryngologist/Head and Neck Surgeon
Aintree University Hospitals NHS Foundation Trust
Liverpool, UK.

Jemy Jose MS FRCS(ORL-HNS)
Consultant Otolaryngologist Head and Neck Surgeon
Hull and East Yorkshire Hospitals NHS Trust
Hull, UK.

Shruti Jyothi BSc MBBS
Specialist Registrar Otolaryngology
Royal North Shore Hospital
St Leonards
New South Wales, Australia.

Yakubu Gadzama Karagama DLO MSc Voice Research FRCS (ORL & HN) PGCertMed
Consultant ENT Surgeon & Laryngologist; and
Honorary Senior Lecturer
University of Manchester; and
Honorary Senior Lecturer
Edge Hill University; and
Honorary Fellow
Royal Northern College of Music Manchester
Department of Otolaryngology–Head & Neck Surgery
Manchester University Hospital NHS Foundation Trust
Manchester, UK.

Karan Kapoor FRCS
Head & Neck Fellow
Guy's and St Thomas' Hospitals
London, UK.

Charles G Kelly MSc FRCP FRCR FBIR DMRT
Consultant Clinical Oncologist
Northern Centre for Cancer Care
Newcastle-upon-Tyne, UK.

Cyrus Kerawala FDSRCS FRCS
Consultant Maxillofacial/Head and Neck Surgeon
Head and Neck Unit
The Royal Marsden Hospital
London, UK.

Murtaza A Khan MBBS MRCP(UK) MRCP Dermatology
Consultant Dermatologist
Mediclinic Al Noor Hospital
Abu Dhabi, UAE.

Raymond King-Yin Tsang MBChC FRCSEd FHKCORL FHKAM
Clinical Assistant Professor
Division of Otorhinolaryngology and Division of Head and Neck Surgery
Department of Surgery
The University of Hong Kong; and
Queen Mary Hospital, Hong Kong
Chief of ENT
University of Hong Kong-Shenzhen
People's Republic of China.

Kenneth Kok MBChB MRCS MSc(Hons) FRCS(Plast)
Consultant Plastic & Reconstructive Surgeon
Queen Elizabeth Medical Centre University Hospital
Birmingham NHS Trust
Birmingham, UK.

Stephanie L Koonce MD
Department of General Surgery
Mayo Clinic
Jacksonville, Florida, USA.

Hitesh Koria BSc(Hons) PDip(Maxfac) PDip(Ortho) MIMPT
Principal Maxillofacial Prosthetist
Department of Maxillofacial Surgery

Consultant Radiologist
Newcastle-upon-Tyne Hospitals NHS Foundation Trust
Newcastle-upon-Tyne, UK.

Foreword

The eighth edition of *Scott-Brown* signals the beginning of a new and exciting era for ear, nose and throat surgeons, and also the end of 10 years of very hard work undertaken by John Watkinson and Ray Clarke, the Editors-in-Chief, their team of subeditors and, not least, the publishers. Whatever subspeciality the current generation of trainees decides to follow, they will all have to read and refer to *Scott-Brown* in order to complete their education and gain accreditation. It will be a constant companion and guide throughout their professional lives.

When asked to write the foreword for this edition, I was immediately reminded that I had read John Ballantyne and John Groves's third edition as a trainee, bought the fourth edition as a senior registrar, written chapters for Alan Kerr and Philip Stell in the fifth edition, edited the *Basic science* volume of the fifth edition and was ultimately Editor-in-Chief of the seventh edition. As each edition takes about 10 years to produce, that makes me very old indeed. John and Ray have one final task as Editors-in-Chief: to recommend their successors to the publishers. That was made easy for me as both of them had proved themselves more than capable with the previous edition, and the eighth edition is now their masterpiece. They can enjoy the next 10 years as thousands of surgeons worldwide recognize and thank them for their industry.

This edition reflects the continued expansion of our speciality into fields that Scott-Brown himself could never have imagined. It lays the groundwork for the current generation to make their contribution that will, no doubt, be prompted by technological developments, an evidence base of what is wise and what is not, together with the experience gained by teamwork with other clinicians in today's multidisciplinary approach to patient care.

Simply looking at the table of contents it is clear to see that our role in endocrine surgery has increased dramatically over the last 10 years. The thyroid and parathyroids now account for 30 chapters. How would Scott-Brown have viewed that when the tonsils and adenoids justify just one chapter each, and the sore throat has a mere passing reference? Times have certainly changed and ENT surgery has grown up. We have reflected on our past practices, and the evidence base for our management protocols that was emphasized in the previous edition of *Scott-Brown* has been taken to heart.

I hope that this edition will find its way into every medical library in the world and onto every ENT surgeon's bookshelf. It will serve and guide surgeons throughout the English-speaking world, whether they live in high- or low-income countries. It is said that the tragedy of getting old is that we feel young. Reading these volumes makes me wish that I had my time all over again.

Michael Gleeson

Preface

When we were asked to head up the editorial team for this, the eighth edition of *Scott-Brown*, we were mindful of Michael Gleeson's towering achievement in bringing the seventh edition to fruition. Michael delivered a much-loved text – conceived in the early post-war years when antimicrobials, the operating microscope and the National Health Service were all in their infancy – in an entirely new format that befitted modern surgical scholarship. Authors, editors and readers alike had become acutely conscious of the need to quote high-quality evidence to guide clinical decisions; the concept of grading clinical recommendations – and, by implication, acknowledging gaps in the evidence base of our practice – was born. Recognizing the enormity of Michael's contribution led us into the trap that has befallen every editor who has come before us; we grossly underestimated the task ahead. We had misjudged the pace of change. What began as an 'update' of some outdated chapters became a complete rewrite to reflect the advances that marked the decade between editions, but we were determined to keep the text to a manageable size. In the end, we have 330 chapters, but with a slightly smaller page count than the seventh edition.

The basic science knowledge that underpins our clinical practice is no longer focused just on anatomy and physiology; genetics, molecular biology, new techniques for auditory implantation, information technology, new medical therapies for many old disorders together with seismic changes in endoscopic technology and in medical imaging have transformed our specialty. Today's head and neck surgery would have been unrecognizable to the early authors and editors. Surgical oncologists have recourse to completely different treatment strategies than did their predecessors and now work as part of multidisciplinary teams. They deal with different disease patterns and vastly changed patient expectations. Thyroid and parathyroid surgery has become almost exclusively the domain of the otolaryngologist. Surgery of the pituitary fossa has come within our ambit, as has plastic and reconstructive surgery of the head and neck as well as aesthetic facial surgery. Neurotology, audio-vestibular medicine, rhinology and paediatric otolaryngology are accepted subspecialties, each with its own corpus of knowledge and skills and each warranting a sizeable section of this text. Contemporary otolaryngology is now a collection of subspecialty interests linked by common 'stem' training and a shared passion for looking after patients with disorders of the upper respiratory tract and the head and neck.

There is a view that a single text – even a multivolume tome of this size – cannot cover the entire knowledge base of modern clinical practice. The subspecialist will, of course, need recourse to supplementary reading. The pace of change shows no sign of slowing down, but there is still a need for a comprehensive working text embracing the whole spectrum of our workload. That was the task we set our authors and section editors; we think they have done our specialty proud.

In the new 'digital' editorial world authors create manuscripts on personal computers. They transmit chapters, figures, amendments and revisions across continents and time zones with a few keystrokes. The bulky packages containing grainy photographic prints and the reams of paper with closely-typed and heavily scored text that accumulated on authors' and editors' desks are a distant memory. References, guidelines and systematic reviews are all available online; the editorial 'red pen' has been replaced by a cursor on the screen. This 'new age' has enabled us to look ever further for expertise. We are proud to have enlisted the support of authors from more than 20 countries for this edition. *Scott-Brown* always enjoyed particular affection and respect in Asia, Australia, Africa and the Middle East. It has been a joy to welcome authors in increasing numbers from many of these parts of the world. We are now a truly global specialty and the eighth edition fully reflects this.

What has not changed is the huge time commitment authors and editors need to make. That time now has to be fitted into an increasingly pressurized work environment. Revalidation, mandatory training, more intense regulatory scrutiny, expanding administrative burdens and ever-expanding clinical commitments leave little time for scholarship. Our section editors are all busy clinicians. They have generously given their time, first instructing authors, cajoling them and then editing their chapters, virtually all of which have been completely rewritten since the last edition. Each author was chosen because of his or her specific clinical and scientific expertise and none has disappointed. Authors and section editors receive no reward other than the satisfaction of knowing that they have made a contribution to teaching and learning in a specialty that has given us all so much professional satisfaction. We are profoundly grateful to them and hope that their endeavours spur the next generation of otolaryngologists to carry on this noble tradition. *Scott-Brown* simply wouldn't happen without this generous and dedicated commitment, unstintingly and graciously given.

It is impossible to produce a book like *Scott-Brown* without the contribution of many individuals working behind the scenes. We would like to express our gratitude to our Publishers, Taylor and Francis, and to the staff who have worked on this project from its early days in 2011 to publication in 2018. In particular we would like to mention Cheryl Brandt who with good humour and patience helped to reel in many of the 330 chapters. Miranda Bromage joined the team in 2016 and her publishing experience and enthusiasm for medical education have helped guide this new edition through its final phases to publication. Finally, we are indebted to Nora Naughton who has dedicated so much more than just her extensive publishing skills to this project. Nora's meticulous attention to detail, combined with her warmth and wisdom have encouraged us all at the end of this endeavour.

We are truly 'passing on the torch' of a huge amount of accumulated knowledge and wisdom; it is this that gives us, the Editors-in-Chief, the greatest pleasure.

Read on and enjoy, our thoughts are yours.

RWC
JCW

I wish to acknowledge the love, happiness and inspiration that have been passed on to me by both my parents and grandparents. I recognise and value the friendship of my dear friend Ray Clarke who has been with me all the way on this rewarding and worthwhile endeavour. I would specifically like to thank Esme, Helen and William, without whom none of this would have been achievable. Their love and support has helped guide me through the years leading up to the publication of this tome, and my final thanks go to Angela Roberts and Sally Holden for their typing and editing skills.

JCW 2018

Thanks to my wife Mary for her patience and support. My parents, Emmet and Doreen Clarke, both sadly died during the preparation of this book. They would have been proud to have played a part in such a scholarly enterprise.

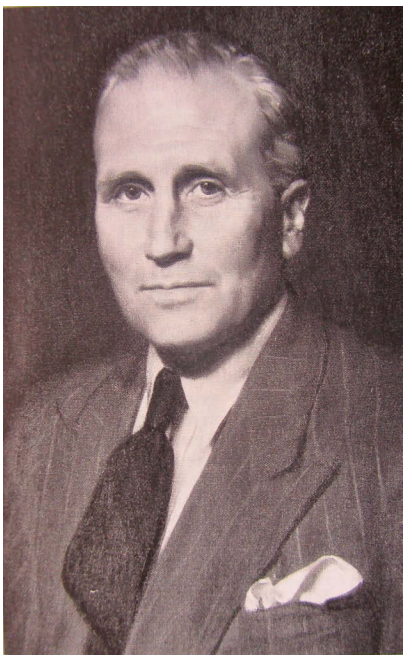
A Tribute to Bill Scott-Brown



Walter Graham ('Bill') Scott Brown. 1897–1987

Walter Graham ('Bill') Scott-Brown was twenty-three when he arrived at Corpus Christi College Cambridge in 1919. One of the generation of young men whose entry to university and the professions was delayed by their participation in the First World War, he had joined the Gunners in 1915 as an 18-year-old. He considered himself blessed to have survived – although wounded – when so many of his contemporaries never returned from the Front. In those early post-WW1 years the medical school at St Bartholomew's ('Barts') in London was keen to attract 'gentlemen'. To this end a series of scholarships – 'Shuter's scholarships' – was established to lure those with humanities degrees from Oxford and Cambridge into medicine. It was via this scheme that the young Scott-Brown qualified MB, BCh in 1925. By now married to Margaret Bannerman, one of the very few women medical graduates of her generation, the two established a general practice in Sevenoaks, Kent. His work here involved looking after children with poliomyelitis, which was then commonplace, and his MD thesis was on polio-related bulbar palsy. It earned him the Copeman Medal for research from the University of Cambridge. While working in general practice, Bill pursued his interest in the then fledgling specialty of otolaryngology, securing fellowships from London and Edinburgh. Postgraduate training was haphazard; there were no structured programmes or even junior posts, so the young Scott-Brown was fortunate to be awarded a Dorothy Temple Cross Travelling Fellowship. Mrs Florence Temple Cross had set up these awards (now administered by the Medical Research Council) in memory of her daughter, who died in 1927 aged thirty-two. They were made available to young physicians to help them travel to overseas centres specifically to study tuberculosis, then rampant and one of the commonest causes of death in young adults. The young Scott-Brown visited the leading pioneers of the day in Berlin, Vienna, Budapest, Stockholm, Copenhagen, Madrid and Venice. Here he developed his considerable endoscopy skills. He reported that his first bronchoscopies were done on a Venetian street entertainer who, for a few coins, would inhale sundry objects that the doctors would then dexterously retrieve from his main stem and segmental bronchi – without of course any anaesthesia!

Times were lean on Scott-Brown's return. Margaret ('Peggy') was now a popular and well-established GP who supported him as his private practice developed. Eventually he secured appointments at East Grinstead, the Royal National and Royal Free Hospitals. He had a thriving Harley Street practice and was the favoured otolaryngologist of the aristocracy. His reputation was such that he become laryngologist to the Royal family, was appointed Commander of the Victorian Order and was a particular favourite of the then Princess Royal, HRH Mary the Countess of Harewood.

By 1938 he was wealthy enough to purchase a farm in Buckinghamshire where he bred prize-winning shorthorn cattle. Ironmongery and blacksmith work were hard to come by during the war years, so Scott-Brown prided himself on his ability to make his own agricultural implements, cartwheels and farm wagons in a makeshift forge he himself established on the farm. He would while away endless hours here at weekends following a busy week in London. An accomplished fly fisherman, he was part of the exclusive Houghton Club whose members fished the River Test in Hampshire, where he numbered aristocrats including the Prince of Wales among his circle.

Scott-Brown's celebrated textbook came about in the early 1950s, when he became ill with jaundice and heart trouble. He was advised to rest, and took 6 months off work. Not satisfied with editing what has become the standard UK textbook, he took up painting as well. He became a celebrated artist whose work is still prized in many private collections. One of his pastels is reproduced on the preceding page.

Bill Scott-Brown lived to be 90. He died in July 1987, six weeks after his beloved Peggy and just as the fifth edition of the celebrated textbook that still bears his name was going to press. His legacy lives on in the pages of this book, and we are proud to continue the tradition of scholarship and learning which he established all those years ago.

We would like to thank Martin Scott-Brown for his help in compiling the biography above.

John C. Watkinson and Raymond W. Clarke
London, 2018

Acknowledgements

We acknowledge our debt of gratitude to the many authors who have contributed to previous editions of Scott-Brown's Otorhinolaryngology, and in particular to authors from the seventh edition, published in 2008. We are also grateful to Neil Bateman who helped with the initial planning of the Paediatrics section.

Chapter 7, Nasal cavity and paranasal sinus malignancy, contains some material from 'Nasal cavity and paranasal sinus malignancy' by Brent A McMonagle and Michael Gleeson. The material has been revised and updated by the current authors.

Chapter 42, Benign oral and dental disease, contains some material from 'Benign oral and dental disease' by Crispian Scully and Jose-V Sebastian Bagan. The material has been revised and updated by the current authors.

Chapter 48, Physiology of swallowing, contains some material from 'Physiology of swallowing' by Paula Leslie and Stephen McHanwell. The material has been revised and updated by the current authors.

Chapter 50, Functional investigations of the upper gastrointestinal tract, contains some material from 'Functional investigations of the upper gastrointestinal tract' by Lisa J Hirst. The material has been revised and updated by the current authors.

Chapter 58, Anatomy of the larynx and tracheobronchial tree, contains some material from 'Anatomy of the larynx and tracheobronchial tree' by Nigel Beasley. The material has been revised and updated by the current authors.

Chapter 61, Assessment and examination of the larynx, contains some material from 'Assessment and examination of the upper respiratory tract' by Jean-Pierre Jeannon and Marcelle Macnamara. The material has been revised and updated by the current authors.

Chapter 63, Structural disorders of the vocal chords, contains some material from 'Disorders of the voice' Julian McGlashan. The material has been revised and updated by the current authors.

Chapter 67, Phonosurgery, contains some material from 'Phonosurgery' Meredydd Harries. The material has been revised and updated by the current authors.

Volume 1 – Table of Contents

Section 1 Basic Sciences

Cell biology

1: Molecular biology
Michael Kuo, Richard M. Irving and Eric K. Parkinson

2: Genetics in otology and neurotology
Mohammed-Iqbal Syed

3: Gene therapy
Seiji B. Shibata and Scott M. Graham

4: Mechanisms of anticancer drugs
Sarah Payne and David Miles

5: Radiotherapy and radiosensitizers
Christopher D. Scrase, Stewart G. Martin and David A.L. Morgan

6: Apoptosis and cell death
Angela Hague

7: Stem cells
Navin Vig and Ian C. Mackenzie

8: Aetiology and pathogenesis of goitre
Neil Sharma and Kristien Boelaert

9: Genetics of endocrine tumours
Waseem Ahmed, Prata Upasna and Dae Kim

Wound healing

10: Soft and hard tissue repair
Sarah Al-Himdani and Ardeshir Bayat

11: Skin flap physiology
Colin MacIver and Stergios Doumas

12: Biomaterials, tissue engineering and their application in the oral and maxillofacial region
Kurt Busuttil Naudi and Ashraf Ayoub

Immunology

13: Defence mechanisms
Ian Todd and Richard J. Powell

14: Allergy: Basic mechanisms and tests
Sai H.K. Murng

15: Evaluation of the immune system
Moira Thomas, Elizabeth Drewe and Richard J. Powell

16: Cancer immunology
Osama Al Hamarneh and John Greenman

17: Human papillomavirus
Mustaffa Junaid and Hisham M. Mehanna

18: Connective tissue diseases: ENT complications
Eileen Baildam

Microbiology

19: Microorganisms
Ursula Altmeyer, Penelope Redding and Nitish Khanna

20: Viruses and antiviral agents
Richard B. Townsley, Camille A. Huser and Chris Hansell

21: Fungal infections
Emily Young, Yujay Ramakrishnan, Laura Jackson and Shahzada K. Ahmed

22: Antimicrobial therapy
Ursula Altmeyer, Penelope Redding and Nitish Khanna

23: Human immunodeficiency virus
Neil Ritchie and Alasdair Robertson

Haematology

24: Blood groups, blood components and alternatives to transfusion
Samah Alimam, Kate Pendry and Michael F. Murphy

25: Haemato-oncology
Robert F. Wynn and Mark Williams

26: Haemostasis: Normal physiology, disorders of haemostasis and thrombosis
Elizabeth Jones and Russell David Keenan

Pharmacotherapeutics

27: Drug therapy in otology
Wendy Smith

28: Drug therapy in rhinology
Wendy Smith

29: Drug therapy in laryngology and head and neck surgery
Wendy Smith and Rogan Corbridge

Perioperative management

30: Preparation of the patient for surgery
Michael Murray and Urmila Ratnasabapathy

31: Recognition and management of the difficult airway
Valerie Cunningham and Alistair McNarry

32: Adult anaesthesia
Daphne A. Varveris and Neil G. Smart

33: Adult critical care
Robert I. Docking and Andrew Mackay

34: Paediatric intensive care
Louise Selby and Robert Ross Russell

Safe and effective practice

35: Training, accreditation and the maintenance of skills
B. Nirmal Kumar, Andrew Robson, Omar Mirza and Baskaran Ranganathan

36: Communication and the medical consultation
Uttam Shiralkar

37: Clinical governance and its role in patient safety and quality improvement
Samit Majumdar and S. Musheer Hussain

38: Medical ethics
Paul Baines

39a: Medical jurisprudence in otorhinolaryngology
Maurice Hawthorne

39b: Medical negligence in otorhinolaryngology
Maurice Hawthorne

40: Non-technical skills for ENT surgeons
Simon Paterson-Brown and Stephen R. Ell

Interpretation and management of data

41: Epidemiology
Jan H.P. van der Meulen, David A. Lowe and Jonathan M. Fishman

42: Outcomes research
Iain R.C. Swan and William Whitmer

43: Evidence-based medicine in medical education and clinical practice
Phillip Evans

44: Critical appraisal skills
Paul Nankivell and Christopher Coulson

Advances in technology

45: Electrophysiology and monitoring
Patrick R. Axon and Bruno M.R. Kenway

46: Optical coherence tomography
Jameel Muzaffar and Jonathan M. Fishman

47: Recent advances in technology
Wai Lup Wong and Bal Sanghera

48: Image-guided surgery, 3D planning and reconstruction
Ghassan Alusi and Michael Gleeson

49: Interventional techniques
James V. Byrne

50: Laser principles in otolaryngology, head and neck surgery
Brian J.G. Bingham

51: Contact endoscopy of the upper aerodigestive tract
Mario Andrea and Oscar Dias

Section 2 Head and Neck Endocrine Surgery

Overview

52: History of thyroid and parathyroid surgery
Waraporn Imruetaicharoenchoke, Ashok R. Shaha and Neil Sharma

53: Developmental anatomy of the thyroid and parathyroid glands
Julian A. McGlashan

54: Developmental anatomy of the pituitary fossa
John Hill and Sean Carrie

55: Physiology of the thyroid and parathyroid glands
Martin O. Weickert

56: Physiology of the pituitary gland
Mária Hérincs, Karen Young and Márta Korbonits

57: Imaging in head and neck endocrine disease
Steve Colley and Sabena Fareedi

58: Thyroid and parathyroid gland pathology
Ram Moorthy, Sonia Kumar and Adrian T. Warfield

Thyroid disease

59: Clinical evaluation of the thyroid patient
Andrew Coatesworth and Sebastian Wallis

60: Investigation of thyroid disease
Anthony P. Weetman

61: Benign thyroid disease
Christopher M. Jones and Kristien Boelaert

62: Management of differentiated thyroid cancer
Hisham M. Mehanna, Kristien Boelaert and Neil Sharma

63: Management of medullary thyroid cancer
Barney Harrison

64: Management of anaplastic thyroid cancer/lymphoma
James D. Brierley and Richard W. Tsang

65: Management of locoregionally recurrent differentiated thyroid cancer
Iain J. Nixon and Ashok R. Shaha

66: Non-surgical management of thyroid cancer
Laura Moss

Thyroid surgery

67: Thyroidectomy
Ricard Simo, Iain J. Nixon and Ralph P. Tufano

68: Surgery for locally advanced and nodal disease
Joel Anthony Smith and John C. Watkinson

69: Minimally invasive and robotic thyroid surgery
Neil S. Tolley

70: Surgery for the enlarged thyroid
Neeraj Sethi, Josh Lodhia and R. James A. England

Parathyroid disease

71: Clinical evaluation of hypercalcaemia
Mo Aye and Thozhukat Sathyapalan

72: Investigation of hyperparathyroidism
M. Shahed Quraishi

73: Management of hyperparathyroidism
Neil J.L. Gittoes and John Ayuk

74: Management of persistent and recurrent hyperparathyroidism
David M. Scott-Coombes

75: Management of parathyroid cancer
Pamela Howson and Mark Sywak

Parathyroid surgery

76: Bilateral parathyroid exploration
R. James A. England and Nick McIvor

77: Minimally invasive parathyroidectomy
Parameswaran Rajeev and Gregory P. Sadler

78: Surgical failure and reoperative surgery
Schelto Kruijff and Leigh Delbridge

Thyroid and parathyroid outcomes

79: Complications of thyroid and parathyroid surgery and how to avoid them
Erin A. Felger, Dipti Kamani and Gregory W. Randolph

80: Thyroid and parathyroid surgery: Audit and outcomes
David Chadwick

81: Medicolegal aspects of head and neck endocrine surgery
Barney Harrison

Pituitary disease

82: Clinical evaluation of the pituitary patient
Sean Carrie, John Hill and Andrew James

83: Investigation of pituitary disease
Thozhukat Sathyapalan and Stephen L. Atkin

84: Primary pituitary disease
Christopher M. Jones and John Ayuk

85: Surgical management of recurrent pituitary tumours
Mihir R. Patel, Leo F.S. Ditzel Filho, Daniel M. Prevedello, Bradley A. Otto and Ricardo L. Carrau

86: Adjuvant treatment of pituitary disease
Andy Levy

Section 3 Rhinology

87: Anatomy of the nose and paranasal sinuses
Dustin M. Dalgorf and Richard J. Harvey

88: Outpatient assessment
Martyn L. Barnes and Paul S. White

89: Physiology of the nose and paranasal sinuses
Tira Galm and Shahzada K. Ahmed

90: Measurement of the nasal airway
Ron Eccles

91: Allergic rhinitis
Quentin Gardiner

92: Non-allergic perennial rhinitis
Jameel Muzaffar and Shahzada K. Ahmed

93: Occupational rhinitis
Hesham Saleh

94: Rhinosinusitis: Definitions, classification and diagnosis
Carl Philpott

95: Nasal polyposis
Louise Melia

96: Fungal rhinosinusitis
Eng Cern Gan and Amin R. Javer

97: Medical management for rhinosinusitis
Claire Hopkins

98: Surgical management of rhinosinusitis
A. Simon Carney and Raymond Sacks

99: The frontal sinus
Salil Nair

100: Mucoceles of the paranasal sinuses
Darlene E. Lubbe

101: Complications of rhinosinusitis
Stephen Ball and Sean Carrie

102: The relationship between the upper and lower respiratory tract
Nigel K.F. Koo Ng and Gerald W. McGarry

103: Nasal septum and nasal valve
Shahram Anari and Ravinder Singh Natt

104: Nasal septal perforations
Charles East and Kevin Kulendra

105: Management of enlarged turbinates
Andrew C. Swift and Samuel C. Leong

106: Epistaxis
Gerald W. McGarry

107: Nasal and facial fractures
Dae Kim and Simon Holmes

108: CSF leaks
Scott M. Graham

109: Granulomatous conditions of the nose
Joanne Rimmer and Valerie J. Lund

110: Abnormalities of smell
Richard L. Doty and Steven M. Bromley

111: Disorders of the orbit
Nithin D. Adappa and James N. Palmer

112: Diagnosis and management of facial pain
Rajiv K. Bhalla and Timothy J. Woolford

113: Juvenile angiofibroma
Bernhard Schick

114: Endoscopic management of sinonasal tumours
Alkis J. Psaltis and David K. Morrissey

115: Surgical management of pituitary and parasellar diseases
Philip G. Chen and Peter-John Wormald

116: Extended anterior skull base approaches
Carl H. Snyderman, Paul A. Gardner, Juan C. Fernandez-Miranda and Eric W. Wang

117: Imaging in rhinology
Gregory O'Neill

Volume 2 – Table of Contents

Section 1 Paediatrics

1: Introduction to paediatric otorhinolaryngology
Raymond W. Clarke

2: The paediatric consultation
Raymond W. Clarke

3: Recognition and management of the sick child
Julian Gaskin, Raymond W. Clarke and Claire Westrope

4: Anaesthesia for paediatric otorhinolaryngology procedures
Crispin Best

5: The child with special needs
Kate Blackmore and Derek Bosman

6: The child with a syndrome
Thushitha Kunanandam and Haytham Kubba

7: Management of the immunodeficient child
Fiona Shackley

8: Hearing screening and surveillance
Sally A. Wood

9: Hearing tests in children
Glynis Parker

10: Management of the hearing impaired child
Chris H. Raine, Sue Archbold, Tony Sirimanna and Soumit Dasgoupta

11: Paediatric implantation otology
James Ramsden and Payal Mukherjee

12: Congenital middle ear abnormalities
Jonathan P. Harcourt

13: Otitis media with effusion
Peter J. Robb and Ian Williamson

14: Acute otitis media
Peter A. Rea and Natalie Ronan

15: Chronic otitis media
William P.L. Hellier

16: Microtia and external ear abnormalities
Iain Bruce and Jaya Nichani

17: Disorders of speech and language
Suzanne Harrigan and Andrew Marshall

18: Cleft lip and palate
David M. Wynne and Louisa Ferguson

19: Craniofacial anomalies
Benjamin Robertson, Sujata De, Astrid Webber and Ajay Sinha

20: Balance disorders in children
Louisa Murdin and Gavin A.J. Morrison

21: Facial paralysis in children
S. Musher Hussain

22: Epistaxis
Mary-Louise Montague and Nicola E. Starritt

23: Neonatal nasal obstruction
Michelle Wyatt

24: Rhinosinusitis and its complications
Daniel J. Tweedie

25: Lacrimal disorders in children
Caroline J. MacEwen and Paul S. White

26: The adenoid and adenoidectomy
Peter J. Robb

27: Paediatric obstructive sleep apnoea
Steven Powell

28: Stridor
Kate Stephenson and David Albert

29: Acute laryngeal infections
Lesley Cochrane

30: Congenital disorders of the larynx, trachea and bronchi
Chris Jephson

31: Acquired laryngotracheal stenosis
Michael J. Rutter, Alessandro de Alarcón and Catherine K. Hart

32: Juvenile-onset recurrent respiratory papillomatosis
Rania Mehanna and Michael Kuo

33: Paediatric voice disorders
Ben Hartley and David M. Wynne

34: Foreign bodies in the ear, nose and throat
Adam J. Donne and Katharine Davies

35: Paediatric tracheostomy
Mike Saunders

36: Perinatal airway management
Pensée Wu, May M.C. Yaneza, Haytham Kubba, W. Andrew Clement and Alan D. Cameron

37: Cervicofacial infections
Nico Jonas and Ben Hartley

38: Diseases of tonsils, tonsillectomy and tonsillotomy
Yogesh Bajaj and Ian Hore

39: Salivary glands
Neil Bateman and Rachael Lawrence

40: Tumours of the head and neck
Fiona McGregor and James Hayden

41: Cysts and sinuses of the head and neck
Keith G. Trimble and Luke McCadden

42: Haemangiomas and vascular malformations
Daniel J. Tweedie and Benjamin E.J. Hartley

43: Drooling and aspiration
Haytham Kubba and Katherine Ong

44: Reflux and eosinophilic oesophagitis
Ravi Thevasagayam

45: Oesophageal disorders
Graham Haddock

Section 2 The Ear

Audio-vestibular medicine

46: Anatomy and embryology of the external and middle ear
Peter Valentine and Tony Wright

47: Anatomy of the cochlear and vestibular system: Relating ultrastructure to function
Jonathan Gale and Andrew Forge

48: Physiology of hearing
Soumit Dasgupta and Michael Maslin

49: Physiology of equilibrium
Floris L. Wuyts, Leen K. Maes and An Boudewyns

50: Perception of sounds at the auditory cortex
Frank E. Musiek and Jane A. Baran

51: Psychoacoustic audiometry
Josephine E. Marriage and Marina Salorio-Corbetto

52: Evoked measurement of auditory sensitivity
Jeffrey Weihing and Nicholas Leahy

53: Prevention of hearing loss
Shankar Rangan and Veronica Kennedy

54: Hearing aids
Harvey Dillon

55: Beyond hearing aids: An overview of audiological rehabilitation
Lucy Handscombe

56: Age-related sensorineural hearing impairment
Linnea Cheung, David M. Baguley and Andrew McCombe

57: Noise-induced hearing loss and related conditions
Andrew McCombe and David M Baguley

58: Autosomal dominant non-syndromic SNHL
Polona Le Quesne Stabej and Maria Bitner-Glindzicz

59: Ototoxicity
Andy Forge

60: Idiopathic sudden sensorineural hearing loss
Tony Narula and Catherine Rennie

61: Tinnitus and hyperacusis
Don McFerran and John Phillips

62: Evaluation of balance
Adolfo M. Bronstein

63: Ménière's disease
Vincent W.F.M. van Rompaey

64: Benign paroxysmal positional vertigo
Yougan Saman and Doris-Eva Bamiou

65: Superior semicircular canal dehiscence
Harry R.F. Powell and Shakeel R. Saeed

66: Vestibular neuritis
Charlotte Agrup

67: Vestibular migraine
Louisa Murdin and Lina Luxon

68: Vestibular rehabilitation
Marousa Pavlou

69: Auditory neuropathy spectrum disorder and retrocochlear disorders in adults and children
Rosalyn A. Davies and Raj Nandi

70: Understanding tinnitus: A psychological perspective
Laurence McKenna, Elizabeth Marks and David Scott

71: Auditory processing disorders across the age span
Doris-Eva Bamiou and Cristina Ferraz B. Murphy

72: Neuropsychiatric aspects of vestibular disorders
Julius Bourke, Georgia Jackson and Gerald Libby

Otology

73: Clinical examination of the ears and hearing
George G. Browning and Peter-John Wormald

74: Furunculosis
Malcolm P. Hilton

75: Myringitis
Samuel A.C. MacKeith

76: Keratosis obturans, primary auditory canal cholesteatoma and benign necrotizing otitis externa
Tristram H.J. Lesser

77: Acquired atresia of the external ear
Jonathan P. Harcourt

78: Otitis externa and otomycosis
Simon Carney

79: Periochondritis of the external ear
James W. Loock

80: Exostosis of the external auditory canal
Phillip J. Robinson and Sophie J. Hollis

81: Osteoradionecrosis of the temporal bone
James W. Loock

82: Acute otitis media and otitis media with effusion in adults
Anil Banerjee

83: Chronic otitis media
George G. Browning, Justin Weir, Gerard Kelly and Iain R.C. Swan

84: Myringoplasty
Charlie Huins and Jeremy Lavy

85: Ossiculoplasty
Daniel Moualed, Alison Hunt and Christopher P. Aldren

86: Eustachian tube dysfunction
Holger H. Sudhoff

87: Otoendoscopy
David A. Bowdler, Annabelle C.K. Leong and David D. Pothier

88: Tuberculosis of the temporal bone
Ameet Kishore

89: Otosclerosis
Christopher P. Aldren, Thanos Bibas, Arnold J.N. Bittermann, George G. Browning, Wilko Grolman, Peter A. Rea, Rinze A. Tange and Inge Wegner

90: Otological effects of Paget's disease
Ian D. Bottrill

91: Ear trauma
Stephen C. Toynton

92: Otalgia
Philip D. Yates

Implantation otology

93: Bone-conduction hearing aids
James Ramsden and Chris H. Raine

94: Cochlear implants
Andrew Marshall and Stephen Broomfield

95: Middle ear implants
Maarten J.F. de Wolf and Richard M. Irving

96: Auditory brainstem implants
Shakeel R. Saeed and Harry R.F. Powell

Section 3 Skull Base

97: Imaging of the temporal bone
Steve Colley

98: Anatomy of the skull base and infratemporal fossa
Charlie Huins

99: Evaluation of the skull base patient
Jeyanthi Kulasegarah and Richard M. Irving

100: Vascular assessment and management
Joe J. Leyon, Kurdow Nader and Swarupsingh Chavda

101: Natural history of vestibular schwannomas
Mirko Tos, Sven-Eric Stangerup and Per Caye-Thomasen

102: Surgical management of vestibular schwannomas
Shakeel R. Saeed and Christopher J. Skilbeck

103: Stereotactic radiosurgery
Paul Sanghera, Geoffrey Heyes, Helen Howard, Rosemary Simmons and Helen Benghiat

104: Neurofibromatosis 2
Gareth Evans

105: Non-vestibular schwannoma tumours of the cerebellopontine angle
Simon K.W. Lloyd and Scott A. Rutherford

106: Middle fossa surgery
Raghu N.S. Kumar, Sunil N. Dutt and Richard M. Irving

107: Jugular foramen lesions and their management
Rupert Obholzer

108: Petrous apex lesions
Michael Gleeson

109: Approaches to the nasopharynx and Eustachian tube
Gunesh P. Rajan

110: Tumours of the temporal bone
Marcus Atlas, Noweed Ahmad and Peter O'Sullivan

111: Clinical neuroanatomy
John J.P. Patten

112: The facial nerve and its non-neoplastic disorders
Michael Gleeson

113: Tumours of the facial nerve
Patrick R. Axon and Samuel A.C. MacKeith

114: Osteitis of the temporal bone
Cheka R. Spencer and Peter Monksfield

115: Squamous carcinoma of the temporal bone
Liam Masterton and Neil Donnelly

116: Complications of skull base surgery
Abdul Karim Nassimizadeh and Chris Coulson

Abbreviations

18FDG	18F fluoro-deoxyglucose
3D	three-dimensional
3D-CRT	3D-conformal radiotherapy
5-FU	5-fluorouracil
A	anterior; *or* asthenia
AASM	American Academy of Sleep Medicine
ABC	aspiration biopsy cytology
AC	anterior commissure
ACC	adenoid cystic carcinoma
AcCC	acinic cell carcinoma
ACE	adult comorbidity evaluation; *or* angiotensin converting enzyme
ACNOS	adenocarcinoma not otherwise specified
ACR	American College of Rheumatology
ACTH	adrenocorticotropic hormone
ACV	Acyclovir
AdCC	adenoid cystic carcinoma
ADD	anteromedial displacement of the disc
ADDR	anteromedial disc displacement with reduction
ADL	additive layer manufacture
AECG	American European Consensus Group
AEWD	automatic endoscope washer-disinfector
AF	ameloblastic fibroma
AFD	ameloblastic fibro-dentinoma
AFDS	ameloblastic fibrosarcoma fibro-dentinosarcoma
AFIP	Armed Forces Institute of Pathology
AFO	ameloblastic fibro-odontoma
AFS	ameloblastic fibrosarcoma
AFTER	Adjustment to the Fear, Threat or Expectation of Recurrence
AFX	atypical fibroxanthoma
AgNOR	argyrophilic nucleolar organizer regions
AHA	alpha-hydroxy acid
AHI	apnoea-hypopnoea index
AHNOGB	Association of Head and Neck Oncologists of Great Britain
AHNS	American Head and Neck Society
AIDS	acquired immunodeficiency syndrome
AJCC	American Joint Committee on Cancer
AKs	actinic keratoses
Allo-HSCT	allogeneic hematopoietic stem cell transplantation
ALM	additive layer manufacture; *or* acral lentiginous melanoma
ALS	amyotrophic lateral sclerosis
ALT	alternative lengthening of the telomeres; *or* anterolateral thigh
amBED	acute mucosal BED
ANA	antinuclear anti-bodies
ANCA	anti-neutrophil cytoplasmic antibody
AOT	adenomatoid odontogenic tumour
AP	anterior-posterior
APC	antigen-presenting cell
APPS	anterior parapharyngeal space
ART	anti-retroviral therapy; *or* adaptive head and neck radiotherapy
ASA	American Society of Anesthesiologists
ASHA	The American Speech and Hearing Association
ASSIDS	Assessment of Intelligibility of Dysarthric Speech
ASV	adaptive servo-ventilator
ATLS	advanced trauma life support
ATM	ataxia telangiectasia mutated
ATP	adenosine triphosphate
ATR	ataxia telangiectasia and Rad3-related
ATSG	adjustable tracheostoma valve
ATSV	adjustable tracheostoma valve
AUG	acute ulcerative (necrotizing) gingivitis
AULS	awake unsedated laryngeal surgery
B	breathiness
BAC	basal cell carcinoma
BAHA	bone-anchored hearing aid
BAHNO	British Association of Head and Neck Oncologists
BCC	branchial cleft cyst; *or* basal cell carcinoma; *or* basal cell cancer
BCW	blue collar workers
BD	Bowen's disease
BDD	body dysmorphic disorder
BED	biologically effective dose
BER	base excision repair
bFGF	basic fibroblast growth factor
BHA	beta-hydroxy acid
BKPyV	BK polyomavirus
BLEC	benign lymphoepithelial cysts
BLEL	benign lymphoepithelial lesions

BMI	body mass index
BOT	base of tongue
BP	blood pressure
BTX-A	botulinum toxin type A
BVCMI	bilateral vocal cord mobility impairment
CAD/CAM	computer-aided design/computer-aided manufacture
CAH	clinically assisted hydration
Camp	3',5'-monophosphate; *or* Cyclic AMP
C-ANCA	anticytoplasmic autoantibody
cANCA	cytoplasmic antinuclear cytoplasmic antibody
CAPE-V	Consensus Auditory Perceptual Evaluation of Voice
CAPSO	cautery assisted palatal stiffening operation
CAUP	coblation assisted upper airway procedure
CBCT	cone beam computerized tomography
CBT	carotid body tumour
CBTI	cognitive behavioural therapy for insomnia
CCC	clear cell carcinoma
CCG	clinical commissioning groups
CCI	Charlson comorbidity index
CCOC	clear cell odontogenic carcinoma
CCOT	calcifying cystic odontogenic tumour
CD	Crohn's Disease
CDK	cyclin-dependant kinases
CDKi	cyclin-dependant kinases inhibitors
cDNA	complementary DNA
CEOT	calcifying epithelial odontogenic tumour
CFD	colour-flow duplex doppler
CFTCR	cystic fibrosis transmembrane conductance regulator
CGF	concentrated growth factor
cGVHD	chronic graft-versus-host disease
CH	cluster headache
CHC	Chronic Hyperplastic Candidiasis
CHEP	cricohyodoepiglottopexy
CHOP	cyclophosphamide, doxorubicin, vincristine, prednisolone
CHP	cricohyoidopexy
CI	confidence interval
CICO	can't intubate, can't oxygenate
CIN	cervical intraepithelial neoplasia
CIT	complementary integrated therapies
CLH	cystic lymphoid hyperplasia
CMV	cytomegalovirus
CN	cranial nerve
CNAs	copy number alterations
CNS	clinical nurse specialist; *or* central nervous system
CO_2	carbon dioxide
COAD	chronic obstructive airways disease
COF	cemento-ossifying fibroma
COMT	catechol-O-methyltransferase
COP	clinical outcomes publication; *or* carcinoma of occult primary
COPD	chronic obstruction pulmonary disease
COS	core outcome sets
COSD	Cancer Outcomes and Services Data set
COSMIN	Consensus-based Standards for the selection of Health Measurement Instruments
CPAP	continuous positive airway pressure
CPET	cardiopulmonary exercise training
CPG	central pattern generator
CQx	contact quotient measurement
CRCs	colorectal cancers
CRDS	Cancer Registration Data Set
CRT	chemoradiotherapy
CSA	central sleep apnoea
CSCI	continuous infusion
CSR	Cheyne-Strokes respiration
CSR-CSA	Cheyne-Strokes respiration with central sleep apnoea
CSE	clinical swallowing evaluation
cT	clinical T stage
CT	computed tomography; *or* clinical terms
CTA	computed tomography angiography
CTCAE	common terminology criteria for adverse events
CTLA4	cytotoxic T-lymphocyte-associated protein 4
cTNM	clinical (pre-treatment) classification
C-TORS	cervical-transoral robotic surgery
CTV	clinical target volume
CUP	carcinoma of unknown primary
CW	continuous wave
CXR	chest X-ray
D	dose
DA	desmoplastic ameloblastoma
DAHNO	Data for Head and Neck Oncology
DARS	dysphagia-aspiration risk structures
DAT	digital audiotape
DB	distobuccal
DBCL	diffuse B cell lymphoma
DC	dentigerous cyst
DCF	diced cartilage wrapped in fascia
DCIA	deep circumflex iliac artery
DDR	DNA damage response
DFS	disease-free survival
DFSP	dermatofibrosarcoma protuberans

DGCT dentinogenic ghost cell tumour
DID Diagnositic Imaging Dataset
DIEP deep inferior epigastric perforator
DIGEST Dynamic Imaging Grade of Swallowing Toxicity
DILS diffuse infiltrated lymphocytosis syndrome
DISE drug-induced sedation endoscopy
DM diabetes mellitus
dMRI dynamic MRI
DNSI deep neck space infections
DOI depth of invasion
DR drug resistance
DSA digital subtraction sialography
DSB double-strand break
dsDNA double-stranded DNA
DSI dysphonia severity index
DSS disease-specific survival
DVLA Driver and Vehicle Licensing Authority
DVT deep vein thrombosis
DWI diffusion-weighted imaging
DW-MRI diffusion-weight magnetic resonance imaging

EA early antigen
EAM external auditory meatus
EAT Eating Assessment Tool
EBER Epstein-Barr-encoded RNA
EBNA Epstein-Barr nuclear antigens
EBV Epstein-Barr virus
ECD extracapsular dissection
ECM extracellular matrix
ECS extracapsular spread; *or* extracapsular extension
ED ectodermal dysplasia
EDS excessive daytime sleepiness
EEG electroencephalography
EFS event-free survival
EGF epidermal growth factor
EGFR epidermal growth factor receptor
EGG electroglottographic
EIA enzyme immunoassay
ELG electrolaryngography
ELISA enzyme-linked immunosorbent assay
ELR endoscopic laser resection
ELS European Laryngological Society; *or* electrolaryngeal speech
EM erythema multiforme
EMC epithelial-myoepithelial carcinoma
EMG electromyography
EMR endoscopic mucosal resection
EMST expiratory muscle strength training
EMT epithelial-mesenchymal transition
END elective neck dissection
ENE extranodal extension
ENT ear, nose and throat
EOG electro-oculography
EoO eosinophilic oesophagitis
EOR extra-oesophageal reflux
EORTC European Organisation for the Research and Treatment of Cancer
EPAP expiratory positive airway pressure
EPSCC extrapulmonary small-cell carcinomas
ERAS enhanced recovery after surgery
ERCC1 excision repair cross-complementation group 1
ERCP endoscopic retrograde cholangiopancreatography
ERND extended radical neck dissection
ES oesophageal speech
ESR erythrocyte sedimentation rate
ESS Epworth Sleepiness Scale
ESWL extracorporeal shock wave lithotripsy
ET endotracheal tube
EUA examination under anaesthetic
EUS endoscopic ultrasound
EVT Estill Voice Training
EXIT ex utero intrapartum treatment

FA Fanconi's anaemia
FAMM facial artery myomucosal flap
FBC full blood count
FD fibrous dysplasia
FDA Food and Drug Administration
FDG fluorodeoxyglucose
FDG-PET fluorodeoxyglucose positron emission tomography
FEES functional endoscopic evaluation of swallowing
FEESST flexible endoscopic evaluaton of swallowing with sensory testing
FESS functional endoscopic sinus surgery
FEV_1 forced expiratory volume in one second
FFPE formalin-fixed paraffin embedded
FFT fast Fourier transform
FGD fluorodeoxyglucose
FISH fluorescence *in situ* hybridization
FISS fast-interrupated steady state
FK Feyh-Kastenbauer
FLIM fluorescence lifetime imaging
fMRI functional magnetic resonance imaging
FNA fine-needle aspiration
FNAB fine-needle aspiration biopsy

FNAC fine-needle aspiration cytology
FOIS functional oral intake scale
FONA front of neck airway
FoR fear of recurrence
FS Frey's syndrome
FTA-abs fluorescent treponemal antibody absorbed test
FTSG full-thickness skin grafts
FVC forced vital capacity

G glucose; *or* grade
GA general anaesthesia; *or* glycolic acid
GAN greater auricular nerve
GAS group A streptococcus
GBI Glasgow Benefit Inventory
GCS Glasgow coma scores
G-CSF granulocyte colony stimulating factor
GERD gastro-oesophageal reflux disease
GF growth factor
GFR growth factor receptors
GI gastrointestinal
GMC General Medical Council
GM-CSF granulocyte-macrophage colony-stimulating factor
GORD gastro-oesophageal reflux
GPA granulomatosos with polyangiitis
GPU gastric pullup
GRBAS grade, roughness, breathiness, asthenia, strain
GSW gunshot wound
GTV gross tumour volume
GVHD Graft Versus Host Disease

HA hyaluronic acid
HA/ALG hyaluronic acid/mildly cross-linked alginate
HAART highly active antiretroviral therapy
hAdMSCs human adipose-derived MSCs
HANA Head and Neck Audit
HCV hepatitis C virus
HDTV high-definition television
HDU High Dependency Unit
H&E haematoxylin and eosin
HEM heat and moisture exchanger
HES hospital episode statistics
HGF hepatocyte growth factor
HGT high-grade transformation
HHV-8 human herpes virus 8
HIV human immunodeficiency virus
HL Hodgkin lymphoma
HLA human leucocyte antigen
HNC head and neck cancer
HNR harmonics-to-noise ratio
HNSCC head and neck squamous cell carcinoma
HP hyperparathyroidism
HPF high power fields
HPV human papillomavirus
HQIP Healthcare Quality Improvement Partnership
HR homologous recombination; *or* heart rate
HRHPV high-risk human papillomavirus
HRM high-resolution manometry
HRQOL health-related quality of life
HSPL horizontal supraglottic partial laryngectomy
HSV herpes simplex virus
hTERT human telomerase reverse transcriptase expression
HTLV-1 Human T-lymphocytic virus 1
hVFFs human vocal fold fibroblasts
Hz Hertz

INTRODUCTION

The pace of change in the treatment of head and neck tumours has accelerated since the 1950s with a remarkable transition from predominantly ablative surgery to combined therapies focused on preservation of the form and function of the anatomic structures of the head and neck. This chapter will summarize the history of head and neck surgery, with information gleaned from published summaries of this history and original articles.[1–9]

The term 'head and neck surgery' dropped into obscurity from 1906 until 1948, when Hayes Martin used it in one of his early papers.[10] In the same year, Grant Ward published an editorial[11] which defined the future parameters of this 'new' surgical specialty.[9, 10] This surgical discipline was progressed by several groups of surgeons which included Grant E. Ward and James W. Hendrick (1901–1992) of Johns Hopkins Hospital in the United States, who published of their extensive experience in caring of head and neck cancer patients in *Tumors of the Head and Neck in 1950*,[12] with Sir Stanford Cade (1895–1973) General Surgeon and Radiotherapist, Westminster Hospital, Arthur John Gardham (1899–1983) General Surgeon, William Douglas Harmer (1873–1962), Otolaryngologist and Radiotherapist, St Barts. Hospital, Ronald William Raven (1904–1992), General Surgeon and Radiotherapist, St Barts. Hospital and others in Britain, and Henri Redon (1899–1974), Paris and Georges Portmann (1890–1985), Bordeaux who are to be credited with the formation of modern head and neck surgery.[13]

THE MIDDLE AGES

Some of the earliest attempts at head and neck surgery can be credited to Egyptian physicians who attempted ablative and reconstructive procedures of the oral cavity and lip. The 'Edwin Smith Papyrus' (named after the dealer, an American Egyptologist who bought it in 1862), the origins of which are dated at 3000–2500 BCE, contains some of the first descriptions of surgical management of mandibular and nasal fractures, as well as lip tumours.

Arguably, the first documented efforts of reconstructive head and neck surgery are found in the Sanskrit texts of ancient India written approximately 2600 years ago. During this period of Indian history, reconstructive surgery of the nose and ear was highly valued, as invaders from surrounding territories would often stigmatize their victims by amputating the nose or ear. Contained within the publication of Sushruta Samhita (Sushruta's compendium), an ancient Sanskrit text on medicine and surgery, are described numerous surgical techniques for the reconstruction of head and neck defects, dating from the mid-first millennium BCE. Sushruta, regarded as the 'father of Indian surgery', described a variety of pedicle and rotation flaps, similar to many of the techniques utilized in the nineteenth and twentieth centuries. He is reasonably considered the pioneer of reconstructive nasal surgery, having described more than 15 different methods.[14]

Whether Hellenistic or Roman physicians were exposed to the Indian techniques through Alexander the Great's expedition to India in the 4th century BCE is debatable.

Certainly, Roman and Hellenistic physicians described similar techniques to those described in India. Aulus Cornelius Celsus, (c. 25 BC–c. 50 AD), considered to be the greatest of the Roman medical authors and surgeons, also described a variety of techniques similar to those practised in India in his medical text of the 1st century, *De Medecina*, and is credited with one of the first head and neck cancer procedures describing excision of a lip malignancy.[15]

After the fall of Rome in the 5th century and the diffusion of Barbarians and Christianity throughout the Middle Ages, a significant decline in the advancement of all surgery, in particular reconstruction, occurred. This decline was certainly aided by Pope Innocent III (1160b: 1198–1216d Papal Reign), who prohibited surgical procedures of all types. It is interesting to note that physicians of the time considered surgery to be a manual skill and below their intellectual and societal stature. Physicians tended to be academics, working in universities, and mostly dealt with patients as an observer or consultant. Thus appeared the concept of the barber surgeon, and the decline of the role of surgery and surgeons ensued. Despite this, surgery of the head and neck was practised and developed in the Middle Ages but documentation of this is scarce.[16]

The period of Renaissance in the 14th century signalled a rebirth of science, medicine and surgery. In 1442, the Branca family gained prominence in the field of wound reconstruction and, in particular, they reintroduced the previously described Indian methods of nasal reconstruction, using cheek and forehead flaps.[17] Branca's son Antonius modified this technique developing the use of a delayed skin flap donated from the arm. This Italian method, as it became known, was eventually learned by other surgical dynasties (surgical practice at this time in Italy was very much a family affair). Prominent examples include Gasparro Tagliacozzi's (1546–99) work around nasal reconstruction, also using skin donated from the arm. It is believed that Tagliacozzi learned his surgical techniques from members of the Vianeo family from Calabria. Following his own work, he is credited with making significant contributions to facial reconstructive surgery describing and refining the use of distant pedicled flaps for a variety of head and neck reconstructions.[18]

PRE-20TH CENTURY

Oral cavity surgery

Pimpernelle, in 1658, is reported to have been the first who employed a hemiglossectomy to treat macroglossia caused by mercury administration,[1] whilst Marchetti (1589–1673) is credited with the first surgical removal of a malignant tumour of the tongue in 1664.[19] The first published description of a case of lingual cancer was made some 30 years earlier by an Englishman, Alexander Reade (1586–1641), in 1635.[20]

Surgical haemorrhage was a major limitation in the development of head and neck surgery. Accordingly, Germanicus Mirault (1796–1879) in 1813 and Konrad Johann Martin Langenbeck (1766–1851) in 1819 described the ligation of the lingual artery or the use of haemostatic sutures before proceeding with tongue surgery, in an attempt to reduce likelihood of death from exsanguination.[3, 6] A further advance in haemostasis was made by Albretch Middledorpf (1824–68) in 1834, who introduced the galvanic cutting current, the first description of cutting diathermy, to reduce surgical bleeding during incision. Developing this theme, the meticulous approach to haemostasis during surgical dissection proselytized by Emil Theodor Kocher (1841–1917) became the accepted surgical approach throughout the world.[4]

The intra-oral route of excision of tongue lesions was recognized as inadequate for more complicated and advanced tumours and therefore new, open surgical approaches were developed to enhance surgical exposure of lesions of the oral cavity; Joseph H Cloquet (1787–1840) in 1827 and Giorgio Regnoli (1797–1859) in 1838, both Italians used the suprahyoid route to improve access to the base of tongue;[4] Theodor Billroth (1829–94) and Vincenz Czerny (1842–1916) further modified this approach, describing the addition of lateral vertical incisions to the transverse suprahyoid incision. Regnoli went further, describing a retrograde 'pull-through' technique, which was later popularized in the 1860s. However, it was Philibert Joseph Roux (1780–1854) (France) in 1836, followed by James Syme (1799–1870) (Scotland) and Billroth, who described the precursor approach of the lip-split mandibulotomy, which is still commonly used in contemporary head and neck surgical practice, whereby the lip initially is incised in the midline and, deep to this, the mandible is incised through the symphysis, allowing the retraction of the mandibular rami to gain unfettered access to the oral cavity and oropharynx. In 1875, using a variation of the theme, Bernard Rudolf Konrad von Langenbeck (1810–87) divided the mandibular ramus opposite the first molar tooth and ligated the underlying lingual artery prior to removing the enlarged regional lymph nodes in addition to the primary tumour sited in the base of the tongue. Access to the oral cavity from the neck following the raising of a superiorly based musculocutaneous flap as developed by Billroth (1829–1894) of Vienna, was further modified by Kocher of Bern.[20] By the turn of the century Henry Trentham Butlin (1843–1912)[21] and Anton Wolfler (1890–1917) (a member of Billroth's surgical school) had refined the final approaches that established future surgical approaches to the oral cavity, removal of the primary lesion with its regional lymph nodes.[3, 4]

Laryngeal surgery

Visualization of the larynx in life, prior to the invention of the laryngoscope, was not a trivial matter.

An inspection device using mirrors and candles or sunlight for illumination was devised during the early part of the 1800s and almost perfected by John Avery (1807–55), a surgeon at Charing Cross Hospital, London, in 1848 and by Ephraim Cutter (1832–1917) of Boston around 1858. However, Manuel Patricio Rodriguez García (1805–1906),

a Professor of Singing at the Paris Conservatoire who had settled in London, is widely accredited as the first person to view the larynx (his own) in a living human using two mirrors and the sun as a light source.[22] The first clinical application of the indirect laryngoscope was made by Ludwig Turck (1810–68), a neurologist from Vienna, around 1858. By the early period of the 1860s Georg Richard Lewin (1820–96) declared that he had seen more than 60 cases of laryngeal neoplasms and performed surgery using either cutting devices or caustics.[7]

On 23 April 1895 in Berlin, Alfred Kirstein (1863–1922) performed the first direct laryngoscopy, using a modified oesophagoscope.[23] Despite the limitation in visualizing the larynx – and in particular the functioning larynx – there have been a number of reports of larynx tumours being removed 'per viam naturalis'. In 1770, G Koderik, a surgeon in Brussels, reported the ligation of a laryngeal polyp by a snare device. Moreover, the operation of cricothyrotomy and thyrohyoid laryngectomy were devised by French surgeons Felix Vicq d'Azyi (1748–1794) in 1776 and Joseph-François Malgaigne (1806–1865) in 1850 respectively. The first laryngofissure, credited to Ludolph Brauers (1865–1951) of Louvaine in 1833 which was performed without a covering tracheostomy. Laryngofissure was performed under chloroform anaesthetic by Gordon Buck (1807–77) in the United States in New York in 1851, and in London, England by Sir George Duncan Gibb (1821–76) in 1864.[7, 8]

The London laryngologist Morell Mackenzie,[3, 24] (1837–92), having been trained in Vienna and Budapest under Johann Czermak (1828–73), commenced practice in 1862 and is considered the father of British laryngology. As the first English laryngologist, he was the founder of the first hospital for diseases of the throat in the world, which opened in London in 1865. Among Mackenzie's succession of assistants at Golden Square were Lennox Browne (co-founder of the British Rhino-Laryngological Association), Gordon Holmes (author of the first history of laryngology), Felix Simon (Semon's Law), Grenville Macdonald (Professor of Laryngology, King's College Hospital), Norris Wolfenden (co-founder of The Journal of Laryngology and Otology), John Nolan Mackenzie (of Johns Hopkins Hospital), Samuel Johnston (Surgeon to the Baltimore Eye, Ear and Throat Charity Hospital and one of the founders of the American Laryngological Association), Charles Louis Taylor (subeditor of the British Medical Journal), James Donelan (the first laryngologist at the Italian Hospital) and Mark Howell (who assisted during the treatment and attended until the death of Emperor Frederick III June 1888).[7]

The first total laryngectomy was performed by Professor Theodor Billroth (1829–94) of Vienna on 30 December 1873, having excised a laryngeal tumour via a thyrotomy incision, preserving the right vocal cord some weeks earlier. The patient died of local recurrence 7 months following his major surgery. The last success on record was achieved by Enrico Bottini (1837–1903), of Turin. The long survivor was achieved for 15 years after total laryngectomy performed in 1875. Jacob da Silva Solis-Cohen (1838–1927) was the first, in 1884, to perform a total laryngectomy in America – the patient survived 11 years without a recurrence. Based on his contribution to the discipline, it has been proposed that Solis-Cohen be acknowledged as America's first head and neck surgeon.[25]

Paranasal sinuses and nasopharynx surgery

The first total maxillectomy was reportedly performed in 1827 in Lyon, by Joseph Gensoul (1797–1858) without anaesthesia. With further practice, it was said that Gensoul perfected his technique and could complete the procedure in two-and-a-half minutes. A variety of incisions have been suggested over time by various surgeons including Alfred Velpeau (1807–73) of Paris, Karl Otto Weber (1827–67) from Frankfurt, Sir William Ferguson (1808–77) and Thomas Tatum (1802–1879) of London, and James Syme (1799–1870) of Edinburgh. Auguste Nelaton (1807–73) of Paris promoted a transpalatal approach to the nasopharynx in 1859, whilst Pierre Charles Huguier (1804–73), also of Paris, advocated a transmaxillofacial or lateral nasal approach. In 1902, Emil-Jules Mourne (1855–1914) of Bordeaux, published his 'lateral rhinotomy' approach and Alfred Denker (1863–1941) in 1905 described a sublabial approach to the nasal cavity and maxillary antrum.[8]

THE 20TH CENTURY

Following the death of Pimpernelle, in the mid-17th Century, an interval of almost 200 years passed during which it appears from the absence of historical evidence that the development of surgery of the head and neck stagnated.[1] The reasons for lack of significant progress related to the lack of what are now considered fundamental needs for any surgery, such as general anaesthesia, antiseptic techniques, blood banking, antibiotics, surgical pathology and skilled nursing care. The discovery of anaesthesia occurred in the 1840s: ether in 1842; nitrous oxide in 1844; and chloroform in 1847. Local anaesthetic in the form of cocaine was not discovered until 1880.

The introduction of binocular operating microscope heralded the possibility of performing microsurgery of the larynx and other sites. The principal changes in endoscopy have occurred since the 1950s and have been associated with technical improvements in lighting, magnification and instrumentation as well as documentation of clinician findings. Harold Hopkins (1918–94) and Narinder Singh Kapany (b.1926) developed and subsequently introduced the rigid and flexible fibreoptic systems in 1954.[26] Harold Hopkins' solid rods, with their different angles connected to a proximal light source by a fibreoptic cable, have become essential tools for diagnostic and therapeutic procedures in the head and neck. Fibreoptic light sources aided both rigid endoscopy and the flexible fibrescopes, introduced in 1957, allowed improved visualization of the mucosal head and neck subsites and the early detection and diagnosis of cancer in the awake patient. Advancement in pathology, radiology and radiotherapy have expanded the 'team approach' to improve the patient's diagnosis, improved staging of disease

and expanded the options available for the management of patients with head and neck cancer.

Head and neck pathology

The modern era was heralded by the development of the achromatic microscope, which allowed pathologists to first view tissues under magnification.[1, 27] The mid-19th century was dominated by developments in the pathologic description of tumours, including those by the father of modern oncologic pathology, Rudolf Virchow (1821–1902).[28] Virchow, the pioneer of cellular pathology, published the first study of the pathology of tumours in 1858. Surgical pathology, however, only began to develop as a distinct specialty from the 1960s onwards. Two fundamental concepts regarding head and neck cancer were published by Albert C Broders (1885–1964) of the Mayo Clinic in the early 1920s. First, he defined the grading system of squamous cancer of the lip,[29] and subsequently applied it to sites of the head and neck.[30] Broders also described carcinoma *in situ*, although the topic was more firmly established by a subsequent detailed report by John D Crissman and Richard J Zarbo in 1989.[31] Several of the early head and neck surgeons were also experienced pathologists: Joseph H Ogura (1915–83), Barnes Hospital, and John J Conley (1912–99), New York checked their own frozen sections during the weekends.[32] John A Kirchner (1915–2011), Yale, performed serial sections of 100 total laryngectomy specimens in his search for the anatomical pathways by which laryngeal cancer spread.[33] It was at the Centennial Conference on Laryngeal Cancer in 1974 (100 years after the death of Billroth) that the first public interaction between surgeons and pathologists took place and a new era of working practices was established.[34] The appointment of Vincent J Hyams (1924–98) in 1968 as Director of Otolaryngologic Pathology at the Armed Forces Institute of Pathology, Washington and in 1974 the publication of the textbook *Tumors of the Head and Neck* by John G Batsakis (1929–2013)[33, 34] were other landmark events in the development of head and neck pathology. The specialty of head and neck pathology has culminated in the publication, by the World Health Organization, of *A Classification of Head And Neck Tumours* ('The Blue Book'), the most recent edition of which was published in 2017.[35]

Radiology

Computerized tomography (CT) was invented and its early clinical application defined at the Atkinson Morley Hospital, London, England in 1971. The pioneering work of Sir Godfrey Hounsfield (1919–2004) in collaboration with Allan Cormack (1924–98), which underpinned the development of CT, led to both sharing the 1979 Nobel Prize for Physiology or Medicine. Subsequently, magnetic resonance imaging (MRI) was developed by Paul C Lauterbur (1829–2007) of Pittsburg and Peter Mansfield (1933–2017) of Nottingham. Their pioneering work culminated in them sharing the Nobel Prize for Physiology or Medicine in 2003. Continuing the progression of the development of ever more sensitive imaging modalities, in 1999, David Townsend, Ronald Nutt and colleagues in Pittsburg, developed positron emission tomography (PET/CT) for diagnostic use in clinical oncology.[8] This technique is now firmly established in the investigative work-up of patients with head and neck cancer, particularly in patients presenting with occult primary disease or in those where treatment failure is suspected.

Radiotherapy

In the 1920s, ionizing radiation, delivered as an external beam or by the placement of interstitial rods, was first used to treat patients with head and neck cancer. Henri Coutard (1876–1950) described his technique of protracted radiation therapy, which became so popular and accepted in many centres[36] that, for a time, surgery was partially displaced as a primary modality in the treatment of head and neck cancer. Hayes Martin, an admirer of Crile and a pioneer of head and neck surgery, although trained in the use of ionizing radiation, was vociferous in his resistance to the use of radiation for many cancers, primarily because of its toxicity profile and unpredictable ability to effect cure.[37] As outlined above, in these early days, the administration of radiotherapy was limited to orthovoltage generators and radium implants, resulting in a high degree of skin damage, poor cure rates and a myriad of attendant complications. By the 1950s the era of modern radiotherapy had begun with the advent of the linear accelerator and telecobalt units, which generated supervoltage radiation. Early advocates, such as Gilbert Fletcher (1911–92) in the United States,[38] and Manuel Ledermann (1912–84) in the UK,[39] strongly recommended external beam radiotherapy as the primary treatment modality for larynx cancer and cancers of other head and neck sites. The net effect of the work of these early advocates was that radiotherapy as a primary treatment for many head and neck cancers became popular and remains so, even today, in much of Northern Europe, the United States and Canada. The use of post-operative radiotherapy, following definitive surgical resection, became standard care during the 1970s. This combined management, which involved radiotherapy commencing after healing and within 6 weeks of surgery, was shown to definitively improve cure rates when compared with either surgery or radiotherapy alone or when salvage surgery was used after radiotherapy failure.[40] During the late 1980s advancements in computer software and imaging technology led to the development of three-dimensional (3D) image-guided targeting of radiation fields in an attempt to maximize tumour dose whilst minimizing radiation doses to adjacent normal tissues. The introduction of multileaf collimators facilitated an increase in the numbers of beams that could be delivered without a prolonged extension of the treatment time. The result was the emergence of 3D conformal radiotherapy, which allowed further refinement of radiation delivery to image-defined targets. Further improvements to radiation delivery precision occurred throughout the 1990s with the introduction of intensity-modulated radiation therapy (IMRT), which offers a higher degree of dose conformality

to maximize tumour dosing with greater sparing of normal tissue toxicity.[41]

Radiotherapy alone or in combination with cisplatin-based chemotherapy remains today a mainstay of treatment for many cancers of the head and neck in many centres throughout the world – particularly the developed world. Important studies which have led to this situation include the Department of Veterans Affairs (VA) Laryngeal Cancer Study, which, in 1991, demonstrated that response to chemotherapy was an excellent predictor to response to radiation therapy in cases of advanced laryngeal cancer.[42] Many high-quality randomized studies have also shown the utility of concomitant chemoradiotherapy in the management of head and neck cancers. The attraction of this approach is the avoidance of surgery and therefore, particularly for larynx cancer, the potential for preserving laryngeal function. This approach, however, is the subject of much ongoing debate as the treatment is toxic and difficult to tolerate by older patients with poorer performance status. Moreover, it has yet to be firmly established that preservation of the larynx amounts to the same as preservation of laryngeal *function* for the majority of patients treated this way.[43]

Surgery of the oral cavity

By the turn of the 19th century, it had become obvious to surgeons treating oral cavity cancer that treatment failure was most frequently associated with recurrent disease at the primary site and locally in the neck. This prompted surgeons to undertake more radical incisions of the primary tumour and to include removal of the cervical lymph nodes in an attempt to minimize the risk of locoregionally recurrent disease. Polya and von Navratil, in 1902, described the lymphatic drainage of the oral cavity, demonstrating that 50% of the lymphatics traversed the mandibular periosteum [published in German]. This resulted in the development of the concept of *en-bloc* resection and laid the foundations of the original composite (soft tissue and bone) resection for oral cancer. Almost concurrently, in 1906, the American surgeon and pioneer of neck dissection surgery, George Crile (1864–1943) described his approach to head and neck tumours, thus laying the foundation of the present-day approaches to neck dissection surgery.[44] Crile was an extremely creative surgeon, even developing pneumatic suits for patients to maintain their blood pressure during extensive surgical procedures. He also developed a carotid clamp that would reduce but not completely occlude carotid blood flow in an attempt to reduce the technical challenge of surgical bleeding as well as reducing blood loss. In Britain, the pioneering work in head and neck surgery of Henry Butlin (1845–1912) (considered to be the first head and neck surgeon), was continued by John Bland-Sutton (1855–1936) and later St. Clair Thompson (1859–1943) and Alexander Marsden (1832–1902), as well as Wilfred Lewis Trotter (1872–1939).[7] In spite of Crile's efforts to promote ever more radical surgery, the vogue for extensive procedures faded from the scene for a time, because of excessive mortality and apparent indifference in the surgical community.[13, 27]

Neck surgery

In 1927, George Harold Semken (1875–1946) who worked in the New York Skin and Cancer Hospital, excised *en bloc* (later called a composite operation) a primary mouth lesion that involved the corner of the mouth, buccal mucosa and lower jaw and the lymph nodes of the neck. In 1932, Grant E Ward (1896–1958), in Johns Hopkins, performed the first composite *en-bloc* resection, which consisted of a subtotal excision of the tongue, floor of mouth, and mandible in continuity with a radical neck dissection.[1, 45, 46] In 1951 Hayes Martin published a large series of 1450 cases of radical neck dissections, for involved lymph nodes as part of treatment for tumours emanating from all primary sites: so-called therapeutic neck dissection. He did not advocate surgery for the neck in the absence of obviously involved lymph nodes: so-called elective neck dissection.[47]

As an aside, a major innovation in the management of head and neck cancer at this point in time was the description in 1934, by Martin and Ellis, of fine-needle aspiration cytology (FNAC) as a diagnostic tool for enlarged cervical lymph nodes, a development that would dramatically alter the treatment of head and neck malignancy and thyroid disease over the next 75 years.[48]

Neck dissection surgery, the landmark publication by Hayes Martin in 1951,[47] suggested an extension of the surgery previously described by George Crile in 1906 to include resection of the spinal accessory nerve, even when not involved by tumour. In contrast, Crile had recommended preservation of the nerve when not involved by tumour.[46]

Surgical opinion differed about the need for elective neck dissection and those supportive of the approach considered that a radical neck dissection was 'too radical' and clinically unnecessary.[49, 50] This debate continues to this date about the radicality of surgery for tumour positive neck disease. Ettore Bocca (1914–2003) from Italy, popularized the modified neck dissection, where fascial compartment dissection of the cervical lymph nodes with preservation of the non-lymphatic structures (internal jugular vein, spinal accessory nerve and sternocleidomastoid muscle) was performed. Management of neck disease evolved throughout the 1960s and 1970s following the descriptions of selective neck dissection by Osvaldo Suarez (1914–1979) in South America and Ettore Bocca in Italy.[51–53] In 1990 Jatin Shah and colleagues evaluated the histological patterns of lymph node metastasis in patients undergoing elective and therapeutic radical neck dissection, in a series in which all patients underwent a radical neck dissection, irrespective of the primary pre-treatment nodal stage. Based on these data, which showed that the patterns of lymph node metastasis could be largely predicted, elective dissection of selective lymph node levels most at risk was proposed as an alternative to elective modified radical or radical neck dissection.[54]

In addition to the data that show metastatic spread in cervical lymph nodes could be predicted, the spread of tumour within a lymph node to broach the lymph node fibrous capsule – extracapsular spread (ECS) – was identified as an important negative prognostic factor even when

present in small apparently non-metastatic lymph nodes. ECS was identified in 20% of clinically negative necks in patients with supraglottic cancer who underwent elective neck dissection. This finding of ECS and multiple positive lymph nodes, by the Eugene Nicholas Myers (1933b) team from Pittsburgh, became indications for post-operative radiotherapy and currently chemotherapy is also suggested in the context of ECS.[55]

The trend towards modified radical and elective neck dissection was stimulated in an effort to avoid the not insignificant functional and cosmetic consequences of radical neck dissection. Data reported in the 1990s confirmed that selective neck dissection was as effective as modified neck dissection in patients with clinically positive lymph node disease.[56, 57] Identification and removal of the first echelon drainage lymph nodes, so-called sentinel lymph nodes, following the injection of isotope solution into or around the primary oral cancer, is increasingly used to determine whether neck dissection is needed at all.[57–59] It has been proposed and agreed by the International Head and Neck Scientific Group (IHNSG) that a logical nomenclature for the different types of neck dissections be recommended both for clinical and research purposes.[60] Consequently, the IHNSG has summarized the current philosophy in the surgical management for head and neck squamous cell carcinoma.[61]

Reconstructive surgery

The most important surgical innovations of the past 40–50 years have, however, been in the development of approaches to reconstruct ablative defects of the head and neck. In the 1960s, several surgical innovations helped reduce the morbidity of head and neck ablative surgery. In particular the increasing use of very reliable axial pattern flaps to reconstruct large oral cavity and neck defects resulted in decreased morbidity and a considerable shortening of post-operative hospital stay. Foremost among these were the descriptions of the forehead flap for oral reconstruction popularized by Ian McGregor (1921–98) and his wife Mary McGregor[62] and the deltopectoral flap described in the United States by Vahram Y Bakamjian (1918–2010) and colleagues. A H Martin Littlewood (1923–2004), who was a UK Fellow for six months at Roswell Park at the same time (1961), who returned to Warrington and practiced as a plastic surgeon.[63] In the late 1970s, the description of the pectoralis major myocutaneous flap by Stephan Ariyan[64] transformed head and neck oncologic surgery as patients could be offered a single-stage reliable reconstruction with minimal donor site morbidity. In addition, the ease of harvest and transfer of the pectoralis major flap made it a technique that any head and neck-trained surgeon could perform, broadening the scope of reconstructive surgery to other disciplines outside plastic surgery.

The late 1960s and early 1970s heralded the era of reconstructive microsurgery, which has since transformed the practice of contemporary head and neck surgery, to the enormous benefit of patients and healthcare providers. The concept of free-tissue transfer had been developed years earlier, but was limited by the quality and availability of microvascular sutures, appropriate instruments and operating magnification. Jacobsen and Suarez first described the repair of vessels under 2 mm diameter in 1960. The first free-tissue transfer of a composite (soft tissue and bone) flap was performed by G Ian Taylor and Rollin K Daniel in 1973.[65] Subsequent developments in reconstructive microsurgery have resulted in the description of a plethora of free flaps available for head and neck reconstruction championed by a number of extremely gifted reconstructive microsurgeons, including Kiyonori Harii, Harry J Buncke (1922–2008), Ralph T Manktelow, Mark Urken and many others.

Commonly used flaps in contemporary head and neck surgical practice include: the radial forearm flap described by GF Yang in 1983[66] and popularized for oral cavity and oromandibular reconstruction by David Soutar; the composite fibular flap, originally described by G Ian Taylor of Australia in 1977[67] and popularized by David Hidalgo and Alica Rekow for mandibular reconstruction in 1995;[68] and the anterolateral thigh flap described by YG Song et al in 1984[69] and popularized for head and neck reconstruction by Fu-chan Wei et al in 2002.[70] The ubiquitous application and the expansion of training in the use of microvascular free flap techniques has resulted in major changes in the specialty backgrounds of surgeons performing these techniques. Head and neck reconstruction is no longer the preserve of the plastic surgeon, with maxillofacial surgeons and even otolaryngologists/head and neck surgeons assuming pre-eminence in this field.[71, 72]

HEAD AND NECK SOCIETIES AND LEADERS

Hayes Martin (1892–1977) and Grant Ward (1896–1958) in 1952, and 50 selected American general surgeons were invited to serve as founding members of the Society of Head and Neck Surgeons, most were their former residents/students, and practiced in general or plastic surgery. Martin, the first president of SHNS, prioritized his training position for general surgeons, at the exclusion of otolaryngologists. In 1958, a group of otolaryngologists, John Conley (1912–99) the first president, George Sisson (1920–2006) and others conceived the American Society for Head and Neck Surgery, with a desire to foster participation with the American College of Surgeons.[73] Both organizations thrived in parallel for several decades, but as general surgeons waned in their enthusiasm and otolaryngologists became the dominant specialty in head and neck surgery, the two societies merged into the American Head and Neck Society (AHNS – www.ahns.org) in 1998.[74]

In Britain during the 1960s, a similar discussion was had as had been in the US, between a number of general surgeons about setting up a national head and neck society and linking such national societies with an International Association of Head and Neck Oncologists. In late 1967, a decision was taken to set up the Association of Head and Neck Oncologists of Great Britain (AHNOGB) with Mr. Ronald Raven (1904–1992), a London

general surgeon, as President, Professor Brian ED Cooke (1920–2007), an oral medicine and oral pathologist, from the University of Cardiff and Dr Manuel Lederman (1912–1984), a London radiotherapist, both as Vice-Presidents, Mr Douglas Ranger (1916–1997), a London ENT Surgeon as Honorary Secretary, and Mr Michael Harmer (1912–1998), a London general surgeon, as Honorary Treasurer. An additional nine members were invited to join the National Committee, and 78 letters of invitation were sent to doctors working in the field about the formation of a head and neck society. In January 1968, the inaugural meeting was held of the AHNOGB at the Royal Marsden Hospital.[75] In 1995, a decision was made to change the name of the organization to the British Association of Head and Neck Oncologists (BAHNO – www.bahno.org) to more reflect its broader clinician base, multidisciplinary working and membership of the society.

Unlike in many other countries, head and neck cancer surgical services are provided by otorhinolaryngology – head and neck surgery (ORL-HNS) and oral and maxillofacial surgery (OMFS) in an equitable fashion.[2] This resulted in the UK when NHS hospital consultant dentists (BDS) had to admit their patients overnight under the case of a named consultant medical clinician. To remedy that clinical situation, dentists who wished to pursue a career in head and neck surgery, which commenced in the mid-1970s, became doubly qualified both in dentistry and medicine.

It is appropriate that recognition be given to a number of our former UK head and neck surgeons / leaders:

Ian Alexander McGregor (1921–1998) a head and neck plastic and reconstructive surgeon at Cannisburn Hospital Glasgow, Scotland. He graduated from Glasgow Medical School 1944, MRCS and FRCS 1950, and FRCS Glasgow 1962. He studied with Dr. Herbert Conway, New York Hospital in 1955, and set up the West of Scotland Regional Plastic Unit 1959. He authored two major publications Fundamental Techniques of Plastic Surgery and their Surgical Application (1975) which ran for nine editions, and Cancer of the Face and Mouth (1986). He was former President of the Royal College of Physicians and Surgeons of Glasgow 1984–1986, and Presidents of the British Plastic Surgeons and the Association of Head and Neck Oncologists of Great Britain.

Sir Donald Harrison (1925–2003), a London Otolaryngologist, was the first UK Professor of ORL 1963. He published on the Anatomy and Physiology of the Mammalian Larynx, and Tumours of the Upper Jaw. He retired and was knighted in 1990;

Philip Stell (1934–2004), of Liverpool, and when appointed was the second UK Professor of ORL 1979. He did his fellowship with Joseph Ogura, St Louis, USA in 1956. He founded the ORS Society 1978, and the Journal Clinical Otolaryngology 1975. Stell couthored with Arnold Maran the first UK textbook on Head and Neck Surgery in 1972 which is now going into its 6th Edition. A prolific writer and linguist who was fluent in Dutch, German, French and Spanish, Stell translated 11 foreign medical textbooks into English. He retired from clinical practice in 1992 on grounds of ill health. He was awarded an MD on medieval history at York University and was recognized with a MBE by the Queen for his contribution to medieval history.

John Samuel Pattison (Iain) Wilson (1923–2006), a London plastic surgeon who worked at St Georges, Queen Mary's Roehampton, the Westminster and Royal Marsden; he was greatly liked as a teacher by his residents.

Henry Jagoe Shaw (1922–2007), a London Otolaryngologist, appointed surgon in 1962 at the Royal Marsden and St Mary's Hospitals, he did a fellowship with Hayes Martin in New York (1953–1954) and another year at Bellview Hospital, New York.

Barrie Thomas Evans (1946–2015), an Oral and Maxillofacial Surgeon at Southampton General Hospital, appointed in 1988. Developed a major head and neck, skull base surgical service before retiring in 2012 from the National Health Service.He was the first Chairman of the head and neck Interface Training Programme at the Royal College of Surgeons.

Omar Shaheen (1931–2016), an Otolaryngologist at Guy's Hospital, did his fellowship in Iowa, returning in 1963, specialized in thyroid disease, and trained a generation of young surgeons to follow his surgical principles and techniques which resulted in many of the current head and neck surgeons in the UK.

Arnold (Arnie) George Dominic Maran (1937–2017), an Edinburgh Otolaryngologist who when appointed was the third UK Professor of ORL in 1988, he did his fellowship with Brian McCabe, Iowa (1966–1967) before returning to Scotland, and was ultimately appointed at the Edinburgh Royal Infirmary in 1975. Not only was he an expert on head and neck cancer but set up the first voice centre in the late 1980s for which he became dubbed 'the voice doctor'. He was a frequent co-author with his colleague Professor P M Stell in the 1970s including the textbook *Head and Neck Surgery* in 1972. He authored several textbooks on ORL and travelled widely acquiring many accolades. He was elected President of the Royal College of Surgeon of Edinburgh from 1997 to 2000. He was a musician and jazz enthusiast, as well as a golfer – all resulting in publishing books in his retirement, including one on the Sicilian Mafia influenced by his heritage and an incident involving his great uncle.

The European Head and Neck Society (EHNS – www.ehns.org) was formally established in 2006 in Brussels by the signing of the official documents by the founding Board: Jean Louis Lefebvre (France), Rene Leemans (Holland), Jan Olofsson (Norway), Dominique Chevalier (France), Guy Andre (Belgium) and Patrick Bradley (UK). Over several decades the Dutch, British and Scandinavian head and neck societies had met frequently and these gatherings were considered of benefit to all who attended. A decision was made to hold a European Head and Neck

Meeting in Lille, France in 2001, followed by a second meeting in 2003; these suceessful meetings led to a consensus decision to create the European Head and Neck Society. The EHNS is composed of individual persons, national and multi-national societies, and associated study groups oriented towards head and neck cancer research, training and treatment throughout Europe.[74]

The International Federation of Head and Neck Oncologic Societies (IFHNOS – www.ifhnos.org) was established by Dr. Jatin Shah, New York who formed a steering committee at a meeting in London 1987 with representatives of 16 Head and Neck Organizations from around the World.[5] A constitution and bylaws were formulated and Jatin Shah was elected Secretary General. IFHNOS is a global organization established through cooperation of national and regional Societies and Organizations in the Specialty of Head and Neck Surgery and Oncology with membership from national and regional multidisciplinary organizations, representing 65 countries. The purpose of the Federation is to provide a common platform for Specialists in the field of Head and Neck Cancer to interact in professional matters of mutual interest. The Federation has grown with a membership of 43 Head and Neck Oncologic organizations, representing 65 countries. The Federation is able to reach over 5000 specialists. Quadrennial World congresses of the Federation have been held since 1998.

HEAD AND NECK SURGICAL TECHNIQUES

Surgery of the oropharynx

OPEN APPROACH

Over recent decades in the developed world, management of squamous cell carcinoma of the oropharynx, whether human papilloma virus (HPV) associated or not, has become dominated by non-surgical modalities, namely, radiotherapy +/– concurrent cisplatin-based chemotherapy. As a consequence, the surgical management of tumours of the oropharynx involving open access procedures including mandibular osteotomies or lingual release techniques has fallen into abeyance. That said, there are cases where the approach is still used – for example, in patients with advanced stage but still operable disease, who are unfit or too old for primary chemoradiotherapy. In these cases reconstruction of the ablative defect is almost always essential and techniques involving free-flap reconstructive surgery predominate.

TRANSORAL APPROACH

Transoral *en bloc* resection for tonsil tumours was initially described in 1951 by Pierre Charles Huet (1896–1947), a surgeon based in Paris.[77] Current transoral approaches for tonsil cancers in patients with early stage primary disease include transoral laser surgery (TOLS) and transoral robotic surgery (TORS) with integrated neck dissection and risk stratified radiation therapy, pioneered by Heinrich H Rudert, Wolfgang Steiner and Petra Ambrosch (Germany) and Gregory Weinstein (USA), respectively. Such approaches avoid the overall early- and long-term toxicity burden of non-surgical treatments, the morbidity associated with open approaches and free-flap reconstruction, whilst potentially conferring equitable oncological outcomes with better functional outcomes.

Surgery of the larynx

OPEN APPROACH

In 1913, Themistocles Gluck (1853–1942) and Johannes Sorensen (1862–1939) described improved approaches to the creation of the tracheostoma and repair of the pharynx after laryngectomy and arguably became the foundation of modern laryngopharyngeal ablative and reconstructive surgery.[78] It was not until the late 1950s that partial laryngeal surgery was considered an option to treat early stage cancer. The anatomy of the larynx had been studied by Joel Pressman (1901–68) of UCLA and John Kirchner (1915–2011) of Yale, who recognized compartmentalization of the glottis and supraglottis by fibrous bands and ligaments.[79–81] Many partial laryngeal resection procedures have been described over time, providing a wide range of choices of conservation surgical treatments, retaining the goal to cure while preserving laryngeal function in terms of voice and non-tracheostomized breathing. Jean Leroux-Robert described a frontolateral partial laryngectomy for unilateral vocal cord carcinomas, with minimal extension to the opposite side.[82] In 1951, Justo M Alonso (1886–1974) from Uruguay, one of the pioneers of partial laryngeal surgery, described techniques of vertical laryngectomy and horizontal supraglottic laryngectomy.[83] Many variations of this procedure have been described and are all encompassed within the term hemilaryngectomy.

The development of supraglottic laryngectomy was an extension of technique of pharyngectomy (superior and inferior), as described by Wilfred Trotter (1872–1939) in 1920; this resulted in Joseph Ogura (1915–83),[84] Max Som (1904–1990)[86] and Ettore Bocca[81] modifying the technique of supraglottic laryngectomy to that understood by the term today. In the late 1950s a more radical excision of more extensive glottic and supraglottic cancers was reported using a technique of supracricoid partial laryngectomy by Eduard Herbert Majer (1909–1991) and Walter Rieder (1921–1992), surgeons in Vienna, which became popular in Europe.[87] Olivier Laccourreye et al[88] popularized the procedure in the late 20th century in Europe, and Gregory Weinstein from Philadelphia[89] in the United States. A large series of 297 patients from the Institute Gustave-Roussy treated by subtotal laryngectomy between the years 1974 and 1997, reported 3- and 5-year overall survival rates of 92% and 88% respectively.[90] Italian surgeons continued to expand the indications laryngeal sparing surgery, building on the teachings of Italo Serafini (1936–2010) from Vittorio Veneto, who classified open partial horizontal laryngectomy, into three types: supraglottic laryngectomy (Type I); supracricoid

laryngectomy (Type II); and supratracheal laryngectomy (Type III), Type III being indicated for intermediate-to-advanced laryngeal cancers with subglottic extension.[91]

TRANSORAL APPROACH

Francis E 'Duke' Le Jeune Sr. (1894–1977) from New Orleans is credited as a pioneer of the modern era of endoscopic micro dissection of vocal cord cancer, but he had continued the work of Robert Clyde Lynch (1880–1931). The technique of micro laryngeal examination had been first reported by Gustav Killian (1860–1921) from Germany in 1910. Following the publication of the experience of Le Jeune, Charles Vaughan (1926–2014) and colleagues from the United States.[92] Following on from Lejeune, Charles Vaughan (1926–2014) and colleagues from the United States, and Oskar Kleinsasser (1929–2001) from Germany progressed and popularized the developments in minimally invasive surgery of the larynx,[93, 94] initial techniques that have been expanded and popularized by others. For example, M Stuart Strong and Geza J Jako (1930–2015) from Boston are credited with introducing the CO_2 laser for microsurgery of the larynx in the early 1970s;[95] Heinrich Rudert, Wolfgang Steiner and Petra Ambrosch from Germany,[96] published their systematic approach to the endoscopic transoral laser microsurgery (TLM) of laryngeal tumours fundamentally altered the landscape of the management approach for laryngeal malignancy. The introduction of transoral robotic surgery (TORS) in 2007 has further expanded the capabilities of endoscopic surgery.[97] The European Laryngological Society working committee, in an attempt to standardize the reporting of endolaryngeal surgical resection in the clinical and research setting, developed a classification based on the extent of glottic and supraglottic transoral endoscopic resection.[98, 99]

Surgery of the hypopharynx

OPEN APPROACH

Surgery for hypopharyngeal cancer was changed in the 1920s by Wilfred Louis Trotter (1872–1939) from London, and revived in the 1940s by Harold William Wookey (1889–1980) who worked in Toronto. Trotter described a lateral pharyngotomy to gain access, and using local cervical skin flaps to repair the defect, Wookey described the repair of a circumferential defect using a two-layered skin tube to create a neopharynx.[98, 99] who described a lateral pharyngotomy to gain access to the pharynx using local cervical skin flaps to repair the defect, thus avoiding the previously used more extensive pharyngolaryngectomy.[100, 101] As for pharyngolaryngectomy, the transcervical approaches to the hypopharynx may be classified into partial pharyngectomy with partial laryngectomy, total laryngectomy with partial pharyngectomy or circumferential laryngopharyngectomy with or without oesophagectomy.[102] The techniques used for repair of the pharyngeal defect (partial or total) progressed through all of the phases of development of flap reconstruction methods: local skin, pedicle skin, axial myocutaneous and viscus (stomach and colon), free soft tissue +/– bone and free viscus (gastro-omental flap), over a period of 60 years.[103]

TRANSORAL APPROACH

As with larynx cancer surgery, although function-sparing non-surgical treatment is considered standard of care in many centres in the developed world, TLM or TORS has been proposed for the management of hypopharynx cancer with the same aim of reducing the extent of surgery as well as the burden of post-treatment morbidity.[96, 104] The selection of appropriate treatment is of crucial importance in the achievement of optimal functional results and likely survival for these patients.[105]

Surgery of the paranasal sinuses and nasopharynx

OPEN APPROACH

The open approach using the lateral rhinotomy and the Weber-Ferguson transfacial incisions to access tumours of the ethmoid and maxillary sinus was not introduced until the 1970s. In 1963, Alfred Ketcham (1924–2017) first reported a series of patients who had undergone a combined craniofacial approach to anterior skull base malignancies.[106] Other surgeons have since continued and expanded on the trans cranial +/– endoscopic approaches. Noteworthy examples include Victor Schramm, Paul Donald and Dennis Kraus from the USA, Anthony Cheesman from the UK, William Wei from Hong Kong and Sultan Pradham from India. Developments have led to a reduction in post-operative complications and improved survival. As a consequence of the heterogeneous nature of tumours which may occur in this region, histology plays a great role in prognostication. Moreover, tumour extension, particularly intracranial extension, whether dura and/or brain, involvement and positive surgical resection margins all impact negatively on outcome.[107] As an extension of earlier techniques, William Wei from Hong Kong described the anterior-lateral maxillary swing approach in 1998, and reported his long-term results of 246 patients. During surgery, frozen section was used and clear margins were achieved in 78% of cases resulting in a 5-year local control rate of 75%. These were selected patients, however, and did not include patients with erosion at the skull base or invasion of the carotid artery.[108]

TRANSNASAL APPROACH

In the early 1980s, Erik Wigand (b.1931), Wolfgang Draf (1940–2012) and Walter Messerklinger (b.1920) as well as Heinz Stammberger (b.1946)[109] and colleagues from Graz, Austria introduced the concept of functional endoscopic sinus surgery (FESS), thereby providing the technical foundation for the development of minimally invasive nasal surgery. A number of groups around the world, most notably Amin Kassam, Ricard Carrau and Carl Snyderman[110] from the USA, Valerie Lund and Nicholas Spencer Jones from the UK and Giulio Cantu,

Pierro Nicolai and Paolo Casteinuovo from Italy, have extended these concepts and techniques, developing transnasal approaches to the management of anterior skull-base tumours. Endoscopic nasopharyngectomy has been reported to show promising short-term outcomes for early-stage recurrences of nasopharyngeal carcinoma but long-term follow-up is necessary to confirm effectiveness.[111] It is suggested that improvements in technology, robotic-assisted transnasal approaches, and improved suturing techniques and closure devices, will help decrease the rate of CSF leaks and lead to better patient outcomes.[112]

SURGERY OF THE TEMPORAL BONE MALIGNANCIES

Primary temporal bone malignancies are exceedingly rare, squamous cell carcinoma being the most common and are generally the focus of most publications. In a review of 100 temporal bone resections in 1975,[113] John S Lewis (1920–2005) from the Memorial Hospital, New York, published data on 80 patients with these tumours. The death rate reduced from 10% in 1954 to 5% in recent years. The overall 5-year cure rate was 25% for squamous cell carcinoma. Prior to this publication, primary temporal bone cancer was considered incurable, and was treated by radiotherapy alone. Currently, with improvements in disease staging by imaging techniques, surgery remains the primary treatment of temporal bone malignancy, with the use of radiotherapy as an adjuvant to surgery.[114, 115]

HEAD AND NECK SURGERY: THE PRESENT

With great foresight, Hayes Martin, on appointment as Chief of the Head and Neck Service in 1934, set up a weekly head and neck tumour board (multidisciplinary clinic). During the 20th century, this concept was introduced more widely and whilst it was adopted with varying enthusiasm initially, a multidisciplinary team (MDT) approach is now accepted as the 'gold standard' environment within which to manage patients with head and neck cancer (See Chapter 32, Multidisciplinary team working).[116, 117] Case presentations at an MDT, when all things are considered, may affect the treatment offered and will certainly standardize treatment approaches and improve standards of care to the benefit of patients.[118] The problems associated with the occasional head and neck surgeon ('the dabbler') on the treatment outcome was most forcefully highlighted by John ('Jack') J Lore (1923–2004) in a publication of 1987, when he advocated the need for added qualifications and training for future head and neck surgeons, as well as accreditation of the hospital ('dabblice') as being a suitable environment to perform such surgery, and referred to the market place as 'dabbloge'.[119] While the USA, Canada, some European nations (Finland, Netherlands and UK) and Brazil have developed structured additional education and training in head and neck oncology, awarding a 'Certificate of Completion of Fellowship', others have informal training programmes (Italy, Germany and Spain). The concept of such specialist training for future head and neck surgeons has not been universally embraced. Moreover, when instituted, the training programmes need formal assessment of competence on completion of training, overseen by an accrediting body.[120] The modern head and neck surgeon may specialize in a number of parent surgical disciplines including general surgery, plastic and reconstructive surgery, otolaryngology/head and neck surgery, oral and maxillofacial surgery, neurosurgery or endocrine surgery. This confirms the necessity for contemporary head and neck surgeons to assimilate broad but complementary surgical skillsets in order to optimally undertake the complex management of patients presenting with cancers of the head and neck region.

From the early 21st century the training of head and neck surgeons relied on the sheer volume of clinical exposure, rather than specifically designed curricula. In addition, it is recognized that there is a critical mass required to assimilate the necessary expertise to become a competent surgeon, hence the creation of tertiary surgical centres. As in many other surgical specialties and in keeping with the history of surgery, surgical advances are dependent upon advances in technology – and this is increasingly the case in the modern era. Recent developments have resulted on more emphasis being placed on minimally invasive strategies with the aim of maximizing cure whilst minimizing treatment-related short- and long-term side effects. This dynamic environment dictates that surgical training needs to maintain flexibility and relevance.[121–123] Future head and neck surgeons will be trained to work within specialist oncology teams that treat subsites of the head and neck: skull-base surgery, endocrine surgery, endoscopic surgery, laryngology and voice surgery, as well as reconstructive surgery. Additionally, there may be a future need for a head and neck rehabilitation specialist to optimally manage patients coping with adverse effects of treatment.

The era of expanding non-surgical treatment options and precision medicine, and difficulties in recruitment and retention of head and neck surgical trainees has led to commentaries such as 'Has head and neck surgery a real future?'[124] and 'Head and neck surgery in crisis',[125] raising questions about the future of head and neck surgery as a specialty. The modern head and neck surgeon should consider his or her role as a leader and coordinator of the MDT, consider him- or herself as an oncologist, and become an educator, researcher and incorporator of technological advances.[126] The future head and neck surgeon will remain an essential member of the head and neck MDT and accordingly, a stylized job description pertinent for the future head and neck surgeon has been proposed.[127] It is essential that all members of the MDT head and neck cancer team embrace and participate in ongoing research into personalized medicine and targeted therapies, where genomic characterization of tumour tissue or blood is anticipated to play an increasing role in how cancer treatment is selected and individualized.[128]

HEAD AND NECK SURGERY: THE FUTURE

Head and neck surgeons, for the foreseeable future, can rest assured that there will always be a need for their services in the diagnosis and management of patients with cancer of the head and neck. While the indications and selection of treatments fluctuate with time, the success of any cancer treatment is captured by the adage, 'first treatment is always best'. Presently patients with locally advanced disease, (T3 and T4, >N2), of the larynx and hypopharynx, and oropharynx, are treated primarily with chemoradiotherapy. This function-sparing approach has resulted in enhanced organ retention but there is a poor evidence-base to confirm that the retained organ's function in a meaningful way to the extent that overall quality of life is truly enhanced in patients treated this way.

Oral cavity cancers remain best treated by primary surgery, as are other head and neck malignant tumours such as thyroid and salivary glands, skin and temporal bone cancers. The salvage of the failure of organ preservation approaches and for patients treated by minimal invasive surgical strategies represents a difficult challenge for the head and neck surgical oncologist, particularly the selection of patients for whom further treatment will be curative or life enhancing.

Early stage cancers of the larynx and hypopharynx are also best treated surgically with no need for adjuvant treatments.

What is also essential, and which might not have been the case in days gone by, is the need for surgeons to understand the biology of the disease they are treating, to fully appreciate the advantages and limitations of the non-surgical treatments offered to patients, to quality assess and quality control surgical outcomes and validated surgical approaches as part of high-quality, optimally designed and powered randomized clinical trials. Only then will they be able to contribute fully within the multidisciplinary environment to the future management of patients presenting with head and neck cancer.

KEY POINTS

- The term Head and Neck Surgery was reintroduced to surgical specialties in the middle of the 20th century by Hayes Martin and Grant Ward, both general surgeons.
- Oral cancer was described in the 17th century and surgeons mainly concentrated on the removal of mouth and neck tumours. Laryngeal cancer was made more manageable with the introduction of cocaine in the 19th century. The use of radiation therapy was discovered in the late 19th century and was introduced in a formalized therapeutic manner for larynx cancer in the early quarter of the 20th century.
- Early head and neck surgeons were brave, courageous, fearless and speedy in the era before anaesthetic, blood transfusion, and antibiotics.
- Resulting from World Wars, reconstructive procedures were rekindled and rapid progress was made shifting from split skin to axial and regional flaps. The advent of revascularized free transfer of tissue in the late 20th Century, which including muscle and bone, further advanced the surgeon's ability to resect and reconstruct more major and more repair complex defects.
- In the US the Society of Head and Neck Surgeon was established in 1954 by a group of general surgeons, because of an exclusion law, the otolaryngologists formed The American Society for Head and Neck Surgeons in 1956. In 1998, both societies amalgamated into The American Head and Neck Society and agreed a structured training programme for future head and neck surgeons. Similar events have been repeated in other countries.
- While progress was being achieved by performing more major resection on more advanced stage disease and being able to reconstruct the defect, a common event was that the tumour recurred locally, evidence was shown that post-operative radiotherapy reduced such an event happening.
- With advances in diagnostic imaging and anaesthesia it became possible for surgeons to change the extent of surgery from the traditional 'open approach' to a 'closed approach' using endoscopic telescope equipment under radiological monitoring and allowed surgical access to several 'hidden corners', such as the skull-base, parapharynx and temporal bone, inventing the term 'minimally invasive surgery'.
- The introduction of the surgical robot has proven to be an effective technique to safely treat most tumours of the head and neck irrespective of site or access. So far the evidence shows that the functional and cosmetic results are equal if not improved when compared with the standard open surgical approach. The comparison with non-surgical treatment may be difficult due to the inherent selection bias of favourable patients and tumour selected.
- There will always be a role for surgery in the diagnosis and management of head and neck tumours but the role may change over time. It is therefore important that future surgeons be educated as surgeon oncologists and play a major role in the decision-making process for treatment of patients. In time in the developed world at present centralization of head and neck cancer treatment will continue to be advocated and funded to optimize patient survival and minimize morbidity. It is paramount that this role is practiced and enforced within the multi-professional and multidisciplinary clinical group.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: head and neck cancer aetiology and head and neck cancer causes.

INTRODUCTION

Squamous cell cancer constitutes the most common head and neck malignancy and is related to tobacco and/or alcohol usage. Non-squamous malignancy includes thyroid cancer, salivary gland cancer and sarcomas. These malignancies are not associated with tobacco and/or alcohol usage.

According to the National Cancer Institute's Surveillance, Epidemiology and End Results (SEER) programmes of the United States, between 1975 and 2010 the incidence for most head and neck cancers sites has globally decreased except for tongue, tonsil, salivary glands and thyroid.[1] Estimated new head and neck cancer cases and deaths for 2013 are shown in **Table 2.1**.[2] A decreased incidence of oral cavity cancer has been reported in the last 15 years, widely attributed to a reduction in tobacco use.[3] In contrast, the incidence of oropharyngeal cancer has risen in recent years, a phenomenon that has been linked mainly to the emergence of human papillomavirus (HPV) infection.[4] A more comprehensive treatment of epidemiology of head and neck cancers is discussed in Chapter 3, Epidemiology of head and neck cancer.

SQUAMOUS MALIGNANT TUMOURS

Squamous cell carcinoma of the head and neck encompasses cancer of the oral cavity, oropharynx, larynx and hypopharynx, nasopharynx, nasal cavity and paranasal sinuses. The two most important factors in the aetiology of head and neck cancer are tobacco and alcohol.[5] There is a synergistic interaction between these two agents that is multiplicative for the mouth, additive for larynx and between additive and multiplicative for oesophagus.[6]

TABLE 2.1 Estimated new cancer cases and deaths in United States, 2013

	Estimated cases			Estimated deaths		
	Both sexes	Male	Female	Both sexes	Male	Female
Oral cavity/oropharynx	41 380	29 620	11 760	7890	5500	2390
Tongue	13 590	9900	3690	2070	1380	690
Mouth	11 400	6730	4670	1800	1080	720
Other oral cavity	2460	1790	670	1640	1260	380
Oropharynx	13 930	11 200	2730	2400	1790	610
Larynx	12 260	9680	2580	3630	2860	770
Thyroid	60 220	14 910	45 310	1850	810	1040

A large case-control study from the United States shows good evidence of a dose-response relationship for both tobacco and alcohol.[7, 8] Other factors are also implicated in the aetiology of squamous cell head and neck cancer such as diet, viruses, occupational agents, pollutants and genetic influences, but few case-controlled epidemiological studies have been carried out.

Since the histological distribution and aetiopathological considerations for cancers at various sites within the head and neck are distinct, these tumours will be discussed in more detail under separate anatomic sites.

Cancer of the oral cavity

The main aetiological factors for oral cavity cancer are smoking and alcohol.[7, 8] It is estimated that in 2013 there will be 27 450 new cases of oral cavity cancer in the United States, 14 420 male and 9030 female.[2] In the UK it is the 15th most common cancer among men, and 16th among women.[9] The incidence and mortality increase with age with over 85% cases occurring after the 5th decade. Over the last 30 years there has been a slight increase in oral cancer mainly attributable to the increase in tongue cancer in young women.[10–12] A detailed treatment of the global epidemiology is found elsewhere in the text.

TOBACCO

Tobacco consumption

Tobacco is the most important factor and over 90% of patients have a history of smoking. Tobacco contains over 30 known carcinogens such as polycyclic aromatic hydrocarbons and nitrosamines.[13] There is a synergistic interaction with alcohol due to the increased mucosal absorption of these carcinogens due to increased solubility of the carcinogens in alcohol compared with aqueous saliva. The use of filtered cigarettes reduces this exposure and stopping smoking reduces the risk of head and neck cancer.[14] The risk of oral cancer is reduced by 30% in those who have discontinued for 1–9 years and by 50% for those who have discontinued for more than 9 years,[15] but it is unlikely that it ever returns to the baseline as compared to the rest of the population.[16] Pipe and cigar smokers have an increased risk of oral cancer compared to other head and neck subsites.[17] This is thought to be due to the type of tobacco used. Several reports have shown a progressive decline in tobacco consumption over the last 25 years.[18] It is possible that the decrease in tobacco use accounts for the decrease in oral cancer incidence. Also, a decrease of the prevalence of tobacco use has been reported among oral cancer patients. A recent descriptive report of the prevalence of tobacco use among oral cancer patients has shown a significant decrease of smoking in oral cancer patients.[19] This could suggest that other etiological factors could be responsible for part of patients with oral cancer. Further studies on the aetiology of oral cancer in non-smoking patients are warranted.

Smokeless tobacco

Oral cancer is strongly associated with different forms of smokeless tobacco consumed by chewing. These include Bidi, Chutta, Paan, Khaini and Toombak. This is particularly common in the Indian subcontinent and accounts for the high incidence of oral cancer in these countries. Oral cancer increases in a dose dependent fashion with these agents.[20, 21] There is also a strong association between the subsite of oral cancer and the site where the tobacco is placed. In India and parts of Asia, oral tobacco is mixed with betel leaf, slated lime and areca nut to form a quid called 'paan'. The lime lowers the pH, which accelerates the release of alkaloids from both the tobacco and areca nut. Chewing paan correlates with alveolobuccal cancer.[22] Paan is also strongly associated with a premalignant lesion oral submucous fibrosis.[23] Bidi smoking causes cancer of the oral commissure, oral tongue and also base of tongue. Chutta is associated with cancer of the hard palate and palatine arch in India.[24] Khaini, a mixture of tobacco and lime that is retained in the inferior gingivobuccal sulcus, leads to cancer in this site.[25]

Marijuana

When marijuana is smoked, a wide range of potential carcinogens are released and absorbed including polycyclic aromatic hydrocarbons, benzopyrene, phenols, phytosterols, acids and terpenes.[26, 27] A study from Memorial Sloan Kettering Cancer Center reported an overall risk of 2.6 compared to non-users.[28]

ALCOHOL

Alcohol is believed to act in a synergistic fashion with tobacco.[7, 29, 30] However, some case control and cohort studies have shown an increased risk of cancer even in non-smokers.[31] The precise mechanism by which alcohol causes cancer is not clearly defined as alcohol itself is not a carcinogen. Possible mechanisms include:

- Alcohol may act as a solvent increasing the cellular permeability of tobacco carcinogens through the mucosa of the upper aerodigestive tract.[29]
- The non-alcohol constituents of various alcoholic beverages may have carcinogenic activities.
- The immediate metabolite of ethanol is acetaldehyde and this may have a locally damaging effect on cells.[32]
- Chronic alcohol use may upregulate enzymes of the cytochrome p450 system, which may result in the activation of procarcinogens into carcinogens.
- Alcohol can also decrease the activity of DNA repair enzymes resulting in increased chromosomal damage.
- Alcohol impairs immunity due to a reduction in T cell number, decreased mitogenic activity and macrophage activity.
- Alcohol is high in calories, which suppresses appetite in heavy drinkers. Metabolism is further damaged by liver disease resulting in nutritional deficiencies and therefore lowered resistance to cancer.

DENTAL FACTORS

Poor oral hygiene is associated with oral cancer. This may be due to chronic inflammation of the gingiva.[33]

Alternatively, it may be due to an alteration in the oral microbiome.[34, 35] Painful or loose fitting dentures have also been associated with oral and oropharyngeal cancer.[36] This may also be due to chronic inflammation. There is some evidence suggesting mouthwashes containing alcohol may also be important.[37]

INFECTIONS

In oral cancer, several viruses have been implicated in carcinogenesis including human papilloma virus (HPV), human immunodeficiency virus (HIV) and herpes simplex virus (HSV).

Human papillomavirus

For oral cancer, the pathogenetic relationship with HPV is unclear. Some authors have dismissed a link between oral cavity cancer and HPV infection, based on the very low prevalence rates reported in some studies.[38–40] For instance, in the International Agency for Research on Cancer multicentre study, HPV DNA was detected in biopsy specimens in only 3.9% of 766 cancers of the oral cavity with valid PCR results.[38] In contrast, other authors have reported that the infection of oral cavity cells by HPV is not a rare phenomenon. Analysis of reports focused only on oral cavity cancer have reported a prevalence as high as oropharynx, around 60% or 70%,[41, 42] even in subsites not common for this infection (such as gums or floor of mouth). Therefore, the relationship between oral cavity cancer and HPV infection is not a closed case, and further research is necessary to elucidate its role.

Human immunodeficiency virus

A recent study from New York showed HIV infection in 5% of head and neck cancer patients.[43] In patients under 45, HIV infection was present in over 20%. Due to the depressed immunity in HIV patients, the head and neck cancers observed were more advanced in the HIV group. In addition, HIV infection is more common in inner city populations and certain socioeconomic groups and this will also contribute to the advanced stage at presentation of these patients.[44]

Herpes simplex virus

Several studies have shown that patients with oral cancer have higher antibodies to HSV, but this does not prove a causal relationship.[45] Antibody levels are higher in smokers and even higher in smokers with oral cancer. It is possible that the immunosuppression produced by smoking may lead to a HSV chronic carrier state resulting in raised antibody levels. HSV-type protein has been reported in 42% of patients with oral cancer and 0% in control patients.[46] However, there is little evidence that HSV gene sequences are present in oral cancer cells or any evidence of gene integration. Therefore, there is currently little emphasis on HSV in head and neck cancer.

NUTRITIONAL FACTORS

Several studies suggest high fruit and vegetable intake is associated with a decreased risk of head and neck cancer. This may be due to increased intake of the antioxidants or free radical scavenging vitamins A, C and E.[47–49] La Vecchia et al, estimated that up to 15% of oral and pharyngeal cancers in Europe can be attributed to dietary deficiencies.[50] Some studies have shown an increased risk with red meat intake and salted meat.[51, 52]

GENETIC AND IMMUNOLOGIC PREDISPOSITION

Although smoking is the main risk factor, not all people who smoke develop head and neck cancer. Therefore, genetic and immunologic factors also play a role. There are several genetic conditions that are associated with increased risk. Li-Fraumeni syndrome, an autosomal dominant condition involving mutation of the *p53* gene, has been associated with head and neck cancer in patients with minimal tobacco exposure.[53, 54] Fanconi's anaemia, Bloom syndrome and ataxia-telangiectasia are autosomal recessive disorders associated with increased chromosomal fragility and cancer susceptibility. There is an increased incidence of head and neck cancer in each of these conditions.[55–58] There is a genetic susceptibility in the capacity to metabolize carcinogens and repair consequent DNA damage. This involves polymorphisms in GST genes,[59–61] CYP genes,[62, 63] and the cytochrome *p450* system.[64]

Immunologic factors are also important. Patients treated for bone marrow transplants and organ transplants have an increased incidence of skin cancer and oral cavity cancer. This may be due to the long-term use of immunosuppressive drugs.[65, 66]

Cancer of the oropharynx

Recent studies have shown a dramatic change in the aetiology of oropharyngeal cancer from a cancer caused by smoking and alcohol to a cancer now predominantly caused by HPV.[3] Cancer of the oropharynx is the third most common head and neck cancer after larynx and oral cavity. It is estimated that in 2013 there will be 13 930 new cases of oropharynx cancer in the United States, 11 200 male and 2730 female.[2] In the UK, it has an increasing incidence, reported in near 6% annual percentage change, especially among men.[67, 68] Raised incidence rates are observed in Netherlands, India, France and Italy.[69–71] This increase in tonsil and base of tongue cancer over the last decade is largely due to HPV infection of the palatine and lingual tonsils, and has been called an epidemic of HPV-associated oropharyngeal cancer.[72, 73]

HPV has been extensively studied and there seems to be a definite association between virus and tumour formation.[72, 74] The proportion of cancers with HPV varies with site with a strong association with tonsil cancer.[75,76] Steinberg and DiLorenzo reported HPV infection to be highest in tonsil (74%), followed by larynx (30%), tongue (22%), nasopharynx (21%) and floor of mouth (5%).[77] HPV exists in many different serotypes and specific serotypes are associated with head and neck cancer. For example,

benign lesions such as the common wart are associated with 'low-risk types' and include HPV 6, 11, 13, 32.[78] High-risk types are associated with premalignant lesions and squamous cell carcinoma and include HPVs 16, 18, 31, 33, 35, 39.[78, 79] HPV 16 and 18 appear to be the most common types associated with squamous cell carcinoma. HPV 31, 33 and 35 are more commonly associated with cervical cancer and are not found in oropharyngeal cancer.[80, 81] The E6 and E7 open reading frames (ORFs) of the high risk HPVs are particularly important. They bind to and inactivate tumour suppressor genes *p53* and *pRb* respectively.[82] This allows uncontrolled cell proliferation, which can result in genomic instability and cellular transformation.[83] There is no relationship between clinical stage and HPV status in squamous cell carcinoma of the head and neck. This suggests HPV infection is not a late event in the evolution of head and neck cancer. As mentioned above, the highest incidence of HPV is found in tonsil cancer suggesting that there is a predilection of HPV infection for patients with tonsillar carcinoma.[75, 76] Patients with HPV positive tonsil cancer tend to be young, non-smokers and non-drinkers. The molecular characteristics are completely different to HPV negative tonsil cancers where *p53* is often mutated due to carcinogens in tobacco smoke and amplification of cyclin D1. HPV-positive cancers often have abnormalities in the PIK3/AkT/mTOR pathway resulting in activation of this pathway.[84, 85] Probably due to the different pathogenetic origin, HPV-positive tonsil cancers have shown a better prognosis.[86]

Cancer of the larynx and hypopharynx

The American Cancer Society estimates that 12 260 new cases of laryngeal cancer (9680 in men and 2580 in women) will be diagnosed, and 3630 people (2860 men and 770 women) will die from the disease in the United States in 2013.[2] These numbers are falling by around 2% to 3% a year, mainly because fewer people are smoking.[1, 3] About 60% of larynx cancers start in the glottis, 35% develop in the supraglottic region and the remaining 5% occur in the subglottis.[87]

Cancer of the hypopharynx accounts for 10% of all squamous cell cancers of the upper aerodigestive tract.[87] In the UK, the overall incidence is 1 per 100 000 per annum. There is a high incidence in northern France of 14.8 per 100 000.[88, 89] Subsites of the hypopharynx include pyriform fossa (70%), postcricoid area (15%) and posterior pharyngeal wall (15%).[87] The pyriform fossa is the commonest subsite in North America and France. Postcricoid lesions appear more commonly in Northern Europe. The mean age at presentation is 60 years. Pyriform fossa and post pharyngeal wall have a male predominance of 5 to 20 : 1 in North America[90, 91] with 50 : 1 in France.[92] Postcricoid lesions show a female preponderance 1.5 : 1.[93–95]

TOBACCO AND ALCOHOL

There is a strong association between laryngeal cancer and cigarette smoking. The relative risk of laryngeal cancer between smokers and non-smokers is 15.5 in men and 12.4 in women.[96] Environmental tobacco smoke also increases the risk of laryngeal cancer.[97] The combined use of tobacco and alcohol increases the risk of laryngeal cancer by 50% over the estimated risk if these factors were considered additive.[98–100] Risk is greater for hypopharyngeal cancer than laryngeal cancer.[101] This variation in the risk of alcohol is shown for different sites in the larynx (i.e. supraglottic cancer patients are more likely than glottic and subglottic patients to be heavy drinkers of alcohol).[102, 103]

OTHER FACTORS

Laryngeal cancer is associated with nickel and mustard gas exposure.[104] There may also be association with asbestos exposure.[105, 106] Machinists and car mechanics are at increased risk.[107, 108] Long-term exposure to sulphuric and hydrochloric acid in battery plant workers is associated with an increased risk.[109] Postcricoid carcinoma is associated with previous radiation[93, 110] and sideropenic dysphagia.[93–95] Between 4% and 6% of patients have a history of Patterson-Brown-Kelly or Plummer—Vinson syndrome. Radiation is also implicated in posterior pharyngeal wall carcinomas.[111] Several studies associate high fruit and vegetable intake with a decreased risk of head and neck cancer. This may reflect increased intake of the antioxidants or free radical scavenging vitamins A, C and E.[112, 113] As in oral cavity and oropharyngeal cancer, HPVs may also be a factor in some cases of laryngeal and hypopharyngeal cancers. However, a causative role has been described in only small proportion of patients (5–30%).[114, 115] Laryngeal and hypopharyngeal cancers are also more common in people who are immunosuppressed due to HIV or organ transplantation.[116]

Cancer of the nasopharynx

Nasopharyngeal cancer (NPC) is rare with an incidence in the UK of 0.5/100 000[9], approximately 400 new cases every year.[117] It accounts for 1–2% of all head and neck cancers. In the United States there are approximately 2000 cases per year.[2] However, in southern China and Hong Kong the disease is endemic with an incidence rate of 50 per 100 000.[118] It is also common among Inuits of Alaska and in immigrant groups in the United States, such as recent Chinese immigrants and those from Southeast Asia such as the Hmong. In the last few years the rate at which Americans, including Chinese immigrants, have been developing this cancer has been slowly dropping.

According to the World Health Organization, there are three subtypes:[119] WHO type 1-keratinizing squamous cell carcinoma; WHO type 2-non-keratinizing (differentiated) carcinoma; and WHO type 3-undifferentiated carcinoma. In North America, type 1 accounts for 68% of cases.[120] In the Far East, types 2 and 3 account for 95% of cases.[121]

NPC is the result of interaction of genetic and environmental factors. The association is strongest for WHO types 2 and 3.[122] The genetic association is with different types of HLA types; in ethnic Chinese, NPC is associated

with HLA types A2, B17 and Bw46.[123, 124] HLA B17 carries the same risk as Bw46 and is associated with younger onset disease and poorer prognosis.[124, 125] In addition, family members of people with NPC are more likely to get this cancer. The most important environmental factor is infection by Epstein—Barr virus (EBV). Almost all NPC cells contain EBV.[126] There is a strong association between undifferentiated nasopharynx cancer and positive serology for EBV antigens. Antibody titres to EBV antigens correlate with stage of disease and a fall reflects tumour response to treatment whereas a rise in antibody levels means progression of disease.[126–128]

Dietary factors are also important. People who live in areas of Asia, northern Africa and the Arctic region, where NPC is common, typically eat diets very high in salt-cured fish and meat.[129] Studies indicate that foods preserved in this way that are cooked at high temperatures may produce chemicals that can damage DNA. Ho has reported accumulation of carcinogenic nitrosamines in salted fish.[130] In southeast China, the rate of this cancer is dropping as people begin eating a more 'Western' diet.

Cancer of the nasal cavity and paranasal sinuses

Cancers of the nasal cavity and paranasal sinuses are rare.[131] About 1200 people in the United States develop cancer of the nasal cavity and paranasal sinus each year, representing 3% of head and neck cancers.[132] Men are about 50% more likely than women to get this cancer. Nearly 80% of the people who get this cancer are between the ages of 45 and 85. About 60% to 70% of cancers of the nasal cavity and paranasal sinuses occur in the maxillary sinus, 20% to 30% in the nasal cavity, 10% to 15% in the ethmoid sinuses, and less than 5% in the frontal and sphenoid sinuses.[133]

As in all head and neck cancer, smoking tobacco is a risk factor for nasal cavity cancer. Occupational factors are also important. These include occupational exposure to dust from wood, textiles and leather and even perhaps flour.[134, 135] Other substances linked to this type of cancer are glues, formaldehyde, solvents used in furniture and shoe production, nickel and chromium dust, mustard gas, isopropyl ('rubbing') alcohol, and radium.[136] HPV infection has been reported in patients with benign and malignant tumour of the sinus.[137, 138] HPV DNA type 16 has been detected in over 50% of non-keratinizing carcinomas;[139] it likely represents a distinct histopathologic entity related to HPV infection. However, the clinical significance of these findings is not completely determined.

NON-SQUAMOUS MALIGNANT TUMOURS

Carcinoma of the thyroid

This is more common in women with a ratio of 3:1 and affects mainly young people with nearly two-thirds of cases in the age group 20–55 years. The commonest type is differentiated (80%) which includes papillary (85%) and follicular (15%) cancer. The poorly differentiated cancer accounts for 10% of cases, anaplastic 5% and medullary thyroid cancer 5%.[140] The incidence of thyroid cancer is increasing and this increase is mostly related to papillary carcinoma diagnosis, without any significant difference in the less frequent histologies. The increase is the result of the incidental detection of early thyroid cancer because of increasing use of imaging such as computerized tomography (CT), magnetic resonance imaging (MRI), ultrasound (US) and positron emission tomography (PET).[141] Between 1983 and 2006, the number of subcentimetre well-differentiated thyroid cancers (WDTC) increased five-fold. The incidence of WDTC > 2 cm and also larger WDTCs (> 4 cm and > 6 cm) at least doubled.[142] Therefore, the increase is due to subclinical diagnosis but also due to a true increase in disease incidence. The mortality rates for well differentiated thyroid cancer have remained relatively static and the prognosis is excellent with a 5-year survival of 97% of cases.[143] Thyroid cancer is more common in areas of the world where people's diets are low in iodine, and the opposite in areas with high iodine intake.[144, 145] However, there is not a strong epidemiological relationship between iodine intake and cancer and further studies are warranted.[146] A history of radiation treatment in childhood is a known risk factor. In the past, radiation was used to treat children with acne, fungal infections of the scalp, an enlarged thymus and tonsillar and adenoidal hypertrophy. Subsequent studies showed that there was an increased incidence of thyroid cancer in these children.[147] In contrast, exposure to radiation in adults carries little risk of thyroid cancer. Children exposed to radioactive fallout from nuclear power plant accidents or nuclear weapons also have an increased incidence of thyroid cancer. For example, children exposed to nuclear fallout from Chernobyl have an eight times incidence of thyroid cancer.[148–150]

Inherited medical conditions such as Gardner syndrome, familial polyposis and Cowden disease have an increased incidence of thyroid cancer. Certain families also have an increased incidence of papillary thyroid cancer. Medullary thyroid cancer (MTC), which constitutes approximately 5% of all thyroid malignancies, originates from the parafollicular C-cells, secretes calcitonin and occurs in both sporadic and hereditary forms.[151] Seventy-five per cent of MTC occurs as a sporadic form and 25% as a hereditary form. The hereditary forms can occur in three different settings: as a single component in a hereditary disease (FMTC); in the hereditary syndrome multiple endocrine neoplasia syndrome type A (MEN-2A) associated with parathyroid disease and phaeochromocytoma; and lastly in the hereditary syndrome MEN-2B associated with pheochromocytoma and a specific phenotype characterized by mucosal ganglioneuromas, intestinal ganglioneuromatosis and a marfanoid habitus. Both MEN-2 syndromes are autosomal dominant genetic disorders characterized by mutations in the *RET* proto-oncogene.[152, 153] Patients can now be stratified into high-, intermediate- and low-risk groups according to the type of *RET* mutation.[154]

Salivary gland carcinomas

There are two main types of salivary glands, the major salivary glands (parotid, submandibular and sublingual glands) and the minor salivary glands. About 80% of all salivary gland tumours are in the parotid gland, 10–15% in the submandibular gland and the rest in the sublingual and minor salivary glands.[140] Most tumours of the parotid gland are benign whereas 40% of submandibular gland tumours and 80% of minor salivary gland tumours are malignant. There are several different types of malignant tumours of the salivary glands due to the different types of cells that make up normal salivary glands. These include mucoepidermoid carcinoma, adenoid cystic carcinoma, acinic cell carcinoma, polymorphous low-grade adenocarcinoma and rare adenocarcinomas such as basal cell, clear cell, salivary duct and mucinous adenocarcinoma. Salivary gland carcinomas are not common and occur with an annual rate of 1.2 per 100 000 in the United States.[1] About one-third-of patients are under the age of 55 years. The incidence of these cancers is increasing but the cause for this is unknown.[155]

Exposure to radiation to the head and neck area for other medical reasons (e.g. radiotherapy for squamous cell cancer) increases the risk of salivary gland cancer.[156] Industrial exposure to radioactive substances and also accidental exposure from atomic bomb blasts also increase the risk of salivary gland cancer.[156] Some studies have also suggested that working with certain metals (nickel alloy dust) and minerals (silica dust) may increase the risk for salivary gland cancer. In men, smoking and heavy alcohol consumption was also associated with higher risk, but these factors were not strongly related to salivary gland cancer in women.[157] Hormonal dependence may also be important; early menarche and nulliparity are associated with increased risk, whereas older age at full-term pregnancy and long duration of oral contraceptive use are associated with reduced risk.[158] Female patients with salivary gland tumours are also 2.5 times more likely to develop breast cancer.[159] Diets low in vegetables and high in animal fat may also be important.[160]

Sarcomas of the head and neck

Sarcomas of the head and neck constitute less than 1% of head and neck malignancies.[161] They are divided into those arising from soft tissue (STS)[161] and those arising from bone (osteosarcoma).[162] STS comprise a heterogeneous group with varied histology and behaviour and include chondrosarcoma, dermatofibrosarcoma protuberans, Ewings sarcoma, leiomyosarcoma, liposarcoma, malignant fibrous histiocytoma, malignant peripheral nerve sheath tumour (MPNT), rhabdomyosarcoma and synovial sarcoma.[162] Rhabdomyosarcoma is rare in adults but is the most common STS in children with over 30% occurring in the head and neck. Dermatofibrosarcoma protuberans is a rare tumour of the dermis that has a high recurrence rate. Malignant fibrous histiocytoma is the most common STS in middle and late adulthood. Only 4% of liposarcomas occur in the head and neck with the neck being the most common site. Synovial sarcomas occur between the ages of 20 and 50 years with the majority arising in the parapharyngeal space. The most common site of chondrosarcoma in the head and neck is the larynx, followed by the maxilla and skull base. Most occur between the ages of 30 and 60 years. The most common site in the larynx is the posterior lamina of the cricoid cartilage (75%). MPNTs are extremely rare but more common in patients with neurofibromatosis type I (NF1).

Osteogenic sarcoma is a rare highly malignant tumour with an incidence of 1 in 100 000 with only 7% occurring in the head and neck region. The majority of these arise in the mandible followed by the maxilla. Head and neck osteosarcoma is most common between ages of 30 and 40 in comparison to long bone osteosarcoma, which is most common in teenage years.

GENETIC PREDISPOSITION

Studies have shown that some groups of individuals are at an increased risk of developing STS.[161, 163] Among them are genetically predisposed individuals, such as those suffering from neurofibromatosis who are at risk of MPNT, individuals with Li-Fraumeni syndrome, and children with retinoblastoma who are predisposed to osteosarcoma, rhabdomyosarcoma, and fibrosarcoma. Other heritable syndromes associated with an increased risk of STS include Gardner syndrome and nevoid basal cell carcinoma syndrome.

RADIATION, VIRUSES AND OTHER FACTORS

Previous exposure to irradiation is another well-documented risk factor[164] for both STS and osteogenic sarcoma. Although radiation-induced sarcoma (RIS) is a well-recognized long-term complication of radiation therapy for other sites, the head and neck is less commonly affected.[165] It is difficult to implicate therapeutic irradiation in the causation of head and neck tumours because of the inherent risk of multiple primary tumours in these patients. In addition, patients with certain types of primary tumours such as retinoblastomas have an increased sensitivity to radiation therapy, but are at increased risk for the development of sarcoma irrespective of the type of treatment.

Environmental carcinogens and chemicals like urethane, ethylene derivatives and polycyclic hydrocarbons have also been reported to increase the risk of STS at sites other than the head and neck.[166]

The role of viruses in the pathogenesis of STS has been investigated, but apart from the association of HIV with Kaposi's sarcoma and the observation that viral oncogenes such as the 'src' in the Rous sarcoma virus can transform cells in culture, no conclusive proof is available for a viral aetiology.[167] Immunosuppression attributable to either HIV infection or antirejection medication in organ transplant recipients may predispose children with latent EBV infection to leiomyosarcoma of the liver.

Patients with chronic lymphedema have an increased incidence of STS formation.[168] Patients with Paget's disease of bone, particularly the skull, are predisposed to osteogenic sarcoma.[169, 170]

KEY POINTS

- Squamous cell cancer is the most common head and neck malignancy, and it is related mainly to alcohol and tobacco use.
- Human Papilloma Virus (HPV) is now the leading cause of cancer of the oropharynx.
- Other malignancies of the head and neck such as thyroid cancer, salivary gland cancer and sarcomas are not related to alcohol or tobacco usage. The main causes of these cancers are less clear. Prior exposure to radiation in the head and neck area is one of the few identified risk factors.
- Genetic predisposition to head and neck cancer is rare and is present in a few inherited conditions such as Fanconi Anaemia and Li-Fraumeni Syndrome. Medullary thyroid cancer is a well-known example of a hereditary thyroid cancer secondary to a specific mutation in RET oncogene.
- There is an important role of head and neck cancer prevention through alcohol and tobacco cessation, HPV vaccination and close follow-up of risk groups such as genetic conditions carriers.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: oral cavity, oropharyngeal cancer, laryngeal cancer, hypopharyngeal cancer, nasopharyngeal cancer, squamous cell carcinoma, HPV, EBV, smoking, alcohol, and/or epidemiology.

INTRODUCTION

Head and neck cancer comprises a diverse array of diseases with distinct anatomical subsites, histopathologic features and risk factors. The most common type of head and neck cancer is squamous cell carcinoma (SCC) of the mucosa of the upper aerodigestive tract (UADT). In 2008, more than 600 000 people worldwide were diagnosed with UADT SCC.[1] The incidence of and risk factors for UADT SCC differ by tumour subsite. The five major subsites are nasopharynx, oral cavity, oropharynx, larynx, and hypopharynx.

Nasopharyngeal cancers are typically related to Epstein–Barr virus, and are a major contributor to the UADT burden in Southern China and Southeast Asia. However, SCCs at this site are relatively rare in other populations. The majority of UADT SCCs worldwide were caused by tobacco and alcohol, and in many countries, public health efforts aimed at reducing tobacco exposure have helped decrease the incidence of UADT SCC. However, in North America, Europe and Australia, there is an epidemic of oropharyngeal SCC (OPSCC) caused by infection with human papillomavirus (HPV), and HPV-positive OPSCC is now more common than tobacco-and-alcohol-associated OPSCC in many of these countries.[2] In contrast, in developing countries where the prevalence of smoking is increasing, the incidence of UADT SCC is also increasing. The rate of oral cavity SCC is higher in South Asian countries than other countries, most likely because of use of oral tobacco and related products, resulting in a global health disparity.

This chapter discusses the incidence of and risk factors for SCC of the oral cavity, oropharynx, larynx and hypopharynx. The shift from tobacco-and-alcohol-related to HPV-related OPSCC is also examined, along with the associated health implications and global variations. A more comprehensive treatment of aetiology is discussed in Chapter 2, Aetiology of head and neck cancer.

SCC OF THE ORAL CAVITY

Worldwide, SCC of the oral cavity is the tenth most common cancer among men, and in 2008, 263 000 people were diagnosed with this disease (171 000 men and 92 000 women).[1] The majority of oral cavity SCCs are related to tobacco and alcohol exposure (61% of oral cavity SCCs in Europe, a higher proportion in India).[3] There is a dose-effect relationship between tobacco and alcohol exposure and risk of oral cavity SCC, and individuals exposed to high levels of tobacco and alcohol have an odds ratio of 7.1 (95% confidence interval [CI], 5.0–10.0) compared to those without tobacco or alcohol exposure.[4] In the United States, because of public health initiatives, the rate of current cigarette smoking declined from 43% in 1965 to 21% in 2004, and in the past three decades there has been a concomitant decrease in the overall rate of oral cavity SCC.[5,6] Globally, as the use of tobacco in developing countries has increased, there has been a subsequent increase in the incidence of oral cavity SCC.[7] Hence, while oral cavity cancer is the tenth most common cancer among men worldwide,

its incidence varies with the prevalence of tobacco use and is higher in many developing countries and lower in many developed countries.

The oral cavity is anatomically subdivided into the oral tongue, floor of mouth and gingivobuccal subsites. In developed countries, the typical patient with oral cavity SCC is a man in the sixth-to-seventh decade of life with a history of smoking and alcohol exposure and a tumour located on the lateral tongue or floor of mouth. These two subsites are the most common subsites of oral cavity SCC; in a National Cancer Database review by Funk et al, 32% of oral cavity SCCs occurred in the lateral tongue and 28% occurred in the floor of the mouth.[8] Oral cavity SCCs are likely to be associated with occult nodal metastasis at presentation, and therefore many patients present with advanced disease.

There is one notable exception to the pattern of decreasing incidence of oral cavity SCC in developed countries: among white patients younger than 40 years in the United States, there has been a 2% annual increase in the incidence of SCC of the oral tongue, though such tumours in young patients are exceptionally rare.[9, 10] Some Scandinavian countries have shown similar increase in incidence of young patients with oral tongue cancer.[11] The explanation for this phenomenon is unclear: not all affected patients have a history of prolonged tobacco exposure, and there is no known viral or other cause for the increase in incidence. Clinical tumour behaviour and survival rates in these young patients with oral cavity SCC mimic clinical tumour behaviour and survival rates in their older counterparts.[12, 13]

Use of smokeless tobacco, tobacco with or without additives that is dipped or chewed, is also a risk factor for oral cavity SCC. Because of global variation in the prevalence of smokeless tobacco use (ranging from less than 5% in the United States to more than 1 in 3 males in India), concurrent smokeless tobacco use and cigarette use, and regional variation in potentially carcinogenic additives, determination of the exact contribution of smokeless tobacco to the risk of oral cavity SCC is difficult.[14, 15] Boffetta et al pooled data from multiple studies and estimated a summary relative risk of 1.8 (95% CI, 1.1–2.9) for users of smokeless tobacco compared to non-users.[15]

Betel nut is an additional risk factor for oral cavity SCC, particularly in developing countries. Betel nut, from the betel or areca palm tree, can be chewed alone or mixed with tobacco and lime and placed in a betel-leaf pouch (in India this is called paan, and there are many variations). Absorption of the red juice produced by the betel mixture results in cholinergic stimulation in the short term but carcinogenesis over the long term. Betel nut use is common throughout South Asia, though exact usage rates are difficult to determine. In India, in 2010, oral cavity SCC was the number one cause of death for men over the age of 30 years, and in 2008, oral cavity SCC was the most common cancer diagnosed in men, in part due to use of betel nut and smokeless tobacco.[16–18]

Oral cavity SCC related to betel nut use most commonly occurs in the buccal mucosa, whereas oral cavity SCC related to tobacco and alcohol use most commonly occurs in the oral tongue or floor of mouth.[19, 20] Betel nut may also cause a benign but devastating submucosal fibrosis of the buccal mucosa, which in severe cases can cause trismus and hinder eating; in some cases, this submucosal fibrosis may be premalignant.[21]

Other risk factors may play a role in oral cavity SCC: multiple studies have examined the role of marijuana as a risk factor; however, no conclusive evidence has been found implicating marijuana use as a cause of UADT SCC at any subsite.[22] These studies may suffer from recall bias, subsite misclassification, confounding due to concurrent tobacco use, and low incidence of heavy marijuana use, and further investigation is needed.[23] Poor oral hygiene has also been identified as a potential risk factor but may be a sign of disease rather than a cause. Defective DNA repair pathways may also play a role in the development of SCC.[24] While HPV plays a strong role in the etiology of OPSCC, there is no evidence that HPV contributes to any great degree to oral cavity SCC.

Patients with Fanconi anaemia are at higher risk than the general population for developing oral cavity SCC.[25] Fanconi anaemia is caused by an autosomal recessive genetic mutation. The disease manifests as congenital anomalies (most commonly skeletal, renal and developmental) and progressive pancytopenia and results in a shortened life expectancy. Leukemia is the most common associated cancer, and there is also an increased risk of head and neck cancers. These occur at a younger age than typical tobacco-related head and neck cancers, most often occur in the oral cavity, and may be aggressive.[25]

SCC OF THE OROPHARYNX

UADT SCC has traditionally been strongly associated with tobacco and alcohol exposure. In the United States, it was expected that the incidence of OPSCC would decrease in parallel with decreasing smoking rates, but in fact, there was only a plateau in OPSCC incidence followed more recently by a dramatic increase.[6, 26, 27] Closer examination revealed that the increase occurred in middle-aged white men, while the incidence of OPSCC in men older than 60 years of all races was decreasing. Furthermore, the middle-aged men who were developing OPSCC often had no history of smoking or were former or light smokers. Because of multiple lines of evidence, the increasing OPSCC incidence in this group is now attributed to HPV.

Two molecularly and epidemiologically distinct types of OPSCC are now recognized, classified according to HPV status. HPV-negative OPSCC is epidemiologically similar to the traditional type of UADT SCC, in which long-term exposure to tobacco and alcohol leads to development of malignancy. The typical patient with HPV-negative OPSCC is a man older than 55 years with a long history of smoking and drinking and a well or moderately differentiated SCC. HPV-negative OPSCC is declining in incidence in the United States, similar to what is occurring with respect to the incidence of other SCCs of the UADT that are caused by tobacco and alcohol but not HPV (SCCs of the oral cavity, larynx and hypopharynx).[2, 28]

In contrast, the typical patient with HPV-positive OPSCC is a middle-aged, non-smoking white man from a higher socioeconomic status and with a history of multiple sexual partners.[29]

HPV-positive OPSCC originates with exposure to high-risk HPV, a sexually transmitted virus, and can develop independently of tobacco or alcohol exposure.[28, 30] HPV is most strongly associated with OPSCC found at the tonsil and base of tongue, and cancers at these subsites account for an increasing proportion of all OPSCCs.[31] Oropharyngeal HPV infection is a necessary event in the development of HPV-positive OPSCC.[30] Although HPV can also be transmitted by less intimate skin-to-skin contact, HPV is transmitted primarily via sexual contact, and the risk of oral cavity/oropharyngeal HPV infection increases with the number of oral sexual partners.[32] The current literature shows that at any given time, approximately 7% of the population has a prevalent oral cavity/oropharyngeal HPV infection.[33, 34] The lifetime oral exposure rate is unknown, but an estimated 65% to 100% of sexually active adults have been exposed to HPV at either anogenital or oropharyngeal sites.[35, 36] Given the high point prevalence of oral/oropharyngeal HPV infection, most such HPV infections are cleared by the immune system and do not progress to cancer. Delayed clearance of oral/oropharyngeal HPV infection may be a risk factor for development of OPSCC, just as prolonged/chronic cervical HPV infections are associated with subsequent cervical cancers.

HPV exposure is so common that the presence of HPV DNA in malignant tissues does not establish causality; for example, a patient with a heavy smoking and drinking history may have a tobacco-induced cancer but also have HPV DNA found in the tumour. However, a cell that has become malignant due to HPV oncogenesis will typically overexpress *p16*. *TP53* is commonly mutated in tobacco-related cancers of the UADT, but *TP53* mutations are not common in HPV-related OPSCC. Therefore, p16 staining and determination of *TP53* mutation status can help distinguish truly HPV-related cancers from cases in which HPV DNA is detectable but the cancer is not HPV-related and cases in which detection of HPV DNA represents a false positive result.

There has been some confusion regarding the role of HPV in UADT SCC at sites other than the tonsil and base of tongue. While HPV DNA has been identified in SCC at other UADT subsites, the causal role of HPV in carcinogenesis at these subsites has not been established, and the proportion of cancers at these other subsites attributable to HPV is likely small. Given the high rates of exposure to HPV, the mere presence of HPV DNA alone cannot support causality. HPV-related oncogenic proteins and downstream events such as *p16* overexpression must be detected as part of proving causality. Additionally, poor classification of the tumour subsite, as well as overlap of some subsites, may also have led to misclassification, particularly in older published studies. For instance, whereas previously some OPSCCs (particularly those of the base of tongue, which are often coded as a generic site 'tongue') were misclassified as oral cavity SCCs, classification of tumour sites has been improving and, in parallel, HPV positivity rates for non-oropharyngeal cancers of the UADT have dropped over time, while HPV positivity rates for OPSCC have risen.[37] Differences in testing methods for HPV may also have contributed to high rates of false-positive findings. Regardless, the rate of HPV-positive SCC has consistently been higher in the oropharynx than in the oral cavity, larynx or hypopharynx.[27]

The incidence of HPV-positive OPSCC is increasing markedly, and it is not hyperbole to call this an epidemic. An estimated 85 000 cases of oropharyngeal cancer occurred worldwide in 2008, and at least 22 000 of these were HPV positive.[38] From 1988 to 2004, there was a 225% population-level increase in HPV-positive OPSCC in the United States (from 0.8 cases per 100 000 individuals in 1988 to 2.6 per 100 000 in 2004) and a concomitant 50% decrease in HPV-negative OPSCC (from 2.0 cases per 100 000 individuals in 1988 to 1.0 per 100 000 in 2004[2, 39] (**Figure 3.1**). In the United States, the percentage of OPSCC cases that were HPV-positive increased from 16% in 1984–89 to over 70% in 2000–04. There has been a 5% annual percentage rate increase in the incidence of OPSCC in the United States and a 6% increase in Finland.[2, 39] Chaturvedi et al estimated that by 2020 the incidence of HPV-positive OPSCC will be greater than

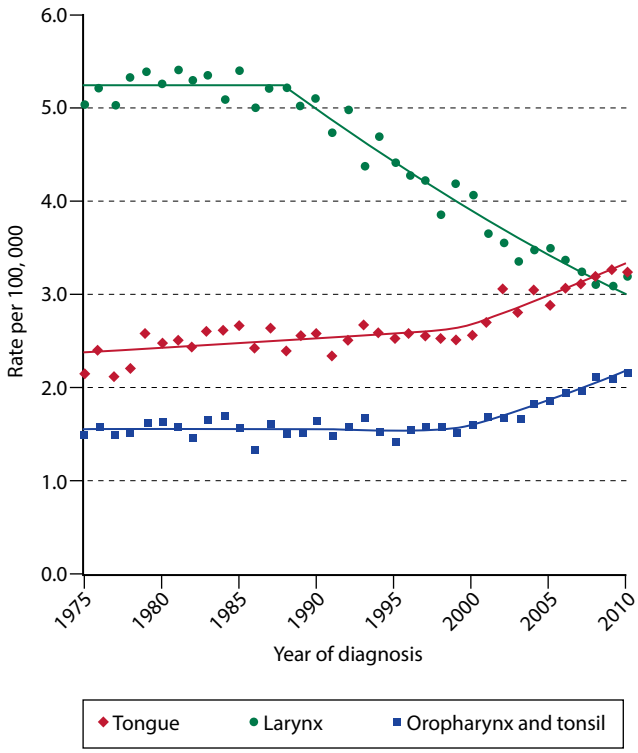

Figure 3.1 Age-adjusted SEER incidence rates by cancer site 1975–2010 (all ages, all races and both sexes). Cancer sites include invasive cases only, unless otherwise noted. Rates are per 100 000 and are age-adjusted to the 2000 US Std Population (19 age groups – Census P25-1130). Regression lines are calculated using the Joinpoint Regression Program Version 4.0.3, April 2013, National Cancer Institute. Incidence source: SEER 9 areas (San Francisco, Connecticut, Detroit, Hawaii, Iowa, New Mexico, Seattle, Utah and Atlanta).

the incidence of cervical cancer, and by 2030, more than half of all head and neck cancers will be related to HPV.[2] The increase in HPV-related OPSCC is well documented in North America, Europe and Australia although marked geographical variation is evident.[2, 40–42] For example, recent data from the UK[43] in a multicentre study involving the HPV typing of tumour samples from ~1400 patients treated between 2002 and 2011, confirmed that whilst the incidence of oropharynx cancer doubled, the prevalence of cases attributable to HPV infection remained stable at ~55% during this decade. Consideration of these, somewhat surprising, data leads to a conclusion that HPV-negative oropharynx cancer has also been increasing in the UK throughout this time period, despite the overall population reduction in tobacco smoking. Why this is, is a matter of conjecture but the authors, citing the parallel increase in oral cavity tumours, suggest a potential role for increased alcohol consumption. Moreover, a similar increase in HPV-positive OPSCC has not been well documented in South America, Africa and Asia, but population-based studies from these regions with careful site classifications and exposure data are limited or non-existent, and different sexual practices and continued high smoking rates may also obscure these trends.

In 2008, using the Surveillance, Epidemiology and End Results (SEER) database (1973–2004), which contains information on a sample of patients in the United States, Chaturvedi et al demonstrated in a landmark study that the rise of OPSCC incidence was occurring specifically among middle-aged white men.[6] There were no significant changes in OPSCC incidence among individuals under 40 years or over 59 years of age, but among middle-aged white men, a 10% annual increase in incidence was seen since 2000.[6] Mehta et al utilized the SEER database to compare the incidence of OPSCC in different age groups during the period from 1973 through 2006.[26] They found that the proportion of patients aged 40–59 years increased from 35% to 45%, while the proportion of oropharyngeal cancer patients aged 60–79 years decreased from 52% to 40%.[26] The increase in OPSCC incidence among Caucasian males is so dramatic as to nearly obliterate a previous racial disparity in the incidence of UADT SCC.[44] In the late 1980s, African American males had more than twice the incidence of OPSCC of white American males; this disparity has been completely eliminated by the increase in OPSCC among white men and continued decrease in OPSCC incidence among African American men.[6]

Patients with HPV-positive OPSCC are less likely to have a history of tobacco exposure; in most series of patients with OPSCC, about 30% of patients in the HPV-positive group are non-smokers, compared with fewer than 5% of patients in the HPV-negative group.[45] Patients with HPV-positive OPSCC are also less likely to use alcohol than are patients with HPV-negative OPSCC patients or those with SCC at other subsites of the head and neck.[46] The past few decades have seen a decrease in the age of sexual debut and an increase in the number of sexual partners, contributing to HPV exposure.[47] However, demographic, exposure and behavioural factors are only somewhat predictive of HPV status in patients with OPSCC and should not replace HPV testing.[48]

Patients with HPV-positive OPSCC are more likely to present with small primary tumours and more extensive and possibly cystic nodal disease.[49] Patients with HPV-positive OPSCC may also present at a younger age than the typical head and neck cancer patient, and thus complaints of neck mass or other symptoms related to the UADT should be carefully evaluated. Finally, HPV-related OPSCC tumour histology is more likely to be basaloid, lymphoepithelial or poorly differentiated.[50] Even though patients with HPV-positive OPSCC are more likely to present with advanced nodal disease, survival is better in patients with HPV-positive OPSCC than in those with HPV-negative OPSCC, which is further discussed in Chapter 13, Oropharyngeal tumours.[49, 51–53]

Over 90% of HPV-positive OPSCC cases are caused by a single HPV type, HPV 16, and few OPSCC cases can be attributed to the other HPV types.[54] This has implications for future public health efforts to decrease HPV-positive OPSCC via vaccination. In the United States, two current Food and Drug Administration-approved HPV vaccines provide strong protection against infection with HPV 16. These vaccines are directed towards the viral capsid L1 or L2, a late protein that is expressed during infection and prior to carcinogenesis. Currently these HPV vaccines are approved in the United States for prevention of cervical cancer and prevention of genital warts and anal cancer in both men and women.[55] There is not currently an indication for prevention of HPV-positive OPSCC, as no studies have been conducted to evaluate the effect of the vaccine on oral/oropharyngeal HPV infection and OPSCC development. Given the decades-long delay between HPV exposure and carcinoma detection, such a study will be difficult and costly. However, because HPV 16 is the cause of the overwhelming majority of HPV-positive OPSCC, it is likely that the vaccine will prevent HPV 16 oropharyngeal infection and subsequent OPSCC development when given to individuals prior to HPV 16 exposure.

SCC OF THE LARYNX

In 2008, 150 000 people worldwide were diagnosed with laryngeal SCC.[1] The majority of patients with laryngeal SCC are men. Laryngeal SCC is strongly related to smoking and alcohol use; multiple studies confirm that the risk in smokers and drinkers is 4–177 times the risk in non-smokers/non-drinkers and that risk increases with duration and frequency of exposure.[3, 56–58] Alcohol or tobacco exposure alone are also significant risk factors for the development of laryngeal SCC.[57] In the United States, the incidence of laryngeal SCC plateaued in 1992 and then decreased 2.8% per year from 1992 through 2009 (to an age-adjusted incidence rate of 3.4/100 000 in 2006–10) as tobacco control efforts began to show an effect, and similar changes were seen across Europe.[27, 59–62] In developing countries, as smoking rates

have increased there has been a concomitant increase in the incidence of laryngeal SCC.[7]

The larynx is divided into supraglottic, glottic and subglottic sites, and the presentation of laryngeal SCC differs by subsite. Supraglottic and glottic carcinoma are the most common and make up over 90% of all laryngeal SCC.[63] Because of their rarity, subglottic cancers are often excluded from analysis. More than 50% of laryngeal SCC arise in the glottis, and such cancers tend to occur in heavy smokers who present early in the course of disease with hoarseness.[56, 58, 64] Because of the paucity of lymphatics in the glottic region, many glottic cancers do not have regional metastasis. Supraglottic lesions make up about 32–35% of laryngeal SCC, tend to occur in people who use alcohol and tobacco and, in contrast to glottic lesions, are more likely to present late with extensive nodal disease due to the rich bilateral lymphatic supply of the supraglottic area and the lack of identifying symptoms associated with small supraglottic lesions.[63–65] Perhaps because of the early presentation of glottic lesions, the survival rate is better among patients with glottic SCC than among those with supraglottic SCC.

Other factors have been implicated in the aetiology of laryngeal SCC, particularly among individuals who do not smoke or use alcohol. Laryngeal SCC may be related to laryngopharyngeal reflux disease or gastro-oesophageal reflux disease, although studies conflict and most are retrospective and may suffer from recall bias and misclassification of reflux disease status.[66–69] Occupational and environmental exposures in the form of inhalation of potentially toxic fumes have also been implicated. These include exposure to diesel exhaust, wood oven smoke, second-hand smoke and asbestos, but the extent of risk is unclear.[70]

SCC OF THE HYPOPHARYNX

The hypopharynx is the least commonly affected of the five major UADT anatomical subsites.[71] Exact numbers of SCCs of the hypopharynx are difficult to determine because in many cancer registries, hypopharyngeal sites are combined with oropharyngeal sites. The hypopharynx is made up of the piriform sinuses bilaterally, the posterior pharyngeal wall and the postcricoid area; the piriform sinus is the subsite most commonly affected. The majority of patients with hypopharyngeal SCC are male (76–80%) and older than 50 years (93–95%) (mean age at diagnosis, 65 years) with a history of smoking and drinking; patients with hypopharyngeal SCC report more excessive use of alcohol than patients with laryngeal SCC.[72, 73] Patients with hypopharyngeal SCC also tend to present late when there is already nodal metastasis, and a Canadian study showed that 80% of patients presented with nodal metastasis and 19% of patients presented with unresectable disease.[73] The distant metastasis rate is higher for hypopharyngeal SCC than for laryngeal or oral cavity SCC: the rate of distant metastasis is 25% at 1 year after completion of initial treatment.[73]

Given the relatively small numbers of patients with hypopharyngeal SCC, as well as the grouping together of multiple pharyngeal sites in reports using data from large cancer databases, there is little published information on hypopharyngeal SCC incidence rates and changes in such incidence attributable to tobacco control efforts. The SEER database shows a slight decrease in the incidence of hypopharyngeal SCC between 1974 and 1999, from 1.0/100 000 to 0.8/100 000.[74]

SUMMARY

The majority of UADT SCCs are related to smoking and drinking, the major exception being HPV-related OPSCCs. In countries where the smoking rate is decreasing, the incidence of UADT SCC is also decreasing. In developing countries, increasing rates of tobacco use are causing a rise in the incidence of UADT SCCs. Tobacco and related products are responsible for oral cavity cancers being the most common cancer in India. Efforts to curb tobacco use should be aimed at high-risk populations. The epidemic of HPV-positive OPSCC necessitates that practitioners be aware of the changing demographics of OPSCC. Future health efforts to increase vaccination against HPV are critical for stemming the increase in OPSCC incidence.

KEY POINTS

- The incidence of laryngeal and hypopharyngeal SCC has decreased after successful implementation of public health efforts aimed at tobacco control.
- In North America, Europe and Australia, there is an epidemic of HPV-positive OPSCC, particularly among middle-aged men, and this epidemic is likely related to sexual behaviours.
- Oral cavity cancer is the most common cancer in India, where the common use of oral tobacco and betel nut is the principal cause.
- The epidemiology of SCC of the UADT differs radically by anatomical subsite.
- HPV is a causative factor for OPSCCs, and these cancers often occur among middle-aged men who do not smoke or drink. There is an epidemic of HPV-related OPSCC in North America, Europe and Australia, and it is most often attributed to prior HPV 16 infection; vaccination against HPV 16 may decrease the incidence of OPSCC in those vaccinated prior to exposure to HPV 16.
- Oral cavity SCC, laryngeal SCC, and hypopharyngeal SCC are most often related to smoking and drinking. Tobacco control efforts are decreasing the incidence of these three cancer types.
- Other risk factors may also play a role in SCC of the UADT, such as environmental exposures, concurrent diseases, and defects in DNA repair mechanisms.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words staging of head and neck cancer. The author also consulted the International Union Against Cancer booklet TNM classification of malignant tumours, eighth edition[1] and AJCC cancer staging manual, eighth edition.[2] The nature of staging has meant that the data to support the concept have been largely drawn from retrospective and observational studies (level 3). Much of the systems development has been through the opinion of expert panels using these data (level 4).

INTRODUCTION

There are many aspects that affect the outcome of patients with a malignant head and neck tumour. These relate to the tumour (the anatomical site and the clinical and pathological extent of the disease), the host (age, general condition and any intercurrent disease of the patient) and management (treatment options, expertise available, patient preference). Concurrently, there are also many proposed systems that try to evaluate these factors and predict outcomes for an individual patient.

Staging of head and neck cancer is a system designed to express the relative severity, or extent, of the disease. It is meant to facilitate an estimation of prognosis and provide useful information for treatment decisions. Classification by anatomical extent of the disease, as determined clinically and histopathologically (when possible), is that with which the tumour, nodes, metastases (TNM) system primarily deals. The concept is that an orderly progression of disease takes place with enlargement of and invasion by the primary tumour (T) followed by spread to the regional lymph nodes (N) and eventually spread beyond these nodes to distant meta- static sites (M). The stage at diagnosis in the life history of an individual cancer is numerically assigned a TNM classification. These individual TNM classifications are then assembled into four groups – stage groups (stages I–IV), each with similar survival outcomes based on the observation that better survival is anticipated for cancers with less extension.

AIMS OF THE TNM STAGING SYSTEM

There are many benefits to staging, but one of the principal purposes is to provide a method of conveying clinical experience to others without ambiguity (**Box 4.1**).

The strengths of the TNM staging system are its simplicity, low cost, relative accuracy, objectivity, universal acceptance and lack of need for special technology. But the system is not without limitations. Inconsistencies, observer variability and differences in stage method contribute to potential bias. Uniformity in the method of data collection, knowledge of the current TNM system and accurate application of the correct stage are therefore pivotal if meaningful information is to be derived.

BOX 4.1 Objectives of staging

1. To aid the clinician in the planning of treatment
2. To give some indication of prognosis
3. To assist in evaluation of the results of treatment
4. To facilitate the exchange of information between treatment centres
5. To contribute to the continuing investigation of human cancer

HISTORY AND DEVELOPMENT OF STAGING

The TNM staging system has developed with contributions from both sides of the Atlantic.

In Europe, Pierre Denoix developed the TNM system for the classification of malignant tumours between the years 1943 and 1952.[3] During the 1950s the International Union Against Cancer (UICC) appointed a Committee on Tumour Nomenclature and Statistics. Agreement was reached on a general technique for classification by anatomical extent of the disease, using the TNM system. In 1958, laryngeal and breast cancer were the first primary sites to be assigned recommendations on clinical stage and presentation of results.[4] A decade later, the first TNM booklet, the 'Livre de poche', was published.[5] Over the years, series of meetings have been held to update and unify existing classifications as well as to develop new ones.

In the United States, the initial staging system proposed by the American Joint Committee on Cancer (AJCC) in the late 1960s and implemented in the mid-1970s was simply based on a 'consensus' of leaders and experts in the specialty who were members of the working group of what was then called The American Joint Committee for Cancer Staging and End-Results Reporting. They reviewed the available literature of that time and added their own experiences to devise the initial staging system. Subsequent revisions were also implemented based on the observations of the committee members on information available in the literature and from institutional experiences.

In 1983, The American Joint Committee for Cancer Staging and End-Results Reporting became the now familiar AJCC. Since 1996, the current AJCC Head and Neck Task Force has utilized the data from the National Cancer Data Base (NCDB). This is maintained by the Commission on Cancer of the American College of Surgeons and supported by the American Cancer Society as well as data from Surveillance, Epidemiology and End Results Reporting (a database maintained by the National Cancer Institute, which represents 14 cancer registries). In addition to this, data from state cancer registries are also used on occasion. Review of the literature is performed by the task force, who are all selected for their breadth of expertise and depth of knowledge, to incorporate new information and/or new data, which may impact upon revisions on the staging process.

The eighth edition of the UICC and American Joint Committee on Cancer (AJCC) Staging Manual, Head and Neck Section introduces significant modifications from the prior seventh edition. The most significant update creates a separate staging algorithm for high-risk human papilloma virus associated cancer of the oropharynx, distinguishing it from oropharyngeal cancer from other causes. Other modifications include: the reorganization of skin cancer (other than melanoma and Merkel cell carcinoma) from a general chapter for the entire body to a head and neck-specific cutaneous malignancies chapter; changes to the tumour (T) categories for oral cavity, skin, and nasopharynx; and the addition of extranodal cancer extension to lymph node category (N) in all but the viral-related cancers and mucosal melanoma. One other key change from prior editions of the TNM system is the elimination of the T0 category in sites other than the nasopharynx, HPV-associated oropharyngeal cancer, and salivary gland cancers (which can be identified by their unique histology). If no primary lesion can be identified, then the lymph node may have emanated from any mucosal site, so it is considered that there is no rationale to support retaining the T0 designation outside of the virally associated cancers of the oropharynx and nasopharynx.[1, 2, 6, 7] Thyroid staging has been altered with a change in the increased risk age from 45 to 55 years.

The UICC contains rules of classification and staging that correspond exactly with those appearing in the AJCC cancer staging manual and has approval of all national TNM committees.[1, 2]

GENERAL RULES FOR STAGING

The TNM system for describing the anatomical extent of the disease (**Table 4.1**) is based on three components:

- T – extent of the primary tumour
- N – absence or presence and extent of regional lymph node metastases
- M – absence or presence of distant metastases.

All cases should be confirmed microscopically. Two classifications should be documented for each site, namely: clinical (pre-treatment) classification (cTNM), and pathological (post-surgical histopathological) classification (pTNM). The clinical stage is essential to select and evaluate therapy, while the pathological stage provides

TABLE 4.1 The TNM system for describing the anatomical extent of the disease

T – Primary tumour		N – Regional lymph nodes		M - Distant metastasis	
TX	Primary tumour cannot be assessed	NX	Regional lymph nodes cannot be assessed	MX	Distant metastasis cannot be assessed
T0	No evidence of primary tumour	N0	No evidence of regional lymph node metastases	M0	No distant metastasis
Tis	Carcinoma in situ	N1, N2, N3	Increasing involvement of regional lymph nodes	M1	Distant metastasis
T1, T2, T3, T4	Increasing size and/or local extent of the primary tumour				

the most precise data to estimate prognosis and calculate end results. It should be remembered that if there is doubt concerning the correct T, N or M category to which a particular case should be allocated, then the **lower** (i.e. **less advanced**) category should be chosen. Midline nodes are considered ipsilateral except in thyroid cancers. After assigning the cTNM and pTNM categories, the patient should then be classified into a stage group. Once established this must remain unchanged in the medical records. The eighth edition recommends a prognostic factors classification and uses a 'prognostic factors grid' for each subsite.[8] This relates three prognostic factors grouped to relate to the 'tumour' (e.g. T and N stage, level of nodes), the 'host' (e.g. performance status, comorbidity, age) and the 'environment' (e.g. expertise, quality of treatment) under the narrative of essential, additional and new and promising.[1, 2, 8]

The TNM classification applies only to carcinomas and the following sites are included:

- lip and oral cavity
- pharynx: oropharynx (p16-negative and p16-positive), nasopharynx, hypopharynx
- larynx: supraglottis, glottis, subglottis
- nasal cavity and paranasal sinuses (maxillary and ethmoid sinus)
- unknown primary carcinoma – cervical nodes
- malignant melanoma of upper aerodigestive tract
- major salivary glands
- thyroid gland.

Carcinomas arising in minor salivary glands of the upper aerodigestive tract are classified according to the rules for tumours of their anatomic site of origin (e.g. oral cavity). Each site is described, with rules for classification, anatomical sites and subsites where appropriate, the cTNM classification, the pTNM classification, G histopathological grading, stage grouping and a summary. The main aspects are described here, but specific details can be found in the most recent UICC/AJCC TNM booklets.[1, 2]

Histopathological grading

The histological grading of squamous cell carcinoma represents estimation by the pathologist of the expected biological behaviour of the neoplasm. It has been suggested that such information in conjunction with other characteristics of the primary tumour would be useful in the rational approach to therapy.[8] Others have reserved doubts as to the validity of the method because of its subjective nature.[9, 10] Although grading of squamous cell carcinoma of the upper aerodigestive tract mucosa is a common practice, it has not evolved as an important factor in planning therapeutic strategies.

In a systematic review of 3294 patients, it was found that 46% of patients with poorly differentiated tumours had a nodal metastasis at presentation compared with only 28% of differentiated tumours. Distant metastases at presentation were found in 3.4% of poorly differentiated tumours compared with 1.8% of well-differentiated tumours. Primary and nodal recurrence rate rose and survival fell significantly for poorly differentiated tumours.[11] In another retrospective review of more than 1000 patients, grade and distant metastases were considered. It was found that patients with well-differentiated tumours are at low risk of metastases and patients with poorly differentiated tumours are at high risk of distant metastases. It was suggested they should be considered for systemic chemotherapy.[12] Although histological differentiation is subject to inter- and intraobserver error, it is still worthwhile in clinical practice and, therefore, remains an adjunctive part of the TNM system.[1, 2]

The definitions of the G categories apply to all head and neck sites apart from thyroid. They are shown in **Box 4.2**.

BOX 4.2 G = Histopathological grading

GX: Grade of differentiation cannot be assessed
G1: Well differentiated
G2: Moderately differentiated
G3: Poorly differentiated
G4: Undifferentiated

Additional descriptors

When sentinel lymph node biopsy is attempted, designation is now applicable using the suffix 'sn' after N stage. The absence or presence of residual tumour after treatment may be described by the symbol 'R'. A recurrent tumour, when classified after a disease-free interval is identified by the prefix 'r'. The prefix 'a' indicates that classification is first determined at autopsy.

The certainty factor, or C factor, has now been dropped from the introduction rules on staging but is still worthwhile considering during the diagnostic workup. It reflects the validity of classification according to the diagnostic methods employed (C1–C5). C1 is evidence from standard diagnostic means whereas C5 is evidence from autopsy. Pretherapeutic clinical staging of head and neck cancers should be based on a C2 factor, evidence obtained by special diagnostic means such as radiographic imaging (e.g. computed tomography (CT), magnetic resonance imaging (MRI) or ultrasound scan), endoscopy, biopsy and cytology.[1, 2]

Stage grouping

A tumour with four degrees of T, three degrees of N and two degrees of M will have 24 potential TNM categories. It has, therefore, been felt necessary to condense these into a convenient number of TNM stage groups (**Table 4.2**). The grouping adopted is designed to ensure, as far as possible, that each group is more or less homogenous in respect of survival and in addition, that the survival rates of these groups for each cancer site are distinctive. Carcinoma *in situ* is categorized as stage 0, cases with distant metastases as stage IV. The exception to this grouping system are p16-positive oropharyngeal, nasopharyngeal and thyroid cancers (**Tables 4.3, 4.4, 4.5a, 4.5b** and **4.5c**).[1, 2]

Related classifications

The World Health Organization (WHO) has developed a series aimed at classification of tumours. The WHO International Classification of Diseases for Oncology (ICD-O) is a coding system for neoplasms by topography and morphology and for indicating behaviour (e.g. malignant, benign).[13] This coded nomenclature is identical in the morphology field for neoplasms to the Systemized Nomenclature of Medicine (SNOMED).[14] It is recommended that the WHO Classification of Tumours be used for classification and definition of tumour types and that the ICD-O code be used for storage and retrieval of data.

METHOD OF STAGING

The aim is to define in each patient all the factors relevant to the natural history and outcome of the relevant disease, thereby enabling a patient with cancer to be grouped with other similar cases. The sex and age of the patient, the duration and severity of symptoms and signs, and the presence and severity of intercurrent disease should all be documented.

CT and MRI are now established as the mainstay investigations in the pre-operative workup of patients with head and neck cancer. Not every patient requires a scan but they are useful in delineating the extent and size of the primary tumour, determining the presence (particularly when risk of occult nodes is >20%), number and position of cervical lymph nodes, searching for an occult primary and locating a synchronous primary or distant metastases (particularly in the chest). Appropriate screening for synchronous tumours and distant metastases is particularly important in advanced tumours. Several studies have suggested that a CT scan should be obtained in preference to a plain chest radiograph as this may miss significant lung disease.[15, 16]

Scans to evaluate the primary site should be performed **prior to biopsy** to avoid the effect of upstaging from the oedema caused by biopsy trauma.

Endoscopy and biopsy should be performed by a senior surgeon and in all cases by the head and neck surgeon responsible for any future procedure. For each tumour, this should include a description and diagrammatic representation, and preferably also photographic documentation. Routine panendoscopy (oesophagoscopy and bronchoscopy) is contentious. Proponents point out that these procedures require very little time, and may be performed easily during planned, direct laryngoscopy. A large meta-analysis found a small advantage to panendoscopy in detection of second primary tumours during analysis of multiple prospective studies.[17] Opponents point out that the appropriate use of symptom-directed investigations, in addition to routine chest imaging, have a similar detection rate compared with screening endoscopy and avoid unnecessary risk and expense in asymptomatic patients.[18]

Therefore, panendoscopy is only recommended for symptomatic patients or patients with primary tumours known to have a significant risk of a second (synchronous) primary tumour.

There is a natural desire to confer a stage on the tumour at presentation in the clinic and, certainly, after endoscopy. This should be avoided. It is better to rely on descriptive text to avoid changing the stage as more information becomes available. The cTNM classification based on examination, imaging, endoscopy and biopsy should be clearly documented in the case file only when all the above information is collated. The UICC book should be available in every theatre and clinic to assist in applying the **correct stage**.

Regional lymph nodes

The status of the regional lymph nodes in head and neck cancer is of such prognostic importance that the cervical nodes must be assessed for each patient and tumour. Lymph nodes are described as ipsilateral, bilateral, contralateral or midline; they may be single or multiple and are measured by size, number and anatomical location. Midline nodes are considered ipsilateral nodes, except for thyroid cancers. Direct extension of the primary tumour into lymph nodes is classified as lymph node metastasis.[1, 2]

Imaging for node detection and delineation is advisable if the neck is being scanned as part of the evaluation of the primary tumour, if there is a high chance of occult disease (e.g. supraglottic primary), to assess the extent of nodal disease, to define any deep nodal fixation, or if clinical detection is difficult because of a short, fat or previously irradiated neck.

Lymph nodes are now subdivided into specific anatomical sites and grouped into seven levels for ease of description (**Table 4.6**). The pattern of lymphatic drainage varies for different anatomical sites. However, the location of the lymph node metastases has prognostic significance. Survival is significantly worse when metastases involve lymph nodes beyond the first echelon of lymphatic drainage.[19] It is particularly poor for lymph nodes in the lower regions of the neck (i.e. level IV and level V (supraclavicular area)).

The UICC booklet alludes to the importance of levels in some sites, but does not present any definitions. The AJCC cancer staging manual gives a much more thorough account. It recommends that each N staging category be recorded to show, in addition to the established parameters, whether the nodes involved are in the upper (U) or lower (L) regions of the neck, depending on their location above or below the lower border of the thyroid cartilage.[1, 2]

The definitions of the N categories (**Table 4.7**) are the same for most head and neck sites (oral cavity, p16-negative pharyngeal carcinoma, larynx carcinoma, sinus carcinoma, salivary gland carcinoma). The UICC/AJCC eighth edition recognizes the importance of extranodal extension (previously called extracapsular spread). A patient with evidence of extranodal extension is automatically considered to be N3b reflecting their poorer prognosis. The presence of skin involvement or soft tissue invasion with deep fixation/tethering to underlying muscle or adjacent structures or clinical signs of nerve involvement are classified as clinical extranodal extension.

The latest edition has also introduced two separate staging systems (cTNM and pTNM) for neck metastases for human papilloma virus (p16-positive) oropharyngeal cancer (**Tables 4.8a and 4.8b**). Studies have shown a significant difference in outcome based on the number of pathologically positive lymph nodes, defining two categories: those with 1 to 4 (N1) versus 5 or more (N2) positive nodes. As the number of nodes can only be counted in the neck dissection specimen, a separate N system based on histological assessment of the neck dissection specimen

TABLE 4.6 Nomenclature of anatomical site of lymph node

Level I	Contains the submental and submandibular triangles bounded by the posterior belly of the digastric muscle, the hyoid bone inferiorly and the body of the mandible superiorly.
Level II	Contains the upper jugular lymph nodes and extends from the level of the hyoid bone inferiorly to the skull base superiorly.
Level III	Contains the middle jugular lymph nodes from the hyoid bone superiorly to the cricothyroid membrane inferiorly
Level IV	Contains the lower jugular lymph nodes from the cricothyroid membrane superiorly to the clavicle inferiorly
Level V	Contains the posterior triangle lymph nodes bounded by the anterior border of the trapezius posteriorly, the posterior border of the sternocleidomastoid muscle anteriorly and the clavicle inferiorly.
Level VI	Contains the anterior compartment lymph nodes from the hyoid bone superiorly to the suprasternal notch inferiorly. On each side the medial border of the carotid sheath forms the lateral border.
Level VII	Contains the lymph nodes inferior to the suprasternal notch in the upper mediastinum.

TABLE 4.7 Clinical N stage

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension without extranodal extension
N2	N2a – Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension without extrandodal extension N2b – Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension, without extranodal extension N2c – Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension, without extranodal extension
N3a	Metastasis in a lymph node more than 6 cm in greatest dimension without extranodal extension
N3b	Metastases in a single or multiple lymph nodes with clinical extranodal extension

TABLE 4.8a Clinical N stage for HPV (p16-positive) related oropharyngeal cancer

Nx	Regional lymph nodes cannot be asessed
N0	No regional lymph node metasases
N1	One or more ipsilatetal lymph nodes, none larger than 6 cm
N2	Contralateral or bilateral lymph nodes, none larger than 6 cm
N3	Lymph node(s) larger than 6 cm

TABLE 4.8b Pathologic N stage for HPV (p16-positive) related oropharyngeal cancer

Nx	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metasases
pN1	Metastasis in 4 or fewer lymph nodes
pN2	Metastasis in more than 4 lymph nodes

TABLE 4.9 N staging for nasopharynx

N - Regional lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Unilateral metastasis, in cervical lymph node(s), and/or unilateral or bilateral metastasis in retropharyngeal lymph nodes, 6 cm or less in greatest dimension, above the caudal border of cricoid cartilage
N2	Bilateral metastasis in cervical lymph node(s), 6 cm or less in greatest dimension, above the caudal border of cricoid cartilage
N3	Metastasis in cervical lymph node(s) greater than 6 cm in dimension and/or extension below the caudal border of cricoid cartilage

Note: Midline nodes are considered ipsilateral nodes, and the supraclavicular triangle is defined by the lines joining the following three points – the superior margin of the clavicle at its sternal and acromial ends, and the point where the line of the neck meets the shoulder.

TABLE 4.10 N staging for thyroid carcinoma

N - Regional lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
N1a	Metastasis in Level VI (pretracheal, prelaryngeal, paralaryngeal) or upper/ superior mediastinal lymph nodes
N1b	Metastasis in other unilateral, bilateral or contralateral cervical (levels I–V) or retropharyngeal nodes

has been created (pTNM). Recognizing that lymph node size >6 cm does not have a prognostic role in surgically treated necks, no pN3 category exists.

The natural history and response to treatment of cervical nodal metastases from the nasopharynx are different, in terms of their impact on prognosis; thus, they justify a different N classification (**Table 4.9**). Regional lymph node metastases from well-differentiated thyroid cancer do not significantly affect the ultimate prognosis and, therefore, also warrant a unique system (**Table 4.10**).

Pathological classification (pTNM)

The pT, pN and pM categories correspond to the T, N and M categories. The extent of the tumour in terms of the location and level of the lymph nodes should be documented. In addition, the number of nodes that contain tumour and the presence or absence of extranodal extension of the tumour should be recorded. Histological examination of a selective neck dissection specimen usually includes ten or more lymph nodes; a radical or modified radical neck dissection specimen includes 15 or more lymph nodes.[1, 2]

Lip and oral cavity

The oral cavity extends from the skin-vermilion junction of the lips to the junction of the hard and soft palate above and to the line of the circumvallate papillae below. The anatomic sites and subsites are as follows:

- lip:
  - external upper lip (vermilion border)
  - external lower lip (vermilion border)
  - commissures
- oral cavity:
  - buccal mucosa
  - mucosa of the upper and lower lips
  - cheek mucosa
  - retro molar areas
  - buck-alveolar sulci, upper and lower (vestibule of mouth)
  - upper alveolus and gingiva (upper gum)
  - lower alveolus and gingiva (lower gum)
  - hard palate
  - tongue – dorsal surface and lateral borders anterior to vallate papillae (anterior two-thirds). inferior (ventral) surface
  - floor of mouth.

The eighth edition of the staging system recognizes the importance of depth of invasion and this is shown in **Table 4.11**.

(Superficial erosion alone of bone/tooth socket by gingival primary is not sufficient to classify a tumour as T4a).

TABLE 4.11 TNM clinical classification for lip and oral cavity

T – Primary tumour	
T1	Tumour 2 cm or less in greatest dimension and 5 mm or less depth of invasion
T2	Tumour 2 cm or less in greatest dimension and more than 5 mm but no more than 10 mm depth of invasion or tumour more than 2 cm but not more than 4 cm in greatest dimension and depth of invasion no more than 10 mm
T3	Tumour more than 4 cm in greatest dimension or more than 10 mm depth of invasion
T4a	Lip: tumour invades through cortical bone, inferior alveolar nerve, floor of mouth, or skin (chin or nose)
T4a	Oral cavity: tumour invades through cortical bone, into deep/ extrinsic muscle of tongue, maxillary sinus or skin of face.
T4b	Lip or oral cavity: tumour invades masticator space, pterygoid plates, or skull base, or encases internal carotid artery

Pharynx

The pharynx is divided into three regions: nasopharynx, oropharynx and hypopharynx. There have been significant changes in the eighth UICC/AJCC edition to reflect the very different biological and etiological differences between nasopharyngeal carcinoma, HPV-associated oropharyngeal carcinoma and non-HPV-associated oropharyngeal carcinoma, and hypopharyngeal cancer. The eighth edition staging manual has been divided into three separate entities – nasopharynx; HPV-associated (p16-positive) oropharyngeal cancer; and hypopharynx and non-HPV-associated (p16-negative) oropharyngeal carcinoma – to better reflect the variety of diseases arising in the pharynx.[1, 2]

Each region is subdivided into specific sites as summarized below.

OROPHARYNX

The oropharynx is the portion extending from the plane of the superior surface of the soft palate to the superior surface of the hyoid bone (or floor of the vallecula). It includes:

- anterior subsites (glosso-epiglottic area)
- base of tongue (posterior to the vallate papillae or posterior third)
- vallecula
- lateral subsites
- lateral wall
- tonsil
- tonsillar fossa
- tonsillar pillar
- posterior wall
- superior subsites
- inferior surface of soft palate
- uvula.

T categories in both p16-positive, HPV–associated oropharyngeal carcinoma and p16-negative, non-HPV-associated oropharyngeal carcinoma were equally valid from a prognostic standpoint and thus remain the same with two exceptions: the p16-positive classification includes no carcinoma in situ (Tis) (because of the non-aggressive pattern of invasive of p16-positive oropharyngeal carcinoma and the lack of a distinct basement membrane in the epithelium of Waldeyer's ring), and the T4b category has been removed from p16-positive oropharyngeal carcinoma (OPC) (because the survival curves of the T4a and T4b categories prove indistinguishable).[2] **Tables 4.12a** and **4.12b** summarize these changes.

TABLE 4.12a Oropharynx: p16-negative cancers or p16 immunohistochemistry not performed

T – Primary tumour	
T1	Tumour 2 cm or less in greatest dimension
T2	Tumour more than 2 cm but not more than 4 cm in greatest diameter
T3	Tumour more than 4 cm in greatest dimension or extension to lingual surface of the epiglottis
T4a	Tumour invades any of the following: larynx, deep extrinsic muscles of tongue genioglossus, hyoglossus, palatoglossus and styloglossus), medial pterygoid, mandible and hard palate
T4b	Tumour invades any of the following: lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, skull base; or encases the carotid artery

TABLE 4.12b Oropharynx: p16-positive cancers

T – Primary tumour	
T1	Tumour 2 cm or less in greatest dimension
T2	Tumour more than 2 cm but not more than 4 cm in greatest diameter
T3	Tumour more than 4 cm in greatest dimension or extension to lingual surface of the epiglottis
T4	Tumour invades any of the following: larynx, deep extrinsic muscles of tongue (genioglossus, hyoglossus, palatoglossus and styloglossus), medial pterygoid, mandible and hard palate, lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, skull base; or encases the carotid artery

NASOPHARYNX

The nasopharynx begins anteriorly at the posterior choana and extends along the plane of the airway to the level of the free border of the soft palate. It includes:

- superior wall
- posterior wall: from the level of the junction of the hard and soft palates to the superior wall
- lateral wall: including the fossa of Rosenmuller
- floor: superior surface of the soft palate.

The margin of the choanal orifices, including the posterior margin of the nasal septum is included with the nasal fossa.

There are two changes in nasopharynx T classifications relating to anatomic markers rather than depth of invasion (**Table 4.13**). The previous T4 criteria used synonymous terms 'masticator space' and 'infratemporal', which are now be replaced by a specific description of soft-tissue involvement to avoid ambiguity. In addition, adjacent muscle involvement (including medial pterygoid, lateral pterygoid and prevertebral muscles) are down-staged to T2 based on them having a more favourable outcome.[20]

HYPOPHARYNX

The hypopharynx is that portion of the pharynx extending from the plane of the superior border of the hyoid bone (or floor of the vallecula) to the plane corresponding to the lower border of the cricoid cartilage. It includes the piriform sinuses, the postcricoid area and the lateral and posterior pharyngeal walls. The current staging summary for hypopharynx is summarized in **Table 4.14**.

- Postcricoid area (pharyngo-oesophageal junction): extends from the level of the arytenoid cartilages and connecting folds to the inferior border of the cricoid cartilage, thus forming the anterior wall of the hypopharynx.

TABLE 4.13 Nasopharynx

T – Primary tumour	
T1	Tumour confined to nasopharynx, or extends to oropharynx and/or nasal cavity without parapharyngeal involvement
T2	Tumour with extension to parapharyngeal space and/or infiltration of the medial pterygoid, lateral pterygoid and/or prevertebral muscles.
T3	Tumour invades bony structures of skull base cervical vertebra, pterygoid structures and/or paranasal sinuses
T4	Tumour with intracranial extension and/or involvement of cranial nerves, hypopharynx, orbit, parotid gland and/or infiltration beyond the lateral surface of the lateral pterygoid muscle

Note: Parapharyngeal extension denotes postero-lateral infiltration of tumour beyond the pharyngo-basilar fascia.

TABLE 4.14 Hypopharynx

T – Primary tumour	
T1	Tumour limited to one subsite of hypopharynx and 2 cm or less in greatest dimension.
T2	Tumour invades more than one subsite of hypopharynx or an adjacent site, or measures 2–4 cm in greatest dimension, without fixation of hemilarynx.
T3	Tumour measures >4 cm in greatest dimension, or with fixation of hemilarynx or extension to oesophagus
T4a	Tumour invades any of the following: thyroid/cricoid cartilage, hyoid bone, thyroid gland, oesophagus, central compartment soft tissue
T4b	Tumour invades prevertebral fascia, encases carotid artery, or invades mediastinal structures

Note: Central compartment soft tissue includes prelaryngeal strap muscles and subcutaneous fat.

- Piriform sinus: extends from the pharyngo-epiglottic fold to the upper end of the oesophagus. It is bounded laterally by the thyroid cartilage and medially by the hypopharyngeal surface of the aryepiglottic fold and the arytenoid and cricoid cartilages.
- Posterior pharyngeal wall: extends from the superior level of the hyoid bone (or floor of the vallecula) to the level of the inferior border of the cricoid cartilage and from the apex of one pyriform sinus to the other.

Larynx

The anatomical sites and subsites are:

- supraglottis:
  - suprahyoid epiglottis (including tip, lingual [anterior], and laryngeal surfaces)
  - aryepiglottic fold, laryngeal aspect
  - arytenoid
  - infrahyoid epiglottis
  - ventricular bands (false cords)
- glottis:
  - vocal cords
  - anterior commissure
  - posterior commissure
- subglottis.

Tables 4.15–4.17 detail the T stages for the various laryngeal cancer sites.

TABLE 4.15 Supraglottis

T – Primary tumour	
T1	Tumour limited to one subsite of supraglottis with normal vocal cord mobility
T2	Tumour invades mucosa of more than one adjacent subsite of supraglottis or glottis or region outside the supraglottis (e.g. mucosa of base of tongue, vallecula, medial wall of pyriform sinus) without fixation of the larynx
T3	Tumour limited to larynx with vocal cord fixation and/or invades any of the following: postcricoid area, pre-epiglottic tissues, paraglottic space and/or with minor thyroid cartilage erosion (e.g. inner cortex)
T4a	Tumour invades through thyroid cartilage, and/or invades tissues beyond the larynx, e.g. trachea, soft tissues of the neck, including deep/extrinsic muscle of the tongue (genioglossus, hyoglossus, palatoglossus and styloglossus), strap muscles, thyroid and oesophagus
T4b	Tumour invades prevertebral space, mediastinal structures, or encases carotid artery

TABLE 4.16 Glottis

T – Primary tumour	
T1	Tumour limited to vocal cord (s) (may involve anterior or posterior commissure) with normal mobility. T1a – tumour limited to one vocal cord T1b – tumour involved both vocal cords
T2	Tumour extends to supraglottis and/or subglottis, and/or with impaired vocal cord mobility
T3	Tumour limited to larynx with vocal cord fixation and/or invades paraglottic space, and/or with minor thyroid cartilage erosion (inner cortex)
T4a	Tumour invades through thyroid cartilage or invades tissues beyond the larynx, e.g. trachea, soft tissues of neck including deep/extrinsic muscle of tongue (genioglossus, hyoglossus, palatoglossus and styloglossus), strap muscles, thyroid and oesophagus
T4b	Tumour invades prevertebral space, mediastinal structures, or encases carotid artery

TABLE 4.17 Subglottis

T – Primary tumour	
T1	Tumour limited to subglottis
T2	Tumour extends to vocal cord(s) with normal or impaired mobility
T3	Tumour limited to larynx with vocal cord fixation
T4a	Tumour invades through cricoid or thyroid cartilage and/or invades tissues beyond the larynx, e.g. trachea, soft tissues of neck including deep/extrinsic muscle of tongue (genioglossus, hyoglossus, palatoglossus, and styloglossus), strap muscles, thyroid, and oesophagus
T4b	Tumour invades prevertebral space, mediastinal structures, or encases carotid artery

Nasal cavity and paranasal sinuses

The anatomical sites and subsites are:

- nasal cavity:
  - septum
  - floor
  - lateral wall
  - vestibule
- maxillary sinus
- ethmoid sinus.

Other than the changes to the N stage (consistant with with oral caity, p16-negative oropharynx and larynx) there are no other alterations to sinus tumour stages (**Tables 4.18** and **4.19**).

Salivary glands

The classification applies only to carcinomas of the major salivary glands. Tumours arising in minor salivary glands (mucus-secreting glands in the lining membrane of the upper aerodigestive tract) should be staged according to their anatomic site of origin (e.g. lip). There should be histological confirmation of the disease. The anatomical sites and subsites are (**Table 4.20**):

- parotid gland
- submandibular gland
- sublingual gland.

TABLE 4.18 Maxillary sinus

T – Primary tumour	
T1	Tumour limited to the antral mucosa with no erosion or destruction of bone
T2	Tumour causing bone erosion or destruction, including extension into hard palate and/or middle nasal meatus, except extension to the posterior wall of maxillary sinus and pterygoid plates
T3	Tumour invades any of the following: bone of posterior wall of maxillary sinus, subcutaneous tissues, floor or medial wall of orbit, pterygoid fossa or ethmoid sinuses
T4a	Tumour invades any of the following: anterior orbital contents, skin of cheek, pterygoid plates, infratemporal fossa, cribriform plate and sphenoid or frontal sinus
T4b	Tumour invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than maxillary division of trigeminal nerve, nasopharynx, clivus

TABLE 4.19 Nasal cavity and ethmoid sinus

T – Primary tumour	
T1	Tumour restricted to one subsite of nasal cavity or ethmoid sinus without bone erosion
T2	Tumour involves two subsites or extends to involve an adjacent site within the nasoethmoidal complex, with or without bony invasion
T3	Tumour extends to invade the medial wall or floor of the orbit, maxillary sinus, palate or cribriform plate
T4	Tumour invades any of the following: anterior orbital contents, skin of nose or cheek, minimal extension to anterior cranial fossa, pterygoid plates, sphenoid or frontal sinuses
T4b	Tumour invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than maxillary division of trigeminal nerve, nasopharynx, clivus

TABLE 4.20 Salivary gland

T – Primary tumour	
T1	Tumour 2 cm or less in greatest dimension without extraparenchymal extension*
T2	Tumour more than 2 cm but no more than 4 cm in greatest dimension without extraparenchymal extension*
T3	Tumour more than 4 cm and/or tumour with extraparenchymal extension
T4a	Tumour invades skin, mandible, ear canal or facial nerve
T4b	Tumour invades base of skull, pterygoid plates or encases carotid artery

* Extraparenchymal extension is clinical or macroscopic evidence of invasion of skin, soft tissues or nerve, except those listed under T4a and T4b. Microscopic evidence alone does not constitute extraparenchymal extension for classification purposes.

TABLE 4.21 Thyroid gland

T – Primary tumour	
T1	Tumour 2 cm or less in greatest dimension, limited to the thyroid T1a – tumour 1 cm or less in greatest dimension, limited to the thyroid T1b – tumour more than 1 cm but not more than 2 cm in greatest dimension, limited to the thyroid
T2	Tumour more than 2 cm but not more than 4 cm in greatest dimension, limited to the thyroid
T3	Tumour more than 4 cm in greatest dimension, limited to the thyroid or any tumour with gross extrathyroid extension involving only the strap muscles (e.g. sternohyoid, sternothyroid or omohyoid muscles) T3a – tumour more than 4 cm in greatest dimension, limited to the thyroid T3b – tumour of any size with gross extrathyroidal extension invading strap muscles (sternohyoid, sternothyroid or omohyoid muscles)
T4a	Tumour extends beyond the thyroid capsule and invades any of the following: subcutaneous soft tissues, larynx, trachea, oesophagus, recurrent laryngeal nerve
T4b	Tumour invades prevertebral fascia, mediastinal vessels, or encases carotid artery
T4a*	(Anaplastic carcinoma only) – tumour (any size) limited to the thyroid
T4b*	(Anaplastic carcinoma only) – tumour (any size) extends beyond the thyroid capsule

Note: Multifocal tumours of all histological types should be designated (m) (the largest determines the classification).

* All anaplastic carcinomas are considered T4.

Thyroid gland

The four major histopathologic types are:

- papillary carcinoma (including those with follicular foci)
- follicular carcinoma (including Hürthle cell carcinoma)
- medullary carcinoma
- undifferentiated (anaplastic) carcinoma.

In the new UICC/AJCC staging system the definition of T3 has been revised for follicular and medullary carcinomas. In addition, the age for a poor prognosis has changed from 45 to 55 years. The current staging system is summarized in **Table 4.21**.

Unknown primary – cervical nodes

There should be histological confirmation of squamous cell carcinoma with lymph node metastases but without an identified primary carcinoma. It should be appreciated that this is a dynamic concept as eventual discovery of the primary site means that the carcinoma is no longer an unknown primary. Current recommended diagnostic methods include an early PET CT scan with targeted biopsies based on the findings. Transoral laser or robotic excision of the tonsil and tongue base mucosectomy are also recommended in cases which remain as an unkown primary. Histological methods should be used to identify EBV and HPV/p16-related tumours. If there is evidence of EBV, the nasopharyngeal classification is applied. If there is evidence of HPV and positive immunohistochemistry p16 overexpression, the p16-positive oropharyngeal classification is applied.[1, 2] One key change from previous versions of the TNM system is the elimination of the T0 category in sites other than the nasopharynx, HR-HPV–associated OPC, and salivary gland cancers (which can be identified by their unique histology). If no primary lesion can be identified, then the lymph node may have emanated from any mucosal site, so there is no rationale to support retaining the T0 designation outside of the virally associated cancers of the oropharynx and nasopharynx.

Skin carcinoma of the head and neck

This is now presented in a separate chapter in the eighth edition of the UICC/AJCC manuals.[1, 2] The classification aplies to cutaneous carcinaomas of the head and neck region excluding the eyelid (as an antomical site), Merkel cell carcinoma and malignant melanoma. The T stage is presented in **Table 4.22**, and N stage follows the same as nodal metastases from other sites of the head and neck. The following sites are recognized:

- lip
- external ear
- other and unspecified parts of the face
- scalp and neck.

TABLE 4.22 Head and neck skin cancer

T1	Tumour 2 cm or less in greatest dimension
T2	Tumour >2 cm and <4 cm in greatest dimension
T3	Tumour >4 cm in greatest dimension or minor bone erosion or perineural invasion or deep invasion*
T4a	Tumour with gross cortical bone/marrow extension
T4b	Tumour with skull base or axial skeleton invasion including foraminal involvement and/or vertebral foramen involvement to the epidural space

* Deep invasion is defined as invasion beyond the subcutaneous fat or >6 mm (as measured from the granular layer of adjacent normal epidermis to the base of the tumour), perineural invasion for T3 classification is defined as clinical or radiographic involvement of named nerves without foramen or skull base invasion or transgression.

Malignant melanoma of the upper aerodigestive tract

The classication in **Table 4.23** applies only to mucosal malignant melanomas of the head and neck region. The regional lymph nodes are staged according to the site in the upper aerodigestive tract of the tumour. As malignant melanoma are aggressive tumours, T1 and T2 are omitted as are stages I and II.

LIMITATIONS OF T STAGING

For most sites in the head and neck, emphasis is placed on tumour size. It is, however, well recognized that T stage alone is of limited prognostic significance in many head and neck carcinomas. It is a significant factor in the presence of nodes on presentation. Patients with larger tumours are more likely to have nodes than those with smaller tumours.[21] In carcinoma of the larynx, the poorer prognosis with increased T stage is explained by the increasing propensity to nodal metastases with larger tumours. If nodal metastases are removed as a confounding factor then T stage per se does not influence prognosis.[22]

Tumours of the larynx are classified according to the number of anatomical surfaces involved. This has led to several problems. For example, a large 3 cm tumour of the supraglottis may remain T1, whereas in the glottis this will almost certainly be a T3. This mitigates against supraglottic tumours in terms of outcome. In addition, depth of invasion is not measured, but is of prognostic and therapeutic importance. For example, a superficial tumour of the vocal cord mucosa would be T1a. The same tumour may be deeply infiltrating into the vocalis muscle and yet the stage will remain T1a.

TABLE 4.23 Malignant melanoma of the upper aerodigestive tract

TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
T3	Tumour limited to the epithelium and/or submucosa (mucosal disease)
T4a	Tumour invades deep soft tissue, cartilage, bone or overlying skin
T4b	Tumour invades any of the following: brain, dura, skull base, lower cranial nerves (IX, X, XI, XII), masticator space, carotid artery, prevertebral space, mediastinal structures

In the oral cavity and the oropharynx, the size of the tumour is not always easily measured. There is little difficulty in defining a T1 or T4 tumour, but problems can occur when the tumour measures between 1.5 and 3 cm. Furthermore, increasing severity with a T4 tumour is reflected in deep invasion into muscle, bone or adjacent structures. There is then a reliance on the predictive power of radiographic modalities including CT and MRI. The depth of invasion of lesions of the floor of the mouth has been shown to be of prognostic significance and this is similarly difficult to assess by either clinical or radiographic means.[23]

Tumours of the hypopharynx are classified in terms of both their size and anatomical extent. The anatomical boundaries of the hypopharynx have been contentious in the past and it is occasionally difficult to be certain of the exact origin of some of the larger tumours. The dual listing of the aryepiglottic fold in both the supraglottis and hypopharynx sites invokes a problem in trying to classify the site of origin in some situations.

LIMITATIONS OF N STAGING

The reliability of clinical examination of nodes is contentious with studies showing that observers disagree on their presence.[23] Furthermore, palpable nodes do not always harbour tumour. During clinical examination, the size of the node should be measured with callipers, and allowance made for the intervening soft tissues. There is considerable inter- and intra-observer error in estimating the size of the node by palpation alone without a measuring device.[24] Most masses over the size of 3 cm in diameter are not single nodes, but will represent confluent nodes or tumour in the soft tissue compartments of the neck.

One of the main criticisms over many years was the failure of the TNM system to provide a description of the level of nodal involvement. Various studies have confirmed the importance of this parameter[25] and it is now included in the current classification (engaging the Memorial Sloan-Kettering system of lymph node levels).[1, 2]

LIMITATIONS OF STAGE GROUPING

There are now seven stages for head and neck cancers arising at mucosal sites (0, I, II, III, IVa, IVb, IVc) and six stages for salivary gland cancers (I, II, III, IVa, IVb, IVc). Differentiated thyroid cancers also have six stages (I, II, III, IVa, IVb, IVc) with undifferentiated (anaplastic) cancers having three, as all cases are stage IV (IVa, IVb, IVc). Many authorities have concluded that problems exist with the current staging system.[25–28] One of the main criticisms is that the size of some groups defined by the combinations of the TNM classifications is small, preventing accurate prediction from previous experience.

Groome et al.[29] identified four criteria that a stage-grouping scheme should meet:

1. The subgroups defined by the T, N and M that make up a given group within a stage grouping scheme should have similar survival rates (hazard consistency).
2. The survival rates should differ among the groups (hazard discrimination).
3. The prediction of cure should be high (outcome prediction).
4. The distribution of patients across the groups should be balanced (thereby maximizing statistical power in each group).

Compelling arguments have been advanced to show that alternative groupings of the same T, N and M categories will result in an improved system.

The T and N integer score (TANIS) combines the integers of the T and N to create a new score. Thus, a T1N0 would be a TANIS 1, T2N2 would be a TANIS 4, and so on. First reported by Jones et al.,[28] this is an easy to use system evaluated primarily for cancers of the oral cavity and oropharynx. It treats T and N as equivalent with respect to survival. Many authors have studied this system and recommended grouping several TANIS scores to improve hazard discrimination. In their initial report, Jones et al. found little statistical difference between groups 1–3 and 5–7. They recommended pooling TANIS scores 1–3 together as TANIS 1, 4 as TANIS 2 and 5–7 as TANIS 3. Others have tried different groupings based on the TANIS system.[29, 30]

The advantages of the TANIS score are its ease of application, ability to define a reasonable number of groups and ability to be applied retrospectively if the TNM score is known. The main disadvantage is that the concept of T and N equivalence does not hold true. Many studies have confirmed the more significant impact of N status over T status. For example, a T2N0 carcinoma does not have the same survival as a T1N1 at any site although both of these would be categorized TANIS 2. The TANIS system does not account for M1 disease, although most would agree that any M1 would automatically put the patient in the highest TANIS group. It is also apparent that by pooling groups, because there is little difference in survival between them (attempting to improve hazard discrimination), there is an implicit trade-off with hazard consistency.

Others have also tried to improve on the current stage grouping and TANIS system with subtle variations,[26, 31, 32] all claiming that their system is an improvement on any other. It seems that excellent systems have been devised that may improve predictive power, hazard consistency, hazard discrimination and balance over the current UICC/AJCC T, N and M stage grouping system. Lydiatt et al.[33] provide a review of these. They observe that one of the main disadvantages is that the systems are not intuitive and would require a chart for most clinicians to stage their patients. In most publications, analyses comparing the authors' systems with other systems, including the UICC/AJCC, are flawed because the new system under consideration was not externally validated on an independent dataset. Therefore, because the system was created from the dataset, it would naturally perform well. The true test is whether the results from an independent dataset would yield similar results.

The five major sites of the head and neck (oral cavity, oropharynx, larynx, hypopharynx and paranasal sinuses)

share the same system. Arguably, they should be independent of each other. One advantage of an independent system is better groupings within each site. Different systems are in use for the nasopharynx and thyroid, which are sufficiently different with respect to risk factors, behaviour and treatment. In their rebuttal of these views, the AJCC Task Force maintains the opinion that independent systems would create problems for clinicians and investigators not remembering which group was staged by which system. They are of the view that any new system should be comprehensive and easily applicable to all the major sites.[33]

FUTURE RESEARCH

- Definitions of TNM categories may be altered or expanded for clinical or research purposes as long as the basic definitions are recorded and not changed. Changes in the TNM classification should and will only occur, based on the appropriate collection, presentation and analysis of data, in the forum of the UICC and AJCC.
- The TNM system embraces the concept of orderly description of disease with increasing size and extent. While fallible, it is founded on sound principles and relates the combined experience and data from many surgeons and centres. Many of the shortcomings in the system represent the complexity of the disease of head and neck cancer.
- Future versions of the staging system may well incorporate nomograms and personalized approaches; but, for now, the eighth edition strikes a balance between a personalized, complex system and a more general, simpler one that maintains the user-friendliness and worldwide acceptability of the traditional TNM staging paradigm.

KEY POINTS

- Staging of head and neck cancer is a system designed to express the relative severity, or extent, of the disease. It is meant to facilitate an estimation of prognosis and provide useful information for treatment decisions.
- Classification of the anatomical extent of head and neck cancer as determined clinically and histopathologically is called the TNM system.
- Radiological investigations to evaluate the primary site should be performed prior to biopsy to avoid the effect of upstaging from the oedema caused by biopsy trauma.
- The age and sex of the patient, the duration and severity of symptoms and signs, and the presence and severity of intercurrent disease should all be documented. The literature does suggest that symptom severity[34] and comorbidity[35] have a significant impact on outcomes. It is therefore recommended that these data be recorded and this additional information can be used as part of the prognostic grid.
- Assessment by endoscopy and biopsy should be performed by a senior surgeon and in all cases by the head and neck surgeon responsible for any future procedure.
- The clinical (pre-treatment) classification (cTNM) based on examination, imaging, endoscopy and biopsy should be clearly documented in the case file only when all the information is collated.
- Individual TNM classifications should be assembled into four stage groups (Stages I to IV), each with similar survival outcomes.
- The UICC book[1, 2] should be available in every theatre, MDT meeting and clinic to assist in applying the correct stage.

INTRODUCTION

This chapter describes principles to be followed in capturing high quality cancer data. The principles are transferable to other aspects of otolaryngology. A description is provided of the changing nature of cancer information collection and collation with the National Cancer Outcomes and Services Data Set, unification of cancer registration in England and national radiotherapy and chemotherapy data collection, as well as the National Comparative Audit in Head and Neck Cancer (Data for Head and Neck Oncology, DAHNO).

WHAT ARE DATA?

Data are a collection of directly observed facts, and the storage of these facts in a standardized format and content comprise a database.

For standardization of content, data gathering requires an underlying 'skeleton' of items: a data set. The items need to have defined meaning, standard terminology should be used, and choice of fields should have a consistent coding structure. Use of free text should be avoided. The items are the building blocks from which the construction of information can then subsequently occur. If the data set has been correctly defined and is fit for the purpose, then it should contain all the items needed for the outputs proposed without the need to resort to additional data capture.

WHY COLLECT CANCER DATA?

All clinicians managing patients with cancer have a responsibility to assess the quality of the care they provide.[1] This is reflected in the impact or consequences of the management and treatments they apply to individuals or groups of patients. In order to discharge this responsibility, the prospective collection of data on each patient to derive simple outcomes is a minimum requirement. Potential outcomes are: knowledge of the range of malignancies treated; stage distribution; the types of treatment provided; complications of treatment; survival; and quality of life measures.

Clinicians seek to provide for their patients a prognosis for their disease. This is affected by tumour-specific factors (e.g. stage,[2] pathological features), host factors (e.g. performance status and comorbidities) and environmental factors (e.g. access to services and the availability of treatments).[3] Traditionally, prognosis has been based on anecdote and the 'best of class from the literature' but by routine data capture it can (if sufficient

numbers are obtained) be converted into a true local focus. Customization for an individual's personal circumstances is becoming increasingly important as illustrated by the impact of comorbidities. These are the additional burdens of other diseases present at the time of diagnosis of the index cancer. A series of standardized indexes are available, with the adult comorbidity evaluation (ACE-27) having significant prognostic value.[4]

WHY A MINIMUM DATA SET?

Applying the principle of a minimum data set is based on the fact that the smaller the volume of items the greater the speed of entry, the higher the accuracy and the greater the likelihood of compliance in usage. This has to be balanced against the requirements of components to deliver the necessary outcomes, without additional data entry at a later stage. To produce a minimum data set, each item proposed should be critically examined both in its definition and by it having a defined purpose for inclusion, and these should be reviewed in the light of any piloting.

An ongoing recording of current status in relation to the absence or presence of the index cancer is needed with capture of recurrence or metastasis events, to allow for the censoring of records ultimately in certain types of survival analysis. Creation of a supporting data manual providing an expanded description of each item, its purpose in inclusion and any associated codes and classifications, is of value to support staff, institutions and software writers.

HOW TO DEVELOP CANCER DATA COLLECTION

In commencing an initiative to record cancer data, the goal has to be to collect data at the point of contact with the patient along their care journey (real or near real time data capture). This reduces error and increases likely compliance from health professionals. Duplication is reduced and the data collection process can deliver added value by-products such as referral or discharge letters.

The key steps are shown in **Figure 5.1**. Some items will be derived. For example, it is better to record date of birth and date of an event, then calculate the age at the event subsequently, than it is to enter the age as a free field item. The latter is prone to error, as well as being repetitive if a series of events require age as a factor.

At introduction, for a data set to be successfully collected requires a change in culture by all contributory professionals. A sense of ownership is needed as well as carefully focused drives to ensure data quality on a recurring basis. It is appropriate to validate the data, to ensure all relevant cases have been captured within the geographical target area and particularly where patient care crosses organizations the full record has been collected. Useful sources for cross comparison are multi disciplinary (MDT) meeting lists, pathology, and cytology records. The Office for National Cancer Registration and Analysis service collate the small number of additional death certificate-only registrations.

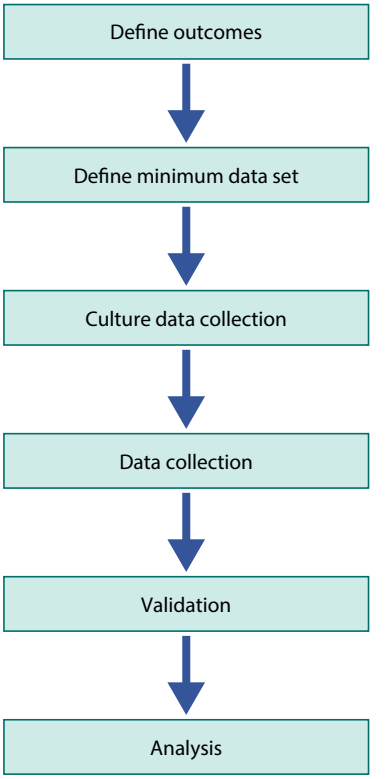

Figure 5.1 The key stages in developing cancer data collection.

When appropriate, data analysis can then occur and this is mostly likely to fail if significant gaps in the data are evident. Only with high quality data can relevant and useful information be assembled.

The data set should not be seen as fixed, but its items should be reviewed on a regular basis both to encompass any changes and confirm that their continued collection remains relevant and of value.

STRUCTURE OF A COMPUTERIZED DATABASE

Each subject on the database requires a unique identifier, and a record of registration is created. In England the mandated identifier is the NHS number. Diagnosis of cancer produces a care spell or event, to which is then tagged each recurrence or metastasis and each treatment plan and treatment. An additional new primary creates a new care spell. A relational database tree is thus constructed.

In selecting database software to support this, a number of factors should be considered:

- local familiarity, including the ability to write in the software to amend for item changes
- flexibility to deliver changes in relationship between events and to support different system packages
- ability to link with other host institutional systems for automated data capture (e.g. link to patient administration systems)
- ability to export data in a number of formats is also of value.

CONFIDENTIALITY – SECURE DATA

Patients expect that information about them will be held in confidence by the health professionals who care for them. Where information is stored in computerized or paper records, it must be effectively protected against improper disclosure at all times.

For the majority of audit purposes anonymized data will meet requirements. If data cannot be used in an anonymized format then permission should be sought from the patient.

Legislation controls confidential information disclosures (Section 251 of the NHS Act 2006) which allow sharing of confidential information in the 'public interest.' It sets a high threshold before the duty of confidentiality can be set aside for the purposes of audit not directly associated with care.[5]

CODING CLASSIFICATIONS

Standardized nomenclature is essential to allow assimilation of data from different units and specialities, and should wherever possible be recognized internationally (e.g. International Classification of Disease (ICD)-10); nationally (e.g. Office for Population Censuses and Surveys (OPCS)-4 operation codes, Systematized Nomenclature of Medicine – Clinical Terms (SNOMED CT)); or national professional (e.g. BAHNO extension codes). Locally derived codes should be avoided wherever possible. To illustrate coding classification structures, some are described briefly here.

ICD-10 tumour site codes

The classification of neoplasms is broken down into categories based on their point of origin and behaviour.[6] Sites for malignant neoplasms are prefixed by C, whilst sites for *in situ* and benign neoplasms are prefixed by D, but grouped into much broader categories (see **Box 5.1**).

For each anatomical site the initial three alphanumeric code is supplemented by a decimal point and an additional digit to identify subsite 0 to 7, or an overlapping site 8 (unless specifically indexed), or unspecified subsite 9 (see **Box 5.2**).

BOX 5.1 ICD-10 tumour site codes (benign and malignant)

C00–C75	Covers specified primary sites (but excludes lymphoid, haematopoietic and related tissues)
C76–C80	Covers ill-defined, secondary and unspecified sites
C81–C96	Malignant neoplasms of lymphoid, haematopoietic and related tissues
C97	Malignant neoplasms of multiple independent primary sites
DOO–DO9	Relates to *in situ* neoplasms
D10–D36	Relates to benign neoplasms
D37–D48	Relates to neoplasms of uncertain or unknown behaviour

BOX 5.2 ICD-10 tumour site codes for the tonsil

CO9	Malignant neoplasm of tonsil (excludes lingual tonsil CO2.4, pharyngeal tonsil C11.1)
CO9.0	Tonsillar fossa
CO9.1	Tonsillar pillar (anterior and posterior)
CO9.8	Overlapping lesion of tonsil (i.e. involves pillar and fossa and not clear which is site of origin)
CO9.9	Tonsil unspecified (i.e. subsite not stated or known)

ICD-O-3 – morphology codes

ICD-10 includes a copy of this coding system to allow it to be used in conjunction with the above site codes, to identify histological type.[7] Morphology codes are prefixed by M. Some histological types of neoplasm are specific to certain sites or types of tissue and C and D site codes are shown after these. For example, M93103 ameloblastoma malignant (C41.0, C41.1) identifies that the morphology only relates to tumours occurring in the maxilla and mandible.

Four identity digits for the histological type of neoplasm, and then a one-digit behaviour code follow:

0 benign
1 uncertain benign or malignant
2 carcinoma *in situ*
3 malignant or primary site
6 malignant metastatic, or secondary site

This system as it applies to squamous carcinoma is illustrated in **Box 5.3**

The morphology section of the Systematized Nomenclature of Medicine – Clinical Terms (SNOMED CT)[8] is similar to ICD-O-3 , but it gives a broader description of pathological terminology to aid coding.

OPCS operation codes

The basic structure of the classification comprises anatomically based chapters, each of which is given an alphabetical code.[9] The next two digits describe the operation group, based on the largest operation first, descending to the smallest, followed by a decimal point and a fourth digit to identify the procedure itself. If the procedure specified does not match these categories, then provided the procedure is recorded a .8 can be added, and where unspecified a .9 can be added. Within the classification, certain codes do encompass multiple procedures, but otherwise the operation needs to be coded from its component parts (e.g. having defined the primary resection procedure, separate codes for type of flap and its site of harvest need to be added). Operations on the salivary glands are illustrated in **Box 5.4**.

BOX 5.3 ICD-O-3 morphology codes for squamous carcinoma

M8070/2	Squamous cell carcinoma *in situ*
M8070/3	Squamous cell carcinoma (not otherwise specified)
M8070/6	Squamous cell carcinoma metastatic (i.e. in a node with an unknown primary)

BOX 5.4 OPCS operation and procedure codes: salivary gland procedures

F44	Excision of salivary gland
F44.1	Total excision of parotid gland
F44.2	Partial excision of parotid gland
F44.3	Excision of parotid gland (not elsewhere classified)
F44.4	Excision of submandibular gland
F44.5	Excision of sublingual gland
F44.8	Other specified
F44.9	Unspecified

NATIONAL CANCER REGISTRATION

Increasingly, cancer data capture is based on national initiatives. In Europe this has focused on registry-based systems,[10] and in the United States registry databases feed to the National Cancer Database.[11]

The Cancer Reform Strategy (2007)[12] identified better information as one of the key drivers to achieve the goal that cancer services in the UK should be amongst the best in the world. The subsequent *Improving Outcomes: A Strategy for Cancer* (January 2011) further supported this concept.[13]

In the UK, 2013 saw completion of the deployment of a National Cancer Registration System (NCRS),[14] in which the individual English cancer registries have been unified into a single online system. Regional registries have become eight regional cancer registration offices. There are also three cancer registries in Wales,[15] Scotland[16] and Northern Ireland.[17] NCRS receives data from a variety of sources including death certification from the Office for National Statistics (ONS) and direct feeds from pathology systems, MDTs and national audits, as well as treatment data on radiotherapy from the National Radiotherapy Data Set (RTDS) and on chemotherapy from the Systemic Anti-Cancer Therapy (SACT) data set. NCRAS is overseen by Public Health England.

CANCER OUTCOMES AND SERVICES DATA SET

In January 2013 the Cancer Outcomes and Services Data Set (COSD) replaced the previous National Cancer Dataset as the new NHS national requirement for reporting cancer in England. It incorporates a revised generic Cancer Registration Data Set (CRDS) and additional clinical and pathology site-specific data items relevant to different tumour types including items specific to head and neck.[18] The latest version of COSD can be found at http://content.digital.nhs.uk/isce/publication/dcb1521.[19]

COSD items are required to be submitted electronically by English NHS trusts to the National Cancer Registration and Analysis Service (NCRAS) on a monthly basis.[20]

COSD is aligned with, and shares data items with, other related data sets such as the National Cancer Waiting Times Monitoring Data Set (NCWTMDS),[21] the RTDS, the SACT data set, the Diagnostic Imaging Dataset (DID)[22] and the national clinical audits.

From 1 April 2009, all facilities providing radiotherapy services in England have been required to return the RTDS, which includes treatments delivered and aspects of fractionation.[23]

Submission of the SACT data set, which covers chemotherapy treatment for all solid tumour and haematological malignancies, including those in clinical trials for all patients receiving cancer chemotherapy in or funded by the NHS in England, commenced in 2013.[24]

NATIONAL CANCER DATA REPOSITORY AND THE FUTURE OF CANCER INFORMATION

By taking multiple data sources such as NCRAS, hospital episode statistics (HES), ONS death data and audit data, and linking these by NHS number, a comprehensive bank of data has been created in the National Cancer Data Repository,[25] which will be of value for national information reporting and analysis, as well as acting as a high quality clinical database for researchers enabling studies of treatments where it is impracticable to carry out randomized controlled studies.

NATIONAL CANCER INTELLIGENCE NETWORK HEAD AND NECK INFORMATION HUB

The National Cancer Intelligence Network (NCIN)[26] is a UK-wide initiative, working to drive improvements in standards of cancer care and clinical outcomes by improving and using the information collected about cancer patients for analysis, publication and research.

The NCIN Head and Neck Cancer Hub provides data and intelligence on head and neck cancers in England.[27] It is aimed at a wide range of professionals working in the field, including NHS providers, commissioners, cancer networks, charities and clinicians. Detailed reports are available on geographic variation, the impact of travel times and changes in head and neck surgery. It also provides information and links for patients and the general public who wish to understand more about head and neck cancers, including data sheet information about incidence and mortality, and past and current trends.

NATIONAL COMPARATIVE AUDIT IN HEAD AND NECK CANCER IN ENGLAND AND WALES

In England and Wales a partnership between the British Association of Head and Neck Oncologists (BAHNO) and the Health and Social Care Information Centre South East Knowledge and Intelligence Team, sponsored by the Healthcare Quality Improvement Partnership (HQIP), delivered Data for Head and Neck Oncology (DAHNO),[28] a national comparative audit for head and neck cancer.

Core issues addressed in the audit were:

- delivery of appropriate primary treatment (including adjuvant therapy) in management of head and neck cancer by an MDT, and delivery of care to agreed standards
- to assess in more detail, care provided by specialist nurses, dieticians and speech and language therapists.

The audit compared reported delivery against clinical standards produced by BAHNO as well as making peer-to-peer comparisons between organizations, MDTs and cancer networks.

The project defined outcomes deliverable by items from the core and head and neck specific COSD data set. The first annual report looking at outcomes related to patients with laryngeal and oral cavity cancer was published in March 2006. Subsequent reports extended across a broad range of anatomic sites, including the pharynx, major salivary glands and most recently the nose and nasal sinuses. More than 54 000 cases have been collated and the tenth annual report, published in September 2015[29] had universal coverage from all hospitals delivering head and neck cancer care in England and Wales.

In a subsequent partnership between BAHNO and a charity Saving Faces, a new national comparative audit in head and neck cancer (HANA) is in development.[30]

EVOLVING SURGEON-SPECIFIC DATA

Publishing of outcomes data by named consultant is well established in a number of countries around the world, particularly in North America. This has now extended to head and neck cancer surgeons in England.

In December 2012, the NHS Commissioning Board (from April 2013 NHS England) published its planning guidance for 2013/14, *Everyone Counts: Planning for patients 2013/14*,[31] commencing a process in which specialist bodies (in conjunction with NHS Choices) were required to publish activity, clinical quality measures and survival rates from 10 national clinical audits, which included head and neck cancer. The aim of using consultant-level data was to drive up quality, facilitate patient choice and support the requirements of professional revalidation. It also aimed to reassure the public that clinical practice is being actively monitored, and that the overall standard of care is very high. Under the Clinical Outcomes Publication (COP), an NHS England initiative, commissioned and managed by HQIP information on aspects of head and neck cancer, including mortality and surgeons' activity, was published openly for the first time at individual consultant surgeon level on NHS choices in 2013.[32] This demonstrated the commitment of BAHNO and the head and neck community to the transparency agenda, and the latest report is now available.[33]

BEST CLINICAL PRACTICE

✓ The measures for improving outcomes in head and neck cancer issued by the National Institute for Clinical Excellence (NICE) support the proposition that clinicians should routinely collect data to assess care.[34]

FUTURE RESEARCH

➤ The relative rarity of head and neck cancer means that, in order to assess and compare results from different treatment regimes and practice and reach statistical significance, it requires comprehensive data collection from as many units as possible across the UK. The goal has to be to achieve high levels of completeness on a regular and systematic basis.

KEY POINTS

- Data gathering requires an underlying 'skeleton' of items – a data set. The items need to have defined meaning, standard terminology should be used, and choice fields should have a consistent coding structure.
- All clinicians managing cancer patients have a responsibility to assess the quality of the care they provide. In order to discharge this duty, the prospective collection of data on each patient to derive simple outcomes is a minimum requirement.
- In commencing an initiative to record cancer data, the goal has to be to collect data at the point of contact with the patient along their care journey.
- Patients have a right to expect that information about them will be held in confidence by the health professionals who care for them.
- The National Cancer Outcomes and Services Data Set (COSD) for England was introduced in January 2013.

SEARCH STRATEGY

The data in this chapter are based on a PubMed searches including the following Medical Subject Headings (MeSH) and keywords: head and neck neoplasms, carcinoma, squamous cell, molecular biology, genome, papillomaviridae and tumour virus infections.

The rule is, jam to-morrow and jam yesterday—but never jam to-day.

Lewis Carroll, *Through the Looking-Glass, and What Alice Found There*

BACKGROUND – INTRODUCTION TO MOLECULAR BIOLOGY

Cancer is a genetic disease. Molecular biology permits the analysis of genes and their function and offers the chance to understand the information we can read in the genome and to predict the consequences for biological and pathological processes.

What is molecular biology? More importantly, why should a clinician or surgeon be interested in it – indeed, should they be at all? The *Oxford English Dictionary* defines molecular biology as 'the branch of science concerned with the formation, organization, and activity of macromolecules essential to life (nucleic acids, proteins, etc.)'. Many diseases arise from errors in biochemical processes (diabetes, for example), and many of these are due to genetic changes or inherited polymorphisms or mutations (cystic fibrosis, for example). (Polymorphism is a common (>1%) variant allele, cf. mutation or mutant allele: a rare <1% or acquired somatic change in nucleic sequence, usually but not always in the coding sequence of a gene.) Moreover, many of the modern treatments for disease, such as some of the monoclonal antibody drugs (mAbs), such as cetuximab (Erbitux®), nivolumab (OPDIVO®) and adalimumab (HUMIRA®) used to treat diseases including cancer and rheumatoid arthritis,[1–3] have been generated using molecular biological techniques (DNA cloning and sequencing). Thus it seems obvious that to understand disease, and to understand many of the treatment options, requires some level of understanding of molecular biology.

If we had tried to write this chapter only 10 years ago, there would have been some amazing technology and some wonderful insights into the nature of the disease, but whilst molecular biology promised much, it had yet to deliver substantially in the clinic, hence the quotation from *Alice in Wonderland* that starts this chapter. Happily that situation is no longer the case, and molecular biology has enabled the development of novel treatments for many types of cancer that are having a dramatic impact on patients, albeit often coming with a heavy financial burden. In the UK, in 2015–16, six of the seven most expensive hospital prescriptions for NICE-approved drugs were produced using molecular biological techniques (either as mAbs or recombinant peptides) and cost the system approximately £1.3 billion. This also highlights the fact that the rate of change is now overwhelming. At the time of writing there are 67 US Food and Drug Administration (FDA)-approved mAbs and in the region of 400 at various stages of testing and development.

Molecular biology is impacting on many aspects of clinical medicine, but for several reasons it has a special relevance to oncology. Essentially this is because cancer is fundamentally a genetic disease, or perhaps it is better to say that cancer is a disease of our genes. No gene

mutations = no cancer, even when a virus is involved as a causative agent! So the use of the technology of molecular biology to analyze tumours has followed hot foot upon the advances in molecular technologies. In the middle of the second decade of the twenty-first century, technology provides us with the potential essentially to identify all of the mutated genes in a biopsy of tissue from an individual tumour site. (There are even tests that reveal their answers in hours, such as One-Step Nucleic Acid Amplification (OSNA), permitting peri-operative information such as nodal involvement to be provided to surgeons.)[4]

From this it follows that if we could understand the function of the mutated genes and how alterations of these impacted on cellular processes, then we could predict the behaviour of the tumour both in terms of its growth and its progression and even how it will respond to a given therapy. However, tumours arise in an individual body, and so the same genetic information, that of the host or patient, should also be able to inform us about the way the patient's body will react to the tumour. So, the potential exists to have a high-resolution image of both the tumour and the body in which it arises, and thus potentially to understand how the tumour will behave, and how the body will respond to that. This particular level of understanding has not yet been reached, but it is clear that the potential is real and seems likely to be substantially achieved sometime during the next decade or so.

In many healthcare systems, there are other limitations to exploiting state-of-the-art technologies, but even for those without access to the very latest technology it remains possible, and increasingly clinically important, to obtain information from molecular analyses that are already being used as part of the routine diagnosis and stratification of patients, with immunohistochemistry for p16 being a good example of a biomarker with particular significance in oropharyngeal squamous cell carcinomas (OPSCC).[5–7]

The aim of this chapter is to review some of the available knowledge and to try to explain the ideas behind our molecular understanding of the basis of cancer, which is also the basis for understanding new diagnostic and therapeutic approaches

We will first briefly mention the technology, then review in more detail the fundamental process of carcinogenesis as it is understood at a molecular level, including how mutations and alterations arise. (For a more detailed treatise on the molecular basis of cancer, both editions of *The Biology of Cancer* by Robert A. Weinberg are highly recommended.)[8, 9] We will then summarize some of the molecular pathways that have been most commonly identified to be altered in head and neck cancers. This will entail a brief discussion of some of the critical tumour suppressors and oncogene networks that are known to harbour mutations and we will briefly describe the normal function of these and the consequences of the observed tumour alterations. Then we will briefly discuss some of the applications of this information and lastly the challenges and limitations facing the effective use of this information for patient benefit.

MOLECULAR TECHNOLOGY

As a practical subject, molecular biology was born following the discovery of restriction endonucleases, enzymes that could cut double stranded DNA at defined sites by recognizing specific sequences in the DNA.[10] The next major developments included the invention of a means to sequence DNA (most often by the di-deoxy sequencing method invented by Fred Sanger)[11] and a process to amplify specific sequences of DNA (the polymerase chain reaction invented by Carey Mullis).[12] However, our understanding of head and neck cancer has been revolutionized by so-called next-generation sequencing of whole genomes and exomes. These technologies vary and have been developed in parallel by several companies. The two most commonly used technologies, Illumina/Solexa and SOLiD, have been used to generate enormous quantities of data. Both approaches enable a high depth of sequence coverage, which is particularly important for studies of cancer since the tumour biopsy may contain a mixture of normal and tumour tissues and, moreover, due to the heterogeneity of cancers, there may be many clones with some common and some distinct mutations. In addition to high depth of coverage sequence analysis, it is now possible to examine the transcriptome (the mRNA products of the genes being actively transcribed) in greater detail and more quantitatively using RNA-Seq.[13] In addition, the application of RNAscope™ is beginning to impact on the analysis of fixed tissue biopsy sections. In particular, this has been used for the detection of human papilloma virus (HPV) gene expression.[14, 15] Much of what we now know about head and neck cancer molecular biology has been generated in the last few years by next-generation sequencing, as will become clear later.

THE MOLECULAR BIOLOGY OF HEAD AND NECK CANCER

Introduction to cancer molecular biology

Cancer is essentially a disease caused by genetic modifications of the information content of the genome such as base mutations and translocations or other chromosomal rearrangements. Indirect effects resulting in altered gene regulation through epigenetic alterations that affect chromatin structure and gene expression may also occur and are important factors in the development of cancer. In all cases, the carcinogenic events typically affect the function of a subset of critical genes regulating processes such as cell survival, proliferation, invasiveness and interactions with the host (the hallmarks of cancer, see **Figure 6.1**). Mutations may be inherited or acquired as somatic mutations (see **Figure 6.2**). However, unlike cancers of the colon and breast, there are no common inherited cancer syndromes that lead to head and neck cancer. Whilst individuals with the rare autosomal recessive disease Fanconi anaemia that affects approximately 3/1 000 000 individuals worldwide[16] do display an increased risk of developing cancers of the head and neck,[17] none of the genes

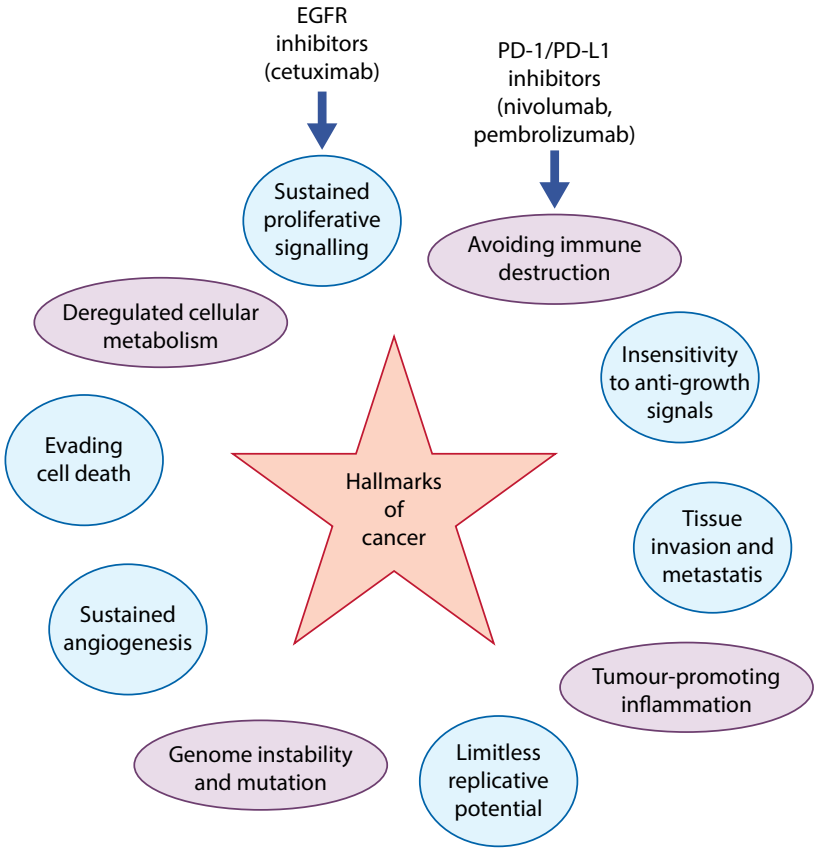

Figure 6.1 The hallmarks of cancer. The illustration shows the six originally proposed hallmarks in addition to the two emerging ones – avoiding immune destruction and deregulating cellular metabolism – and also the two enabling characteristics – tumour-promoting inflammation and genome instability and mutation. Also indicated are drugs targeting some of the hallmarks that are currently in use for the treatment of head and neck cancer (red). Adapted from Hanahan and Weinberg.[79, 80]

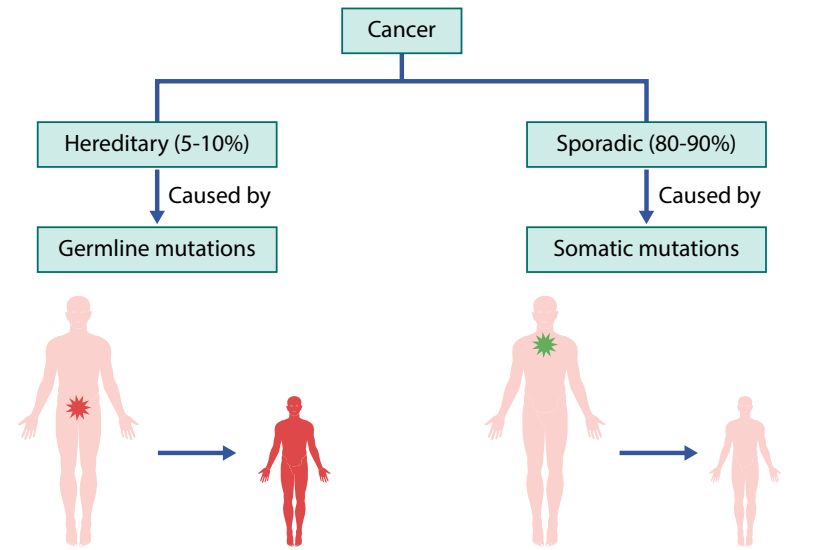

- Occur in germline cells: oocytes and spermatozoa
- Are heritable
- Cause cancer family syndromes (e.g. Fanconi anaemia or Li Fraumeni syndrome)

- Occur in non-germline tissues (e.g. head and neck)
- Are not heritable

Figure 6.2 Somatic versus germline mutations. Germline mutations occur in germline cells: oocytes and spermatozoa. They are heritable, and offspring of a person with a somatic mutation will have the same mutation in all cells of their body (e.g. *BRCA1/2* or *RB*, tumour suppressor genes, indicated in red). This increases their chance of developing cancer because only one additional mutation is required to completely inactivate the gene in question (Knudsen's two-hit hypothesis), since most tumour suppressor gene mutations are recessive at a cellular level. Sporadic mutations can occur in any cell in the body (e.g. head and neck cells, indicated in green), spontaneously or as a result of carcinogen exposure. These mutations are not passed onto the offspring unless, by chance, such a mutation occurs in a germline cell. Most cancers are sporadic and are caused by accumulation of somatic mutations. The figures for sporadic and hereditary incidence are for cancers in general. The contribution to head and neck cancer incidence from inherited cancer syndromes is negligible.

implicated in the different complementation groups of this disease have been found to be mutated in sporadic head and neck cancers.[18] (Complementation groups is a genetic term for a situation in which mutations in different genes can cause the same phenotype – in this case, a disease. The term derives from the genetic test for this; if matings between two affected individuals produce healthy offspring, then the mutations cannot be in the same gene. Of course, this only works for a recessive trait.) Other inherited cancer syndromes, including Lynch-II syndrome (genes most commonly implicated include *MSH2*, *6* or *MLH1*), Bloom syndrome (inherited mutations in the *BLM* gene), xeroderma pigmentosum (associated with defects in DNA repair genes: *XPC*, *ERCC2* and *POLH*), ataxia telangiectasia (associated with mutations in the *ATM* gene), and Li-Fraumeni syndrome (mutations in the *TP53* and *CHEK2* genes), have also been found to display an increased risk of head and neck cancers.[19–24] However, only the *TP53* and *CHEK2* genes (and the latter only very rarely) have been found to be mutated in sporadic head and neck cancers, and thus none of these syndromes appear to be major contributors to patient numbers or to a better understanding of the disease head and neck cancer.[18] In 1953, Slaughter et al introduced the concept of 'field cancerization' in oral cancers.[25] This notion can now be understood for head and neck cancers at a molecular level, since we know that these cancers are essentially diseases of sporadic mutations arising through a process of sequential mutations and clonal selection. As mutations arise and the populations of cells harbouring the mutations expand with some ultimately becoming cancers (see **Figure 6.3**), populations of cells that arise early on, do not disappear, but may continue to survive and proliferate, ultimately occupying areas outside that of the cancer.[26] These cells can spread and create the 'fields' of abnormal cells harbouring some critical mutations that may provide the raw material for subsequent primary tumours if not removed or killed by treatment. To understand cancer properly at a molecular level, it is necessary to understand the biological process of evolution through natural selection, since the same forces of mutation and selection acting on individual cells harbouring genetic alterations drive the evolution of a tumour during cancer development. **Figure 6.3** illustrates the process of evolution of malignant cells from normal cells through the acquisition of critical genetic alterations that occurs in cases of sporadic carcinogenesis. As cells acquire mutations, the key issue from a cancer perspective is whether any of the mutations that arise by chance in an individual cell provide a selective survival, or clonal advantage (often referred to somewhat imprecisely as a growth advantage or more correctly as a proliferative advantage). What this means is that cells that acquire characteristics that enable that cell, and all of the daughter cells derived from it, to compete more successfully with the surrounding cells and thus have a selective advantage leading to these cells gradually increasing in number. Eventually such cells can proliferate sufficiently to form a pathologically detectable tumour. Since the causes of the mutations in different types of cancer can vary, we will first look at the processes promoting carcinogenesis in head and neck cancers (when we refer to head and neck cancers we mean squamous cell carcinomas of the head and neck). Then

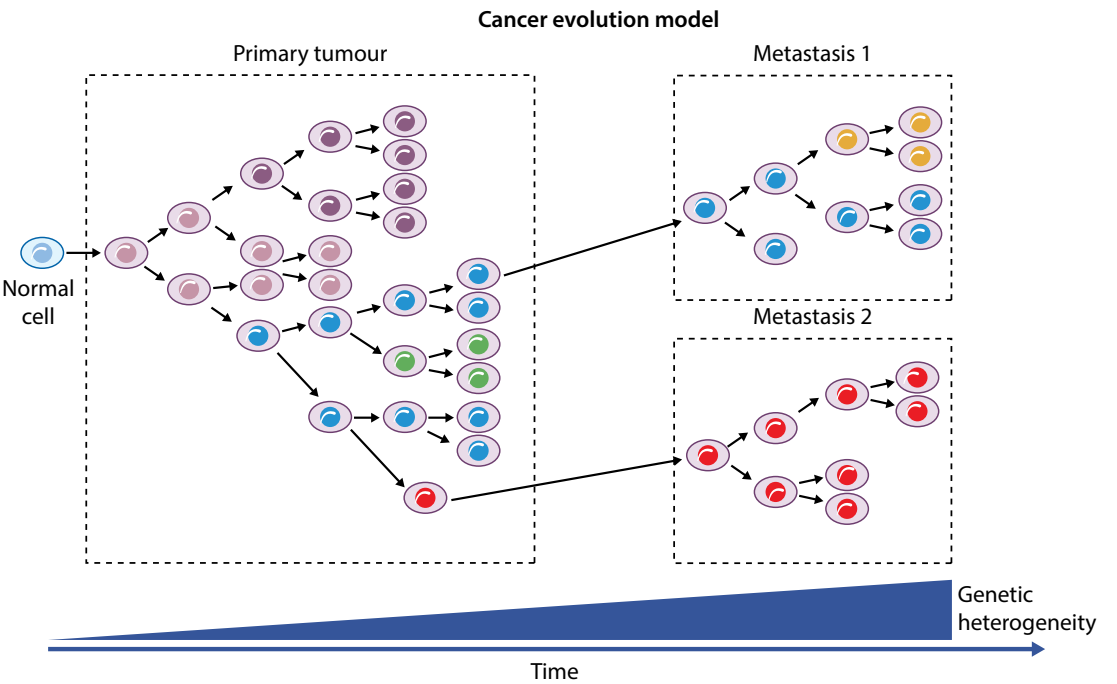

Figure 6.3 Model of cancer evolution. A normal cell (cell with a pale blue nucleus) acquires the initiating somatic mutation giving rise to the founder clone (lavender nucleus). Accumulation of additional mutations will lead to cancer heterogeneity represented by subclones of cells with purple, blue, green and red nuclei. Some of these subclones will acquire metastatic potential (blue and red nuclei) and form metastatic sites (Metastasis 1 and Metastasis 2). Additional mutations can be acquired at any time including post-metastasis (gold nucleus in Metastasis 1). Adapted from Caldas.[27]

we will look at the specific genes that are most frequently altered in head and neck cancers and briefly how these alterations contribute to the disease process.

Mutagenic events, viruses and epigenetic modifications

DNA damage occurs every day in our cells and depending upon the type of damage the frequency can vary from as few as ~10 double stand breaks per cell/day up to ~10^4 bases altered by oxidative damage per cell/day and similar levels of replication errors and single strand breaks.[28] Importantly, much of this DNA damage is repaired and therefore does not lead to stable alterations or mutations. However, DNA damage leads also to mutations being established each day when the damage is not successfully repaired. The most common sources of this DNA damage include normal biochemical processes such as the production of reactive oxygen species (ROS) generated by oxidative phosphorylation through the electron transport chain.[29, 30] Of particular interest for cancers are agents that increase the rates of DNA damage and resulting mutations and thus increase the likelihood of carcinogenesis. In head and neck cancers there are three broadly distinct processes promoting the genetic changes that lead to cancer:

1. Mutations arising from exposure to chemical carcinogens (especially from tobacco smoke and alcohol)
2. Infection by oncogenic viruses (specifically oncogenic strains of HPV), typically leading to loss of tumour suppressor gene (TSG) function
3. Epigenetic modifications, typically leading to loss of TSG expression.

At the present time, the vast majority of data derive from studies from North America and thus the impact of betel quid and asbestos exposure are not being captured by large scale sequencing initiatives, and therefore the undoubted impact of these in some geographical areas remains to be determined by genomic studies.[31, 32]

MUTAGENIC EVENTS

Probably the most significant mutagenic events are those caused by environmental carcinogens, because they affect the most patients and result in cancers with poorer outcomes. The two primary sources of these carcinogens for head and neck cancers are tobacco smoke and alcohol. A critical feature of carcinogenic chemicals is that they often produce chemical modifications, typically of the nucleic acid bases, for which no specific repair pathway exists. This is hardly surprising since the variety of different chemical adducts that smoking alone can cause may exceed one hundred (tobacco smoke contains approximately 50–60 carcinogenic compounds that may display multiple effects on the DNA).[33–35] In contrast, the oxidation of one of the DNA bases, guanine, to 8-oxo-guanine by the endogenous production of ROS – one of the most common chemical modifications of DNA to occur – can be repaired by base excision repair (BER) mechanisms initiated by an enzyme that specifically recognizes this common lesion: 8-oxoguanine glycosylase (OGG1).[36–38]

Alcohol consumption is another major source of risk for developing head and neck cancer.[39–42] Although alcohol may not be chemically as complex a carcinogen as tobacco smoke, the interactions of alcohol with the body are highly complex, ranging from the provocation of an inflammatory response, to mutagenic and epigenetic effects. Alcohol is readily metabolized to acetaldehyde, which is a genotoxin.[43] While most alcohol will be metabolized in the liver, there is good evidence that alcohol is also metabolized in the oral cavity and in the oesophagus.[44, 45] In the oral cavity, the concentrations of acetaldehyde resulting from local alcohol metabolism are estimated to be equivalent to concentrations that have been shown to be mutagenic *in vitro* and, potentially worryingly, this can be achieved by drinks ranging from a single sip of a strong liquor to gargling with an alcohol-containing mouthwash.[46, 47] As with tobacco smoke, the details of alcohol promoted carcinogenesis in the head and neck are too complex to discuss in detail in this chapter. However, to give some idea of the complexities, there is also evidence of carcinogenicity that is not due to the classical ethanol metabolism described above, but rather to additional carcinogenic effects of acetaldehyde that already exists in alcoholic drinks.[48] Further complicating our understanding of this process and the link between alcohol and head and neck cancers is the fact that laryngeal cancer is linked with alcohol as a risk factor,[49–51] but the larynx seems an unlikely site to be directly affected as in normal swallowing action, the alcohol will not come into direct contact with internal laryngeal structures.

Of considerable importance is the interaction between tobacco smoking and alcohol, with several reports suggesting that the interaction leads to a greater than additive effect.[52, 53] It remains unclear how these processes might act synergistically, although it has been suggested that concomitant exposure may alter rates of uptake of some carcinogens and *in vitro* studies support the existence of synergy.[54, 55]

VIRUSES

In the past decade, it has become apparent that a specific subtype of head and neck cancer, with a different biology/molecular biology and significantly different clinical behaviour,[56] has been on the increase. The incidence of OPSCC has risen sharply and this has been particularly apparent in more developed countries.[57–62] This increase has been a surprise, since the smoking incidence has followed a downward trend in most of the developed world,[63] and thus the increase has been observed in the context of a generally stable or even reducing incidence of most head and neck cancers.[64] The most obvious characteristic that distinguishes the vast majority of these patients with OPSCC is the presence of viral DNA derived from the human papilloma virus strain 16 (HPV-16).[57, 65] HPV has long been known as the causative agent of cervical cancers, and so a robust understanding of the oncogenic role of

the virus has been developed.[66] HPV is a double stranded DNA virus (dsDNA); that is, it has a genome that exists as double stranded DNA, and many such viruses (examples include adenoviruses and polyomaviruses) have a strategy to ensure that the infected cell provides the DNA replication machinery needed for viral replication by promoting progression of the cell cycle into S-phase[67] in HPV infection (this involves viral oncoproteins E6 and E7, which are discussed in more detail below). Detailed sequence analysis[18, 68, 69] has shown that HPV+ tumours have fewer mutated genes than similar site of origin HPV– tumours and critically that there are different mutational profiles in HPV+ and HPV– cancers, which may well have important consequences for tumour responses to treatment.[18]

EPIGENETIC MODIFICATIONS

Epigenetic modification of gene expression and function is another major mechanism that promotes cancer in the head and neck. There are many different types of epigenetic changes but the most commonly observed ones with strong links to cancer are the methylation of cytosine residues at so-called CpG islands in the promoter regions of TSGs.[70, 71] (The most common epigenetic modification of DNA is the methylation of cytosine residues to 5-methylcytosine. This occurs predominantly in residues that are 5' to a guanine base, i.e. a CpG site. In many genes the concentration of CpGs is higher in the non-coding promoter regions 'the islands'. Typically, increased methylation of cytosines in CpG islands results in reduced gene transcription; epigenetic silencing.) For example, in head and neck cancers, *CDKN2A (*$p16^{INK4A}$) hypermethylation has been observed to be associated with reduced overall survival in population-based studies.[72–74] Although the enzymes that carry out the methylation of cytosine bases are well known,[75] it is unclear what determines whether a gene will become hyper- or hypo-methylated during the lifetime of an individual. Dietary folate may be one factor, since it ultimately provides the single carbon (i.e. methyl groups) units, but the links between folate levels in diet and gene methylation are complex and often counter-intuitive.[76–78] Some of the genes that are altered in cancers (see below) impact on epigenetic processes, but for the time being, it seems that whilst epigenetic modifications arise, we are not able to say what causes this.

Molecular pathways involved in head and neck cancer

In a recent study from The Cancer Genome Atlas (TCGA), critical and comparatively common mutations were described in 30 genes with mutation frequencies ranging from as high as 80% to as low as 0% for the same gene (this may look like an error, but the gene might be commonly mutated in HPV+ and not mutated in HPV– disease or vice versa), depending on HPV status of the cancer.[18] (HPV+ = HPV positive, i.e. HPV promoted disease, not simply harbouring some HPV DNA; HPV– = HPV negative disease, i.e. disease not driven by HPV, may contain HPV DNA. Whether the disease is driven by HPV or not depends essentially upon whether or not the viral oncogenes E6 and E7 are expressed. Expression of cellular protein $p16^{INK4a}$ is one surrogate biomarker that is linked with HPV+ disease, but it is not 100% specific. See Chapter 13, Oropharyngeal tumours.) In addition, these analyses demonstrated that the majority of tumours harboured copy number alterations (CNAs) with loss of chromosomal regions in 3p and 8p, and gains of 3q, 5p and 8q being the most common.[18] We now know all of the mutations in the whole genome (or in some cases all of the mutations in exon sequences) from several hundred patients with head and neck cancers from a number of studies,[18, 68, 69] and although there is incomplete concordance between studies with respect to the lists of genes identified and the frequency of gene mutations, there is a strong and largely consistent indication of the most frequent and most critical genetic lesions in head and neck cancers. (Exons are the coding parts of gene sequences, in contrast to the introns, which are non-coding and are removed by splicing of the nascent mRNA.) To understand this complex situation, we can simplify the process of carcinogenesis by considering how mutated or silenced genes affect the 'hallmarks of cancer'.

In 2000, Douglas Hanahan and Robert Weinberg published a seminal paper that has been cited more than 14 000 times, introducing their cancer hallmarks.[79] They described how many of the most common mutations that arise in cancers affect six primary, tumour phenotypes or characteristics:

1. Self-sufficiency in growth signals
2. Insensitivity to anti-growth signals
3. Evading apoptosis
4. Limitless replicative potential
5. Sustained angiogenesis
6. Tissue invasion and metastasis.

The significance of this article is that it has provided a clear framework for trying to understand the often complex molecular interactions that have been detected in cancers. The list was augmented in 2011 by the same authors to include enabling characteristics of cancers and two additional emerging hallmarks:[80]

- Enabling characteristics:
  - genome instability and mutation
  - tumour-promoting inflammation
- Emerging hallmarks:
  - Avoiding immune destruction
  - Deregulating cellular energetics.

As we will see, these characteristics are ubiquitous in cancers and understanding the biology that regulates these processes provides a means to incorporate the complex genetic data being generated by the latest technologies.

In 2011, the year that the hallmarks were revisited, an excellent review of head and neck cancer molecular biology was published, based upon a pre-'omic' view of the disease.[26] Considering the 'hallmarks', we can try

to categorize the most frequently mutated genes according to their known roles in these phenotypes. (Note that human gene symbols are typically capitalized and italicized, whereas the protein is not italicized e.g. *TP53* and *MYC* genes encode p53 and MYC proteins. Other species gene symbols usually only capitalize first letters, for example the *Myc* gene in mice or other mammals.) Genes such as *TP53* (p53), *CDKN2A* (p16INK4a), *CCND1* (Cyclin D1), *PIK3CA*, and *MYC*, which were known to be mutated in head and neck cancers, could be identified as having roles in cell cycle regulation (insensitivity to anti-growth signals), cell proliferation (self-sufficiency in growth signals) and cell survival (evading apoptosis). Note though that many commonly mutated 'cancer genes' have roles that impact on more than one hallmark process. So for example, *MYC* is implicated in self-sufficiency in growth signals, insensitivity to anti-growth signals, evading apoptosis and also in acquiring limitless replicative potential, whilst *TP53* has functions that regulate the insensitivity to anti-growth signals, evading apoptosis, acquiring limitless replicative potential, sustained angiogenesis and loss of function has also been linked to tissue invasion and metastasis.[81] If that isn't sufficient, both *MYC* and *TP53* have also been implicated in the deregulation of cellular energetics (see section). In addition, *TP53* has been famously dubbed the 'guardian of the genome' because of its critical role in suppressing one of the 'enabling characteristics': genome instability and mutations.[82] In contrast some 'cancer genes' only appear to impact on one hallmark phenotype. *CDKN2A* is a critical gene for normal cell cycle regulation since it encodes a protein $p16^{INK4a}$ (often simplified to p16),[73, 83] which is a regulator of cyclin dependent kinases that control cell cycle progression (see **Figure 6.4**). Thus mutations or epigenetic suppression of this gene contribute to loss of normal cell cycle control. On its own, this is insufficient to lead to self-sufficiency in growth signals since normal control is retained by the G1-S checkpoint through the *RB* gene, but is sufficient to produce an insensitivity to anti-growth signals that would stimulate p16-mediated G1-S arrest in cells already stimulated to progress through the cell cycle.[85, 86]

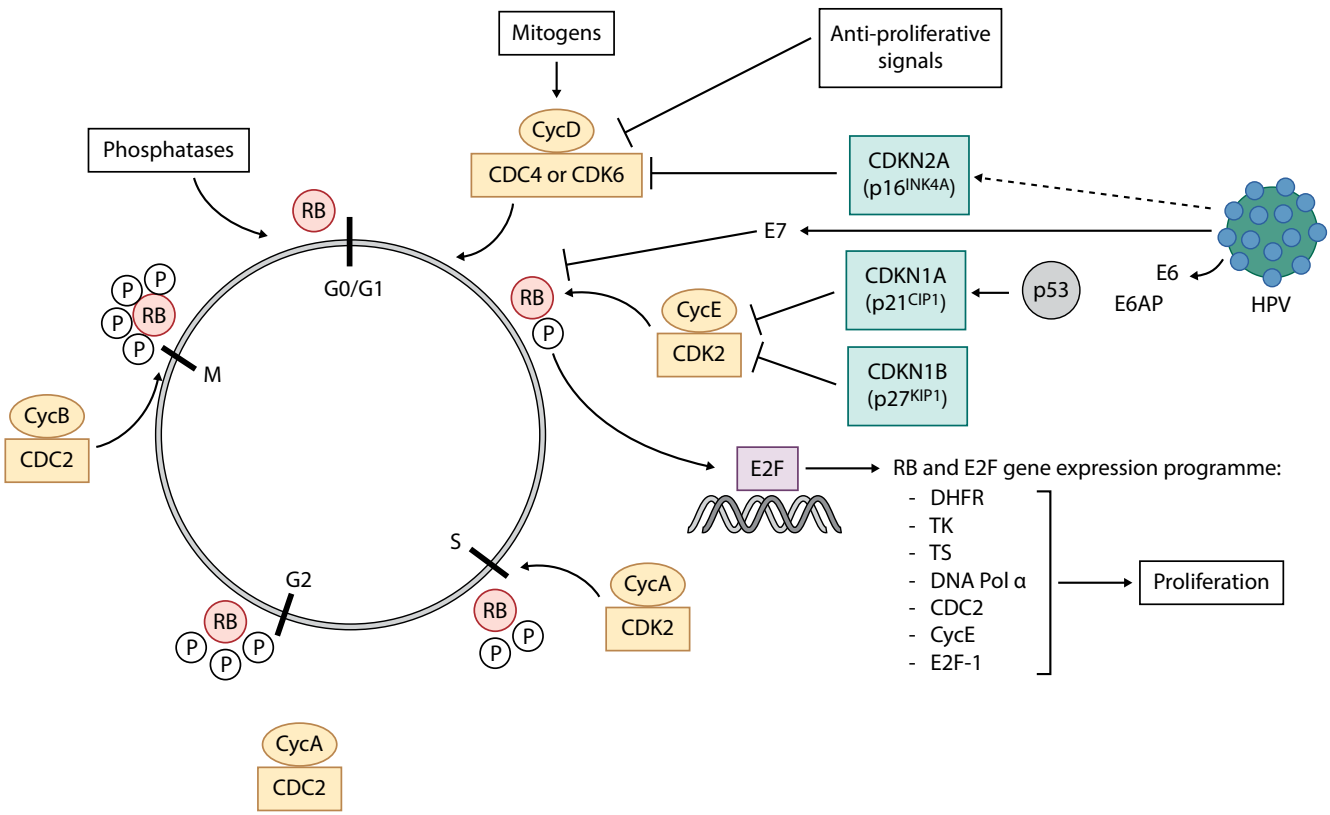

Figure 6.4 Cell cycle regulation. The cell cycle is regulated by coordinated action of cyclins (CycX) and cyclin-dependent kinases (CDKs and CDCs [cell division cycle proteins]) that phosphorylate the RB protein. In the absence of mitogenic signals RB protein is in an under-phosphorylated state and bound to E2F transcription factor rendering E2F inactive. Mitogens activate CycD/CDK4 or CycD/CDK6 complexes that phosphorylate RB protein causing it to release the E2F transcription factor that activates expression of a set of genes that mediate cell cycle progression into S phase, including DNA polymerases and CycE. During the cell cycle RB protein is sequentially phosphorylated by CycE/CDK2, CycA/CDK2, CycA/CDC2 and CycB/CDC2 complexes. Following mitosis RB is de-phosphorylated by phosphatases. Anti-proliferative signals activate $p16^{INK4A}$ protein, encoded by the *CDKN2A* gene that inhibits CycD/CDK4/6 complexes. In response to DNA damage and replication errors p53 protein is activated and up-regulates the transcription of *CDKN1A* gene encoding for CycE/CDK2 inhibitor $p21^{CIP1}$. E6 and E7 proteins, encoded by the HPV genome, target p53 and RB respectively, causing an increase in cellular proliferation. Molecules implicated in head and neck cancer are marked in red. Adapted from Knudsen ES, Knudsen KE.[84]

If the above seems complicated, then the current situation in the now 'omic' era is potentially more daunting because, in the last few years, the amount of genetic data that is available on cancer has been significantly expanded by genomic (and other 'omic') analyses of many different types of cancer. However, whilst the quantity of data has expanded phenomenally, the essential understanding of the disease has not changed too much and in many ways has actually become clearer. Whole genome sequencing (WGS) and whole exome sequencing (WES) of cancer genomes have become fairly routine thanks to the development of so called next-generation or high-throughput/second-generation sequencing technology. As a result, several studies have examined the head and neck cancer genome using a range of different technology platforms,[68, 69] with the most extensive recent studies, already alluded to above, coming from the TCGA consortium.[18]

These studies have confirmed the findings of many older studies that had, for example, correctly identified that the most commonly mutated gene in head and neck cancers was the *TP53* tumour suppressor. In addition, however, these studies identified several genes as harbouring mutations in head and neck cancers that had not been identified by earlier studies.

Another feature of head and neck cancers that has been illuminated by WGS and WES analysis of tumours has been the detection of distinct mutational profiles associated with specific carcinogens or with viral oncogenesis.[18] For example, where smoking and/or drinking contribute to tumorigenesis, then distinctive mutational spectra are observed that are linked with the carcinogen and its mode of action.[87–89] This includes C>A substitutions (identical but complementary to G>T referred to in some of the older of these papers), which are greatly increased in larynx cancers in smokers and it is known that these mutations can be induced by polycyclic aromatic hydrocarbons such as benzo[a]pyrene (for more detail on smoking and mutations induced in cancers, see the excellent recent study by Alexandrov et al[89]). Interestingly, this signature is much less obvious in oral cavity cancers, even though pack years correlate with mutational frequency in oral cancers.[90, 91]

As explained above, epigenetic regulation is an important mechanism contributing to carcinogenesis to the extent that it has been proposed by some as an additional emerging hallmark in cancer development[92–94] (Jones and Baylin, 2002; Muntean and Hess, 2009; Dawson and Kouzarides, 2012). Considerable evidence points to epigenetic alterations playing an important role in the development of head and neck cancers,[70, 95] and data from genomic studies also support this conclusion. For example, the TCGA network found mutations in the histone H3 methyltransferase gene MLL2 in 18% of head and neck cancers studied.[18]

In addition to mutations in genes that catalyse the creation (e.g. methyltransferases) or removal (e.g. demethylases) of epigenetic modifications, other events contribute to this process since gene methylation has been observed to change with time in 'normal' ageing tissues[96] and ageing and cancer are biologically linked processes.[96–99] Whilst it is not known what environmental (such as dietary) factors determine or affect changes in epigenetic regulation, it is clear that some specific genes are modified epigenetically more than others and that this alters the level of expression, typically leading to silencing (down-regulation) of TSGs in head and neck cancers.[70] This occurs in both HPV+ and HPV– carcinogenesis, but the genes that are altered may differ depending on the presence or absence of HPV (see below and also Chapter 13, Oropharyngeal tumours).[18]

The impact of specific genes on the hallmarks of head and neck cancer

Examining the pathways that are affected by mutations in head and neck cancers it is immediately apparent that there are two clearly different patterns of genetic alterations, and which genes are mutated depends to a significant extent upon whether the disease has been promoted by HPV or not.[18, 68, 69] A note of caution needs to be added here: categorization is a human approach to simplifying complex systems; we like to pigeonhole things. But in reality, genes and gene function don't really fit into the neat characteristics to which we want to reduce cancer cell pathways.

LOSS OF CELL CYCLE CONTROL (INSENSITIVITY TO ANTI-GROWTH SIGNALS)

The most common pathway affected in both HPV+ and HPV– disease is loss of normal cell cycle control, which occurs in 90–100% of both types of cancer (genes most commonly implicated: *TP53, RB1, CDKN2A, CCND1, E2F1, MYC, HPV E6*, and *HPV E7*). This pathway primarily regulates the hallmark insensitivity to anti-growth signals, but also impacts upon evading apoptosis and limitless replicative potential and sustained angiogenesis.

TP53

The most common mutations in cancer generally, and in head and neck cancer specifically, affect the *TP53* gene, which has been found to be mutated in approximately 50–60% of all head and neck cancers.[100–109] TCGA network analysis showed that this varied from approximately 80% in HPV– cancers, to 0% in HPV+ cancers.[18] This difference is not surprising, since HPV is oncogenic in part because it can inactivate the p53 protein encoded by the *TP53* gene (discussed below).[18, 110, 111] Importantly, loss of p53 function, typically as a consequence of missense mutations, has been found to be associated with patient outcomes in head and neck cancers with patients harbouring disruptive mutations that compromise p53 function displaying reduced overall survival compared to those with wild-type or non-disruptive mutations.[112, 113] Missense point mutations change the codon such that a different amino acid is encoded (cf. nonsense mutations that introduce a premature stop codon into the sequence). Generally tumour suppressors are inactivated by either nonsense or

missense point mutations, whereas oncogenes can only usually be activated by a very limited number of missense point mutations (not surprisingly, since most amino acid substitutions are more likely by chance to have a negative effect on protein function. Disruptive mutations = non-conservative amino acid substitutions in critical parts of the DNA binding domain. Wild-type = normal, the form of the gene found in the wild, non-disruptive mutations of TP53 = amino acid substitutions that do not disrupt DNA binding or only have a limited effect upon transcription regulations by p53).

The p53 protein functions primarily as a sequence specific DNA binding protein[114] that regulates the expression of a considerable number of genes (estimates range from a few hundred to more than a thousand). p53 protein is a potent inducer of apoptosis (programmed cell death) and so it is not surprising to find that under normal circumstances not one but two genes (*MDM2* and *MDM4*) are responsible for maintaining p53 at low levels in an inactive form. However, following a wide range of cellular stresses, in particular genotoxic stresses (stress induced by damaging DNA), p53 and MDM2 interaction is prevented resulting in an increase in the p53 protein level and a consequent up-regulation of p53 target genes that may mediate cell cycle arrest or apoptosis depending upon the nature of the damage. For more detailed descriptions of the role of p53 and the consequences of loss of p53 function in cancer in general and in head and neck cancer respectively, we direct the reader to Vousden and Lane[114] and Loyo et al respectively.[115]

RB, E2F1 and CDKN2A

RB was the first TSG to be identified and any treatise on the *RB* gene will usually include mention of Alfred Knudsen, retinoblastoma, and the two-hit hypothesis that he proposed.[84, 116, 117] *RB* functions to regulate the G1-S phase transition of the cell cycle and it does this by binding to and inhibiting the activity of a family of transcription factors called E2Fs. As the cell enters the cell cycle at the G1 phase in response to mitogenic signalling (see **Figure 6.4**), the signal passes intracellularly from the activated transmembrane receptor molecules at the cell surface to promote the transcription of cyclins. (Mitogenic signals are induced by mitogens: factors that stimulate mitosis such as growth factors e.g. epidermal growth factor (EGF).) Cyclins that are produced then bind to cyclin-dependent kinases (CDKs) that perform phosphorylation reactions targeting a range of genes, one of these being *RB*.[84] Phosphorylation of RB leads to inactivation of RB since it no longer binds to E2F and as a result, E2Fs promote transcription of their target genes, which *inter alia* includes genes involved in DNA synthesis i.e. S-phase (see **Figure 6.4**). As a consequence, RB not only regulates the cell cycle, but also regulates the cell cycle arrest that is a requirement for terminal differentiation (which is frequently regulated by RB related proteins p107 and p130).[118, 119]

Frequently inactivated in head and neck cancers by promoter hypermethylation, the *CDKN2A* gene encodes two proteins with tumour suppressor activities (p14 [$p14_{ARF}$] and p16 [$p16_{INK4a}$]). p16 inactivation, either through mutation or via promoter hypermethylation has been implicated in many cancers.[120, 121] p16 functions as a negative regulator implicated in many cancers.[120, 121] p16 functions as a negative regulator of G1-S phase progression that acts by binding to and inhibiting the cyclin dependent kinases CDK4 and CDK6.[122] (Some TSGs, including *CDKN2A*, become transcriptionally repressed as a consequence of increased promoter methylation. This can arise as an individual ages, or may be associated with disease. In cancer, changes in methylation of CpG islands (both increases and reductions in methylation) are commonly observed, and loss of *CDKN2A* function either through mutation or increased promoter methylation is a common event affecting more than 50% of HPV– head and neck cancers.)

CCND1 and let-7c

Cyclin D1 is the protein encoded by the *CCND1* gene and this gene has frequently been found to be amplified in a range of cancers including head and neck cancers.[18, 123–125] Cyclins are the critical regulators of the cell cycle and are typically short-lived proteins that are regulated transcriptionally.[126, 127] In the case of cyclin D1, expression is regulated by the MAPK pathway, which is activated following receptor mediated tyrosine kinase activation, by for example, growth factors (EGF binds to the EGF receptor EGFR, see **Figure 6.4**), cyclin D1 associates with cyclin dependent kinases 4 and 6 to promote phosphorylation of target proteins, in particular of the RB TSG leading to its inactivation and cell cycle progression. Thus, gene amplification of *CCND1* provides for constitutively increased cyclin D expression and loss of normal cell cycle regulation at the G1-S checkpoint.[128] let-7c is a microRNA (miRNA) that regulates a number of target genes and that has been found to be down-regulated/deleted in approximately 40% of HPV– head and neck cancers and this was associated with increased *CDK6* expression, anticipated to promote cell cycle progression in combination with *CCND1*.

MYC

The role of the *MYC* gene (also called *c-MYC* or *cMYC* to distinguish it from the viral oncogene originally identified as the v-Myc gene from the avian myelocytomatosis virus and from two other alleles in the human genome: *N-MYC* and *L-MYC*)[129] in cancer has a long and fascinating history due ultimately to the complexity of MYC functions with roles in cell cycle regulation, cell proliferation, cell survival/apoptosis, and more recently identified roles in cancer cell metabolism.[130–135] One of the reasons that *MYC* function has proven difficult to dissect is that MYC has effects on a huge number of genes including *CCND1*, *TP53* and *TERT* (Telomerase – a gene implicated in immortalization of cancer cells).[131, 136] MYC functions as a hetero-dimer to regulate transcription associating with either MAX, leading to activation of gene expression, or with MAD leading to repression of gene expression to regulate control of critical genes that are required for cell

proliferation and survival. More recently it has been found that *MYC* acts not only to regulate the initiation of gene expression similar to many other transcriptional regulators, but also affects other aspects of transcription and post-transcriptional processes such as modulating the stability of newly synthesized RNA molecules and through these additional activities MYC has been revealed to exert an ever greater impact on gene expression.[137] Amplification of the *MYC* locus occurs in over 10% of HPV– cancers, leading to increased MYC signalling and thus promoting cell survival and proliferation.

HPV E6, E7 and E2F1

Human papilloma viruses are doubled stranded DNA viruses that require the host cell DNA replication machinery for viral genome replication.[138] WGS and WES analyses reveal clear differences in the patterns of genetic alterations between HPV+ and HPV– head and neck cancers (note that the vast majority of HPV+ head and neck cancers are derived from the oropharynx).[18, 68, 69, 74, 115] HPV encodes two critical onco-proteins: E6 and E7 that promote S-phase progression in infected cells (see **Figure 6.4**). Together these viral oncogenes inactivate two TSGs, *TP53* and *RB* respectively,[139] with the consequence of promoting S-phase progression in cells.[138]

Normally, this leads to viral DNA replication, and virion assembly and production, which may also lead to cell death. Rarely however, the infection can become abortive, either as a result of recombination leading to integration of part of the viral genome into the host cell genome or as result of the effects of E6 and E7 expressed as episomal genes in a cell that therefore fails to continue to differentiate preventing late gene expression.[140] (Episomal DNA is DNA that can be replicated independently of the chromosomal DNA, typically unintegrated into the genome.) Providing that the infected cell retains both of the oncogenic genes (E6 and E7), this can promote deregulated cell cycle progression through the G1-S checkpoint in the cell, and in all of the daughter cells it produces. The accumulation of a population of cells harbouring such a defect significantly increases the risk of carcinogenesis since two critical TSGs are already inactivated in all of these cells. Another consequence of HPV-mediated TSG inactivation is that fewer additional events are required for tumorigenesis.[68, 69]

E6 functions by binding to the p53 protein and it also binds to a cellular protein E6AP (encoded by the *UBE3A* gene [ubiquitin-protein ligase E3A]), which promotes the poly-ubiquitylation of p53 and thus targets p53 protein to the 26S proteasome for degradation.[141, 142] E7 functions by binding to the RB protein and preventing it from interacting with E2Fs, thus allowing E2F-regulated genes to become transcribed.[143] Recent studies have also identified that binding of E7 to RB also promotes degradation of the RB protein by the ubiquitin – proteasome route.[144, 145] In HPV+ cancers, E6 and E7 expression appear to be ubiquitous, further supporting a role for retaining expression of these to maintain continued cell cycling. In HPV+ cancers, *E2F1* expression was also often increased (in approximately 19% of tumours); this would be expected to result from inactivation of the *RB* and *TP53* genes by E7 and E6 respectively.

Curiously, although we know so much about RB, and we know that loss of RB function resulting from inactivation by HPV E7 protein (see below) leads to upregulation of p16 (*CDKN2A* expression), we do not at the present time know exactly why this is so. Clearly RB represses expression of p16, but since p16 is not known to be a direct target of any of the E2F family of transcription factors that RB suppresses the details remain obscure.

GROWTH AND PROLIFERATION SIGNALLING (SELF-SUFFICIENCY IN GROWTH SIGNALS)

The next most frequently altered pathway identified is the receptor tyrosine kinase (RTK) signalling pathway that regulates the mitogen activated protein kinase (MAPK) signalling pathway. This primarily controls the hallmark: self-sufficiency in growth signals. Genes that regulate this pathway are altered in approximately 60% of head and neck cancers regardless of HPV status (most commonly implicated genes: *PIK3CA, EGFR* and *PTEN* plus *CCND1* and *MYC* listed above).

EGFR, PTEN and PIK3CA

In normal cells the signalling pathway that promotes cell entry into the cell cycle is stimulated in epithelial cells by a soluble ligand mitogen the epidermal growth factor EGF.[146] EGF binds to the extracellular domain of the epidermal growth factor receptor EGFR, a transmembrane receptor protein that has intracellular tyrosine kinase activity (the ability to catalyse the transfer of phosphate onto specific tyrosine residues in substrate proteins). Binding of the EGF receptor ligand causes the receptor to dimerize at the cell surface, which promotes activation of the RTK activity leading it to phosphorylate substrates on tyrosine residues (see **Figure 6.5**). Target proteins that are post-translationally modified by phosphorylation include the receptor itself (auto-phosphorylation) and proteins of the MAPK pathway.[147]

PIK3CA encodes the enzyme phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit (also called p110α), which is the catalytic subunit of a heterodimeric enzyme that catalyses the addition of phosphate from ATP to phosphoinositol lipids that regulate a number of signalling pathways, specifically converting PIP2 to PIP3 and thus activating AKT (also known as protein kinase B or PKB) which plays an important role in cell survival and also regulates several other pathways including ones that control cell movement and metabolism. (PIP2 is phosphatidylinositol (4,5)-bisphosphate; PIP 3 is phosphatidylinositol (3,4,5)-trisphosphate (PtdIns(3,4,5)P3).) This conversion of PIP2 to PIP3 is part of the signalling pathway from RTKs that ultimately controls a wide range of cellular signalling programmes including transcriptional programs that activate progression through the cell cycle and non-transcriptional survival programs such as activating the mTOR pathway that promotes protein synthesis

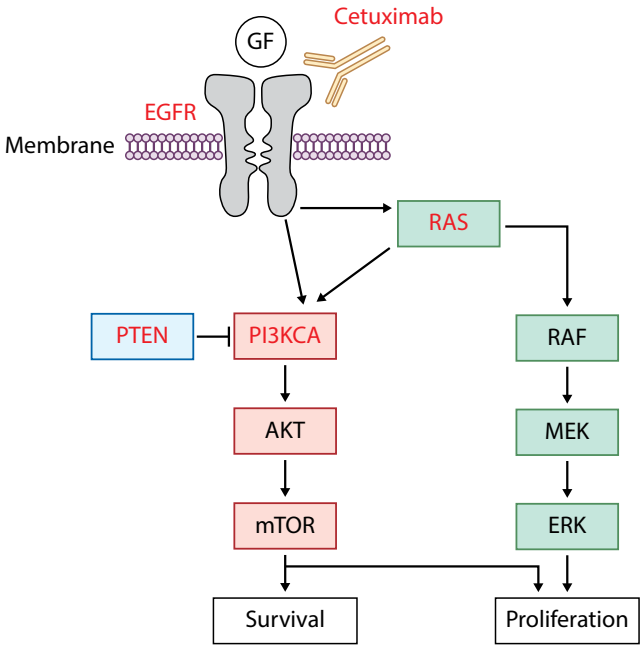

Figure 6.5 Epidermal growth factor receptor (EGFR) pathway. Upon binding of the mitogenic ligand/growth factor (GF) such as EGF (epidermal growth factor), EGFR undergoes dimerization and auto-phosphorylation initiating intracellular signalling via several pathways including the RAS-mediated protein kinase pathway and PI3K/AKT survival pathway. Activation of RAS leads to a signalling cascade involving several mitogen-activated protein kinases (MAPK), including MEK and ERK ultimately leading to cellular proliferation. Activation of the PI3K/AKT pathway is involved in cellular proliferation as well as in apoptosis resistance (survival) via activation of mTOR. PI3KCA is a catalytic subunit of PI3K often mutated in head and neck cancer. Tumour suppressor PTEN is an inhibitor of PI3K/AKT pathway that often undergoes inactivating mutations in head and neck cancer. Cetuximab is a monoclonal antibody that binds to the EGFR that inhibits activation of the EGFR pathway (and recruits antigen directed cell cytotoxicity) and is used clinically for the treatment of metastatic head and neck cancer. Molecules implicated in head and neck cancer are marked in red. Adapted from Ladanyi and Pao.[150]

needed for cell growth as part of the process of promoting cell proliferation and survival.[148, 149] The reverse reaction, converting PIP3 to PIP2, is, interestingly, carried out by the product of the other commonly mutated gene in head and neck cancers, the *PTEN* gene, which encodes an enzyme: the phosphatase and tensin homolog.[151–153]

In head and neck cancers, localized amplifications of the EGFR gene located on chromosome 7 occur in more than 10% of cases and amplification presumably leads to increased signalling from the receptor.[18] Mutations in PIK3CA are common in HPV– cancers (>30% of cases), but are significantly more common in HPV+ cancer (>60% of cases). Typically mutations in PIK3CA were concentrated in three hotspots that are known to lead to constitutive activation of the protein, whereas for PTEN, which functions as TSG to oppose the activity of PIK3CA (and therefore also of EGFR activation), mutations typically inactivate the protein and may be nonsense or missense point mutations. Thus all three of these genes have roles in the same signalling pathway to promote cell growth, proliferation and survival, and mutations in these compromise normal cell signalling and the regulation of cell growth, proliferation and survival.

CELL DIFFERENTIATION REGULATION (LIMITLESS REPLICATIVE POTENTIAL)

The third most commonly affected pathway implicated in between 40% and 60% of HPV+ and HPV– cancers respectively controls cellular differentiation of the squamous epithelium.[18] De-differentiation and the suppression of normal differentiation are prerequisites for immortalization (terminally differentiated cells exit the cell cycle and so do not replicate further) and in the case of HPV+ cancers, arresting differentiation is likely to promote early gene expression at the expense of late gene expression with the predicted consequence of cellular transformation being promoted over viral production.[154] Genes implicated specifically in this pathway include *TP63, NOTCH* and *FAT1*, but also *MYC* which has been shown to upregulate *TERT*,[155] in addition to having a role in cell cycle regulation, cell proliferation and survival.

TP63, NOTCH and FAT1

One of the first new discoveries to come from the early genome wide analyses was that *NOTCH1* (and more rarely other alleles *NOTCH2* and *NOTCH3*) was mutated in a significant percentage of head and neck cancers and moreover that the mutations would be predicted to inactivate NOTCH function.[68, 69] *NOTCH* is best understood because of its role in preventing differentiation of stem cells and through this contributing to their proliferative capacity.[156] Thus mutations that inactivate *NOTCH* would appear to have an anti-proliferative effect and might even promote differentiation. More recently, it has been found that *NOTCH*, and also *FAT1* (also mutated predominantly in HPV– head and neck cancers) negatively regulate the critical *WNT*-gene target β-catenin (encoded by the *CTNNB1* gene) (see **Figure 6.6**).[125, 157] This function might provide an explanation for the presence of *NOTCH* mutations in HPV+ and HPV– cancers (and also for *FAT1*, which is predominantly mutated in HPV– disease). The WNT signalling pathway has been long studied for its role in colorectal cancers (CRCs), and indeed studies of mutations in CRC led to the creation by Bert Vogelstein and his colleagues of what became known as the 'Vogelgram' illustrating the sequence of genetic events and the associated phenotypic changes that commonly occur in CRC as the disease progresses.[158, 159] *TP63* was originally discovered because of sequence homology in its DNA binding domain with that of the p53 tumour suppressor,[160] and subsequent studies have revealed a complex splicing pattern for the gene that can produce p63 isoforms, which display either positive or negative effects on p63 mediated transcription that normally plays a role in squamous epithelial differentiation.[161–163] (Isoforms are two or more forms of a protein that have similar but non-identical sequences (one may be simply shorter), usually

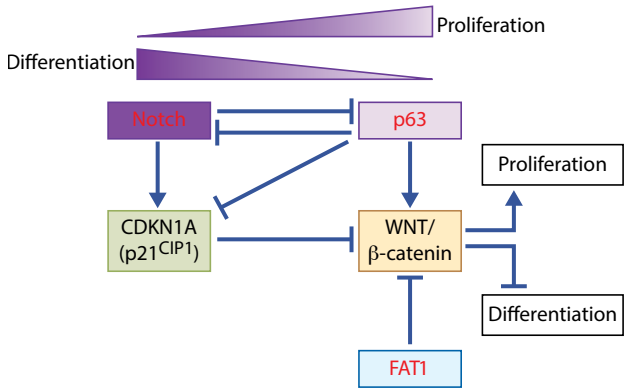

Figure 6.6 NOTCH, p63 and FAT1-mediated regulation of cellular proliferation and differentiation. NOTCH-p63 interplay maintains the balance between cellular proliferation and differentiation. Generally speaking NOTCH promotes cellular differentiation via activation of $p21^{CIP1}$ that suppresses the inhibitory activity of the WNT/β-catenin pathway on the process of differentiation. p63 has the opposite effect by inhibiting $p21^{CIP1}$ as well as by activating WNT/β-catenin pathway that results in an increase in cellular proliferation. In addition, tumour suppressor FAT1 that is frequently inactivated in head and neck cancer inhibits WNT/β-catenin pathway leading to a decrease in cellular proliferation. Molecules implicated in head and neck cancer are marked in red. Adapted from Dotto.[164]

produced by differences in the way that the exons are spliced together or because transcription initiates in different places in the gene.) Thus, changes in splicing would result in altered cellular differentiation and consequently proliferation, with the specific effects depending upon the ratios of expression between splice variants.[165]

CELL DEATH REGULATION (EVADING APOPTOSIS)

The fourth most commonly affected pathway with specific mutations identified in 30–40% of head and neck cancers impacts upon the regulation of cell survival and death, which also impacts upon inflammation and immunity. These disparate responses are partly co-ordinated by the NF-κB pathway.[166–168] Genes implicated in this pathway include *FADD, TRAF3* and *CASP8*, but also the genes *TP53, MYC* and *PIK3CA* already listed above for their roles in cell cycle regulation and survival and cell proliferation signalling. At the present time how these genes contribute to tumorigenesis is not as well understood as the roles of the more extensively studied cell cycle and growth and proliferative pathway genes.

FADD, CASP8 and TRAF3

FADD (fas-associated protein with death domain) has been found to be amplified, predominantly in HPV– cancers, and in several instances, the *FADD* gene was found to be co-amplified with the cyclin D *CCND1* gene, which may suggest an interaction between these.[18] FADD links so-called death receptors such as FAS and TNFR1 (tumour necrosis factor receptor 1), which are transmembrane proteins that connect extracellular signals regulating cell survival and death with the intracellular survival regulatory machinery via NF-κB and also with caspase effectors of apoptosis such as caspase 8 (encoded by *CASP8*).[169] *CASP8* encodes the critical effector caspase 8 for the so-called extrinsic apoptotic signalling pathway and in head and neck cancers. *CASP8* inactivating mutations (found predominantly in oral cavity tumours) were often found associated with wild-type *TP53* (thus p53 is competent to induce apoptosis through the intrinsic pathway but caspase 8 which acts through the extrinsic pathways is not).[170] (There are essentially two main effector pathways for apoptosis: the extrinsic, regulated by cell surface receptor signalling; and the intrinsic, regulated by intracellular stimuli such as DNA damage, hypoxia and metabolic stresses.)[170] *TRAF3* is a member of the TNF receptor associated factor (TRAF) protein family, which mediates signals from transmembrane receptor proteins of the TNF (tumour necrosis factor) such as TNFR1 (which acts via FADD see above). *TRAF3* mutations were almost exclusively found in HPV+ disease, which is interesting since TRAFs have been implicated in anti-viral responses mediated by interferons and several viruses inactivate TRAF proteins.[171, 172]

Inflammation is a known risk factor for promoting carcinogenesis[173, 174] and one of the key regulators of inflammatory responses is the gene *NF-κB*.[175, 176] It seems likely that genes such as *FADD*, *TRAF3* and also *PIK3CA*, *TP53* and *MYC* impact on the regulation of NF-κB activity and thus impact on inflammatory processes.

SUSTAINED ANGIOGENESIS

Tumour hypoxia is a well recognized phenomenon that arises as a consequence of increasing tumour size and poor local vascularization.[177] Hypoxia is linked with radioresistance, and is also an independent predictor of poor prognosis.[178] Tumours typically adapt to combat hypoxia through altering transcriptional programs regulated by the oxygen-sensitive hypoxia inducible factor 1α gene; *HIF1α*.[179, 180] Analyses of head and neck cancer genomes might at first sight appear to reveal only limited genetic evidence of frequent disruption of angiogenic regulatory processes. However, common mutations such as those in *TP53* likely alter angiogenesis; for example, p53 has been reported to regulate expression of angiogenesis suppressor thrombospondin 1 (*THBS1*) and also promotes degradation of HIF1α, and in so doing suppresses neoangiogenesis.[181] In addition, several other genes identified through genomic analyses in head and neck cancers including *FADD*, *TRAF3*, *CASP8*, *PIK3CA* and *MYC* that alter signalling through NF-κB are known to affect angiogenesis[182] (as well as invasion and metastasis, see below), and thus some of the most common mutations that occur in head and neck cancers likely have an impact on angiogenesis.

TISSUE INVASION AND METASTASIS

The ability of cancer cells to invade surrounding tissue and metastasize to distant sites is one of the hallmarks of

cancer (**Figure 6.1**) and is also the leading cause of morbidity and mortality in cancer patients.[80] Metastasis is a complex, multistep process during which cancer cells need to leave the primary tumour site, invade the surrounding tissue, intravasate the lymphatic or vascular circulation, survive in the circulation in order to arrive at the metastatic site where they extravasate and establish a secondary tumour.[183] Epithelial-mesenchymal transition (EMT), a process during which cancer cells acquire mesenchymal phenotype characterized by increased migratory and invasive capabilities, is an integral part of the metastatic phenotype.[184] Several molecular pathways that play a role in metastasis have been identified, including signalling from the TGFβ (transforming growth factor β) pathway that has been shown to be important for EMT in a number of cancers, including head and neck cancer.[185] Indeed, mutations and deletions of *TGFβR2* (transforming growth factor β receptor 2) have been found mostly in oral cavity tumours.[185] In addition, deletions in *SMAD4* (Sma + Mad 4, for 'Mothers against decapentaplegic homolog 4'), a transcription factor that is a member of TGFβ pathway, were identified in particular in HPV–head and neck cancers.[18, 185]

Emerging hallmarks

AVOIDING IMMUNE DESTRUCTION

It has been well documented that the interactions between cancer cells and the surrounding stroma or microenvironment play a role in the initiation and progression of cancer and ultimately determine patient prognosis.[186] Tumour microenvironment consists of a number of components, including extracellular matrix (ECM), blood vessels, immune system cells and fibroblasts. More recently, the immune system and its role in carcinogenesis have come into focus with development of drugs that suppress the ability of cancer cells to avoid destruction by the immune system. In particular, PD-1/PD-L1 interaction inhibitors have shown potential for the treatment of a number of cancers, including lung, metastatic melanoma and kidney cancer.[187, 188] Following positive outcomes in several clinical trials, nivolumab, a PD-1 inhibitor, has been approved by the FDA for the treatment of several cancers including head and neck cancer.[189, 190] In depth analysis of the immune microenvironment has demonstrated that head and neck cancer is characterized by high levels of immune cells infiltration and immunosuppression, regardless of HPV status.[191] In particular, as a result of these studies regulatory T (Treg) and natural killer (NK) cells have emerged as potential therapeutic targets.

DEREGULATING CELLULAR ENERGETICS

As long ago as the 1920s Otto Warburg performed experiments on tumours aimed at determining the metabolic processes used by cells in the tumour, which revealed high levels of glycolysis ('fermentation') as well as respiration typical of normal tissues.[192] However, it was not until the 1950s that more quantitative experiments revealed that tumour cells generate much of their energy from fermentation (i.e. glycolysis) whereas normal cells typically use mostly respiration.[193] This observation has been put to good use in PET-CT using the increased capacity of tumour to uptake a radioactive glucose analogue to image tumours.[194] It seems extraordinary, but it is only in the last decade or so that cancer biology has begun to focus in earnest on the so-called Warburg effect, namely the tendency for cancer cells to obtain substantial amounts of energy from aerobic glycolysis. This effect is so ubiquitous that many are now trying to take advantage of this phenomenon for therapeutic purposes. Many of the genes found altered in head and neck cancers have been implicated in metabolic alterations in cancer cells, chief amongst these being *TP53*,[195] *MYC*[196] and *PIK3CA*,[197] all of which have been shown *in vitro* to modulate cancer metabolic profiles. In the case of *TP53*, studies have already identified potential strategies for therapeutic interventions.[198]

CONCLUDING REMARKS

Ultimately what matters is how the enormous amounts of data now being generated by the research community can be used to impact upon patients, whether it be through developing diagnostics or devising new or more precisely targeted treatments (precision medicine). We now know essentially all of the gene mutations that commonly arise regardless of HPV status, but many of these events present huge challenges for exploitation for therapy. Many of the genes that are activated in cancer cells (oncogenes), have important normal functions in cell growth and proliferation (and survival) and thus selective targeting may prove difficult. Rescuing loss of TSG function is even more challenging. Immunotherapy appears to hold great promise and trials of nivolumab (recently approved by the FDA for treatment of head and neck cancers) and other similar agents are ongoing. Another relatively new area of research that seems likely to lead to novel therapeutic approaches is targeting of tumour metabolism, which is already being used in some other cancers such as renal cancer.[199, 200]

Regardless, what these genomic analyses reveal is that there are identifiable molecular pathways that regulate the key processes, the hallmarks, that are altered in cancers of cell cycle regulation, cell survival and death, cellular differentiation, oxidative stress, immunity and some of these impact also on inflammation, angiogenesis and cell migration (invasion). It seems highly likely that new agents that target aspects of these pathways/molecules will be developed; the problem may be one of availability due to the diminishing returns resulting from the cost of developing so many specialized therapeutic molecules for ever more precisely defined molecular subsets of patients.

KEY POINTS

- Cancer is essentially a genetic disease resulting from an accumulation of somatic mutations (no mutations = no cancer).
- Head and neck squamous cell carcinomas are promoted by carcinogens found in tobacco smoke and alcohol (which act synergistically), or exposure to the HPV (OPSCC), or to other carcinogenic substances such as are found in betel quid.
- Genome wide studies have revealed essentially all of the critical gene mutations that occur in head and neck cancers in North American populations, as well as the changes in gene expression and epigenetic alterations that arise in patients with tobacco smoking/alcohol drinking and HPV-associated tumours (we do not currently have similar detailed data from patients from other high-risk exposure activities e.g. betel chewing).
- The potential exists to obtain genome wide data from individual patient tumours. However at the present time the usefulness of such information is limited.
- Cancer cells display characteristic phenotypes that have been called the 'Hallmarks of Cancer' and we can understand the role of genetic and epigenetic changes in cancer cells in the context of these Hallmarks.
- The most commonly affected cellular genes in head and neck squamous cell carcinomas are: *TP53, PIK3CA, CDKN2A, NOTCH, FADD, let-7c, FAT1, CCND1, PTEN, TP63, EGFR and MYC*.
- In HPV driven disease the viral genes E6 and E7 are critical.

SEARCH STRATEGY

Data in this chapter may be updated by a Pubmed search using the generic keywords: 'nasal cavity neoplasms' and 'paranasal sinus neoplasms' but focusing on the diagnosis and management of these conditions.

INTRODUCTION

In this chapter, we discuss the management of malignant tumours that develop in the nasal cavity and paranasal sinuses. Malignant conditions involving the nasal vestibule and external nose are discussed in Chapter 85, Nasal reconstruction.

Sinonasal malignancies are a diverse group of tumours, some of which are unique to the nose. They are uncommon, accounting for less than 1% of all neoplasms. Initially they produce little in the way of symptoms and in the early stages can be misdiagnosed as more common benign conditions such as rhinosinusitis. As a result, the diagnosis is often delayed and only made at a relatively advanced stage when symptoms caused by local disease extension supervene. The average delay between the first symptom and diagnosis is approximately 6 months. By the time of presentation erosion of bone and infiltration of sensory nerves may have produced facial pain and concurrent sensory deficits. Extension of the tumour into the orbit, brain and infratemporal fossa not only produce further symptoms but also have profound implications on treatment and likely outcome in terms of both morbidity and prognosis.

Accurate staging of nasal and sinus tumours remains difficult despite recent advances in endoscopy and almost universal access to refined radiological cross-sectional imaging techniques such as CT and MRI. Current staging systems are only applicable to maxillary and ethmoid sinuses.

Surgery and radiotherapy remain the mainstays of treatment. All treatment regimens inflict considerable morbidity including facial disfigurement, altered mastication and, in some cases, loss of sight. The prognosis for patients with sinonasal malignancies has improved over the last three decades but remains relatively poor compared with other head and neck subsites. Consequently, quality of life issues are of particular importance when considering treatment options, particularly in those presenting with extensive disease.

EPIDEMIOLOGY

Sinonasal malignancies have an incidence of 0.5–1 per 100 000 per year.[1] They account for 0.2–0.8% of all malignancies and 3% of upper aerodigestive tract neoplasms.[2] Most develop in the fifth and sixth decades of life. The incidence in men is twice that of women.[3] The misconception that certain races are more susceptible than others to sinus malignancies is explicable by occupational exposure to carcinogens.[2]

AETIOLOGY

Several carcinogenic compounds have been identified with inhalation of these carcinogens being responsible for around 40% of reported sinonasal malignancies. Foremost among these occupational hazards is exposure to hard woods in the furniture industry. It is thought that biologically active compounds in wood dust impair mucociliary clearance and predispose to carcinogenesis.[4] Acheson et al. reported high rates of nasal cavity and sinus adenocarcinoma in the High Wycombe area and proposed that this was secondary to wood dust exposure.[5] Workers exposed to hard wood have a 70 times increased incidence of sinonasal adenocarcinoma, particularly of the ethmoid sinuses. The UK Government recognizes this as an occupational risk and as such it is a prescribed disease under the 1959 National Insurance Regulations: Reference D6. It remains the duty of a doctor to accordingly inform patients of their rights.

The type of wood is a significant factor. While hardwood exposure increases the risk of developing adenocarcinoma, soft wood exposure is more commonly associated with squamous cell carcinoma (SCC). African mahogany appears to be the most carcinogenic. This wood is often burned by Bantu tribesmen, who have the highest incidence of maxillary sinus cancer in the world. Sinonasal adenocarcinoma that develops in wood-workers has a better prognosis than other nasal adenocarcinomas.[4]

Other occupational hazards include exposure to nickel, which increases risk of developing sinonasal SCC 250-fold. The interval between exposure to nickel and the development of the tumour can be prolonged, with Pedersen et al. reporting a latent interval of between 18 and 36 years.[6] Smoking is also thought to play a role in the development of these tumours, perhaps in a synergistic fashion with wood dust.[4] Other chemicals linked to sinonasal malignancy include chromium, polycyclic hydrocarbons, aflatoxin (found in certain foods and dust), mustard gas and thorotrast (thorium dioxide used in paints for watch dials). Radiation, viral and genetic causes have also been proposed. There is no evidence that chronic sinusitis predisposes to cancer with the incidence of chronic sinusitis in patients with sinonasal malignancies equating to that in the general population.[2]

SURGICAL ANATOMY

The anatomy of the nose and paranasal sinuses is described in detail in Volume 1, Chapter 87, Anatomy of the nose and paranasal sinuses.

General considerations

Sinonasal malignancies spread most commonly by local invasion. The ethmoid and maxillary sinuses are intimately related to the orbit and separated from it by thin bone that is deficient in places to permit the passage of nerves and blood vessels. These anatomical features favour relatively early tumour spread into the orbital contents. The roof of the frontal sinus is similarly thin and this, in combination with perforations in the superior part of the nasal cavity through which the olfactory nerves pass, means that tumours developing at these sites tend to spread intracranially.

In 1933 Öhngren described a line running from the medial canthus of the orbit to the angle of the mandible which he used to separated tumours into two groups, namely those that developed above it and those that developed below it.[7] He suggested that superiorly-based tumours tended to be more aggressive and poorly differentiated, whereas tumours arising inferior to the line were more amenable to treatment and, as a consequence, had a better prognosis. Although this may well be the case, the classification was described before the concept of craniofacial resection was developed. This in combination with the huge advances in radiation oncology that have taken place in the last few decades make Öhngren's suggestion largely of historical interest.

Lymphatic drainage

The lymphatic drainage of the nose and paranasal sinuses is relatively scant. Two lymphatic pathways have been described, the anterior and the posterior. The lymphatics of the anteroinferior part of the nasal cavity and skin of the nasal vestibule drain via the anterior pathway to the first eschelon facial, parotid and submandibular lymph nodes. These in turn drain into the upper deep cervical chain. The remainder of the nose and paranasal sinuses drain through a posterior pathway which runs anterior to the Eustachian tube to first eschelon nodes in the retropharyngeal space and then onwards to the upper deep cervical chain.

PATTERNS OF TUMOUR SPREAD

The advanced stage of tumours at the time of presentation can make their precise origin difficult to determine. Nevertheless, maxillary sinus tumours are the most common (55%) followed by the nasal cavity (35%), ethmoid sinuses (9%) and, rarely, frontal and sphenoid sinuses (1%).

Local invasion

In general, sinonasal carcinomas tend to consume the sinus cavity from which they arise before eroding its bony walls. Periosteum, perichondrium and dura appear to act as a temporary barrier and resist tumour expansion to some extent, a feature possibly explained by the fibroelastic connective tissue component of these tissues.[8] By contrast the bone of the anterior maxilla and orbital floor is very thin and readily destroyed by tumour. Only 25% of maxillary sinus carcinomas are contained within the antrum at the time of presentation.[9] Patterns of local spread are summarized in **Table 7.1**.

Maxillary sinus tumours spread medially from the sinus into the lateral wall of the nasal cavity, laterally into the

TABLE 7.1 Patterns of local spread

Primary site	Anteriorly	Posteriorly	Medially	Laterally	Superiorly	Inferiorly
Frontal sinus	Skin	Anterior cranial fossa, frontal lobes				Ethmoid sinus, nasal cavity
Ethmoid sinus	Skin	Sphenoid, nasopharynx, clivus, pituitary gland	Nasal cavities, cribriform plate	Orbit	Anterior cranial fossa, frontal lobes	Nasal cavity
Maxillary sinus	Cheek, skin	Pterygopalatine fossa, infratemporal fossa, temporal bone, middle cranial fossa	Nasal cavity	Cheek, skin	Orbit	Palate
Sphenoid sinus	Ethmoid sinuses	Clivus, pituitary gland, posterior cranial fossa		Middle cranial fossa, cavernous sinus	Pituitary gland, hypothalamus	Nasopharynx
Nasal cavities	Skin	Sphenoid sinus, nasopharynx		Maxillary sinuses	Anterior cranial fossa, frontal lobes	Palate

cheek, superiorly through the inferior orbital fissure into the orbit, inferiorly into the palate and posteriorly into the infratemporal and pterygopalatine fossae (**Figure 7.1**).

Tumours that arise in the ethmoid sinus spread medially into the nasal cavity, laterally into the orbit, superiorly into the anterior cranial fossa and inferiorly into the maxillary sinus (**Figure 7.2**).

Frontal sinus tumours extend through the posterior wall into the anterior cranial fossa and frontal lobes, as well as anteriorly into the skin of the forehead and inferiorly into the nasal cavity. Tumours arising in the sphenoid sinus tend to spread laterally into the cavernous sinus and anteriorly into the ethmoids and nasal cavity (**Figure 7.3**).

Regional spread

Lymphatic spread to regional nodes becomes apparent in 25–35% of patients at some time during the course of their disease. Around 10% of patients present with nodal disease, which is usually a marker of locally-advanced disease. The submandibular and jugulodigastric nodes are the most commonly involved. Bilateral lymph node involvement can occur in patients who develop tumours near the midline.

Distant metastases

Distant metastases at the time of presentation are unusual. They develop in around 20% of patients with adenocarcinomas in contrast to just 10% of those with SCCs.[10] When found they are usually associated with local recurrence.[11]

Figure 7.2 An ethmoid carcinoma spreading into the orbit and producing proptosis.

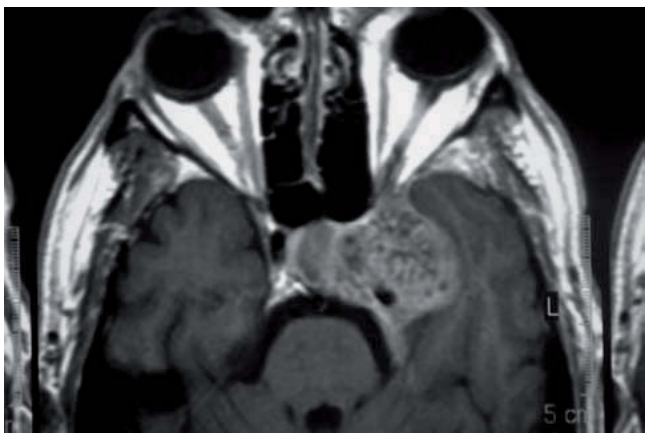

Figure 7.3 MRI of sphenoid tumour that has spread into the cavernous sinus and presented with diplopia secondary to a VIth cranial nerve palsy.

The most common sites for metastases are bone, brain, liver, lung and skin. Unsurprisingly the presence of distant metastases is associated with a poor prognosis except in the small subgroup of patients with metastatic pulmonary adenoid cystic carcinoma (ACC), who can survive for some time if the primary site remains controlled.

STAGING

Staging systems have only been devised for carcinomas of the maxillary sinus, ethmoid sinus and the nasal cavity. These systems are not applicable to mesodermal tumours and have no relevance to olfactory neuroblastoma (OAN) for which separate schemes exist. The TNM classification system for the maxillary sinus (**Figure 7.4**), ethmoid sinus (**Figure 7.5**) and nasal cavity is shown in **Table 7.2**. The staging matrix is presented in **Table 7.3**.[12]

SURGICAL PATHOLOGY

Squamous cell carcinoma

SCC is the most common sinonasal malignancy. The highest incidence is in the seventh decade of life and there is a male preponderance. Most SCCs arise from the lateral wall of the nasal cavity with 50% developing on the turbinates. Two-thirds of septal SCCs are found anteriorly in the region of the mucocutaneous junction. Transformation of Schneiderian papillomas into SCC is a recognized risk. Batsakis reported a 14.6% incidence of SCC in a series of 322 patients with Schneiderian papillomas.[13] Approximately 85% of SCCs are well differentiated tumours. Papillary and exophytic histological patterns are also recognized. It is said that differentiation has little bearing on the ultimate prognosis but this probably reflects the poor overall outcome for these patients and the relative rarity of poorly differentiated forms. Macroscopically some sinonasal SCCs have a polypoid appearance, while others are more obviously fungating, friable and keratinizing.

Adenocarcinoma

Adenocarcinoma accounts for 9% of sinonasal malignancies. Like SCC it too has a male predilection and tends

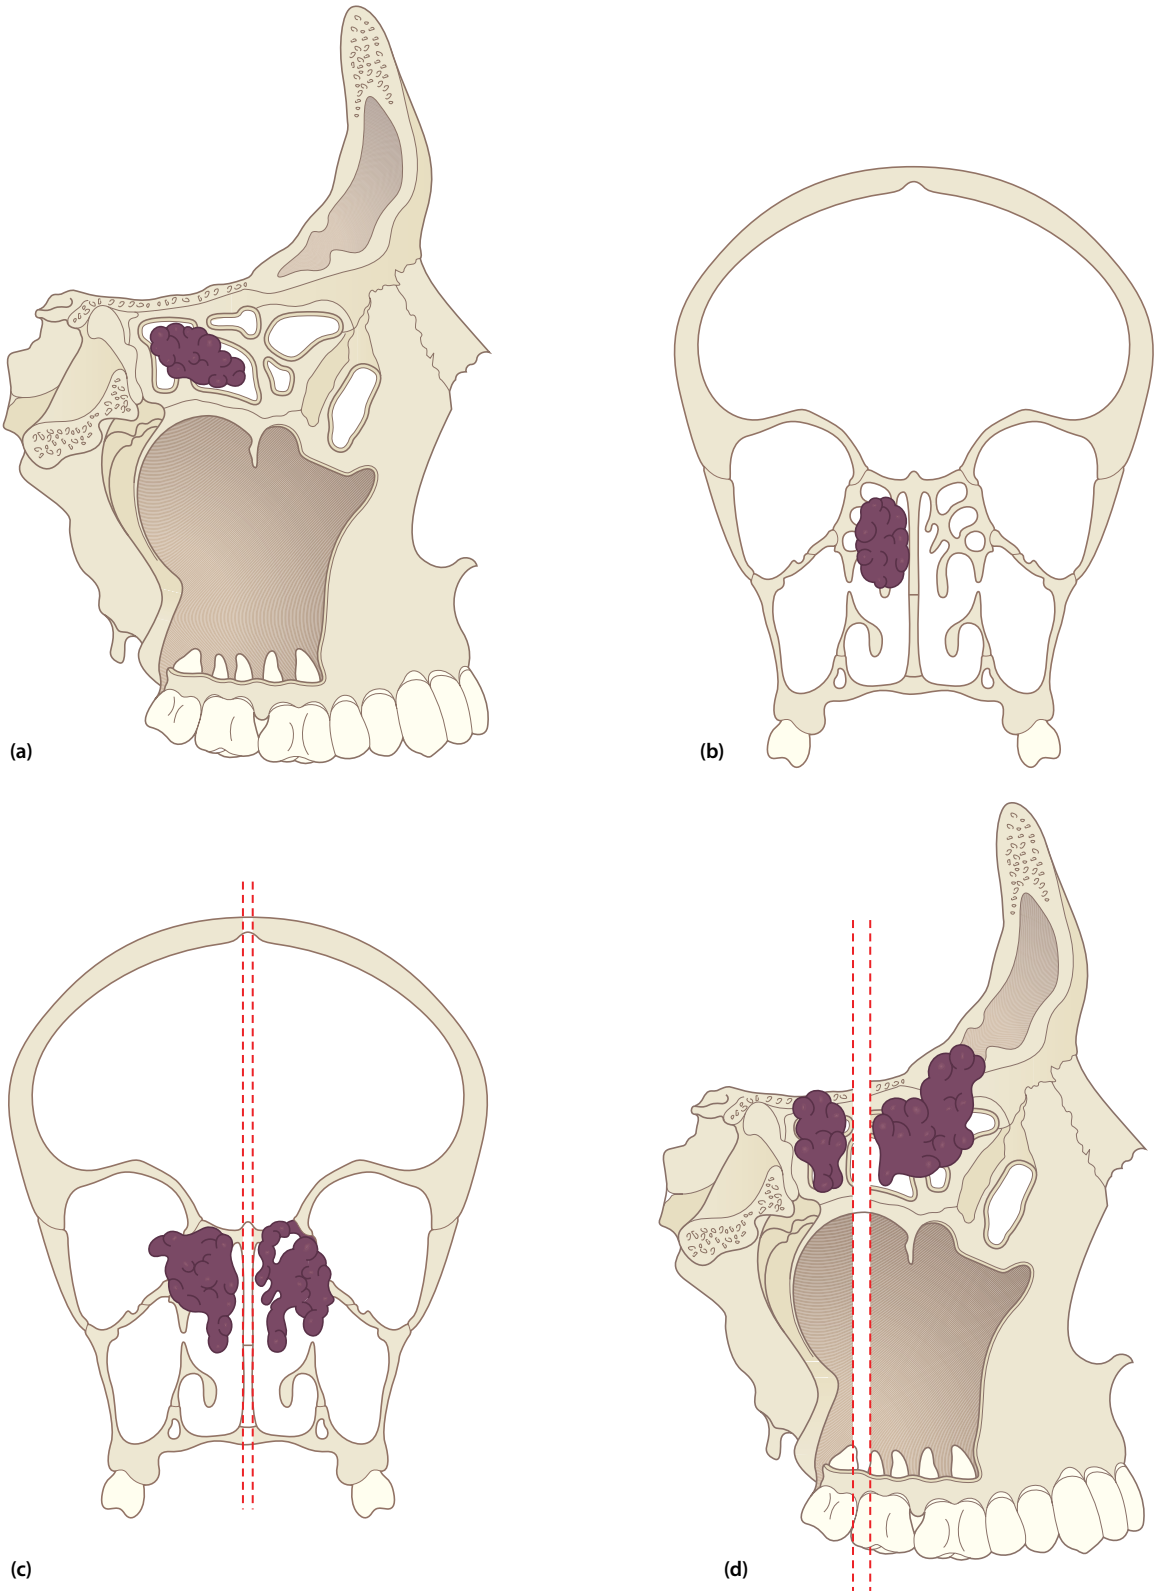

Figure 7.5 TNM diagrams of ethmoid sinus carcinoma. **(a)** T1; **(b)** T2; **(c)** T3; **(d)** T4. (*Continued*)

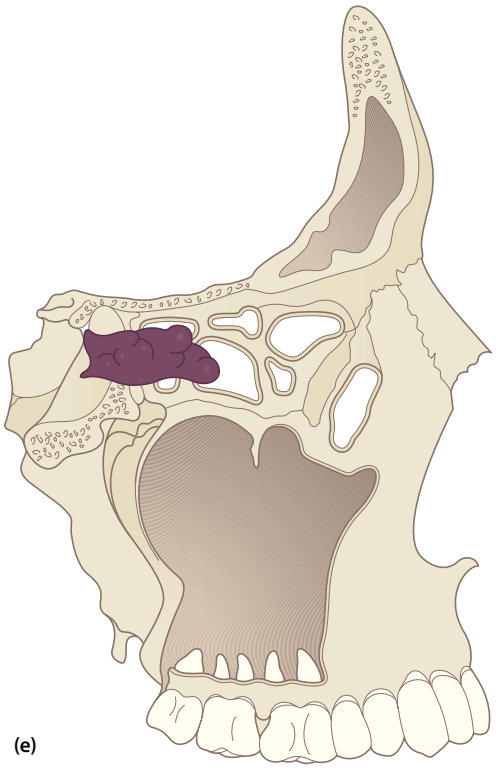

(e)

to affect those in the sixth and seventh decades of life. Adenocarcinomas are generally found in the upper nasal cavity and ethmoid sinuses. They have a slow growth rate and rarely metastasize. Several histological subtypes of sinonasal adenocarcinoma are recognized, namely papillary, sessile, mucoid, neuroendocrine, intestinal and undifferentiated. Papillary adenocarcinomas are the least aggressive form. The intestinal variety is most often associated with woodwork-induced tumours. Sessile and mucoid adenocarcinomas have the worst prognosis.[5]

Adenoid cystic carcinoma

A little less than 5% of sinonasal malignancies are ACCs. As elsewhere ACCs tend to grow slowly but inexorably with early perineurial and vascular spread. All variants of the tumour are seen. The maxillary sinus is the most commonly affected site and patients usually present with a long history of facial pain that can defy diagnosis for many months if not years.

Olfactory neuroblastoma (aesthesioneuroblastoma)

OAN arises from basal cells within the olfactory neuroepithelium. OAN represents less than 5% of all sinonasal malignancies.[14] The incidence of this tumour has a

TABLE 7.2 TNM classification

Stage	Description
Maxillary sinus	
T1	Tumour limited to the antral mucosa with no erosion of bone
T2	Tumour causing bone erosion or destruction, except for the posterior antral wall, including extension into the hard palate and/or middle meatus
T3	Tumour invades any of the following: bone of the posterior wall of the maxillary sinus, subcutaneous tissues, skin, floor or medial wall of the orbit, infratemporal fossa, pterygoid plates, ethmoid sinus
T4a	Tumour invades any of the following: anterior orbital contents, skin of cheek, pterygoid plates, infratemporal fossa, cribriform plate, sphenoid or frontal sinuses
T4b	Tumour invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than the maxillary division of V2, nasopharynx or clivus
Ethmoid sinus	
T1	Tumour confined to ethmoid with or without bone erosion
T2	Tumour extends into the nasal cavity
T3	Tumour extends into the anterior orbit and/or maxillary sinus
T4a	Tumour invades any of the following: anterior orbital contents, skin of the nose or cheek, minimal anterior intracranial extension, pterygoid plates, sphenoid or frontal sinuses
T4b	Tumour invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than V2, nasopharynx or clivus
Nasal cavity[a]	
T1	Tumour involves one subsite
T2	Tumour involves two subsites or ethmoid
T3	Tumour extends into the anterior orbit and/or maxillary sinus
T4a	Tumour invades any of the following: anterior orbital contents, skin of the nose or cheek, minimal anterior intracranial extension, pterygoid plates, sphenoid or frontal sinuses
T4b	Tumour invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than V2, nasopharynx or clivus.

[a] Within the nose, four subsites are recognized, namely septum, floor, lateral wall and vestibule.

bimodal distribution with peaks at 20 and 50 years of age. Unlike most sinonasal malignancies it is more common in women than men. OAN is a neuroendocrine tumour capable of causing paraneoplastic syndromes by secreting peptides. Patients with OAN causing Cushing's syndrome, inappropriate antidiuretic hormone secretion or hypertension produced by vasoactive peptides have been reported in the literature.

OAN is one of a group of 'small round blue cell tumours' and needs to be differentiated from sinonasal undifferentiated carcinoma (SNUC), neuroendocrine tumour, small cell carcinoma, rhabdomyosarcoma and lymphoma. Expert histopathological review is therefore recommended. OAN typically expresses neuroendocrine markers (neurone specific enolase, synaptophysin and chromogranin) and is negative for keratins. S-100 may show positivity around the periphery of the tumour only, helping to differentiate OAN from sinonasal melanoma. Negativity for vimentin, actin and desmin excludes rhabdomyosarcoma.[15]

Hyams et al.[16] developed a four-point histological grading system for OAN based on such features as the degree of differentiation, the tumour architecture, mitotic index, nuclear polymorphism, fibrillary nature of the matrix and tumour necrosis. This tumour can either be extremely aggressive (grade 4) or relatively indolent (grade 1). There are little data for the role of cytogenetics in the diagnosis of OAN.

Survival for more than 20 years is not unusual while others are less fortunate, succumbing to highly aggressive disease with widespread metastases within a few months.[17] Up to 25% of OAN invade the dura and anterior cranial fossa. In 5% of patients metastases to cervical nodes are evident at the time of presentation and distant metastases are already present in around 7% of patients.[17]

OAN can often be predicted from imaging characteristics, based on its location focused on the cribriform plate (**Figure 7.6**).

Disease-specific staging systems have been devised for OAN. The most useful and commonly used systems are those attributed to Kadish et al,[17] Morita et al.[18] and Dulguerov and Calcaterra[19] (**Tables 7.4** and **7.5**).

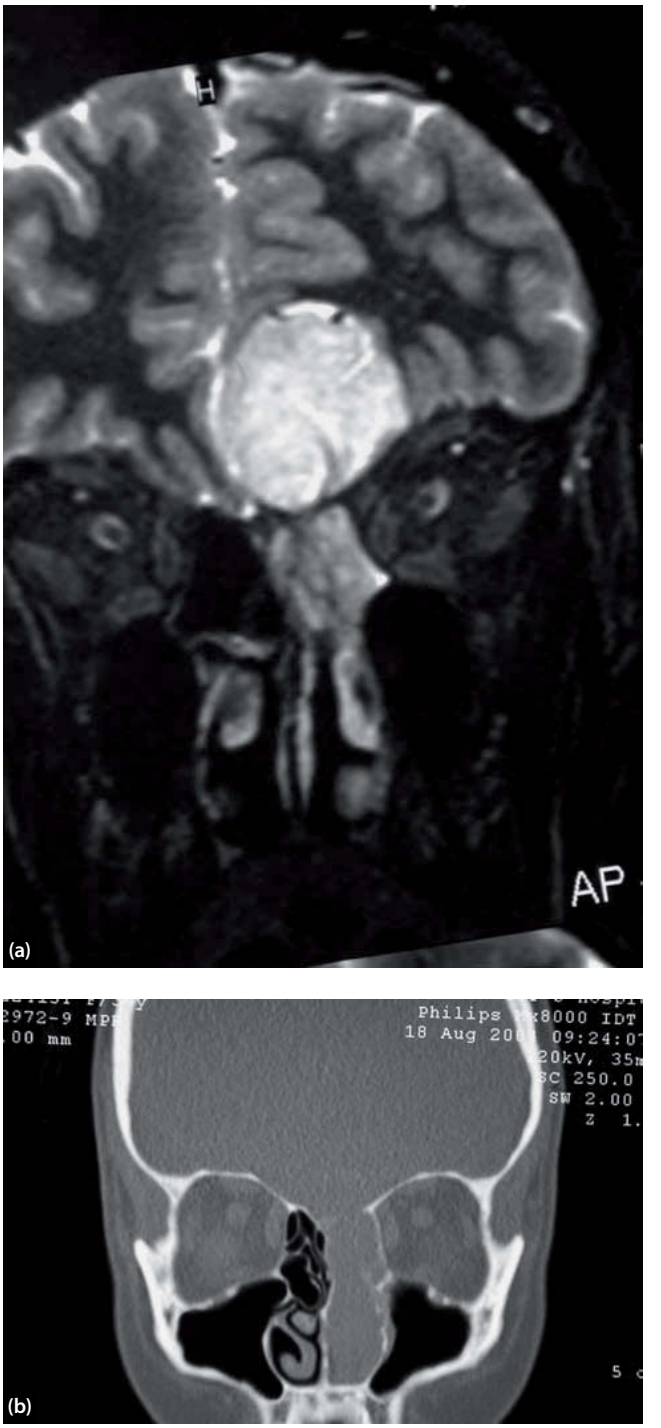

Figure 7.6 (a) MR and (b) CT scan of a patient with a Kadish C olfactory neuroblastoma. The tumour is characteristically centred on the cribriform plate.

TABLE 7.4 Kadish staging system[17] (with Morita's modification)[18]

Stage	Characteristic
A	Limited to nasal cavity
B	Involving nasal cavity and sinuses
C	Extension beyond nasal and paranasal sinuses cavities
D	Tumour with metastasis to cervical nodes or distant sites

TABLE 7.5 Dulguerov staging system[19]

Stage	
T_1	Tumour involving the nasal cavity or paranasal sinuses (excluding the sphenoid sinus) sparing the most superior ethmoidal cells
T_2	Tumour involving the nasal cavity or paranasal sinuses (including the sphenoid sinus) with extension to or erosion of the cribriform plate
T_3	Tumour extending into the orbit or protruding into the anterior cranial fossa without dural invasion
T_4	Tumour involving the brain
N_0	No cervical lymph node metastases
N_1	Any form of cervical lymph node metastases
M_0	No metastases
M_1	Any distant metastases.

Sinonasal undifferentiated carcinoma

SNUC was described relatively recently by Frierson et al.[20] It is otherwise known as anaplastic carcinoma and can be hard to distinguish from high-grade OAN. It is a highly aggressive and invasive tumour commonly containing areas of necrosis but, paradoxically, often produces few symptoms despite its extensive nature. Typically SNUC is negative for Epstein–Barr virus, helping to distinguish it from WHO Type 3 nasopharyngeal carcinoma.[21]

Melanoma

Melanoma accounts for 3.6% of all sinonasal malignancies.[22] It is more common in women than men and tends to affect the elderly. The nasal cavity and the septum are usually the sites of origin. Appearances vary from a polypoid mass to an area of ulceration. While some are pigmented, others are not. Immunohistochemistry shows positivity for S100 and HMB-45.[23] Sinonasal melanoma metastasizes less frequently to regional cervical lymph nodes than melanoma that develops elsewhere, but more often to the lungs and brain.[24]

Haemangiopericytomas

These are rare neoplasms that develop from pericytes within the outer capillary wall. They account for less than 5% of all sarcomas. Within the head and neck 20% of all haemangiopericytomas develop in the nasal cavity or sinuses.[25] They have been associated with steroid therapy, coincidental trauma, hypertension and pregnancy. Macroscopically they appear as red-grey, firm, polypoid lesions. Haemangiopericytomas rarely metastasize. Complete surgical excision is necessary as they are relatively radioresistant. There is a 10–60% recurrence rate.

PRESENTATION

Tumours of the nasal cavity cause progressive unilateral stuffiness and blockage, sinus outflow obstruction, bleeding or spot nasal secretions. Distortion of the nose occurs late. The presentation of most sinus malignancies is usually delayed until the sinus of origin is filled with tumour with symptoms being caused by erosion of its walls and extension beyond.

Figure 7.7 Spread of tumour into the cavernous sinus can result in lateral rectus palsy.

Maxillary sinus carcinomas cause facial pain with or without progressive sensory change within the skin of the cheek secondary infiltration of the infraorbital nerve. Erosion of the medial wall is associated with epistaxis and epiphora caused by obstruction of the nasolacrimal duct. Destruction of the posterior wall and spread into the pterygopalatine and infratemporal fossae results in progressive trismus as well as maxillary and mandibular trigeminal nerve deficits. Destruction of bone inferiorly leads to oral masses and teeth mobility. Spread of a tumour superiorly into the orbit gives rise to proptosis and diplopia. A visible swelling or distortion of the cheek develops when tumour breaches the anterolateral wall.

Ethmoid sinus carcinomas usually present with unilateral nasal obstruction and epistaxis. Epiphora, orbital swelling, proptosis or diplopia are not uncommon (**Figure 7.7**). Orbital symptoms and signs also prevail with frontal sinus tumours. Tumours that develop in the sphenoid sinus usually invade the cavernous sinus and infiltrate the contained cranial nerves to produce diplopia and facial pain.

CLINICAL EVALUATION

Endoscopy

A thorough endoscopic examination of the nasal cavity is mandatory in anyone suspected of having a malignancy. While the appearance of some tumours can be obvious with an ulcerative growth others are less conspicuous. It is not unusual for tumours to produce a polypoid reaction in the overlying mucosa. Some of this will be infiltrated but a casual biopsy in the outpatient setting may well be non-diagnostic (**Figure 7.8**).

Imaging

A combination of both computed tomography (CT) and magnetic resonance imaging (MRI) is commonly required for patients with sinonasal malignancies since the former alone may be insufficient for accurate evaluation and staging purposes particularly if it has been adversely affected by amalgam artefact. CT reconstruction gives accurate detail of bone erosion and potential involvement of the skull base. Both axial and coronal views are necessary.

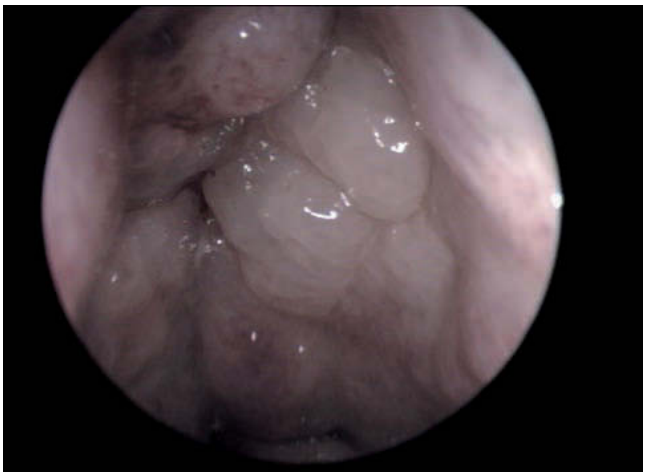

Figure 7.8 Endoscopic view of an extensive SNUC.

Unparalleled information concerning the soft tissue component of tumours is derived from MR imaging. Gadolinum-enhanced MR imaging provides tumour detail that can include flow voids suggesting intense vascularity. It will also detect dural or cerebral infiltration and give an accurate assessment of orbital invasion. T2 and diffusion-weighted sequences are useful in distinguishing between retained secretions, tumour or mucosal thickening (**Figure 7.9**).

Arteriography is rarely required but might be undertaken if pre-operative embolization is being considered to facilitate removal of a vascular tumours such as haemangiopericytoma. FDG positron emission tomography (PET)/CT is not usually necessary for staging the primary tumour but may be helpful in excluding distant disease, for example in melanoma, or in identifying a primary site if there is concern that the disease is metastatic in nature.

Biopsy

Tissue diagnosis is a mandatory part of tumour evaluation. A number of sinus tumours can be excessively vascular and if biopsies are attempted in the outpatient setting facilities should be available to arrest any haemorrhage that might ensue. Biopsies performed under general anaesthesia reduce the rate of non-diagnostic samples and provide the opportunity to sample from within the sinus itself. A Caldwell–Luc approach should be avoided if it is felt this would seed tumour or potentially compromise a subsequent resection (**Figure 7.10**).

TREATMENT

General principles

Malignancies of the nose and paranasal sinuses are rare in contrast to their presenting symptoms. As such many patients still present with advanced disease and there will inevitably be some who are incurable from the outset. Likewise, in some elderly patients concurrent general medical conditions might preclude any major intervention. At initial consultation it is therefore essential that all necessary investigations

Figure 7.9 MRI and CT scans are complementary and help distinguish between tumour, retained secretions and dural infiltration. This patient had an extensive tumour that had spread into the cavernous sinus, infiltrated the dura of the temporal lobe (small arrows) and the infratemporal fossa (large arrow). The MRI, shown here, shows the true extent of the disease. The spread was not apparent on the CT scan, which had shown a relatively small tumour affecting the sphenoid.

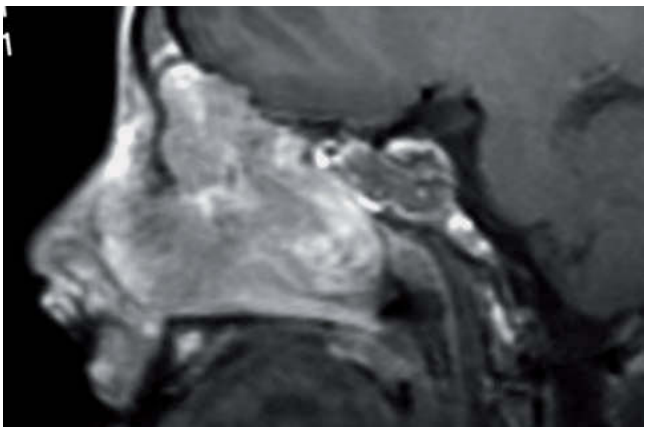

Figure 7.10 This patient lost two litres of blood after a biopsy was taken.

are arranged so that the tumour can be staged accurately and an appropriate treatment plan formulated.

In general, cases should be carefully discussed in a multidisciplinary forum to determine treatment approach and also to facilitate smooth and timely transfer between specialities, so avoiding unnecessary delays in adjuvant therapy. A high quality prosthetic rehabilitation service is an essential component of the MDT. With a palatal resection the defect must be sealed with either an obturator fitted with teeth to restore both speech and normal deglutition or by composite free flap and microvascular techniques. Orbital resections leave an obvious cosmetic deformity but titanium implants have revolutionized the construction and retention of facial prostheses. Radiotherapy is not a contraindication to their use.

There is usually a choice between curative and palliative treatment. In contemplating the latter, it is necessary to balance symptoms and their impact on their life along with the extent of the disease and the potential for distant metastases. Surgery for these patients is both morbid and can raise hopes unrealistically and palliative radiotherapy

might be considered. There are instances, however, when palliative surgery can be useful. Patients with advanced malignant melanoma, for instance, may have a significant reduction in local symptoms with debulking surgery and post-operative radiotherapy. While treatment is likely to be only palliative in patients with large adenoid cystic tumours that have a long natural history, it is often possible to achieve significant periods of good quality survival with local debulking of tumour and adjunctive radiotherapy.

Patients who present early with T1 maxillary tumours may be cured with surgery alone but the majority of patients will require combination therapy. For those patients who are potentially curable most centres recommend a combination of radiotherapy and surgery with the addition of chemotherapy in selected cases. Intensity modulated radiotherapy techniques are generally adopted in order to achieve tumour coverage whilst meeting organ at risk constraints. Post-operative radiotherapy should start within 6 weeks of surgery with 60–65 Gy delivered over 30 fractions. OAN is treated with a combination of surgery and postoperative radiotherapy. Chemotherapy has been used in more advanced cases.[26,27] Multimodality therapy (surgery, radiotherapy and chemotherapy) has generally been demonstrated to be the most effective approach in the treatment of SCC and SNUC.[28–30] The optimal sequencing of those modalities is not clear but if operable surgery followed by post-operative radiotherapy with concomitant platinum-based chemotherapy is the most common approach. In large volume tumours initial non-surgical treatment with (chemo)radiotherapy or chemotherapy alone followed by chemoradiotherapy appears to give better results. Recent evidence based reviews and guidelines support this approach.[31,32] There is increasing experience with proton beam radiotherapy where available, with the possibility of reducing radiation-related morbidity.[33]

There is no role for chemotherapy in the initial treatment of mucosal melanoma, the mainstay of which is surgical resection followed by radiotherapy. In the absence of phase III data it is difficult to draw definitive conclusions regarding the optimal sequencing of treatment modalities in these rare tumours. Topical application of 5-fluorouracil has been advocated by Knegt et al. for adenocarcinoma of the ethmoid sinus.[34]

Other than the stage of disease, patient's wishes and concurrent comorbidity, there are relatively few contraindications to treatment. Local invasion of the anterior cranial fossa and skull base are not necessarily contraindications given the development of modern surgical techniques. Distant metastases confer a poor prognosis and by definition render such patients incurable. Involvement of the facial skin is likewise not a contraindication to treatment and in practice many such patients do well. The involved area is best excised and repaired with either a rotation flap or free flap. Concerns that radiotherapy interferes with healing are less with modern radiotherapeutic regimens.

Surgery for maxillary tumours

A variety of operations has been described, the choice of which is determined by the extent of the tumour and amount of bone that needs to be removed.

PARTIAL MAXILLECTOMY

This entails partial removal of the upper jaw skeleton. Two variants are in common use:

- **medial maxillectomy**, which involves clearance of the lateral wall of the nose including the ethmoid sinuses
- **palatal resection** along with the adjacent alveolus, which is used for tumours of the oral cavity that involve the hard palate. In its simplest form this is called a fenestration although this term is technically incorrect since palatal fenestration was originally described for placing radium implants into the cavity of the antrum. Most partial maxillectomy defects are nowadays reconstructed with free flaps, but for some patients there is still some advantage with the less sophisticated procedure of obturation since this obviates a donor site and allows visualization of the treated cavity during surveillance for recurrence.

TOTAL MAXILLECTOMY

This entails the total removal of the upper jaw, preferably as a bony box containing the tumour.

EXTENDED MAXILLECTOMY

An extended maxillectomy is required when the tumour extends beyond the upper jaw. If this involves the skull base the term craniofacial resection is used.

Surgical approaches

To facilitate the various bony resections it is necessary to use the appropriate soft tissue access procedure, of which three are commonly described:

- **Lateral rhinotomy**. Although this approach is usually attributed to Moure[35] it was originally described by Michaux[36] some 50 years earlier in 1854. It gives excellent exposure of both the nasal cavities and medial maxilla with a cosmetically acceptable incision in the lateral nasal crease (**Figure 7.11**).

Figure 7.11 Extended lateral rhinotomy incision to include the lip. In most cases division of the lip to gain additional lateral exposure is unnecessary.

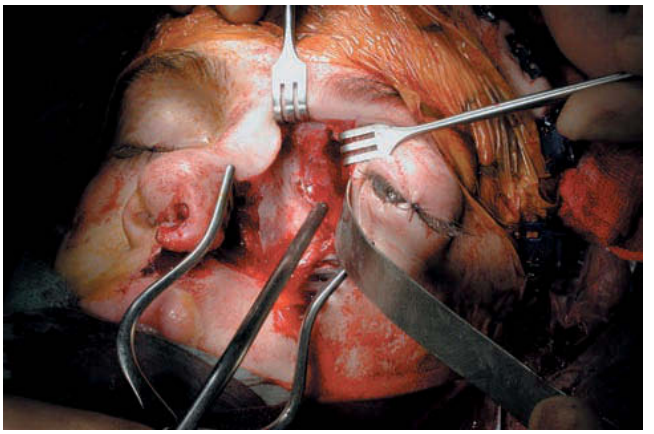

Figure 7.12 Weber–Fergusson incision.

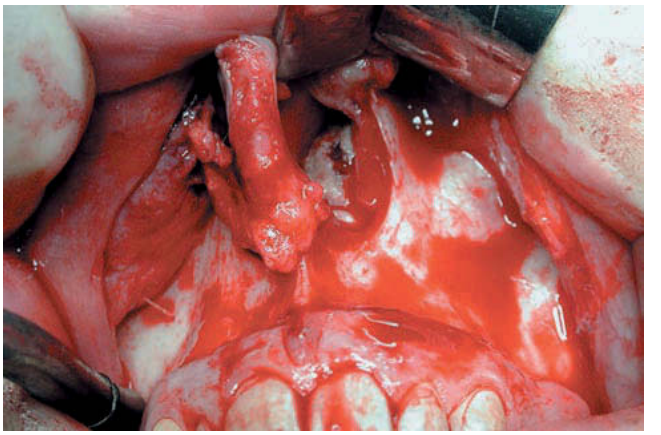

Figure 7.13 Midface degloving exposure.

- **Weber–Fergusson**. This approach is incorrectly attributed to both Fergusson and Weber and was instead originally described by Gensoul in 1833 (**Figure 7.12**).
- **Midfacial degloving**. Casson et al.[37] described the addition of intercartilaginous incisions to the sublabial incisions advocated by Converse[38] to allow elevation of the soft tissues of the midface. This has been popularized in the UK and well described by Howard.[39] The sublabial incisions should extend from maxillary tuberosity to the contralateral tuberosity to gain maximum exposure. The soft tissues of the cheek are elevated in the subperiosteal plane to the infraorbital nerves. Incisions into the nasal fossa are then made along the piriform aperture on both sides. Bilateral intercartilagenous incisions are extended to a transfixion incision and the skin elevated over the dorsum of the nose using standard rhinoplasty techniques. The incisions are then connected to allow complete elevation of the midface to the infraorbital nerves and medial canthi. With division of the infraorbital nerve the whole of the anterior face of the maxilla to the inferior orbital rim can be exposed. Relevant osteotomies permit varying degrees of maxillectomy. As well as access to the maxilla, pterygopalatine fossa and nasal fossa midface degloving can give wide access to the central skull base and with a Le Fort I osteotomy can be extended to allow better access to the clivus (**Figure 7.13**).[40, 41] The selection of the specific approach depends on the pre-operative assessment, but generally if the anterior ethmoids, frontonasal duct, orbit or zygoma is involved a different approach is indicated. In most other tumours a lateral rhinotomy or midfacial degloving approach will usually give good access for medial maxillectomy and requires little rehabilitation. Extensive tumours require some form of craniofacial approach.

ANAESTHESIA

Skilled anaesthesia is essential. Topical anaesthesia of the nasal mucosa with a decongestant solution along with hypotensive general anaesthesia are of considerable benefit to the surgeon. An oral tube (or tracheostomy) is required for a midfacial degloving.

Maxillectomy

SOFT TISSUE APPROACH

The maxilla is best exposed by the Weber–Fergusson incision. The transverse limb should be placed close to the lid margin to maintain cosmesis, commonly in the first crease. Any lateral extension into a crow's foot should likewise run in an inferolateral direction to minimize post-operative oedema. In the medial canthal region, where the potential for skin loss as a result of radiotherapy is greatest, it is helpful to curve the incision forward over the nasal bones for additional support. An incision along the crest of the philtrum and stepped on the lip is more acceptable than a midline incision. The mucosal incision along the midline of the hard palate turns laterally at the junction with the soft palate passing behind the maxillary tuberosity and then round the alveolus anteriorly. The facial skin flap is raised in a submuscular plane and all the soft tissue incisions are gently dissected free of the bone to allow the subsequent osteotomies (**Figure 7.14**).

OSTEOTOMIES

The body of the zygoma, midline of the palate and pterygoid plates need to be divided. The palatal osteotomy is placed in the floor of the nasal cavity and is most easily carried out using power tools. The pterygoid plates are best separated from the maxilla with a curved osteotome and subsequently dissected free from the muscles. Osteotomies are made medially through the ethmoid cells and then frontal process of the maxilla, the latter after dividing the lacrimal sac. The maxilla is separate from the skull above by osteotomies through the frontal process of the maxilla. Laterally the osteotomy is made through the body of the zygoma. In tumours that are laterally placed, and in which the zygoma needs to be included in the resection then the osteotomy is best made in the lateral orbital wall below Whitnall's tubercle and through the zygomatic arch (**Figure 7.15**).

The remaining bony attachments in the posterior ethmoid cells and antral roof break readily on mobilizing the maxilla. Soft tissue remnants are then divided with Mayo scissors and the maxilla removed. Bleeding from the internal maxillary artery is controlled by packing,

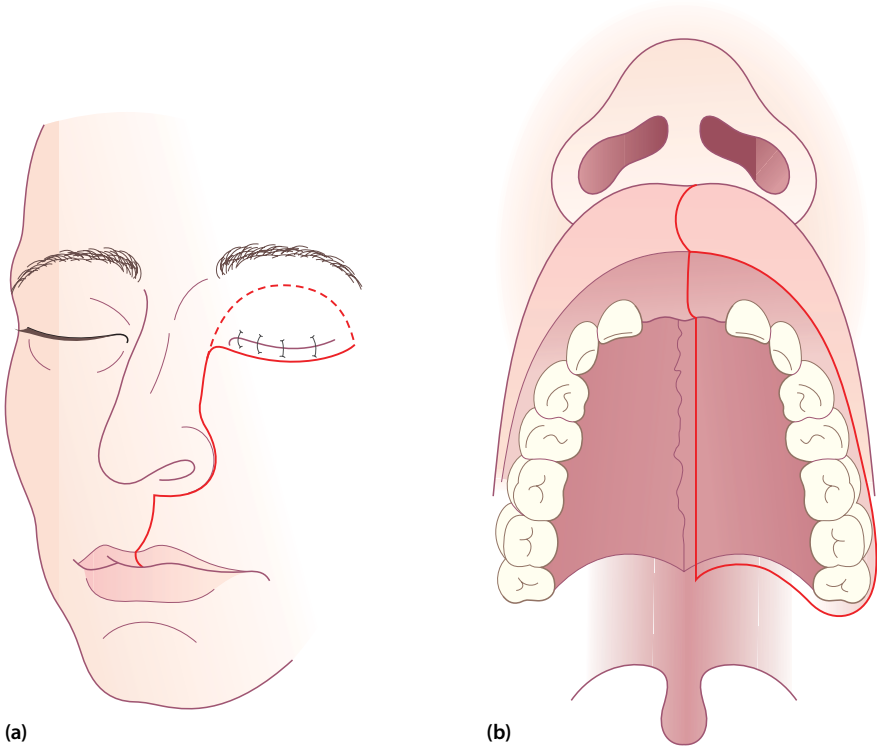

Figure 7.14 Classic maxillectomy. **(a)** Weber–Fergusson incision; **(b)** palatal incision.

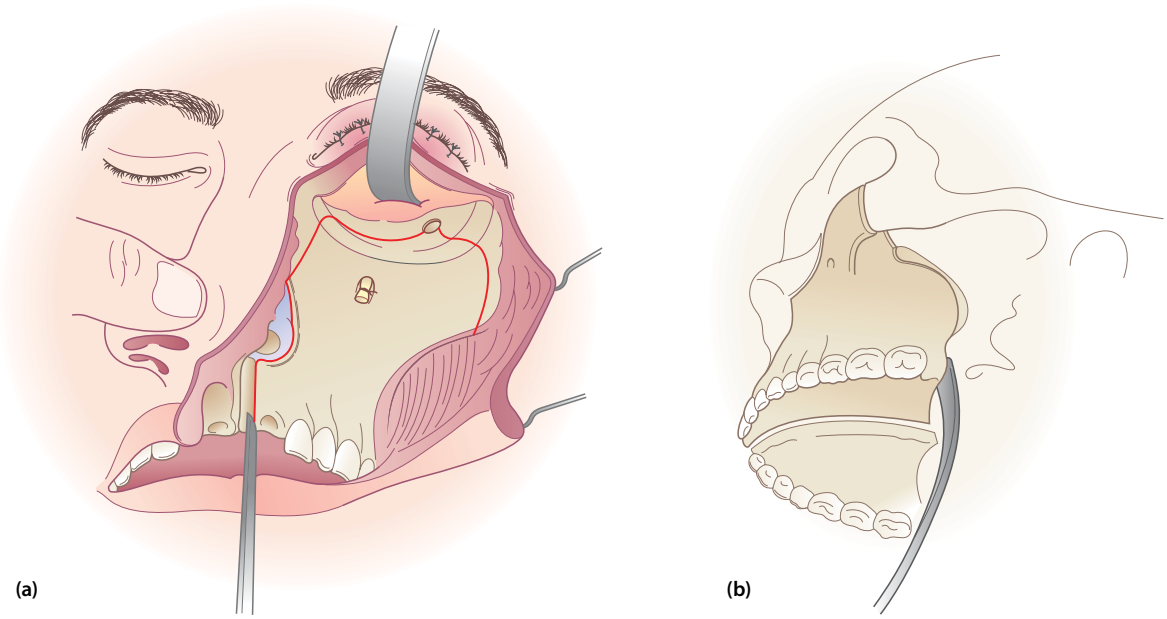

Figure 7.15 Classical maxillectomy. **(a)** Following the elevation of the facial flap, the maxilla is freed with osteotomies through the zygoma, palate and frontal process of the maxilla; **(b)** freeing the pterygoid plates.

Ligaclip application, diathermy or haemostatic matrices, are often used in combination.

COMPLETION OF THE RESECTION

Following removal of the maxilla, further tissue removal is often necessary to promote drainage from the remaining sinuses. The ethmoid cells should be exenterated completely and both the sphenoid and frontal sinuses opened widely. If there is obvious involvement of the orbital periosteum then exenteration is generally indicated. The support of the globe is complex and virtually all the medial and inferior orbital walls can be removed without enopthalmus developing. However, the removal of Whitnall's tubercle laterally results in lack of support for the eye, which can be corrected by transposing the temporalis muscle medially. Orbital exenteration is achieved by an extraperiosteal dissection and transection of the muscle cone at the apex with

Mayo scissors. Bleeding from the ophthalmic artery can be stopped by applying local pressure or bipolar coagulation. Following orbital exenteration the eyelids are preserved but the lid margins and tarsal plates sacrificed, so producing a smooth skin-lined cavity onto which an onlay prosthesis can be fitted.

NECK DISSECTION

Some controversy remains about management of the neck in SCC of the paranasal sinuses. Unlike the plethora of information that exists regarding elective neck dissection in other head and neck sites there are few reports of the use of elective selective neck dissection for management of the maxillary sinus. The rate of occult metastasis is less than 10% with no suggestion in retrospective reviews that elective selective neck dissection contributes to an improved rate of neck control or overall survival.[42]

RECONSTRUCTION AND REHABILITATION

Patients requiring midface reconstruction for malignant disease have undergone extensive ablative surgery and most will require post-operative radiotherapy. This type of facial reconstruction attracts controversy not only because of the many reconstructive options available but also because dental and facial prostheses can be successful in selected cases. Careful rehabilitation, be it biological or prosthetic, aims to ensure a good cosmetic and functional outcome with separation of the nasal and oral cavities.[43, 44]

Low defects not involving the orbital adnexae can often be successfully treated with dental obturators. For the more extensive maxillary defects there is consensus that a free flap is required. Composite flaps of bone and muscle harvested from the iliac crest with internal oblique or the scapula tip with latissimus dorsi can more reliably support the orbit and cheek than soft-tissue free flaps and non-vascularized grafts, and also enable an implant-borne dental or orbital prosthesis. Nasomaxillary defects usually require bone to augment the loss of the nasal bones, but orbitomaxillary cases can be managed more simply with local or soft-tissue free flaps.

In cases where a dental obturator is used, healing of the bony cavity can be rapid but it is advantageous to apply a split-skin graft to the under surface of the facial skin flap. After resuturing the facial incision, the cavity should be immediately fitted with a temporary prosthesis to cover the palate and restore normal facial contours. The prosthesis can be secured with either circumzygomatic wires attached to cleats or more simply fixation screws inserted into any remaining aspect of the hard palate. This primary prosthesis is changed after some 14 days and appropriate adjustments made. This process is repeated several times over the subsequent weeks until such time as it is judged that the cavity has healed and a final prosthesis can be constructed.

Medial maxillectomy using the lateral rhinotomy approach

This approach gives good access to the nasal cavities, the ethmoids, nasopharynx, sphenoid and the pterygopalatine fossa (**Figure 7.16**). For more extensive tumours an en bloc resection can be achieved by combination with an anterior craniofacial approach. The incision is cosmetically acceptable as it passes along the lateral border of the nose to the upper edge of the alar margin. For more extensive resections the incision can be continued into the nasal cavity without compromising the final cosmetic outcome. The upper end should start just above the level of the medial canthus. The orbital periosteum is elevated as for an external ethmoidectomy and extended laterally over the maxilla to the infraorbital nerve. The lacrimal sac and duct are exposed by removing the overlying bone. The orbital contents can then be completely freed medially by dividing the sac low down, clipping and dividing the anterior ethmoidal artery and also by freeing the insertion of the trochlea by sharp dissection. Access to the nasal cavities, ethmoids and antrum is achieved by extending the bony window as required with little cosmetic defect. The mucosa of the nose, antrum and ethmoids can be resected along with the entire lateral nasal wall. The view obtained following the removal of this main block of tissue is excellent and the resection can be extended into the sphenoid and frontal sinuses or alternatively into the pterygopalatine fossa. Packing is rarely required after resection.

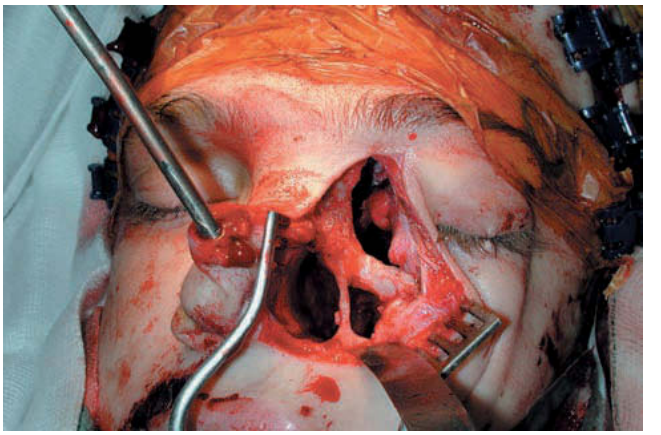

Figure 7.16 Medial maxillectomy approach used to remove a tumour of the ethmoid.

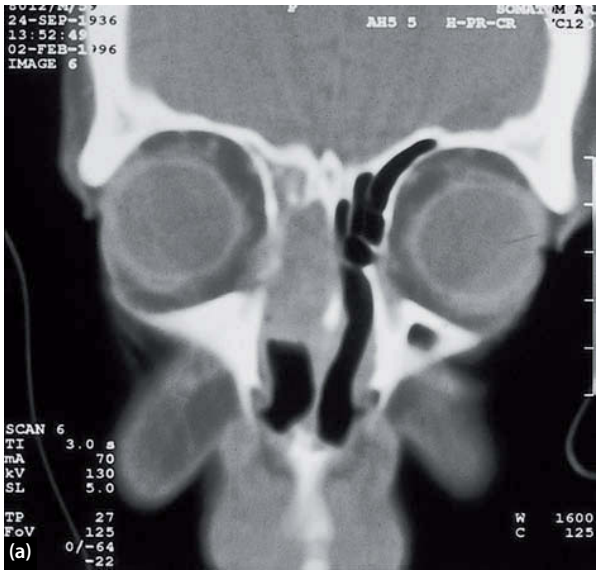
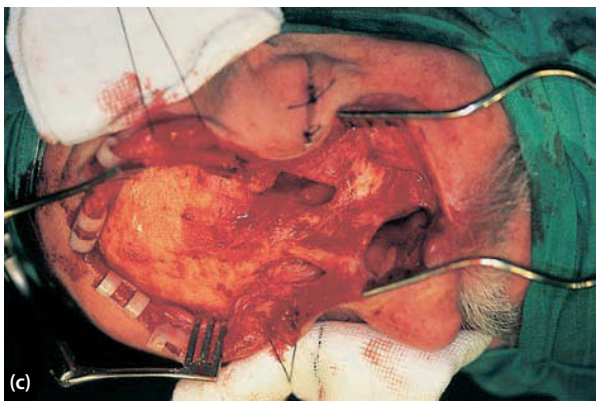
This sort of resection can also be obtained using an entirely endoscopic approach utilizing the appropriate drills and debriders (see below).

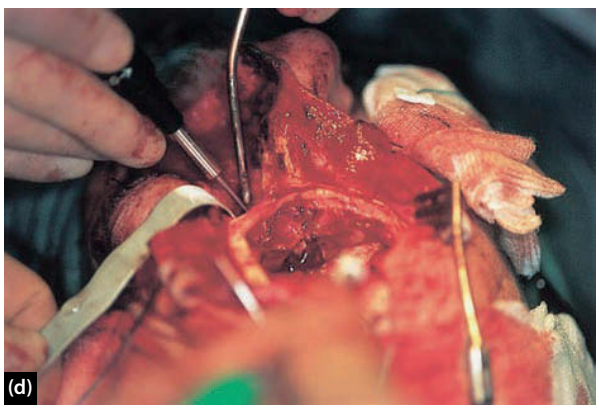
Surgery for ethmoidal tumours

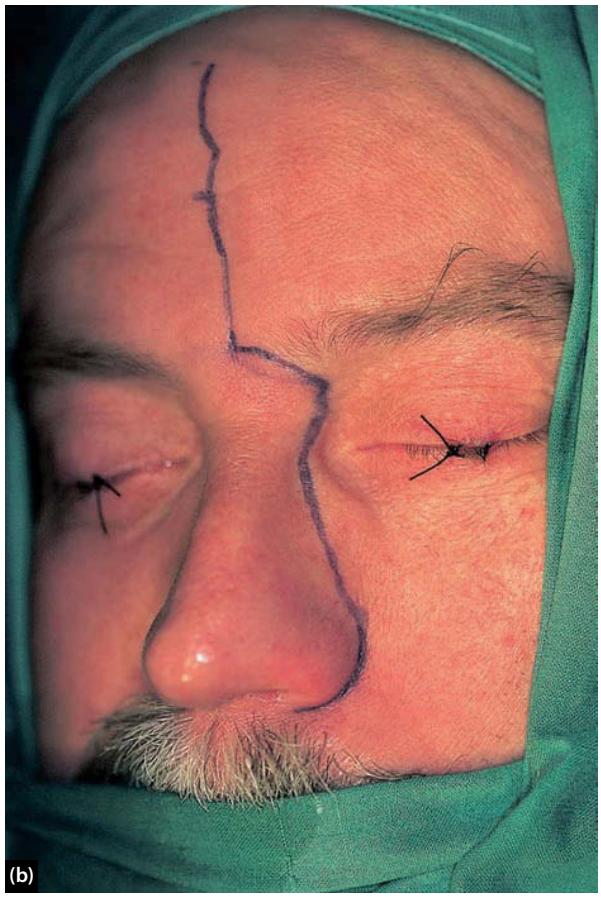
Involvement of the cribriform plate region was recognized as one of the major reasons for failure to control ethmoid neoplasms with some of the above approaches. Ketcham et al,[45] Clifford[46] and Cheesman et al.[47] (**Figure 7.17**) described a combined intracranial and transfacial approach that controls and allows resection of tumours involving the cribriform plates, dura and even some tumours invading the frontal lobes. The appropriate selection of approach has been best summarized by Cheesman and Reddy,[48] who subclassified the craniofacial procedures into three types:

- **Type 1: craniofacial (transorbital) resection.** This procedure is essentially an extended medial maxillectomy using a lateral rhinotomy incision. The operation entails careful









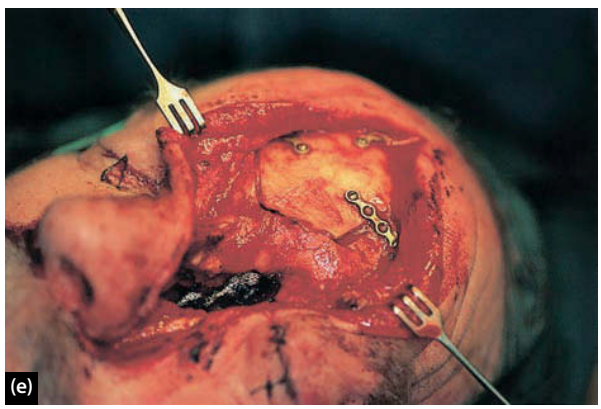


Figure 7.17 Stages of an anterior craniofacial resection.
(a) pre-operative CT acquired face down; **(b–e)** resection; **(f)** post-operative CT.

exploration of the anterior nasal cavities using the operating microscope and frozen section control. The wide exposure allows resection and repair of both the ethmoid roof and orbital periosteum if indicated. A similar approach has been described by Draf and Samii.[49]

- **Type 2: craniofacial (window craniotomy) resection**. In this procedure a lateral rhinotomy approach is used for anterior access and a bicoronal incision utilized to provide a pericranial flap and access to the frontal bone. A small midline 'window' craniotomy usually utilizing the frontal sinus is made giving access to the floor of the anterior cranial fossa. The dura is elevated from the roof of the ethmoids and cribriform plate and the area is encompassed with a cranial osteotomy. This osteotomy, in conjunction with those of the lateral rhinotomy, allows the en bloc resection of both ethmoid complexes. Involved dura and olfactory bulbs can be excised and repaired with fascia lata and pericranium. The window bone flap is replaced and fixed with miniplates. Following soft tissue closure, remarkably little cosmetic defect is evident. The combined approach not only gives excellent visualization of the ethmoid region but also readily allows extensions of the resection into the sphenoid, orbit, pterygopalatine fossae and central skull base.
- **Type 3: craniofacial resection**. This operation is performed in conjunction with a neurosurgeon and combines a transfacial approach with a neurosurgical approach, such as a frontolateral craniotomy, to allow the resection of extensive tumours (**Figure 7.18**). Skull base surgery demands an interdisciplinary approach.

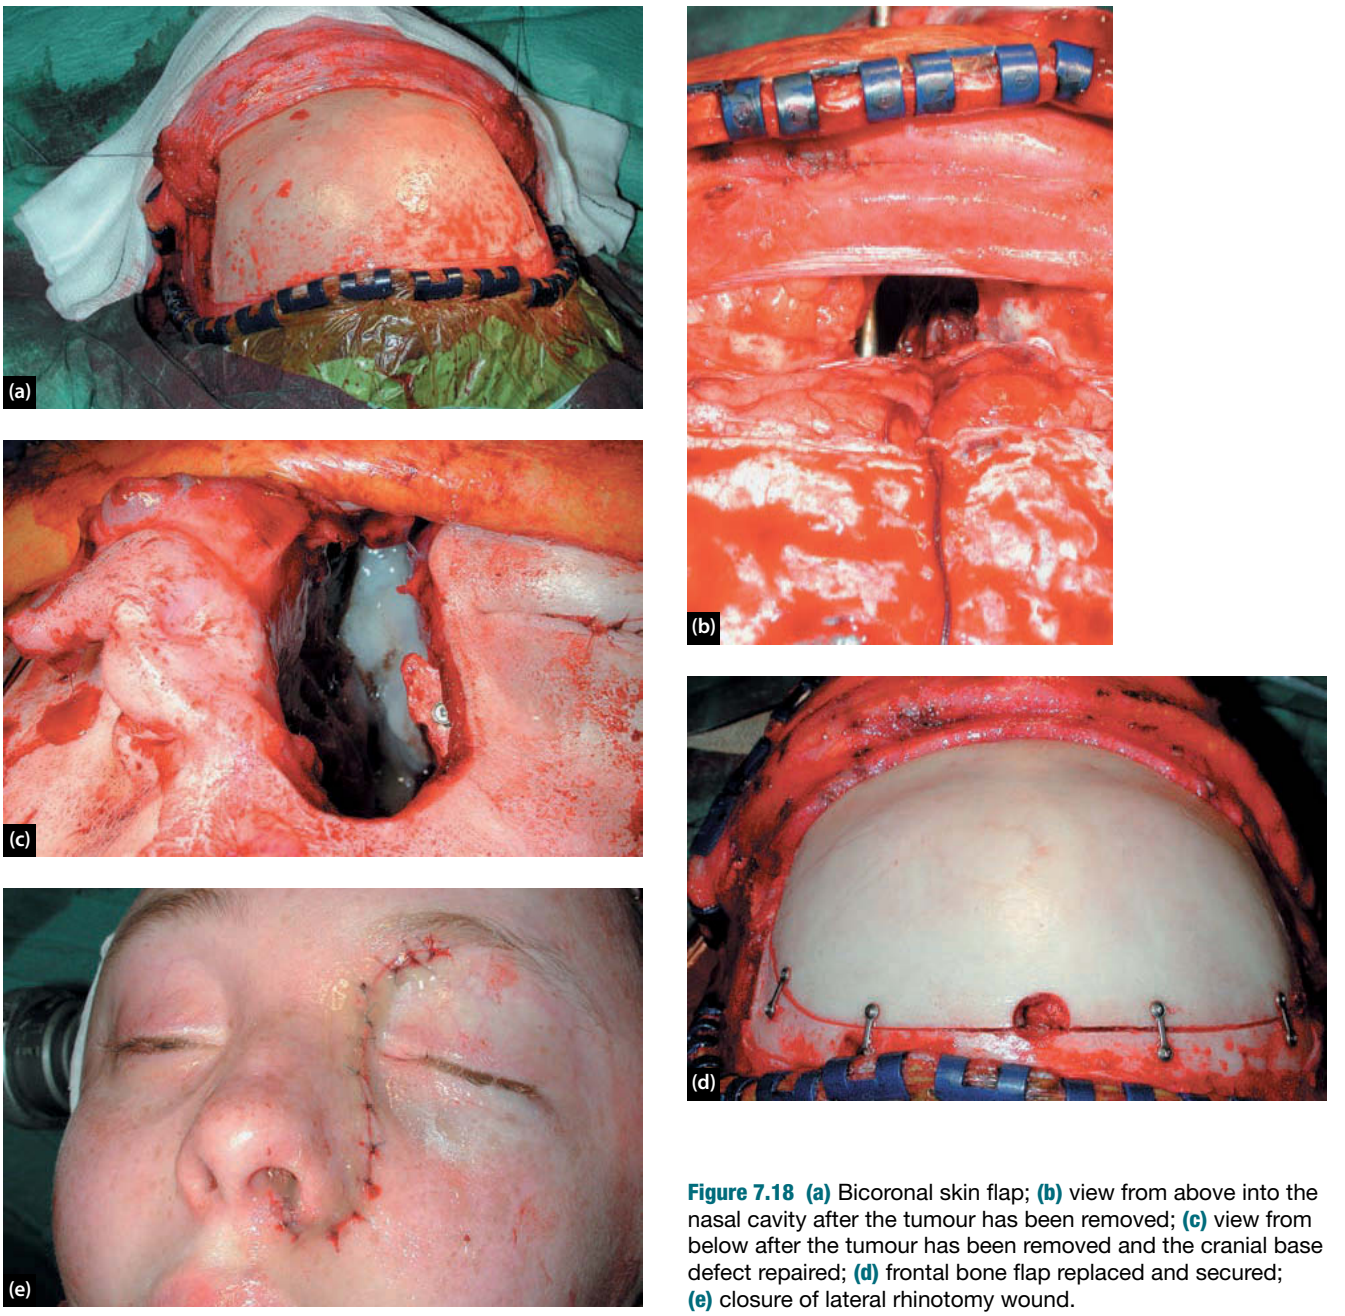

Figure 7.18 **(a)** Bicoronal skin flap; **(b)** view from above into the nasal cavity after the tumour has been removed; **(c)** view from below after the tumour has been removed and the cranial base defect repaired; **(d)** frontal bone flap replaced and secured; **(e)** closure of lateral rhinotomy wound.

There is a trend nowadays for the otorhinolaryngologist to use endoscopic techniques in order to guide the neurosurgeon's osteotomies from below.

Many tumours suitable for Type 1 craniofacial resections can now be approached with endoscopic techniques and extensive tumours requiring a type 3 approach might often be deemed incurable.

Endonasal endoscopic approaches

The introduction and rapid expansion of endoscopic surgery for inflammatory conditions of the sinuses in the 1980s was followed by the extension of these techniques to the skull base and tumour surgery.[50–53] Tumour debulking is usually necessary along with some septal resection for access. The involved sinuses are widely exposed and all bone adjacent to the tumour removed. Resection can continue to include orbital periosteum, dura, crista galli and olfactory bulbs as necessary. Dissection involves drills, debriders and bipolar diathermy as well as standard endoscopic sinus instruments. Neuronavigation and sometimes ultrasonic aspiration are also required especially for intracranial extension. Careful endoscopic repair of dural defects and orbital periosteum with septal mucosal flaps, fascia lata or temporalis fascia complete the procedure. Involvement of the nasal bones, frontal sinus, dura lateral to the ethmoidal roof and orbital contents are contraindications to endoscopic approaches although these may also be combined with transcranial approaches or orbital exenteration where appropriate. A much more detailed treatment of endoscopic resections of sinus tumours is available in Volume 1, Chapter 114, Endoscopic management of sinonasal tumours.

Management of the orbit

Attempts to preserve the orbital contents and reduce mutilation often result in orbital recurrence. If the orbital muscles, globe or orbital apex are involved a lid sparing exenteration is required. The lids provide good skin cover of the defect and can also be used to cover osseointegrated implants, which can be placed at the time of the surgery. However, the orbital periosteum may be involved with tumour while the underlying fat and orbital contents are not, and the use of peri-operative frozen section can determine those patients whose orbits can be safely retained. If frozen section confirms tumour has not penetrated the periosteum it can be resected and repaired without adversely affecting outcome.[54, 55] Orbital involvement despite exenteration significantly affects survival.[56]

PROGNOSIS

The overall prognosis of sinonasal malignancy is directly related to the degree of local control.[1] Absolute local control rates for all malignancies are 50% at 5 years, 31% at 10 years and 21% at 15 years.[57]

Prognosis varies very significantly for different pathologies, however, with very high 5-year survival rates for OAN and ACC and extremely poor prognosis for SNUC and malignant melanoma. For the first two diagnoses in particular, patients may continue to develop relapses for several decades after treatment. In the Memorial Sloan Kettering Cancer Centre series of 166 patients undergoing anterior skull base resection, patients who did experience a recurrence were most likely to fail locally (66.7%). Distant metastases (46.4%) and regional failures were less common (16.7%).[58] Factors associated with prognosis are shown in **Table 7.6**.

TABLE 7.6 Factors affecting prognosis

Factor	Percentage
Anatomical factors: location[1]	
Nasal cavity	77
Maxillary sinus	62
Ethmoid sinus	48
Above Ohngren's line	Worse prognosis
Pathological factors: histological type[39]	
OAN	88
Adenocarcinoma	68
SCC	51
Undifferentiated carcinoma	44
Mucosal melanoma	18
Tumour stage[1]	
T_1	91
T_2	64
T_3	72
T_4	49

5-year actuarial survival.

BEST CLINICAL PRACTICE

- ✓ A combination of CT and MRI scans should be acquired as part of the staging and planning process. These imaging techniques provide complementary information on bone erosion, dural, brain and orbital invasion.
- ✓ Biopsy is most appropriately obtained using endoscopic techniques.

FUTURE RESEARCH

- What is the most appropriate treatment for SCC and SNUC? Are the results for neoadjuvant chemoradiotherapy better than the traditional approach of surgery followed by radiotherapy? Does the addition of chemotherapy improve survival or just add morbidity? Which regimen is optimal? Should the surgical margins incorporate the initial extent of the tumour or just that remaining after chemoradiotherapy?
- Management of the N_0 neck has yet to be determined. Should only N_+ disease be treated or should patients with advanced (T_{3-4}) N_0 tumours also undergo treatment of the neck? Should all histopathological subtypes receive treatment of the N_0 neck or just SCC and OAN? Which levels should be dissected – levels I-III, I-IV or I-V dissection?
- What is the role of surgery for palliation in incurable disease? Is it really justified?
- In reconstruction of the midface, when should an obturator be used and when is a free composite flap appropriate?

KEY POINTS

- Sinonasal malignancies can be difficult to differentiate from non-neoplastic lesions.
- Sinonasal malignancies are uncommon, representing <1% of all malignancies and <3% of all upper aerodigestive tract cancers.
- A large number of sinonasal malignancies are caused by inhaled carcinogens. Risk factors include:
  - wood dust
  - nickel
  - chrome
  - polycyclic hydrocarbons
  - aflatoxin
  - mustard gas
  - thorotrast.
- Maxillary sinus tumours are the most common (55% of all sinonasal malignancies), followed by nasal cavities (35%), ethmoid sinuses (9%) and rarely frontal and sphenoid sinuses (1%).
- Sinonasal malignancies tend to present late.
- The main treatment modalities are surgery and radiotherapy.
- Chemoradiotherapy followed by surgery is advocated for SNUC and advanced ethmoidal SCC.
- Contraindications to aggressive treatment are spread to the sphenoid sinus, middle cranial fossa, optic chiasma, cavernous sinus or prevertebral fascia, as well as the presence of distant intracranial or systemic metastases.
- The prognosis of sinonasal malignancies has improved over the past three decades, but remains poor overall, and is directly related to the degree of local control.
- Absolute local control rates for all malignancies are 50% at 5 years and 31% at 10 years.
- Olfactory neuroblastoma and adenoic cystic carcinoma may relapse after a decade and thus patients should be followed up for at least 15 years

SEARCH STRATEGY

Apart from the standard textbooks on nasopharyngeal carcinoma, the data in this chapter are based on a Medline search using nasopharyngeal carcinoma against the following keywords: diagnosis, pathology, immunology, treatment and complications.

INTRODUCTION

The nasopharynx is situated deep inside the head and the carcinoma arising in the epithelium of the nasopharynx has a different aetiology, epidemiology and biology compared to other cancers of the upper aerodigestive tract. The deep location of the nasopharynx and the wide spectrum of presenting symptoms make early diagnosis difficult. The distinct tumour biology requires different staging and treatment paradigms compared to other head and neck cancers. Nasopharyngeal carcinoma has been called an enigmatic tumour.[1]

APPLIED ANATOMY

The nasopharynx is the most superior part of the pharynx with the inferior border defined as the lower level of the soft palate. Anteriorly it connects to the nasal cavities through the posterior choana. Superiorly the roof of the nasopharynx is formed by the floor of the sphenoid sinus and slopes down to become the posterior wall, which is formed by the clivus bone. The inferior outlet normally opens into the oropharynx but is closed by the soft palate during swallowing and phonation. The cartilaginous Eustachian tubes on both sides open on the lateral wall of the nasopharynx. A recess extends postero-laterally on both sides of the posterior wall of the nasopharynx to form the lateral recess of the nasopharynx, also known as the fossa of Rosenmüller. The depth of the fossa of Rosenmüller is variable. The posterior cushion of the Eustachian tube opening forms the anterior wall of the fossa of Rosenmüller. Most early stage nasopharyngeal primaries originating from the fossa of Rosenmüller are difficult to detect unless the area is carefully inspected during endoscopy.[2] Cancers arising from the fossa of Rosenmüller therefore frequently invade the Eustachian tube and affect function, leading to the development of otological symptoms.

The nasopharynx is covered with pseudostratified squamous epithelium similar to the mucosa of the nasal cavities and paranasal sinuses. The second layer is the muscular layer formed by the superior constrictor muscles. At the upper part of the clivus and roof, the nasopharynx, the superior constrictor is absent. The pharyngobasilar fascia forms the outermost layer of the nasopharynx wall. The pharyngobasilar fascia anteriorly attaches to the medial

pterygoid plates on both sides. Except for the pterygoid plates in the anterior part of the lateral nasopharynx, the lateral walls of the nasopharynx are devoid of bone. Immediately lateral to the pharyngobasilar fascia are the parapharyngeal spaces with the fat pads and muscles of the soft palate (levator palatini, tensor veli palatini and salpingopharyngeus) on both sides. Cancer of the nasopharynx readily spreads to the ipsilateral parapharyngeal space. Just anterior to the posterior choana, in the posterior part of the lateral nasal wall, is the sphenopalatine foramen. Cancers from the lateral wall can spread to the pterygopalatine fossa via the sphenopalatine foramen. From the pterygopalatine foramen, the cancer then spreads along the foramen rotundum and into the cavernous sinus intracranially, producing ophthalmoplegia. The floor of the sphenoid that forms the anterior part of the roof of the nasopharynx is thin and cancer can easily spread into the sphenoid sinus. From the sphenoid sinus, the cancer can then spread into the orbital apex and cause eye symptoms.

There is extensive lymphatic drainage to both sides of the neck from the nasopharynx. The first echelon of lymphatic drainage is the retropharyngeal lymph nodes (nodes of Rouvière). From the retropharyngeal lymph nodes, the lymphatic drainage continues to the upper jugular nodes, the upper posterior triangle nodes and then further down to the lower neck in a step-wise fashion. The internal carotid artery is located postero-lateral to the fossa of Rosenmüller and is wrapped by the carotid sheath. The carotid sheath extends medially to form the prevertebral fascia. The retropharyngeal lymph node closely abuts the carotid sheath. An enlarged retropharyngeal lymph node caused by cancer metastasis may partially or completely encase the parapharyngeal internal carotid artery. Cancer can also spread along the carotid sheath superiorly into the foramen lacerum and into the intracranial cavity.

EPIDEMIOLOGY

In 2012, there were estimated to be more than 86 000 new cases of nasopharyngeal carcinoma (NPC) worldwide with over 50 000 deaths.[3] The incidence of NPC demonstrates one of the largest geographical variations among all head and neck cancers and the incidence in endemic areas can be 50 times higher than low prevalence areas.

The area with the highest incidence is in Southern China among the Cantonese population of the Guangdong Province. In Hong Kong, where the majority of the population is Guangdong in origin, the age-standardized incidence rate of NPC for men in Hong Kong was once 30 per 100 000 in the 1980s, but it has shown a gradual decline over the last 30 years.[4] Even inside China, there is a large variation in the incidence of NPC in different parts of the country. South China has the highest incidence, followed by Southwest China, Central China, East China, Northwest China and North China. The incidence in South China is three times higher than the second highest region, Southwest China.[5]

Outside China, Southeast Asia has the highest incidence of NPC, especially among countries with significant Malay and Indonesian populations. Populations in North Africa, especially Tunisia and Algeria, also have an elevated incidence.[6] Inuits in Alaska, North Canada and Greenland are another population group with elevated incidence of NPC.[7] Migrants to North America of South Chinese origin also have increased incidence though the incidence decreases among the second and third generation migrants.[8] The Japanese and Koreans, like Western populations, have an annual incidence rate of less than 1 case per 100 000.[7] The marked variation in the incidence of NPC implies that there exists a genetic susceptibility in the high incidence population.

The male to female ratio of the disease is 3 to 1, with a similar ratio observed in endemic areas and among low incidence populations. The peak age group of presentations of NPC in endemic areas is 50–55 years old, and it decreases with increasing age.

In Hong Kong, there has been a gradual decline in incidence of NPC in the last three decades. The incidence decreased by 30% from 38.5 per 100 000 males per year in 1980–84 to 20.2 per 100 000 males in 1995–99. The decreases in incidence in females followed a similar trend.[9] This decrease in not observed in other high-risk populations in Singapore, Malaysia or Guangdong province, People's Republic of China.[10]

AETIOLOGY

The exact sequence of events in the development of NPC has not been elucidated. A complex interplay of genetic susceptibility, Epstein—Barr virus (EBV) infection and environmental factors leads to the development of the cancer.[11]

Genetic factors

The presence of genetic susceptibility to NPC can be implied from the wide variation in cancer incidence across the world. Migrants from high-risk populations who settle in low incidence areas, like Southern Chinese emigrants to North America, have higher incidences than the native population though the incidence reduces in later generations.[8] On the other hand, migrants from low incidence areas do not experience an increased risk of NPC even when they emigrate to high incidence areas, like Indian emigrants in Singapore.[7] About 10% of NPC patients have familial clustering of cases.[12] Although a familial cluster can be explained by genetic factors, members of the same family, especially siblings, may be exposed to similar environmental factors. Therefore, the presence of familial clustering may imply the presence of either genetic or environmental factors, or both.

HLA subtypes and NPC

An early attempt to identify subgroups with genetic susceptibility was to correlate the risk of different human leukocyte antigen subtypes with the risk of developing NPC in high-risk populations in Singapore, Malaysia

and Hong Kong. Recent meta-analysis of the studies on HLA subtypes with NPC showed that HLA A2, B14 and B46 are associated with increased risk of NPC while HLA A11, B13 and B22 are associated with lower risk of NPC.

Recent genetic studies using advanced molecular biology techniques have yielded more information on the role of HLA genes in the development of NPC. A genome wide association study showed that genes at the 6p21 locus within the HLA region are strongly associated with NPC.[13, 14] Other genes in the HLA region were also associated with the development of NPC. The details of these genes are beyond the scope of this chapter. Hildesheim and Wang wrote an excellent review article on the genetic predisposition factors of NPC.[15] Current thinking is that individual HLA subtypes associated with NPC may have impaired immune response to EBV infection and clearance of the virus from the epithelium. The establishment of latent EBV infection in the epithelium of the nasopharynx may lead to pre-malignant changes in the epithelium, later progressing to invasive cancer.

Other cancer-associated genes including *MDM2* and *TP53* and the cell-migration gene *MMP2* have been shown in multiple studies to be associated with NPC, albeit in the later stages of cancer development.[16–20]

Environmental factors

Second and third generation Southern Chinese who had migrated to North America had a decreased risk of developing NPC compared with native Southern Chinese, though the risk was still higher than the local population. This implied that although genetic factors played a role in NPC development, environmental factors might also contribute to the cancer development.

Early studies in the 1970s and 1980s in Hong Kong identified that childhood consumption of salted fish increased the incidence of NPC in early adulthood.[21] Salted fish was shown to be carcinogenic when fed to rats in the laboratory.[22] Consumption of other preserved foods were also shown to increase the risk of development of NPC.[23] The carcinogenic effect of these preserved foods may be due to the high nitrosamine content.[24]

Multiple studies have shown that smoking increases the risk of NPC development and this risk increase is seen in both low and high incidence populations.[25, 26] However, the effect of smoking on NPC development is more pronounced on the well-differentiated type of NPC in the Western population than on the undifferentiated type of NPC in Southern China.[27] Jia and Qin have summarized the effect of environmental factors on the development of NPC in a systematic review.[28]

Epstein—Barr virus

Central to the pathogenesis of NPC is the carcinogenic Epstein—Barr virus (EBV). The virus was first associated with Burkitt lymphoma in sub-Saharan Africa. In the late 1960s, serological studies showed that NPC patients had elevated antibiodies against EBV, similar to levels found in patients suffering from Burkitt lymphoma.[29] Improvement in molecular genetics finally confirmed that EBV DNA sequences were found in the nucleus of the carcinoma cells of NPC.[30, 31] EBV is found only in the poorly differentiated and undifferentiated form of NPC, which is the prevalent histological subtype in high incidence areas.

The exact role of EBV in the development of NPC is still unknown. EBV typically infects B-lymphocytes and produces the acute syndrome of infectious mononucleosis. In the endemic areas, EBV has already infected the majority of the population by early adulthood, yet only a minority develop NPC. The virus does not commonly infect normal nasopharynx epithelium. It is postulated that the combination of genetic susceptibility, environmental factors and EBV infection all contribute to development of NPC. Genetic susceptibility may confer increased risk of a latent EBV infection, while environmental and dietary risk factors may transform the normal nasopharynx epithelium to a premalignant stage, supporting the EBV genome in the transformed nasopharynx epithelium. EBV genome, when incorporated into the nasopharyngeal epithelium, may cause malignant transformation. The virally infected cells may alter the cytokine environment and assist the cancer cells to avoid detection by host immune-surveillance. Tsao et al have summarized the current knowledge of EBV and NPC in a review article.[11]

The association of EBV with NPC can be exploited in the diagnostic process, therapeutic strategies and preventive treatment in NPC. These will be elaborated further later in the chapter.

PATHOLOGY

The commonest type of malignancy in the nasopharynx arises from the epithelium. The World Health Organization (WHO) originally categorized the epithelial malignancies from the nasopharynx into three subtypes: well-differentiated keratinizing squamous cell carcinoma (WHO type 1); non-keratinizing carcinoma (WHO type 2); and undifferentiated carcinoma (WHO type 3). The classification was later revised to two subtypes: keratinizing squamous cell carcinoma; and combining type 2 and type 3 into non-keratinizing carcinoma. The non-keratinizing carcinoma can be further subclassified as differentiated and undifferentiated types. The histology of the keratinizing squamous cell carcinoma is similar to other well-differentiated squamous cell carcinoma in the upper aerodigestive tract. On the other hand, there are some distinctive histological features in the non-keratinizing carcinoma, which is predominant in the high incidence/endemic regions. Histologically, the malignant cells are infiltrated with lymphocytes and plasma cells. These lymphocytes are predominately T-cell and are CD8+.[32] The term lymphoepithelial carcinoma has been coined to describe this histological feature that is different from other undifferentiated carcinoma of the head and neck region like sinonasal undifferentiated carcinomas. Other than the nasopharynx, lymphoepithelial carcinoma

can be found in salivary glands, paranasal sinuses and lungs. When lymphoepithelial carcinoma is found outside the nasopharynx, it is important to distinguish between primary cancer and metastatic cancer from the nasopharynx primary. **Figures 8.1** and **8.2** are histological slides showing a well differentiated NPC (WHO type I) and undifferentiated NPC (WHO type II) respectively.

EBV is ubiquitously found in all the cancer cells in non-keratinizing NPC. Immunostaining for EBV in the cancer cells can help to differentiate between NPC and different types of head and neck cancer, especially in tissue obtained from metastatic lymph nodes by excisional biopsy or fine needle aspiration. Immunostaining for EBV virus encoded small ribonucleic acid (RNA) (EBER) is commonly used to detect the presence of EBV inside the cancer cells.

In endemic areas like Southern China, non-keratinizing type of NPC constitute over 95% of the histological subtype of NPC. In low incidence populations like Japan or USA, non-keratinizing carcinomas still are the majority with only 25% of the NPC being the keratinizing subtype. Basaloid squamous cell carcinoma is a rare subtype of epithelial cancer seen at this site.

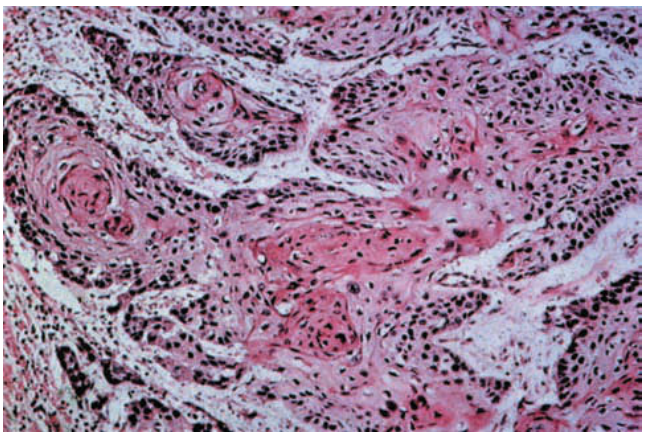

Figure 8.1 H&E stained histological slide of a keratinizing NPC (WHO type I). Note the keratinization.

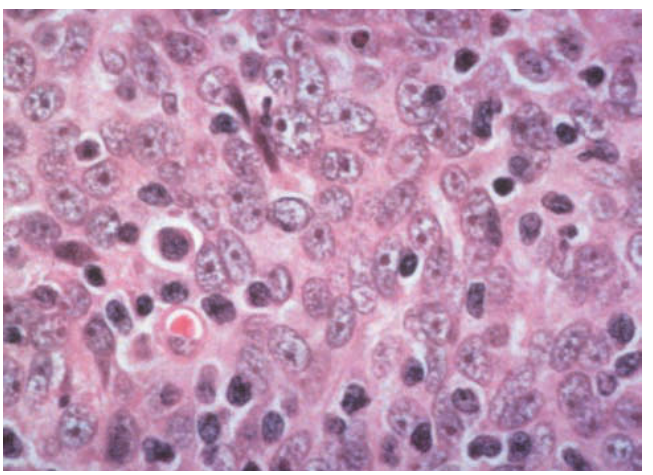

Figure 8.2 High power view of the H&E stained histological slide of an undifferentiated NPC (WHO type III). Note the abundant lymphocytes mixed with the cancer cells.

Salivary gland carcinomas are another important group of cancers that can occur in the nasopharynx, although the incidence is relatively low. The histology and behaviour of salivary gland carcinomas found in the nasopharynx are similar to other minor salivary gland cancers in the head and neck area.

Apart from epithelial carcinomas, soft tissue malignancies can occur in the nasopharynx, including sarcomas, lymphomas and malignant melanomas. Malignant fibrosarcomas and osteosarcomas are the commonest form of radiation-induced sarcomas in the nasopharynx in NPC patients treated with radiotherapy. For radiation-induced carcinomas, the histological subtype is typically well-differentiated squamous cell carcinoma with EBV absent in the cancer cells. Head and neck lymphoma frequently involves the lymphatic tissue in the Waldeyer's ring, including the lymphoid tissue in the nasopharynx. Certain lymphomas like Hodgkin lymphoma and T-NK lymphoma also harbour EBV in the cancer cells. It is important not to misdiagnose lymphoma as undifferentiated type of NPC based only on the presence of EBV in the biopsy. **Table 8.1** lists the types of benign and malignant neoplastic lesions that can occur in the nasopharynx.

TABLE 8.1 WHO classification of tumours of the nasopharynx

I Epithelial tumours	
a Benign	**b Malignant**
1 Papilloma	1 Nasopharyngeal carcinoma
2 Pleomorphic adenoma	2 Adenocarcinoma
3 Oncocytoma	3 Papillary adenocarcinoma
4 Basal cell adenoma	4 Mucoepidermoid carcinoma
5 Ectopic pituitary adenoma	5 Adenoid cystic carcinoma
	6 Polymorphous low-grade adenocarcinoma
II Soft tissue tumours	
a Benign	**b Malignant**
1 Angiofibroma	1 Fibrosarcoma
2 Haemangioma	2 Rhabdomyosarcoma
3 Haemangiopericytoma	3 Angiosarcoma
4 Neurilemmoma	4 Kaposi's sarcoma
5 Neurofibroma	5 Malignant haemangiopericytoma
6 Paraganglioma	6 Malignant nerve sheath tumour
	7 Synovial sarcoma
III Tumours of bone and cartilage	
IV Malignant lymphomas	
1 Non-Hodgkin lymphoma	
2 Extramedullary plasmacytoma	
3 Midline malignant reticulosis	
4 Histocytic lymphoma	
5 Hodgkin disease

CLINICAL FEATURES AND MODES OF PRESENTATION

Early cancers of the nasopharynx produce minimal and trivial symptoms that may be neglected by the patients and undetected by physicians. Moreover, the central location of the nasopharynx in the head means that cancer can spread in all directions, affecting many surrounding organs like the ears and eyes, producing symptoms that would not immediately relate to the nasopharynx. Broadly speaking, local symptoms and signs of NPC can be classified in to four categories: nasal; otological; cervical; and neurological. Patients rarely present with exclusive symptoms and signs of systemic metastasis without any local symptoms.

Nasal symptoms and signs

The majority of patients have some form of nasal symptom but may choose to neglect them until more sinister symptoms arise. Around 50% of the patients have suffered from nasal symptoms on presentation when asked directly. The most common symptoms are blood stained nasal discharge or post-nasal drip. If the tumour is large enough to obstruct the posterior choana, the patient may present with nasal blockage. Patients may also report cacosmia or a smell of blood due to bleeding from the tumour.

The nasopharynx is a difficult area to examine without special equipment. Physical examination often cannot identify the presence of the tumour unless the primary tumour has extended into the anterior nasal cavity or down into the oropharynx. Examination of the post-nasal space with a post-nasal mirror may reveal the presence of a tumour but this examination is difficult, especially in patients with strong gag reflex.

Otological symptoms and signs

Between 30% and 40% of NPC patients suffer from some form of ear symptom. Otological symptoms are usually caused by Eustachian tube dysfunction secondary to tumour bulk and/or invasion. Patients complain of recent onset of ipsilateral hearing loss, muffled sound, tinnitus and sensation of ear blockage. Unfortunately, patients and physicians may regard these as transient Eustachian tube dysfunction symptoms suffered during an upper respiratory tract infection, leading to a delay in diagnosis. Otoscopic examination will reveal the presence of a middle ear effusion. The nasopharynx should always be examined in adults with unexplained persistent middle ear effusion.

Neck symptoms and signs

An enlarging upper neck mass is the commonest symptom that prompts patients to seek specialist care. Up to 70% of patients with NPC have enlarged neck lymph nodes on presentation and one third of the patients have bilateral enlarged neck lymph nodes. The most frequently involved nodes are level II (upper jugular) and upper level V (apex of posterior triangle). Lymphatic spread of NPC occurs in an orderly fashion from superior to inferior,[34] with skip metastases being very rare. An isolated enlarged supraclavicular lymph node is almost never a lymph node metastasis from NPC. For patients with lymph node spread down to supraclavicular fossa, the disease is considered as a very advanced type of nodal metastasis, staged as N3b disease.

Occasionally, NPC patients can present with metastatic neck lymph nodes from an unknown primary. In these cases, the primary is usually very small and may not be obvious on endoscopy. New imaging modalities like magnetic resonance imaging and positron emission tomography (PET) may reveal the presence of small cancer in the nasopharynx. Additional investigations like serological testing for EBV and immunohistochemical staining of the cytological material for EBV can also point to a nasopharyngeal primary.

Neurological symptoms and signs

The presence of neurological symptoms usually signals advanced disease. Headache is the most common neurological symptom and is present in up to 20% of patients. The headache is usually localized to the vertex or occiput and caused by the invasion of the clivus bone by the tumour. Facial pain and midface numbness can also be a presenting symptom, caused by tumour invasion into the pterygopalatine fossa and the branches of V2. Cranial nerve (CN) palsies are caused by extension of the tumour into the skull base or intracranially. Common cranial nerves to be involved at presentation are V2, V3 and VI. Involvement of CNIII and CNIV are indicative of cavernous sinus invasion by tumour. Rarely, patients present with ophthalmoplegia, decreased vision and proptosis caused by direct invasion of the tumour into the orbital apex. Trismus is rare unless the tumour has directly invaded the pterygoid

muscles in the masticator space. Horner syndrome can occur if the tumour or metastatic lymph node encases the carotid vessels. This is an uncommon mode of presentation as the carotid sheath is a tough fascia that impedes direct tumour invasion. The presence of Horner syndrome is usually associated with other cranial nerve involvement like CNX and CNXI. Patients from endemic regions with isolated CN palsies should be investigated for the presence of NPC, either by imaging or by nasal endoscopy.

Symptoms of systemic metastasis

NPC presentation with systemic metastasis is uncommon and is usually associated with advanced local or nodal diseases. Common sites of distant metastases are liver, lung and bone, with brain metastasis being rare.

One special scenario that can lead to confusion is the finding of histologically proven lymphoepithelial carcinoma in a lung nodule, which can be a primary lymphoepithelial carcinoma of the lung or distant metastasis from a nasopharyngeal primary. A PET scan can help differentiate between a lung primary and a distant metastasis. If the disease is confined to the lung on imaging, the patient should be treated as appropriate for a primary lung cancer.

Para-neoplastic syndrome

Around 1% of NPC patients develop dermatomyositis as a para-neoplastic syndrome. A study performed in an NPC endemic area showed that up to 12% of dermatomyositis patients developed NPC.[35] Dermatomyositis can develop concurrently with NPC, late after the diagnosis of NPC or months before the NPC is clinically and symptomatically apparent.

DIAGNOSIS

An approach to diagnosis based on the resources and expertise available should be formulated and followed to shorten the time taken for diagnosis. Such a guide to the diagnostic process is especially useful in areas where NPC is endemic. **Figure 8.3** outlines an approach to the diagnosis of NPC in an endemic region.[36] A good history, together with a thorough clinical examination including endoscopy of the nasopharynx, is the basis for making the diagnosis. In most patients, a tumour mass will be found in the nasopharynx and a biopsy should be taken without delay. In less than 5% of patients, the nasopharynx may appear normal and other investigations may then be necessary to confirm or definitively exclude the diagnosis of NPC.

History

NPC should be a differential diagnosis for patient who presents with any of the four groups of symptoms discussed above, especially if they are from a high incidence region. Symptoms of tinnitus, ear blockage or blood stained nasal discharge may seem benign but they should be investigated further if no apparent cause is found. The ancestry of the patient should be inquired about, especially in Chinese patients, who should be asked whether they are from Northern or Southern China. A family history of NPC is also important as 10% of NPC patients have familial clustering of the cancer.

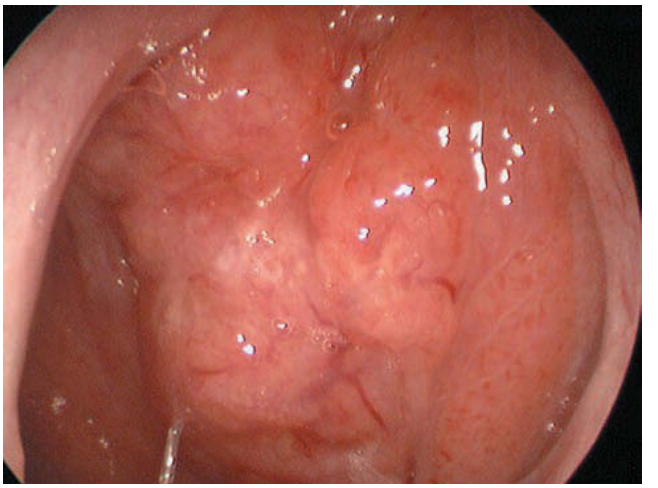

Figure 8.3 View of the nasopharynx through a 0° rigid nasoendoscope. A tumour can be seen obliterating the left fossa of Rosenmüller extending to the right across the midline.

General examination

A full head and neck examination is essential in all patients. Care should be taken to look for otitis media with effusion (OME), CN lesions and cervical lymphadenopathy. When nodes are palpable, their site and size must be carefully assessed as part of the staging process.

Examination of the nasopharynx and nasopharyngoscopy

Traditionally, examination of the nasopharynx was performed by the indirect mirror examination. This technique of examining the nasopharynx is often inadequate due to poor illumination and a strong gag reflex. Additionally, biopsy of any lesion found in indirect mirror examination is nearly impossible in the outpatient setting. Substituting the post-nasal mirror with a 70 degree or 90 degree telescope may solve the problems of poor illumination and poor visualization but the problems of gag reflex and inability to obtain biopsy would still be present.

Antegrade nasopharyngoscopy can be performed with either a rigid telescope or a flexible endoscope. With improvements in technology, the diameter of the new endoscopes is smaller, with improved optics. Both rigid and flexible endoscopes are now available with diameters of less than 4 mm. The choice of using a flexible or rigid endoscope depends on the clinical setting. A flexible endoscope would be more desirable if the larynx and hypopharynx need to be examined in the same setting or if nasal anatomy precludes the use of a rigid telescope. For rigid telescopes, a 0 degree telescope provides a more

direct view but a 30 degree telescope can be turned to examine the lateral wall of the nasopharynx and fossa of Rosenmüller better. **Figure 8.3** shows the view of the nasopharynx with a tumour left fossa of Rosenmüller extending to the left nasopharynx.

Ideally, the nasal cavities should be prepared by the application of local anaesthesia and vasoconstrictor prior to performing nasopharyngoscopy. Traditionally, 5% cocaine was used given its anaesthetic and vasoconstriction properties. However, owing to the disadvantages of being a controlled drug with significant cardiovascular toxicities, other agents are preferred: 2–5% lignocaine with the addition of a vasoconstrictor like 1 : 10 000 adrenaline, 0.5% phenylephrine or 0.1% xylometazoline. The local anaesthetic can be applied by placing cotton pledges soaked with the drug or by spraying the drug into the nasal cavities. The endoscopy should be performed a few minutes later to allow the vasoconstrictors to act so that the nasal mucosa can shrink adequately for better inspection of the nasal cavities and nasopharynx. Occasionally, in patients with deep fossa of Rosenmüller or bulky Eustachian tube cushions, the fossa cannot be adequately visualized. The patient should then be instructed to swallow and then say 'arh'. This will close the velopharynx and pull the Eustachian cushions anteriorly, exposing the deep fossa.

Most of the cancers are readily apparent under endoscopy, presenting as a mass with abnormal capillaries on the surface with areas of ulceration. Occasionally, the tumours are infiltrative and no mass may be seen. However, close inspection will reveal abnormal capillaries in the mucosa; easy contact bleeding is a sign of NPC.[37] Cross-sectional imaging, especially MRI, will pick up this type of submucosal NPC.

Biopsy of the nasopharynx

If an obvious tumour can be seen during endoscopy in the outpatient setting, biopsy of the lesion can usually be performed concurrently. Flexible endoscopes with a biopsy channel for use in nasopharyngoscopy usually have a small biopsy channel; thus, it is advisable to obtain multiple biopsies to avoid inadequate tissue for histological diagnosis. Alternatively, a biting ethmoid forceps used in endoscopic sinus surgery can be passed into the nasal cavity above or below the endoscope under endoscopic guidance for obtaining biopsy (**Figure 8.4**). For procedures using rigid endoscopes, the biopsy technique is similar. Some mild mucosal bleeding can be expected after the biopsy but this should be self-limiting. Patients on anticoagulation drugs should have the coagulopathy corrected before the biopsy procedure.

Biopsy under general anaesthesia may be required if multiple deep biopsies are needed to rule in or rule out the diagnosis of NPC. Patients with metastatic neck lymph nodes with an unknown primary, persistently raised tumour markers and normal nasopharynx on endoscopy or inconclusive biopsy results will be candidates for general anaesthesia. Multiple deep biopsies including biopsies from the roof of nasopharynx, central nasopharynx and mucosa of both fossae of Rosenmüller should be obtained.

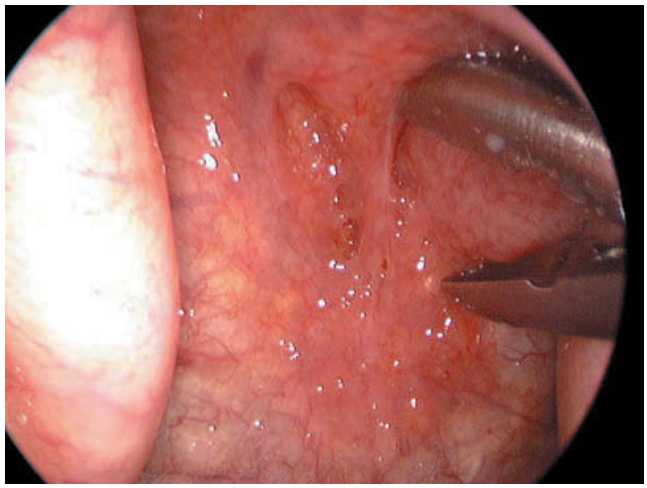

Figure 8.4 Biopsy of the left nasopharynx under direct visualization from a 0° nasoendoscopy. The nasoendoscope was introduced through the right nostril while the ethimoid biting forceps was introduced through the left nostril. Alternatively, both instruments can be introduced through same nostril after decongesting the nasal cavities.

DIFFERENTIAL DIAGNOSIS

Several entities may resemble NPC on clinical examination. These include inflammatory disease in the nasal cavities like rhinosinusitis or nasal polyposis, infections in the nasopharynx including viral infections or tuberculosis of the nasopharynx and other rare malignancies, such as T-NK lymphoma (midline lethal granuloma), mucosal melanoma, sinonasal undifferentiated carcinoma and olfactory neuroblastoma involving the nasopharynx.

LABORATORY TESTS

Although biopsy of the nasopharynx remains the gold standard in diagnosis of NPC, several laboratory tests can aid the diagnosis or be useful for monitoring and screening the disease. Blood tests are especially useful for screening purposes as they are less invasive and easier to deploy than endoscopic examination of the nasopharynx.

EBV antibodies serology

The first association of endemic NPC with EBV was found when patients with NPC regularly were found to have elevated levels of EBV antibodies in the serum.[38] IgA antibodies against viral capsid antigen (VCA), early antigen (EA) and EBV nuclear antigen 1 (EBNA1) are commonly used as tumour markers to screen for NPC. On the other hand, serum EBV IgG titre signifies prior infection by the virus and elevated serum EBV IgM titre indicates recent infection. EBV IgG serology and IgM serology are not useful in screening NPC as most adults will have been infected by EBV at an earlier age. EBV IgA VCA is sensitive but not specific for NPC while EBV IgA EA is specific but not sensitive for detecting NPC. Combining both tests

can increase the sensitivity and specificity of the serological tests. A large single centre review of more than 5000 subjects, of which 215 suffered from NPC, showed the sensitivity and specificity of EBV IgA VCA to be 89% and 80% while the sensitivity and specificity of EBV IgA EA was 63% and 95%.[39] A recent meta-analysis of 20 published reports on EBV IgA VCA serology sensitivities in Chinese literature showed a similar sensitivity of around 91%.[40]

EBV serology is not an ideal tumour marker for NPC as the serology has weak correlation with the stage of the disease, unable to reflect the tumour response to therapy and does not show increasing titre in recurrent disease.[41] Despite its deficiency, EBV serology is still widely employed in endemic areas for screening or initial diagnostic work up, due to its low cost.

Plasma EBV DNA titre

EBV genome is found in all cancers cells of the endemic form of NPC and EBV DNA will be shed into the patients' blood stream during cell turnover. More advanced stage NPC will have a higher tumour load and larger cancer cell turnover. Detection of EBV DNA in the plasma could therefore be used as a tumour marker of NPC. Improvements in molecular genetics studies has allowed the number of copies of the DNA in the plasma to be assessed using the quantitative (real-time) polymerase chain reaction (rt-PCR). Establishing a threshold level of plasma EBV DNA can help to differentiate between a genuine case of NPC and low levels of DNA due to reactivation of infection. Lo et al first reported the use of qt-PCR assay of EBV DNA in plasma for the detection of NPC.[42,43] The reported sensitivity and specificity of plasma EBV DNA for NPC detection were 96% and 93% respectively. Studies comparing EBV serology with plasma EBV DNA for detection of NPC have found the latter to be a superior test.[33,41]

Apart from diagnostic and screening purposes, plasma EBV DNA levels can have a prognostic implication.[44,45] A high level of EBV DNA before treatment correlates with the larger tumour load and more advanced stage of the cancer.[46] Plasma EBV DNA levels rapidly decrease to undetectable or very low levels within 1–2 weeks after completion of treatment.[47] Persistently elevated plasma EBV DNA titre after treatment may signify persistent loco-regional disease or development of distant metastasis and has been used as a justification for adjuvant chemotherapy.[48,49] An initial drop of plasma EBV DNA levels after treatment and a later progressive rise in the level may represent tumour recurrence.[49] Plasma EBV DNA titre has also been used for monitoring of treatment response during chemotherapy in lieu of imaging, reducing the cost and inconvenience to the patients.[50] Overall, plasma EBV DNA assessment has proved to be a versatile tumour marker for NPC.

The only caveat when interpreting plasma EBV DNA is that levels will be elevated in any disease associated with EBV, like infectious mononucleosis and EBV-associated lymphoid malignancy.[51] Also, plasma EBV DNA levels lack sensitivity in detecting small local recurrences after radiotherapy.[52]

Nasopharyngeal brushing for EBV DNA

To tackle the problem of elevated plasma EBV DNA in other EBV-associated diseases, direct detection of EBV in the nasopharynx has been devised.[53,54] Brushing of the nasopharynx is performed and the cells obtained are sent for EBV DNA detection with qt-PCR. Theoretically, this test should be more sensitive and specific than plasma EBV DNA level. Although early brush designs fell out of favour due to being impracticable, newer designs of transoral brushing and detection of EBV DNA show promising results. The test is easy to perform and has a very high sensitivity and specificity of 98.9% and 99.3% respectively.

Cytology

When analyzed by an experience cytologist, cytological smears from the fine-needle aspiration of enlarged neck lymph nodes can often differentiate between metastasis from squamous cell carcinoma and undifferentiated carcinoma. With the addition of immunohistochemical staining for EBV RNA (EBER), a definitive diagnosis of NPC with neck lymph node metastasis can be made. Performing fine-needle aspiration avoids open biopsy of the neck lymph node.

IMAGING

Imaging studies are indispensable for staging of the disease and can also aid in the differential diagnosis in cases with atypical presentations. When cost is not a concern, imaging studies are useful for post-treatment monitoring.

Plain radiograph

A plain radiograph of the nasopharynx is neither sensitive nor specific enough for any clinical use and has been superseded by other modalities.[55] A plain chest X-ray can be done as an initial screening for lung metastasis and general health status. Orthopantomogram is often performed by a dentist treating patients prior to radiotherapy.

Computerized tomography

The use of a computerized tomography (CT) scan as a staging modality has been replaced by magnetic resonance imaging (MRI) as more and more centres adopt newer three-dimensional radiotherapy techniques. CT scans are still used by many clinicians as they are more widely available and can clearly show bone erosions in the skull base. Newer scanners can reconstruct the images in any plane with fine details and high accuracy. The new linear accelerators capable of three-dimensional radiotherapy treatments have inbuilt CT scanners, an essential tool for radiation planning.

Magnetic resonance imaging

MRI is the preferred imaging modality for NPC staging and treatment because of its superior soft tissue resolution. For assessment of tumour extent, MRI can better delineate parapharyngeal extension of tumour, perineural spread and marrow infiltration. MRI can also differentiate between tumour infiltration from retained secretions in the paranasal sinuses, and can define better the limits of the optic chiasma, optic nerves and brainstem. Accurate delineation of these structures is important for preservation of these organs at risk in the newer radiotherapy techniques. New generations of radiation planning software systems allow fusion of MRI with CT images for determination of tumour extent and radiation planning, allowing the best of both worlds. Additional imaging modalities like PET-CT can also be fused.

MRI is more useful than CT in monitoring the disease after treatment and imaging recurrent diseases. Post-treatment fibrosis can be difficult to differentiate from recurrent tumour. Traditional MRI sequences may not be much superior to CT[56] but with newer MRI sequences like diffusion weighted images, the diagnostic accuracy of MRI for recurrent disease has increased.[57] The diagnostic accuracy of modern MRI is on par with PET-CT in detecting residual and recurrent disease.[58]

Ultrasound scan

Ultrasound scan is a widely available, inexpensive and non-invasive tool especially suited for investigating neck lymph node metastasis. Ultrasound combined with fine-needle aspiration cytology can achieve a very high sensitivity and specificity for detection nodal metastasis in NPC. In patients with equivocal findings of nodal status on cross-sectional imaging, additional ultrasound guided fine-needle aspiration cytology can provide the diagnosis without resorting to expensive functional imaging modalities like PET-CT scan. The disadvantage of ultrasound scanning is that its accuracy is dependent on the operator. Also, the images and information acquired cannot be fused with other cross-sectional images.

Positron emission tomography

PET is increasingly being used in the management of NPC. A PET scan is a functional imaging study and is normally combined with a cross-sectional imaging modality like a CT scan for anatomical localization. For use in NPC, 18F fluoro-deoxyglucose (18FDG) is the most frequently used isotope. 18FDG is similar to glucose and areas with increased glucose metabolism will be highlighted on PET scans. PET-CT can supplement other imaging modalities in detecting the tumour extent and nodal metastasis but cannot replace MRI scans. PET-CT is less accurate in the delineation of tumour extent in the skull base.[59] Since PET-CT is a whole body scan, it can also detect distant metastases in addition to loco-regional disease extent. Patients with bulky nodal disease have an increased chance of distant metastases, and PET-CT is highly recommended for this group of patients prior to treatment.

PET-CT is very useful in assessing residual and recurrent disease after treatment. Conventional MRI is inferior to PET-CT and the clinician may need serial MRI scans to detect recurrence.[60] PET-CT detects both loco-regional failures and distant failures and is especially recommended in patients with a rising trend of EBV DNA titre after treatment.[61]

STAGING

The biological behaviour and prognosis of NPC is vastly different from squamous cell carcinoma of the head and neck region and the staging system is also different. The modified Ho's stage classification was widely used in the last millennium and was based on the treatment results with conventional two-dimensional radiotherapy techniques. This has now been replaced by the newer International Union Against Cancer (UICC)/American Joint Committee on Cancer (AJCC) staging systems that rely more on cross-sectional imaging for staging and reflect the improved outcomes with newer radiation techniques like intensity modulated radiotherapy and concurrent chemoradiotherapy. The new AJCC eighth edition staging of NPC has several major changes reflecting these improvements.[62] **Table 8.2** sets out the TNM and group stages as per the eighth edition of the AJCC system.

PRIMARY TREATMENT

The non-keratinizating subtype of NPC is a very radiosensitive tumour. Radiotherapy is the mainstay of treatment for primary NPC and surgical treatment is reserved for salvage of radiation failures. The two major advances in NPC management are the introduction of intensity-modulated radiotherapy (IMRT) and the discovery that concurrent chemoradiation improves the efficacy of radiotherapy.

Radiotherapy

Radiotherapy is the cornerstone of loco-regional treatment for all stages of NPC without distant metastases (i.e. from stage I to IVB diseases). Early stage diseases, including stage I and low-risk stage II NPC, can be treated with radical radiotherapy alone. Stage II disease with higher tumour load and stage III, IV disease require combination chemotherapy and radiotherapy.

Intensity-modulated radiotherapy (IMRT) is the standard of care for radiation treatment of NPC. Radiotherapy planning starts with making an individualized immobilization device, usually a thermoplastic cast for the head and neck for each patient. Then, a planning CT scan is obtained with the patient in cast and in treatment position.

TABLE 8.2 AJCC stage classification for NPC[62]*

Primary tumour (T)>		Regional lymph nodes (N)	
Tx	Primary tumour cannot be assessed	**N1**	Unilateral metastasis, in cervical lymph node(s), and/or unilateral or bilateral metastasis in retropharyngeal lymph nodes, 6 cm or less, above the caudal border of cricoid carilage
T1	Tumour confined to nasopharynx, or extends to oropharynx and/or nasal cavity without parapharyngeal space involvement	**N2**	Bilateral metastasis in cervical lymph node(s), 6 cm or less above the caudal border of cricoid cartilage
T2	Tumour with extension to parapharyngeal space and/or infiltration of the medial pterygoid, lateral pterygoid, and/or prevertebral muscles	**N2**	Metastasis in cervical lymph node(s) greater than 6 cm in dimension and/or extension below the caudal border of cricoid cartilage
T3	Tumour invades bony structures of skull base cervical vertebra, pterygoid structures, and/or paranasal sinuses		
T4	Tumour with intracranial extension and/or involvement of cranial nerves, hypopharynx, orbit, parotid gland and/or infiltration beyond the lateral surface of the lateral pterygoid muscle		

Metastatic disease (M)	
M0	No distant metastasis
M1	Distant metastasis present

Stage groups			
I	T1	N0	M0
II	T1 T2	N1 N0, N1	M0 M0
III	T1, T2 T3	N2 N0-, N1, N2	M0 M0
IVA	T4 Any T	N0, N1, N2 N3	M0 M0
IVB	Any T	N3	M0
IV	Compressed previous stage IVB now IVA

The planning CT scan is used for localization of targets and normal tissues. The required doses to targets and the dose constraints to normal tissues are input into the computer planning system, which will generate the optimal radiation plan that concentrates the radiation dose in targets while minimizing the dose to normal tissues.

There are different treatment targets: gross tumour volume (GTV, both for the primary in NP and for involved neck nodes); clinical target volume (CTV, which includes the GTV and covers for subclinical disease spread around NP and neck); planning target volume (PTV, which includes the CTV with a margin to allow for possible errors in daily positioning and treatment of patient during radiotherapy).

GTVs will include the tumour in NP and any enlarged (>6 mm) retropharyngeal and neck nodes or lymph nodes with necrotic centres. CTV1 includes the GTVs with margin and requires radiation dose of around 70 Gy. The high risk subclinical disease is covered by CTV2, which include CTV1 with margin plus areas at risk of microscopic involvement, including the entire NP, retropharyngeal nodal regions, skull base, clivus, pterygoid fossae, parapharyngeal space, sphenoid sinus, and the posterior part of the nasal cavity/maxillary sinuses that includes the pterygopalatine fossae.[63, 64] CTV 2 requires at least 60 Gy for treatment. The neck is always irradiated together with the primary and the CTV would include bilateral level I through V nodal regions. At levels with nodal involvement, the dose to CTV should be at least 60 Gy. A lower dose, 54–60 Gy, may be given for prophylactic irradiation of uninvolved nodal regions.

IMRT has 'dose-painting' capacity that allows different dose levels to different regions to be applied in the same treatment. For example, in a course of IMRT with 33 fractions over 6.5 weeks, CTV1 may be treated to 70 Gy at 2.12 Gy/fraction while CTV2 can be treated to 66 Gy at 1.82 Gy/fraction. This simultaneous-integrated boost technique allows for a degree of accelerated fractionation in tumour without overdosing the normal tissues. With IMRT, local control rates of over 90% have been reported. The complications from conventional two-dimensional radiotherapy such as hearing loss, xerostomia, temporal lobe neuropathy, trismus and neck fibrosis, are reduced.[65] **Figure 8.5** shows a screen capture from the planning software depicting the dose-painting technique of IMRT.

Chemotherapy

NPC is known to be sensitive to both chemotherapy and radiotherapy. Several studies combining chemotherapy and radiotherapy in treatment of NPC have been published, but the sequence of administration of chemotherapy in relation to radiotherapy and the choice of chemotherapy is important.

The pivotal Intergroup study 0099 established concurrent cisplatin during radiotherapy followed by adjuvant cisplatin and fluorouracil as the standard of care for advanced NPC.[66] The Meta-Analysis of Chemotherapy in Nasopharyngeal Carcinoma (MAC-NPC) showed a survival benefit with the use of chemotherapy in addition to radiotherapy in treatment of NPC.[67] The effect was most significant when chemotherapy was used concurrently with radiotherapy (pooled hazard ratio of death: 0.6). An update of the meta-analysis was reported in 2014

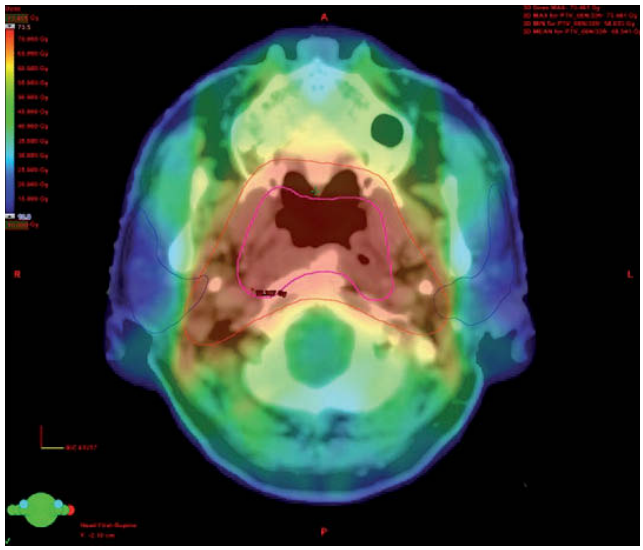

Figure 8.5 Dosimetry plot of IMRT on the nasopharynx. The patient was treated with dose-painting with IMRT: the NP was treated to 70 Gy while the high-risk area was treated to 66 Gy in 33 fractions. The parotids on both sides were treated to 20 Gy or less. Red ~ 65–70 Gy, green ~ 45–50 Gy and blue ~ 20 Gy.

that included additional trials (overall 19 trials and 4798 patients) since the last meta-analysis.[68] There was a significant benefit of chemotherapy in addition to radiotherapy in improving overall survival (hazard ratio: 0.79). There was a significant interaction between treatment effect on overall survival and the timing of chemotherapy, in favour of concurrent chemotherapy with or without adjuvant chemotherapy compared with induction or adjuvant chemotherapy alone.

Cisplatin is the usual agent used concurrently with radiotherapy. Weekly (30–40 mg/m^2) or 3-weekly (100 mg/m^2) cisplatin are acceptable standards of care. A total dose of 200 mg/m^2 administered during radiotherapy is required to benefit survival. The benefit of adjuvant chemotherapy in addition to the concurrent chemoradiotherapy is less certain. Recently, there has been renewed interest in the use of induction chemotherapy, especially in addition to concurrent chemotherapy. The preliminary results of the NPC-0501 study reported from Hong Kong showed that outcomes were not significantly impacted by changing from the concurrent-adjuvant sequence to induction-concurrent sequence with potential benefit of using induction cisplatin and capecitabine in place of cisplatin and fluorouracil.[69]

Unlike squamous cell carcinoma of the head and neck region, epidermal growth factor receptor tyrosine kinase inhibitors like cetuximab had not been shown to be beneficial, either as a single agent for palliative treatment or in addition to chemoradiation for primary treatment. As of 2014, there are no randomized controlled trials on the benefits of adding cetuximab in the treatment of NPC. There are small-scale phase II open labelled trials on the addition of cetuximab with concurrent chemoradiation for treatment of primary NPC[70] or cetuximab with carboplatin for recurrent/metastatic NPC that failed first line chemotherapy.[71] The results showed acceptable toxicities but no definite superiority. Further research is required to develop suitable target therapy for NPC.

With the advancement of radiotherapy and improved local control, distant metastases become the dominant pattern of disease failure. Patients who recur now have usually been exposed to cisplatin and fluorouracil in primary treatment. New chemotherapy agents such as taxanes and gemcitabine have been found to be useful in the treatment of recurrent or metastatic NPC. How best to incorporate these newer agents into the primary treatment of NPC and how to use newer prognostic markers like EBV DNA in selecting high-risk patients for more aggressive treatment are areas of intense research.

MONITORING OF TREATMENT AND FOLLOW-UP PLAN

With the introduction of concurrent chemoradiotherapy, persistence of local and regional disease has dropped to less than 10%. Still, it is prudent to confirm that the disease has fully regressed after treatment. Patients should have endoscopy and biopsy of the nasopharynx to confirm disease resolution after the completion of radiotherapy. This should not be performed too early after radiotherapy as tumour cells continue to undergo apoptosis weeks after completion of radiotherapy. One observational study has shown that patients with a nasopharyngeal biopsy showing tumour cells at 8 weeks after radiotherapy will continue to undergo complete regression by 12 weeks, suggesting that disease should only be considered persistent if biopsy is positive at 12 weeks after radiotherapy.[72]

Long-term follow-up of all patients is essential. Most failures occurs within 2 years of treatment[73] but a small percentage of patients develop local recurrence more than 10 years after the primary treatment.[74] Distant failure can occur several years after treatment and long-term complications of radiotherapy may not be seen until 5 years after treatment. There is no consensus on the optimal follow up schedule. Given the insight from patterns of failure, regular 2–3-monthly follow-up in the first 2 years, increased to 3–4 times per year in the third to fifth years, followed by 6-monthly or yearly reviews is advisable.

SALVAGE TREATMENT

Salvage treatment for NPC is moderately successful but with significant morbidities. A large survey of 200 local failures treated with different modalities showed an overall 3-year survival of 74%.[75] As patients with recurrences have already been exposed to the toxicities of previous treatment, the choice of the salvage treatment would need to consider the tolerance of the normal tissue.

Radiotherapy for local failures

Radiotherapy for treatment of local failures can be delivered by external beam or by local brachytherapy. The main limiting factor in re-irradiation is the tolerance of the vital organs like brainstem, optic chiasma and temporal lobe to radiation. Traditional two-dimensional re-irradiation for local failure had poor results, with one study showing a 5-year survival of only 7.6%.[76] The dismal result was due to the dosimetry constraints to avoid excessive radiation to vital organs. With the development of three-dimensional radiotherapy techniques like 3D stereotactic radiotherapy and IMRT, it is possible to reduce the dose or radiation to these vital organs;[77–79] however, adjacent non-vital organs will still be exposed to higher doses. A small series of 30 patients showed the 5-year overall survival and local control using stereotactic radiotherapy to salvage local recurrence were 40% and 57% respectively.[80]

Brachytherapy delivers a high dose of radiation with limited penetration inside the nasopharynx to treat local failures without deep invasion. The main radioactive sources used are iridium-192 (Ir192) and gold 198 (Au198). Both isotopes emit gamma radiation. Delivering brachytherapy needs special techniques. For Ir192, the radioactive source is loaded into a tailor-made plastic mould fitted into the nasopharynx of the patient beforehand. The plastic mould is placed into the nasopharynx via the oral cavity under local anaesthesia.[81, 82] For Au198, the gold grains are implanted to the nasopharynx after the soft palate is split open under general anaesthesia.[83] Both techniques are only suitable for small tumours less than 2 cm in maximal dimension. The 5-year survival rates for salvaging with this technique is in the range of 50–60%.[84]

Radiotherapy for nodal failures

In the era of concurrent chemoradiation, isolated nodal failure is an uncommon event. Only 5% of patients may suffer from isolated nodal failures.[73] Therefore, it is imperative to investigate for any simultaneous local recurrences in patients who present with nodal recurrence. Patients who have persistently enlarged neck lymph nodes 3 months after completion of radiotherapy should be considered to have persistent nodal diseases and offered salvage treatment.[85] In the era of 2D radiation, re-irradiation of isolated nodal failures showed poor results, with less than 20% 5-year survival.[86] Additional radiotherapy also increases the radiation damage to the soft tissues in the neck; therefore, re-irradiation treatment for salvaging nodal failure is not recommended.

Due to the limited penetration of brachytherapy techniques, they can be used for treatment of nodal failure in conjunction with surgical resection of the nodal metastasis. This will be discussed later in the chapter.

Surgery for local failure

The nasopharynx is notoriously difficult to access surgically. Most routes of access require facial incisions and multiple osteotomies, and transgress a significant amount of normal tissue to expose the nasopharynx. Therefore, surgical resection of the nasopharynx, namely nasopharyngectomy, is only reserved for salvaging radiation failures. The decision to offer nasopharyngectomy for salvaging local failures depends on the location of the tumour and the general condition of the patient. The patient should be fit for a 5-hour operation under general anaesthesia. Tumours that show internal carotid artery encasement, extensive skull base infiltration or intracranial extension are not suitable for salvage surgery. Alternative salvage treatment should be offered instead. Since the introduction of nasopharyngectomy for salvaging NPC local failures in the 1980s, significant experience has accumulated at several large volume centres. Nasopharyngectomy in experienced hands has low peri-operative mortality and acceptable morbidities. The 5-year local control is in the range of 70%. A large case series in treatment of local failures showed that there was no significant difference in terms of overall survival in patients treated with a second course of radiotherapy or surgery but nasopharyngectomy was associated with lower morbidities. Only patients with rT1 and rT2 diseases had survival advantage; patients with rT3 and rT4 diseases showed no improvement in survival with retreatment by either means.[75]

As the nasopharynx is in the central part of the head, various approaches can be used. Below is a brief discussion of various approaches.

TRANSPALATAL APPROACH – INFERIOR APPROACH

This approach is extensively used for salvaging NPC local failures. A mucoperiosteal flap of the hard palate is elevated from the bony hard palate from anterior to posterior to expose the attachment of the soft palate. The soft palate is then detached from the bony hard palate and retracted inferiorly to expose the nasopharynx. The posterior edge of the hard palate can be removed to increase the exposure and the recurrent tumour excised under direct vision. The palatal flap is subsequently re-sutured back to the anterior hard palate mucosa at the conclusion of the procedure. The advantages of the procedure are minimal bone removal and no facial incision; disadvantages include limited lateral access to the parapharyngeal space and risk of palatal fistula. Fee et al reported a series of 37 patients treated with this approach with a 5-year overall survival of 52% and local control of 67%.[87]

TRANSCERVICO-MANDIBULO-PALATAL APPROACH – INFEROLATERAL APPROACH

Morton et al first described this approach for salvaging NPC in 1996.[88] This approach improves the exposure of a transpalatal approach by the addition of the lip-splitting mandibulotomy. The mandible is swung laterally and the floor of mouth incision is extended superiorly along the anterior pillar of the tonsil to divide the soft palate from the hard palate. The nasopharynx can then be visualized from the inferio-lateral fashion. This gives a wider view and can offer access to the ipsilateral parapharyngeal space.

However, owing to disruption of large amounts of normal anatomy, significant long-term morbidities are associated with this technique. King et al reported the morbidity profile in a series of 11 patients who underwent nasopharyngectomy via this approach: eight patients had a palatal defect; six patients suffered from trismus; six patients had dysphagia; and three patients had malunion of the mandible.[89]

MIDFACIAL DEGLOVING APPROACH – ANTERIOR APPROACH

The procedure is similar to the midfacial degloving approach for resection nasal cavity cancers and juvenile nasopharyngeal angiofibromas. To increase the exposure of the nasopharynx and room for instrument manipulation, bilateral medial maxillectomies and posterior nasal septectomy should be performed. In a series of 15 cases, the surgeon was able to achieve clear margins in 12 cases but the long-term oncological outcome was not reported.[90] The obvious advantages of this approach are the lack of facial scar and avoiding the risk of a palatal fistula. Exposure can be poor, even when the medial maxillary walls are removed. There is also limited lateral access with this approach. In one cohort, the oncological outcome of the midfacial degloving approach was significantly worse than the maxillary swing approach.[91] The postulation was that NPC frequently had lateral extension and inability to remove disease in the lateral nasopharynx and parapharyngeal space might contribute to the poor oncological outcome.

MAXILLARY SWING APPROACH – ANTERO-LATERAL APPROACH

The approach starts with a standard incision for radial maxillectomy – the Weber-Ferguson-Longmire incision. Osteotomies are made: at the anterior maxilla inferior to the orbital rim; midline at the hard plate just lateral to the nasal septum; at the anterior zygoma separating the maxilla from the zygoma; and finally between the posterior maxillary wall and the pterygoid plates at the maxillary tuberosity. The maxilla is left attached to the anterior cheek skin and the whole maxilla with the cheek skin is retracted laterally to expose the parapharyngeal space and nasopharynx.[92] This approach provides wide exposure of the nasopharynx and parapharyngeal space, allowing the surgeon to perform resection of the tumour not only in the nasopharynx centrally but laterally in the parapharyngeal space and to the origin of the pterygoid muscles. In addition, the surgeon can localize the parapharyngeal internal carotid artery by palpation during dissection in the parapharyngeal space. After performing the resection, the maxilla is put back and the bony osteotomies fixed with titanium plates. Wei reported his 20 years experience of the maxillary swing approach in 246 patients. The treatment results were very encouraging with a 5-year local control of 74% and 5-year disease-free survival of 56%.[93] The disadvantage of this approach is the presence of a facial scar, risk of trismus and palatal fistula formation.

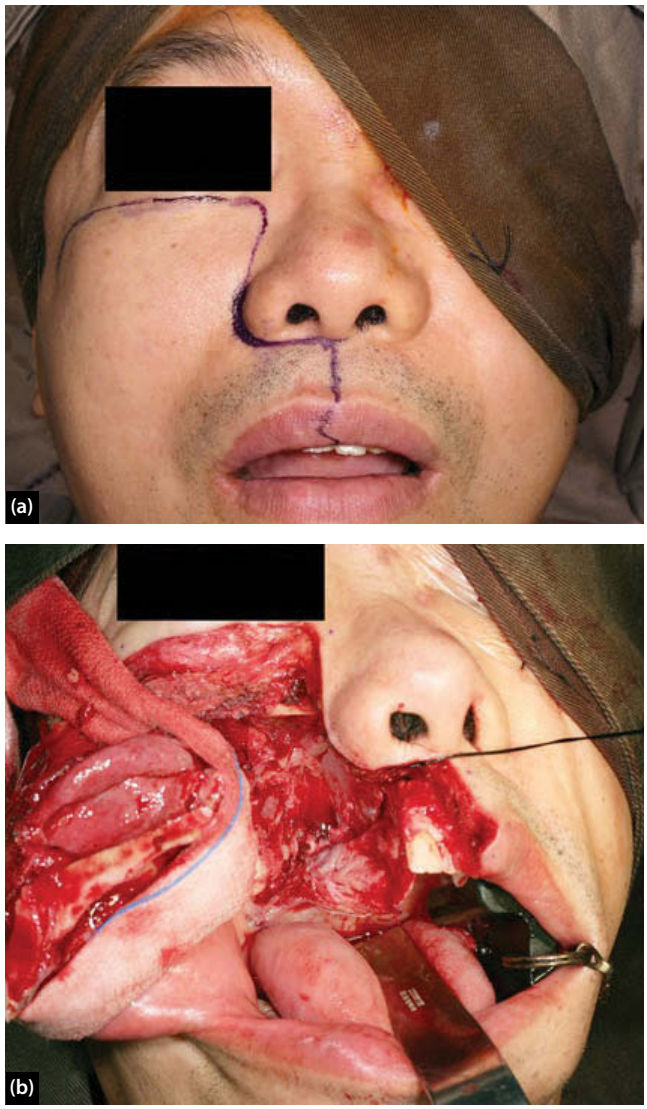

Figure 8.6 (a) Weber-Ferguson-Longmire incision for maxillary swing approach to the nasopharynx. (b) View of the nasopharynx after swinging the maxilla laterally.

Figure 8.6 shows the facial incision for the maxillary swing approach and view of the nasopharynx after swinging the maxilla laterally.

FACIAL TRANSLOCATION APPROACH – ANTERO-LATERAL APPROACH

An alternative approach is the facial translocation procedure. In this approach, the whole maxilla, including the floor of the orbit, lateral orbital rim, malar prominence and zygomatic arch, is removed. Part of the coronoid process is also removed to provide exposure to the infratemporal fossa and masticator space. The maxilla is detached from the cheek flap and is replaced back to the facial skeleton as a free bone graft, secured with titanium plates. Hao et al report in a 53-patient cohort using this approach a 5-year local control rate of 53.6% and a 5-year overall survival rate of 48.7%, comparable to the maxillary swing approach.[94] The facial translocation approach has better

lateral exposure than the maxillary swing approach at the expense of jeopardizing the blood supply to the maxilla bone. This lateral exposure is usually not required in small recurrent tumours in the nasopharynx and a maxillary swing approach should suffice for resection of most locally recurrent NPC.

LATERAL SKULL BASE APPROACH – LATERAL APPROACH

This approach is based on neurotological principles.[95] Via an extended post-auricular incision, the external auditory canal is closed as a blind sac and the whole auricle is retracted anteriorly with the flap. An extended mastoidectomy and total parotidectomy are then performed to allow the rerouting of the facial nerve. The zygomatic arch is removed and the temporalis muscle is then divided so that the base of the middle cranial fossa can be accessed. To improve the exposure, the condylar process of the mandible can be removed. The mandibular branch of the trigeminal nerve has to be divided and the pterygoid muscles removed from the attachment to the lateral pterygoid plate. The internal carotid artery is then identified and retracted. The tissue in the parapharyngeal space including the cartilaginous Eustachian tube can be resected *en bloc* with the tumour in the nasopharynx.

The advantage of this approach is the early identification and protection of the internal carotid artery. The major disadvantage is the extent of mobilization of normal tissues that needs to be performed to expose the tumour and subsequent morbidity. The visualization of the midline of the nasopharynx and access to resect lesions extending anteriorly to the nasal cavity and paranasal sinuses is poor. Of the 13 patients treated with the approach by Fisch et al, six patients with small recurrences had good local control.[96] Few other reports exist of the use of this approach for resecting recurrent NPC, given that other simpler approaches provide more direct exposure.

ENDOSCOPIC APPROACH

Endoscopic endonasal approach to the anterior skull base is now an established surgical approach to resect tumours in the nasal cavities, paranasal sinuses and anterior skull base.[97] Employing the endoscopic approach to resect nasopharynx tumour is a natural extension of application. Since the first decade of the 21st century, several case series on using the endoscopic approach to resect recurrent NPC have been published. Most of the cases were small tumours with short follow-up periods. The oncological results of endoscopic nasopharyngectomy are respectable, with most series having a 2-year local control of over 80%.[98] The endoscopic approach causes no damage to normal structures of the facial skeleton and minimal loss of function.

An extension of the endoscopic approach is the application of the da Vinci surgical robot (Intuitive Surgical Inc., Sunnyvale, USA) to assist the minimally invasive nasopharyngectomy. The da Vinci surgical robot has been successfully applied to resection of early oropharyngeal, laryngeal and hypopharyngeal cancers. The advantages of the surgical robot include 3D optics, superior manipulation of surgical instruments in tight space, motion scaling and tremor filtration. The nasopharynx is a confined space and endoscopic surgery suffers from lack of space for triangulation of instruments. The da Vinci surgical robot can allow complex movements like suturing, blunt and sharp dissection to be performed in the confined space of the nasopharynx similar to open procedure. Ozer and Waltonen in 2008 first reported a cadaveric experiment on using the da Vinci surgical robot to perform nasopharyngectomy[99] and Wei and Ho in 2010 reported the first clinical case of robotic assisted nasopharyngectomy.[100] Tsang et al have reported a case series of 12 patients who underwent robotic assisited nasopharyngectomy and the 2-year local control was 86%, comparable to other endoscopic nasopharyngectomy series.[101] The advantage over open nasopharyngectomy included shorter hospital stay and less blood loss. **Figure 8.7** is a screen capture from the da Vinci surgical robot performing a robotic nasopharyngectomy.

SURGERY FOR NODAL FAILURES

The poor results and high complication rate for salvaging nodal failures with re-irradiation means alternative management options should be sought for treating nodal failures. Radial neck dissection is considered as the standard of care for management of nodal failures.[85] The rationale for performing radical neck dissection instead of a lesser operation is based on several clinical observations on nodal failures in NPC. First, there are usually multiple nodes that are involved in NPC, even if pre-operative imaging suggests only single-node involvement. Second, extra-capsular involvement is high, reported as high as 70% in one study.[102] As further radiation may not be possible, sparing structures like the internal jugular vein or sternocleidomastoid muscle may leave behind microscopic disease that would not receive post-operative radiotherapy. The spinal accessory nodes are frequently involved in

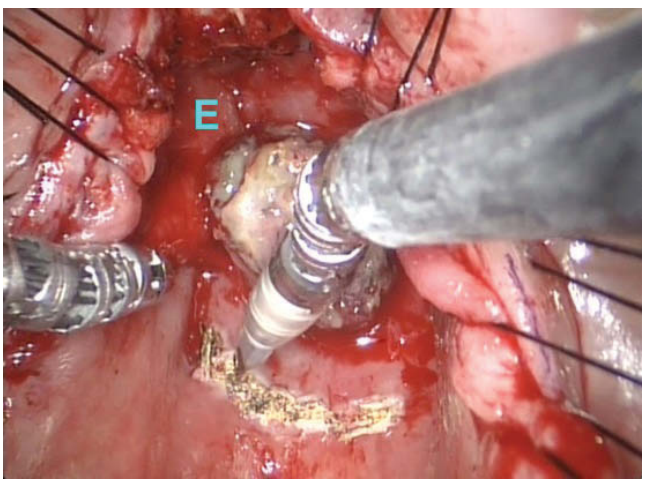

Figure 8.7 Screen capture from the da Vinci surgical robot performing robotic nasopharyngectomy. The soft palate was split in the middling to facilitate placement of the robotic arms.

NPC metastasis and together with the high risk of extracapsular spread, a type I modified radical neck dissection is still suboptimal. However, recent studies have shown that level I lymph nodes are rarely involved and can be spared in the neck dissection.[103]

For advanced nodal disease where the tumour may invade vital structures like the brachial plexus or fully encases the carotid artery at the skull base level, complete excision with sacrifice of these structures may not be advisable. If appropriate, surgery with palliative intent can be offered, as long as realistic goals for the procedure are set. The patient can then be prepared for brachytherapy with after-loading of radioactive source. Special plastic nylon tubes can be placed across the affected area 1 cm apart (**Figure 8.8**). The overlying skin should be removed as it may undergo necrosis after the re-irradiation. The skin defect can then be covered with an appropriate reconstructive option based on patient factors and the expertise available. After the completion of the brachytherapy, the plastic tubes can be removed at the bedside.

Salvaging nodal recurrent disease with radical neck dissection has a 5-year local control rate of 66% and 5-year overall survival of 37%.[104] In one series, the 5-year overall survival and 5-year local control for salvaging advanced nodal disease with radical neck dissection and brachytherapy were 72% and 48% respectively, comparable to less advanced disease treated with neck dissection only.

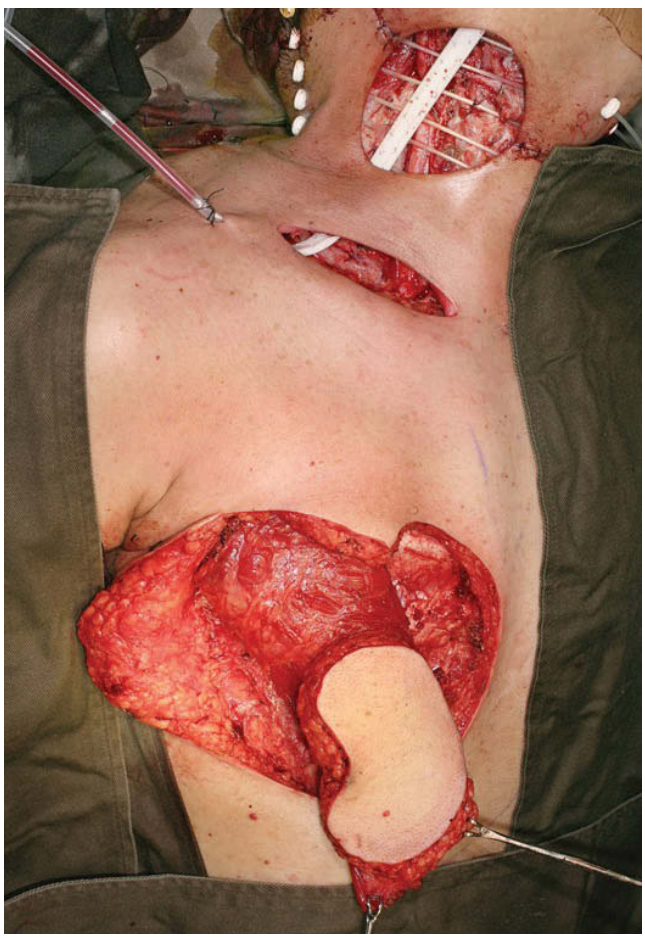

Figure 8.8 Salvage neck dissection for nodal recurrence in NPC. Plastic tubes were placed 1 cm apart for insertion of radioactive sources during brachytherapy. The overlying skin was involved and resected. A pectoralis myocutaneous flap was used to cover the defect.

TREATMENT OF METASTATIC DISEASE

Treatment for oligometastasis

Traditionally, distant metastases were not treated with surgery. With successful surgical resection and long-term survival for solitary metastasis from colon cancer, interest in curative treatment of distant disease in head and neck cancer has been renewed. A large single-centre review showed that 34% of patients with metastatic disease had single organ metastasis, and 16% with solitary metastasis at the time of diagnosis.[105] Options for treatment of oligometastasis include surgical resection, radiofrequency ablation and radiotherapy.[106–108] Although reports are usually case series and prone to selection bias, addition of curative treatment shows significantly better survival than chemotherapy alone in cases where the metastasis can be completely ablated. This area is now a focus of additional research and may redefine our current definition of incurable disease.

Chemotherapy for distant metastasis

Survival of over 6 months after development of distant metastasis was once considered a rarity. With increasing choice of new chemotherapeutic agents, there are now more options for continuation of palliative chemotherapy should one regimen fail. Traditional first-line chemotherapy for metastatic NPC is a combination of cisplatin and 5-florouracil and the medial overall survival is around 12 months. Second-line drugs include gemcitabine, docetaxel, capecitabine and paclitaxel. The newer agents have reported response rates of 50–70% and are well tolerated.[109] Palliative chemotherapy should be offered unless the patient's general condition is not fit.

PROGNOSIS

The treatment results of NPC have shown remarkable improvement in the last 40 years. The age standardized mortality rate for NPC in Hong Kong in 1983 was 9.8 per 100 000, dropping to 7.4/100 000 in 1993 and 3.0/100 000 in 2012. This threefold reduction in mortality is partly caused by 30% reduction in incidence but, more importantly, by the improvement in curative treatments. The two main reasons for improvement are the introduction of IMRT and concurrent chemoradiation as a standard of care in Hong Kong. Most contemporary studies report locoregional control rates of over 90% at 2–5 years and distant disease accounts for most failures. A large series from Hong Kong with more than 2600 patients showed a 5-year distant recurrence rate of 19%.[73]

Analyzing the survival, with the AJCC eighth edition stage classification, of more than 900 patients from 1998–2007 treated with 3D conformal radiation or IMRT with or without chemotherapy, Lee et al reported the 5-year disease-specific survival for stage I was 100%, stage II 90%, stage III 67%, stage IVA 67%, stage IVB 68% and stage IVC 18%.[110] This is a remarkable improvement as in the last edition of this book, the quoted 5-year survival for stage IVA-B was in the range of 20–40%.

COMPLICATIONS OF TREATMENT

Radical radiotherapy for NPC inevitably exposes normal tissue in the vicinity of the tumour to a damaging dose of radiation. Acute, subacute and late complications are well recognized and reported in the literature. A useful source of information on the subject can be obtained from the comprehensive review of Lee.[111]

As the mucosa of the head and neck region is the radiation volume, mucositis of the oral cavity, oropharynx and hypopharynx occurs to a varying degree during treatment. The mucositis can be severely aggravated if concurrent chemotherapy is given. Up to 90% of patients may need enteral feeding via a gastrostomy or nasogastric tube. Salivary function will be decreased during radiotherapy and depending on the dose to the major salivary glands, the salivary function may or may not recover. With IMRT, it is now possible to reduce the dose to the contralateral parotid gland in T1-T2 tumours and reducing the incidence of lifelong xerostomia.[112]

Otological complications frequently occur after radiation. OME, acute otitis media and otitis externa are common complications. The treatment of OME should be conservative as current evidence shows that the use of a grommet during or soon after radiotherapy is associated with a high incidence of persistent perforation and purulent otorrhoea.[113] Late complications of radiotherapy to the ears include sensorineural hearing loss and osteoradionecrosis of the temporal bone. A minor proportion of sensorineural hearing loss patients may lead to complete deafness but, fortunately, most can be salvaged by cochlear implants. Minor osteoradionecrosis of the external auditory canal can usually be managed conservatively with frequent cleaning and antibiotic ear drops. Significant osteoradionecrosis of the temporal bone can lead to deafness, facial nerve palsy and intracranial infection. The necrotic bone may need to be debrided and the defect covered with a local temporalis muscle flap or a vascularized free flap.[114, 115] With the introduction of IMRT and limitation of the radiation dose to the cochlea and temporal bone, the incidence of temporal bone complications are expected to reduce.[116]

Olfactory dysfunction, nasal crusting, rhinosinusitis and intranasal adhesions are common nasal complications. Olfactory dysfunction, usually transient, occurs in quite a number of patients towards the end of radiotherapy and slowly recovers over the next few months. Nasal crusting and symptoms of rhinosinusitis (thick nasal catarrh and foul smelling nasal discharge) are very common following radiotherapy. Regular saline nasal douching in the first few years after radiotherapy with courses of antibiotics may be needed for adequate control. Minor nasal adhesions between septal spurs and the nasal turbinates are quite common and need no treatment. Occasionally, marked scarring at or close to the choana (**Figure 8.9**) may occur, particularly in patients with more advanced local disease requiring a higher local dose of radiation through afterloading brachytherapy. These adhesions should be removed to facilitate future endoscopic assessment of the nasopharynx.

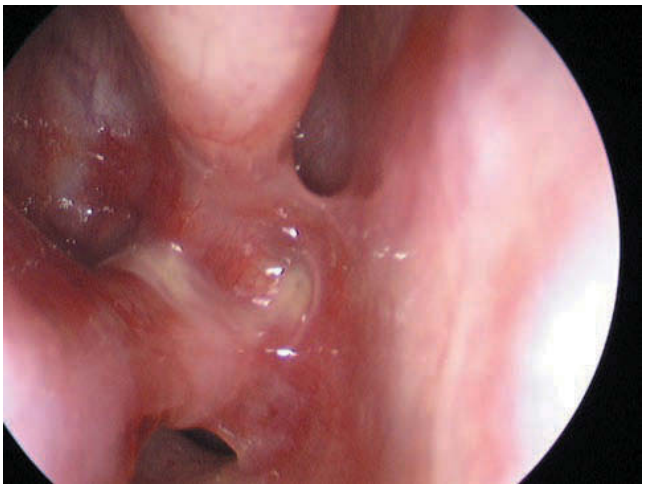

Figure 8.9 Early intranasal adhesions after radiotherapy as seen through a 0° rigid nasendoscope situated inside the right nostril. Note the adhesions around the posterior ends of the middle and inferior turbinates and the nasal septum.

The latent interval of late complications can vary from several months to many years after irradiation, owing to irreversible damage. Tissues that have poor powers of regeneration, such as sensory and neural tissues, are particularly prone. Apart from the total radiation dose, the dose fractionation and timing of delivery will affect the occurrence of late complications.

With the old 2D radiotherapy techniques, the reported incidence of late complication can be more than 30%.[117] Data on long-term complications with the modern IMRT is still lacking but as the dose to the normal tissue is reduced, hopefully we will see a reduction in the long-term complications in the future. On the other hand, the addition of concurrent chemotherapy increases the long-term toxicity of radiation. Swallowing problems in NPC patients treated with radiotherapy is very common and can occur early after treatment.[118] Late dysphagia can affect up to 50% of the head and neck cancer patients treated with concurrent chemoradiation[119] and this increase in late dysphagia is also seen in NPC patients.[120, 121] Dysphagia not only affects quality of life[122] but can also lead to life-threatening aspiration pneumonia.[123]

Radiation-induced fibrosis is another late complication that can lead to neck stiffness and trismus. Apart from osteoradionecrosis of the temporal bone, the skull base and mandible are also at risk for this complication.

Initial treatment including local debridement and hyperbaric oxygen is helpful, but some patients may need definitive resection of the involved bone segment and reconstruction with a free osteocutaneous flap. Osteoradionecrosis of the skull base and radiation fibrosis can lead to lower cranial nerve palsies.[124, 125] The differential diagnosis of late lower cranial nerve palsies is local recurrence and can be difficult to differentiate from osteoradionecrosis or post-radiation fibrosis. Hypothalamic-pituitary dysfunction may result in a range of hormonal deficiencies requiring lifelong replacement therapy. The symptoms and signs of hormonal dysfunctions are subtle and require a high index of suspicion for their diagnosis. Temporal lobe necrosis can develop in patients that were treated with the old radiation techniques but, with modern IMRT, the dose to the temporal lobe is minimal, unless it is for re-irradiation. The symptoms and signs of temporal lobe necrosis are subtle, including personality changes, memory loss and loss of cognitive function. The overt cases may present with epileptic attacks and the more severe cases with symptoms and signs of raised intracranial pressure.

Radiation-induced malignancies mostly develop beyond 5 years after radiotherapy and occur in around 0.3–3% of patients. Radiation-induced malignancy is more important in NPC than other head and neck cancers as patients are younger and coupled with the high cure rate, more patients can survive long enough to develop a radiation-induced cancer. Radiation-induced malignancies can be broadly divided into mucosal squamous cell carcinomas and radiation-induced sarcomas. Unlike atomic bomb survivors, radiation-induced thyroid malignancy is rare in NPC patients. Mucosal squamous cell carcinoma commonly can occur in the edge of the radiation field, including the external auditory canal, middle ear, paranasal sinuses, oral tongue, oropharynx and hypopharynx. It can also occur in the nasopharynx, which needs to be differentiated from local recurrence. Radiation-induced sarcomas are often of the fibrosarcoma or osteosarcoma subtype and usually occur in patients who have received a high dose of radiation. Radiation-induced sarcomas are often difficult to diagnose and can be confused with radiation fibrosis or radionecrosis.[126] Curative resection with clear margins is still the best treatment for radiation-induced malignancies. The prognosis of radiation-induced malignancy is often poor due to the delay in diagnosis, inability to deliver further multimodality treatments and poor performance status of the patients as they suffer from other complications of radiation.[127]

Internal carotid artery aneurysm is a rare life-threatening complication after radiotherapy for NPC. The typical patient will present with minor sentinel bleeds followed by massive epistaxis a few hours to a few days later. Treatment includes prompt airway control followed by endovascular stenting of the internal carotid artery to exclude the aneurysm or ligation of the affected internal carotid artery with vascular bypass. A high index of suspicion is required to diagnose the condition before the patient develops massive rupture of the aneurysm.[128]

CONCLUSION

NPC is a unique disease with a highly variable geographical distribution, distinct viral aetiology interplaying with individual genetic susceptibility and environmental carcinogens. The last two decades have seen a remarkable advance in the treatment in all fronts; from 2D radiation to IMRT, single agent chemotherapy to targeted therapy and open surgery to endoscopic resection. Future developments in in the basic science of the disease include a vaccine for EBV, better understanding of the molecular genetics and newer tumour markers for screening and monitoring of the disease. Newer radiotherapy techniques including image-guided radiotherapy, adaptive radiotherapy and proton radiotherapy are available and may become the mainstream treatment modality. Technological advancements may enable surgeons to perform more endoscopic or robotic surgeries as salvage, reducing the morbidity from open resection.

BEST CLINICAL PRACTICE

- ✓ Nasopharyngeal biopsy under endoscopy should be the first and definitive investigation to establish the diagnosis.
- ✓ NPC is highly radiosensitive; radiation is the first-line treatment for all primary NPC.
- ✓ Radiation delivered in the form of IMRT with up to 66–72 Gy to the gross tumour and involved lymph nodes. 60 Gy of radiation should be given to clinically negative cervical lymph nodes. IMRT will enable delivery of adequate radiation to target the tumour while reducing the radiation dose to adjacent normal structures.
- ✓ Radiation with concurrent chemotherapy is the gold standard for more advanced disease, including stage II disease with bulking lymph nodes and all stage III and stage IV diseases. Cisplatin, delivered either weekly at 40 mg/m^2 or 3-weekly at 100 mg/m^2, is the gold standard.
- ✓ Patients should be followed up regularly after treatment to detect recurrence and complications from treatment.
- ✓ Salvage surgery should be considered for local or regional recurrence as surgery can spare the significant morbidity from re-irradiation.
- ✓ Effective new chemotherapeutic agents are now available for patients with disseminated disease and can offer useful palliation and prolong overall survival.

FUTURE RESEARCH

- The exact role of EBV in the carcinogenesis of endemic form of NPC.
- What are the exact genetic factors in the carcinogenesis of NPC and can these genes be used to define high-risk patients?
- Can the development of a successful EBV vaccine reduce future NPC development in an endemic population?
- What is the best strategy to deploy a mass-screening programme in endemic areas that is cost-effective and improves treatment outcome?
- How can long-term morbidities from chemoradiation, especially in terms of late dysphagia, be further minimized? Can we further reduce the radiation dosage to normal tissue without jeopardizing disease control?
- What is the role of minimally invasive surgeries like endoscopic surgery and robotic surgery in salvaging local recurrence?
- The development of target therapy and newer chemotherapeutic agents with similar or better efficacy than the current line of chemotherapy but with less toxicities.

KEY POINTS

- Nasopharyngeal carcinoma is unique among all head and neck cancers because of wide geographical and ethnic variation in incidence rates. The annual incidence rate in areas with high prevalence of the disease can be up to 50 times higher than low prevalence areas.
- The highest incidence is found in Southern China, including Taiwan, Hong Kong and Macau. Migrants originating from high incidence areas also have a high incidence of developing NPC, though the risk decreases in second or third generation migrants.
- Populations from Malaysia, Indonesia, Arabia, North Africa, Thailand and the Philippines, and Inuits (from Canada and Greenland), have intermediate incidence of NPC.
- Caucasians and populations from Northern China and East Asia (Japan and Korea) have a low incidence of NPC.
- The commonest histological form of NPC in an endemic area is the poorly differentiated type or undifferentiated type (WHO types II and III). The endemic form of the cancer is associated with EBV, and EBV genomes are found in all cancer cells.
- The peak incidence of NPC is around the fourth to fifth decade, a decade earlier than other head and neck squamous cell carcinoma.
- Consumption of salted fish and preserved foods, especially at a young age, are considered as aetiological factors. Smokers also have a moderate increase in risk.
- The aetiology of NPC is the result of a complex interplay of genetic factors, early latent infection by EBV and its subsequent reactivation and exposure to environmental carcinogens. The carcinogenesis of NPC is probably a multistep process.
- Serum EBV IgA antibiodies against viral capsin antigen (VCA), early antigen (EA) and Epstein—Barr nuclear antigens (EBNA) are elevated in patients suffering from NPC and can be used as a tumour marker for screening the cancer. These serological markers are not useful for monitoring of treatment efficacy and screening for recurrence.
- Plasma EBV DNA is a more sensitive and specific tumour marker for NPC. It is also useful for prognostication, monitoring of treatment response and screening for tumour recurrence.
- Symptomatology of NPC can be vague, easily ignored and confused with other conditions. Physical examination often cannot pick up the diagnosis. A high index of suspicion is required to avoid delaying the diagnosis, especially if the patient ethnicity is from an endemic area.
- The most common complaint at presentation is the presence of upper neck swelling: unilateral neck swelling is most common, but bilateral neck metastases are not infrequent. Cervical lymphadenopathy is the presenting complaint in almost 50% of patients. A significant proportion of patients presenting with other complaints also have cervical lymphadenopathy on examination.
- 30% of patients present with nasal symptoms, including blood-stained nasal discharge, nasal obstruction, postnasal drip or even frank epistaxis.
- Approximately 20% of patients present with aural symptoms, including deafness, tinnitus and otalgia. A retracted tympanic membrane or OME is a very common clinical finding. This finding usually correlates with the side of the nasopharynx that has bulkier disease. Adult patients with unexplained unilateral persistent OME should be screened for the presence of occult NPC.
- Neurological complaints include headaches or cranial nerve symptoms. Headaches are a common complaint, occurring in almost 20% of patients, but they may be referred pain when distal branches of the trigeminal nerve are invaded by the tumour in the nasopharynx or nose. However, they can also be the result of bony erosion of the skull base. Cranial nerve symptom(s) may be isolated or multiple. In either case, it occurs late in the disease from the spread of the tumour through the foramina of the base of the skull or with parapharyngeal involvement of the last four cranial nerves. Cranial nerves V and VI are the most commonly involved. When cranial nerves III–VI are affected together, cavernous sinus involvement is the cause. Horner syndrome is rare, but if present is typically accompanied by paresis of one or more of the last cranial nerves.
- MRI is the imaging of choice for delineating the extent of disease in the skull base. CT scan is useful in detecting cortical bone erosion in the skull base but cannot often differentiate between normal structures and tumour invasion in the skull base. PET CT is a useful adjunct to delineate the extent of disease, nodal metastasis and distant metastasis.
- The nodal staging of NPC is different from other head and neck squamous cell carcinoma. The number of lymph nodes involved is not considered in the nodal staging. The laterality (bilateral = N2), size (>6 cm) and inferior location (extends below caudal border of cricoid cartilage) are the considerations in nodal staging.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search of publications that focused on the pathology, aetiology and management of benign salivary gland tumours.

INTRODUCTION

There are a number of important issues to address in patients with tumours of the major salivary glands. Accurate and rapid pre-operative diagnosis is imperative, in order to diagnose malignancy. There is some controversy in the choice of correct operation of the commonest type and location of tumour: a pleomorphic adenoma of the parotid gland. The anatomical relationship of a tumour to the facial nerve (or branch) in the parotid gland is nearly always intimate and the potential for a catastrophic cosmetic handicap can make surgery challenging. In is interesting to observe that, whist there has been a great deal of commentary regarding adequate workload in, for example, thyroid surgery, there has been almost none regarding parotid surgery; and yet the consequences of suboptimal surgery that includes incomplete tumour resection and facial palsy are potentially catastrophic for the patient.

In this chapter, these issues and others are addressed and guidelines for the management of benign salivary gland tumours are established.

EPIDEMIOLOGY AND DISTRIBUTION

Bradley and McGurk[1] analyzed the incidence of salivary gland tumours in a defined population in Nottinghamshire, UK between 1988 and 2007. They reported an incidence of benign parotid neoplasms of 5.3–6.2 per 100 000 population and 0.5–0.55 per 100 000 of benign submandibular tumours. The distribution between sites conformed to the traditional teaching of approximately 80% within the parotid gland, and 10% within the submandibular and minor salivary glands respectively. From these data, there does not appear to be a change in annual incidence of benign salivary gland tumours over the 20-year reporting period in the paper.[1]

All age groups are affected with a peak incidence in the sixth decade. There is a female preponderance, with the exception of Warthin's tumours, which are more common in males.[2]

Table 9.1 compares information from Bradley and McGurk[1] (1065 cases including malignant tumours) with a 1985 publication of British Salivary Gland Tumour data of 2410 cases.[2]

The distribution between histological types is shown in **Table 9.2**.

AETIOLOGY

Whilst radiation can induce malignant salivary gland tumours, the evidence that it can induce benign tumours is much weaker; restricted to a possible association with Warthin's tumours.[3] In recent years, public concern has focused on the use of mobile telephones and the development of regional malignancies, induced by electromagnetic fields. However, there is no evidence of an increased risk of salivary gland tumours.[4] It has been speculated that human papillomavirus 16 (HPV16) may be associated with pathogenesis of benign salivary tumours, but there is no convincing evidence for such.[5, 6]

PRESENTATION

Most parotid and submandibular gland tumours grow slowly over a long period of time without causing symptoms. A very small number cause discomfort by obstructing salivary flow. Most benign tumours will be smooth, relatively mobile and painless to palpate. The following symptoms and signs suggest the tumour may be malignant or be undergoing malignant transformation:

- pain
- paraesthesia (especially adenoid cystic carcinoma)
- rapid growth or an increase in rate of growth
- facial nerve palsy/other nerve palsy
- skin involvement
- fixity
- irregularity.

A further consideration is the age of the patient and the site of the tumour. Malignancy is relatively more likely in younger patients and in submandibular tumours (40% malignant).

The patient with a parotid tumour eventually becomes aware of a firm mass that is steadily getting bigger behind the angle of their jaw in the retromandibular region, in front of the tragus or in the cheek (**Figure 9.1**). Deep lobe parotid and parapharyngeal space tumours may displace the tonsil and palate medially and are often impalpable

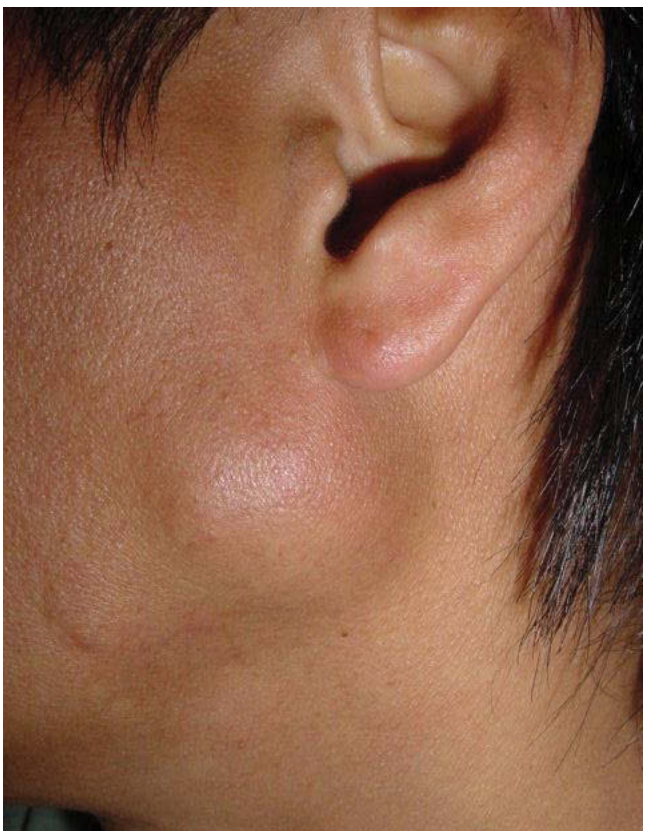

Figure 9.1 Typical presentation of a pleomorphic adenoma of the parotid gland, a retromandibular swelling.

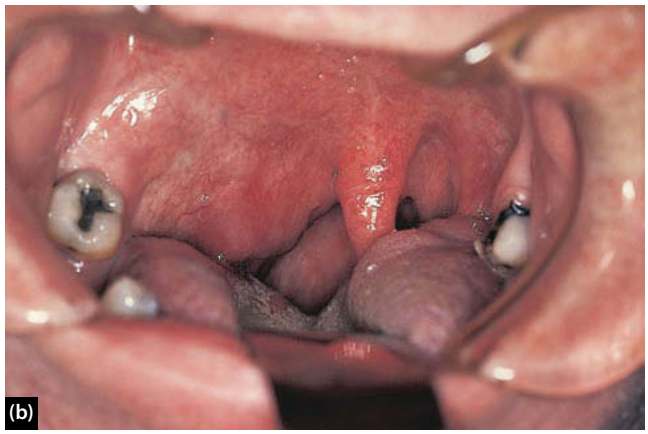

Figure 9.2 **(a)** MRI of a very large deep lobe parotid tumour that had caused Eustachian tube dysfunction, altered the quality of voice and resulted in obstructive sleep apnoea; **(b)** typical intraoral appearance of a deep lobe tumour with medial displacement of the right tonsil.

Figure 9.3 A pleomorphic adenoma of the submandibular gland presenting as a swelling in the submandibular triangle.

Figure 9.4 Unilateral swelling of the left side of the palate, typical of a minor salivary gland tumour.

from outside. Very large parapharyngeal salivary tumours cause stertor, sleep disordered breathing, affect the quality of the patient's voice and may even interfere with Eustachian tube function (**Figure 9.2**). Increasing numbers of salivary gland tumours are being detected as incidental findings on CT, MRI and PET-CT scans performed for other indications. These tumours are asymptomatic and their management poses unique challenges.

Tumours arising in the submandibular gland present as swellings in the submandibular triangle which can be sometimes localized more accurately by bimanual palpation of the floor of the mouth (**Figure 9.3**). It is sometimes difficult to differentiate a tumour arising in the posterior aspect of the submandibular gland from one that is in the tail of the parotid gland and, in turn, either can be mistaken for a lymph node. Benign tumours in the minor salivary glands of the oral and pharyngeal mucosa present as firm submucosal swellings (**Figure 9.4**). Ulceration is rarely if ever seen unless there has been local trauma and, in the absence of that, malignancy should be suspected.

INVESTIGATION

Imaging

In general, every patient with a major salivary gland tumour requires some form of imaging. The arguments for routine imaging are:

- Ultrasound scan can be done at the time of fine-needle aspiration cytology (FNAC), ideally in the setting of a neck lump one stop clinic. FNAC is more accurate if ultrasound-guided.
- Diagnostic information to complement FNAC; if FNAC suggests benignity, imaging may or may not be commensurate with this. If not (i.e. benign cytology but imaging shows, for example, an irregular margin), the cytology should either be repeated and/or the excision performed sooner rather than later.
- If the FNAC is non-diagnostic, imaging may assist in diagnosis and plan urgency of resection.

- If FNAC is non-diagnostic or false negative, and tumour is then found to be malignant, the imaging performed pre-operatively will help to stage the tumour and plan further treatment if necessary.
- Distinguishing:
  - a parotid lump from either high-level 2 lymph node
  - a parotid lump from diffuse parotid enlargement
  - a submandibular lump from an adjacent level 1 (anterior) or level 2 (posterior) lymph node
  - a submandibular tumour from a tumour of the tail of parotid.

Ultrasound imaging can be performed at the time of an initial clinic visit, and fulfils most of the requirements of imaging.[7] It can also demonstrate sialolithiasis and sialectasis very clearly. However, axial (MR or CT) should be performed under the following circumstances:

- tumours that are large (e.g. > 3 cm)
- deep lobe/parapharyngeal space involvement (note that an ultrasound scan may well miss a 'dumbbell' (**Figure 9.5**) tumour in which the greater component of the tumour lies in the parapharyngeal space)
- suspicion of malignancy.

MR is generally preferred because it gives better definition of tumour–normal salivary gland interface.[8] It also is not affected by dental artefact.

Imaging features (on any modality) that suggest malignancy include an irregular capsule, or extracapsular invasion, hypervascularity and imaging features consistent with necrosis.

Fine-needle aspiration cytology and needle core biopsy

Malignant tumours must be detected pre-operatively wherever possible because the staging, workup and surgery may differ. Most salivary gland tumours are investigated by FNAC, at least initially. The accuracy for the diagnosis of benignity or malignancy in most large series is around 80–90%[9, 10] and on systematic review, and concordance with histology for 80% in cancers and 95% in benign tumours.[11] The accuracy will vary from centre to centre. The use of core biopsy can improve the accuracy of diagnosis further. Whilst more invasive, there is no evidence that there is a greater chance of tumour seeding with core biopsy.[12] Some authors advocate the use of core biopsy primarily instead of FNAC. An alternative view is to use core biopsy as a second-line investigation, or when FNAC shows possible malignancy. Such a protocol has been shown to give rise to a sensitivity of 100% and specificity of 92%.[13] The use of ultrasound (a) increases FNAC and core biopsy 'hit rate' and (b) gives useful diagnostic information.[7]

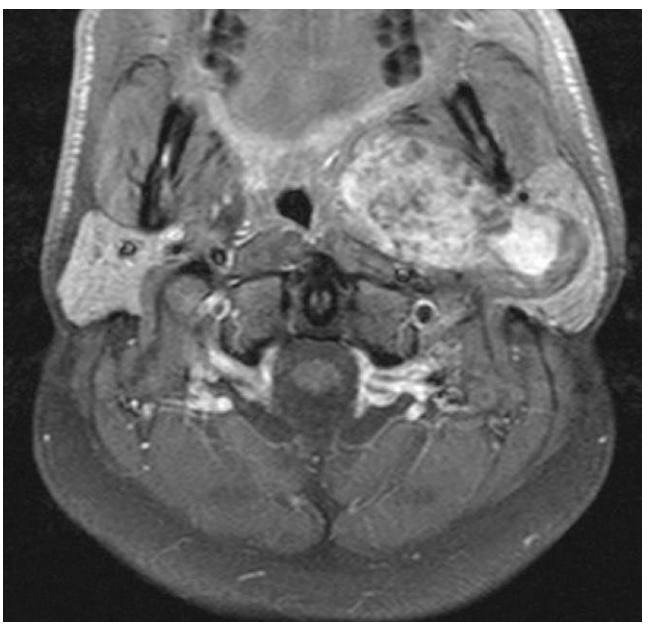

Figure 9.5 MR scan of dumbbell tumour.

THE MANAGEMENT OF COMMON BENIGN TUMOURS

Pleomorphic adenoma

Most patients with a pleomorphic adenoma should be offered and advised to have surgery on the basis of:

1. definitive histology
2. continued growth if left untreated
3. small chance of malignant transformation (see below).

Most parotid pleomorphic adenomas are within the superficial lobe but a small but significant proportion arise either within the deep lobe or involve it by direct growth. Pleomorphic adenomas, left untreated for many years, can attain a large size (**Figure 9.6**). Pleomorphic adenoma can also arise from accessory parotid tissue along the line of the duct (**Figure 9.7**). If far enough anteriorly in this area, they then may only be visible when the mouth is opened and the tumour is pushed outward by the forward movement of the coronoid process of the mandible. Pleomorphic adenomas can also arise in the submandibular gland, or minor salivary glands (e.g. soft palate, see **Figure 9.4**).

The firmness of these tumours varies with the nature and amount of the stromal component and thus ranges from soft, in the case of the more mucinous tumours to hard in the case of tumours with an extensive chondroid or collagenous component.

The myxoid stroma of pleomorphic adenomas is one of its most characteristic features. It can form the major part of the tumour and can bulge into the normal gland parenchyma without any capsule intervening. The almost mucoid nature of many pleomorphic adenomas makes them extremely fragile so that they can rupture at operation. Rupture of the tumour inevitably seeds the operative field and significantly increases the chance of later recurrence.

The cartilage of pleomorphic adenomas, though often termed 'pseudo-cartilage', does not appear distinguishable in any way from true cartilage. Calcifications or bone

Figure 9.6 A large pleomorphic adenoma.

formation are unlikely to develop in any other salivary gland tumour and may be seen clearly in scans. Their presence in a salivary gland or a parapharyngeal mass strongly suggests that the tumour is a pleomorphic adenoma.

It is widely accepted that pleomorphic adenomas are derived from intercalated duct and myoepithelial cells which differentiate into epithelial and connective tissue structures. The epithelial cells are interspersed by stromal elements. Squamous metaplasia with keratinization is common and does not imply malignant change.

It is critical to understand that, in virtually all pleomorphic adenomas, the capsule is exceptionally thin (<20 micron) in at least one area and incomplete in about 50%, more so in the mucoid type which are therefore much more prone to potential spillage during surgery.[14]

The relevance of this and the choice of operation is discussed in the next section.

Another critical feature that influences management is the risk of malignant change. It has always been known that a small percentage of pleomorphic adenomas can undergo malignant transformation. The risk is essentially unknown in terms of x% over y years and historically a figure of about 1–5% in 10 years has been adopted. However, it is known that that only 0.15% of pleomorphic adenomas have features of malignant change[15] and so the actual risk of transformation is probably very low.

CHOICE OF OPERATION

Pleomorphic adenomas of the submandibular gland are treated with excision of the gland. This should be extra capsular and, as a result, there is a higher rate of marginal mandibular facial nerve injury.[16] Pleomorphic adenomas

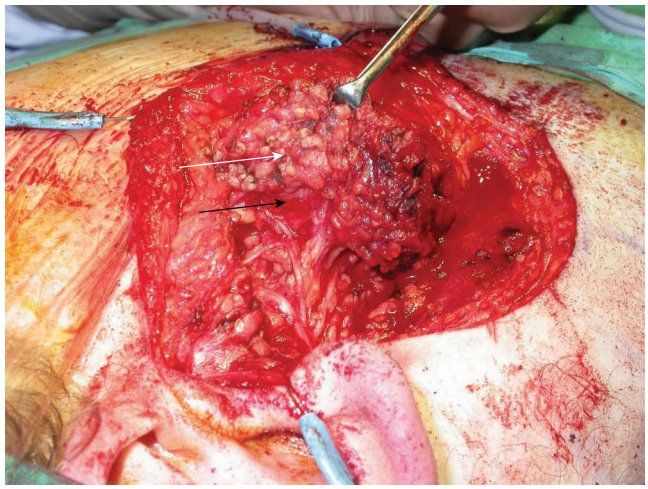

Figure 9.7 Despite taking a cuff of normal tissue, at least one aspect of the tumour capsule is adjacent to the facial nerve/branch. Partial parotidectomy with cuff. White arrow shows cuff but note black arrow show that narrowest margin is capsule only where tumour is adjacent to buccal branch of facial nerve.

of the minor oral salivary glands is treated by wide local excision.

The controversy in management of these tumours largely applies to the parotid gland. As a result of poor encapsulation and a tendency to rupture during resection, enucleation frequently results in subsequent recurrence and is an unacceptable historic practice. However, there is controversy regarding the extent of parotidectomy, from total superficial parotidectomy, through to a partial superficial parotidectomy (the tumour and a cuff of normal tissue) through to extracapsular dissection. The most common practice in the UK is partial superficial parotidectomy.[17]

The key theoretical argument for taking a cuff is the incomplete and thin capsule. However, most tumours, with the exception of very small tumours at the tail of the parotid, will be near the facial nerve or a significant branch thereof. This is the point demonstrated in **Figure 9.8**, i.e. there will almost always be one margin in which the tumour capsule is next to a facial nerve branch, no matter what type of operation is performed. Indeed, histological analysis shows that, even with 'standard' superficial parotidectomy, 81% had some degree of capsule exposure and this was >50% of the surface in 60%.[18]

Therefore, a less invasive approach using careful extracapsular dissection, when possible, can be justified on that basis. The majority of evidence shows at least similar rates of recurrence and facial nerve injury, with many showing lower rates of these complications and others.[19–21] These findings are not universal, but it should be noted that much evidence to the contrary involves analysis of very old data (e.g. going back to the 1960s–1980s).

If there is to be a cuff, there is no consensus as to the amount required. Many surgeons, in effect, will compromise between the two approaches, taking a narrow cuff (e.g. 1 cm) around the tumour. There is not much point in taking a large cuff e.g. a 'superficial' parotidectomy when at least one margin is likely to be negligible next to a nerve branch (see **Figure 9.8**).

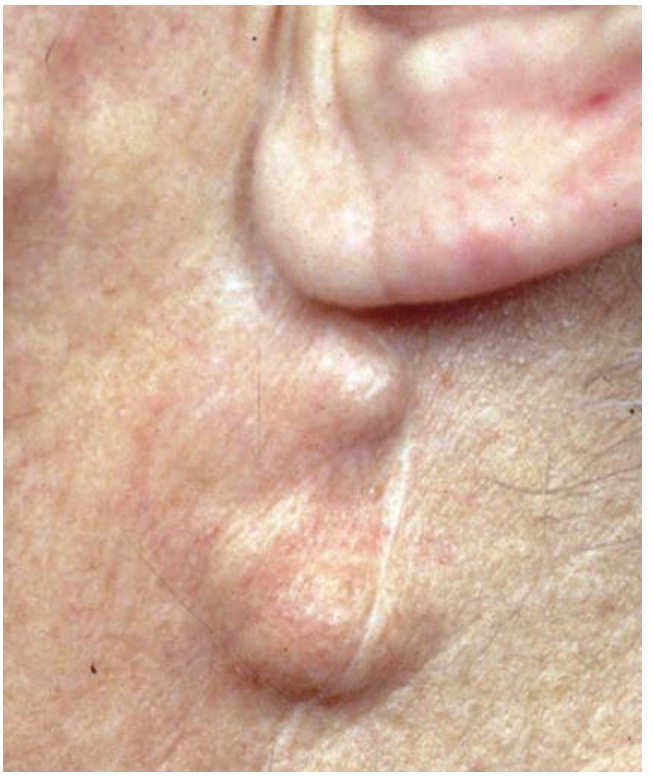

Figure 9.8 Clinical photograph showing recurrent pleomorphic adenoma presenting as multiple nodules. Note the scar from the previous surgery.

The salient argument arguments in favour of each approach are shown in **Table 9.3**.

DEEP LOBE TUMOURS

Deep lobe tumours generally require total conservative parotidectomy. However, for some smaller tumours, access via a limited superficial partial parotidectomy may facilitate an approach to the tumour inferior to the facial nerve, mobilizing just the inferior branches to access the tumour in order to perform an extracapsular dissection. This is the same approach (cervico-parotid) as for parapharyngeal tumours (which may include the deep lobe), except that division of the digastric muscle and styloid process ligaments may not be required.

PARAPHARYNGEAL SPACE PLEOMORPHIC ADENOMAS

These can be excised via a cervico-parotoid approach or, if too big and too anterior for this, via a transmandibulotomy/ transpharyngeal approach. Transoral robotic surgery offers an alternative approach, especially instead of the latter, and can be combined with a cervical approach if necessary.[22]

RECURRENCE OF PLEOMORPHIC ADENOMA

The overall recurrence rates of pleomorphic adenomas are in the region of 2% and occur typically about a decade after original surgery,[20, 23] although data from a Dutch national pathology database showed a 6.7% recurrence rate over 20 years.[15] Most recurrences are multi-centric (see **Figure 9.8**). A number of recurrences arise as a result of previous per-operative rupture or spillage of the tumour and seedlings may have been spread over a wide area, although this is probably much less the reason for recurrence than has been previously been cited anecdotally.[24]

An MR scan is the imaging of choice, both to characterize the identified recurrence(s) and detect further foci. It will also determine how much parotid tissue has been left behind after the primary surgery (which will often have been done in another institution).

Assuming the recurrence is still benign, the key issue for the surgeon to assume that this represents the last good opportunity for 'cure' with a good chance of facial nerve preservation without radical salvage surgery. In general, all remaining parotid tissue should be resected with the recurrences and the resection should be carried out mindful that there is a small but significant chance of the recurrent tumour being malignant. The necessary skills that may be required include retrograde nerve branch dissection; identification of facial nerve in mastoid; and nerve repair and cabling by micro-anastomosis. In some cases with, for example, superficial recurrence(s) only, there may be a role for limited surgery of these on the basis that this may be preferable to the significant chance of facial

TABLE 9.3 Arguments in favour for extracapsular dissection and partial parotidectomy with cuff in the surgical treatment of parotid pleomorphic adenoma

Extracapsular dissection	Partial parotidectomy with cuff or superficial parotidectomy
Recurrence rates are the same in this method as in superficial parotidectomy	On histopathology, the tumour capsule is incomplete and tumour cells extend through into adjacent tissue. Therefore, a cuff of tissue is necessary to achieve microscopic clearance and reduce chance of recurrence
Less cosmetic deformity	If the histology demonstrates an unexpected malignancy then clearance may still be adequate (if a low-grade tumour)
Lower incidence of Frey's syndrome	
There is no possible cuff in the tumour adjacent to one significant facial nerve branch in most cases	Dissecting close on the capsule may cause rupture (although when this does happen, it tends to be when dissecting capsule off facial nerve branch (i.e. no scope for a cuff here anyway)
If revision surgery is required (e.g. malignant on histopathology) then the tissue planes used to dissect and identify the main facial nerve and some braches are virginal	

nerve injury that may be inherent in formal revision parotidectomy surgery.

After a comprehensive resection, consideration of postoperative radiotherapy should be given. Radiotherapy is effective in reducing further recurrence of pleomorphic adenoma.[25]

It should be also emphasized that there is a much higher chance of malignant change within recurrent tumours, about 3%.[15] In the assessment, it is essential to

- repeat the FNAC (do not rely on the original histology)
- formally image with MR (mandatory regardless because of possible multifocality)
- get the original histology reviewed by a head and neck pathologist.

Further surgery for a second recurrence after radiotherapy is challenging in terms of minimizing morbidity and will be for disease which is, by definition, aggressive. Fortunately, these cases are rare but might include temporal bone resection, mandibulectomy and reconstruction for the resultant tissue defects as well as facial nerve reconstruction or reanimation (see **Figure 9.10**). This underlies the importance of aggressive treatment of recurrent disease at a point when it can be done in a non-mutilating fashion (i.e. at the first recurrence).[26]

Recurrent tumours of the submandibular gland should be treated with a selective neck dissection (1–3), which will remove the soft tissue that harbour recurrent disease.[16]

The management issues in recurrent disease are not straightforward and involve a working relationship between surgeon, pathologist and radiation oncologist – an example of benign disease that should be managed by a head and neck cancer multidisciplinary team.

Warthin's tumour

This tumour is also known and referred to as either adenolymphoma or papillary cystadenoma lymphomatosum. The latter terms are slightly ambiguous and tend not to be used. It accounts for 20% of benign parotid tumours. It is rare outside of the parotid gland.

The peak incidence of Warthin's tumours is in the seventh decade. Formerly, it was thought that these tumours predominantly developed in men, series quoted a 10:1 incidence ratio. More recent series suggest that this was either a misconception or that the sex distribution is becoming more equal with a male:female ratio of just 1.6:1.[27] There is a strong association between the development of Warthin's tumours and smoking and secondly a racial association in that it is comparatively rare in afro-caribbeans.[28, 29]

Warthin's tumours are comprised of lymphoid stroma and oncocytic epithelium. The lymphoid stroma suggests it arises from intra-parotid or peri-parotid lymph nodes, explaining why it is so rare in the submandibular gland, which contains no lymphoid tissue.

There is some controversy as to the exact nature of Warthin's tumours. Some studies have suggested a polyclonal origin for the epithelium, which would suggest a non-neoplastic origin for these lesions. This has led to a conclusion that Warthin's tumour arises from salivary duct inclusions within intra parotid lymph nodes, in a similar manner to the hypothesis of branchial cysts arising from epithelial inclusions within cervical lymph nodes.[30] However, other work suggests a clonal origin associated with a fusion oncogene transformation.[31]

These tumours typically grow slowly to form soft, painless swellings, usually at the lower pole of the parotid gland. They are not infrequently bilateral. A few may undergo rapid expansion possibly caused by cystic change.

Carcinomatous change in Warthin's tumours has only exceedingly rarely been reported and may, in some cases, be secondary to irradiation. Onder et al. have reported a case of poorly differentiated adenocarcinoma in a Warthin's tumour with severe dysplasia of the oncocytic cells in other areas. They have also summarized the features of 14 previous reports in the English literature. These show that the carcinomas can be adenocarcinomas, squamous cell or undifferentiated.[32] This may not represent malignant transformation as such, but represent dual pathology, or erroneous pathology.

The treatment of Warthin's tumour is generally through surgical excision. FNAC will often be diagnostic or at least suggestive of the diagnosis and most tumours are managed through a partial superficial partotidectomy. However, bearing in mind these tumours may not grow, are not associated with a significant chance of malignant transformation and often occur in the older age group, patients with Warthin's tumours can be managed conservatively with observation only, given a diagnostic FNAC result.[33]

Myoepithelioma

Myoepithelial cells are a prominent component of pleomorphic adenomas. Tumours derived solely from myoepithelial cells are rare. Myoepitheliomas are considered to be variants of pleomorphic adenoma that are characterized by overwhelming myoepithelial proliferation. A carcinomatous variant is also recognized. This tumour has no distinctive clinical characteristics. The average age at presentation is 40 years but both children and the elderly can be affected. There is no apparent predominance in either sex and all salivary glands can be affected. Management is essentially the same for pleomorphic adenomas.

Oncocytoma (oxyphilic adenoma)

Oncocytomas are rare tumours. They are predominantly tumours of those over middle age. Women, usually in the seventh or eighth decade, are more likely to be affected. The parotid glands are by far the most frequent site. These tumours are slow growing and may rarely be bilateral. Oncocytomas are benign and excision is curative. There have been occasional reports of recurrences and this is likely to be due to other nodules of tumour tissue in the gland.[34]

SURGERY

Parotid gland

Removal of the tumour within an appropriate part of the superficial lobe of the parotid gland (partial parotidectomy) is adequate treatment for the majority of tumours. Those extending into the deep lobe demand a total conservative parotidectomy, although small tumours of the deep lobe may not necessitate removal of the entire superficial lobe (but there is potential concern regarding first bite syndrome – see 'Cervico-parotid approach' below). There is growing evidence in support of extracapsular dissection, yet it still remains a minority practice for parotid tumours.[33]

INFORMED CONSENT AND MANAGEMENT OF COMPLICATIONS

Prior to superficial or total conservative parotidectomy the patient should be warned about the following serious or frequent complications.

Facial weakness

The risk of temporary or permanent facial weakness must be carefully explained as it has a very significant impact on quality of life. The risk of facial nerve damage is related to the extent of the disease, the type of resection and the experience of the surgeon. Neuropraxia usually recovers within 4–6 weeks. More severe injuries cause some degree of degeneration and recovery may never be complete and take 6–12 months or even longer to take place. The risk of permanent facial palsy is in the region of 1–2%.[20] There is a lack of clear data regarding more detail on facial nerve outcomes after parotid surgery, with grading data for example.

Sensory loss

A degree of sensory loss in the distribution of the greater auricular nerve, over the angle of the mandible and inferior two-thirds of the pinna, is unavoidable. Most patients learn to accept this deficit and few are severely troubled by it. The area of sensory loss generally decreases in the first 12 months post-operatively. If the posterior branch of the greater auricular nerve can be preserved at surgery, there may be less reduction of sensation, both long term and short term.

Cosmetic defects

The cosmetic appearance of the incision rarely causes huge concern, because the most visible components of a Blair's incision (if used) are in skin crease lines. Loss of bulk behind the ramus of the mandible may be visible, more so in thinner patients. This can be mitigated with fat transfer.

Frey's syndrome

Gustatory sweating or flushing (Frey's syndrome) is a socially embarrassing complication of parotidectomy (see **Figure 9.9**). Although it is a problem only in a minority of patients, nearly all patients have some evidence of it if tested with Minor's starch iodine test. The frequency of this complication is sufficient to warrant pre-operative explanation together with the reassurance that it is rarely significantly disconcerting. When it does emerge as a problem, simple preventive measures such as the application of

Figure 9.9 Frey's syndrome. **(a)** Classical facial blush elicited by eating flavoured crisps; **(b)** gustatory sweating demonstrated by painting the side of the face with iodine. After this had dried the face was dusted with starch powder. As soon as salivation was stimulated, sweating caused the characteristic starch-iodine reaction.

an anti-perspirant can be used. Otherwise, the standard of care is subdermal injections of botulinum toxin. These need to be repeated at 6–12 monthly intervals.

The risk of Frey's syndrome is decreased by more conservative surgery and the restoration of integrity of the superficial muscular aponeurotic system (SMAS) layer. The use of interpositional flaps (e.g. sternomastoid) can be effective, although the frequency of this complication as a major issue probably does not warrant this as a matter of routine.

Salivary fistula or collection (sialocoele)

Except in total parotidectomy, there will always be a cut surface of the parotid gland from which saliva will leak. This saliva can form a collection (sialocoele) (**Figure 9.10**) or leak through the incision (fistula). When this occurs, it tends to occur within a few days of the surgery. A collection can be quite tense and painful, especially when eating. Collections are aspirated in clinic and this may need to be repeated on several occasions. A leak will need appropriate dressing and maintenance of wound hygiene. Antibiotics should be considered to prevent or treat secondary infection that can occur. Both leaks and collections almost always settle, but it can take 1–2 weeks. Quite why salivary fistulas are not more common is unknown. It could be speculated that those with a significant volume of residual gland, perhaps with an extensive cut surface are more prone to the complication. If there has been ligation of the duct, then it will always happen. Hyoscine patches can be used to reduce saliva production. The next line of treatment when the fistula does not settle conservatively is to inject Botulinum toxin into the main/residual parotid gland (under ultrasound control) and this essentially stops saliva production within a few days and reverses with time (2–3 months).

Figure 9.10 Sialocoele after parotid surgery.

Stump neuroma of the greater auricular nerve

When the greater auricular nerve is cut, its end can form a painful neuroma. When this happens, it is often several months/over a year post-operatively. It presents as a very localized tender nodule just anterior to the superior part of the sternomastoid muscle. It can be managed by simple local excision and burying of the fresh nerve end in the muscle. The latter manoeuvre may avoid the complication. If the posterior branch of the nerve is preserved, this may also mitigate against this complication also.

OPERATIVE PROCEDURE

The fundamental principle of superficial parotidectomy is exposure of the facial nerve and then removal of the gland and diseased tissue from around it. The surgeon should be aware that the branching pattern of the facial nerve can be quite varied and that the nerve may have been displaced from its normal position by tumour. Deep lobe tumours may displace the nerve laterally. Identification of the facial nerve and safe manipulation of the tissues around it can be significantly aided by the use of a facial nerve monitor.

Superficial / partial parotidectomy (Figure 9.11)

The patient should not be paralyzed (or at least short-acting agent used only) and be placed in the reverse trendelenberg (head up) position.

Most tumours can be removed through a 'lazy S' (or modified Blair) incision. However in some cases a modified facelift incision is satisfactory and avoids a scar on the anterior (visible) part of the neck. Infiltration of the area with 1:100,000 adrenaline reduces haemorrhage and makes identification of the facial nerve slightly easier. Skin flaps are raised which contain the subcutaneous tissue superficial to the parotid fascia, including SMAS layer. The parotid is then mobilized from the cartilage of the tragal cartilage superiorly and adjacent muscles, the sternocleidomastoid and posterior belly of digastric muscles. It is at this point of the dissection that section of the greater auricular nerve becomes necessary, but preservation of the posterior branch of this nerve should be performed if possible. Wide exposure from superior to inferior, dissecting the gland off the tragal cartilage completely, mastoid tip and sternomastoid with judicious use of traction will aid identification of the facial nerve. When the tumour is around this area, the surgeon should be wary of applying too much traction, as this can cause capsule rupture.

Tragal cartilage, mastoid tip and sternomastoid with judicious use of traction and counter traction will aid identification of the facial nerve.

The facial nerve trunk is then identified. A number of anatomical landmarks facilitate this part of the procedure:

- **The inferior portion of the cartilaginous external auditory canal (tragal pointer)**. The facial nerve lies 1 cm deep and inferior to its tip. The tragal pointer is slightly mobile when retracted so care must be taken when using this as a landmark.

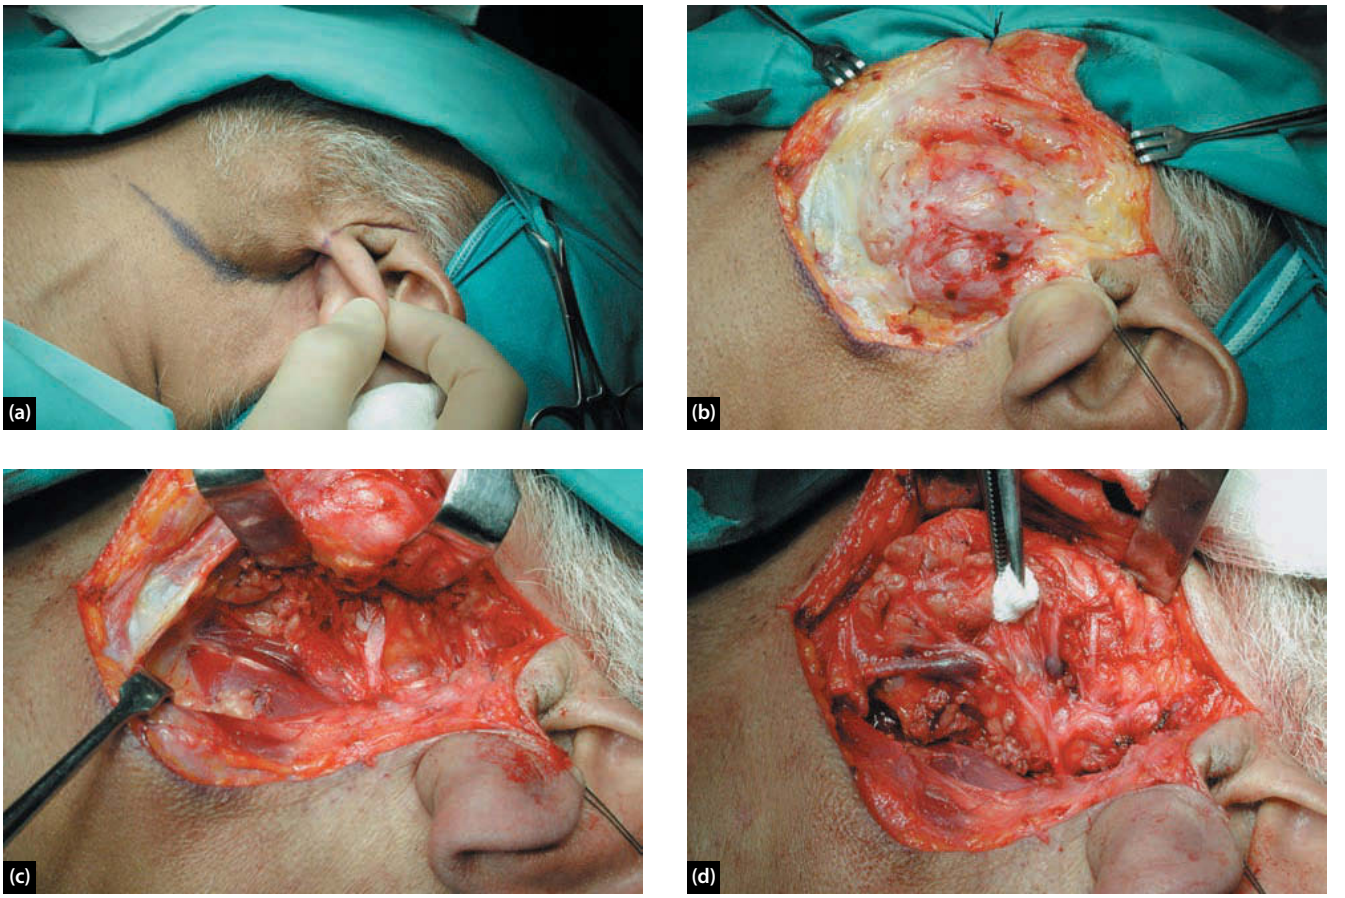

Figure 9.11 Superficial parotidectomy: (a) skin incision; **(b)** identification of posterior branch of greater auricular nerve **(c)** identification of the facial nerve; **(d)** completed dissection.

- **The tympanomastoid suture**. The facial nerve lies immediately deep and inferior to this at its point of exit from the skull. This groove is very easy to feel; and this is an extremely reliable landmark. The surgeon can, literally, get a 'feel' for where the nerve is expected to be.
- **The anterior border of the posterior belly of the digastric muscle**. The facial nerve leaves the skull immediately anterior to the attachment of this muscle. The facial nerve can be exposed by careful dissection in the area immediately anterior to the posterior belly of the digastric in the region of the mastoid process.
- **Care is needed in using the styloid as a landmark**. Whilst easy to palpate it lies deep to the exit of the nerve from the skull so dissection onto the styloid may increase the risk of facial nerve damage.

Rarely, for example in those with large or soft tumours immediately overlying the main trunk of the nerve and in surgery for recurrent disease, it is neither possible nor wise to access the facial nerve trunk at the skull base at the outset of the operation. In these cases it is better to locate and identify one of the major branches and dissect it in a retrograde manner from there. The mandibular branch can be found at the angle of the mandible, as it lies superficial to the facial vessels. The cervical branch of the nerve can be located at the point where it pierces the deep fascia below the body of the mandible. The zygomatic and temporal branches of the upper trunk cross the zygomatic arch anterior to, and within 1–2 cm of, the superficial temporal artery.

In summary, there are a variety of landmarks that can be used to aid identification of the facial nerve and its branches. With experience, the surgeon learns how and when to use this information. Whilst there is no evidence that the routine use of facial nerve monitoring for parotid surgery prevents permanent facial nerve injury[35] and UK practice is variable in this regard, most surgeons would advocate its use in difficult or revision cases.[33] Familiarity with nerve monitoring is therefore essential and it is arguably this, more than any other consideration, that makes a compelling case for its routine use in parotid surgery.

The superficial lobe, or relevant part of the parotid gland and tumour, are then dissected off the divisions and branches of the facial nerve. By this means, the superficial lobe (or part of) is separated from the deeper and other parotid tissue.

In the event of tumour rupture, which, for the reasons explained earlier, can occasionally occur despite good technique, the spillage should be contained and the tissues immediately deep to it removed, including the adjacent aspect of the deep lobe. In this way tissue contamination and seeding is minimized. There is controversy surrounding the traditional teaching of copiously irrigation with

water (not saline) in these situations. That teaching centres on the hypotonic effect on any spilled cells. However, it can also disperse the tumour cells over a wide area.

Haemostasis is then achieved and the wound closed. Drains are usually used, but may not be necessary for lesser resections especially if haemostatic tissue glue is used. Care should be exercised when placing vacuum drains, particularly if there are sections of unsupported facial nerve within the field, as they can be the cause of inadvertent neuropraxia.

Extracapsular dissection (ECD)

The principle of this operation is that the facial nerve is not formally identified. The same incision is made for a standard parotidectomy, and the tumour assessed for suitability for ECD after raising of flaps. Use of the facial nerve monitor is essential. Mobile lesions in the parotid tail are most suitable for ECD, or smaller tumours fairly superficial within the superficial lobe. Inflammatory lesions, large tumours and those extending into the deep lobe are unsuitable for ECD, as are those where malignancy is suspected. An incision is made through the fascia over the lesion and careful bloodless dissection is made down to the region of the tumour. A plane is developed between the capsule of the tumour and normal parotid tissue, with the aid of traction and counter traction from an assistant. The nerve stimulator is used prior to dividing tissue. Care should be taken if retraction distorts normal anatomy, for example if the nerve is inadvertently pulled laterally putting it at risk of damage. If there is doubt about the position of the nerve conversion to a partial parotidectomy with formal nerve identification should be undertaken.

Total conservative parotidectomy (Figure 9.12)

It may be necessary to remove the deep lobe of the gland when either tumour has developed within it or extends into it. Spillage of tumour during superficial parotidectomy is another indication for local resection of the deep lobe. In the latter case, segments of parotid tissue deep to and in between the branches of the facial nerve must be removed and this can be achieved in a piecemeal fashion.

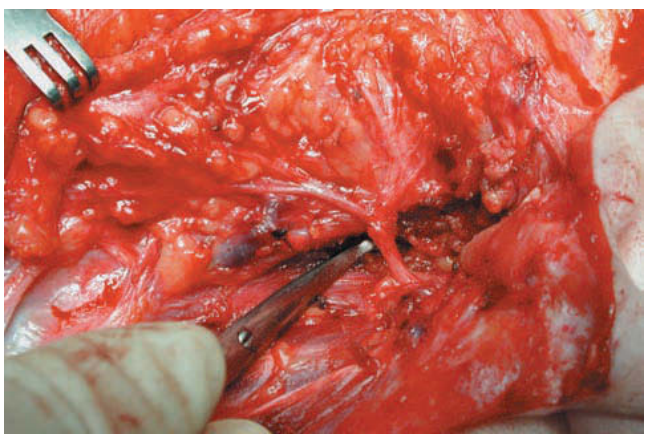

Figure 9.12 Total conservative parotidectomy: the entire gland both superficial and deep to the facial nerve has been removed.

In the case of a deep lobe tumour, usually a superficial parotidectomy is performed. This can be restricted to the inferior. The facial nerve must be mobilized with care. A plane deep to the main trunk is developed followed by more peripheral mobilization. The tumour is removed with all remaining parotid tissue, although this is scant and loose. Hence, the resection generally amounts to an extracapsular dissection.

Cervico-parotid approach to parapharyngeal space adenomas (Figure 9.13)

A complete superficial parotidectomy is not generally required. The lobe portion inferior the main facial nerve trunk and lowest main branches needs to be removed. The facial nerve can then be partly mobilized superiorly. The deep lobe is then removed (unless it is contains part of the tumour (e.g. a dumbbell tumour), in which case it is part of the resection. Access to the parapharyngeal space is then easily established, involving division of the posterior belly of digastric and all of the muscles/ligaments that attach to the styloid process. This should be done accurately, being mindful of the nearby glossopharyngeal nerve. If the process is long, gentle fracture of it can help with access. These manoeuvres allow the ramus of the mandible to be retracted anteriorly, opening up access to the parapharyngeal space.

First bite syndrome

A number of patients develop "first bite syndrome". This is intense pain in the parotid gland when just about to eat and it quickly passes after beginning to eat. There is little published literature on the subject. It probably occurs as a result of sympathetic dennervation of remaining parotid tissue. In the author's experience, treatment with botulinum toxin into the parotid gland can be effective as can high dose gabapentin or Pregabalin. However, this syndrome can be quite debilitating although patients can be reassured that it is generally self-limiting. There is a theoretical argument for performing total parotidectomy at the time of the cervico-parotid approach in order to avoid it, but this would be at the expense of cosmesis and salivary gland function.

Transmandibulotomy/transpharyngeal approach (Figure 9.14)

This is rarely needed. The cervico-parotid approach will facilitate excision of most parapharyngeal space adenomas and this can be combined with transoral robotic access if necessary.

The essential operative steps are as follows:

- Incision – skin crease with lip split. This can be curved alongside the mental skin crease, straight, or angled – all have their advocates.
- Dissection deep and under submandibular gland onto digastric/hyoglossus muscles.
- Identification of hypoglossal nerve.

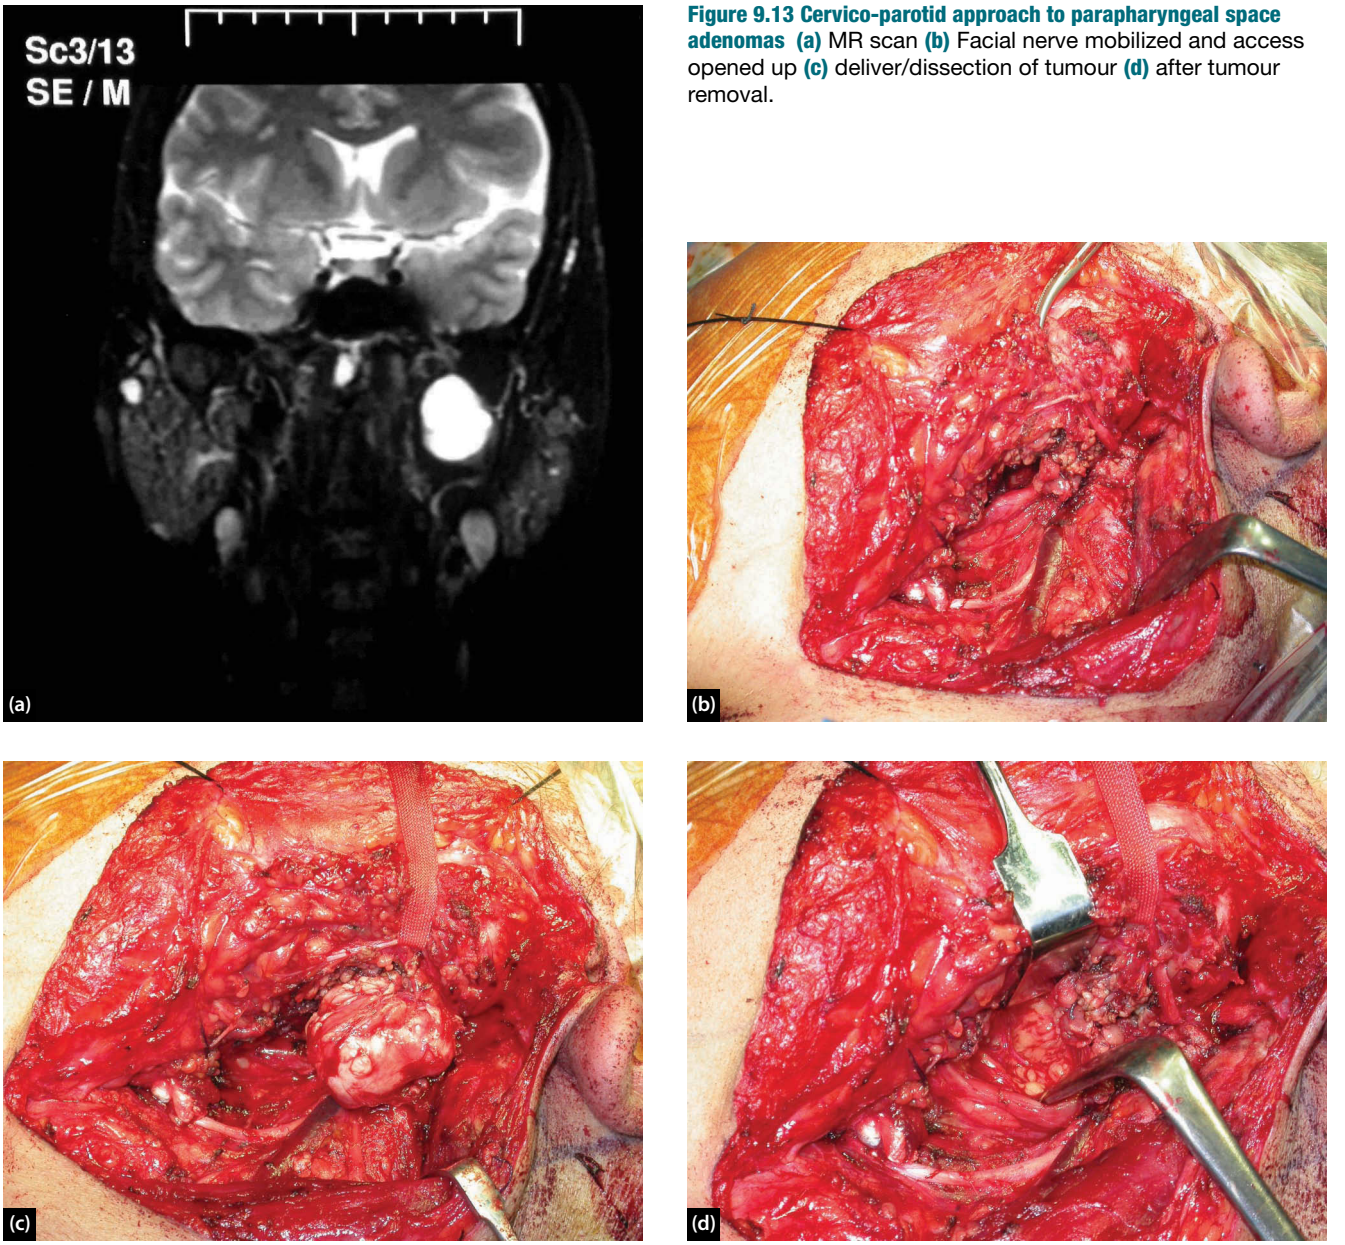

Figure 9.13 Cervico-parotid approach to parapharyngeal space adenomas **(a)** MR scan **(b)** Facial nerve mobilized and access opened up **(c)** deliver/dissection of tumour **(d)** after tumour removal.

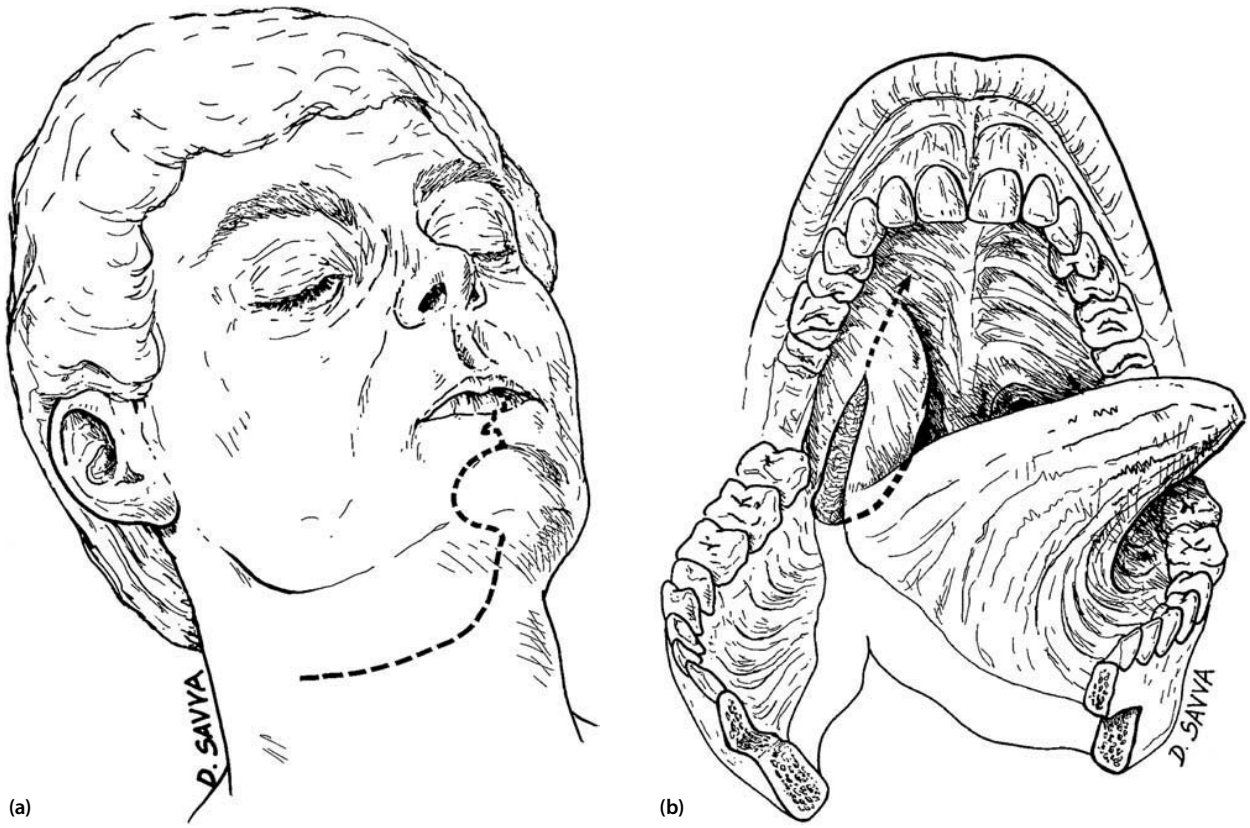
- Paramedian mandibulotomy with pre-plating (2 plates usually). A site between divergent teeth roots can be chosen but sometimes an extraction will be necessary to create the space required).
- The mandible is then retracted laterally so that the incision can be extended between the papillae of the submandibular ducts, along the floor of the mouth and up the anterior faucial pillar to the superior pole of the tonsil. During this part of the exposure the lingual and hypoglossal nerves should be identified and displaced medially, but not overstretched or cut if possible. While it is relatively simple to preserve the hypoglossal nerve, this is not the case with the lingual nerve, which is frequently damaged. Because of this, the patient must be forewarned of the probability of hemilingual anaesthesia following surgery.
- At this stage the exposure is complete and the tumour may be mobilized and removed by blunt dissection. This technique provides excellent exposure of the medial and superior aspects of the tumour which, by any other method, have to be approached blindly. However, caution should be used when dissecting the posterior aspect of the tumour, which is not infrequently adherent to the styloid process/deep parotid lobe. Traction here can cause capsular rupture.

Submandibular gland

Unlike the parotid where only a part of the gland is removed, total resection of the submandibular gland is always indicated for tumours of the submandibular gland.

INFORMED CONSENT

The patient should be warned about the following serious or frequent complications:



(a) (b)

Figure 9.14 Transpharyngeal approach to deep lobe tumours: (a) outline of skin incision; **(b)** osteotomy and opening of floor of mouth and parapharyngeal space. Figures drawn by Despina Savva.

- **Damage to the marginal branch of the facial nerve.** This may result in either a temporary or permanent weakness of the angle of the mouth that will be most noticeable on smiling and puckering the lips. The incidence of this as a permanent complication is around 2–3%.[36]
- **Lingual and hypoglossal nerve damage.** Neuropraxia of the lingual and hypoglossal nerves is unusual but possible. It is more likely to be sustained when the gland is removed for chronic sialadenitis rather than tumour as, in these cases, the gland is likely to be densely tethered to adjacent structures that become more difficult to identify and preserve. This complication is a common source of litigation and so must be included in the consent process. Motor dysfunction of the tongue initially impairs articulation and mastication but the patient rapidly compensates. Ultimately, the tongue muscles waste on that side but without further symptomatic deterioration. The incidence of these complications should be significantly less than 1%.
- **Cosmetic defects.** The patient should be reassured that a properly placed skin incision is unlikely to leave a cosmetically unsightly scar, but that this remains a possible outcome in any patient.[3]

OPERATIVE PROCEDURE

The incision is made in or parallel to a natural skin crease approximately 2.5 cm below the lower border of the mandible and extending for approximately 10 cm anterior to sternomastoid muscle (**Figure 9.15**). It is deepened through the platysma muscle and flaps developed in the fascial plane immediately beneath it. Care must be taken in development of the superior flap as the marginal mandibular branch of the facial nerve runs in the same tissue plane. This nerve enters the neck 1 cm in front of the angle of the mandible, loops over the facial artery and vein 2 cm below the lower border of the body of the mandible before sweeping superiorly to the angle of the mouth. The mandibular branch of the facial nerve can be protected from inadvertent damage by one of two manoeuvres. The facial vessels can be transected at a low level on the surface of the submandibular gland and reflected superiorly. The nerve, which lies lateral to the facial vessels, can then be lifted out of the operative field by traction on the transected end of the vessels. Alternatively, the capsule of the gland can be opened at the level of the hyoid bone and dissection continued beneath it. The elevated capsule protects the nerve in a similar fashion to the first technique. Occasionally, it is very difficult to identify the mandibular branch, and in these cases a nerve stimulator or monitor is extremely helpful.

The superficial part of the gland is mobilized by either blunt or sharp dissection and retracted posteriorly in order to expose the deep portion that lies on the hyoglossus muscle and is partly covered by the mylohyoid muscle. Retraction of the mylohyoid anteriorly, together with posterolateral traction on the gland, brings the lingual nerve, duct and more proximal part of the facial

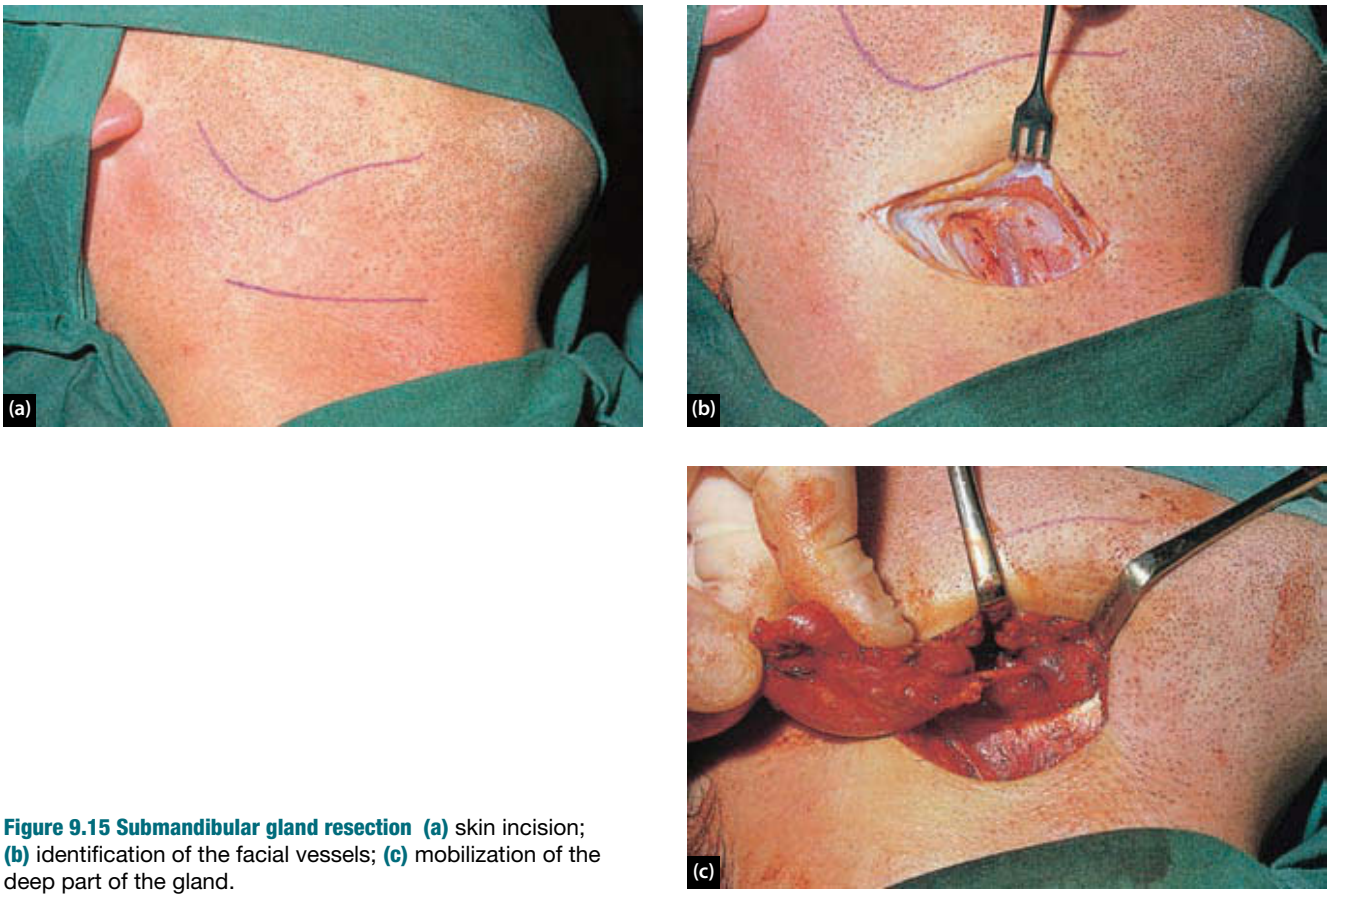


Figure 9.15 Submandibular gland resection **(a)** skin incision; **(b)** identification of the facial vessels; **(c)** mobilization of the deep part of the gland.

artery into the operative field. The lingual nerve appears as a ribbon-like band loosely attached to the body of the gland by a few fibres – the parasympathetic secretomotor supply. Section of these fibres releases the nerve from the gland and permits it to assume a more superior relation. At this stage the hypoglossal nerve may be seen inferior and parallel to the lingual nerve but is sometimes partially covered by the posterior belly of the digastric muscle. The proximal part of the facial artery is usually ligated at this point. The gland is then further mobilized from the hyoglossus muscle about its duct so that this may be ligated and transected as far anterior as possible. A small vacuum drain is inserted and brought out through the skin posteriorly. The wound is closed in two layers.

POST-OPERATIVE FOLLOW-UP

Long-term follow-up for all cases with surgically treated benign disease is unnecessary.[18] For pleomorphic adenoma, the chance of local recurrence is small; when it does occur, the median to recurrence is around a decade; and it is the patient who usually detects the recurrence.

Patients in whom long-term follow-up is advisable include those with:

- incomplete resection (as distinct from completely excised but with incomplete capsule)
- tumour rupture/spillage at operation
- complications that need management
- recurrent disease.

BEST CLINICAL PRACTICE

- ✓ A retromandibular fossa or cheek mass should be considered a salivary gland tumour until proven otherwise.
- ✓ Undertake fine-needle aspiration biopsy on all suspected salivary gland tumours, preferably under ultrasound guidance.
- ✓ Image all deep lobe tumours, those in which malignancy is suspected, congenital tumours and those patients with recurrent disease.
- ✓ Undertake an appropriate parotidectomy every time and never an enucleation.
- ✓ Use facial nerve monitoring in parotid surgery.

FUTURE RESEARCH

- ➤ There is a lack of multi-institutional prospective outcome data for benign parotid surgery.

KEY POINTS

- The incidence of salivary gland tumours is around 6–7 / 100 000 / year.
- Most of these develop in the parotid gland and are pleomorphic adenomas.
- Around 75% of salivary gland tumours are benign.
- The chance of malignancy is higher in submandibular gland and minor salivary gland tumours.
- Most benign salivary gland tumours present in an insidious fashion, growing slowly over a long period of time with little else in the way of symptoms.
- Imaging is performed in most patients. Ultrasound is the primary and initial imaging modality for benign tumours. Cross-sectional imaging should also be performed for larger tumours and complicated cases, such as suspected deep lobe extension or malignancy.
- Fine-needle aspiration biopsy should be undertaken in all salivary tumours, preferably under ultrasound control. Tru-cut biopsy is an alternative, but is usually reserved as a second line investigation.
- The degree of encapsulation of pleomorphic adenomas varies between and within tumours. Areas of deficient or complete absence of capsule are common and this predisposes these patients to recurrence.
- Some pleomorphic adenomas are extensively mucinous and consequently soft and fragile. These rupture easily if not handled with care.
- Recurrence of pleomorphic adenomas may develop many years (typically around one decade) after primary surgery and occurs in around 2% overall according to most data.
- The incidence of malignant change is low in primary disease (around 1/1000) but greater in recurrent disease (around 3%).
- Synchronous or metachronous tumours are more frequently associated with Warthin's tumours than any other salivary tumour.
- Parotid tumours can be managed by an appropriate parotidectomy (with a safe margin of normal tissue around the tumour where possible and with reference/dissection of the facial nerve) or, when possible, by extracapsular dissection (ECD).
- Submandibular gland tumours are managed by total extracapsular gland excision.

SEARCH STRATEGY

The data in this chapter may be updated by a Medline and Pubmed using the following keywords: salivary gland neoplasms, parotid gland, submandibular gland, minor salivary gland, carcinoma, review, management, molecular biology, pathology, surgery, radiotherapy and chemotherapy.

INTRODUCTION

The broad pathological classification of malignant tumours of the salivary gland comprises epithelial tumours, being the most frequently encountered (>80%), mesenchymal tumors which are a very mixed group (<20%), and haematolymphoid tumours (lymphoma and plasmacytoma) making up the remainder of the 2017 WHO classification. Epithelial salivary gland malignancies form one of the most complex diseases in head and neck oncology, due to their low incidence and heterogeneity, both in microscopic appearance and clinical behaviour. A distinction should be made between the paired major salivary glands (parotid, submandibular and sublingual) and the minor salivary glands. The latter are unencapsulated seromucinous glands distributed throughout the entire upper aerodigestive tract, numbering between 500 and 1000, with the majority (<90%) being located in the oral cavity and oropharynx.[1]

INCIDENCE

Epithelial tumours account for the majority (95%) of malignant salivary gland tumours, but are infrequently encountered. Malignant salivary gland tumours are diagnosed in 4 to 135 new patients per million in the population per year, the highest incidence being found in the Inuit community of Greenland and the Canadian Arctic.[1,2] The incidence in the United States of America (USA) is 10 new patients per million per year.[3] For Europeans, the incidence is lower; a Danish population-based study reported a comparable crude incidence of 11 per million per year,[4] with lower incidences reported elsewhere in Europe (with Belgium, the Netherlands, the UK and Finland having about 6–7 new cases per million per year).[5–8] Ethnicity and geographical location presumably account for the observed differences in incidence.[2] Interesting data on the 'population impact' of these cancers were published in the Netherlands in 1995, where 89 new salivary gland carcinomas were diagnosed

that year on a population of 15.5 million inhabitants (Netherlands Interdisciplinary Demographic Institute). When spread across the healthcare sectors, it was estimated that a General Practitioner would see one such patient in 50 years of practice, an Otorhinolaryngologist would see about one or two patients a year, and an average Head and Neck Oncology Centre about ten new patients a year.[6]

As these malignancies occur at different anatomical locations, incidence data are reported by anatomical site. Up to 70% arise in the parotid gland[4–6, 9] and typically 1–3% of all head and neck carcinomas are reported to be parotid carcinomas.[10] The World Standard Population age-adjusted incidence of parotid carcinoma in Belgium in the period 2004–2005 was 6 for men and 4 for women per 10^6 person-years, accounting for 3.9% of Belgian head and neck cancers.[5] Ten to 25% of salivary carcinomas arise in the minor salivary glands.[4, 11] The rest are submandibular carcinomas, with sublingual carcinomas being very rare. An example of the proportion is given by the population-based incidence per 10^6 person-years in the Southern Netherlands of 3.2 parotid carcinomas for men and 1.9 for women, as compared to an incidence of 1.0 for men and 0.4 for women for submandibular and sublingual malignancies.[6]

RISK FACTORS FOR DEVELOPMENT OF SALIVARY NEOPLASMS

The influence of environmental and nutritional factors on incidence has been studied in detail. Follow-up of atomic bomb survivors in Japan and atomic disaster survivors in Chernobyl[12] reveals an increased incidence of both benign (Warthin's tumour and pleomorphic adenoma) and malignant (mucoepidermoid carcinoma) salivary gland tumours.[13] The incidence of Warthin's tumour is doubled and multicentric in smokers.[14] Epstein—Barr Virus (EBV) has been implicated in the genesis of bilateral Warthin's tumours and undifferentiated parotid carcinoma.[15, 16] Cytomegalovirus (CMV) infection may have a tenuous link to the development of mucoepidermoid carcinoma, both in mice and in humans.[17] An inverse relationship exists between a diet rich in polyunsaturated fatty acids and the registration of salivary cancers.[18–23] A Danish study found an increased risk of salivary cancer in workers involved with livestock feed processing, possibly related to naturally occurring mycotoxins produced by *Aspergillus spp.* and are described as one of the most carcinogenic substances known.[24]

KEY POINTS

- The incidence of malignant salivary gland neoplasms in the western world is 7 to 12 per 1,000,000 person-years.
- Salivary malignancy increases with exposure to environmental factors, low-dose ionizing radiation and aflatoxins.
- Smoking of cigarettes is related to development of Warthin's tumours.
- EBV infection may predispose to the development of Warthin's tumour and undifferentiated carcinoma.

HISTOGENETIC THEORIES FOR TUMOURIGENESIS

The normal histology of the salivary gland differs according to their anatomical location (major and minor glands) and consists of different combinations and proportions of the basic components, the acini and the ductal system (**Figure 10.1**). Whereas the major glands have a true excretory ductal system, the minor salivary glands are composed of unencapsulated acini with a short or absent ductal system.[11]

Serous acinus cells predominate in the parotid and the submandibular gland, and form only a minority of acini in the sublingual gland. Mucous acinus cells are the main source of saliva in the sublingual and submandibular glands, and are the only source of saliva in minor salivary glands.

The duct system consists of, in increasing diameter, intercalated ducts, striated ducts and excretory ducts. The luminal cells in the ducts are well-differentiated epithelial cells. Abluminal cells, those not in contact with the lumen, consist of myoepithelial cells that are also found at the abluminal side of the acini, and pluripotent basal cells.[25, 26]

Two theories have been proposed to explain the histogenesis of the complicated appearance of normal salivary gland tissue and the complex 'multicellular' histological appearance of salivary gland tumours. The 'multicellular theory' favours a transformation of the entire

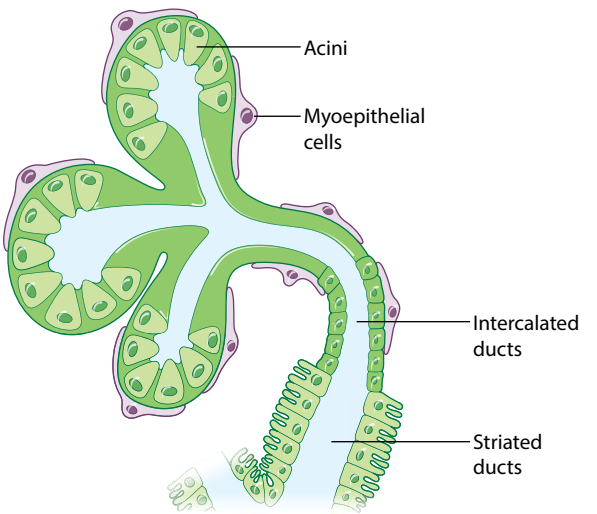

Figure 10.1 Diagram of the normal salivary gland unit. One layer of myoepithelial cells invests the terminal secretory ductoacinar unit – the intercalated duct and the acinus. Source: Tucker AS. Embryology and Clinical Anatomy. *Salivary Gland Disorders and Diseases: Diagnosis and Management*. Bradley PJ, and Guntinas-Lichius, (ed.) Reprinted by permission of Thieme Publishers.

ducto-acinar unit and requires the various 'differentiated' cells to become 'de-differentiated', deranged in their growth pattern, resulting in the microscopically different components observed in the various types of salivary gland tumours.[25] The 'reserve cell theory' states that both the normal salivary gland unit and the different tumour types are the result of differentiation of undifferentiated pluripotent precursor cells, and tumour cells originate from a problem in the normal differentiation process. The earlier in differentiation that a problem occurs, the more undifferentiated and 'high-grade' is the resulting salivary malignancy.

The role of the precursor or 'stem' cell is attributed to the 'epithelial basal ductal cells' that rest on the basement membrane at the abluminal side of the ductal system. Originally, the 'reserve cell theory' was called the 'bicellular' reserve cell theory, distinguishing two types of reserve cells, one at the abluminal side of the intercalated ducts and another at the abluminal side of the excretory ducts.[26–28] The tumours originating from the intercalated duct reserve cells are adenocarcinoma not otherwise specified (ACNOS), acinic cell carcinoma (AcCC), adenoid cystic carcinoma (AdCC), mixed malignant tumour and oncocytic tumours); those said to originate from the excretory duct reserve cells are mucoepidermoid carcinoma (MEC), squamous cell carcinoma (SCC) and salivary duct carcinoma (SDC). The reserve cell theory is supported by recent research indicating the common origin of both the epithelial, myoepithelial and the mesenchymal components of pleomorphic adenoma in exactly these epithelial basal ductal cells.[29]

CLINICAL PRESENTATION AND IMAGING WORKSHOP

The majority of tumours (64–80%) arise in the parotid glands, of which 15–32% are malignant. Seven to 11% arise in the submandibular glands with 41–45% being malignant. Less than 1% occurs in the sublingual gland, where the majority (70–90%) are malignant. Minor salivary gland tumours account for 9–23%, with +/– 80% being malignant.[1, 30]

Parotid gland

The majority of parotid tumours present as asymptomatic, discrete pre-auricular or infra-auricular lumps. With 80–90% of parotid salivary tissue being located lateral to the facial nerve (VIIN), a similar proportion of all neoplasms (benign and malignant) arise in the superficial lobe. A small percentage present only as a swelling of the soft palate or lateral oropharynx,[31] and 1% arise in the accessory parotid gland (along the Stensen duct).[32]

About 1 in 4 parotid tumours are malignant[33] and a diagnosis of a malignancy is suggested by a rapid increase in size, pain, associate cervical lymphadenopathy, fixation of the salivary mass to deep structures or facial skin (**Figure 10.2**), or the presence of VIIN dysfunction.[30] Of patients presenting with parotid cancer, 44% have pain[34]

Figure 10.2 Parotid cancer with skin invasion. Source: *Prognosis in Head and Neck Cancer*, Robert J Baatenburg de Jong, editor. V. Vander Poorten: Prognosis in patients with parotid carcinoma; Chapter 21, p 356. Reprinted by permission of Taylor and Francis.

and 25% have VIIN paresis or paralysis which is independent of the tumour size.[30, 34–41] Rarely, the presentation can be insidious. The incidence of parotid carcinoma has been estimated to be as high as 6% in patients presenting with a lower motor neuron VIIN paralysis where no aetiology has been identified after initial MRI scans. This is more likely if the paresis has been slow in onset, progressive in nature, shows no evidence of recovery, affects only isolated branches of the VIIN and if facial tics are present.[42, 43]

The evaluation should include the size, extent, location and the likelihood of the mass being benign or malignant. Imaging is strongly advised when the tumour mobility is impaired, the tumour >4 cm, the VIIN is clinically involved, and there are palpable cervical nodes.[30, 44, 45] Magnetic resonance imaging (MRI) is superior to computerized tomography (CT) in evaluating parotid tumours and allows better demonstration of the retromandibular parotid, the stylomastoid foramen area, VIIN invasion and possible perineural extension.[43, 44, 46] Conventional MRI is complementary to fine-needle aspiration cytology (FNAC) in the pre-operative assessment of a parotid mass.[47] Diffusion weighted MRI (DW-MRI) is considered to have superior diagnostic efficacy in identifying malignancy based on a specific diffusion pattern.[48] Where malignancy is suspected, appropriate imaging should be performed to exclude distant metastases.[49] Positron emission tomography/CT (PET-CT) imaging has high false-positive rates in differentiating benign from malignant salivary disease as common benign tumours (Warthin's tumours and pleomorphic adenomas) demonstrate an increased FDG uptake.[50]

Submandibular gland

Most patients present with a slow-growing, painless mass or swelling under the jaw or occasionally present with distortion of the floor of the mouth, accompanied in exceptional cases by skin invasion or ulceration or even more rarely with local nerve paresis or paralysis. The hypoglossal nerve is most at risk, followed by the trigeminal nerve and then the mandibular branch of the VII nerve. Thirty percent of patients complain of local pain suggesting local tissue extension.[51] Cervical lymphadenopathy is present in 25% of patients. The median symptom duration in the patient group of The Netherlands' Cancer Institute was 13.5 months, ranging from <1 month to >27 years. The median duration of complaints may range from 3 years for low-grade malignancy to 6 months for high-grade malignancy.[52–56] Evaluation of submandibular gland malignancies by radiological imaging is similar to the principles for the parotid gland.

Minor salivary glands (MiSG)

As MiSG are found throughout the entire upper aero digestive tract, the signs and symptoms depend upon the anatomical site involved. The majority of patients diagnosed are in the 5th to 6th decade, but tumours have been documented in children.[11, 56, 57] Fortunately, when diagnosed in children MiSG cancers are low-grade and can frequently be excised with clear margins.[58] Akin to the normal distribution of salivary glands, the most frequent sites of MiSG cancer development are the oral cavity and oropharynx. The most frequent primary site is the hard palate, where MiSG density is highest. The classical presentation is as a painless submucosal swelling, with fixation of the tumour to the overlying mucosa. There may be a small central area of ulceration. Some patients present complaining of their dentures not fitting comfortably as the tumour alters the positioning of the dentures (**Figure 10.3**). When MiSG tumours present in the nose and pharynx, most patients present with obstructive symptoms. Pain or paraesthesia as a complaint has been recorded in >26% of patients[11, 59] and, when present, MRI is required to evaluate named nerve invasion.[60, 61] The presence of regional metastasis is reported in 1 out of every 6 patients.[11, 62, 63]

To estimate the anatomical involvement of the disease process aiming to predict the likelihood of surgical management it is mandatory that CT +/– MRI is performed. Recent reports suggest that the T-max (time to maximum contrast enhancement) in contrast to enhanced MRI scanning is helpful in differentiating benign from malignant MiSG tumours.[64] DW-MRI, which is of value for the pre-operative identification of malignancy based on the tissue-specific diffusion pattern of major salivary gland tumours, has not been studied specifically for MiSGC.[48]

Figure 10.3 (a) and (b) MiSGC of palate with ill-fitting denture. Source: *Squamous cell cancer of the neck*, Robert Hermans (ed). V. Vander Poorten: Epidemiology, pathology and clinical presentation: Chapter 1: p. 15. Reprinted by permission of Cambridge University Press.

It can be questioned however whether this complex imaging will yield any additional information, when, for MiSG tumours, an incisional diagnostic biopsy is necessary and will provide the histological information needed to plan further treatment. As stated above for major salivary gland cancers, PET with or without CT is useful for the exclusion of metastatic disease.[65]

STAGING OF SALIVARY GLAND CANCERS

All patients should be staged as per the TNM system used for major salivary gland cancers following evaluation (**Table 10.1**).[66] Minor salivary gland cancers are staged as per the anatomic site they originate in.[11, 56, 59, 63, 67–69] The use of a uniform classification system, such as the TNM, allows comparison of outcomes following different treatments to similar tumour stages. TNM components also have an independent prognostic role as shown by numerous studies, which help define and refine guidelines for treatment.[10, 37, 41, 70–73] Similar to major salivary gland cancer, the TNM components and stage groupings for MiSG cancers have been found to be the strong prognostic factors,[11, 56, 63, 74–76] and many studies report that TNM overrules the histological grade.[11, 56, 63, 68] Carrillo attributed an additional independent prognostic value to grade for oral and oropharyngeal MiSG cancers, in addition to anatomical extent as reflected in UICC stage.[57, 77]

KEY POINTS

- The smaller the salivary gland, the less frequent a tumour is likely to manifest, but when it does the more likely is the tumour to be malignant.
- Parotid tumours
  - rapid increase in size or volume, the presence of pain, enlarged neck lymph nodes, fixation to deep structures or skin, or VIIN dysfunction should alert a likely diagnosis of malignancy
  - tumour imaging aims to estimate the extent (summarized in the TNM classification), location and probability of malignancy
  - MRI scanning is mandatory to evaluate invasion of the VIIth nerve, fixation to the deep structures, location at the stylomastoid foramen or deep lobe with the use of CT imaging to evaluate suspected bone invasion.
- Submandibular tumours, although frequently symptomless, are often malignant.
- MiSG tumours commonly present at an advanced disease stage and their extent is summarized as per the TNM classification for that anatomic location.

PRE-TREATMENT HISTOPATHOLOGY TYPING

Accurate characterization of the histology of any malignant tumour is a crucial part of the diagnostic workup. This will confirm true salivary origin of the tumour and permit appropriate treatment planning.

TABLE 10.1 8th Edition (2017) UICC TNM classification and stage regrouping for major salivary gland malignancies

T – Primary Tumour	
Tx	Primary tumour cannot be assessed
T0	No evidence of primary tumour
T1	Tumour 2 cm or less, without extraparenchymal extension*
T2	Tumour >2–4 cm, without extraparenchymal extension
T3	Tumour >4–6 cm, and/or extraparenchymal extension
T4a	Tumour invades skin, mandible, ear canal and/or VIIth nerve involvement
T4b	Tumour invades base of skull, and/or pterygoid plates and/or encases carotid artery
N – Regional Lymph Nodes	
N1	Metastasis in a single ipsilateral node, 3 cm or less in greatest dimension, without extranodal extension
N2a	Single ipsilateral node >3–6 cm, without extranodal extension
N2b	Multiple ipsilateral nodes <6 cm
N2c	Bilateral or contalateral nodes <6 cm
N3a	Node(s) >6 cm, without extranodal extension
N3b	Single or multiple nodes, with extranodal extension**
M – Distant Metastasis	
M0	No distant metastasis
M1	Distant metastasis

Stage Grouping			
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
	T1, T2, T3	N1	M0
Stage IVa	T4A,	N0, N1, N2M0	
	T1, T2, T3, T4a	N2	M0
Stage IVb	T4B	any N	M0
	Any T	N3	M0
Stage IVc	Any I	any N	M1

* extraparenchymal extension is clinical or macroscopic invasion of soft tissues or nerve, other than those listed under T4a and T4b. Microscopic evidence alone does not constitute extraparenchymal extension for classification purposes. Reproduced with permission.[66]

** The presence of skin involvement or soft tissue invasion with deep fixation/tethering to underlying muscle or adjacent structures or clinical signs of nerve involvement is classified as clinical extra nodal extension. Midline nodes are considered ipsilateral nodes.

Fine-needle aspiration cytology

FNAC is an important tool in the diagnosis of salivary neoplasms. Accurate tumour typing is not to be expected as a routine, but when performed by an experienced cytologist, FNAC is safe, associated with minimal morbidity and is a reasonably accurate way to differentiate between malignant and benign lesions (accuracy 79%).[78–80] This information aids with the prioritization and timing of

treatment, with the planning of the excision and possible reconstruction, and allows for appropriate counselling. Performing FNAC with ultrasound guidance (UgFNAC) not only helps with diagnosis of the primary tumour but also aids with synchronously staging of the neck and is to be recommended.[46] Immediate on-site processing and evaluation of the cellular quality of the aspirate should be provided, and if the aspirate is deemed unsatisfactory the FNAC can be repeated; this results in higher diagnostic accuracy.[44, 81, 82] The real-life performance of this technique can be deduced from a large French series of 1355 salivary gland FNACs which were correlated with subsequent histological assessment, showing an 80.5% true positive rate, 4.6% suspicious lesions, 11.9% false negatives and 3% of uninterpretable samples.[78] Even if the FNAC suggests benign disease, removal of the tumour for further histopathology analysis remains mandatory.[83] Diagnostic accuracy of FNAC could be improved in the future by implementing high throughput techniques such as cDNA microarrays on the aspirate to give a tumour-specific overview of overexpressed oncogenes and underexpressed tumour suppressor genes.[84]

Incision biopsy

For MiSG tumours, FNAC can often correctly classify the tumour as benign or malignant, but may be unable to distinguish between subtypes or provide tumour grading. Whereas incisional biopsy is not recommended for the diagnosis of major salivary gland tumours (except for large tumours with skin ulceration or infiltration), it is appropriate for MiSG locations, where the mucosal tumour is readily accessible for biopsy and will not interfere with subsequent definitive treatment. Excisional biopsy of MiSG tumours has a high rate of positive margins, makes orientation and margin assessment of the definitive resection specimen more difficult and is not to be recommended.

The most important factor in the pre-operative evaluation is to obtain an accurate histopathologic subclassification of the MiSGC (**Table 10.2**) and, when possible, an indication of the tumour grade.[85] The caveat to interpreting these biopsies is that many salivary gland tumour types have overlapping histological features. Without seeing the interface between the tumour and the surrounding normal tissue, invasion cannot be adequately assessed which complicates differentiation between benign and malignant tumours. Similar issues are encountered in interpreting FNAC where less information is to be obtained from individual cells, without the architecture.[86] Some tumours at presentation will be at an advanced stage and the biopsy may be the only tissue sample obtained. Additional histological prognostic features, such as perineural growth (**Figure 10.4**), lymphovascular invasion, and involved margins, can usually only be obtained from a resection specimen. Increasingly, molecular biological studies are performed, and many can be carried out also on the incisional biopsy material.

TABLE 10.2 The WHO* 2017 Histologic Classification of Malignant Salivary Gland Tumours[204]

Type WHO	Abbreviation
1. Mucoepidermoid carcinoma	MEC
2. Adenoid cystic carcinoma	AdCC
3. Acinic cell carcinoma	
4. Polymorphous adenocarcinoma	PAC
5. Clear cell carcinoma	CCC
6. Basal cell adenocarcinoma	BAC
7. Intraductal carcinoma	
8. Adenocarcinoma, NOS	
9. Salivary duct carcinoma	SDC
10. Myoepithelial carcinoma	
11. Epithelial-myoepithelial carcinoma	EMC
12. Carcinoma ex pleomorphic adenoma	
13. Secretory carcinoma	
14. Sebaceous adenocarcinoma	
15. Carcinosarcoma	
16. Undifferentiated carcinoma	
17. Large cell neuroendocrine carcinoma	
18. Small cell neuroendocrine carcinoma	
19. Lymphoepithelial carcinoma	
20. Squamous cell carcinoma	
21. Oncocytic carcinoma	
22. Sialoblastoma (uncertain malignant potential)	

* WHO: World Health Organization. Modified from the WHO publication to include only the malignancies.

(ed.). *Head and Neck Cancer Imaging*, Vander Poorten V. Epidemiology, risk factors, pathology and natural history of head and neck neoplasms; Chapter 1, p. 13.

Core biopsy

There have been several recent reports discussing the added value of ultrasound-guided core biopsies (UGCB) in salivary gland tumours, with some stating that GCB is so much more accurate than FNAC, that it should become the new standard.[87, 88] There is, however, a theoretical increased risk for complications in the form of tumour seeding (not clearly reported in the literature – but probably strongly underreported) and, especially for parotid tumours, the risk of facial nerve damage (not reported, but in the practice of one of the authors, two patients were documented with VIIth nerve frontal branch damage following UGCB). As these complications are probably poorly reported, and follow-up is frequently too short to know the real effect of tumour seeding, a recent meta-analysis finding no difference between FNAC and USCB, has probably limited bearing.[89] A balanced attitude is probably that, in clinical units where FNAC is quite accurate, USCB can be utilized when FNAC is equivocal or non-diagnostic.[90, 91]

KEY POINTS

- Pre-treatment cytological assessment should be performed for major salivary gland tumours should be performed using FNAC; in selected instances UGCB can be performed, and UGCB or incisional biopsy can be considered when there is associated skin ulceration.
- Incisional or punch-biopsy for MiSG tumours is the standard of care.

SURGICAL TREATMENT

Parotid cancer

PRIMARY SITE

There is strong evidence that primary surgical excision of parotid cancer is the treatment modality providing the best chance of cure.[9, 71, 92] The extent of primary surgery is determined by the size of the lesion, the relationship to the VIIN and extraparotid tissue invasion. The majority of parotid cancers (80%) are located in the superficial or lateral parotid lobe, with a normal functioning VIIN. Performing the standard superficial or lateral parotidectomy would appear to be adequate in the majority of small cancers. Until a prospective randomized evaluation proves the oncological benefit of removing the deep lobe to address occult metastatic disease, to date very little local recurrence has been observed in tumours that are well localized in the superficial lobe and that are adequately removed. It is very likely that the use of post-operative radiotherapy will also aid with the control of possible located microscopic deep lobe lymph node deposits.[93]

Tumours <4 cm, located in the parapharyngeal or deep lobe, or with VIIN involvement should have a more extended surgical procedure, such as a total or radical parotidectomy (**Figure 10.5**). The reasoning for a total parotidectomy is that in locally advanced, high-grade parotid malignant salivary tumours, intraparotid lymph nodes may harbour metastatic disease and be overlooked or not resected should a lesser procedure be performed.[33, 94, 95] Indeed, Armstrong et al. showed that the parotid lymph nodes are involved in 53% of elective neck dissections.[96] Most pre-operatively intact nerves can be dissected macroscopically free from the tumour. VIIN branches are only to be resected when pre-operatively paralyzed or peri-operatively invaded by or surrounded by tumour.[97] More sensitive than clinical examination is electromyography and this can be performed in suspected malignant tumours to support in counselling the patient on the possible need for nerve resection and reconstruction.[98] There is consensus that microscopic disease left behind on a spared nerve branch can be controlled by the use of post-operative radiotherapy.[38, 71, 83, 97, 99, 100] Nerve sacrifice in these instances often induces disproportionate morbidity at the expense of minor gain in tumour control.[39, 97, 100] When the facial trunk or branch resection has been performed, frozen section of the cut margins is recommended to avoid the possibility of leaving tumour skip metastases. Immediate cable grafting results in optimal functional outcomes. The greater auricular nerve (GAN) combines easy access, good diameter and adequate arborization; [101, 102] for longer defects the same donor nerve can be traced back to include cervical sensory branches. The sural nerve is a good alternative.[98] Electromyographic (EMG) signs of reinnervation appear after 4.5 months, followed by the first movements about the 6th month. It can be up to 2 years before the final function is realized, usually a House-Brackman grade III to IV.[98, 101, 102] Factors that negatively impact on the final result of nerve grafting include age >60 years and the presence and duration of the pre-operative VIIN dysfunction.[98] Radiotherapy does not impair the final results of cable grafting: Brown et al. reported a House-Brackmann grade III or IV in 69% of irradiated patients versus 78% of non-irradiated patients (p = 0.54), and replicated previous reported experimental findings of 80% axon recovery in both irradiated and non-irradiated facial nerves.[102, 103]

NECK DISEASE

N+ neck

Parotid cancer related cN+ disease requires a comprehensive (modified radical) neck dissection, removing levels I to V.[104] Where appropriate, based on invasion or proximity to the metastatic disease, the non-lymphatic structures (nerve XI, jugular vein or sternocleidomastoid muscle) may need to be sacrificed.[105] Recent studies corroborated this 'old knowledge': pN+ involvement in a recent study from the Memorial Sloan Kettering Cancer Center reached 52% in level I, 77% in level II, 73% in level III, 53% in level IV and 40% in level V.[106] Also a comparable Korean study reported pN+ rates of 43% in level I, 90% in level II, 40% in level III, 57% in level IV and still 43% in level V.[107] In pN+ patients, post-operative adjuvant radiotherapy to the parotid and the ipsilateral neck doubles locoregional control and improves survival.[73, 105, 108–110]

N0 neck

In patients with a cN0 neck at presentation, performing an elective neck surgery depends on the presence of the

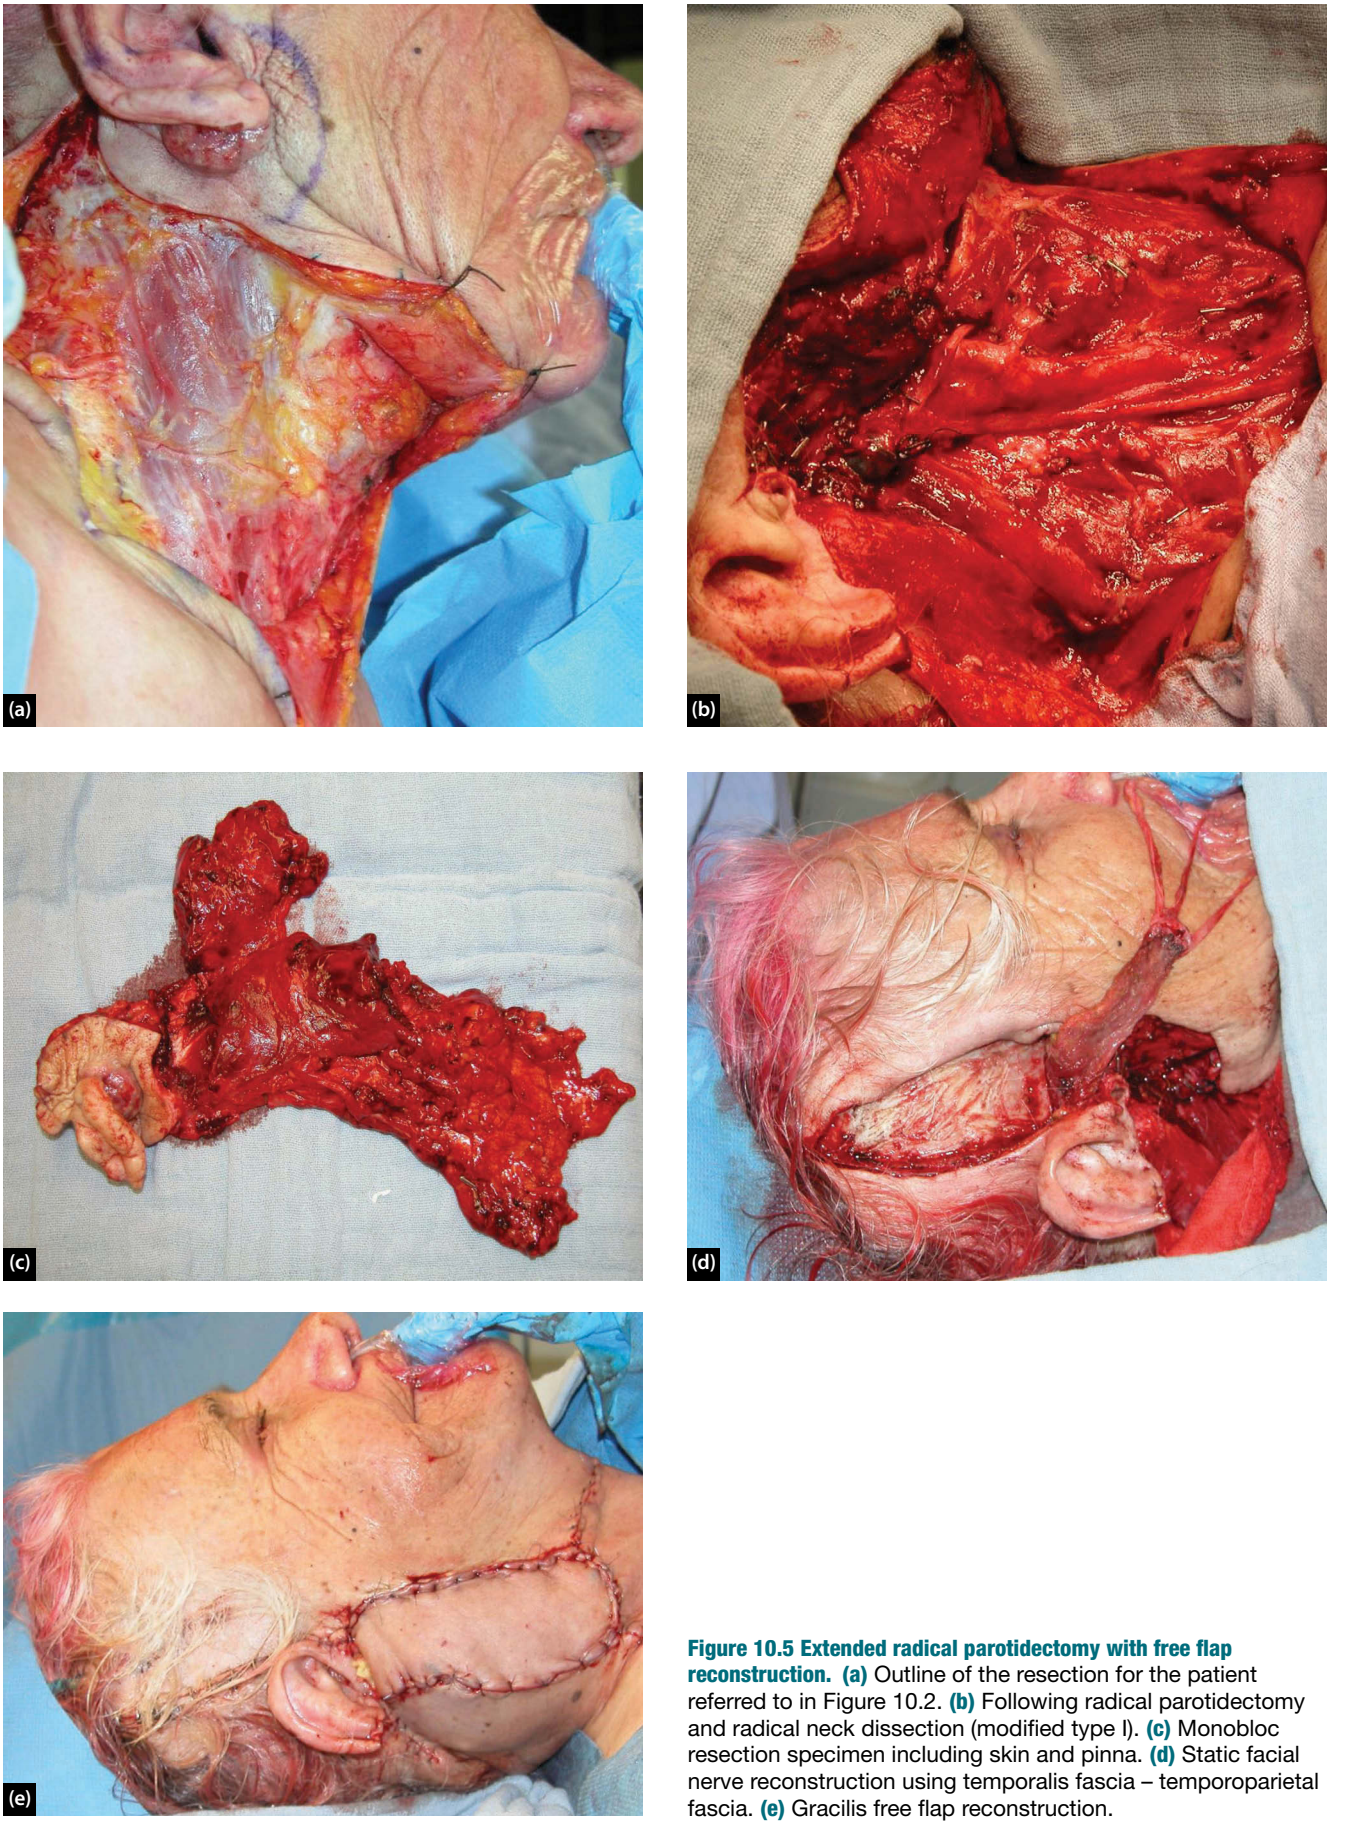

Figure 10.5 Extended radical parotidectomy with free flap reconstruction. **(a)** Outline of the resection for the patient referred to in Figure 10.2. **(b)** Following radical parotidectomy and radical neck dissection (modified type I). **(c)** Monobloc resection specimen including skin and pinna. **(d)** Static facial nerve reconstruction using temporalis fascia – temporoparietal fascia. **(e)** Gracilis free flap reconstruction.

risk factors for occult neck disease, but the alternative of using elective radiotherapy is also shown to be effective in controlling neck disease.[109] The authors routinely perform frozen section of level II nodes at the commencement of the procedure and if these contain macrometastases, we consider the neck as cN+ and proceed with a neck dissection.[41, 80, 83, 92] The recognized risk factors for the presence of occult neck disease are tumour size >4 cm and histology with clinical high-grade behaviour, implying a 20% and 49% risk for occult nodal metastasis respectively.[96, 109, 111] Age >54, perilymphatic spread and extraparotid extension, together correspond to a 95% risk.[111] These high-risk patients require elective neck treatment, be it neck dissection or radiotherapy. Parotid AdCC rarely causes lymph node metastasis, so an elective neck dissection is not really indicated in this high-grade malignancy.[92]

Some authors propose a routine elective neck dissection of for all parotid carcinoma patients; using this strategy Zbären finds a 22% occult rate and a better 5-year locoregional control as compared to that of 'an observation policy', but the patients in this series did not receive radiotherapy.[112, 113] Stennert reports even a 45% occult rate in a large series of patients all of whom underwent neck dissection.[33] A Brazilian study reported a 37% occult metastases rate predicted by T-classification, severe desmoplasia and histology (adenocarcinoma, undifferentiated carcinoma, high-grade MEC, SDC and SCC, together resulting in a 68% occult rate).[114] The surgical approach to the N0 neck can be fine-tuned using pre-operative USgFNAC of the neck and the use of peri-operative frozen section.

The MD Anderson strategy is elective radiotherapy to the N0 neck in high-risk patients, relying on definitive histopathology of the resected primary; this is appealing because the indications for elective neck treatment concur with the indications for post-operative radiotherapy to the primary, and also because pre- and peri-operative typing of salivary carcinomas is very difficult (accuracy 51–62%).[111, 115] This means that the information required to pre-operatively classify a parotid tumour as high risk is often not available during elective surgery and at the time of decision to perform a neck surgery.[44, 105, 115] Furthermore, radiotherapy may still be indicated if a cN0 neck turns out to be pN+.[93, 110] Only conducting a prospective randomized trial will answer the question whether an elective neck dissection (followed by radiotherapy if indicated) provides a better result than elective radiation alone to the cN0 neck.

Submandibular gland cancer

The standard treatment in the last decades has shifted from a rather aggressive and extended surgery as monotherapy[52, 63, 107, 116] to more limited and functional surgery, tailored to the local pathological involved anatomy, supplemented by post-operative radiotherapy.[53–55, 71, 117, 118] The typical standard operation included the submandibular gland in a radical neck dissection, often with *en bloc* excision of the floor of mouth and lower rim of the mandible.[52, 116] The move over time toward conservation surgery was illustrated by Spiro et al.,[71] who described the use of level I-II-III neck dissection for none of the patients in the period 1939–1965 to 38% of the surgeries in the study period 1966–1982. In the Netherlands' Cancer Institute, the level I-II-III dissection comprising the submandibular gland was used, in the cN0 neck and absence of invasion of bone or floor of mouth, and accounted for 66% of operative procedures in the period 1973–1983 and for 71% of the procedures between 1984 and 1994.[55] The current agreement is that for early stage, low-grade disease, the minimal procedure that should be performed, should be complete excision of the gland within a levels Ia and Ib lymph node dissection. For most other disease that is further cN0, a level I-II-III elective dissection encompassing the submandibular gland is the recommended extent of surgery. This operation should only be extended beyond the boundaries of the supraomohyoid dissection, if the local extension of the disease dictates so.[53] Commonly there is cN+ disease, and then a comprehensive neck dissection is mandated.[119]

Sublingual gland cancer

AdCC is the most common malignant tumour of the sublingual gland (72%), followed by MEC, however other SGC have also been reported, usually as case reports. The initial treatment should be surgery, performed after confirmation of histology and imaging, to encompass the extent of the primary tumour. Tumours <2 cm in size and mobile may be resected intraorally but it is also recommended that the ipsilateral submandibular gland or level I be removed, as the submandibular duct is likely to be resected. Tumours >2 cm should receive an *en-bloc* resection, possibly using a 'pull through' procedure or a mandibulotomy approach. Performing an elective neck dissection (levels I–IIa) may facilitate such a surgical procedure in the N0 situation. In the N+ neck, a therapeutic neck dissection such as a modified radical neck dissection should be performed. Adjuvant post-operative radiotherapy is indicated for patients with advanced stage disease (stage III/IV, high-grade tumours, perineural involvement, positive surgical margins, >2 N+ lymph nodes and/or pathological evidence of extracapsular extension.[120]

KEY POINTS

- The preferred treatment of parotid and submandibular gland cancer treatment is surgery.
- VIIN-preserving parotidectomy (allowing for microscopic remnant disease if unavoidable – followed by radiotherapy) in a patient with a pre-operatively functioning VIIN is considered the standard of care.
- Gross tumour involvement of the VIIN requires nerve resection followed by immediate cable grafting.
- The N+ neck requires surgery, the N0 neck should be treated electively surgically or by radiotherapy, depending on the risk factors.
- Post-operative radiotherapy improves locoregional control depending on the prognostic factors present.
- For submandibular gland malignancy, the minimally required surgery is a gland resection within a level I-II-III neck dissection (selective neck dissection); the indication for post-operative radiotherapy follows that for parotid gland malignancy.

Minor salivary gland cancer (MiSGC)

GENERAL CONSIDERATIONS

The primary

The treatment of choice for MiSGC is wide local resection with tumour-free margins. Resectability is determined pre-operatively, based on clinical and imaging findings, the anatomical site of origin, the histology and the available surgical expertise. These factors also determine the extent of resection necessary and the functional implications of a resection. In all reported series, resection margin status is one of the most important survival outcome prognostic factors that correlate strongly with both anatomical extent and histological type.[11, 121, 122]

The neck

Currently, surgical treatment of the neck is only indicated when 1) there is clinical or radiological evidence of regional metastasis (N+), or when 2) the risk of subclinical disease in a clinically negative neck exceeds 15–20% and when 3) the neck is surgically entered as an approach to the primary.

Clinical N+ disease occurs in about 15% of patients.[11, 123] Except in patients with high-grade cancers such as high-grade mucoepidermoid carcinoma, the occult metastasis rate is too low to justify elective surgical treatment.[124, 125] Nasopharyngeal salivary cancers are also an exception, where a high rate of occult disease has been reported following elective neck dissection in a series of patients amenable to surgery.[126] For patients with pN+ disease, post-operative radiotherapy improves locoregional control and survival.[73, 110]

SITE-SPECIFIC CONSIDERATIONS[122]

Oral cavity

The most common subsites are the palate, buccal mucosa, retromolar trigone and upper lip, accounting for +/– 75% of cases. The palate is the most common site (55%) with +/– 60% of these being malignant. In a series from the Netherlands' Cancer Institute, 78% of minor salivary gland cancers were located in the oral cavity.[11] In 149 patients with palatal MSGT seen over a 46-year period at the MD Anderson Cancer Center, malignant tumours were found in 116 patients (78%), with 50% of these tumours on the hard and the other 50% on the soft palate.

The majority (up to 90%) of the oral cavity MiSGC are MEC, AdCC and PAC.[122, 127] Akin to the growth pattern, patients with MEC tend to have localized space-occupying lesions, which present at an earlier stage compared to patients with AdCC, which display an infiltrative submucosal and perineural growth and are at an advanced disease stage when diagnosed. In the MD Anderson series, extensive disease diagnosed locally by radiological imaging showed: local bone invasion 31%, the sinonasal cavities 31%, the sinonasal cavities 31%, the pterygoid muscles 5%, the nasopharynx 3%, and intracranially 3%, but only 3% presented with detectable cervical lymphadenopathy.[75] The latter group need a therapeutic neck dissection in combination with wide excision of the primary. Resection of the primary palatal tumour may require a palatal obturator or free-tissue reconstruction, depending on the size and location of the surgical defect.

Oropharynx

There are few series focusing specifically on the oropharynx, but the tongue base is the most common site of origin. In the Netherlands' Cancer Institute series of patients the posterior tongue was the only oropharyngeal subsite involved.[11] Like in the oral cavity, the most frequent histologies are AdCC and MEC (up to 60%), followed by ACNOS. Treatment – if feasible – is surgery, ranging from transoral laser microsurgery or transoral robotic resections for smaller circumscribed lesions, to suprahyoid release or mandibulotomy and free-flap reconstructions for the larger tumours. Most resected tumours will require post-operative radiotherapy, which is detailed in 'Post-operative radiotherapy' below.

Larynx

MiSGs are found in the submucosa of the subglottis, glottis (floor of the ventricle and the undersurface of the anterior commissure) and supraglottis (especially in the aryepiglottic folds, and petiole of the epiglottis) and account for about 1% of all tumours of the larynx, both benign and malignant. The most frequent laryngeal MiSGC is subglottic AdCC, followed by MEC. Typically, these laryngeal MiSGC are diagnosed at an advanced disease stage when diagnosed, due to their submucosal growth and large size at the time of presentation. The treatment of choice is surgical resection, with endoscopic resection, open partial and total laryngectomy being the options. Post-operative radiotherapy should be considered in all patients especially when unfavourable prognostic factors are present, or in the case of cartilage, perineural or vascular invasion. Laryngeal MiSGC patients frequently develop distant metastasis, usually to the lungs.[128, 129]

Nose, paranasal sinuses and nasopharynx

AdCC is the most frequent MiSGC found in the nasal cavity and paranasal sinuses and due to its advanced stage at presentation results in a worse prognosis than in any other site of the head and neck, implying local recurrences and early perineural and hematogenous spread; around 50% present with distant metastases. Locoregional control is better in those patients receiving more radical primary surgery, with or without post-operative radiotherapy, but there is little data to support radical management over a more conservative approach. Recent progress in surgery, including endoscopic resection, facilitates local surgical radicality and improved surgical reconstruction that allows for timely and optimum post-operative radiotherapy. Use of the gamma knife for residual or recurrent disease optimizes the chances of cure and improves remaining quality of life. A significant number of patients have unresectable

disease at presentation and are treated with primary radiotherapy, explaining why the proportion of MiSGC at this subsite is overrepresented in reported series of AdCC from radiation oncology centres (e.g. 40% in the University of Florida series).[63]

For MiSGC located in the nasopharynx, the most common histology is AdCC (94%), and rarely MEC (6%). AdCC comprised 48% of a large surgical series (n = 23 accumulated during 12 years), MEC 35% and ACNOS 17%. Like MiSGC located in the nose and paranasal sinus, nasopharyngeal MiSGC presents late, typically at an advanced stage of disease with invasion of the skull base, cranial nerve paralysis and intracranial invasion. Complex surgical resections (varying approaches have been described such as lateral infratemporal middle fossa, subfrontal, midfacial degloving, lateral rhinotomy, transoral palatal or maxillary swing approach), possibly transposing or resecting the carotid artery, resection of dura and dissection of cancer from the cavernous sinus, are only possible in a minority of cases. These complex resections demand that expertise for a wide variety of reconstructive options be available, ranging from dural repair using temporalis fascia or a pericranial flap to vascularized flaps. Exceptionally for MiSGC, elective neck dissection reveals occult metastatic disease in about 50% of the patients with tumours in the nasopharynx.[126] Post-operative radiotherapy is always required and will be detailed in 'Postoperative radiotherapy' below. This strategy carries 5- and 10-year disease-specific survival (DSS) rates of 67% and 48% respectively. In non-resectable nasopharyngeal AdCC radical primary external-beam photon radiation seems a good option with a reported local control rate of 45% at 5 years and 5- and 10-year survival rates of 78% and 49%, respectively. Long-term complications may be serious and are less expected with modern IMRT techniques.

KEY POINTS

- The optimum curative treatment for minor salivary gland tumours is surgery.
- The surgical approach and resection should be dictated by the site of origin and can encompass the entire spectrum of head and neck surgical resective and reconstructive procedures.
- Meaningful clear-margin surgery is often impossible to achieve at certain sites because of the extensive local anatomical invasion by tumour at diagnosis (skull base and perineural invasion); in these instances, primary radical radiotherapy may be the first and only choice of treatment available.

RESECTED SPECIMEN: HISTOTYPING, GRADNG AND MOLECULAR STUDIES

Salivary malignancies are categorized as per the 2017 WHO classification (featuring 22 different phenotypes: **Table 10.2**). The characteristics that will also be reported include the tumour grade, and describe negative features such as perineural, vascular and perilymphatic invasion and the margins status. Increasingly, molecular biological markers are being identified and studies suggest that their usage may aid with a more accurate histologic diagnosis and prognosis.[130, 85]

Histologic typing: Light microscopy and immunohistochemistry

The primary histological diagnosis of SGCs is challenging, as can be seen in the 29% reclassification rate resulting from a new histological classification system reported by van der Wal et al.[4, 122, 123, 131] and by a substantial inter-observer variability between pathologists.[60, 132] The Netherlands' Cancer Institute series displayed a 22% reclassification rate.[11] Reclassification, interobserver variability, geographical variation and referral bias all contribute to disparities in the published literature. Only a population-based study can give an accurate idea of the incidence of different histological types.

A clear relationship between histological type and biological behaviour is often lacking, as commented by Spiro[30] and Leivo.[134] In population-based studies, most major SGCs are AcCCs (15–17%), AdCCs (16–27%), and MECs 14.5–19.2%).[8, 40] All 22 malignant salivary tumour types have been described across most sites. In most studies of MiSGCs, AdCC (32–71%) and MEC (15–38%) account for the majority of histological types and far outnumber the other histological variants.[11, 56, 57, 59, 60, 63, 67, 68, 73, 76, 134–137]

The most critical aspect of pathological examination is differentiating these tumours from benign entities, which can demonstrate overlapping histologic features. The proportion of benign to malignant varies across series; those with a higher percentage of malignant disease may suffer from referral bias seen at tertiary centres that are more likely to publish their results.[30, 63, 138]

Grading

Grading is a standard procedure that is performed as a surrogate marker for the biological behaviour within tumours of the same histological type. However, grading suffers from poor inter- and intra-examiner consistency and low independent prognostic power.[11, 56, 131, 132, 139] A clear relationship between histological grade and biological aggressiveness is thus often lacking.[133, 140] In addition, grading often has no therapeutic relevance as most salivary gland cancers are treated similarly with surgery and post-operative radiotherapy, with the exception of completely resected low-grade, low-stage MEC and polymorphous low-grade adenocarcinoma, where post-operative radiotherapy is not required.[44]

Clinical grading combines information from histological type and grade

To facilitate clinical use, the different histological subtypes are divided into low, intermediate and high grades as shown in **Box 10.1**.

BOX 10.1 Grading of salivary gland malignancies based on clinical behaviour

Low:	AcCC, PAC (formerly PLGA), and low-grade MEC
Intermediate:	AdCC and epithelial myoepithelial carcinoma
High:	High-grade MEC, SDC, carcinoma expleomorphic adenoma, ACNOS and undifferentiated carcinoma

When one chooses to work with two groups the intermediate group is clubbed with the high-grade group for the following reasons: AdCC is hard to cure often with a protracted clinical course, and epithelial myoepithelial carcinoma is linked to a recurrence rate of 40% and a DSS of only 60%.[141, 142] It must be noted that this grade assignment does not always parallel clinical behaviour.

Despite these limitations, grading is still an essential part of the workup and decision-making for the three most commonly encountered SGCs: AdCC,[140, 143–145] MEC[132, 139, 146–150] and AcCC.[85, 151, 152] As clinical grading is strongly associated with other consistent prognostic factors such as age[11] and TNM-stage,[56, 140] it is often not retained in the final model in multivariate analysis.

Molecular biology[92, 122, 153]

Protein products of various genes and their corresponding genes in salivary gland cancers have been intensively studied to identify potential prognostic factors and treatment targets.

PROGNOSTIC FACTORS

Cell cycle-based proliferation markers likely represent the endpoint of the accumulation of genetic and epigenetic events that induce deranged growth, reflecting the number of cells going through the cell cycle. The first subject to interest cell biologists in SGC were silver-staining or argyrophylic nucleolar organizer regions (AgNOR); an increased AgNOR cluster to nucleolus volume reflects proliferative activity and correlates with the degree of malignancy. Other intensively studied factors include Ki-67 expression (anti-apoptotic nuclear antigen in proliferating cells), proliferating cell nuclear antigen expression (PCNA, co-factor of DNA polymerase delta), human telomerase reverse transcriptase expression (hTERT) and TUNEL [terminal deoxynucleotidyl transferase (TdT)-mediated dUTP-biotin nick end labelling identifying DNA breaks in apoptotic cells] assays. In SGC, these proliferation markers correlate with optical grading and have prognostic power in AdCC, AcCC, SDC and MEC. Importantly, their contribution is proven by remaining independent factors in multivariate models that include classical clinicopathological factors. The advantage of these proliferation indices is that they are not too expensive, widely applicable, correlate well with prognosis and thus could improve prognostic grouping. In this respect, Ki-67 staining is probably the best studied and most readily available supplementary examination to aid in locating a specific SGC on the scale of biological aggressiveness.

Some of these proliferation markers have also been investigated as therapeutic targets and these are tabulated in **Table 10.3**. What follows is an overview of major advances in SGC molecular biology.

Growth factor receptor proteins and their ligands

Stem cell factor receptor (c-KIT, a transmembrane tyrosine kinase), angiogenesis-related growth factor receptors (VEGFR, PDGFR, bFGFR, IL-8, PlGF , TGFβ), nerve growth factor (NGF), the ErbB/HER family of human epidermal growth factor receptors (EGFR, also named HER-1 through -4 or ErbB-1 through -4), insulin-like growth factors IGF–I/II and receptor IGF-1R, and fibroblast growth factors 1 and 2 and fibroblast growth factor receptor 1 belong to this category. c-KIT is detected in 80–94% of AdCC and in 100% of lymphoepithelial-like SGCs and myoepithelial carcinomas, and in a subset of other tumours as well. In AdCC, the relation between high c-KIT expression (>50%) and grade remains unresolved. In one study this feature was significantly more common in solid type AdCC but Freier et al.[154] found the opposite: high expression only in cribriform and tubular AdCC. As for angiogenesis-related growth factor receptors, Lim et al.[155] describe a prognostic value for vascular endothelial growth factor (VEGF) expression in many SGC. In multivariate analyses, VEGF expression was associated with advanced stage and with worse DSS. EGFR identification and overexpression parallels aggressiveness in MEC, SDC, and AdCC. HER-2 has been found overexpressed in adenocarcinoma, undifferentiated carcinoma, AdCC, SDC and in 30% of MEC. Furthermore, it is a negative prognostic marker in multivariate analysis, independent of histopathological grade, tumour size and regional metastasis. On the other hand, in a recent study, ERBB1/CCND1/PIK3CA co-amplification was the most consistently observed pattern (29%). EGFR amplification correlated with distant metastasis, and the co-amplification pattern translated into a reduced survival. Aggressively behaving AdCC also displays HER-3 expression. Recently increased expression of NGF has been described in AdCC, possibly accounting for its neurotropism. Fibroblast growth factors 1 and 2 and fibroblast growth factor receptor 1 are all overexpressed in salivary gland SGC.

TABLE 10.3 Molecular targets and corresponding therapies studied in salivary gland carcinoma

Molecular target	Salivary gland carcinoma type	Molecular therapy
c-KIT	AdCC	imatinib
ErbB-1	All types	cetuximab gefinitib
ErbB-2	All types	trastuzumab lapatinib
VEGF -family	AcCC	axinitib
NFκB – proteasomes degrading its inhibitor (I-κB)-α	AdCC	bortezomib

Reproduced with permission.[92]

Cell cycle oncogenes

The above-mentioned growth factor-receptor interaction activates cell cycle oncogenes. These include sex-determining region Y-box 4 (SOX-4), nuclear factor κB (NFκB), human rat sarcoma viral oncogene homolog (H-RAS), phosphatidylinositol 3 phosphate kinase/serine-threonine protein kinase Akt (PI3K/AKT), sarcoma (Schmidt-Ruppin A-2) viral oncogene homolog (Src), signal transducer and activator of transcription 3 (STAT3), mammalian target of rapamycin (mTOR, activated by AKT regulates protein synthesis depending on nutrient availability), peroxisome proliferator-activated receptor gamma (PPARgamma), and cyclin D1. In a large microarray analysis of AdCC, Frierson et al. found that SOX-4 was the most significantly overexpressed cell cycle oncogene.[156] Furthermore, increased apoptosis following SOX-4 knockdown suggests that this oncogene exerts its activity via down-regulation of inhibitors of the NFκB pathway (inhibitor protein (I-κB)-α) and by up-regulation of apoptosis inhibitors such as survivin. Mutations of H-RAS are observed in carcinoma ex-pleomorphic adenoma, in adenocarcinoma and in almost half of MECs, where the frequency of H-RAS mutations parallels tumour grade. Cyclin D1 seems frequently overexpressed in AdCC and MEC and correlates with prognosis. In MEC, high-cyclin D1 expression follows inactivation of secreted frizzled-related proteins (SFRPs) by hypermethylation. Nuclear pSTAT3 expression seems to play a role as tumour suppressor in the absence of EGFR, HER-2, and survivin in SGC. RUNX3, a tumour suppressor gene that, when active, facilitates TGF-beta to play its apoptotic role, appears silenced by hypermethylation in AdCC. RB1-inducible coiled-coil 1 (RB1CC1) is a positive regulator for the retinoblastoma tumour suppressor (RB1) pathway, and its expression in SGC implies better prognosis, analogous to observations in breast cancer. Efforts are underway at targeting the PI3K/AKT pathway by blocking mTOR with temsirolimus.

Pleomorphic adenoma gene 1 (PLAG1) is a specific proto-oncogene found in a large percentage of pleomorphic adenomas and is transcribed and overexpressed following a t(3;8)(p21;q12) chromosome translocation resulting in β-catenin-promoter swapping. This causes deregulated expression of PLAG1 target genes by the IGF-II/IGFIR mitogenic signalling pathway. Another fusion oncogene, MEC translocated 1 gene with exons 2–5 of the mastermind-like gene (*MECT1-MAML2*), t(11;19)(q14-21;p12-13) is transcribed into a fusion protein that was initially thought to be exclusive for low-grade MEC. However, high-grade fusion-positive MEC cancers associated with advanced-stage lethal disease have now been described. For AdCC, a recurrent reciprocal translocation of t(6;9)(q22-23; p23-24) resulting in fusion gene partners comprising *MYB* gene and the transcription factor NFIB (previously reported in AdCC of breast and, lacrimal and ceruminal glands) has now been described. In both fusion-positive and a subset of fusion-negative AdCCs, high expression of the transcript Myb was found, suggesting this to be a potential target for new therapies.

Proteins involved in DNA damage repair

p53 and ERCC1 (excision repair cross-complementation group 1) belong in this category. p53 expression and p53 mutations in AdCC are generally associated with worse outcome, but a large Finnish multivariate analysis failed to confirm additional value over a clinicopathological multivariate model. This large study however did not focus on the AdCC subgroup but studied all histological types.

Proteins involved in apoptosis

The Bcl-2 group contains pro-apoptotic proteins such as Bax, Bad and Bak and anti-apoptotic proteins such as Bcl-2, Bcl-xL and survivin. Low expression of Bcl-2 corresponds to higher apoptosis and thus better prognosis, whereas high Bcl-2 expression in SGC relates to poor prognosis and advanced T and N classification. Nuclear survivin expression indicates SGC with worse prognosis.

Proteins involved in cell-cell adhesion (hemidesmosome proteins B180 and B230, E-cadherin, CDH12, α-catenin), migration (matrix metalloprotease, heparanase) and epithelial-mesenchymal transition (NBS-1 and snail) Estrogen, progesterone and androgen receptors

Estrogen receptors have been described in AdCC, whereas androgen receptors are the target of hormonal therapy in SDC.

Microarray technology gives a tumour-specific overview of over- and underexpressed tumour genes, and can be used as a prognostic blueprint of a tumour.

This guides treatment for other tumours such as breast cancer, but to date there have been only limited efforts in SGC. An application of this strategy in AdCC resulted in the identification of a novel oncogene in salivary gland oncogenesis, AQP1, the transcription of which seems epigenetically regulated by (hypo-)methylation status.

Viral aetiology

EBV has been implicated in the genesis of bilateral Warthin's tumours and undifferentiated SGC. CMV infection in mice and in humans seems related to MEC development. This awaits further validation in larger series, but the authors found the CMV protein expressed in almost all cases studied.[17] Other viruses implicated in this disease are HPV, human herpes virus 8 (HHV-8).

SPECIFICS OF THE MAIN HISTOTYPES

In population-based studies of parotid carcinoma, the majority of carcinomas are AcCC (15–17%), followed by AdCC (16–27%) and MEC (14.5–19.2 %).[8, 40] The distribution in submandibular gland cancer and MiSGC is different, with an emphasis on especially AdCC, more than MEC and ACNOS (**Table 10.4**).

TABLE 10.4 Distribution of the major histological tumour types in minor salivary gland carcinomas[122]*

Authors	No. of patients	AdCC %	MEC %	ACNOS %	CAN %	Others %

Acinic cell carcinoma (AcCC)

AcCC usually presents as a painless parotid lump and forms some 15–17% of parotid malignancies, yet they account for only 3% of all salivary gland tumours, indicating a clear parotid predilection.[162] Macroscopic pathology commonly shows a solitary encapsulated lesion but multilobulation does occur. This tumour arises from the acinic cells, but in 75% of AcCC more than one cell type is seen and the histological patterns described include solid microcystic, papillary cystic and follicular. All of these patterns may be seen in one individual tumour.[162] AcCC is generally considered low grade and is considered to have the best survival rate, but a high-grade aggressive subgroup (papillary cystic variety) has poorer prognosis.[71, 152, 161] AcCC has a long natural history and long-term follow-up is mandatory. Spiro found that the cure rate continued to drop from 76% at 5 years to only 55% at 15 years and other authors have found the same.[156] Clearly, this can be an aggressive tumour that should be treated accordingly – early attempts at enucleation yield disastrous survival figures.[163, 165] It is generally accepted that one should not hesitate to use post-operative radiotherapy, which can only be omitted for low-stage AcCC in absence of adverse prognostic factors.[83, 92, 110]

Mucoepidermoid carcinoma (MEC)[122]

Whereas AdCC is the most frequent MiSGC overall, MEC is the most frequent type at the intraoral subsite. MEC represents about 16–37% of all MiSGCs, but about 36–59% of intraoral MiSGCs. As in many salivary malignancies the tumour is formed of several cell types, in MEC there are mucus-secreting cells, epidermoid cells and intermediate cells. The prognosis of MEC is mainly influenced by clinical stage, histological grade, and surgical margins, all strongly interrelated factors. In grading MEC, two- and three-tiered systems have been advocated. Batsakis et al.[162] follow the suggestion of Healey et al.[148] for a three-tiered system, based mainly on the involved cell types. Healey found in univariate analysis that recurrence rates of low- and intermediate-grade carcinomas are quite similar with a recurrence rate of 6% and 20% for low- and intermediate-grade MEC respectively, vs. 78% for high-grade carcinomas. The Armed Forces Institute of Pathology (AFIP) also proposed a three-tiered grading system, based on different criteria, and promoted a more quantitative approach but the clinical data supporting this complicated grading system are not convincing. Brandwein et al. showed a good correlation of these AFIP grades with stage and local control, but revealed a significant grading disparity among five experienced oral pathologists using the 'standard AFIP grading criteria'.[132]

More appealing to clinicians are simpler two-tier grading systems. Evans[150] suggests that >90% solid tumour in MEC indicates a high-grade histology, with only univariate analysis supporting this; Ciccolallo et al. suggest that >90% epithelial cells should be interpreted as high-grade histology, supported by the observation that patients with low-grade tumours have a 5-year survival of 96% whereas high-grade tumours show a death rate 10 times this. Recent large studies find no prognostic difference between low- and intermediate-grade MEC.[167] To summarize, in clinical practice only the low-grade subgroup without further negative prognostic features should be managed with surgery alone. In the intermediate-grade MEC group many patients will have additional negative prognostic factors (e.g. involved surgical margins or soft tissue invasion) that will be an indication for adjuvant radiotherapy.

Adenoid cystic carcinoma (AdCC)[122]

AdCC demonstrates insidious growth over many years, with a tendency for local recurrence and distant metastasis despite aggressive therapy at the primary site. Some patients have severe pain due to nerve invasion, and in the parotid gland VIIN palsy may be evident. In a study from Liverpool dealing with 108 patients with AdCC, nearly one-third occurred in the major salivary glands, and most of the remainder involved the minor glands.[168] Forty per cent of patients had oral cavity tumours and half of these were in the hard palate. Of all tumours 41% were locally advanced at presentation and 11% had distant metastases. Interestingly, revision of the pathology slides led to 15% reclassification as PLGA. In the Netherlands' series, 17% of the parotid cancers were AdCC, as were 40% of the cancers of the submandibular gland.

AdCC thus mainly occurs in the MiSG, where it is the most common subtype (32–71%) and, as shown in **Figure 10.2**, occurs mostly in the palate followed by the paranasal sinuses (14–17%). This tumour will often be diagnosed at an advanced stage, and due to the complex anatomical area in the skull base region, complete excision is frequently impossible[169] and further complicated by the propensity of AdCC for perineural extension, both in the MiSG, and in the parotid and submandibular glands, where large nerves are closely adjacent to the tumour. This perineural growth is notorious for skip lesions, for example, in the VIIN, isolated AdCC deposits can be observed several centimetres from where tumour invasion apparently terminated, both on frozen section and on later paraffin-section histology. The feature 'perineural growth' implies a worse prognosis.

A study from the University of Michigan showed 80% positive margins in operated skull base AdCC cases, even with tumours where experienced surgeons pre-operatively had the feeling they could resect the tumour with clear margins.[166] Every AdCC should be considered a 'clinically high-grade malignant neoplasm': the behaviour of AdCC is relentless and the long-term course is marked by multiple local recurrences, uncommon regional and yet frequent distant metastatic spread to the lungs and bones. It is often said that cure is never achieved in this disease. Sometimes optimistic 5-year survival rates are reported (e.g. 92% in an Australian series),[169] but 10- and 20-year survival rates continuously drop (e.g. in a UK series 40% at 20 years and continuing to drop until 30 years; the actuarial primary site recurrence rate in that study was 100% recurrence at 30 years,[168] and 54% in the Australian series). In a large European study, 10 years survival was 65%.[171]

AdCC uncommonly presents with lymph node metastasis, and recently an interesting hypothesis has been developed to explain this phenomenon. AdCC does produce only very limited amounts of VEGF-C, which translates into very few lymphatic vessels within the tumour due to a reduced interaction with VEGFR-3.[172]

AdCC frequently metastasizes to bone and liver, but most frequently to the lung, in approximately 70% of patients in most series. The latter metastases, although alarming to the oncologist and the patient, frequently grow slowly. A Japanese study analyzed 30 patients where 21 had pulmonary metastases, 4 of these at presentation and 17 during follow-up, and showed a cumulative incidence of distant metastasis in 100% of patients followed for longer than 5 years, regardless of grade and initial stage.[173] The average tumour doubling time of a metastatic deposit was just over one year, which is very slow, compared with lung metastases from other cancers. This tumour doubling time suggests that distant metastasis is often present long before the initial diagnosis of the primary salivary gland tumour, and this obviously puts in perspective the limits of ablative surgery for AdCC in the head and neck.

As stated above, AdCC can be graded histologically. The scheme proposed by Szanto et al.[144] indicates a primarily cribriform or tubular tumour as grade I; tumours with less than 30% solid component are grade II and tumours with greater than 30% solid component are grade III. In patients treated similarly, a solid histological pattern of AdCC carries a worse prognosis in terms of distant metastases and long-term survival on univariate analysis. In multivariate analysis, when including stage at presentation, this prognostic effect is less clear, yet a Brazilian study recently confirmed solid histology as an independent prognostic factor.[174]

Polymorphous adenocarcinoma (PAC; formerly polymorphous low-grade adenocarcinoma (PLGA))[122]

PAC, prior to 1983 considered a low-grade variant of AdCC and initially also referred to as terminal duct adenocarcinoma, has a less aggressive biological behaviour compared to other types of adenocarcinoma. About 75% of these tumours arise from MiSGs. Major salivary gland involvement is relatively unusual. It most frequently arises on the palate. Despite the better prognosis, local recurrence even with negative margins, regional recurrence and distant metastasis have all been described. Recurrence can occur very late in follow-up: in one series, local recurrences occurred at 15 years and regional recurrence occurred at 20 years after initial treatment. Therefore, the term 'low-grade' is omitted in the most recent WHO classification, which now talks about 'Polymorphous Adenocarcinoma'. There are four histological patterns: tubular, cribriform, papillary and lobular, and because of this variable appearance, P(LG)AC may be mistaken for pleomorphic adenoma or other benign tumours, and for AdCC, due to comparable growth patterns and to the presence of neurotropism. Immunohistochemical and molecular biological studies may help to differentiate these two lesions.

Adenocarcinoma NOS

This histology also forms a large subgroup in major series (8–18% of parotid carcinoma), but this proportion

depends on the effort by pathologists to revise the material. A substantial part of the tumours initially classified as adenocarcinoma not otherwise specified (ACNOS) can be specified as one of the subtypes in **Table 10.2** upon revision using modern histopathological techniques.[34, 40, 73] Nonetheless, frequently the remaining ACNOS are aggressive, with advanced locoregional extension at diagnosis and frequently implying perineural growth and positive resection margins.[41]

Carcinoma ex-pleomorphic adenoma

These tumours account for up to 5–25% of all SGC and tend to arise in the major glands.[9, 37, 112, 175] The risk of developing this carcinoma within a pre-existing pleomorphic adenoma increases with the time a pleomorphic adenoma exists, to as much as 10% by 15 years. Carcinogenesis seems associated with frequent earlier attempts at removal of a recurrent benign pleomorphic adenoma, the reason why optimal initial surgery is so much stressed upon in trainee surgeons.[177–179] The tumour may be malignant from onset or carcinomatous transformation can occur.[179] In recurrent pleomorphic adenoma, the rate of carcinoma found ranges from 7% to 16%.[177, 178, 180] In the 2005 WHO classification, for the previous term 'carcinoma ex-pleomorphic adenoma' a distinction is made between carcinoma in pleomorphic adenoma (which can be a nidus of non-invasive carcinoma in pre-existent pleomorphic adenoma or a true invasive carcinoma), the very rare and aggressive carcinosarcoma, and the metastasizing mixed tumour, in which metastases contain typical benign structures. The prognosis of a carcinoma in pleomorphic adenoma is poor: the MSKCC cause-specific survivals for this disease are 40% at 5 years, 24% at 10 years and 19% at 15 years.[181]

KEY POINTS

- The histopathological workup of SGC, i.e. typing and grading, is among the most complex areas in histopathology.
- This holds for the light microscopic, immunohistochemical and molecular biological aspects of the histopathological workup.
- Enormous advances in SGC molecular biology in the last two decades have resulted in better prognostic fine-tuning, but to date have not resulted in advances in treatment, nor in improved treatment results.

POST-OPERATIVE RADIOTHERAPY

Parotid and submandibular salivary gland malignancies

Following resection and classical histological and molecular biological workup, post-operative radiotherapy is frequently indicated in patients with salivary gland cancers. In the past, these cancers were believed to be 'radioresistant'. As an example, for submandibular gland carcinomas, Conley stated in the early 1970s[52] that there was no indication that irradiation should be given when an adequate operation has been performed; thus, only 12% of his patients were treated in a combined fashion, and there are reports of series advocating radiotherapy in less than 3% of surgically treated patients.[116] In contrast, in the Netherlands' Cancer Institute series, 67% received combined treatment, as did 59% of patients in the Princess Margaret Hospital series, Toronto, with significant reported improvement in locoregional tumour control.[54] Post-operative radiotherapy to the primary tumour used to be delivered by conformal wedged-pair beams to a dose of 60 Gy[44, 73, 110, 182, 183] but has been replaced by 3-dimensional (3D) conformal radiotherapy and lately intensity-modulated radiotherapy (IMRT), which is now considered the 'standard of care'.[184, 185]

Radiotherapy is indicated in advanced stage disease (stage III and IV) and in the presence of histopathological adverse prognostic factors. Lacking randomized trials, the evidence for this approach comes from retrospective reports, with a bias of selecting prognostically negative patients for combined therapy, yet demonstrating improved locoregional control in the combined treatment group.[51, 70, 110, 185–187] The study of the Dutch Head and Neck Oncology Cooperative Group illustrates this by a relative risk (RR) for local recurrence in surgical patients being 9.7 times the risk of patients receiving combined surgery and radiotherapy. These findings are consistent with the older matched pair analysis by Armstrong et al., describing a significantly improved DSS and local control in patients with stage III and IV disease treated with radiotherapy following resection.[108] Post-operative radiotherapy can only be omitted for stage I-II lesions in AcCC and low-grade MEC if complete resection does not reveal other adverse pathological factors (close surgical margins, perineural or perilymphatic invasion, or recurrent disease).[41, 55, 83, 92] For high-risk major salivary gland carcinomas, two reports recently documented the benefit of a post-operative platinum-based concomitant chemoradiation scheme.[188, 189]

Minor salivary gland cancer

Once the MiSGC has been resected and pathologically staged and graded, post-operative radiotherapy to the primary site is recommended for most patients. Only in 'clear margin' early stage disease (stage I and II) without lymphovascular or perineural invasion (a set of conditions usually restricted to low-grade variants), can post-operative radiotherapy be omitted without loss of disease control[11, 73, 110, 122, 125] Adverse prognostic factors, such as positive or close surgical margins,[67, 76, 125, 131] a high-grade histology,[60, 67, 125] perineural growth (particularly 'named' nerve invasion),[75, 125, 190, 191] bone and muscle invasion, paranasal sinus localization, and high T- and N-classification,[11, 67] are indications for post-operative radiotherapy. In addition to what has been said for the major salivary gland cancers, for MiSGC, proton-beam radiotherapy may be considered to reduce the risk of damage to the brain and visual apparatus in patients with

cancers involving the nasal cavity and paranasal sinuses. Improved locoregional control does not invariably lead to higher survival rates. Spiro et al.[56] were unable to demonstrate a survival benefit for patients receiving post-operative radiotherapy after matching for stage, site and histology. The unaffected incidence of distant metastases is the probable explanation: 36% of patients in the series by Garden et al, with good local control following combined treatment, eventually developed distant metastases.[67]

RADIOTHERAPY AND CHEMOTHERAPY IN UNRESECTABLE DISEASE[92, 122, 192]

Primary radiotherapy is indicated for patients who are inoperable, who refuse surgery, or who have an unresectable tumour. Unresectable SGC or resectable cancer in poor surgical candidates is controlled by conventional photon radiotherapy, with disease control rates from 17 to 57% at 10-year follow-up. The percentages at the upper limit of this range are found in series dealing with mainly early stage disease. Newer techniques such as IMRT promise better results, especially in combination with non-photon radiation, such as proton or carbon ion boost, where locoregional control seems to improve and toxicity remains limited.

Neutron radiotherapy reaches 5-year local control in up to 75% in unresectable disease, especially for AdCC, and this is ascribed to a reduced oxygen-enhancement factor, less variability of sensitivity through the cell cycle and decreased repair of sublethal cell damage. This option remains unattractive because of a lacking survival benefit (distant metastasis occurs in 40% of these patients after 51 months) and severe late side effects, including cervical myelopathy, sensorineural hearing loss, and necrosis of the soft tissues, the mandibular and temporal bone and the temporal brain lobe. Recently, the University of Washington neutron irradiation team reported even better long-term local control after giving a boost using the gamma knife at the end of neutron radiotherapy. Reports have also been published on the use of concurrent chemo-radiation for unresectable disease, showing good tumour control but with acceptable morbidity. Unfortunately, these are reports of small series and not randomized clinical trial data. For recurrent MiSGC, there have been reports on combining re-irradiation with concomitant chemotherapy, resulting in locoregional control of 72% at one year and on combining re-operation with intra-operative radiotherapy.[192]

Currently, chemotherapy remains of palliative use only in salivary gland cancer. A temporary complete remission in about 20% seems the best achievable at the moment. In metastatic ACNOS, high response rates are observed with cisplatin, doxorubicin and cyclophosphamide. Unfortunately these responses are generally short-lived. **Table 10.4** lists the explored targeted therapies that have so far been used clinically; unfortunately, none has significantly improved results. A recent high-quality meta-analysis focusing on AdCC reaches the same conclusion. In this study the activity of cytotoxic drugs given in combination was studied in 143 patients enrolled in 17 trials. In 14 studies, cisplatin-based regimens led to objective responses in 29 of 118 patients (response rate 25%). Response duration ranged from 6 to 77 months.[195] Recent phase II studies explored the combination of cytotoxic and targeted therapy (imatinib and cisplatin, and bortezomib and doxorubicin) in AdCC and concluded that the results warrant further investigation of this approach.

KEY POINTS

- Post-operative radiotherapy is a proven adjunctive treatment to surgery in the management of SGC and has a proven effect on locoregional control in most patients.
- Of all head and neck neoplasms, for SGC treatment, the recent (r)evolution towards IMRT has probably its greatest merits in improving dose delivery to the target volume, while minimizing 'collateral damage' to the non-involved surrounding healthy tissues.
- In SGC, cytotoxic chemotherapy and targeted therapies remains experimental and should be tested in clinical trial settings; to date most are of a palliative use only.

TREATMENT RESULTS AND PROGNOSIS ACCORDING TO SITE

Major salivary gland cancer: Parotid[92]

Treatment results in major treatment centres have to be appreciated in their specific context of stage, percentage high-grade, treatment period and corresponding treatment regimens, patient inclusion criteria and adequacy of follow-up (**Table 10.5**). The decision to exclude palliative intent patients in the 1999 Manchester series,[99] results in a patient cohort with relatively low stage (1 in 5 patients in Stage III-IV) and high DSS as opposed to the 1999 Amsterdam series that includes palliative patients, increasing the proportion of advanced stage disease (1 in 4 in stage IV), reflected in a lower overall DSS.[41]

Many univariate and multivariate statistical analyses have focused on identifying prognostic factors in SGC. Variables such as histological subtype,[72, 195] grade, stage, age, gender, pain, skin invasion and VIIN dysfunction, resection margins and comorbidity have been identified as statistically significant prognostic factors. Several outcomes have been used as the dependent variable, including overall survival, DSS and recurrences. However, it is difficult to meaningfully communicate the data from these disparate studies in a clinical setting.

To empower the consultation and enable effective communication of prognosis, the authors have designed a prognostic index combining several important patient and tumour-specific prognostic factors, appropriately weighted, to provide a point estimate of tumour recurrence. We constructed such an index from the Dutch

TABLE 10.5 Disease-specific survival (DSS) for parotid carcinoma

Research group	Publication year	Number of patients	DSS 5 y	DSS 10 y
Spiro[9]	1986	623	55%	47%
Spiro et al.[71]	1989	62	63%	47%
Kane et al.[10]	1991	194	69%	68%
Poulsen et al.[205]	1992	209	71%	65%
Leverstein et al.[38]	1998	65	75%	67%
Therkildsen et al.[205]	1998	251	76%	72%
Renehan et al.[99]	1999	103	78%	65%
Vander Poorten et al.[41]	1999	168	59%	54%
Harbo et al.[207]	2002	152	57%	51%
Godballe et al.[208]	2003	85	52%	
Vander Poorten et al.[40]	2003	231	62%	
Lima et al.[209]	2005	126	72%	69%
Mendenhall et al.[210]	2005	224		57%
Vander Poorten et al.[34]	2009	237	69%	58%
Guntinas-Lichius et al.[211]	2015	295	82%	82%

Reproduced with permission.[86]

patient population for the situation before (PS1) and after (PS2) surgical treatment. When the requisite data is input into the prognostic equation, the resultant score places the patient in one of four prognostic groups. This prognostic index has been validated in a nationwide and in an international database, indicating its usefulness in parotid carcinoma patients in general. It is available online at (www.uzleuven.be/parotid).[34] A recent validation effort in a Brazilian population did not show the index to have similar prognostic accuracy, but a critical analysis of the population and the methods used identified several reasons for this lack of concordance.[196]

Since the discovery of molecular biology in salivary gland research, it is likely that this new information will contribute to the prognosis. Batsakis rightly commented 26 years ago that critical multivariate assessment of putative molecular biological, clinical and pathological factors with rigorous validation will be needed.[140] Ideally this exercise should be done on a large multicentre datasets.[171]

Submandibular salivary gland

With the use of adjuvant radiotherapy, treatment results for submandibular gland cancer have improved in recent publications.[9, 116] The 5-year survival rate of 50% and the 10-year survival rate of 36% in the series of the Netherlands' Cancer Institute are comparable to the results of a nationwide analysis[6] showing a 5-year survival rate of 52%.[117, 118] An exceptionally high figure was described by Weber et al, who reported a 5-year survival rate of 69% in a population with a surprising majority of T4b disease.[53] The 5-year DSS of 61% and the 10-year DSS of 51% in Amsterdam are almost similar to the findings in Toronto with a 5-year DSS of 60% and a 10-year DSS of 48%. In the past, submandibular gland cancers were ascribed a worse prognosis than their parotid counterparts.[9, 116, 197] Recent studies[51, 70, 71, 198, 199] and our own experience[55] do not support this stance.[122]

Negative prognostic factors for survival, DSS and locoregional control are increasing age at diagnosis,[54, 55] TNM stage,[53, 54, 116–118] extra-glandular soft-tissue extension[53–55] and perineural growth.[55] As for other sites, the finding of a better locoregional control in patients with negative prognostic factors treated with surgery and adjuvant radiation evidence for the efficacy of post-operative radiation.[51, 53, 54, 70, 108, 198]

MiSG cancer[122]

Published overall survival rates vary widely, with 5-year survival ranging from 66% to 80% and 10-year survival ranging from 56% to 70%. This wide range is attributed to differences in non-tumour related deaths, referral bias and selection bias. Selection bias occurs when comparing overall results of all localizations to those of only oral or palatal MiSGCs, known to present at lower stages. Short follow-up periods do not capture long-term treatment failures. In the Netherlands' Cancer Institute series recurrences appeared up to 139 months after treatment (median 23 months). All recurrences after 5 years were in patients with AdCC. Bias can also be caused when patients with prior treatment or delayed referral, or distant metastases are excluded.

Initial tumour control after therapy is expected to be 56–62%. Distant metastasis from MiSGC in patients who are M0 at presentation seems to follow a '1 in 5 rule'. i.e. 20% of patients will develop M+ disease during follow-up.[11, 56, 76] MiSGCs overall do not imply a worse prognosis than their submandibular and parotid counterparts,

although specific involvement of subsites (e.g. the skull base) are associated with a worse outcome.

Clinicopathological prognostic factors[122]

Many univariate and multivariate statistical analyses have focused on prognostic factors in MiSGC to relate the individual's prognosis to the overall results. For example, decreasing overall survival parallels increasing age at diagnosis, but this difference is less clear for DSS where patients dying of other causes are not considered as treatment failures. Also for tumour control, the studies that include age as a prognostic parameter do not retain it as having a prognostic effect, so age alone should not determine treatment policy. In a cohort that also includes major SGC, comorbidity remained an independent factor.[201] As stated before, when a MiSGC arises in the nose, paranasal sinuses, or nasopharynx, very poor treatment results have been observed. This relationship of site to prognosis is most likely confounded by stage. Treatment of late-stage skull base MiSGC is complicated by poor surgical access. UICC Stage determines prognostically separate groups for survival, DSS and tumour control. T-classification alone also predicts all outcomes, as does increasing N classification and M1 classification.

Histologically, soft-tissue invasion including perineural and vascular invasion by the primary tumour are negative prognostic factors, as is the strongly related factor radicality of resection. The problem of surgical access to MiSGC results in a high percentage of close or positive margins, ranging from 23% or 27%[11, 137, 201] up to 40%.[67] When looking at specific sites for specific types, margins are reported in up to 80%.[170] In a homogenous series of 67 patients with oral MiSGC, multivariate analyses showed that clinical T-status, anatomical subsite and margin status were independent predictors for overall survival; T-status and margin status were independent predictors for locoregional recurrence-free survival.[202] Histopathological high grade is strongly correlated with these features. Independent prognostic power is sometimes lost due to its strong interrelationship with other negative prognostic factors. The most frequent histological type, AdCC, is considered a clinically high-grade tumour by most authors. According to da Cruz Perez et al,[199] clinical stage, solid-growth pattern and expression of p53 were the most important prognostic factors in children with AdCC. It is unclear whether grading of AdCC is useful in patient management. There is morphological overlap between solid conventional AdCC and high-grade transformation, and the transition from conventional AdCC to high-grade transformation is often gradual. Basically, the aggressive features common to both variants are more exaggerated in high-grade transformation, while solid conventional AdCC shows only slight deviation from tubular or cribriform patterns.[85, 203] Costa et al have studied the genetic profile of AdCC with high-grade transformation (HGT) versus solid type, and concluded that AdCC-HGT may not necessarily reflect a more advanced stage of tumour progression, but rather a transformation to another histological form in which the poorly differentiated forms presents a genetic complexity similar to the solid AdCC.[204] Although not frequently encountered, neck metastasis also heralds poor DSS. All of previously mentioned clinicopathological factors have been considered for their ability to predict the outcome 'positive neck disease' in a recent large-scale analysis of the Surveillance, Epidemiology, and End Results (SEER) database. The analysis yielded a simple prognostic index including the factors male gender, T3-T4 classification, pharyngeal origin of the MiSGC, and high-grade for adenocarcinoma and MECs. However, this index still needs validation.[123]

KEY POINTS

- Treatment results for both major and minor SGC are comparable and in the range of 60–70% 5-year survival and 50–60% 10-year survival.
- For an individual patient, this expected treatment result varies highly depending on an extensive list of patient-, tumour-, and treatment-related prognostic factors.
- For parotid cancer, prognostic estimates can be performed using validated online calculators.
- For submandibular and MiSGC, the clinician is dependent on the published literature to 'guess-timate' the expected outcome following treatment.

COMPLICATIONS OF TREATMENT

Parotid gland surgery[205]

The typical complication for parotid surgery is temporary or permanent facial palsy, but in experienced hands, normal function can be achieved in 96% of patients after superficial parotidectomy. Further complications are haemorrhage, infection, skin necrosis, Frey syndrome and salivary fistula.

Frey syndrome is rarely encountered in parotid cancer patients, as most of them receive radiotherapy, inhibiting its development. Treatment of this condition with topical anticholinergics is usually unsuccessful owing to poor compliance. The current treatment of choice is chemodenervation using botulinum toxin type A. The median effectiveness is 8–11 months and the treatment can be repeated. Interposition grafts that have been proposed as preventive strategies include the sternocleidomastoid muscle flap. Although there are opponents, this flap is considered effective by most clinicians. In malignant pathology there is a drawback to its use as it complicates revision surgery if needed. The same remark holds for the superficial musculoaponeurotic system (SMAS) flap, reported to be quite effective in prevention of Frey syndrome. Interposed foreign material has an unacceptable rate of complications (haematoma, seroma and salivary fistula).[206]

Paresthesia in the GAN area occurs in 57% of patients after sectioning the GAN, but 90% of patients do not report this to be cumbersome with no impact on quality of life is reported.[208] Recent evidence suggests that the posterior branch of the GAN can be saved in 2/3 of patients undergoing parotidectomy, at the expense of little extra

surgical time, resulting in sensibility returning to normal in 80–100% of patients. Furthermore, the preserved GAN can be a good interposition graft for VIIN reconstruction in surgery for malignant disease.[92]

Submandibular gland surgery

Typical surgical complications of submandibular gland cancer relate to the nerves that may have to be sacrificed in the removal of the submandibular gland for malignancy. Nerves at risk are the mandibular and cervical branches of the facial nerve, the hypoglossal nerve and the lingual nerve. Normally, the lower facial branches should not be damaged unless they loop particularly inferiorly to the mandible or a wide excision of soft tissue is necessary. Neuropraxia resulting from traction is the commonest cause of this problem; recovery is rare. Sacrifice of the hypoglossal nerve leads to paralysis of one side of the tongue but functional adaptation is good and rarely causes severe problems. Damage to the lingual nerve is less likely as it is high up behind the mandible but if damage does occur it is potentially a serious problem as the loss of sensation allows repeated trauma to the tongue from dentition. Repair tends to be unsuccessful.

Radiotherapy

Radiotherapy complications include mucositis, skin ulceration, hair loss, mandibular and temporal bone osteoradionecrosis, fibrosis, cerebral radionecrosis, hearing loss (sensorineural and conductive due to refractory external otitis) and xerostomia. With the advent of IMRT some of these complications can be abrogated.[122]

CONCLUSION

Salivary gland cancer is a particularly demanding tumour for both patient and the multidisciplinary team. Every step in the management algorithm is complicated: the clinical and radiological evaluation, the histological diagnosis, the ablative and reconstructive surgery, the adjuvant radiotherapy and the management of complications. The best care can undoubtedly be provided when these patients are centralized in specialized tertiary referral centres.

KEY POINTS

- The incidence of malignant salivary gland neoplasms in the Western world is 7 to 12 per 1,000,000 person-years.
- Salivary malignancy increases with exposure to environmental factors, low-dose ionizing radiation and aflatoxins.
- Smoking of cigarettes is related to development of Warthin's tumours.
- EBV infection may predispose to the development of Warthin's tumour and undifferentiated carcinoma.
- The smaller the salivary gland, the less frequent a tumour is likely to manifest, but when it does the more likely is the tumour to be malignant.
- Parotid tumours
  - rapid increase in size or volume, the presence of pain, enlarged neck lymph nodes, fixation to deep structures or skin, or VIIN dysfunction should alert a likely diagnosis of malignancy
  - tumour imaging aims to estimate the extent (summarized in the TNM classification), location and probability of malignancy
  - MRI scanning is mandatory to evaluate invasion of the VIIth nerve, fixation to the deep structures, location at the stylomastoid foramen or deep lobe with the use of CT imaging to evaluate suspected bone invasion.
- Submandibular tumours, although frequently symptomless, are often malignant.
- MiSG tumours commonly present at an advanced disease stage and their extent is summarized as per the TNM classification for that anatomic location.
- Pre-treatment cytological assessment should be performed for major salivary gland tumours should be performed using FNAC; in selected instances UGCB can be performed, and UGCB or incisional biopsy can be considered when there is associated skin ulceration.
- Incisional or punch-biopsy for MiSG tumours is standard of care.
- The preferred treatment of parotid and submandibular gland cancer treatment is surgery.
- VIIN-preserving parotidectomy (allowing for microscopic remnant disease if unavoidable – followed by radiotherapy) in a patient with a pre-operatively functioning VIIN is considered the standard of care.
- Gross tumour involvement of the VIIN requires nerve resection followed by immediate cable grafting.
- The N+ neck requires surgery, the N0 neck should be treated electively surgically or by radiotherapy, depending on the risk factors.
- Post-operative radiotherapy improves locoregional control depending on the prognostic factors present.
- For submandibular gland malignancy, the minimally required surgery is a gland resection within a level I-II-III neck dissection (selective neck dissection); the indication for post-operative radiotherapy follows that as for parotid gland malignancy.
- The optimum curative treatment for minor salivary gland tumours is surgery.
- The surgical approach and resection should be dictated by the site of origin and can encompass the entire spectrum of head and neck surgical resective and reconstructive procedures.
- Meaningful clear-margin surgery is often impossible to achieve at certain sites because of the extensive local anatomical invasion by tumour at diagnosis (skull base and perineural invasion); in these instances, primary radical radiotherapy may be the first and only choice of treatment available.
- The histopathological workup of SGC, i.e. typing and grading, is among the most complex areas in histopathology.
- This holds for the light microscopic, immunohistochemical and molecular biological aspects of the histopathological workup.
- Enormous advances in SGC molecular biology in the last two decades have resulted in better prognostic fine-tuning, but to date have not resulted in advances in treatment, nor in improved treatment results.

- Post-operative radiotherapy is a proven adjunctive treatment to surgery in the management of SGC and has a proven effect on locoregional control in most patients.
- Of all head and neck neoplasms, for SGC treatment, the recent (r)evolution towards IMRT has probably its greatest merits in improving dose delivery to the target volume, whilst minimizing 'collateral damage' to the non-involved surrounding healthy tissues.
- In SGC, cytotoxic chemotherapy and targeted therapies remains experimental and should be tested in clinical trial settings; to date most are of a palliative use only.
- Treatment results for both major and minor SGC are comparable and in the range of 60–70% 5-year survival and 50–60% 10-year survival.
- For an individual patient, this expected treatment result varies highly depending on an extensive list of patient-, tumour-, and treatment-related prognostic factors.
- For parotid cancer, prognostic estimates can be performed using validated online calculators.
- For submandibular and MiSGC, the clinician is dependent on the published literature to 'guess-timate' the expected outcome following treatment.

SEARCH STRATEGY

The data in this chapter are based on a search using the following keywords: parapharyngeal tumours, carotid body tumours and paragangliomas.

INTRODUCTION

The parapharyngeal space is an intriguing compartment of the head and neck. Although it is the site of only 0.5% of all head and neck masses, the unusual pathology and proximity to vital anatomy attracts the special interest of surgeons, radiologists and pathologists.

Early reports of these rare tumours were made by McIlrath[1] in 1963 and subsequent reports by Maran[2] in 1984, Som and Biller[3] in 1981 and Pensak and Gluckman[4] in 1994, who had series that averaged three or four cases per year. The definitive literature on the topic, describing the anatomy, pathology and surgical treatment was published by Olsen[5] in 1994. Riffat et al.[7] published a systematic review of the international literature examining the experience with 1143 parapharyngeal space tumours reported over a 20-year period in 2014.

Lesions of the parapharyngeal space may involve a wide spectrum of primary pathologies.[5,6] Pre-operative diagnostic accuracy has improved with the advent of multi-planar radiological imaging including fine-sliced computerized tomography (CT) with contrast and magnetic resonance imaging (MRI) with fat suppression sequences and gadolinium for contrast. Image-guided fine-needle aspiration cytology has improved histological diagnosis. This allows for a better understanding of the nature of these lesions and a better plan for the surgical approach to them.

There has been increasing interest and use of transoral robotic surgery (TORS) in the treatment of benign and malignant tumours of the oropharynx. TORS has the approval of the US Government's Food and Drug Administration (FDA) for use in early oropharyngeal cancers and benign lesions of the head and neck since 2009. The da Vinci surgical robotic system (Intuitive Surgical Inc., Sunnyvale, California) provides three-dimensional, high-resolution visual access with magnification as well as tremor filtration and motion scaling of robotic instruments. This allows for delicate dissection and addresses previous concerns leveled against transoral approaches to the parapharyngeal space with respect to controlled dissection around vital neurovascular structures and tumour spillage.

ANATOMY

The parapharyngeal space is a potential neck space filled with fat and areolar tissue. A variety of names have been ascribed to this space including pterygomaxillary space, pharyngomaxillary space, pterygopharyngeal space and lateral pharyngeal space. However, the term parapharyngeal space is generally accepted.

The parapharyngeal space is classically described as an inverted pyramidal-shaped potential space (**Figure 11.1**). Its base lies superiorly at the skull base and comprises

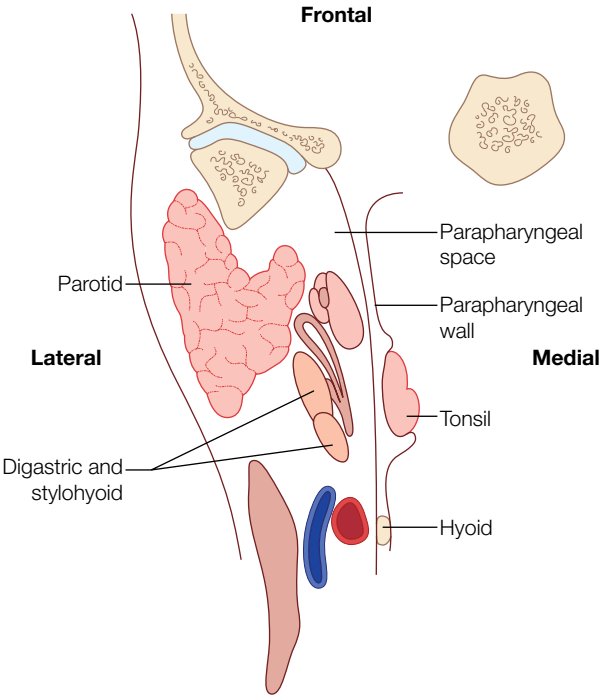

Figure 11.1 The parapharyngeal space resembles an inverted pyramid. Used with permission from Olsen KD. Tumors of the parapharyngeal space. *Laryngoscope* 1994; **104**(5) Suppl 63, Fig 1, p. 2.

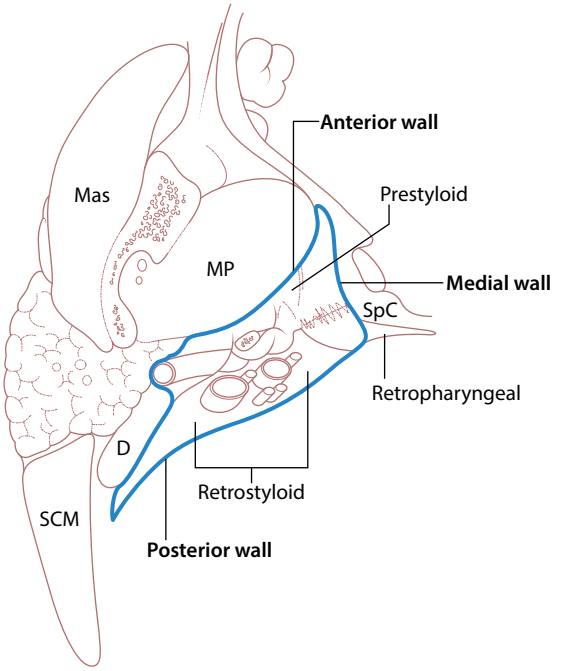

Figure 11.2 Pre-styloid and post-styloid (retrostyloid) compartments separated by condensation of fascia – the aponeurosis of Zuckerkandl and Testut. P, parotid gland; D, digastric; MP, medial pterygoid; Mas, masseter, SCM, sternocleidomastoid. Used with permission from Olsen KD. Tumors of the parapharyngeal space. *Laryngoscope* 1994; **104**(5) Suppl 63, Fig 3, p. 4.

the sphenoid and temporal bones. This area includes the jugular and hypoglossal canal and the foramen lacerum. Its apex lies inferiorly at the greater cornu of the hyoid bone. It has three sides, medial, lateral and posterior and an anterior leading edge which is the pterygomandibular raphe.

The medial surface is distensible and comprises the superior pharyngeal constrictor muscle, the buccopharyngeal membrane and the pharynx. The lateral surface, which is relatively immobile, comprises the medial pterygoid muscle, the ramus of the mandible, and the deep lobe of the parotid gland, and below the level of the mandible, the lateral aspect is bordered by the fascia of the posterior belly of the digastric muscle. It has a posterior surface which is part of the prevertebral fascia, bordered by the carotid sheath posterolaterally and the retropharyngeal space posteromedially.

Two fascial condensations in the parapharyngeal space are of surgical importance. First, the parapharyngeal space is divided into two parts by the fascial condensation called the aponeurosis of Zuckerkandl and Testut (**Figure 11.2**). This fascia joining the styloid process to the tensor veli palatini divides the parapharyngeal space into the pre-styloid and post-styloid compartments. The pre-styloid compartment contains adipose tissue, lymphatics, ectopic salivary gland tissue and small nerves and vessels, a small branch of the trigeminal nerve to the tensor veli palatini muscle and branches of the ascending pharyngeal artery and pharyngeal venous plexus. It is related to the retromandibular, deep aspect of the parotid gland. The post-styloid compartment is posteromedial and contains the internal carotid artery, internal jugular vein, cranial nerves IX to XII, the cervical sympathetic chain, lymph nodes and glomus bodies.

Second, a condensation of cervical fascia forms a band which extends from near the apex of the styloid process of the temporal bone to the angle and posterior border of the mandible (**Figure 11.3**). This stylomandibular ligament, lying posteriorly and the posterior border of the mandible, lying anteriorly, form the stylo-mandibular tunnel. The tunnel is a deep relation of the deep lobe of the parotid gland. Tumours of the deep lobe can extend into the parapharyngeal space through this tunnel giving rise to a dumbbell shaped tumour.

PATHOLOGY

As mentioned above, parapharyngeal space tumours account for 0.5% of all head and neck masses. In a comprehensive review of the literature on parapharyngeal space tumours, Riffat et al. identified approximately 70 different histological subtypes of lesions.[7] Of these 82% were benign and 18% malignant. The most common tumours were of salivary gland origin, accounting for 45% of all lesions. These arose in the pre-styloid compartment. The vast majority (75%) were benign and of these 64% were pleomorphic adenomas. Adenoid cystic carcinoma and muco-epidermoid carcinoma were the commonest reported malignant lesions.

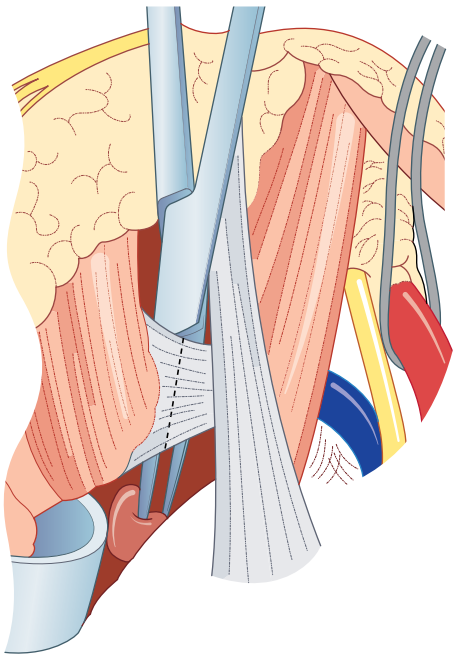

Figure 11.3 Stylomandibular ligament of the left neck from styloid process to posterior border of mandible forming the stylomandibular tunnel. Used with permission from Olsen KD. Tumors of the parapharyngeal space. *Laryngoscope* 1994; **104**(5) Suppl 63, Fig 10, p. 21.

Neurogenic lesions accounted for 41% of lesions in the parapharyngeal space. The majority of these lesions are benign and of these 52% were paragangliomas, 27% were schwannomas and 9% were neurofibromas.

Malignant lesions accounted for 5% and the majority were of neurogenic origin arising in the post-styloid space and the major subtype was malignant peripheral nerve sheath tumour.

A variety of miscellaneous lesions account for 12% of parapharyngeal space tumours. These include internal carotid artery aneurysms, branchial cleft cysts, haemangiomas and meningiomas. Metastatic lesions account for 3% of lesions and 2% of lesions are of lymphoid origin.

Salivary gland tumours

These are the most common neoplasms of the parapharyngeal space. The majority are benign and of these, the majority are pleomorphic adenomas arising from the deep lobe of the parotid gland. A small number arise from ectopic salivary glandular tissue lying in the parapharyngeal space. It is important to distinguish the difference. Tumours arising from the deep lobe of the parotid are generally not suited to contemporary transoral resection using endoscopic or transoral robotic approaches. These tumours may well require a partial parotidectomy and a transparotid and transcervical approach for resection. Parapharyngeal space pleomorphic adenomas, independent of the deep lobe of the parotid gland and arising from ectopic salivary glandular tissue, are amenable to transoral resection and despite their size are suitable for blunt dissection mobilization of the tumour from the skull base. The importance of imaging using both CT and MRI is elaborated in 'Imaging and other investigations' below. In summary, to plan surgical resection, it is important to assess the tumour's relationship to the deep lobe of the parotid gland and to understand if the tumour has a cystic component and the relative thickness of the tumour capsule.

Other benign salivary gland tumours in the parapharyngeal space include Warthin's tumours, basal cell adenomas, monomorphic adenomas, myoepitheliomas and benign lymphoepithelial lesions.

Malignant salivary gland tumours of the parapharyngeal space include adenoid cystic carcinomas, mucoepidermoid carcinomas, squamous cell carcinomas, adenocarcinomas, acinic cell carcinomas and myoepithelial carcinomas. These generally require a parotidectomy with sparing of the facial nerve dependent on pre-operative nerve function with a transcervical approach. The surgical resection may need to be extended to encompass the tumour by means of mandibulotomy for access or mandibular resection if bone is involved in the tumour or access may need to be improved by mastoidectomy or infra-temporal fossa approaches.

Paragangliomas

Paraganglia are groups of cells of neural crest origin belonging to the extra adrenal chromaffin and nonchromaffin cell system (**Figure 11.4**). They are believed to play a role in chemoreception. Paragangliomas are tumours that arise from paraganglia and head and neck paragangliomas may occur from paraganglia along the arterial vasculature and cranial nerves from the skullbase to the aortic arch. About 30% of these tumours are believed to have a genetic origin related to the *Succinyl Dehydrogense* (*SDH*) gene locus. The *SDHA*, *SDHB* and *SDHC* genes are particularly associated with familial head and neck paragangliomas. Head and neck paragangliomas may also be associated with the multiple endocrine neoplasia (MEN) syndromes MEN2a and MEN2b.

Most of these tumours present as an asymptomatic neck mass or an intraoral mass by means of medial displacement of the superior pole of the palatine tonsil. These tumours are believed to be present for months to years prior to the onset of the symptoms and many are the result of an incidental diagnosis. About 10% of paragangliomas are multicentric and should have imaging such as whole body MRI to assess other sites such as the aortic arch and adrenal. About 3% may be secretory and present with systemic symptoms associated with catecholamine release. All patients with paraganglioma should be assessed for catecholamine secretion prior to surgery to avert anaesthetic complications from catecholamine release potentially occurring during surgical manipulation of the tumour. Paragangliomas are slow-growing benign tumours and the decision to perform surgery needs to be well considered. The surgical complications from lower cranial nerve

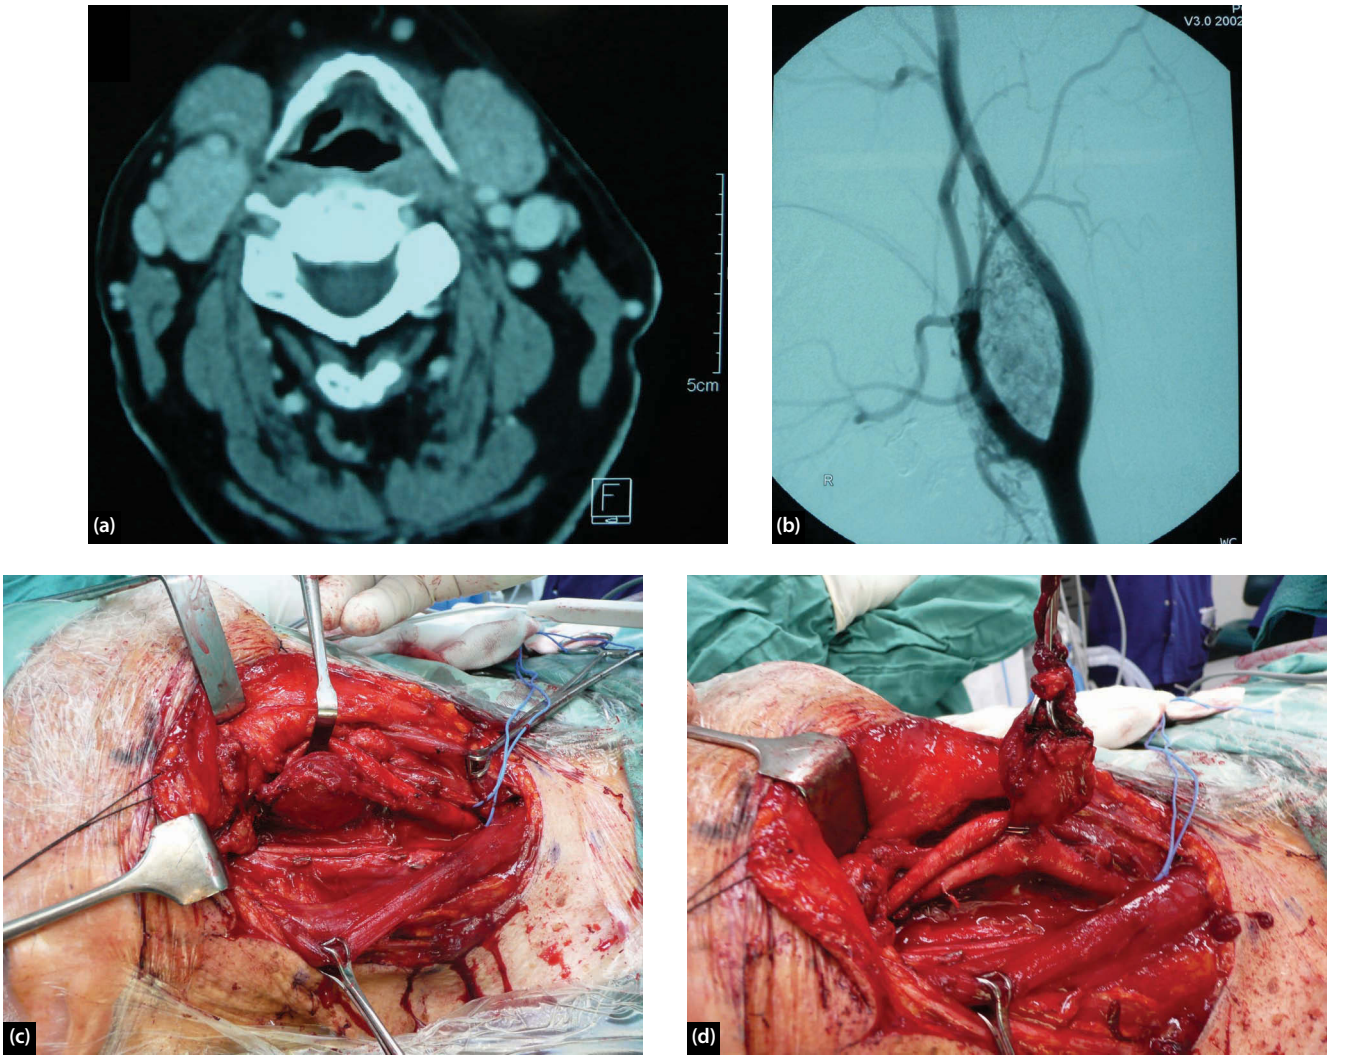

Figure 11.4 **(a)** CT neck showing vascular right carotid body tumour lying between internal and external carotid arteries. **(b)** Angiogram showing vascular right carotid body tumour splaying Internal and external carotid arteries – the 'Lyre' sign. **(c)** Right carotid body tumour. **(d)** Right carotid body tumour dissected off internal and external carotid arteries.

palsies may be more distressing than the lesion and high-vagal paraganglioma may not be amenable to complete resection without significant risk to the vagus, glossopharyngeal, accessory and hypoglossal nerves. The usual indications are suspected malignancy as evidenced by multiple lesions, erosion of adjacent bone or involvement of adjacent cranial nerves or associated regional lymphadenopathy. Surgery may also be indicated if increasing tumour size causes pressure effects on surrounding vascular and neurological structures.

It is difficult to discriminate between benign and malignant paraganglioma unless histological assessment is performed. Both malignant and benign tumours are comprised of the same two major cell types that comprise the paraganglia, these being epithelioid chief cells and sustentacular supporting cells. Together these two cell types form clusters of cells (Zellbalen), which are surrounded by extensive vascular sinusoids. Histological markers such as central necrosis, vascular invasion, and mitosis or nuclear atypia do not appear to be correlated with metastasis or true invasion.[8]

Paragangliomas have characteristic imaging features including demonstration of vascularity, the so called 'salt and pepper' appearance and in the case of carotid body tumours, a displacement of the angle between the internal and external carotid arteries known as the 'Lyre' sign Surgical resection for large lesions requires careful planning and may need transmastoid and infratemporal fossa approaches (**Figure 11.5**).

Schwannomas

Schwannomas are benign neurogenic tumours considered to originate from either Schwann cells or fibroblasts supporting the nerve. They present in patients between 30 and 70 years of age. They usually arise from either the vagus nerve or the sympathetic trunk. The vagus nerve is reported to be the origin of 50% of parapharyngeal

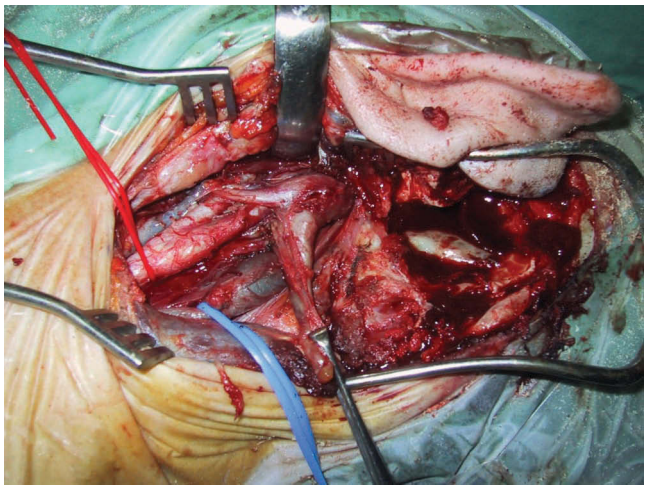

Figure 11.5 Transcervical with transmastoid approach to resect a left vagal paraganglioma. Tumour grasped by Allis forceps. Red ligature loop around carotid artery, blue ligature loop around internal jugular vein and sigmoid sinus on view in mastoid cavity.

schwannomas and cervical sympathetic chain is the next common source. Generally, schwannomas are characterized by slow and asymptomatic growth. However, progressive growth in the parapharyngeal region may result in pressure effects and cause dysphagia and hoarseness of voice. The pre-operative evaluation is critical, with imaging modalities like CT and MRI determining the diagnosis[9] and may indicate the nerve of origin.[10] These tumours are usually fusiform along the long axis of the nerve or may be round. They are of heterogenous signal intensity with hypointense, isointense and hyperintense areas on CT and MRI. Transcervical or transoral biopsy of parapharyngeal space schwannomas is usually associated with unique pain not usually reported by patients undergoing fine-needle aspiration biopsy and may be complicated by haemorrhage, infection and rarely cranial nerve injury.

Metastases to the parapharyngeal space

The parapharyngeal space contains lymph nodes and these drain the mucosa of the upper aero digestive tract and viscera of the neck. It is important to assess the nodal status of the retropharyngeal and parapharyngeal nodes when assessing metastatic neck disease in head and neck cancer. The retropharyngeal and parapharyngeal nodes are not routinely encompassed in surgical fields. However, they are accessible to both surgery and radiation when identified as being involved with metastases.

The most common metastases to the parapharyngeal space is from nasopharyngeal cancer, said to be involved in up to 30% of cases. These nodes may also be involved in tonsil and tongue base cancers and maxillary sinus cancer. Other potential primary sites include the thyroid and parotid glands. Rarely these nodes maybe involved with distant sites such as breast, colon and prostate cancer.

The parapharyngeal space may be directly invaded by malignancy from the nasopharynx, tonsil, retromolar trigone, palate and tongue base.

While benign tumours of the parapharyngeal space enjoy low levels of recurrence with a 5-year progression free survival rates of 93%, malignant tumours of the parapharyngeal space fare worse with a 5-year progression free survival rate of 61%.[11]

CLINICAL PRESENTATION AND EVALUATION

These tumours are usually asymptomatic oropharyngeal masses, found on incidental examination for innocuous symptoms such as a sore throat. They need to be at least 3 cm before they become apparent and present as a neck mass. They may present with a simple nasal obstruction or snoring, or may present with hearing loss due to Eustachian tube occlusion. Rarely they may present with cranial nerve dysfunction causing hoarseness, dysphagia or cough, which may be due to pressure on or involvement of, the hypoglossal, vagus and glossopharyngeal nerve, or Horner syndrome.

Clinical evaluation requires assessment of the airway, speech and swallowing, a full head and neck examination including cranial nerves examination, nasopharyngoscopy and examination of the middle ear for effusion. Bimanual palpation and ballotment helps assess tumour mobility and size and appreciation of the displacement of the tonsil or the posterior pharyngeal wall provides clues to whether the lesion has its origins from the pre-styloid or post-styloid compartment.[12]

IMAGING AND OTHER INVESTIGATIONS

Accurate imaging of the parapharyngeal space is essential to planning surgical resection. Multiplanar imaging with fine slice CT and MRI provides the detail required. Further information regarding vascularity and relationship to the neurovascular structures can be gained from MR angiography and carotid angiography.[13–15] Therapeutic interventions such as pre-operative embolization or balloon occlusion studies can be performed at the same time.

The parapharyngeal space appears as a small triangular space on axial imaging with an image density or signal consistent with fat. Knowledge about the displacement patterns of fat and the internal carotid artery within the parapharyngeal space will aid in the localization of lesions.

The presence of a fat plane between the parotid and a lesion differentiates a truly parapharyngeal space lesion from an extension of a deep lobe parotid lesion through the stylo- mandibular tunnel into the parapharyngeal space

(**Figure 11.6a–d**). A lesion arising in the pre-styloid space may have a rim of parapharyngeal fat antero-medially, but displaces the parapharyngeal fat and internal carotid artery posterolaterally (**Figure 11.7a,b**). However, a lesion in the post-styloid compartment will displace the parapharyngeal fat and internal carotid artery anteromedially. MRI with fat suppression sequences can help delineate this relationship clearly.

CT scans can show evidence of bony detail and erosion by these tumours and may also show calcification within tumours. MRI scans show soft-tissue extension of these tumours including intracranial extension. MRI scan with gadolinium can also show involvement of nerves and perineural spread.

Some lesions have classic imaging characteristics like congenital cysts which on CT are seen as low attenuation

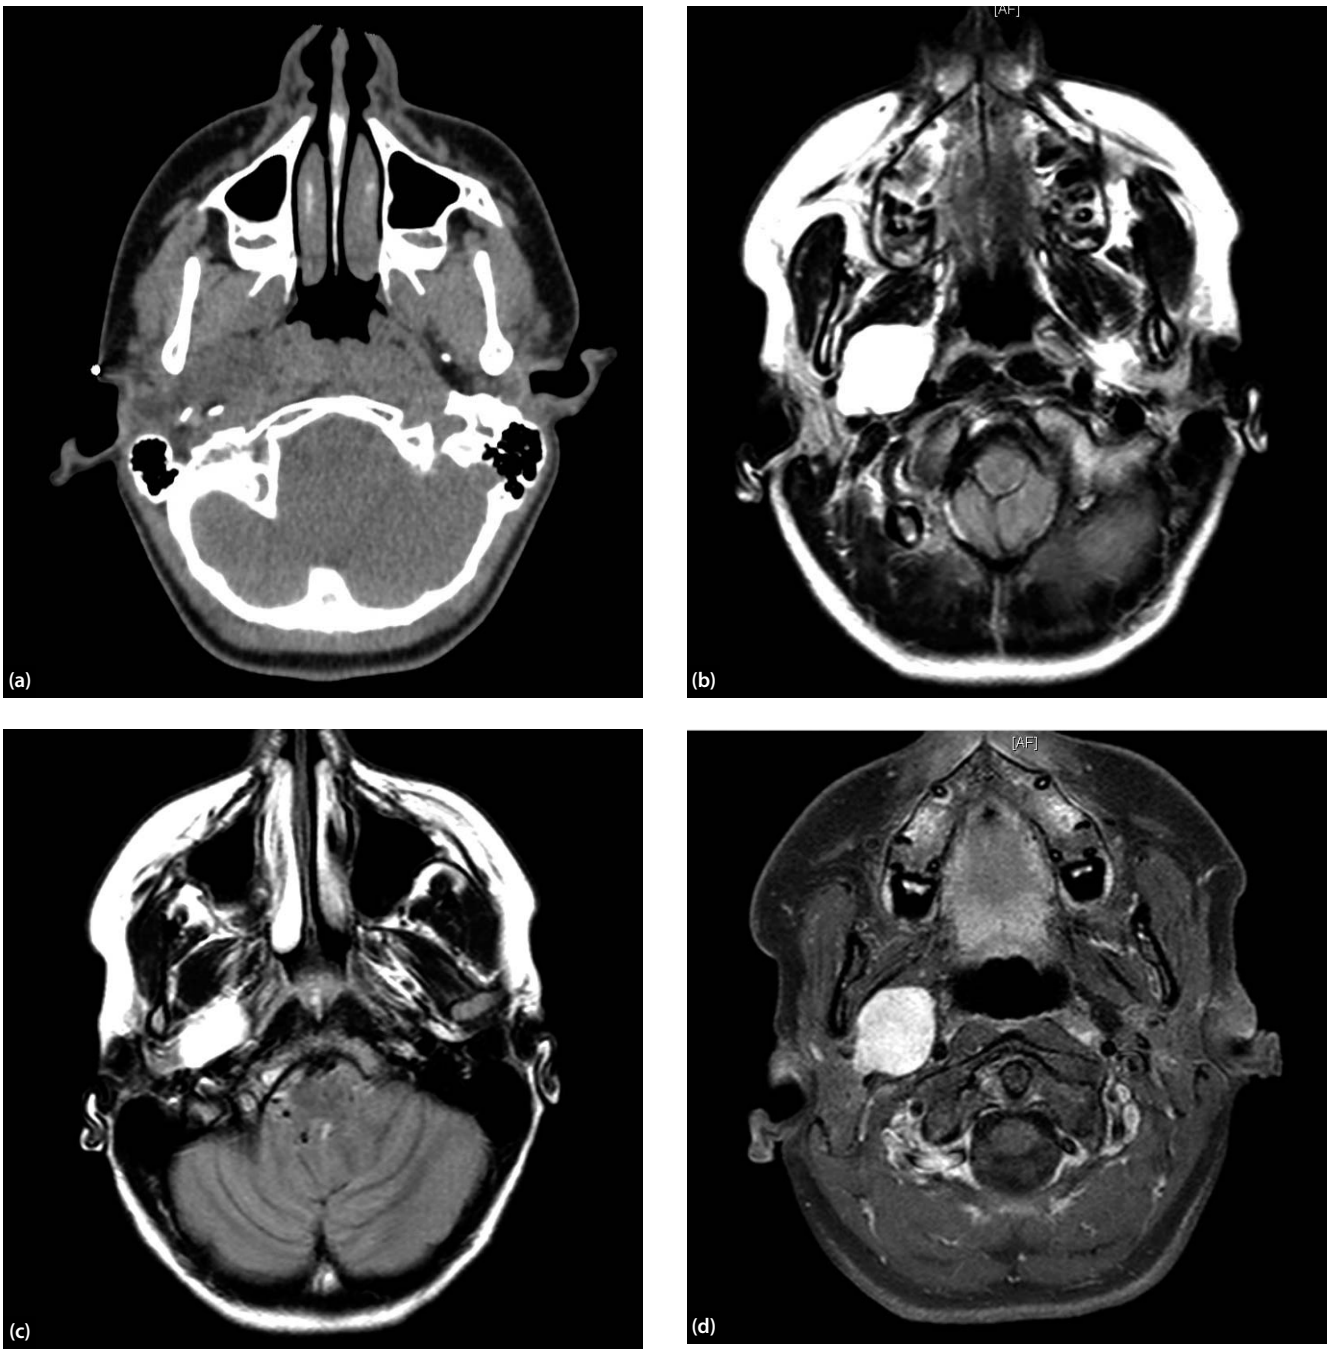

Figure 11.6 **(a)** Right parapharyngeal space tumour on CT shows the mass to be contiguous with the deep lobe parotid. **(b)** The same parapharyngeal tumour on MRI shows the mass to clearly arise from deep lobe of parotid. **(c)** Same right parapharyngeal space tumour on MRI showing limited involvement of deep lobe of parotid. These lesions are ideal for a transcervical – transparotid approach and may be suitable for a combined TORS resection with transparotid identification and protection of the facial nerve. **(d)** T1-weighted MRI with gadolinium and STIR sequence to suppress fat and demonstrate no fat plane in PPS between tumour and deep lobe of parotid.

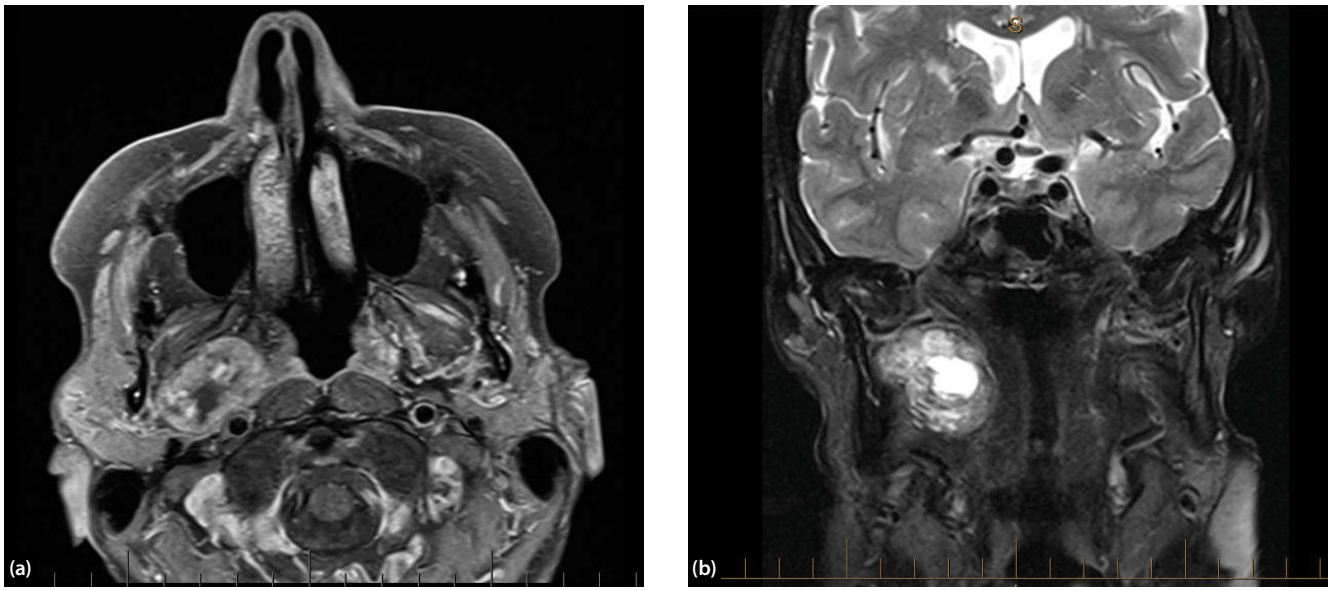

Figure 11.7 **(a)** MRI of right parapharyngeal space tumour. This variation is ideal for a TORS approach to resection. **(b)** Right parapharyngeal space tumour displacing carotid artery laterally. Favourable for TORS.

lesions with a thin uniformly smooth wall. On MRI, they appear as T1-weighted hypointense and T2-weighted hyperintense lesions with peripheral enhancement on post-contrast study. Schwannomas are fusiform, sharply circumscribed masses seen on CT as soft-tissue density masses with few cystic areas within. They show uniform enhancement on post-contrast study. On MRI, they appear heterogeneously hyperintense on T2-weighted images and isointense to hypointense on T1-weighted images. There are no flow voids within them which help to differentiate them from paraganglioma. The flow voids in paraganglioma give them the characteristic 'salt and pepper' appearance on MRI. Functioning paragangliomas may require further investigations including 24-hour urine screen for metanephrine.

Image guidance may be required to obtain a transcervical fine-needle aspiration biopsy for lesions not obvious or accessible in the oropharynx by a transoral approach.[15, 16]

Vascular lesions not amenable to resection may be considered for angiography and embolization. Angiography and embolization is also performed 24–48 hours before the excision of vascular tumours. In patients with lesions that encircle the internal carotid artery and who are at risk of trauma or resection of the internal carotid artery, balloon occlusion tests will need to be performed to assess the risk of neurovascular complications and assist in the decision-making process.

SURGICAL APPROACHES

Lesions of the parapharyngeal space are predominantly treated by surgery. In a systematic review of 1293 cases over a 25-year period, Kuet et al.[11] reported that 96% of patients had surgery. The aim of surgery is to remove the lesion with minimal morbidity. Adjuvant radiotherapy is reserved for malignant lesions or recurrent benign lesions with a high risk of recidivism. Chemotherapy is administered when indicated by specific histology such as rhabdomyosarcoma, positive margin status, tumour histology, perineural and lympho-vascular spread. Radiotherapy has also been used in patients who are considered a high surgical risk or for unresectable lesions. There are reports in the radiation literature of observational studies showing long-term control as defined by stable disease or limited regression in patients with paraganglioma undergoing radiation.[17, 18]

External transparotid, transcervical approaches to the parapharyngeal space have traditionally been considered the only safe access. The external approach was initially promoted in the 1950s mainly because of a poor understanding of the nature of these tumours and the surgical anatomical relationships. CT did not arrive until 1972 and was not in general use until 1979; the first MRI scanners arrived in the mid 1980s and were not in general use until the late 1990s. The improved imaging allowed consideration of approaches other than the traditional external approach.

In his treatise on parapharyngeal space surgery, Olsen[5] provides a clear description of the variety of external approaches. These include the transcervical approach which can be carried out in combination with a transparotid approach with or without a mandibulotomy for tumours that extend into the intratemporal fossa. Other combinations including orbitozygomatic, transmandibular and transpalatal approaches have been described. These approaches all involve wide exposure and a significant disruption of the normal anatomy of the

jaw and neck in order to facilitate safe resection of large or malignant neoplasms.

Transoral approaches, in the past, have generally been discredited. This is predominantly related to the risk to adjacent neurovascular structures, the risk of tumours spilled during resection, and the subsequent difficulty in dealing with recurrent tumour and finally the risk of infection from contamination of oral commensals. However, the advent of robotics and modern endoscopic systems have addressed many of these concerns for suitable tumours of the parapharyngeal space.

The choice of surgical technique is dependent on the tumour size, its relationship to the parotid gland and skull base and if the tumour is malignant.

Transcervical approach

The transcervical approach is the most commonly utilized approach, used in about 46% of cases (**Figure 11.8**).[11] It is ideal for small benign tumours independent of the deep lobe of the parotid gland. The procedure is performed under a general anaesthetic with the patient intubated with a nasotracheal tube. This allows an extra centimetre of anterior distraction of the mandible when accessing the parapharyngeal space. The patient is positioned with the neck extended and rotated opposite to the side of the lesion. The excision is performed through a transverse skin crease incision approximately 5 cm below the mandible to spare the marginal mandibular branch of the facial nerve. The platysma is divided and the superficial fascia of the submandibular gland is identified and raised with the superior flap to protect the facial nerve branches. The submandibular gland can be mobilized and displaced anteriorly to get greater access to the parapharyngeal space. The stylomandibular ligament is identified and divided and the mandible is distracted anteriorly. The parapharyngeal space is located between the digastric muscle and the periosteum of the

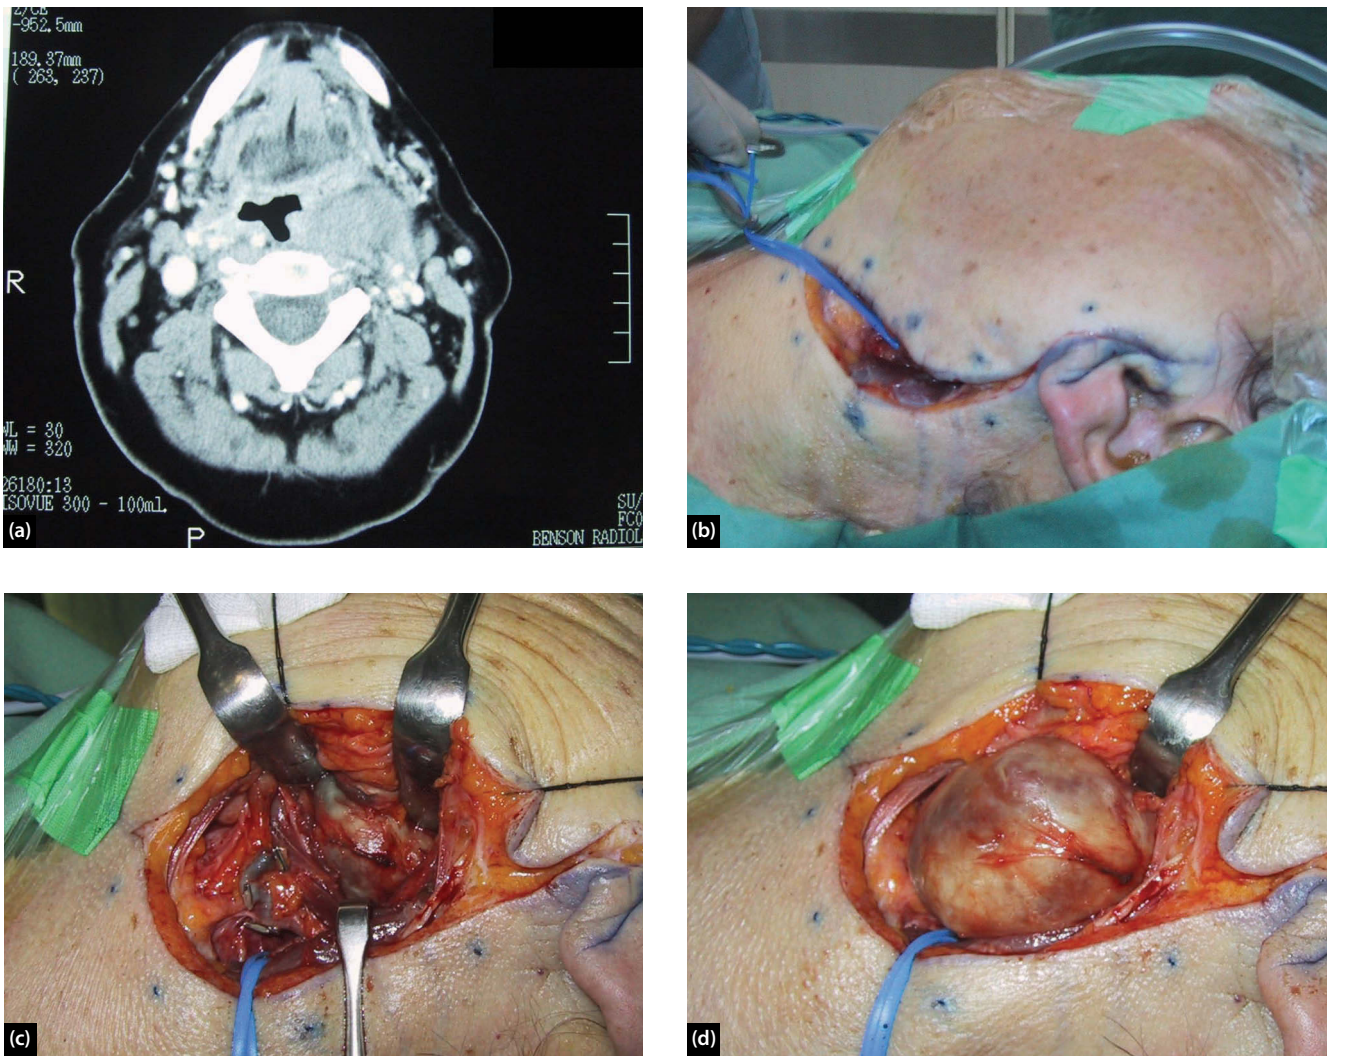

Figure 11.8 **(a)** Large left parapharyngeal space pleomorphic adenoma. **(b)** Large left parapharyngeal space pleomorphic adenoma – transcervical approach incision. **(c)** Large left parapharyngeal space pleomorphic adenoma – transcervical approach: following division of stylomandibular ligament and anterior distraction of mandible, dissection between digastric muscle and mandible provides access to the parapharyngeal space. **(d)** Large left parapharyngeal space pleomorphic adenoma – transcervical approach – delivery of tumour.

mandible and the medial pterygoid muscle insertion into the medial aspect of the mandible. The external carotid artery may need to be ligated to access and remove large tumours. Most of the dissection of the tumour is performed by blunt finger dissection staying close to the capsule of the tumour.

Transcervical – transparotid approach

This is the next most common approach, used in about 27% of cases (**Figure 11.9**).[11] This is well suited for lesions arising from the deep lobe of the parotid gland, for vascular tumours (as it allows access to vessels in the neck) and for the resection of malignant lesions. The operation is performed through a doubly modified Blair's incision as in a routine parotidectomy with a slight anterior extension of the cervical incision. The same procedure as described above for a transcervical excision is performed with an appropriate parotidectomy, identifying and defending the facial nerve.

Mandibulotomy

Transcervical and transcervical–transparotid approaches can be combined with a mandibular osteotomy. This was performed in about 9% of cases in the cumulative literature.[11] This allows access for excision of infiltrating malignancy and multifocal recurrent benign tumours and better visual access to the superior aspect of the parapharyngeal space and the skull base. Mandibulotomy can be performed in the standard paramedian position, or laterally with defence of the inferior alveolar nerve using an

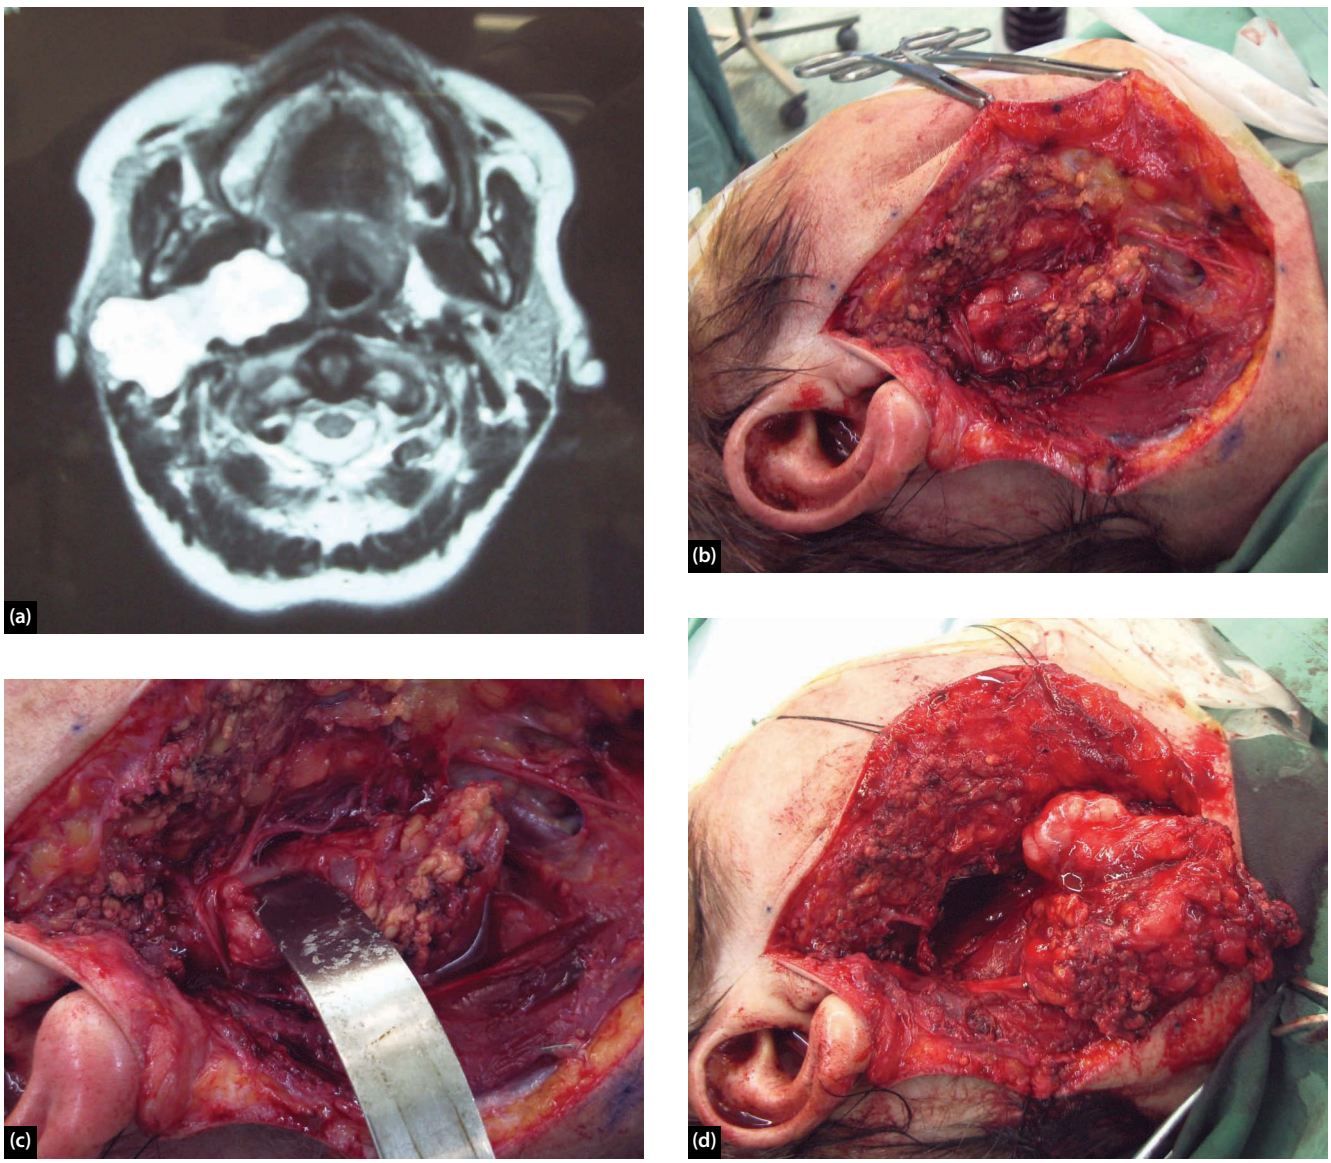

Figure 11.9 **(a)** Large right 'Dumbbell tumour' pleomorphic adenoma in parapharyngeal space. **(b)** Large right 'Dumbbell tumour' removal by transcervical and transparotid approach, superficial parotidectomy performed. **(c)** Large right 'Dumbbell tumour' removal by transcervical and transparotid approach, facial nerve being dissected from tumour. **(d)** Large right 'Dumbbell tumour' removal by transcervical and transparotid approach.

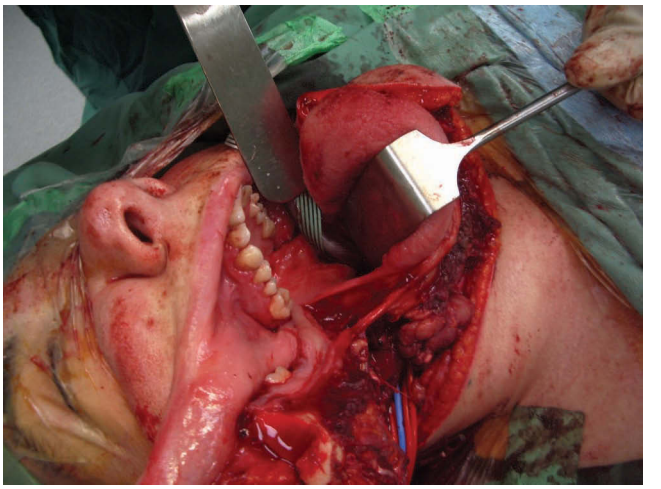

Figure 11.11 Transparotid, transcervical and transpalatal approach with paramedian mandibulotomy.

'inverted L' osteotomy[19] or by using a double osteotomy, above the lingula and in front of the mental foramen, again to protect the inferior alveolar nerve. Patients undergoing a mandibulotomy may require a tracheostomy, or may need to be intubated overnight to protect the airway. These patients may have a longer hospital stay, delay in return to normal nutrition and may be subject to complications such as temporomandibular joint dysfunction and malunion (**Figures 11.10** and **11.11**).

Transoral robotic surgery (TORS) of the parapharyngeal space: the paradigm shift (Figure 11.12a–c)

Embarking on TORS of the parapharyngeal space requires addressing the concerns and criticisms of this approach. The first issue is the risk to vital neurovascular structures. The traditional transcervical approaches are mooted as safer. However, in practice these approaches provide clear visualization of the lower cervical component of parapharyngeal space tumours and their relationship to the neurovascular bundle in the neck. The superior component is often difficult if not impossible to visualize. A true inspection of the relationship of tumour to neurovascular bundle would require wide access techniques such as mandibular osteotomy and/or infratemporal fossa approaches. As most tumours are benign salivary gland lesions, the superior aspect of the dissection is often performed with blunt finger dissection and inferior traction of the tumour to displace it off the neurovascular bundle.

The second issue is the risk of tumour spillage. Undertaking a TORS approach requires meticulous study of the imaging and at examination under anaesthesia, evaluating the mobility of the tumour and its lateral, superior and inferior relationships. The surgeon needs to understand the nature of the lesion, whether it is cystic, solid or mixed, whether it is benign or malignant, the thickness of its capsule and its relationship to the adjacent neurovascular structures.

The traditional support for external approach to the parapharyngeal space is based on a number of case series reports.[20–22] However, these are all retrospective, with a limited period of patient follow-up and with mixed pathological type including vascular tumours. These papers still report recurrence of benign tumours and tumour spillage. In practice, it is not uncommon during a standard transcervical approach for lesions to have their capsule disrupted. Sometimes when tumours are displaced inferiorly by pulling down on the tumour, a fragment of tumour may split off from the main mass of tumour. Careful inspection of the parapharyngeal space cavity with a telescope and irrigation of small fragments is required.

In contrast, there are a few papers reporting the results of a transoral approach.[23–25] There have been case reports of neural sheath tumours, neurofibromas, branchial cleft cyst tumours and benign mixed tumours being removed. Ducic et al. reported transoral resection of a series of benign tumours that displaced the carotid artery anteriorly.[24] Since the introduction of CT and MRI scans and a better understanding of the cross-sectional anatomy of the parapharyngeal space, there has been renewed interest in transoral resection of parapharyngeal space tumours.

The advantages of the da Vinci robotic surgical system have also renewed interest in transoral resection of parapharyngeal space tumours. The first reports of transoral robotic resection of parapharyngeal space by O'Malley et al.[28] described resection of a benign parapharyngeal space cyst without complications. The University of Pennsylvania's series reported ten patients, one of whom was converted to an open transcervical approach due to difficulty in finger dissection and to avoid tumour spillage.[29] Dehiscence of the mucosal incision was observed in two patients, none of the patients had residual or recurrent neoplasms at a follow-up on average 19.9 months. Their case series has reached 25 cases at the time of writing, with no recurrences and no patients requiring mandibulotomy or tracheostomy [personal communication]. Several authors have reported their experience with TORS for

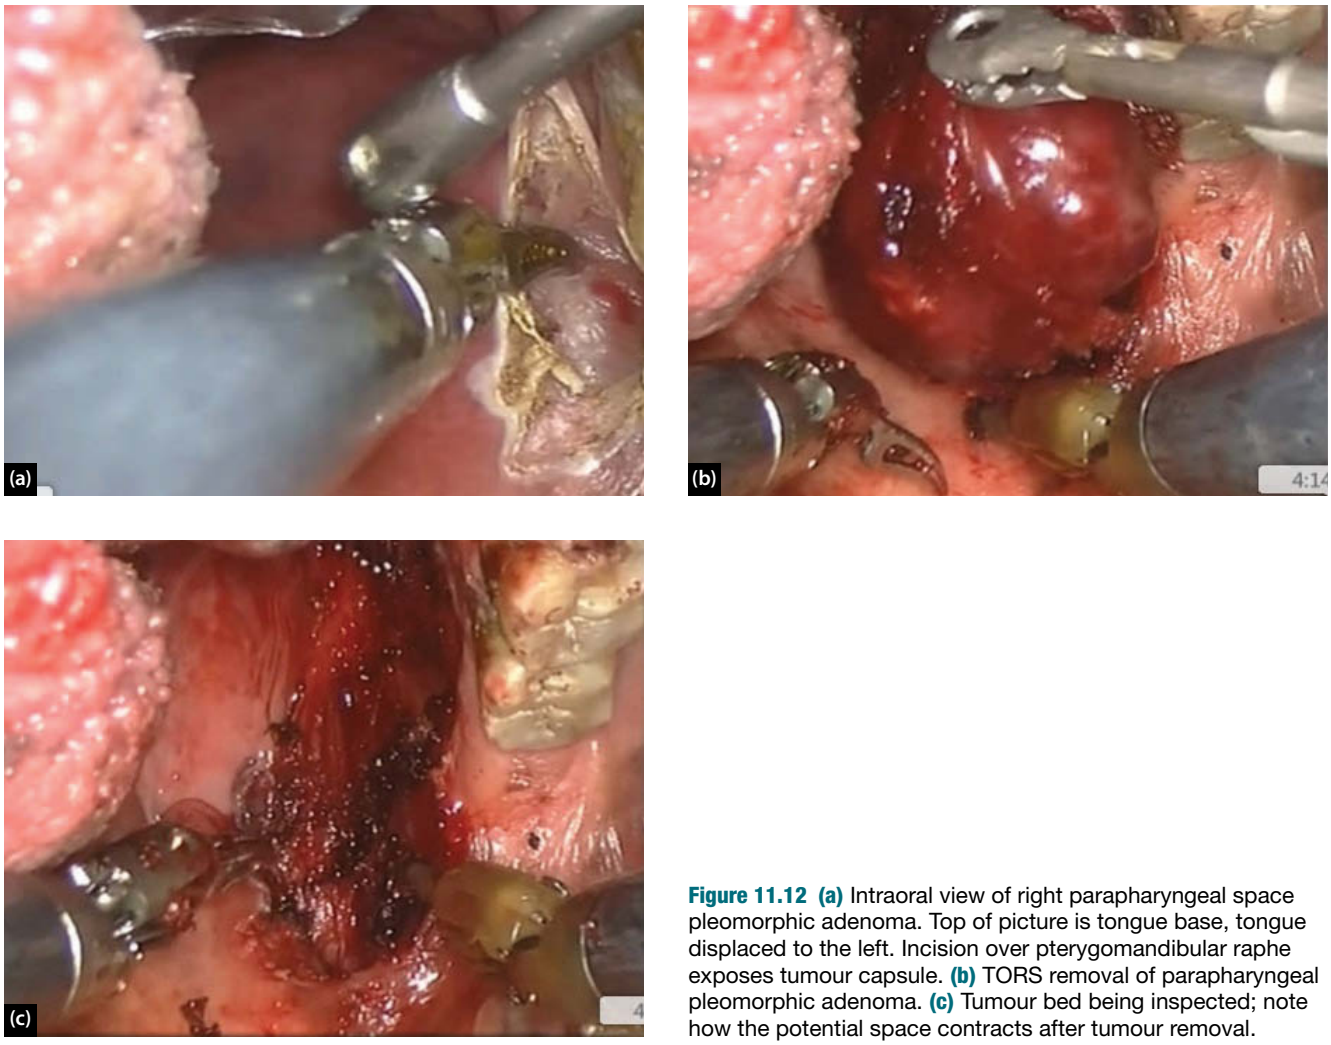

Figure 11.12 **(a)** Intraoral view of right parapharyngeal space pleomorphic adenoma. Top of picture is tongue base, tongue displaced to the left. parapharyngeal space tumour resection,[36–39] including a systematic review by Chan et al.[40]

Whereas the traditional transcervical approach allows the surgeon access to the inferior aspect of the tumour and a blind finger dissection at the superior aspect of the tumour, a transoral approach allows access to all aspects of the tumour. O'Malley et al. described combining the use of the robot to dissect the inferior and medial aspect of the tumour, with a blunt finger dissection to complete the superior and lateral dissection.[29] Patients at our institution are consented for a transoral robotic approach as well as for possible conversion to a transcervical approach with or without mandibulotomy if the transoral approach is not amenable to safe resection of tumour.

Cross-sectional imaging should distinguish vascular tumours and if necessary appropriate angiographic studies performed. The histological nature of tumours should be identified pre-operatively by fine-needle aspiration either by image control or by direct transcervical or transoral biopsy.

The transoral robotic technique has technical advantages, these being the three-dimensional high-resolution image with magnification, as well as the tremor filtration and motion scaling that allows delicate dissection. For those tumours with a thin capsule or with a significant cystic component, however, consideration must be given to other methods to control the spillage of tumours. This may include blunt finger dissection particularly of the superior and lateral aspects of the tumour, or decompression of the tumour medially by a controlled perforation of the capsule and using either a micro-debrider or coblator wand to evacuate the contents of the tumour within its cystic encasement before lateral dissection is proceeded with. It is important that the lateral aspect of the tumour is dissected bluntly and carefully to ensure that tumour rupture is kept to a minimum.

The transoral robotic approach does address some of the concerns previously leveraged against transoral approaches for parapharyngeal space lesions. The robot provides better visual access to the oral cavity, oropharynx and parapharyngeal space with excellent three-dimensional view with either 0-degree scope or a 30-degree scope which can be used to inspect the superior aspects of the parapharyngeal space up to the skull base, as well as be rotated to inspect the inferior extent of tumours of the parapharyngeal space. It has overcome the line-of-site limitations of the microscope and allows examination of the lateral aspects of the parapharyngeal space including

the stylomandibular tunnel. Scaled movement and tremor filtration also allows for dedicated dissection around the tumour capsule ensuring resection with a margin.

Pre-operative assessment and indication for transoral robotic surgery

The use of TORS for parapharyngeal space resection does require accurate pre-operative assessment. The focus of assessment is the relationship of the tumour to the carotid, tumour extent, tumour pathology and the nature of the tumour in terms of thickness of capsule and if the tumour is cystic or has cystic components. Fine-needle aspiration biopsy done either by image guidance or by transoral biopsy is required as benign and low-grade malignancies are considered suitable for TORS.

The ideal indications for TORS parapharyngeal space resection are benign salivary gland tumours occurring in the pre-styloid compartment, displacing the carotid artery posteriorly and laterally. These are the majority of parapharyngeal space tumours. Schwannomas and other benign neural tumours that are not deforming the carotid artery and not displacing the carotid artery medially are suitable for resection. Cystic lesions such as branchial cleft cysts are suitable for resection.

Relative indications include dumbbell tumours or tumours clearly arising in the parotid gland involving the deep lobe of the parotid gland. Such tumours with limited involvement of the deep lobe can be approached by a combined transcervical and transoral approach as described by Lee et al.[35] An absolute contraindication is tumour that is adherent or involving the carotid artery. Other contraindications include dumbbell tumours arising clearly from the parotid gland with significant involvement of the parotid gland (**Figure 11.13 a,b**), vascular tumours such as paragangliomas, tumours with bony involvement of the skull base, and malignant tumours.

POST-OPERATIVE CARE

All patients are managed in a High Dependency Unit (HDU) overnight for airway observation and for TORS patients, monitoring of potential oral bleeding that may compromise the airway. Patients are usually extubated after surgery with no personal experience or reports of post-operative airway compromise and no patient requiring prolonged intubation or tracheostomy. Patients having an external approach can usually commence an oral diet following surgery. Patients undergoing TORS are kept nil by mouth overnight and allowed clear fluids on the first post-operative day, free fluids on the second post-operative day and a soft diet progressing to a normal diet from the third post-operative day. Patients undergoing an external approach will have a drain *in situ* and when drainage subsides it is removed and the patient is discharged home. Subject to analgesic requirements patients are discharged on the second or third post-operative day.

COMPLICATIONS

The complications reported in surgery of the parapharyngeal space are related to vascular injury, lower cranial nerve injury, tumour spillage and recurrence and 'first bite syndrome'. Correct case selection and meticulous attention to pre-operative imaging with respect to tumour relationship to vessels should prevent risk of vascular injury

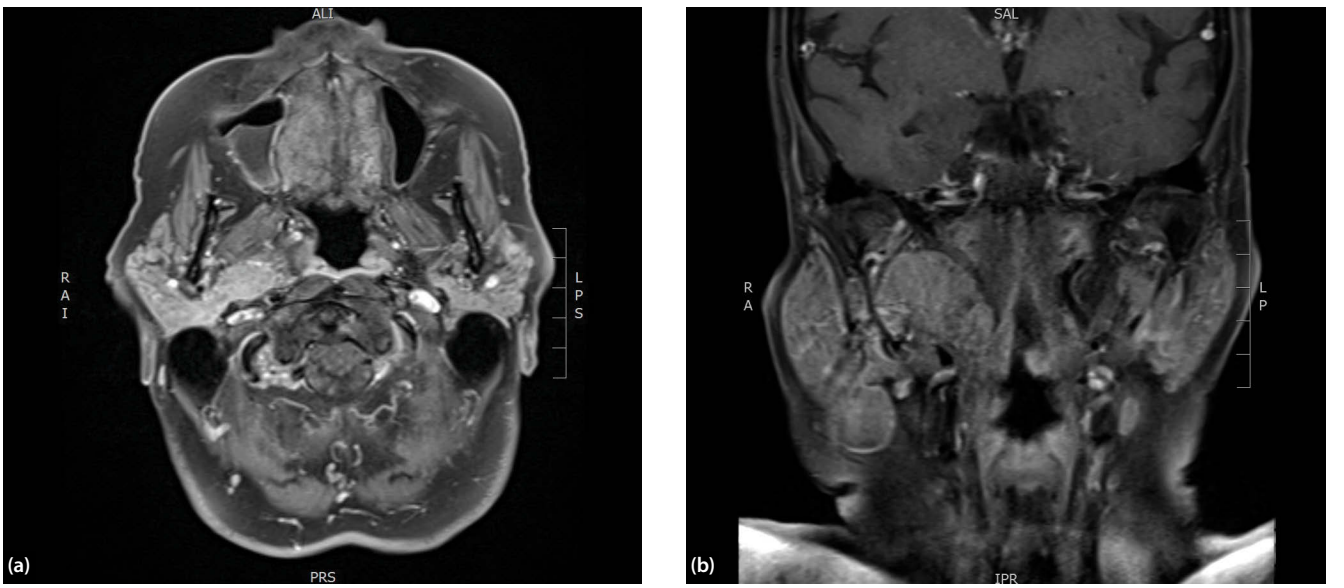

Figure 11.13 **(a)** Axial MRI showing 'Dumbbell' tumour extensively involving the parotid gland with extension through the stylo-hyoid tunnel into the parapharyngeal space. Such tumours are not suitable for TORS resection. **(b)** Coronal MRI showing 'Dumbbell' tumour extensively involving the parotid gland with extension through the stylo-hyoid tunnel into the parapharyngeal space.

including patients selected to undergo TORS for parapharyngeal space tumours. Neurogenic and malignant lesions are associated with greater risk to the facial, glossopharyngeal, vagal, accessory and hypoglossal nerves, with the vagus being the most common to be injured in about 13% of cases.[11] TORS avoids an external incision and avoids parotidectomy, with a reduced risk to the facial nerve and its branches.

It is unclear if tumour spillage will result in definite tumour recurrence. In the Mayo series reported by Hughes et al, tumour rupture was noted in 10 of the 68 cases performed by external approaches. This represents a spillage rate of 15% of pleomorphic adenomas; however, recurrence was only detected in one of those ten ruptured cases.[20] In series reporting experience with transoral resection techniques, Goodwin et al.[23] and Ducic et al.[24] report no tumour spillage seen during transoral resection. Tumuor spillage is not a common occurrence in carefully selected cases with thick capsules and no significant cystic components. In TORS parapharyngeal space tumour resection spillage appears not to be common or worse than with transcervical blunt dissection. The important things are to avoid sharp dissection against the tumour capsule and to use blunt dissection particularly at the lateral and superior and posterior aspects.

There is much debate but no consensus on the actions that need to be taken should the capsule be breached during dissection. The author's practice is to oversew the site of breach after suction drainage of any cystic fluid components within the tumour sac. The operative site should be generously irrigated with sterile water which is hypoosmolar and should promote tumour cell lysis. The role of post-operative radiotherapy is unclear particularly as evidence suggests low rates of recurrence of tumour, despite tumour spillage.[20] The author recommends radiotherapy for large uncontrolled spills with an inability to confirm complete clearance of spilt tumour and for patients undergoing surgery for recurrence with significant risk of facial nerve injury should subsequent surgery be required.

Bleeding can be avoided by meticulous haemostasis using haemoclips and the use of tissue haemostatic agents. Trismus may be present in the early post-operative period but is not a long-term complication, often resolving within 2 weeks of surgery. The other complication reported in external approach surgery is first bite syndrome. As discussed by Chiu et al,[41] it has been theorized to be related to the loss of sympathetic supply to the parotid gland with subsequent increased sensitivity of the myoepithelial cells to parasympathetic innervation. This syndrome has not been reported in transoral resection and is seen as a distinct advantage of transoral resection over external resection.

FUTURE RESEARCH

- More complicated and extended approaches may be required for malignant and complicated tumours involving the carotid artery or extending out of the parapharyngeal space.
- Radiotherapy may have a primary role for high-risk patients unable to have surgery or for select benign vascular lesions where surgery may contribute to significant morbidity from injury to multiple lower cranial nerves.
- Radiotherapy and chemotherapy may have an adjuvant role in some malignant tumours of the parapharyngeal space.
- TORS for parapharyngeal space tumours has advantages for the true pre-styloid benign salivary gland tumour, which is the most common tumour in this space. Its use in other tumours of this space is expanding with better understanding of tumour relationships to vital neurovasculature structures through improved imaging.
- The advent of image guidance and real-time imaging may further enhance the cause of transoral surgery.
- Improvements in robotic instruments, particularly the imminent arrival of single port instruments, will improve access and precision of dissection.
- The introduction of haptic feedback in robotic surgery may contribute to reducing the risk of capsular rupture and tumour spillage.

KEY POINTS

- Parapharyngeal space tumours are a rare subset of head and neck tumours.
- The majority are benign and treated by surgical excision.
- Evaluation of these lesions needs to be meticulous. The use of multiplanar imaging with CT scans with contrast and MRI scans with fat suppression and gadolinium for contrast, when appropriate, can provide accurate details of the nature of the lesion and where it has arisen from.
- Image-guided fine-needle aspiration cytology assists with histologic diagnosis.
- Together, this information helps with planning management of these tumours.
- Some benign vascular and neurogenic tumours are best observed by serial MRI scans, if there is significant risk of debilitating multiple lower cranial nerve palsies from surgery.
- Surgical approaches have to be carefully planned and may include the transcervical approach which can be carried out in combination with a transparotid approach with or without a mandibulotomy.

ORAL CAVITY TUMOURS

Tim Martin

INTRODUCTION

The oral cavity is the uppermost part of the digestive tract. The oral cavity starts at the mucocutaneous junction of the lips (the vermilion border) extending posteriorly to the junction of the hard and soft palate superiorly, anterior fauces laterally and the junction of the anterior two-thirds and posterior third of the tongue inferiorly. Neoplasms of the oral cavity may be classified topographically using the International Classification of Diseases for Oncology,[1] neoplasms of the oral cavity being coded C00–C06 depending on site of tumour (C01 – base of tongue, C05.1 – soft palate and C05.2 – uvula are excluded from this chapter since they form part of the oropharynx).[1]

The oral cavity is lined by stratified squamous epithelium of varying degrees of keratinization. Primary tumours of the oral cavity may be derived from the mucosa, salivary glands, neurovascular tissues, bone or dental tissues. Over 90% of tumours of the oral cavity are squamous cell carcinomas. Globally over 300,000 people are diagnosed with oral cancer each year, it being the eighth most common malignancy.[2] There is considerable geographic variation, the incidence of oral cancer being particularly high in South-East Asia and some Eastern European countries. The incidence of oral cancer in males in England approximates 6 per 100,000 per annum compared to 4 per 100,000 per annum for females. The age-standardized rate for oral cancer in Melanesia is as high as 25 per 100,000 per annum (**Figure 12.1**).

The registration rate for oral cancer has risen by over 20% in the last 30 years in England and Wales, particularly in those under 65 years of age.[3, 4] The increasing incidence of HPV associated oropharyngeal carcinoma may contribute to the reported increase in oral cancer in those publications which do not differentiate between oral cancer and oropharyngeal cancer, however the increase in oral cancer incidence is confirmed in studies specifically isolating the oral cavity site.[5] The author has seen a 10% increase in incidence and 20% increase in prevalence of oral cancer in his own practice between 2000 and 2010, cancers of the oral cavity not being associated with HPV. The increasing incidence of oral cancer has been noted

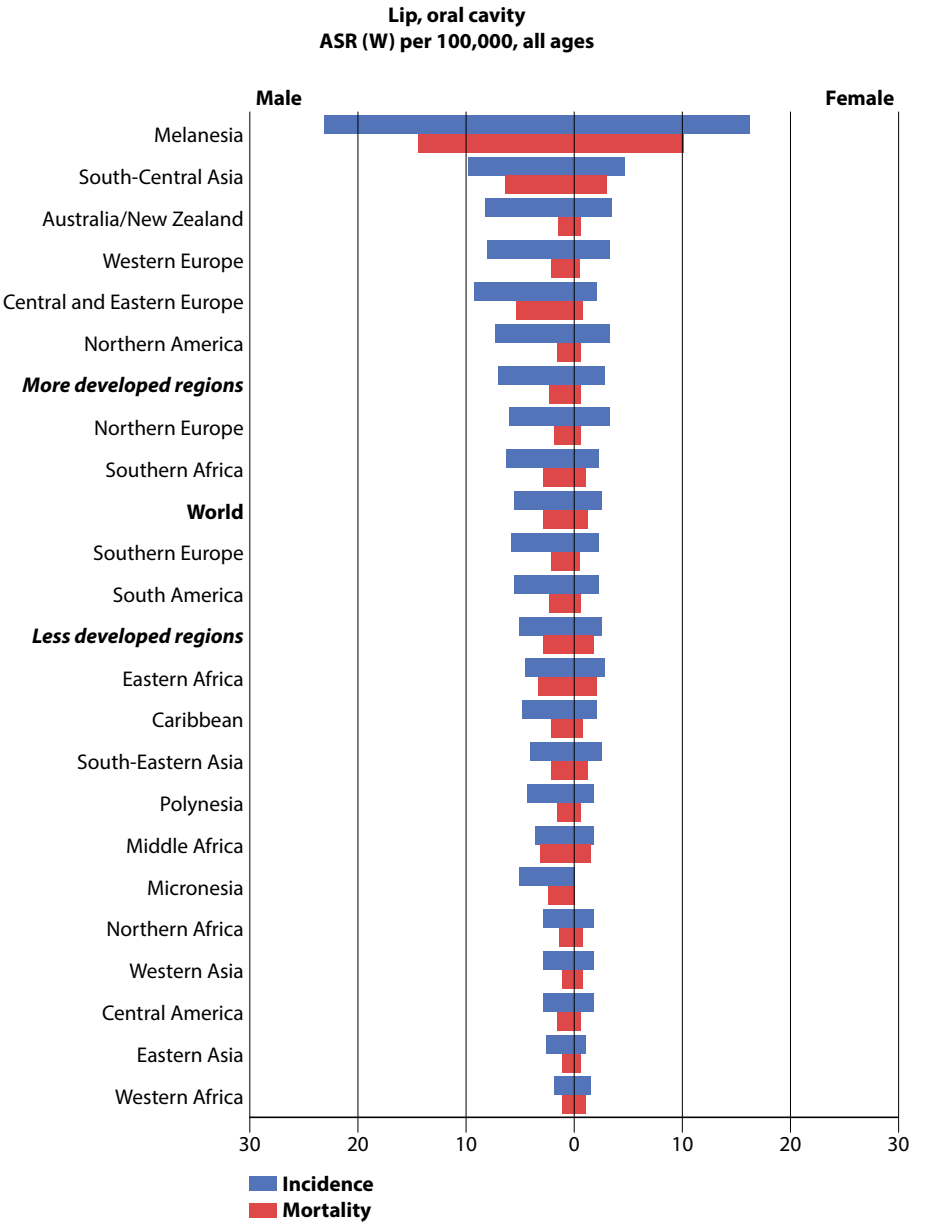

Figure 12.1 Estimated age-standarized rates (World) per 100 000 of lip and oral cavity cancer (Source: GLOBOCAN 2012, http://globocan.fr)

in other populations[6] and may be as a consequence of increasing alcohol consumption. A comprehensive review of international trends in head and neck cancer highlights concerns regarding alcohol consumption.[7] Oral cancer is more common in males, who usually present in the 6th and 7th decade although the incidence of oral cancer in young people seems to be increasing.[8,9] Tobacco and alcohol consumption are the major aetiological factors in the development of oral cancer,[10] oral cancer being considered largely preventable.

If oral cancer is detected when it is confined to the oral mucosa 5-year survival rates exceed 80%, decreasing to 40% for those with regional disease at presentation and 20% if distant metastasis has occurred. Early oral cancer is associated with an improved prognosis and less extensive treatment in attempt to cure the patient. A significant number of patients continue to present with advanced disease and improved public awareness of symptoms associated with oral cancer is a potential solution to this problem.[11,12] Research is required regarding selected or opportunistic screening for oral cancer, but at present there is insufficient evidence to support screening.[13]

The management of patients with oral cancer requires a concentration of medical expertise and resources. For the patient to receive optimal management a truly multidisciplinary approach is required.

WORKUP OF PATIENTS

History

The workup of a patient with suspected oral cancer starts with a detailed accurate history. The patient's symptoms should be documented and a thorough history of each symptom clarified. A short systematic review should be

included, asking specifically for symptoms suggestive of metastatic disease or synchronous aerodigestive tract tumour.

The patient's medical history including medications and allergies should be recorded. A frequently neglected aspect of history taking is the patient's social history. Patients with oral cancer are likely to face the prospect of major surgery, radiotherapy or chemoradiotherapy. The social circumstances of a patient will significantly influence management decisions. Support packages instituted early in the patient's management may help with timely delivery of care and increased patient compliance. If it is anticipated that free-flap reconstruction may form part of the treatment plan then direct questions regarding proposed donor sites should be asked such as hand dominance, intermittent claudication or chronic chest disease.

Examination

While taking a history from a patient the clinician should make note of such things as the patient's mobility when they enter the room, the patients affect, dysarthria or clues to smoking and drinking habits.

The formal examination should ideally be conducted in a dental chair with good lighting. The neck should be systematically palpated for cervical lymphadenopathy, although imaging of the neck in all patients with suspected oral malignancy should be conducted. Using two dental mirrors to help with retraction and visualization, the oral cavity and oropharynx should be examined in their entirety in a systematic manner. All patients should undergo flexible endoscopic assessment of the upper aerodigestive tract mucosa if there is a high index of suspicion for oral cancer. A dental examination should form part of the initial consultation so that dental treatment may be started early in anticipation of surgery or radiotherapy.

Occasionally pain or trismus may limit the examination and in these circumstances an examination under anaesthetic (EUA) should conducted. A restorative dental opinion should be sought before EUA so that necessary dental extractions can be conducted at the same time.

Investigations

Investigations conducted at the initial consultation will depend on the clinician's suspicion that the patient may have oral cancer. Simple investigations that may be conducted at the first appointment include:

- photographs
- incisional biopsy of mucosal lesions
- fine-needle aspiration cytology of suspicious lymphadenopathy
- orthopantomogram
- chest X-ray – if chest CT is not anticipated
- electrocardiogram
- routine bloods – full blood count, urea and electrolytes, liver function tests and clotting.

Biopsy should always be conducted prior to definitive treatment, preferably by a senior member of the team. The timing of a biopsy in relation to other investigations should be carefully considered. If the patient presents with a large tumour where therapeutic or elective management of the neck is anticipated based on primary tumour characteristics, then a biopsy may be safely conducted prior to imaging. If the patient presents with a suspicious small lesion then it is judicious to conduct imaging prior to biopsy to minimize local oedema at the biopsy site or local reactive lymphadenitis, thus upstaging the disease on imaging. Small alveolar tumours should be imaged prior to biopsy since increased marrow signal secondary to inflammation associated with a biopsy may commit the patient to a segmental resection. The biopsy site should be at the periphery of the lesion to include a sample of normal mucosa. A large, deep biopsy may give information regarding depth of invasion and hence the potential necessity to conduct a neck dissection. It has been demonstrated that if tumour thickness on biopsy is >2 mm then the final tumour thickness is usually greater than 3.5 mm,[14] suggesting an elective neck dissection (END) may need to be considered. Unfavourable tumour factors such as perineural spread, vascular permeation and a non-cohesive invasive front are indicators to the probability of positive margins and long-term prognosis. Unfavourable features may lead one to consider wider surgical margins where feasible to reduce local recurrence (accepting that these same features suggest a poorer long-term prognosis) while balancing the quality-of-life issues raised by conducting such a resection.

Once oral malignancy is confirmed histologically additional investigations may be conducted relating to:

STAGING OF THE DISEASE

- CT +/– CT chest
- MRI
- USS (of the neck or primary) +/– USS guided FNA of suspicious lymphadenopathy
- PET.

There has been much debate regarding the extent to which an individual should be screened for second aerodigestive tract tumours or metastatic disease. To subject a patient to major head and neck surgery and an extended hospital stay is clearly inappropriate in the presence of established distant disease, however, extensive surgery may be an excellent mode of palliation. Currently screening for distant metastases is indicated in patients with multiple cervical nodes, recurrence, second primary,[15] or advanced disease.[16] The modality of choice for screening is a CT chest, although ^{18}FDG-PET may have an increasing role.[15] The routine use of panendoscopy in the workup of the patient with oral cancer is not necessarily warranted,[17] although targeted panendoscopy in smokers may reveal synchronous neoplasms in up to 10% of patients.[18] Once the patient has had appropriate investigations the tumour may be staged using the TNM system.[19]

TNM staging

The staging of head and neck cancer will be dealt with in detail in Chapter 4, Staging of head and neck cancer. However, it is worth highlighting recent changes to the TNM staging recommendations published in the American Joint Committee on Cancer (AJCC) 8th Edition Cancer Staging Manual[20] and the Union for International Cancer Control (UICC)[21] which are of particular importance to the staging of oral cavity cancer (OCC). The changes and the rationale behind them are reviewed in detail in Lydiatt et al.[22]

T stage

1. A T0 category is no longer assigned to p16 – OPSCC and other non-HRHPV cancers e.g. larynx, oral cavity and hypopharynx as an exact primary site is, by definition, unable to be established and therefore cannot be assigned to a specific anatomical sub-site.
2. TNM 7th Edition incorporated tumour thickness into the TNM staging criteria as previous data had demonstrated that tumour thickness had prognostic value.[23] However, in TNM 8th Edition tumour thickness has been replaced by an assessment or measurement of tumour depth of invasion (DOI) as this has been shown to be a better prognosticator that tumour thickness.[24]
3. Three DOI groups have been defined: ≤ 5 mm, > 5 mm but ≤ 10 mm and > 10 mm. Each incremental increase in DOI results in an increase in clinical T stage (cT) and pathological T stage (pT) levels.
4. cT DOI relies on clinical examination and measured radiological evidence whilst pT is measured by a perpendicular dropped from a line drawn at the level of the basement membrane (See **Figure 12.1**).[22]
5. These modifications have led to the following revised T stages
   a. **T1:** ≤ 2 cm, ≤ 5 mm DOI
   b. **T2:** ≤ 2 cm, DOI > 5 mm and ≤ 10 mm or > 2 cm but ≤ 4 cm, and ≤ 10 mm DOI
   c. **T3:** > 4 cm or any tumour > 10 mm DOI
6. In addition, 'extrinsic muscle infiltration' is no longer a staging criterion for T4 stage as it has been replaced by DOI.

N stage

1. Extra-nodal extension (ENE) has been added as a prognostic variable in addition to the number and size of metastatic lymph nodes.
2. Radiological evidence alone is insufficient to determine ENE and must be associated with overt clinical evidence of invasion of adjacent anatomical structures (e.g. overlying skin or adjacent nerve).
3. Pathological determination of ENE is subdivided into minor ENE, when ENE < 2 mm beyond the lymph node capsule and major ENE when extension is > 2 mm beyond the capsule +/– soft tissue metastatic deposits are evident. This minor/major distinction is for data collection purpose at this stage and currently, either subdivision is considered ENE positive.

PLANNING OF RECONSTRUCTION

The most appropriate reconstruction will be determined by multiple factors, notably characteristics of the primary site and the anticipated defect, the medical and social history of the patient and potential donor site characteristics. The reconstructive surgeon should have the ability to raise or harvest many different types of local, regional or distant flaps when dealing with head and neck malignancy. For complex bony reconstructions, computer aided planning is invaluable in achieving an optimal cosmetic and functional outcome (**Figure 12.2**).

Focused examination or investigations regarding proposed reconstruction include:

- Allen's test of the vascular supply to the hand if a radial free forearm flap is anticipated
- MRA / angiography of the leg vessels if composite fibula reconstruction is anticipated
- thorough examination of the chest and abdomen if a deep circumflex iliac artery (DCIA) free flap is anticipated
- CAD / CAM models if complex composite reconstruction is anticipated
- dental impressions for all maxillary tumours.

Anaesthetic assessment

It is advisable to liaise with the anaesthetist early in the treatment planning of the patient, especially where a difficult airway is anticipated.

The patient should be seen by the dietician early in their management for dietary advice. Consideration should be given to a percutaneous endoscopic gastrostomy (PEG) to facilitate feeding,[25] however insertion of a PEG is not without morbidity and quality of life issues.[25, 27] A preoperative scoring system has been developed to facilitate decision-making regarding enteral feeding support.[28] Nasogastric feeding may be more appropriate if complex surgery is not anticipated and post-operative radiotherapy (PORT) is unlikely. It is beneficial if the patient meets the speech and language therapist and counsellor prior to starting definitive treatment.

Once the patient has been thoroughly worked up a discussion should occur with the whole Head and Neck team to formulate an appropriate treatment plan. The proposed treatment should then be discussed with the patient and informed consent gained. Informed consent should be tailored to the individual and results achieved in the operating unit. The general success rate of microvascular free-flap surgery is greater than 95%, however 5–15% of patients may require return to theatre for complications such as flap compromise, haematoma or infection. It should be remembered that the peri-operative mortality rate for major head and neck surgery is 1–3%. Patient's age alone should not rule out major surgery and microvascular reconstruction,[29] it being the patient's co-morbidity that primarily influences the incidence of post-operative complications[30, 31] and prognosis.[32] The benefit of major microvascular surgery in patients with significant comorbidity (e.g, an Adult Comorbidity Evaluation Index 27 of Grade 3), should be carefully considered.

SURGICAL ACCESS

The ultimate aim of surgical resection is removal of the tumour with adequate margins. For the majority of oral tumours this may be achieved via a per oral route[33] with good retraction and lighting. Patients with trismus, microstomia, large or posteriorly based oral tumours may require additional access procedures to ensure adequate clearance of the tumour. The role of transoral robotic surgery continues to expand and undoubtedly its application to posterior oral tumours will develop in those institutions able to invest in this technology.

Mandibulotomy

Bone resection is no longer an acceptable method of improving access to oral tumours. A mandibulotomy gives good access to large or posteriorly located tumours. An orthopantomogram (OPG) radiograph is required prior to conducting this procedure to demonstrate the dental anatomy of the area (**Figure 12.3**). Typically, the procedure is accompanied with a lip split. Mandibulotomy without a lip split has been described to minimize facial scars,[34] however access is not as great as when a lip split is conducted. It has been demonstrated that patients have minimal concerns regarding the scar associated with a lip split mandibulotomy.[35]

The neck dissection incision is extended anteriorly to split the lip. Multiple incision designs have been proposed for the lip split.[36] An incision around the chin prominence tends to make the prominence more pronounced, a vertical incision over the chin point producing a more cosmetic result (**Figure 12.4**). Incorporation of a chevron between the chin prominence and vermilion aids closure and breaks up the scar. The intended incision should be marked and temporary tattoos created with needle and ink at the vermilion to ensure accurate reapproximation at the end of the procedure.

The osteotomy should be conducted anterior to the mental foramen to preserve labial sensation. The preferred site for the osteotomy is the paramedian area (between the lateral incisor and canine) since the distance between the tooth roots is greater,[37] dental complications consequently being less than median osteotomies.[38] An osteotomy in the paramedian area preserves the attachments of geniohyoid, genioglossus and digastric to the major segment, only mylohyoid requiring division to mobilize the minor segment. If the distance between the lateral incisor and canine roots is insufficient to accept a saw blade then the lateral incisor should be removed and the osteotomy conducted through the socket to minimize the possibility of osteoradionecrosis should a tooth be damaged. Once the site of osteotomy is established miniplates are adapted and applied to the mandible bridging the proposed osteotomy site. The plates are then removed and the osteotomy conducted using a fine reciprocating saw blade.[39] Application of plates prior to osteotomy ensures maintenance of occlusion at the end of the procedure, although a discontinuity the width of the cutting saw is created. A modified mandibulotomy where only the buccal cortex is cut with a saw, the lingual plate being fractured with a small osteotome, has been described so ensuring bone-to-bone contact at the end of the procedure and may lead to better osseous healing.[40] The mandible and cheek flap may now be retracted laterally and superiorly giving excellent access to the posterior oral cavity and oropharynx.

The non-anatomical position adopted by the temperomandibular joint (TMJ) during this procedure does not give rise to long-term TMJ dysfunction.[41]

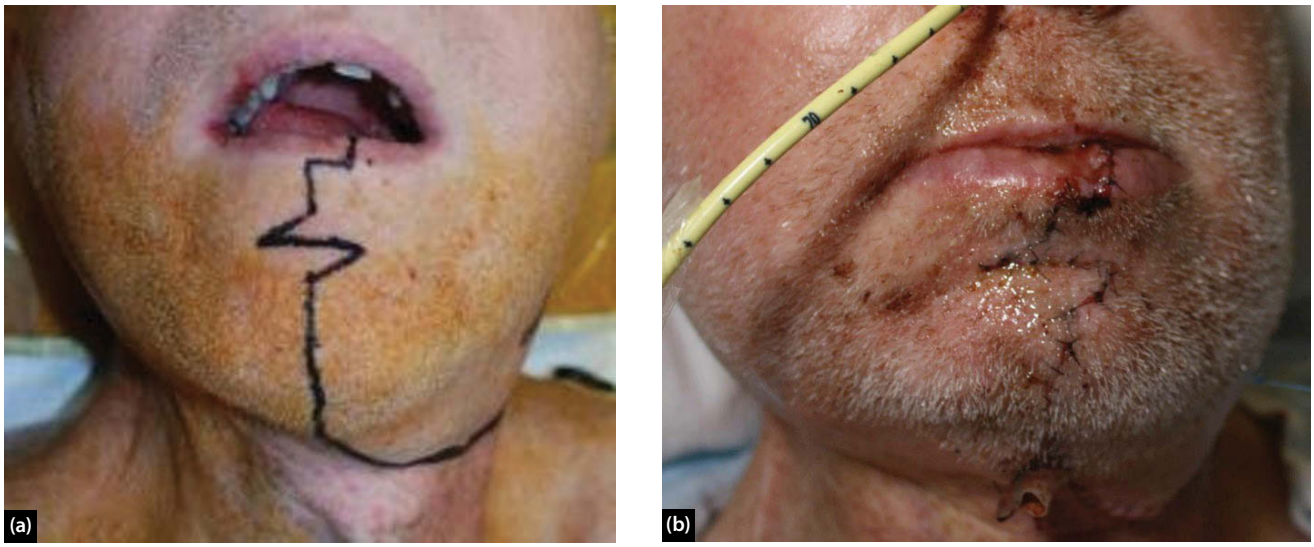

Figure 12.4 Suggested lip split incision that avoids the incision extending around the chin prominence. Figure courtesy of Mr Matt Kennedy, Newcastle upon Tyne.

Visor approach and lingual release

This approach is generally reserved for when bilateral neck dissections are performed. The visor approach may also be appropriate for recurrence or second primary tumours in patients who have received previous radiotherapy to the mandible. The visor approach avoids facial incisions, the incision being located in a cervical skin crease. A mastoid to mastoid visor flap is elevated in the subplatysmal plane to the lower border of the mandible. An intraoral mucosal incision is made in the lingual gingival sulcus from the posterior molar on one side to the posterior molar of the other. In edentulous patients the incision is made on the alveolar crest. The mylohyoid, geniohyoid, genioglossus and digastric muscles are detached from the lingual aspect of the mandible allowing the floor of mouth and tongue to be dropped into the neck. Care should be taken to ensure the lingual and hypoglossal nerves are not injured during the dissection. The reattachment of geniohyoid and genioglossus muscles at the end of the procedure is important to reconstitute the floor of the mouth. This may be facilitated by drilling holes in the lower border of the mandible through which securing sutures are passed. Alternatively, genial muscle reattachment may be facilitated by conducting a small box osteotomy of the lower border of mandible incorporating the muscle attachments and relocating at the end of the procedure with wires or miniplates.

Excellent access may be achieved without the necessity of a lip split, however the expected gain in cosmesis has not been proven and this technique is associated with significantly greater functional deficit post-operatively[41] compared to lip split and mandibulotomy.

Upper cheek flap

The upper cheek flap may be required to augment access to large or posterior maxillary tumours. The cornea of the eye should be protected in all patients. Anterior tumours requiring improved access may be approached via a modified Weber–Ferguson incision without extension. The modified Weber–Ferguson approach is essentially an upper lip split extending into a lateral rhinotomy incision. It is imperative that the incision be marked out accurately and temporary localizing tattoos created prior to starting the procedure. The lip split is usually conducted along the ipsilateral philtral column to the base of the columella. The incision extends laterally along the floor of the nose then follows the alar crease to its superomedial end before continuing to a point 6–8 mm medial to the medial canthus. Locating the vertical limb of the incision on the nose rather than cheek respects the concept of aesthetic facial units and gives a superior aesthetic outcome. The incisions are deepened to bone and the cheek flap raised in the subperiosteal plane, preserving the infraorbital nerve unless it is to be sacrificed on oncological grounds. Elevation of the flap requires a mucosal incision in the gingivo-labial and gingivo-buccal sulcus to a point where the flap incision merges with the resection margins of the tumour. Greater access is afforded by extending the modified Weber–Ferguson incision either with a subciliary incision (Diffenbach extension) or medial canthal incision (Lynch extension). An infraorbital orbitotomy may facilitate access[42] but is not usually required for tumours confined to the oral cavity.

SURGICAL MARGINS

The ultimate aim of surgical resection is adequate clearance of the tumour. Inadequate clearance of tumour results in increased local recurrence and decreased long term prognosis.[43, 44]

Indications for PORT include positive or close margins. However, local recurrence rates following PORT do not approach those in whom adequate clearance is achieved at the primary operation.[44, 45]

Increasing resection margins in the region of the head and neck potentially results in increased functional and cosmetic deficit. Resection margins of up to 2 cm have been advocated, however, such margins may result in significant morbidity following the resection of even the smallest of tumours. One centimetre 3D-resection margins have been demonstrated as acceptable when dealing with oral and oropharyngeal tumours.[46] By adopting 1 cm surgical margins account is taken for the shrinkage of the specimen that occurs following resection and fixation,[47] so ensuring > 5mm pathological margins. A confounding factor that may need consideration when discussing surgical margins is the resecting modality used, differing modalities resulting in variable shrinkage in animal models.[48] It should be remembered that the use of 5 mm as a cut-off point for 'clear' margins is arbitrary and purely represents a margin that is generally considered acceptable,[49] some believing 3 mm is an acceptable histological margin when considering the need for adjunctive treatment.[50] It is vitally important to continually reassess margins visually and by palpation during tumour resection. Adjuncts to assess margin status include intra-operative tissue staining[51] and ultrasound[52, 53] for deep margins and mucosal staining for mucosal margins.[54] If the resection of a tumour is with curative intent then reconstructive considerations should not influence the tumour resection.

Comparison of published data regarding the incidence of positive margins and their influence on survival or local recurrence is complicated by the variable definition of a positive margin.[55] The definition of a positive margin ranges from invasive tumour at the margin,[56] tumour within 1 mm[46] and tumour within 5 mm.[45] The UK Royal College of Pathologists have issued guidelines suggesting clear margins if the histological clearance is > 5 mm, close margins if 1–5 mm and positive margins if < 1 mm.[57]

The incidence of positive margins for tumours of the oral cavity has been demonstrated as being higher than other head and neck sites,[56, 58] potentially due to its complex anatomy and 3D shape. Large tumours, perineural spread, vascular permeation, a non-cohesive invasive front or cervical metastasis are all associated with a greater risk of failing to achieve clear margins.[44, 59] These features suggest that close or involved margins potentially reflect a more aggressive tumour.[44, 46] The incidence of close or involved margins following tumour resection may be greater than 60% depending on tumour site and size, although 15–20% is more representative.

Invariably it is the deep margin that is close or positive.[60] However close deep margins do not necessarily require adjunctive treatment.[61]

Frozen sections are not routinely used by many surgeons,[44, 46] reasons cited being potential cost,[62, 63] inability to reliably prevent positive final margins,[62, 64] failure to influence 5-year survival or primary failure rates[63] and difficulty in identifying the biopsy site should the result be positive.[65] Ninety-nine percent of American Head and Neck surgeons routinely use frozen section intra-operatively, however over reliance on frozen section may result in under treatment of tumours.[55]

When conducting a bony resection a 1 cm margin should be achieved. It has been demonstrated that it is unusual for extension of tumour in bone to exceed the overlying soft tissue extension, consequently the bony resection should be dictated by the extent of soft tissue disease.

BUCCAL CARCINOMA

Surgical anatomy

The buccal mucosa is the mucosal lining of the inner surface of the cheek. The area extends from the oral commissure anteriorly to the retromolar trigone posteriorly. The junction between the buccal mucosa and retromolar trigone is an arbitrary line drawn from the maxillary tuberosity to the distobuccal aspect of the mandibular third molar (or its anticipated position if not present). The inferior and superior boundaries of the area are delineated by the mandibular and maxillary gingiva-buccal sulci respectively. The WHO classifies this anatomical site as ICD-10 C06.0 and C06.1.[1]

The buccal mucosa is not exposed to masticatory loads and so is covered by a lining mucosa with non-keratinizing stratified squamous epithelium. The mucosa is firmly attached to the underlying buccinator muscle. Minor salivary glands are located within the cheek. The parotid duct pierces the buccinator muscle to enter the oral cavity adjacent to the first maxillary molar tooth.

Sensory innervation to the area is via the buccal branch of the mandibular division of the trigeminal nerve. Lymphatic drainage of the site is via the ipsilateral facial and submandibular nodes to the deep cervical chain. The thickness of the cheek, from mucosal lining to external skin, is 1–3 cm.

Epidemiology

The buccal mucosa is the commonest site for oral cancer in South East Asia, up to 40% of oral cancers arising at this site. This contrasts with North America and Western Europe where buccal carcinoma only accounts for 2–10% of oral carcinomas.[46, 66] The consumption of betel quid is socially and culturally embedded in the countries of South-East Asia and is responsible for the difference in site predilection. The ingredients of Betel quid (Paan/Paan Masala) varies throughout South-East Asia. The main ingredients include the Piper betel leaf, slaked lime, spices, tobacco and areca nut. For many years, the tobacco content alone was credited as being the carcinogenic agent in betel quid, however, it is now recognized that the areca nut is also carcinogenic, as well as being the main aetiological agent in oral submucous fibrosis. Individuals who consume betel quid frequently have a preference regarding which side they chew betel, this corresponding to the side of tumour development. There is a strong association with smoking and alcohol consumption in populations where betel chewing is not prevalent.[66–68]

The male to female ratio in Western countries approximates 1:1, however, in South-East Asia the ratio reflects

the consumption of betel quid. In India, the male to female ratio is approximately 4:1 but in the Taiwanese population, where betel quid users are primarily male, the ratio is as high as 27:1.[69]

Buccal carcinoma typically occurs over the age of 40 years, although it may occur in younger patients,[70] particularly when associated with the habit of betel chewing.[71] Oral submucous fibrosis and lichen planus may involve the buccal mucosa, both being considered premalignant conditions.

Presentation

Buccal carcinoma may be described as verrucous, exophytic or ulceroinfiltrative in character. Patients may present with pain, an intraoral mass, ulceration or trismus. Patients who chew betel often have areas of erythroleukoplakia of the buccal mucosa or submucous fibrosis and consequent trismus, making the detection of invasive squamous cell carcinoma difficult. Advanced buccal carcinomas may extend into adjacent sites to include external skin, mandible or maxilla.

It is not unusual for patients to present with advanced disease, 40% or more presenting with Stage III/IV disease,[66, 67, 72] although earlier presentation has been demonstrated in Western populations.[73] Palpable lymphadenopathy on presentation may be as high as 57% for T3/4 lesions. Occult nodal metastasis may be present in 26% of those who are clinically N0 at presentation.[66, 67, 72, 74] It has been suggested that buccal carcinoma associated with Paan chewing is less likely to metastasize to regional lymph nodes, possibly because of local fibrosis associated with submucous fibrosis.[75] Tumours that are greater than T2, are poorly differentiated, have a poor lymphocytic response[74] or are thicker than 5 mm[74, 76] are more likely to demonstrate cervical metastases. Buccal cancers are usually well differentiated.[66, 77]

Workup

Biopsies of buccal carcinomas should be of sufficient depth to help the pathologist give an indication of depth of invasion, since this will help decide on management of the neck. Buccal carcinoma may rapidly extend to adjacent sites, thus accurate imaging is required. Most patients will require MRI/CT imaging, augmented with ultrasound scan if necessary to help in assessment of depth of primary and cervical lymphadenopathy.

Treatment

PRIMARY SITE

Traditional treatment of buccal carcinoma is surgery with PORT for selected patients.[67, 69] T1/2 disease can typically be resected perorally, however, T3/4 disease may require facial access incisions and bony resection of the maxilla and / or mandible.

The primary tumour should be resected with a 1 cm margin,[46] and up to 2 cm if skin is involved.[78] Facial access incisions (upper or lower lip splits) may be required to facilitate access, particularly in patients with concurrent oral submucous fibrosis. The buccinator muscle should be included as the deep margin at the very least.[78] The parotid duct may need to be repositioned or ligated.[77] Ligation of the parotid duct may result in initial parotid swelling which usually subsides as the gland atrophies. External skin should be taken with the specimen if there is any evidence clinically or on imaging that it is involved. Partial maxillectomy or mandibular resection (rim or segmental) may be required.

Small T1 tumours may be resected and reconstructed by primary closure. Healing by secondary intention may be considered, however, post-operative trismus may be anticipated unless vigorous mouth opening exercises are performed. Split-thickness skin grafts may be used with the aid of silicone sheets to stabilize the graft.[79] The use of a skin graft to reconstruct deeper resections may leave a very thin cheek with potentially poor aesthetics. Local flaps such as the buccal fat pad or temporoparietal fascial flap may be used for reconstruction if tumour extension does not compromise their use. Microvascular free-flap reconstruction with a radial-free forearm flap or anterolateral thigh flap[80] restores the thickness of the cheek and if external skin is involved the flaps can be bi-paddled to provide reconstruction of mucosal and skin surfaces. T4 tumours requiring segmental resection of the mandible may require composite free-flap reconstruction. Reconstruction with a radial-free forearm flap has been shown to give better post-operative mouth opening than reconstruction with a split skin graft or buccal fat pad.[81]

Radiotherapy as a single treatment modality for T1/2 tumours has been advocated,[82, 83] however a change of practice from radiotherapy to surgery at Memorial Sloan Kettering was associated with improved prognosis.[84] Brachytherapy or external beam irradiation may be considered.

NECK

Regional spread of disease in buccal carcinoma is usually to the ipsilateral level I and II lymph nodes.[85, 86] Unlike carcinoma of the oral tongue, skip metastases to level IV of the neck are unusual.[75] It has been suggested patients with palpable lymphadenopathy or pathological nodes on imaging should have a comprehensive neck dissection, although if pathological nodes are only located in level Ia level I–III SND may be considered.[87] Nodes in the region of the facial artery as it crosses the mandible should be removed with the neck dissection specimen.

Patients with T2 or greater primary tumours or tumours with a thickness > 5mm should have an END.[67, 88] Some institutions will conduct an END if the tumour is 3–4 mm thick or if histological examination the tumour demonstrates lymphatic infiltration.[67]

PORT

The indications for PORT to the locoregional area are similar to other sites, notably 2 or more nodes in the neck,

extracapsular spread, positive margins or margins less than 3 mm[89] and stage III/IV disease.[72] The beneficial role of PORT in selected patients with buccal carcinoma has been demonstrated by several authors.[90, 91] Some authors suggest that PORT should be considered even in stage I and II disease,[66, 72, 92] or tumours greater than 10 mm thick.[90]

Recurrence

Recurrence rates for buccal carcinoma are 26–80%,[66, 67, 69, 72, 74, 77] usually occurring within 2 years.[67, 69, 77] Involvement of the parotid duct and buccinator have not been found to be significant indicators of recurrence.[66] Factors that influence recurrence include tumour thickness,[74, 76, 93] histological margins less than 3 mm[89] and tumour differentiation.[77] It has been demonstrated that following treatment for buccal carcinoma, distant failure is more common than regional failure compared to tongue carcinoma,[94] although survival rates are similar for both.[94, 95]

Prognosis

Buccal carcinoma is considered by many to be particularly aggressive,[73, 96] but not universally so.[95] Five-year survival figures vary depending on population studied and treatment modality.[67, 72, 97]

Factors that potentially influence survival include regional metastasis,[67, 98] extracapsular spread,[67, 97] tumour thickness >5–6 mm,[74, 76] skin involvement,[69] histological margins less than 2 mm[89, 97, 99] stage[71] and recurrent disease.[74]

KEY POINTS

- Commonest site for oral cancer in South East Asia.
- Associated with Betel / Paan consumption.
- Good surgical reconstruction is required to prevent post-operative trismus.
- Up to 26% have occult nodal metastasis at presentation.
- Consider END (Levels I–III) if tumour >4 mm thick.

FLOOR OF MOUTH CARCINOMA

Surgical anatomy

The floor of mouth is the mucosal lining of the anterior and lateral floor of the mouth. The area is bound anteriorly and laterally by the attached mucoperiosteum of the mandibular alveolus. The lateral floor of mouth is bound posteriorly by the anterior tonsillar pillars. Medially the floor of mouth merges with the ventral and lateral aspects of the tongue. The WHO classifies this anatomical site as ICD-10 C04.[1]

The floor of mouth is lined by non-keratinizing stratified squamous epithelium similar to the buccal mucosa, but with a less dense submucosa. Underlying the mucosa lie minor salivary glands, the sublingual glands, submandibular ducts, hypoglossal nerves, lingual nerves and genioglossus muscles. These structures are located in an area bound by the mylohyoid muscle laterally and hypoglossal muscle medially. The submandibular ducts enter the mouth anteriorly either side of the lingual frenum.

Sensory innervation to the area is by the lingual branch of the mandibular division of the trigeminal nerve. Lymphatic drainage of the lateral floor of the mouth is via the ipsilateral submandibular nodes to the deep cervical chain. Lymphatic drainage of the anterior floor of mouth is via the submental nodes to both the left and right deep cervical chains.[100] Lingual lymph nodes in the floor of mouth, located above the mylohyoid, may have implications in the management of tumours of the floor of mouth.[86, 101]

Epidemiology

The floor of mouth is a common site for oral cancer, 18–33% of oral cancers developing at this site.[46, 102–105] It is thought that the high incidence of cancer at this site may be due to pooling of saliva with dissolved carcinogens or lack of keratinized epithelium.[106] Within this anatomical site tumours are more likely to occur anteriorly.[107–109]

Floor of mouth carcinoma occurs more frequently in men,[104, 105, 108, 110, 111] the age at diagnosis usually being in the 6th–7th decade.[104, 110, 111] Floor of mouth cancer, as does oral cancer at all sites, has a strong association with smoking[106] and the consumption of alcohol.[110]

Presentation

Since the floor of mouth is a relatively small anatomical area, tumours frequently extend into adjacent sites notably the tongue or mandible.[112] Patients may present with a sore lesion, ulceration or obstructive submandibular gland symptoms.[113] Leukoplakia of the floor of mouth may be considered a premalignant condition with an annual transformation rate of 1–2.9%,[114, 115] and it is not uncommon to find a carcinoma focus within an excised leukoplakic lesion.

Stage at presentation varies considerably between institutions, although approximately 50% present with advanced disease.

Cervical lymphadenopathy is present in 17–45% of patients on presentation,[104, 105, 108, 116] up to 22% of those clinically N0 at presentation having occult metastasis.[104, 111, 116, 117] Depending on the location of the tumour up to 28.6% of patients may have bilateral nodal involvement.[105, 116] Many tumours of the floor of mouth are well or moderately differentiated.[108]

Workup

Workup of patients with floor-of-mouth tumours should follow that of any patient with oral cancer. Particularly important in larger floor of mouth tumours is assessment of invasion of the base of tongue or mandible. The loose connective tissue of the floor of mouth presents a poor barrier to local spread.

Treatment

PRIMARY SITE

The need for aggressive treatment of floor-of-mouth carcinomas is well recognized.[118]

Surgical resection with a 1 cm margin should be achieved if surgery is the preferred treatment modality. Even in the best surgeons' hands positive or close margins may be seen in up to 47% of resections,[104, 112] despite the use of intraoperative frozen section.[105] Many floor-of-mouth tumours are infiltrative with indistinct edges, possibly explaining the high incidence of positive margins.[105] Further resection is advocated if margins are positive.[105] Although 1 cm margins are considered by most surgeons to be adequate, extended 2 cm margins have been advocated by some.[119]

The early extension of floor-of-mouth tumours into the tongue or mandible is demonstrated by the fact that many patients require rim or segmental resection of the mandible.[104] Surgical resection of the floor of mouth in the majority of circumstances will involve resection of part of the submandibular ducts. Typically the ducts will be transected at the resection margin, well away from their orifice, although in smaller resections at least 3 mm length of duct proximal to the orifice should be taken to ensure surgical clearance of carcinoma or dysplasia that may extend along the duct.[120] Management of the submandibular ducts is of great importance if a neck dissection is not being conducted with consequent removal of the submandibular gland. Stricture of the duct in the presence of a functioning gland may give rise to obstructive symptoms of the gland and difficulty in differentiating the potential submandibular gland swelling from cervical disease. The ducts should be transected obliquely to minimize stricture formation and repositioned at the margin of resection, ideally being stented.[121] Alternatively, the ducts may be found proximal to the resection margin, a longitudinal incision made and the duct 'marsupialized' to the floor-of-mouth mucosa. Uninvolved branches of the lingual nerve should be identified and preserved.

Small resections may be left to heal by secondary intention or a split-thickness skin graft applied. It has been demonstrated that a better functional outcome is achieved with primary closure, however, this naturally can only be achieved with the smallest of tumours.[122]A more substantial reconstruction may be achieved using local nasolabial[123] or facial artery musculomucosal flaps,[124] but an edentulous segment is required when using both of these flaps to accommodate their pedicle. If a neck dissection is required and surgical facilities allow, microvascular reconstruction provides a far more flexible reconstructive option, without necessarily prolonging operative time if a two-team approach is adopted. The radial free-forearm flap is an ideal reconstructive option for floor-of-mouth defects, easily being converted to a composite flap if segmental resection of an edentulous mandible is required. Prefabricated fasciomucosal free flaps have been described in oral reconstruction,[125] however their role in oncological reconstruction is questioned. The fibula osteocutaneous flap provides superior reconstruction if a segmental resection is anticipated in a dentate patient, but unlike the composite radial free flap, flexibility of the skin paddle is limited. The scapula osteocutaneous flap with two skin paddles, or one skin paddle and muscle left to mucosalize, provides an excellent reconstruction of large defects involving mucosa, bone and external skin.

Radiotherapy techniques (brachytherapy or external beam) for T1/2 primaries have been shown to provide results similar to surgery.[108, 109, 126] The proximity of the floor of the mouth to the mandible is of concern when using brachytherapy since up to 8.5% of patients treated with this modality require segmental resection of the mandible due to osteoradionecrosis within 10 years.[108, 109]

Several units have described a change in practice from brachytherapy to surgery as the primary treatment modality due to the risk of complications.[105, 111, 127] T3/4 lesions are best treated with surgery and PORT.

NECK

Regional spread of disease in floor-of-mouth carcinomas is usually due to the ipsilateral level I to III lymph nodes,[86, 111] with involvement of multiple levels not being unusual. Lesions towards the midline may spread to both sides of the neck, hence bilateral neck dissections should be considered. The presence of lingual lymph nodes has raised the concept of in-continuity neck dissection[128] in an attempt to reduce local recurrence and improve survival. Resection of the tumour accompanied with the complete clearance of the floor of the mouth, preserving mylohyoid, hyoglossus and genioglossus if possible, so clearing the lingual lymph nodes would seem an acceptable method of managing lingual lymph nodes.[101]

The decision to perform an END has been related to tumour size or depth of invasion. Lesions that are T2 or greater should have a I–III/IV selective neck dissection,[104, 129] although ENDs have been advocated for T1 lesions.[108, 129]

Tumour thickness of 4 mm is often used as a 'generic' critical thickness, greater than which an END is indicated, since the risk of occult metastasis is greater than 20%.[130] It has been demonstrated that the risk of cervical metastasis of floor-of-mouth tumours exceeds 20% in tumours as thin as 1.5–2 mm.[131, 132] Using a thickness of 1.5 mm may result in up to 32% of patients requiring END based on thickness criteria.[131]

PORT

The indications for PORT to the locoregional area are similar to other sites, notably two or more involved nodes in the neck, extracapsular spread, positive margins or stage III/IV disease.

The beneficial role of PORT in selected patients with floor-of-mouth carcinoma has been demonstrated.[104, 112, 116]

Recurrence

Recurrence rates for floor-of-mouth carcinoma are 26–55%,[104, 111, 118] usually within the first 2 years.

Factors that influence recurrence include tumour size,[104, 111] margin status[104, 105] and tumour thickness[132] and advanced nodal disease.[111]

Prognosis

Overall 5-year survival for floor-of-mouth carcinoma is 52–76%.[104, 105, 111, 116] Factors that potentially influence survival include nodal status,[105, 116] thickness,[23] margin status and recurrence.[105]

KEY POINTS

- One of the commonest sites for oral cancer.
- Leukoplakia of the floor of mouth has a 1–2.9% annual malignant transformation rate.
- Careful consideration should be given to management of the submandibular ducts.
- Anterior lesions may require treatment of both necks.
- Tendency for cervical metastasis to occur in thinner tumours than other sites.

TONGUE CARCINOMA

Surgical anatomy

The oral tongue is the freely mobile anterior two-thirds of the tongue, demarcated from the base of tongue by the circumvallate papillae posteriorly. The tongue may be subdivided into the tip, dorsum, lateral borders and ventral surface. The WHO classifies this anatomical site as ICD-10 C02.[1] The ventral and lateral surfaces are in continuity with the floor of mouth, having a lining mucosa with non-keratinizing stratified squamous epithelium. The dorsum and tip of tongue are lined by specialized gustatory mucosa, with a thick, primarily keratinized epithelium. The mucosa of the tongue overlies the intrinsic muscles of the tongue, in addition to the four paired extrinsic muscles of the tongue: genioglossus, hyoglossus, styloglossus and palatoglossus.

Motor innervation to muscles of the tongue is via the hypoglossal nerve, except palatoglossus which is supplied by the vagus nerve. Sensation of the tongue is supplied by the lingual nerve, a branch of the mandibular division of the trigeminal nerve. Taste sensation of the oral tongue is supplied by fibres of the facial nerve that run with the lingual nerve before passing to the chorda tympanic branch of the facial nerve.

Lymphatic drainage of the lateral borders of the tongue is to the ipsilateral cervical nodes; however drainage of the midline, tip and base of tongue occurs bilaterally. The blood supply to tongue is provided by the paired lingual arteries, the third branch of the external carotid artery. During resection of posterior tongue lesions the contralateral vascular pedicle should be preserved if the tongue tip is to be maintained. The tongue is a complex structure with an important role in mastication, deglutition and speech.

Epidemiology

In populations where tobacco chewing is not endemic the oral tongue is one of the commonest sites for oral cancer, with 22% to 39% of oral cancers developing at this site.[46, 103, 133]

Within the site most tumours occur in the middle third of the tongue,[134, 135] commonly on the lateral aspect, followed by the ventral aspect of the tongue. Only 4–5% of tongue carcinomas occur on the dorsum of the tongue.[136]

Tongue cancer occurs slightly more frequently in males,[134, 137–140] the age at diagnosis usually being in the 6th–8th decade[134, 138, 139] and 90% of patients are over 40 years of age.[137] The male to female ratio has decreased in recent years, possibly due to increased alcohol consumption by females. Up to 70% report significant tobacco and alcohol use.[134]

Presentation

Patients with tongue cancer may present with several symptoms notably pain, ulceration or a lump on the tongue.[134, 137, 139, 141] Lesions of the oral tongue are more likely to be symptomatic than lesions of the base of tongue but despite this many patients still present with a 4–6 month history of symptoms prior to seeking medical advice.[137, 139, 142] The majority of patients with cancer of the oral tongue present with stage I/II disease,[134, 137, 138, 141] which contrasts significantly with cancers of the base of the tongue that are usually stage III/IV at presentation.[137] Clinically positive cervical lymphadenopathy at presentation is in the region of 21–34%.[134, 138, 140] Occult cervical metastasis has been demonstrated in up to 53% of patients with tongue cancer[134, 139, 142, 143] and may be related to tumour thickness.[144] Tumours arising on the lateral aspect of the tongue tend to be thicker than those of the ventral aspect of the tongue.[140] Up to 4.5% may have occult cervical disease in the contralateral neck.[139] Clinical examination, CT and MRI have relatively poor sensitivity at determining cervical lymphadenopathy.[140, 145]

The majority of tongue tumours are well to moderately differentiated on histological examination.[134, 137, 138, 141]

Workup

As with many sites management of the neck is frequently determined by tumour thickness. Tumour thickness can be assessed accurately with intraoral sonography, or immediate sonography of the resected tumour[52, 146] prior to proceeding to a neck dissection if access to the neck is not required for reconstructive purposes.

Biopsies should endeavour to include the deep margin of the tumour in addition to mucosa at the periphery of the tumour. Deep biopsies may give an indication of tumour depth, but also multifactorial histological malignancy grading of the most dysplastic areas of the invasive front may help in assessing the risk of cervical metastasis.[140]

Treatment

PRIMARY SITE

Resection of the tumour with a 1 cm margin in three dimensions should be conducted if surgery is the treatment of choice. The use of ultrasonography to aid in assessment of surgical clearance has been advocated,[52, 147] particularly for the deep margin. Frozen section is not routinely used in many units. Even with apparently adequate margins during surgery, 10% of resections may demonstrate histologically positive margins.[134]

Resection of tongue tumours using a 'compartmental' approach as adopted by musculoskeletal oncology surgeons has been advocated,[148, 149] with improved outcomes with this technique.[150]

The aim of reconstruction of the oral tongue following resection is to ensure maximum function of the residual tongue tissue, since the complex function of the tongue cannot be replicated with current reconstructive techniques.[151] Preservation of the tip of the tongue, while maintaining oncologically sound resection margins, helps maximize post-operative function.[152]

The use of monopolar electrocautery, 'cutting' through mucosa changing to 'coagulation' when in muscle, or the harmonic scalpel helps reduce bleeding during the resection, however this is at the cost of lack of feel afforded by the use of scalpel or scissors. If both lingual vessels are resected then the viability of the tip of tongue remnant should be carefully assessed. Sacrifice of both hypoglossal nerves results in a non-functioning tongue tip with consequent poor function.

Functional outcomes following reconstruction of the oral tongue are increasingly being scrutinized since many reconstructive methods are increasingly resource intensive.[153, 154] Small lesions may be removed with a laser and allowed to heal by secondary intention. T1 and small T2 primary tumours may be excised with a vertical wedge and the defect closed primarily, if the defect does not extend to significantly include the floor of mouth. Many larger lesions benefit from free-flap reconstruction of the defect, usually with a radial free-forearm flap, although the anterolateral thigh free flap is being used more frequently. The skin paddle of the chosen free flap should be fashioned so as not to restrict residual tongue function and should hopefully augment swallowing. Typically, the reconstruction should be of the same size, or slightly smaller than the defect created by the resection. Care should be taken in the design of the flap when the defect extends to include adjacent sites such as the soft palate or floor of mouth. The mobile tongue and floor of mouth should be 'separated' in the reconstruction to minimize restriction of movement of the residual tongue.[151] Thin radial free flaps may have their bulk increased by extending fascial flaps beyond the skin island, the fascial flaps then being folded and buried underneath the epithelial reconstruction.[151]

Reconstruction of large resections may be accompanied by measures aimed to improve post-operative function such as static laryngeal suspension to the mandible and cricopharyngeal myotomy.[151] Once the specimen is removed it is examined for clearance and orientated for the pathologist, supplemented by a digital photograph.

Radiotherapy as the primary treatment modality has been advocated since it conserves tongue volume and morphology, brachytherapy being considered preferable to external beam radiotherapy.[153] Osteoradionecrosis of the mandible is a recognized complication of brachytherapy of the tongue, up to 9% developing some form of osseous complication.[138] The use of brachytherapy to the primary site requires either surgery or external beam radiotherapy to the neck in an elective or therapeutic manner. When surgery is not used as the primary treatment valuable histological prognostic information is lost. This makes the decision as to whether to conduct an END more difficult. It has been suggested that surgery is superior to brachytherapy in the management of Stage I/II tongue cancer.[154] Surgery as the primary treatment modality ensures that radiotherapy is kept in reserve for either poor prognostic indicators of the resected specimen, for management of recurrence or management of second primaries which may occur at a later date.

NECK

Tumours of the tongue initially metastasize to levels I and II, lateral tongue tumours frequently metastasizing directly to level II nodes.[86] Involvement of level V nodes, in the absence of positive nodes in levels I–IV is rare, however, it is not unusual for nodes in level IV alone to be involved.[140, 155] Hence, in ENDs levels I–IV should be dissected, taking care to manage the thoracic duct appropriately which is the main cause of surgical complication in this area.

Like floor-of-mouth tumours the presence of lingual lymph nodes should be considered and either an in-continuity resection with the neck specimen or clearance of tissue above mylohyoid conducted.[156]

Bilateral neck dissections should be considered in tumours that extend to or beyond the midline, the use of frozen section on ipsilateral nodes having been proposed as method of identifying those in which a contralateral node may be indicated.[157]

The management of the neck in larger primary tumours is usually straightforward since the neck is accessed for microvascular or pedicled flap reconstruction of the primary site. Management difficulties arise with smaller tumours amenable to per oral resection and local closure.[144]

It has been proposed that the increased incidence of nodal metastasis associated with tongue carcinoma may be due to contraction of tongue muscle promoting entry of cancer cells into the lymphatics.[158] It is thought that the mechanism by which tumour thickness is related to cervical metastasis is that thicker tumours have access to wider lymphatics in which tumour emboli can form more readily.

Although tumours arising on the lateral aspect of the tongue tend to be thicker than those of the ventral aspect of the tongue,[140] this may not manifest as a greater risk

of cervical metastasis, since the 'critical thickness' for tumours of the floor of mouth is less than other oral sites.

END or elective neck radiotherapy should be considered for tumours thicker than 3–4 mm,[144, 159, 160] T2 or greater in dimension and T1 tumours that demonstrate poor histological features (poor differentiation, double DNA aneuploidy or degree of differentiation at the advancing front).[135, 160]

A recent randomized trial has largely settled the controversy about elective vs therapeutic neck dissection in the setting of the N0 neck. D'Cruz et al. reported on the oncologic outcomes of 500 patients (245 in the elective-surgery group and 255 in the therapeutic-surgery group), with a median follow-up of 39 months. At 3 years, elective node dissection resulted in an improved rate of overall survival (80.0%; 95% confidence interval [CI], 74.1–85.8), as compared with therapeutic dissection (67.5%; 95% CI, 61.0–73.9). END was associated with a reduced hazard for death in the elective-surgery group (0.64; 95% CI, 0.45–0.92; P=0.01). Patients in the elective-surgery group also had a higher rate of disease-free survival than those in the therapeutic-surgery group (69.5% vs. 45.9%, P<0.001).[159]

Other studies with similar have also demonstrated the survival advantages of END.[142, 143]

PORT

PORT has been advocated for positive margins,[134, 135] multiple cervical nodes,[135] extracapsular spread in the neck,[135] Stage III/IV disease,[134, 135] perineural spread[135] or tumours thicker than 9–10 mm even in the absence of other features.[144, 158, 161] Based on involved margins, ECS of cervical nodes or multiple positive nodes 26–62% of patients receiving surgery as the primary treatment modality may require PORT.[140, 162]

Local failure following PORT to tongue tumours has been demonstrated to be higher than comparable floor-of-mouth tumours, leading some to suggest higher doses of PORT should be considered for tongue tumours.[112]

Recurrence

Recurrence rates for oral tongue carcinoma are 10–50%,[139, 144] usually being locoregional.[134, 140]

Similar to other sites, recurrence usually occurs within the first 2 years.[134, 141]

Factors that influence local recurrence include tumour thickness and the presence of perineural spread.[144, 162] It has been proposed that recurrence of thicker tumours is related to difficulty in assessing deep clearance intraoperatively compared to assessing mucosal clearance.[158]

Patients younger than 40 years have been demonstrated to be significantly more likely to develop locoregional failure, although this does not influence survival.[163] Metachronous second tumours are seen in nearly 10% of patients who have had tongue cancer.[139]

Prognosis

Clinical features of tongue carcinoma remain the most reliable prognostic indicators, although histological characteristics contribute to prognostication.[164] Tumour thickness,[132, 140, 159, 160, 162] the presence of perineural invasion,[144, 162] cervical metastasis[139, 134] or dysplasia at the resection margins[160] have all been demonstrated to influence prognosis. Patients with tumours greater than 9 mm thick have been shown to have a 5-year survival of 66% compared to 100% survival for tumours less than 3 mm thick.[144] It has been reported by several groups that younger patients without usual risk factors have a poorer long-term prognosis.[164, 165]

KEY POINTS

- One of the most common sites for oral cancer.
- Usually presents as Stage I/II disease.
- ENDs should include levels I–IV because of skip metastases.
- Reconstruction should maximize function of the residual tongue.

RETROMOLAR CARCINOMA

Surgical anatomy

The retromolar trigone is a triangular area of mucosa that overlies the ascending ramus of the mandible. The base of the triangle is in the region of the mandibular third molar inferiorly, the apex being adjacent to the maxillary tuberosity superiorly. The area is bound by the buccal mucosa laterally and the anterior tonsillar pillar medially. The WHO classifies this anatomical site as ICD-10 C06.2.[1] The retromolar mucosa is not exposed to masticatory loads and so is covered by a lining mucosa with non-keratinizing stratified squamous epithelium, similar to the buccal mucosa. Sensory innervation to the area is by the buccal branch of the mandibular division of the trigeminal nerve. Lymphatic drainage is to the ipsilateral submandibular and deep cervical nodes.

Epidemiology

The retromolar trigone is a relatively unusual site for carcinoma of the oral cavity, only 6–7% of oral carcinomas arising at this site.[46, 164] The disease is more common in males and like other sites is typically a disease of older individuals.[164–166] Common with other oral sites, there is a strong association with smoking[166, 167] and alcohol consumption.

Presentation

Patients typically present late with pain, trismus, otalgia or lingual parathesia.[164, 167, 168] Since the retromolar tigone is an anatomically small-site tumour which often extends to involve adjacent subsites – buccal mucosa in 84%, oropharynx in 14%, masticator space (medial pterygoid, masseter, temporalis, mandibular branch of the trigeminal nerve) in 22%. Bone involvement of the mandible or maxilla is present in 12–34%[164, 166–169] of retromolar tumours, although a higher incidence of up to 75%

has been reported.[170] The posterior maxilla is more frequently involved than the mandible when bone invasion occurs.[166] Tumour extension into the masticator space or lower pterygoid plates classifies tumours in this area as T4b, however, if resectable outcomes are comparable to T4a tumours.[171]

Retromolar carcinoma usually presents as advanced disease, 55–73% having Stage III/IV disease at presentation.[164–166] Spread to regional lymphnodes occurs in 26–56% of patients at presentation,[164, 166, 172] 8–15% having occult cervical node involvement.[164, 172]

Tumours of the retromolar trigone are usually well or moderately differentiated.[166]

Workup

The complex anatomy of the retromolar region and the frequent extension of retromolar carcinoma make accurate preoperative imaging essential. Clinical examination alone is not reliable at determining underlying bone involvement.[173] CT has been demonstrated to have a high specificity, but low sensitivity for predicting mandibular bone invasion of retromolar carcinomas.[170, 174] MRI is considered the imaging modality of choice for retromolar tumours due to its ability to accurately stage the disease and demonstrate accurately anatomical relationships of the tumour,[175] although mandibular invasion may still be hard to define.

Treatment

PRIMARY

The treatment of choice for retromolar tumours is surgical resection with pre/post-operative radiotherapy or chemoradiotherapy dependant on stage of tumour and histological findings.[164–166, 168, 169, 173] Radiotherapy as a sole treatment modality for retromolar carcinoma has been demonstrated to be associated with significantly worse recurrence rates and disease-free survival,[165, 166] although others have been unable to demonstrate this significance.[167, 176] The debate regarding the use of surgery or radiotherapy as the primary treatment modality is hampered by the lack of data regarding tumour thickness in this anatomical site. It is recognized that tumours in this site may be T3 in size, but superficial in nature.[177]

Resection should be achieved with a 1 cm margin in all planes. It is recognized that the incidence of positive margins following resection of retromolar tumours is higher than other oral sites.[44]

Small tumours of the retromolar trigone may be resected via a transoral route, however, the posterior location of retromolar tumours and frequent extension of disease into adjacent anatomical sites often necessitates a mandibulotomy to facilitate access.[164, 168] Extensive tumours extending into the masticator space may require a cervicofacial incision, parotidectomy, +/– zygomatic osteotomy and preservation of the facial nerve for access, or an anterior approach including maxillectomy.[178]

Defects following the resection of small mucosal tumours may be left to heal by secondary intention, however, larger lesions require reconstruction to prevent trismus. Simple reconstructive methods include use of a split-skin graft or buccal-fat pad reconstruction. Tongue flaps and masseteric flaps have been described,[169] however they lack flexibility and may be compromised in anything but the smallest of tumours.

Given the low-negative predictive value of CT for bone involvement and the high incidence of bone involvement demonstrated in retrospective series, a low threshold for bone resection should be adopted.[173] A posterior marginal mandibulectomy (including coronoid) conducted via a visor or lip split soft-tissue flap is oncologically safe in patients with no history of previous radiotherapy and no radiological signs of cortical bone involvement.[168, 179] Patients demonstrating cortical bone involvement on imaging, or who have previously received radiotherapy, should have a segmental mandibular resection. A posterior maxillectomy should be conducted when indicated.

The combination of mandibulotomy and posterior marginal mandibulectomy for large soft tissue lesions should be avoided in view of the increased risk of osteoradionecrosis; a segmental resection is warranted in these circumstances.[180]

Pedicled myocutaneous flaps such as the pectoralis major flap are stretched to their limit at this anatomical site, often resulting in delayed healing.[168] The use of the radial free-forearm flap or anterolateral thigh flap provides excellent reconstruction of larger soft-tissue defects in the retromolar region. Where the resection involves the soft palate, the combination of free flap and superiorly based pharyngeal wall flap should be considered to minimize nasopharyngeal reflux.

Reconstruction following segmental resection should ideally be with free-tissue transfer such as the fibula, scapula or DCIA flaps. Since radiotherapy will almost certainly be indicated following segmental resection the use of vascularized bone flaps results in more predictable healing with lower risk of non-union or resorption.[168] The use of reconstruction plates and soft-tissue cover alone is particularly prone to failure in the retromolar region.[181]

Large tumours extending into mandible, maxilla, soft palate, tongue base and buccal mucosa require careful consideration regarding reconstructive options. Dual free flaps may provide ideal soft tissue and bony reconstruction but at the increased risk of complications. The scapula flap is versatile enough in thin individuals to be able to reconstruct these extensive defects.

NECK

Lymphatic spread to the neck is usually to levels I and II in the absence of detectable lymphadenopathy, however, involved nodes in levels III–V may occur in the presence of nodes in levels I and / or II.[172]

Unlike tumours at other sites there are little data correlating tumour thickness to incidence of cervical metastasis.

An END (levels I–III/IV) is indicated for any tumour bigger than T1,[164, 168, 172, 179] or where access to vessels in the neck is required for reconstruction.

PORT

Up to 58% of patients may require PORT/chemoradiotherapy,[164] an indication of the typically advanced nature of retromolar carcinomas.

Recurrence

Local and/or regional recurrence may occur in 20–37%,[164–166] depending on primary treatment modality and stage of disease on presentation. Recurrence usually occurs in the first 2 years.[172]

Prognosis

Factors influencing survival are stage, involvement of the masticator space[164] and cervical metastasis,[166, 168, 174] mean survival in patients with masticator space involvement being 38 months.[164] Patients receiving surgery combined with radiotherapy have been demonstrated to have a significant survival advantage over patients receiving radiotherapy alone.[165]

KEY POINTS

- 6–7% of oral carcinomas.
- Frequently presents as Stage III/IV disease with extension into adjacent sites.
- Accurate preoperative imaging is required to determine extent of disease.

MAXILLARY ALVEOLUS AND HARD PALATE

Surgical anatomy

The maxilla comprises the maxillary alveolus and the hard palate. The osseous alveolar process supports the maxillary dentition, being covered by a mucoperiosteum with a stratified squamous epithelium. The maxillary alveolus merges laterally with the buccal mucosa and lips at the gingival sulcus and medially with the hard palate. The alveolar process extends to the upper end of the pterygopalatine arches posteriorly. The hard palate lies within the horseshoe shape of the maxillary alveolus, merging imperceptively with the alveolar mucosa. The hard palate has minor salivary glands located in the submucosa, 33% of palatal tumours being derived from salivary epithelium.[182] Posteriorly, the hard palate merges with the soft palate at the posterior edge of the palatine bone. The WHO classifies these anatomical sites as ICD-10 C05.0 (hard palate) and C03.0 (maxillary alveolus).[1] Sensory innervation to the maxillary mucosa is by branches of the maxillary division of the trigeminal nerve. The nasopalatine nerve supplies the anterior hard palate, passing through the incisive foramen, the posterior palate being supplied by the paired greater palatine nerves that pass through the greater palatine foraminae. Lymphatic drainage is to the ipsilateral cervical nodes via the submandibular nodes or potentially the retropharyngeal nodes in posteriorly located tumours.

Epidemiology

Squamous cell carcinoma of the maxillary alveolus represents 3.5–6.5%[60, 103] of oral cancers, being approximately one-third as common as mandibular alveolar carcinoma. Carcinoma of the hard palate is very unusual representing only 1–3%[183, 184] of oral cancers. Aetiological factors include tobacco use and alcohol consumption. Palatal carcinoma is particularly associated with reverse smoking, a habit practised in parts of India by women.[185–187]

Patients tend to present in their 6th–7th decade of life.[183, 186, 188] There is an even distribution between the sexes, except where reverse smoking is practised when there is a greater frequency in females.[186]

Presentation

Patients may present with pain, ulceration, loose teeth or poorly fitting dentures. Symptoms of advanced disease may include infraorbital parathesia, trismus or nasal obstruction. Most patients present with Stage I or II disease.[183, 188]

Approximately 8% of patients with carcinoma of the hard palate or maxillary alveolus present with cervical lymphadenopathy, a further 27% having occult metastasis.[188]

Workup

The surface extent of a maxillary carcinoma may be relatively easy to determine from clinical examination alone, however, extension into the maxillary antrum and beyond requires additional imaging. Extension of tumour through the pterygoid plates into the masticator space may render a tumour inoperable. CT scans and MRI are complementary in the assessment of maxillary tumours.[189]

Intranasal examination with a nasendoscope should be conducted to determine the extent of tumour through the floor of nose or medial antral wall.

All patients should have impressions taken for the provision of a temporary obturator, even if free-flap reconstruction is anticipated. In the unfortunate situation of free-flap failure the presence of pre-surgical models will make prosthetic salvage considerably easier. If prosthetic reconstruction is to be considered from the outset then early consultation with a prosthodontist is required.

Treatment

PRIMARY

Anaesthesia is usually accomplished with an oral tube, a tracheostomy only being considered for larger resections or free-flap reconstruction. Patients requiring an upper cheek flap for access should have their eyes protected with corneal shields or temporary tarsorraphies.

The surgical goals that apply to hard palate and maxillary alveolar tumours are the same as those at other sites, notably surgical clearance of 1 cm in three dimensions. Small tumours may be approached per orally, however larger tumours may require an upper cheek flap or midfacial degloving to augment access.

Once the mucosal incisions have been completed the soft tissues are elevated in a subperiosteal plane away from the tumour to allow access for bone cuts. Teeth may need to be extracted to allow osteotomy cuts and minimize post-operative complications. The use of a fine reciprocating or saggital saw allows accurate bony resection. Care should be taken to avoid tooth roots. If the margins of resection extend posteriorly the specimen may be disarticulated from the pterygoid plates with a curved osteotome. Posterior dissection may be completed with large curved scissors. The posterior dissection in the region of the pterygoids should be last part of the resection due to the bleeding that occurs in this area. An ipsilateral coronoidectomy should be conducted to minimize impingement of the coronoid on the prosthesis or flap reconstruction. Defects that are to be reconstructed with a prosthesis should be lined with a split skin graft.

Surgical closure of small maxillectomy defects may be achieved with local flaps such as buccal fat pad, temporalis flaps or facial artery musculomucosal flaps. Large defects may require soft tissue[190] or composite free tissue transfer.[191] The use of an appropriate defect classification system[194] allows for planning of reconstruction and communication with colleagues.

NECK

Historically, regional spread from maxillary tumours has been considered low, however this may be due to coregistration of hard palate and alveolar tumours as sinonasal tumours.[182] Cervical metastasis has been demonstrated in 35% of patients with hard palate or maxillary alveolar carcinomas,[188] an elective I–III neck dissection being considered appropriate for lesions of T2 size or greater.[182, 192] Consideration should be given to clearing the facial lymph nodes when conducting a neck dissection for maxillary tumours.

PORT

PORT has been suggested for T3 or greater disease, positive margins, perineural or perivascular invasion or multiple cervical nodes, particularly if they demonstrate extracapsular spread.[182]

Recurrence

Locoregional control of hard palate and alveolar tumours following initial therapy is in the region of 40–45%,[183, 188] increasing to 68% following secondary intervention.[183] Salvage of local recurrence may be achieved in 33% and regional recurrence in 71%.[188] Over 90% of recurrences occur within the first 2 years, similar to other sites.

Prognosis

The 5-year absolute survival for hard palate carcinoma is 57%, 5-year survival for alveolar carcinoma being 49%.[185] Tumour stage and presence of cervical metastasis influence long-term survival.[183] The origin of maxillary carcinoma (oral vs sinus) does not influence long-term prognosis.[193]

Current staging of maxillary tumours categorizes a tumour as T4 if cortical bone is breached. It has been suggested that a more accurate prognostic indication is given if T4 is reserved for tumours that breach the nasal or sinus floor.[194]

KEY POINTS

- Carcinoma of the maxillary alveolus is three times less common than the mandibular alveolus.
- Carcinoma of the hard palate represents only 1–3% of oral cancers.
- Palatal carcinoma is associated with reverse smoking.
- All patients should have dental impressions as part of their workup.
- Some degree of bone removal is nearly always required.
- Selective neck dissection is often indicated.

MANDIBULAR ALVEOLUS

Surgical anatomy

The mandibular alveolus represents that part of the mandible that is 'intraoral'. The osseous alveolar process of the mandible supports the dentition and is covered by a mucoperiosteum. The mandibular alveolus merges laterally with the buccal mucosa/lips at the gingival sulcus and medially with the floor of mouth. The alveolar process extends to the retromolar trigones posteriorly. The WHO classifies this anatomical site as ICD-10 C03.1.[1] Sensory innervation to the mandibular alveolus is by the mandibular division of the trigeminal nerve. Lymphatic drainage is to the ipsilateral submandibular and submental nodes to the deep cervical chain. Lymphatic drainage towards the midline may be bilateral. Following loss of the dentition there is considerable resorption of the alveolar process, leaving only a thin strip of attached mucoperiosteum on the crest of the mandible between the floor-of-mouth and buccal mucosa.

Epidemiology

Squamous cell carcinoma of the mandibular alveolus represents 7.5–17.5%[60, 103, 184] of oral cancers, although it represents up to 30% of oral cancers in the Japanese population.[195] Mandibular alveolar carcinoma is three times more common than maxillary alveolar carcinoma.[196] Rarely primary intraosseous carcinomas may occur, being derived from residues of odontogenic epithelium within the mandible.[197] The use of tobacco, particularly chewing tobacco, and alcohol is associated with alveolar carcinoma.

Patients tend to present later in life in their 7th decade, the disease being slightly more common in males.[195, 196, 198]

Presentation

The most common presenting symptom is pain, occurring in 54–86% of patients.[195, 196, 198] Patients who are dentate may note loosening of teeth while edentulous patients may note a change of fit of their dentures. Labial parathesia may be a presenting feature in up to 14% of patients. Unfortunately patients still present with a history of delayed healing of an extraction socket in up to 28% of cases.[195] The majority of lesions of the mandibular alveolus are located posterior to the canines, extension to the floor-of-mouth or buccal mucosa being common.[196]

Alveolar tumours are staged by their size until there is invasion of tumour through cortical bone into marrow space when the tumour becomes T4. Cervical lymphadenopathy is present in 24–32% of patients at presentation, usually to levels I and II,[195, 196, 198] with 15% of patients having occult metastasis.[196] Up to 94% of patients have evidence of bone involvement clinically.[198] Most tumours at this site are usually well or moderately differentiated.[196, 198]

Workup

The most important aspect of working up mandibular alveolar tumours is to determine the degree of bone involvement since this determines the extent of tumour resection.

Treatment

PRIMARY

Mandibular alveolar carcinoma is considered a surgical disease.[198] Invariably some degree of bone resection is required, 6–7% requiring soft tissue resection only.[196, 198, 199] Small alveolar carcinomas with no clinical evidence of significant bone involvement may be resected via a per oral approach with a marginal mandibulectomy, aiming for a 1 cm soft tissue and bony margin. Larger tumours with obvious bone involvement require segmental resection and extraoral access incisions. Segmental resection should be considered for tumours abutting a mandible previously exposed to radiotherapy, large soft tissue tumours adjacent to the mandible, involvement of the inferior dental nerve or intraosseous tumours (primary or secondary). Marginal mandibulectomy is preferable to segmental resection whenever oncologically acceptable. If a marginal resection is conducted then reconstruction may usually be achieved by primary closure. More extensive mucosal defects may require reconstruction with a skin graft; local flaps such as the FAMM flap, nasolabial flap or buccal fat pad; or microvascular free-tissue transfer to achieve acceptable soft-tissue closure. Segmental mandibular resection should be accompanied with composite microvascular free-flap reconstruction whenever feasible. Small, lateral mandibular defects may be reconstructed with a reconstruction plate and soft-tissue flap only, however central defects or larger lateral defects should be reconstructed with vascularized bone to minimize the risk of complications.[200] The use of a recognized mandibular defect classification helps surgeons plan appropriate reconstruction and communicate effectively with colleagues. The H, C, L, o, m, s classification system[201] accurately describes mandibular surgical defects.

NECK

Regional spread of mandibular alveolar tumours is usually to the ipsilateral level I–III nodes. END is indicated in tumours T2 in size or greater or any tumour with demonstrable bone invasion, clearance of levels I–III being adequate.[202] Lesions overlying the symphysis are thought to be associated with a higher risk of cervical metastasis and may require bilateral neck dissections. It has been argued that a staged neck dissection should be considered if histological examination of the primary tumour demonstrates bone involvement.[202] A more extensive neck dissection should be conducted in the presence of confirmed cervical metastasis, level V requiring treatment.[202]

PORT

Indications for PORT include positive margins (soft tissue or bone), multiple positive nodes or extracapsular spread.[196]

Recurrence

Recurrence rates for mandibular alveolar carcinoma at 2 years are 13–25%.[195, 196, 198] Higher recurrence rates are associated with increasing T stage[199] and positive resection margins.[195, 196]

Prognosis

Overall 5-year survival for lower alveolus carcinoma is 50–60%, disease-specific survival being 73–80%.[195, 196]

Cervical metastasis has been demonstrated to significantly reduce prognosis for lower gingival carcinoma.[202] Increasing T stage and particularly tumours greater than 3 cm,[196] bone involvement (cortical or cancellous),[196] positive resection margins[195, 196] are associated with decreased prognosis.

Tooth extraction at the site of primary tumour does not influence prognosis.[195, 196]

KEY POINTS

- Represents approximately 10% of oral cancers, although up to 30% in the Japanese population.
- 94% of tumours involve bone.
- Alveolar carcinoma is a surgical disease requiring a rim or segmental resection of the mandible.

MANAGEMENT OF THE MANDIBLE

Tumours of the mandibular alveolus, the floor of mouth, buccal mucosa or retromolar trigone may involve the bone of the mandible. Involvement of the mandible has

significant consequences regarding management of the patient.

Squamous cell carcinoma invades the mandible either in an invasive or erosive manner.[199, 203] Invasive tumours demonstrate fingers or islands of tumour advancing deeply into bone with no obvious osteoclastic activity. Erosive tumours have a broad advancing front with osteoclast activity and connective tissue between the tumour and bone, although as the depth of invasion increases they may become more invasive in character. Large, deeply invading tumours are more likely to demonstrate an invasive pattern of spread and involve the mandible.[199, 204]

Tumours enter the mandible at the point of contact,[199, 205] usually the junction of the attached and reflected mucosa, whether the patent is edentulous or dentate. The mandible should be considered at risk at any point where tumour is in contact and this taken into account when planning resection.[206] Clinical fixation of the tumour to bone is not necessary for bone invasion to occur.

It has been demonstrated that it is primarily the size and extent of the tumour that dictates the pattern of spread once in bone rather than anatomical features such as the inferior alveolar nerve or periodontal ligament. Preferential spread within the mandible via the inferior alveolar nerve or medullary space is rare,[199, 207] justifying 1 cm margins.

Tumours demonstrating an invasive pattern of spread are more likely to give rise to cervical metastasis with extracapsular extension,[199] an indication of their more aggressive nature. Pre-operative imaging of the mandible is necessary to determine if bone resection is required, and if so the appropriate type of resection.[208]

At present there is no single investigation that can reliably predict bone invasion. An OPG radiograph should be requested for all cancer patients. This plain radiograph is not only useful for demonstrating bony invasion but also for assessing mandibular height, dental anatomy and dental pathology. It should be remembered that plain X-rays do not detect initial invasion until 30% demineralization has occurred, giving rise to reduced sensitivity.[209] Clinical examination and OPG alone are inadequate for accurate assessment of mandibular invasion.[209]

Axial MRI views with T1 and Short-TI Inversion Recovery (STIR) fat suppression are very sensitive for imaging the primary site of oral cancer with an adequate specificity.[210] Bone scintigraphy or single photon emission computed tomography (SPECT) may be considered in equivocal cases, SPECT being demonstrated to have up to 100% sensitivity in determining bone invasion.[211] When bone involvement is equivocal on pre-operative imaging then periosteal stripping looking for cortical bone disruption at the time of resection may help the clinician plan the resection.

A rim resection/ marginal mandibulectomy should be considered for T1/2 tumours with early invasion (< 5 mm) and adequate bone height of the mandible (dependant on pre-operative imaging, clinical examination and periosteal stripping).[212, 213] Traditionally rim resections have been conducted horizontally, however, with the understanding that tumour may enter the mandible at any point of contact it becomes apparent that the saw cut should be angled to accommodate this.[199] Marginal resections in the retromolar region may include the coronoid process. Every effort should be made to preserve the inferior alveolar neurovascular bundle when conducting a marginal resection in an edentulous mandible so as to minimize the risk of avascular necrosis and iatrogenic fracture. The anterior and posterior margins of a rim resection should be curved so as to minimize the risk of iatrogenic mandibular fracture. Rounding of the edges of the rim resection also minimizes the risk of bone exposure[214] and minimizes the risk of trauma to the pedicle of a microvascular free flap if used for soft tissue reconstruction. If the depth of the mandible following rim resection is less than 10 mm then consideration should be given to converting the resection to a segmental resection.

Segmental mandibular resection and composite reconstruction should be conducted for extensive mandibular invasion or deeply invading soft-tissue tumours that abut the whole depth of mandible. Segmental resection should also be considered in the previously irradiated mandible.[215, 216] The surgeon should aim for a 1 cm margin of the soft tissue tumour, it being highly unusual to get a positive bone margin in the absence of a positive soft-tissue margin.[212]

Usually intra-operative assessment of bony margins is not conducted, however techniques for frozen section analysis of cancellous and cortical bone have been described.[217]

If the planned resection of mandible follows the guidelines set out above then long-term prognosis and recurrence does not differ between marginal resection and segmental resection.[218, 219] The presence of bone involvement, rather than the depth of bone invasion, is the main determining factor of long-term prognosis.[196, 220] It has been proposed that only tumours with an invasive tumour front as opposed to an erosive front be classified as T4 tumours.[220] It is thought that local recurrence following bony resection is usually as a consequence of soft-tissue margin status rather than method of mandibular resection.[221]

Rim resection of the mandible maintains bony continuity and hence is usually associated with an excellent functional and cosmetic outcome. The rim resection in addition to maintaining the structural integrity of the mandible also usually preserves sensation of the lower lip and muscular attachments. With modern reconstructive techniques the Andy Gump deformity should no longer be encountered. Patients' quality of life following mandibular resection is influenced by many factors such as site of bony resection, type of bony resection, the soft-tissue resection, type of reconstruction, adjunctive radiotherapy etc.

It is recognized that whenever oncologically sound, a rim resection should be the resection of choice.[222] However, it has been demonstrated that there is little or no difference in quality of life between a rim resection and segmental resection with composite microvascular free tissue transfer,[226] particularly when the resection is greater than 4 cm.[223]

KEY POINTS

- Bone involvement may be by erosion or invasion.
- Bone involvement occurs at any point where tumour contacts bone.
- MRI, CT, SPECT and periosteal stripping are complimentary in assessing bone involvement.
- Bone margins should be dictated by overlying soft-tissue margins.
- Rim resection should be conducted when oncologically acceptable.

LIP RECONSTRUCTION

Omar A. Ahmed

INTRODUCTION

The lips are complex, highly specialized structures, which are the most mobile elements of the lower third of the face. They serve a critical, aesthetic and functional purpose, which cannot be replicated by any other tissue. Hence it is imperative, wherever possible, to replace lip defects with lip tissue.

The lips are considered to be the beginning of the oral cavity, and they form a fleshy, sensate, highly mobile partition, which separates the intraoral contents from the exterior. They are thus responsible for oral continence, but also play an important role in eating, swallowing, speech, and both verbal and non-verbal communication.

ANATOMY

The lips surround the oral cavity. They are composed externally of skin and internally of mucous membrane. The lips extend from the nose superiorly to the chin inferiorly, and are bound laterally by the nasolabial folds. It is important to have a good knowledge of the anatomical landmarks of the lips (**Figure 12.5**).

The external landmarks of the upper lip are the philtral columns, the Cupid's bow, and the white roll. The philtral columns are a pair of near-vertical ridges, extending from the nasal columella to the vermilion border, which are formed by the underlying orbicularis oris muscles. The philtral columns merge caudally with the white roll, another ridge formed by the orbicularis oris muscle. The philtral dimple is a depression in the central lip between the philtral columns. The Cupid's bow is the curved part of the white roll between the bases of the philtral columns. The main external landmark of the lower lip is the white roll.

A cross-section of the lips reveals the following structures from external to internal: skin and vermilion, subcutaneous tissue, muscle, submucous glands and mucosa (**Figure 12.6**).

The skin of the lips is hair-bearing, with the hair being mostly vellus in women and children. It is rich in sebaceous and sweat glands. Deep to the skin is a significant amount of subcutaneous fat that makes up the bulk of lip thickness. The vermilion extends from the white roll to the wet-dry border, beyond which it transforms into mucosa. It is important to understand the distinction between the vermilion and the mucosa. The vermilion is stratified squamous epithelium with a thin layer of surface keratin. It contains no glands, and is dryer and duller in appearance than mucosa. Mucosa is non-keratinized epithelium that is rich in minor salivary glands and lines the inside of the lip.

The perioral musculature can be classified into three groups based on their attachments (**Figure 12.7**). Group I muscles attach to the modiolus, which is a tendinous thickening at each oral commissure. Group II muscles insert into the upper lip, and Group III muscles insert into the lower lip. Group I muscles include the orbicularis oris, buccinator, levator anguli oris, depressor anguli oris, zygomaticus major and risorius. Group II muscles include the levator labii superioris, levator labii superioris alaeque nasi and zygomaticus minor.

Group III muscles are the depressor labii inferioris, mentalis and platysma.

The paired orbicularis oris muscles are the sphincter muscles of the lips and are essential for oral competence. They also evert and protrude the lips, as in pouting and kissing. They originate at the modiolus, just lateral to the oral commissure. The two muscles insert into a midline raphe in the lower lip, but in the upper lip they cross

the midline to insert into the contralateral philtral column. The orbicularis muscles are innervated by buccal branches of the facial nerve. The second most important lip muscles are the paired mentalis muscles, which are the primary elevators of the lower lip. They maintain the lower lip in a correct position at rest, and help maintain oral competence by pushing the lower lip against the upper lip. The mentalis muscles are large trapezoidal muscles that attach superiorly to the mandible just below the attached gingiva and inferiorly to the chin pad below the labiomental sulcus. Each muscle is innervated by the corresponding marginal mandibular branch of the facial nerve.

The depressors of the lip are the depressor anguli oris and the depressor labii inferioris, innervated by the marginal mandibular branch of the facial nerve, and the platysma, whose nerve supply is from the cervical branches of the facial nerve. The elevators of the upper lip include the levator labii superioris, zygomaticus major and minor, and levator anguli oris, which lift the central upper lip, lateral upper lip and commissure respectively. These muscles are innervated by the zygomatic and buccal branches of the facial nerve.

The sensory innervation of the lip is provided by the infraorbital and mental nerves. The infraorbital nerve is a branch of the maxillary division of the trigeminal nerve, which enters the face through the infraorbital foramen and provides sensation to the nasal sidewall, nasal ala and the upper lip. The mental nerve is a branch of the posterior trunk of the inferior alveolar nerve, which arises from the mandibular division of the trigeminal nerve. The mental nerve exits the mandible between the first and second premolar teeth. It provides sensation to the lower lip. Intraoral infiltration of small amounts of local anaesthetic solution around the bony exit points of these two nerves allows for rapid and complete anaesthesia of the lips, making it easy to perform surgical procedures without general anaesthesia.

The lips have a rich vascular supply (**Figure 12.8**). The arterial supply is from the superior and inferior labial arteries, which are branches of the facial artery. Each labial artery communicates with its counterpart across the lip, forming a continuous arterial circle around the oral sphincter. This allows for considerable versatility in local flap design. The arteries lie at the wet-dry border, just deep to the orbicularis oris muscle, and send numerous perforators through the orbicularis muscle to the overlying skin. The blood supply to the labial skin is so rich that local flaps can survive even when they do not include a labial artery. The venous drainage of the lips is more unpredictable than the arterial supply. The labial veins can drain into the anterior facial veins, transverse cervical veins, the superficial temporal veins and the submental veins.

Knowledge of the lymphatic drainage of the lips is important for oncological considerations. Drainage from the upper lip is primarily to the submandibular nodes, but the commissure can drain to the periparotid nodes. Both of these nodal regions subsequently drain to the jugulodigastric nodes. The drainage is mostly to ipsilateral nodes, although the midline of the upper lip can also drain to contralateral nodes. The lower lip also drains to the ipsilateral submandibular nodes with the exception of the midline lip, which drains into the submental nodes. Drainage from the central lower lip frequently crosses the midline. The submental nodes subsequently drain into the submandibular nodes.

HISTORY OF LIP RECONSTRUCTION

A wide variety of techniques have been described to reconstruct the lips. Functional and aesthetic results are best when the lip tissues are oriented in their correct anatomical positions.

Lip reconstruction has been practised for centuries, and most modern techniques are based on older techniques. Sushruta, the great Indian physician and surgeon, provided one of the earliest written records of lip reconstruction in his compendium of surgery (*Sushruta Samhita*), possibly around 600 BC.[228] The Roman

physician Celsus is credited with the original description of the classic wedge excision and primary closure of the lip in the 1st century AD. The Branca family and, later, Tagliacozzi popularized staged tissue transfer techniques in the late 16th century. Tagliacozzi is also credited with writing the first textbook on plastic surgery. In 1818, von Graefe described lip reconstruction in the second textbook on plastic surgery, and was the first to coin the term 'plastic surgery'. Shortly thereafter, in 1834, Dieffenbach described the first cheek advancement flap techniques.[229] The Italian surgeon Pietro Sabattini (1838) came up with the concept of lip-switch flaps,[230] which were popularized in the late 19th century by Abbe[231] and Estlander[232] and are still in common use. In 1853, von Burow[233] applied his principle of skin triangle excisions to facilitate advancement to bilateral cheek advancement flaps for total lip reconstruction. Bernard[234] described a similar technique in 1852. Modifications of the von Burow and Bernard techniques remain useful to this day, especially that of Freeman[235] (1958) and Webster[236] (1960). In the 1920s Gillies introduced the fan flap, which was aimed at restoring a competent oral sphincter. Karapandzic[237] described his elegant neurovascular lip rotation technique for large defects in 1974. Harii and Ohmori were the first to use microvascular free tissue transfer for extensive defects of the lip (1975).[238]

AETIOLOGY OF LIP DEFECTS

The majority of lip defects requiring reconstruction arise from tumours or trauma. Lip tumours can be congenital or acquired. Haemangiomas and vascular malformations are common congenital tumours. Skin cancers make up the bulk of acquired tumours. Basal cell carcinomas tend to occur in the upper lip and squamous cell carcinomas in the more sun-exposed lower lip. Both of these tumours are more common in the elderly. Malignant melanomas also often occur in the lips and can occur at any age. Traumatic lip defects usually occur in young, healthy patients.

PRINCIPLES OF LIP RECONSTRUCTION

1. In order to maintain oral continence, an attempt should always be made to preserve the nerve supply to the reconstructed lip.
2. Muscle-carrying lip vermilion is precious tissue and should also be preserved.
3. Lip tissue should preferentially be used to reconstruct the lip.
4. Whenever possible the muscles of the lip should be correctly orientated.
5. When a lip defect is too large to be reconstructed by remaining lip tissue, adjacent tissues such as the cheeks should be used.
6. Reconstruction by distant tissues, such as free-tissue transfer, should only be performed when there is insufficient local tissue to reconstruct the defect.

Reconstruction of the vermilion

Scars within the vermilion usually heal extremely well. Small vermilion defects can often be closed directly. Lateral superficial defects can be allowed to heal by secondary intention, as long as they are not too close to the white roll. Larger vermilion defects that do not involve the white roll require flap reconstruction, either lip (vermilion) flaps or non-lip (mucosal and tongue) flaps.

Vermilion flaps are best suited for defects close to the white roll and include vermilion advancement flaps or vermilion 'switch' flaps from the opposite lip. Vermilion advancement flaps are reliable flaps based on the labial vessel. The external incision is made directly on the vermilion border and the mucosal incision is made at the corresponding level inside the lip. In vermilion switch flaps the vermilion is cut in similar fashion to a vermilion advancement, but the flap is inset to the opposite lip. If only part of the vermilion is used, the secondary defect is closed directly at the time of inset. If, on the other hand, the full height of the vermilion is used, the defect in the donor lip is reconstructed by vermilion advancement at the time of flap division.

Mucosal advancement flaps are useful for total vermilionectomy defects after cancer resection. In such situations, it is important to carefully raise the mucosal flap in the plane between submucosa and muscle so as to maximize sensory innervation of the reconstructed vermilion. When a lip 'shave' has been performed for dysplasia, resulting in a shallow defect of vermilion, mucosa can be sutured directly to the skin without undermining. Mucosal advancement is also indicated for broad defects that are remote from the vermilion border. These flaps can be raised in V-Y fashion or as bipedicled flaps.

When mucosa is insufficient, tongue flaps can be used. They are usually raised on the lateral border of the tongue and can be anteriorly or dorsally based for vermilion reconstruction. The anteriorly based lateral tongue flap provides more bulk than the dorsally based flap. Tongue flaps are performed in two stages and are best reserved for lateral vermilion defects.

Reconstruction of the upper lip

Superficial defects of the upper lip, with intact orbicularis oris, can often be reconstructed by simple methods. Central defects involving less than half the distance between the philtral columns can either be repaired primarily or with a wedge resection. In all wedge resections, it is essential that the orbicularis muscle be accurately repaired for normal lip movement. If the defect is superficial and involves more than half of the central lip without crossing the philtrum, a full-thickness skin graft can give adequate results. In men, this graft could be taken from hair-bearing preauricular skin to restore hair growth. For superficial lateral defects which are less than half the width of the

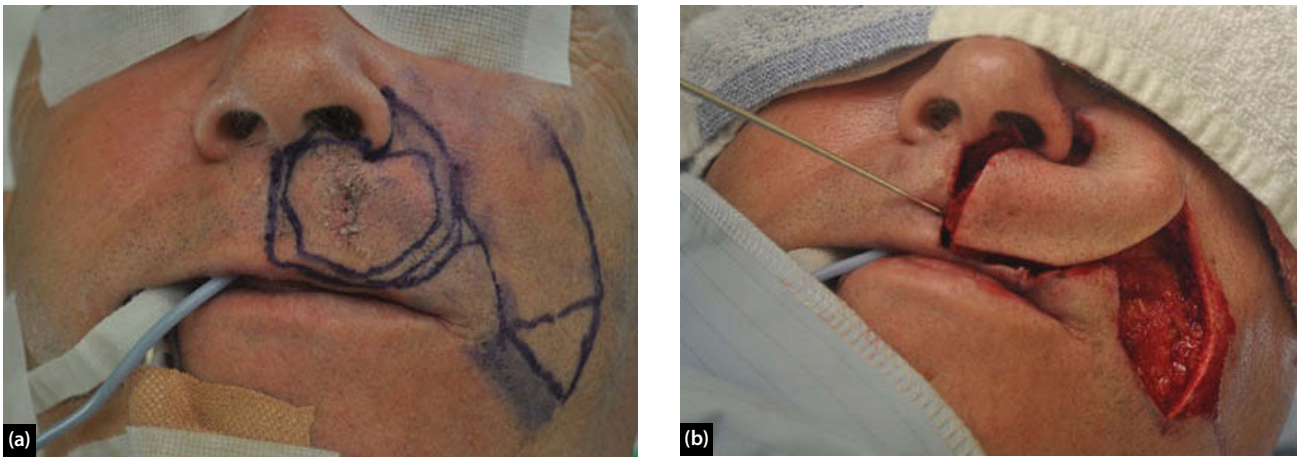

Figure 12.9 (a) Upper lip cancer prior to excision, showing design of a superiorly-based hair-bearing nasolabial flap from left cheek. **(b)** Nasolabial flap being transposed to defect.

lateral lip, wedge resection is a good option. When the defect involves more than half the width of the lateral lip, a local flap from the cheek may be a good option (**Figure 12.9**). Alternatively, a full-thickness graft can be just as acceptable.

The management of full-thickness defects of the upper lip depends on their size and location. Defects up to one-third in width can usually be closed directly, often with the aid of perialar crescentic excisions.[239] If primary closure is employed for central defects it can result in a narrow central lip, but this is usually cosmetically acceptable. When a central defect is greater than half of the upper lip, an Abbe-Sabattini flap from the lower lip is indicated (**Figure 12.10**).

In such situations the whole central lip subunit (from philtral column to philtral column) should be excised. The width and height of the flap should equal that of the upper lip defect. The flap is based on a single inferior labial artery and should ideally be harvested from the central lower lip. It should include the central raphe of the orbicularis oris muscles. When raising the flap, all elements of the lower lip are divided on the non-pedicle side, making a note of the location of the labial artery. On the pedicle side, the artery and a small cuff of mucosa are preserved. The donor defect on the lower lip is generally closed primarily before the flap is inset in layers to the upper lip and columella. The pedicle can be safely divided at 2–3 weeks. This flap is ideal for secondary correction of bilateral cleft lips when there is inadequate upper lip height and volume. A major disadvantage is the two stages required for transfer.

The Abbe-Sabattini flap can also be used to replace lateral lip defects larger than a third if the defect does not involve the oral commissure. If the lip switch flap is combined with perialar crescentic excision and lip advancement, this narrows the lateral upper lip defect so that a smaller flap is required from the lower lip.

For defects of the upper lip greater than 50%, a larger lip switch flap can be used in combination with bilateral perialar crescentic excision and advancement. The large lower lip donor defect can then be closed with the aid of bilateral Schuchardt medial advancement (**Figure 12.11**).

This technique will create microstomia which may require secondary revision. When performing lip-sharing procedures, it is important to maintain a balance between upper and lower lip length.

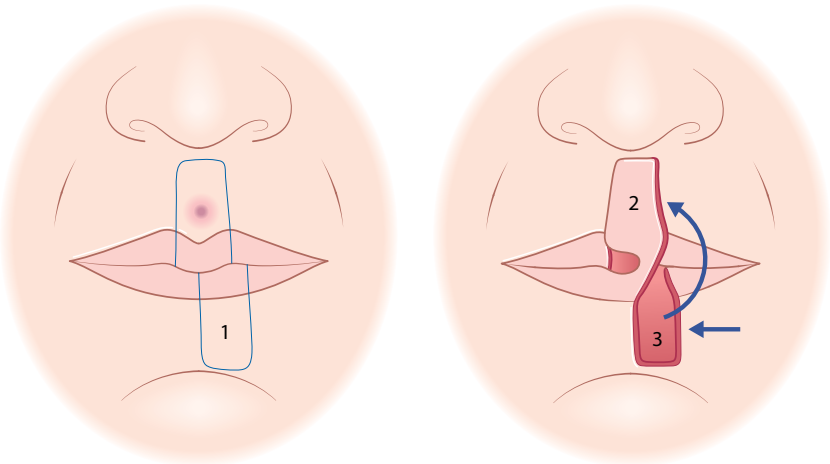

Figure 12.10 Abbe-Sabattini flap. 1. Design of flap and subunit excision. 2. Rotate the flap into the defect on its pedicle. 3. Close the donor site.

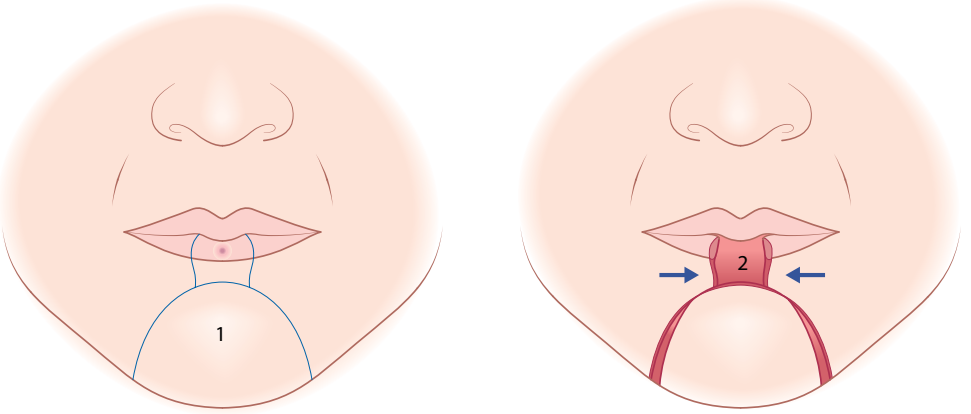

Figure 12.11 Schuchardt bilateral medial advancement flap.
1. Design the full thickness excision and the submental triangles for excision. 2. Advance the lower lip and chin to close the defect.

Subtotal and total upper lip defects are, thankfully, rare and reconstruction with local tissues may not be possible. Fortunately, the upper lip is not as important for oral competence as the lower lip, and static reconstruction with a folded soft-tissue flap, such as a radial forearm free flap, can provide a reasonable total upper lip reconstruction in a single stage.

Reconstruction of the lower lip

Superficial defects of the lower lip are usually best treated by full thickness wedge excision and primary closure, though extensive superficial defects may be simply reconstructed by a full-thickness skin graft, especially if the bulk of lip muscle is still present.

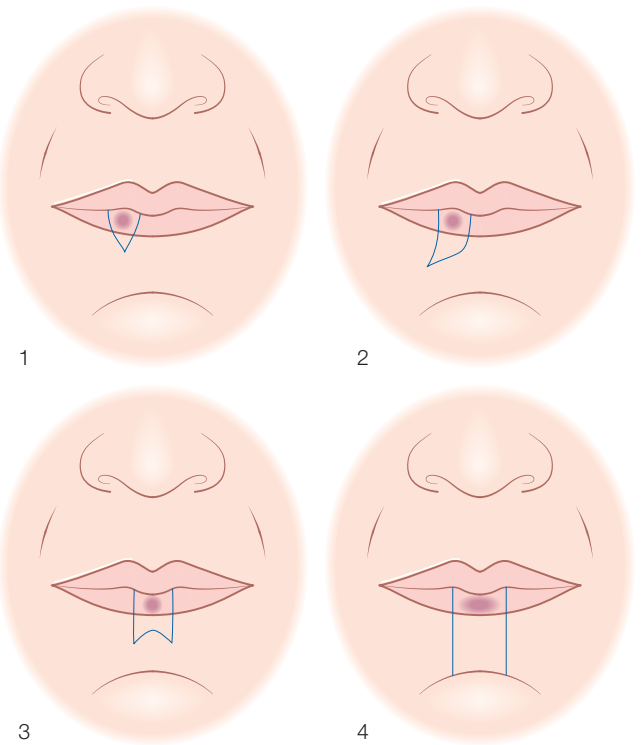

Figure 12.12 Greater than 1/3 lower lip defects closed with (1–3) various wedge techniques or (4) bilateral advancement flap-similar to the Schuchardt reconstruction (see Figure 12.10).

Techniques to reconstruct full-thickness defects of the lower lip can be conveniently classified into three groups, depending upon the size of the lip defect:

1. Defects of up to one-third of the lip width.
2. Defects of between one-third and half of the lip width.
3. Defects greater than half of the lip width.

DEFECTS OF UP TO ONE-THIRD OF THE LIP WIDTH

In the vast majority of cases, up to one-third of the lower lip can be removed by simple wedge excision (**Figure 12.12**) and the resultant defect is then closed primarily in layers. In elderly patients, with greater tissue laxity, this is never a problem (**Figures 12.13a** and **12.13b**).

In a minority of cases the wedge may have to be modified, by extending the incision unilaterally or bilaterally along the labiomental fold and excising skin crescents. This aids in advancing the remaining lip centrally. When the crescents are bilaterally extended as far as the mandibular border, accompanied by mucosal release incisions, this is known as the Schuchardt procedure.

DEFECTS OF BETWEEN ONE-THIRD AND HALF OF THE LIP WIDTH

Rarely, in some elderly patients with lax tissues, it may be possible to primarily close wedge excisions greater than one-third of the width of the lower lip. In the vast majority of cases, however, reconstruction of between one-third and half of the lower lip is best performed by using residual lip tissues, or lip sharing. Lip-sharing techniques preserve lip function and have satisfactory aesthetic results but can cause microstomia.

The Karapandzic technique[237]

This is arguably the best method to reconstruct lower lip defects which cannot be directly closed. This rotation-advancement technique can be used on both lateral and central lower lip (and sometimes upper lip) defects. A unilateral flap can suffice in lateral defects, but for central defects bilateral flaps are required.

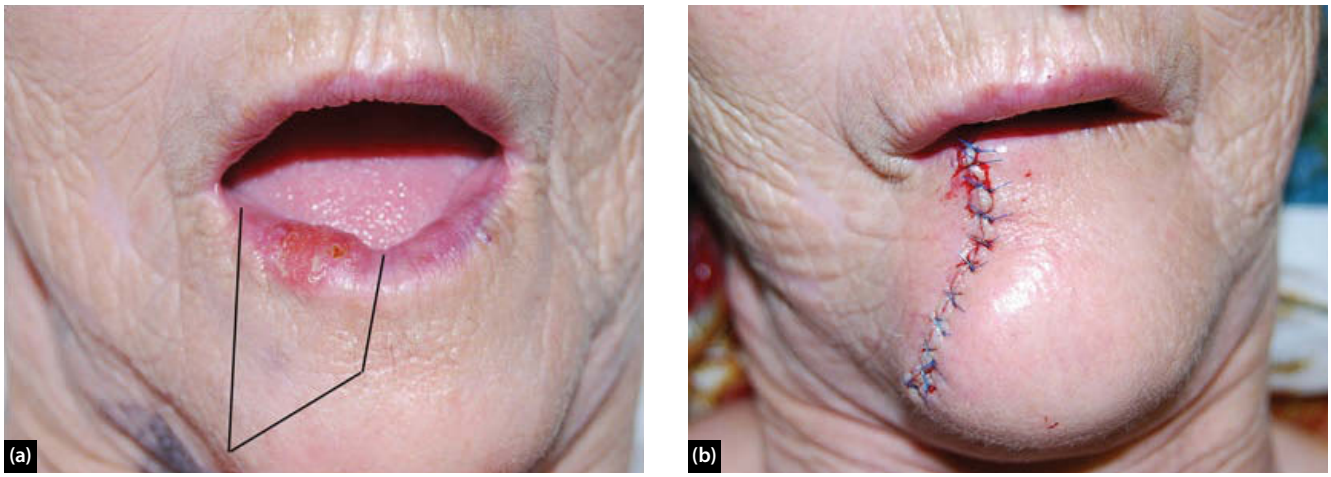

Figure 12.13 **(a)** Modified wedge excision of lower lip squamous cell carcinoma in an elderly patient. **(b)** Closure of wedge excision.

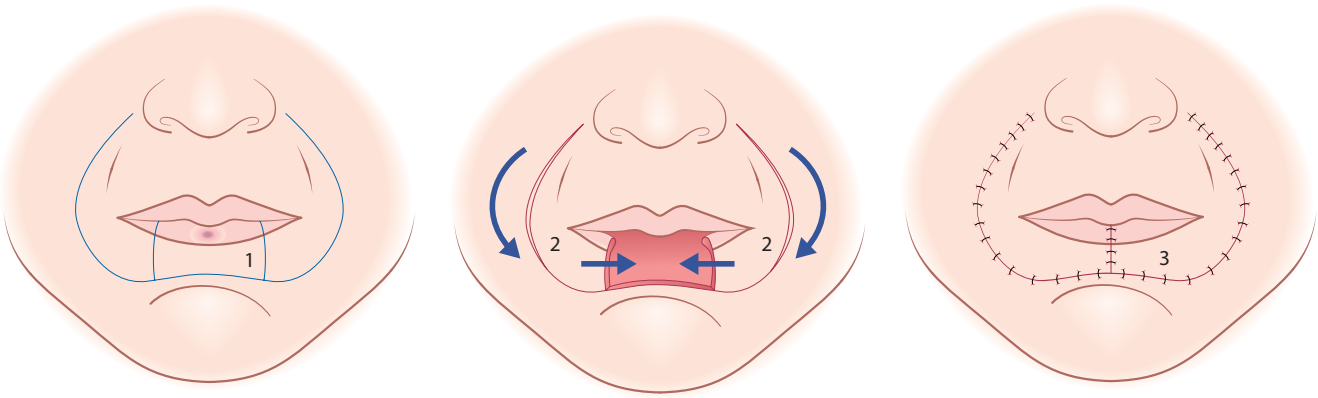

Figure 12.14 Karapandzic technique: 1: Mark out the excision margin and flap. The flap should be the same height as the lip at all points around the flap. 2: After full thickness excision including mucosa, mobilize the crescenteric flaps at equidistance from the free lip margin and full thickness for 2 cm from the postexcisional defect. With scissors the blood and nerve supply around the commissure is preserved. 3: Tension-free rotation of the flaps recreate the lower lip and vermilion.

The Karapandzic technique creates paired full-thickness mucomusculocutaneous lip flaps supplied by branches of the facial artery and preserves the sensory and motor nerves to the lip segment (**Figure 12.14**). It is crucial that the skin incisions are made at a distance from the lip margin equivalent to the height of the lip defect, especially at the commissures, in order to restore normal lip height. It should be noted that the superior incisions are normally placed lateral to the nasolabial creases for this purpose. The mucosal incisions are parallel to the skin incisions but are much shorter: usually about 2 cm on each side. For central lower lip defects, the lip depressor muscles have to be completely divided bilaterally to allow the flaps to move medially. For large defects, the superior incisions are deepened through skin, fat and the superficial layer of facial muscles, with the buccinator and orbicularis oris being preserved. During this manoeuvre, the delicate vessels and nerves to the lip must be carefully preserved. It is important to note that the nerves enter the flaps radially. After flap rotation the superficial muscle layer should be reattached to the orbicularis. For relatively small defects, it is possible to rotate the flaps without necessarily dividing the superficial facial muscles; instead the muscles in the superior incisions can simply be teased or stretched until the flaps are free to advance- the 'cut as you go' approach. After flap rotation, the wounds are closed in layers from within outwards, paying careful attention to the muscle layer. The functional results of this reconstruction are very good, but microstomia is inevitable with large defects (**Figure 12.15**).

Johanson's step technique[240]

This method of lip advancement can only be applied to lower lip defects. The lip lesion is removed as a rectangle and the remaining lateral lower lip segments are advanced medially. To aid this advancement, square or rectangular segments of skin and subcutaneous tissue lateral to the defect are excised in a descending stepwise fashion along the labiomental crease, until advancement of the lateral lip flaps can take place without tension. Each segment excised is approximately half the width of the lower lip resectional defect. The final (caudal) segment to be excised

Figure 12.15 **(a)** Markings for resection of squamous carcinoma of right side lower lip and design of contralateral Karapandzic flap. **(b)** Karapandzic flap assessed for adequate mobilization. **(c)** Karapandzic flap inset. **(d)** Good aesthetic and functional result.

is triangular in shape. As the flaps advance medially, the 'steps' are closed (**Figure 12.16**). The lip should then be closed in layers, with careful reconstruction of the orbicularis. The functional results of this technique are comparable to that of Karapandzic, but the scar can appear unnatural. Reconstruction of larger defects will lead to microstomia.

Lip switch flaps

Defects of the lower lip not involving the commissure can be reconstructed by an Abbe-Sabattini flap from the upper lip (**Figure 12.17**). The flap should be half the width of the lip defect, in order to avoid excess shortening of the upper lip and to evenly distribute tissues between the upper and lower lips.

These flaps lead to an insensate, adynamic segment of lip, and, though a degree of reinnervation eventually occurs, are better suited for upper lip reconstruction. Their main advantage is that they do not blunt the oral commissures.

Defects close to the commissure can be reconstructed in a single stage by the Estlander flap (**Figure 12.18**). This technique is similar to the Abbe-Sabattini flap but reconstructs the oral commissure, though the new commissure is blunted.

The functional results of lip switch flaps are satisfactory, but not comparable to the Karapandzic or Johanson techniques.

DEFECTS GREATER THAN HALF OF THE LIP WIDTH

For larger defects, lip-sharing procedures such as the Karapandzic lip reconstruction can be used when tissue laxity allows (**Figure 12.19**). This preserves lip function, but a degree of microstomia will inevitably occur and secondary revision will usually be required. When the lip defect is greater than three-quarters, in the majority of cases there will be insufficient lip tissue for a satisfactory reconstruction. In such cases, the next best option is to use adjacent tissues. Such reconstructions can achieve satisfactory aesthetic results, but function is always suboptimal.

The Freeman modification of the Bernard-von Burow procedure

The Bernard-von Burow procedure reconstructs the lower lip by medially advancing the cheeks (**Figure 12.20**). Cheek advancement is facilitated by the excision of full-thickness

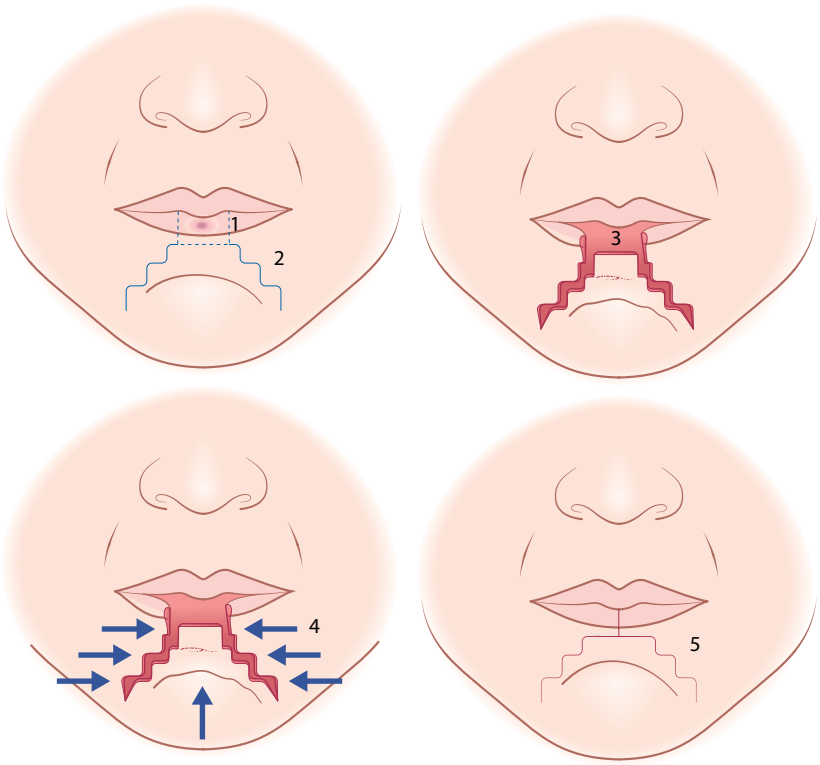

Figure 12.16 Johanson step technique for central defects of the lower lip. 1. Mark out the lesion. 2. Plan the step incision around the labiomental sulcus/chin subunit. 3. Full thickness excision of lesion and incise the step reconstruction full thickness. 4. Bring the medial lip excision margins together and advance the step flaps. 5. Closure.

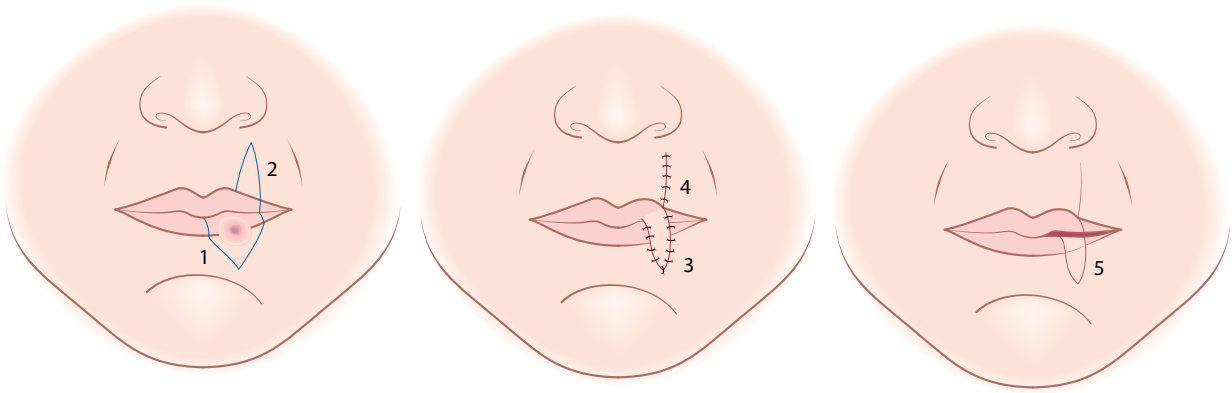

Figure 12.17 Reversed Abbe-Sabattini Flap to one-third lower lip lesion. 1. Lesion marked out for excision 2. Flap design; 3. Full thickness incision of the upper lip flap with the medial free margin of the upper lip inserted in the lateral margin of the lower lip excision. 4. Donor site closure. 5. The medial pedicle is divided and inset at 7 days.

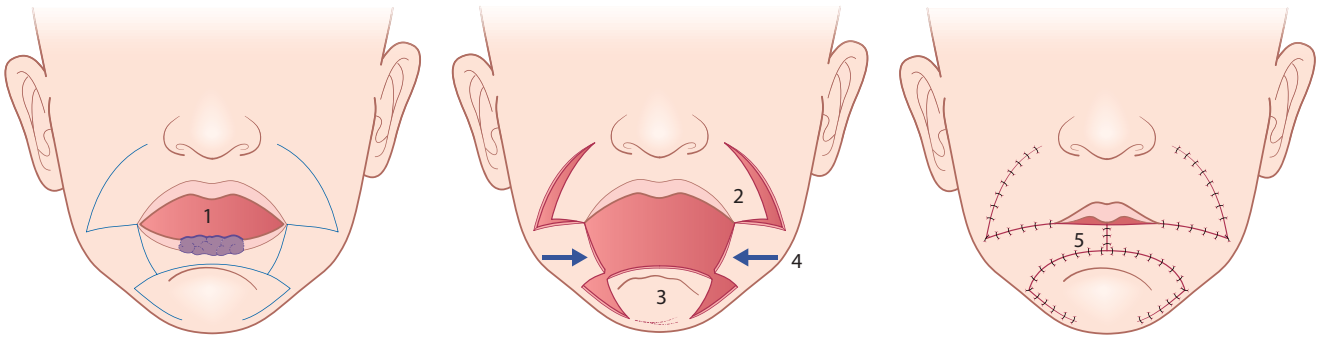

Figure 12.20 Modified Bernard-von Burow technique for up to total lip reconstruction. 1. Lesion marked out and flap with two superior and two inferior Burow's triangles marked out. 2. Burow's triangles are excised into subcutaneous tissue lateral to nasolabial folds. 3. Around the labiomental fold Burow's triangles are excised to allow medial rotation of the lower cheek flaps. 4. Medial advancement of the cheek flaps. 5. 3-layered closure of the midline with a mucosal flap reconstruction of the vermilion.

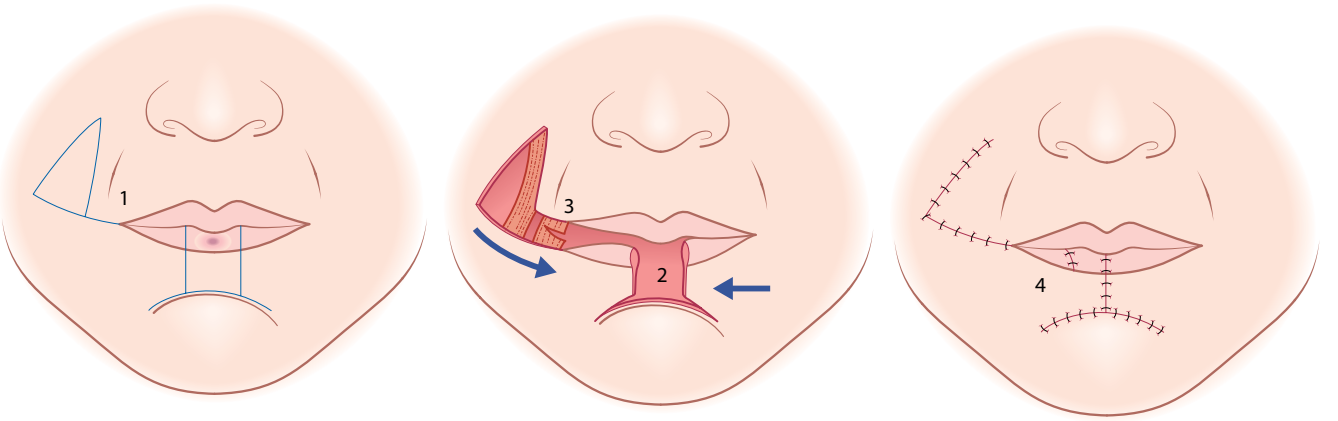

Figure 12.21 Unilateral Freeman modification of the Bernard-von Burow procedure. 1. Mark out excision margin and lateral nasolabial triangle. 2. Advance lower lip into defect. 3. Excision of tissue superficial to the muscle will allow lateral advancement whilst incision of the muscle lateral to the commissure will facilitate a commissuroplasty.

triangles of cheek tissue above and below the defect at the nasolabial fold. The width of the triangular excision is equal to the width of the defect. When both cheeks are advanced, the base of each triangle is half the width of the lip defect. The vermilion is reconstructed by tongue flaps. Webster's modification of this technique mobilizes cheek mucosa to reconstruct the vermilion.

The Freeman modification of the Bernard-von Burow operation is probably the best current cheek advancement technique (**Figure 12.21**).

Freeman converted the lower incision of the Bernard-von Burow operation from a horizontal one to a curved one, following the natural junction between the lip and chin. Only skin and fat is removed in the triangular

Figure 12.22 **(a)** Subtotal defect of the lower lip, with left cheek advancement performed and right Karapandzic flap designed. **(b)** Intra-operative appearance. **(c)** Immediate post-operative appearance. **(d)** Appearance at 3 months.

excisions, in contrast to the full-thickness tissue excision of the older procedure.

Bilateral cheek advancements can be used for total lower lip reconstruction, but there can be significant facial scarring. For the best function, it is important to reconstruct the orbicularis muscle. An alternative for total or subtotal lip reconstruction is to combine unilateral cheek advancement with a contralateral Karapandzic flap (**Figure 12.22**).

The 'bandoneon' technique[241]

A bandoneon is a type of concertina, which is particularly popular in Argentina as an accompaniment to Tango. A mucomusculocutaneous flap from the lower lip can be stretched like a 'bandoneon' and advanced to reconstruct lower lip defects up to two-thirds in width. A zigzag incision through skin, muscle and mucosa is made laterally from the lip defect as far as, or just beyond, the contralateral oral commissure. The incision is placed at the junction of lip and chin. The lower lip flap is then completely freed and stretched towards the lateral border of the lip defect and sutured in three layers (**Figure 12.23**). The zigzag incision facilitates this stretching, akin to the stretching of a bandoneon. In central defects, bilateral flaps can be raised.

Because the orbicularis oris is preserved in the flap, functional outcomes of this reconstruction are good. The oral commissure is shifted medially, however, and microstomia can result from large reconstructions.

The steeple flap[242]

This is an island flap of full-thickness tissue from the cheek. The lower lip defect is first converted to a rectangle. The lower line of excision is then extended laterally for a distance equal to the height of the resectional defect. Two vertical lines are drawn cranially from this line for a distance equal to the length of the lip defect. Thus, a rectangular island flap is marked out to the same dimensions as the rectangular lip defect. A triangle is marked on top of the proposed island flap – this will allow straight-line closure of the wound. The facial artery and its branches are marked with the aid of a hand-held Doppler probe. The flap is then incised full-thickness on its superior, medial and inferior margins. On the lateral margin, the facial artery and a small cuff of soft tissue are preserved. Depending upon the site of entry of the facial artery into the flap, the flap is transposed into the lip defect with either its lateral or medial border forming the upper border of the reconstructed lip. An excess of mucosa is cut

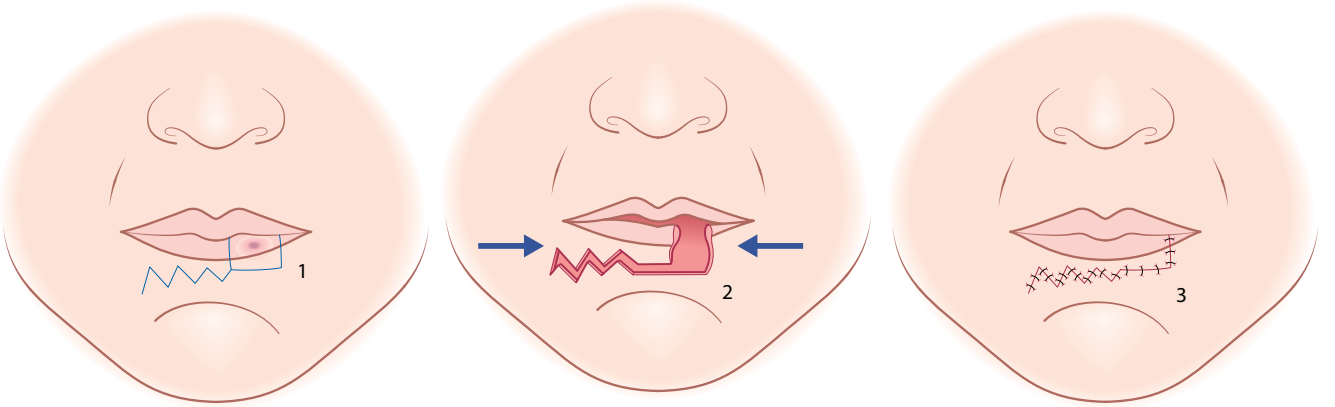

Figure 12.23 Bandoneon flap. 1. Mark out the excision margin and from the lower border of the excision extend a multiple w-plasty just past the commissure following the labiomental junction. 2. Full thickness excision of the lesion and full thickness incision along the lateral zig-zag markings through skin, muscle and mucosa. 3. Advance the lower lip to close the defect.

with the flap; this is used for vermilion reconstruction. For total lower lip reconstruction, bilateral steeple flaps can be used.

This technique avoids significant microstomia, but motor and sensory recovery may be delayed or incomplete.

Microsurgical reconstruction[238]

Subtotal and total reconstruction of the lower lip can be performed by free-tissue transfer, especially when there is scarring or inadequate laxity of the cheeks. Such reconstructions are never natural looking and have poor functional results and should only be used as a last resort. A folded free flap, such as the radial forearm flap, is the best option. The height of the reconstructed lip can be maintained by using the palmaris longus tendon to suspend the flap. This helps with oral continence. Should a sensate reconstruction be required, the lateral antebrachial cutaneous nerve can be anastomosed to the mental nerve.

KEY POINTS

- Lip tissue is precious and should never be discarded unnecessarily.
- Remaining lip tissue is the best option for reconstruction of small to medium lip defects.
- When a lip defect is too large to be reconstructed with remaining lip tissue, adjacent tissue such as the cheeks should be used.
- Reconstruction by distant tissues, such as free-tissue transfer should only be performed when there is insufficient local tissue to reconstruct the defect.

SEARCH STRATEGY

The data in this chapter are based on a search using the following keywords: head and neck cancer, oropharynx cancer, human papillomavirus, transoral laser surgery, transoral robotic surgery, intensity-modulated radiotherapy (IMRT) and clinical trials.

INTRODUCTION

The rapid increase in the incidence of Human papillomavirus – associated oropharyngeal carcinoma (HPV+OPSCC) seen in many countries of the developed world over the last several decades has resulted in a major healthcare problem which requires a major reassessment of the way oropharyngeal carcinoma is diagnosed and treated.

This discrete and novel disease entity presents in younger, fitter, more affluent patients who drink less alcohol and smoke less tobacco compared with patients who present with HPV negative (HPV-) squamous cell carcinoma of the head and neck. Paradoxically, their tumours, which typically present with clinicopathological features (multiple cervical lymph nodes with a high prevalence of extracapsular spread) traditionally considered as harbingers of poor outcome, respond more favourably to treatment.

Whilst this is to be welcomed, contemporary treatments result in high levels of early and long-term toxicity, particularly impacting negatively on swallowing function. As a consequence, greater numbers of younger patients, whilst being cured of their disease, are left with poor swallowing function which has a major impact on health-related quality of life.

Although most patients with HPV+OPSCC do well, a subgroup of patients, who are currently undetectable prior to treatment, together with patients with HPV-OPSCC, still do poorly. This dichotomy in presentation and outcome has resulted in a clinical conundrum for those clinicians treating patients with OPSCC. Whilst, on the one hand there is an urgent need to find novel de-intensified treatments which maintain the advantageous survival outcomes but confer better swallowing outcomes for patients with HPV+OPSCC, there is also a need to define treatments which will improve survival for patients with HPV-OPSCC.

This quest for novel treatments, as well as renewed interest and use of transoral surgical approaches, has re-opened the debate regarding the role of surgery in OPSCC.

Moreover, a better understanding of the biology of HPV+OPSCC is essential if truly novel treatments and accurate methods of risk-stratification are to be developed – particularly in this exciting era of emerging immunotherapeutic interventions.

Prior to any attempt to de-intensify treatment or to accurately prognosticate, there is a need to develop assays with high specificity to ensure HPV status is accurately determined. This necessity has resulted in significant research efforts over recent years to define the most appropriate assays and testing algorithms.

As well as simply trying to understand the emergence of HPV+OPSCC, the advent of prophylactic vaccination and its role in the prevention of HPV+OPSCC has resulted in an urgent need to understand the epidemiology

of HPV+OPSCC better and, in particular, to define better the apparent wide geographical variation seen between and within countries.

Furthermore, in order to address the void of high-quality data relating to the management of HPV+OPSCC, several groups around the world have developed exciting clinical trials, the results of which are awaited with interest.

These issues, which will be discussed in greater detail in the following chapter, conspire to make it a fascinating and potentially rewarding time to be involved in the treatment of patients with HPV+OPSCC.

SURGICAL ANATOMY OF THE OROPHARYNX

The pharynx is a fibromuscular tube forming the upper part of the respiratory and digestive tracts. It extends from the base of the skull to the level of the sixth cervical vertebra at the lower border of the cricoid cartilage where it becomes continuous with the oesophagus. It is divided into three parts: the nasopharynx, oropharynx and hypopharynx. The oropharynx is bounded superiorly by the soft palate, inferiorly by the upper surface of the epiglottis (the lingual surface of the epiglottis to the tip is included in the oropharynx), anteriorly by the palatoglossal arches and the vallate papillae of the tongue and laterally by the pharyngoepiglottic folds. It follows that the posterior third of the tongue, including the vallecula, is included in the oropharynx as are the palatine tonsils situated in the lateral walls between the palatoglossal arches anteriorly and the palatopharyngeal arches posteriorly (previously called the anterior and posterior faucial pillars). The lateral wall, and therefore the tonsil, takes most of its blood supply from the facial artery. Laterally, there is a rich plexus of paratonsillar veins, which may be the source of serious venous bleeding during surgery. The section of posterior pharyngeal wall included in the oropharynx lies anterior to the vertebral bodies of C2 and C3 and extends from a horizontal line drawn through the hard palate cranially to a horizontal line drawn through the hyoid bone caudally.

The oropharyngeal wall comprises four layers. The inner mucosal lining is surrounded by the submucosa. Outside the submucosa is the muscular layer made up of the superior and inferior constrictor muscles, together with the stylopharyngeus, paltopharyngeus and salpingopharyngeus muscles. These, in turn, are surrounded by the outermost buccopharyngeal fascia layer which is separated posteriorly from the prevertebral fascia by the potential retropharyngeal space which is functionally important, allowing free movement of the pharynx on the vertebral column during swallowing, respiration, speech and exercise. The space itself, and the retropharyngeal lymph nodes contained within it, are also of importance in disease when considering the spread of oropharyngeal infection and malignancy.

Surgical access to the structures of the oropharynx may be achieved transorally, anteriorly via mandibulotomy or inferiorly and laterally from the neck. The route chosen will be determined by the anatomical site and/or nature of the pathology as well as the surgical aim.

Microscopic anatomy

The oropharynx, like the remainder of the pharynx, is predominantly lined with stratified squamous epithelium which is predominantly non-keratinizing although islands of keratinizing epithelium may be seen and become more numerous with age, presumably as a consequence of repeated mucosal trauma / irritation. Interspersed through the mucosa are numerous mucous secreting cells as well as minor salivary glands which are most concentrated on the oral surface of the soft palate.

The oropharynx also contains an abundance of lymphoid tissue, in particular the palatine and lingual tonsils which form the anterolateral components of Waldeyer's ring. It is important to appreciate that these aggregates of lymphoid tissue are covered by pharyngeal mucosa which, particularly in the case of the palatine tonsil, form epithelial crypts which extend deep towards the centre of the tonsils. A particularly large crypt is seen at the boundary of the caudal 2/3 and cranial 1/3 of the tonsil. This intratonsillar cleft is the remnant of the embryonic second pharyngeal cleft.

An appreciation of the histology of the structures of the oropharynx is important when considering the histiogenesis of the various tumours which may arise.

FUNCTIONS OF THE OROPHARYNX

The oropharynx is involved in three primary functions, namely swallowing, speech production (articulation) and host defence against ingested or inspired pathogens.

The movements of the muscular wall, base of tongue (BOT) and soft palate are critical in the former two activities, described in greater detail in Chapters 48, Physiology of swallowing and 60, Voice and speech production, whilst the lymphoid tissue of Waldeyer's ring is the primary effector of the latter.

TUMOURS OF THE OROPHARYNX

Benign

Whilst benign tumours may originate from any of the structures of the oropharynx, apart from mucous retention cysts of the vallecula and tonsil, they are extremely rare. Papillomas are the most common benign tumour and are often found incidentally on routine examinations of the throat.

In almost all instances where intervention is decided upon, surgery is the treatment of choice, the nature of which is dictated by the size, position and histology of the tumour.

Deep lobe parotid tumours, most commonly pleomorphic salivary adenomas, whilst not strictly tumours of the oropharynx, may present as an asymmetric mass protruding into the pharynx and/ or soft palate. Surgical excision as part of a partial or total parotidectomy procedure is usually recommended. In most cases, complete excision is achieved by a solely lateral approach as for a total parotidectomy although, on occasion, a combined approach, involving a lip-split mandibulotomy for access, may be necessary for larger or less accessible tumours.

Malignant

LYMPHOMA

Lymphomas arising in the oropharynx, whilst rare, are not uncommonly seen by otolaryngologist – head and neck surgeons. They are almost exclusively non-Hodgkin lymphomas and arise in the lymphoid tissue of the palatine tonsil or BOT. They particularly present in younger patients (45–55 years) and whilst diagnosed by biopsy, are thereafter treated by haemato-oncologists and accordingly their management is beyond the scope of this chapter.

MINOR SALIVARY GLAND TUMOURS

Salivary gland cancers account for up to 6% of all head and neck malignancies and therefore are rare. Approximately 20% of all salivary gland cancers arise in the minor salivary glands (MiSG) and in contrast to the parotid most (80%) tumours of the MSG are malignant. The hard and soft palate are the commonest sites for MSG cancers.

The World Health Organisation lists 24 different malignant histological subtypes, the four most common of which are mucoepidermoid carcinoma, adenoid cystic carcinoma, adenocarcinoma and salivary duct carcinoma.[1]

Surgical resection with adequate surgical margins is the primary treatment of choice. The surgical approach used for MSGs of the oropharynx will depend on the site and size of the mass and the likely functional deficit following resection, and may range from a transoral resection to a major open resection with microvascular free-flap reconstruction. Post-operative radiotherapy is often used, particularly in patients with high-risk factors, although the radiosenstivity of MSG cancers is highly variable. There is no evidence for the use of post-operative chemoradiotherapy Chemoradiotherapy (CRT) and elective treatment of the N0 neck is controversial. A recent systematic review, whilst accepting the lack of availability of good quality data, recommended the following:[2]

- Complete surgical resection should remain as the mainstay treatment.
- A therapeutic neck dissection should be used to treat patients with clinical or radiological evidence of cervical lymph node metastasis.
- An elective neck dissection for patients with no evidence of cervical lymph node metastasis should probably be reserved for patients with advanced stage or high-grade tumours, particularly for mucoepidermoid carcinoma and adenocarcinoma.
- Post-operative radiotherapy (RT) should be recommended for patients with adverse prognostic features such as T3 or T4 tumours, close or involved resection margins, high-grade, perineural or perivascular invasion and N+ disease.
- The use of PORT for T1-weighted and T2-weighted tumours in the absence of adverse prognostic features is not supported.
- For patients with inoperable disease, or who refuse surgery, primary RT should be considered.
- The value of targeted therapies for advanced and/or metastatic disease has yet to be confirmed.

OROPHARYNGEAL SQUAMOUS CELL CARCINOMA

Epidemiology

Squamous cell carcinoma (SCC) is the commonest malignancy presenting in the oropharynx. Over recent decades, across the developed world, there has been a substantial increase in the incidence of oropharyngeal squamous cell carcinoma (OPSCC) affecting the tonsils, tongue base and soft palate. The incidence of OPSCC in the UK underwent a 2-fold increase between 2002 and 2011 [age-standardized rate 2002: 2.1 (95% confidence interval (CI), 1.9–2.2); 2011: 4.1 (95% CI, 4.0–4.3)].[3] (**Figure 13.1**) Whilst alcohol and tobacco use have been well documented as individual or synergistic risk factors for the development of SCC of the head and neck,[4] over the last three decades accumulating evidence has confirmed

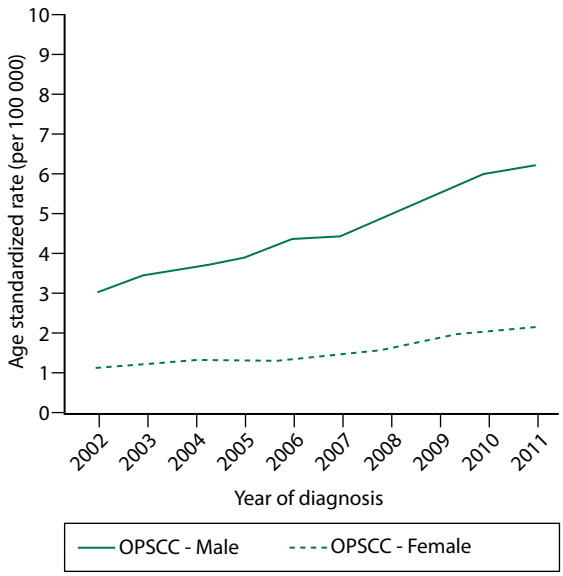

Figure 13.1 Age standardized rate of OPSCC in the UK, 2002–2011. Reprinted from Schache et al, *Cancer Res*; 2016 by kind permission AACR publications.[3]

that human papilloma virus (HPV) – specifically genotype 16 – is an additional, independent, risk factor for OPSCC.[5]

In a recent UK multicentre, cross-sectional study the HPV status of archival tumour tissue blocks collected from 1602 patients diagnosed with OPSCC between 2002 and 2011 was determined. The overall proportion of HPV-positive OPSCC was 51.8% [95% CI, 49.3–54.4] and this remained unchanged throughout the decade [unadjusted RR = 1.00 (95% CI, 0.99–1.02)]. In view of the doubling in incidence, it was concluded that the absolute number of both HPV-positive and HPV-negative cases in the UK was increasing (**Figure 13.2**).[3]

These UK data contrast with published data from other parts of the world where substantial variation has been reported in the proportion of OPSCC attributable to HPV between countries and time periods. This is likely to be a reflection of variations in multiple factors, which may include sexual behaviour and rates of genital HPV infection, as well as tobacco and alcohol consumption and highlights that trends in the aetiology of OPSCC must be considered in a population-specific manner.

Non-HPV associated OPSCC

HPV-OPSCC shares the same risk factors as other SCCs of the head and neck and the pathogenesis of malignant transformation is thought to be similar. Detailed consideration of the pathogenesis of non-HPV-associated OPSCC is therefore, provided in Chapter 6, Introducing molecular biology of head and neck cancer.

In contrast, HPV-associated transformation is limited to the oropharynx and is therefore considered in greater detail below.

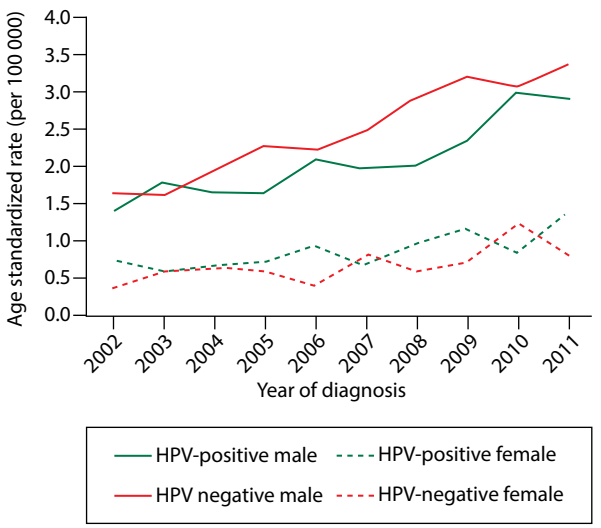

Figure 13.2 Estimated age standardized incidence of HPV-positive and HPV-negative OPSCC in the UK, 2002–2011. Reprinted from Schache et al, *Cancer Res.* 2016 by kind permission AACR publications.[3]

HPV-associated OPSCC

ORAL HPV INFECTION

Prevalence rates

An obvious risk factor for the development of HPV-associated OPSCC (HPV+OPSCC) is an oral infection with high-risk HPV (HRHPV). It follows therefore that an understanding of the epidemiology of HPV oral infection is important when trying to understand the development of HPV+OPSCC and this is comprehensively reviewed in Chung et al.[8]

Data from the US suggest that the prevalence of oral HPV infection is much lower than the prevalence of genital HPV infection: epidemiological studies involving a variety of US populations confirmed a genital infection rate ranging from 27% to 43% in females aged 14–59 years, compared with an oral HPV infection rate ranging from 0.9% to 7.5% in 13–30 year-old men and women.[9–14]

Systematic review data[15] which included 18 studies published between 1997 and 2009 involving ~4500 healthy individuals concluded that the rate of oral infection with any HPV genotype was 4.5% in comparison with 3.5% for infection with any HRHPV genotype and 1.3% for infection with HPV-16.

Similar rates were confirmed in a landmark National Health and Nutrition Examination Survey (NHANES) published in 2012.[9] This cross-sectional study, conducted in 2009–10, involved a general US population comprising ~5500 US men and women. All participants provided mouthwash samples from which DNA was extracted and tested for the presence of one or more of 37 HPV genotypes. Overall prevalence of HPV infection was 6.9%, whilst infection with HRHPV was 3.9% and infection with HPV-16 was 1%.

Whilst similar to the data obtained from the systematic review highlighted above, the overall prevalence identified in the NHANES study was higher, perhaps reflecting the fact that the NHANES data were collected some years later than much of the data included in the systematic review.

Whilst the 'snap-shot' infection rate with HPV-16, at 1%, is low, it is important to reflect that this amounts to >2 million US citizens with an oral HPV infection at any given point in time.

Interestingly, in common with anal and penile HPV infection rates, the prevalence of oral HPV infection has a bimodal distribution with respect to age. The first and smaller peak (~7%) is seen in patients in their early 30s whilst a second peak (~11%) is seen in patients, particularly men, in their early 60s.

Risk factors

Sexual activity appears to be a prerequisite of oral HPV infection as studies have shown that HPV infection coincides with sexual debut. There is also some evidence that vertical transmission, from infected birthing mother to child, is possible resulting in neonatal oral HPV infection.

Whilst an increased number of oral sexual partners have been demonstrated in most studies to correlate with oral HPV prevalence, some studies do not support this assertion.

The NHANES study confirmed that oral HPV infection is increased 8-fold in sexually active individuals compared with individuals who had never had sex (7.5% vs 0.9%). The data also showed that the prevalence of oral HPV infection increased with the number of lifetime sexual partners (vaginal or oral) and with recent sexual activity, with the highest prevalence (>20%) seen in patients reporting >20 lifetime sexual partners.

However, as sexual practices are co-linear, it is difficult to ascertain with precision which sexual practice may result in transmission in any given situation. This is perhaps reflected in the data published by Kreimer et al,[16] which confirmed, in a multi-national study of healthy men, that men who reported never performing oral sex had a similar rate of oral HPV infection to those who reported performing oral sex (3.8% vs 4.1%).

It has been hypothesized that auto-inoculation (oral infection transmitted from infected genitalia in the same individual) may be a significant route of oral HPV infection. There is however, scant evidence to support this. As well as the wide discrepancy between genital and oral infection rates in the same individual, meta-analysis data confirm only a 27% HPV type-specific concordance between genital and oral infection in dually infected women.[17]

It is also clear that additional risk factors are important in the development of oral HPV infection. The NHANES study confirmed that male gender and tobacco use were also important risk factors, as 10% of men were infected in comparison with 3% of women and individuals smoking >21 cigarettes per day had a 20-fold increased risk of oral HPV infection compared with non-smokers. Kreimer et al[16] also established that current tobacco use resulted in a doubling of the odds of an oral HPV infection.

Natural history

As with the epidemiology of oral HPV infection, detailed knowledge of the natural history is also lacking. Existing data suggest that the vast majority of oral HPV infections are cleared within 1 year of infection. For example, Kreimer et al,[18] showed that 85% of incident infections were cleared within 1 year which is similar to the data reported by Moscicki et al,[19] for cervical cancer where they reported that only 10% of women had persistent infection 2.5 years after initial detection.

Link between oral HPV infection and OPSCC

As might be expected, oral HPV infection and other common risk factors have been shown to be associated with the development of OPSCC. For example, HPV-16 DNA is found in ~50% of oral rinses provided by patients with diagnosed OPSCC[20] and patients with OPSCC are 12 times more likely than patients without OPSCC to have an oral HPV infection, a risk which increases 15-fold when HPV-16 infection alone is considered.[21] Moreover, patients with HPV+OPSCC report an increased number of sexual partners.[9]

As well as being a risk factor for oral HPV infection, tobacco use is also associated with an increased risk of HPV+OPSCC.[22, 23] Although median tobacco use is less for patients with HPV+OPSCC compared with those patients with HPV-OPSCC, the majority of patients presenting with HPV+OPSCC are still current or past smokers.[22, 24]

What is clear from increasing numbers of studies is that tobacco use is a dose-dependent risk-stratifier of outcome for patients with HPV+OPSCC, accepting the fact that tobacco use is a likely surrogate of underlying tumour genome mutation load and genetic instability.[6, 7]

Molecular biology of human papillomavirus infection

Virology

The link between HPV and OPSCC was first postulated as early as 1983 by Syrjanen et al[25] A subsequent and increasing volume of clinical data have confirmed its association and HPV-16 is now considered a causative agent.[5]

HPV is a member of the family of papillomaviridae, a virus family recognized in 2004 by the International Council on Taxonomy of Viruses.[26]

The papillomaviridae, together with polyomaviruses, are non-enveloped and contain a circular double-stranded DNA genome. Instead of a phospholipid bilayer envelope derived from the host membrane on infection, they comprise icosahedral capsids in the absence of an envelope.[27] They are obligate epitheliotropic human pathogens in that they have a predilection for infecting human epithelium.

The double-stranded DNA (dsDNA) HPV genome is approximately 8 Kb long and contains eight genes, six of which are expressed early in an infection (*E1, 2 & 4–7*) whilst two are transcribed later in the viral infection cycle (*Ll & 2*). *E1* and *E2* are regulatory genes, controlling the transcription of the remaining genes.[28] Of particular note, *E5–7* are involved in host-cell transformation, and are therefore potentially oncogenic, *L1* and *L2* are structural proteins necessary for the formation of the viral capsids.[29]

Currently, over 200 different genotypes of HPV have been identified. More than 150 have had their genomes completely sequenced and of these 12 have been designated 'high-risk' due to their propensity to provoke malignant transformation of the epithelial cells they have infected.[30] Of these, HPV-16 and -18 are the most important, causing ~70% of HPV-related cancers of which, in addition to oropharynx, the most common are cervix, vagina, vulva, anal and penile.

In OPSCC there is a greater dominance of the HPV-16 genotype compared to cervical cancer (~95% vs ~60%). Why this might be unclear, it may reflect the fact that the different mucosal environments may support the infection of specific genotypes. Conversely, it may reflect a difference in local genotype-specific mucosal immune response.[31]

HPV induced transformation

Little is known about the mode of transmission, route of infection or life cycle of HPV in the epithelium of the oropharynx. Accordingly, much reliance is placed on data derived from cervical cancer research for our current understanding of HPV infection, life cycle and oncogenesis.

Whilst extrapolation of this knowledge to the situation in the oropharynx is necessary as alternative data currently do not exist, this should be done with caution as although there are many similarities in the mucosal structure of both anatomical sites, there are also many differences.

In the transformation zone, between columnar and stratified squamous epithelium in the cervix, the squamous epithelium is stratified, organized in layers of increasing cellular differentiation from deep to superficial. The specific epithelial layers are the basal, para-basal, stratum spinosum and the most superficial desquamating strata.

The basal layer is in contact with the basement membrane and has a low turnover rate. In contrast, the para-basal layer has a high mitotic rate and therefore a rapid turnover of cells.

In the cervix it has been established that microabrasions of the surface epithelium facilitate virus particle infection of the basal and para-basal layer of cells (**Figure 13.3**).[32]

Following infection, the dsDNA viral genome remains in its circular, episomal form in the cytoplasm of the host cell. The virus harnesses the transcriptional and translational machinery of the host cell to instigate viral gene expression followed by viral replication, thereby completing its life cycle.

Transient infections are the norm in the cervix, however, a minority of individuals are unable to clear the initial infection resulting in a chronic inflammatory state. It is assumed that an even smaller percentage of these individuals then progress to develop cervical intraepithelial neoplasia (CIN) prior to developing invasive malignancy. It is important to note that no premalignant lesion similar to CIN has ever been detected in the oropharynx.

For the majority of the cases (85%) proceeding to malignant transformation, viral integration into the host genome is a critical step which results in disruption of the transcriptional repressor gene (*E2*) with the subsequent unregulated expression of the viral oncogenes *E6* and *E7*.[33] The mechanisms by which the remaining 15% of cases in which the dsDNA genome remains in its episomal form, yet still mediates malignant transformation,

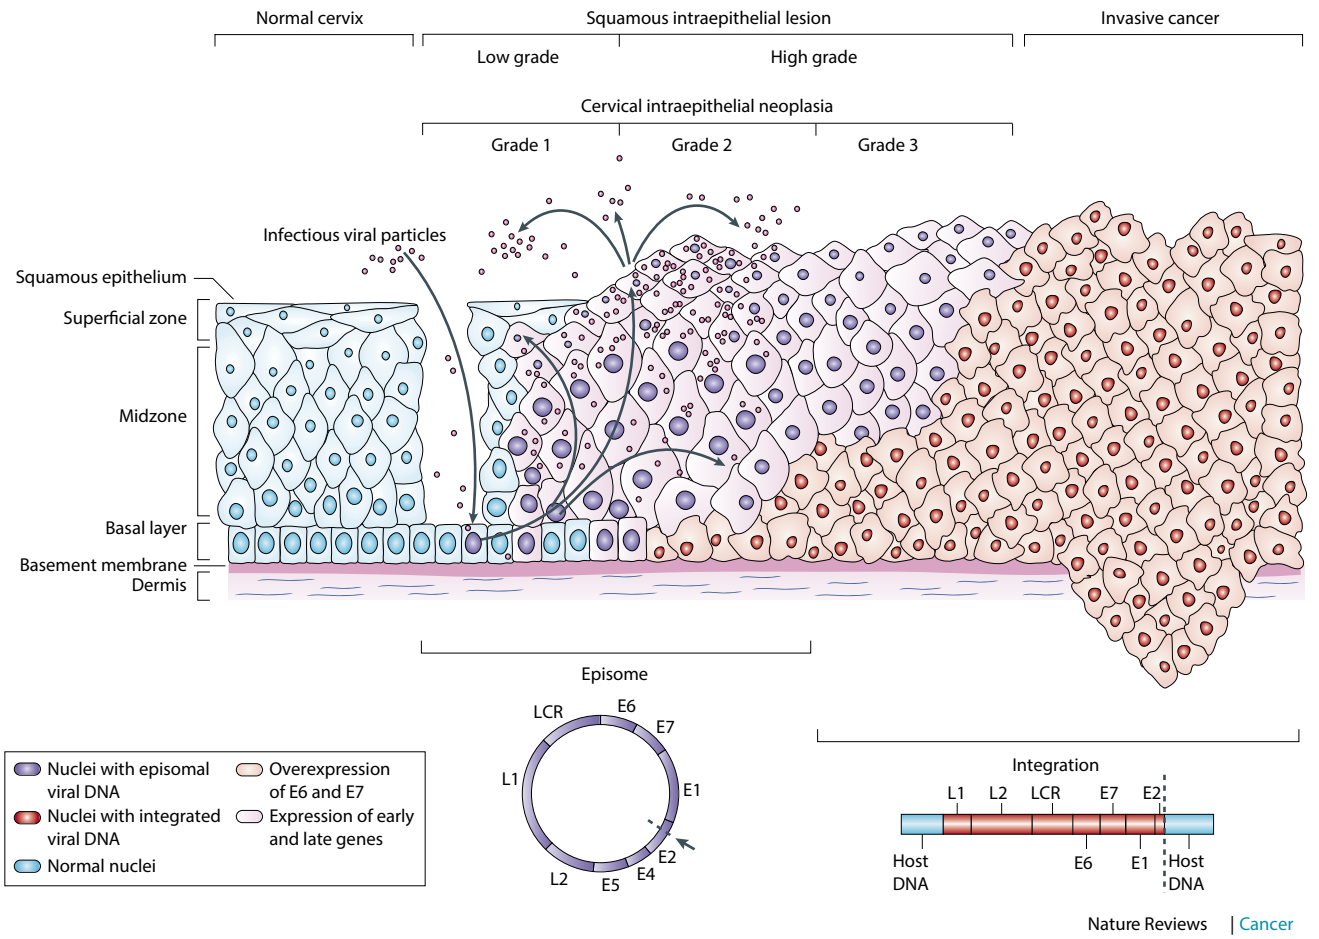

Figure 13.3 A schematic representation of (1) HPV virus infection of the basal layer of cervix mucosa as a consequence of the development of microabrasions. (2) The natural history of the virus life cycle, with virion production which is dependent upon and coincident with the differentiation of the mucosal epithelium prior to release as consequence on epithelial desquamation at the mucosal surface. **(3)** In contrast, the integration of viral genome into host genome resulting in basal cell immortality and cellular progression through dysplasia to invasive neoplasia. Reprinted Woodman CBJ, et al. The natural history of cervical HPV infection: unresolved issues. *Nat Rev Cancer* 2007; **7**: 11–22.

is the subject of ongoing research.[34] A simple model of integration defining the start of a transition to malignancy seems less likely when consideration is made of the relatively low (21–43%) viral integration rates seen in OPSCC.[35] However, epigenetic regulation of the viral Long Promoter Region, from which *E2* transcription is regulated, has been implicated.[36]

The genomes of all eukaryotic organisms are under tight transcriptional control.[37] Whilst certain genes act to switch other genes on to potentiate cell growth and division, antagonistic pathways exist to ensure the regulation of cell growth and division. In order for a cell to grow and divide it needs to advance through the cell cycle. There are four main periods of the cell cycle. G1 is a period of quiescence before the onset of S phase DNA replication. Following completion of DNA replication, S phase is followed by another gap phase, G2, in which cells prepare themselves for mitotic division during M phase. The eukaryotic cell cycle is tightly regulated and various molecular checkpoints exist throughout the cell cycle. At each checkpoint competing growth promoting and growth inhibiting signals are assimilated by the cellular molecular machinery and a 'decision' for the cell to proceed to the next stage of the cell cycle or for progression to become impeded is made. Tumour suppressor protein (TSP) expression is critical for the coordinated progression of the cell through each cell cycle checkpoint. Any perturbation of this checkpoint control mechanism will result in disordered cell cycling and aberrant cell growth, including the ultimate development of cancer.

Two of the most well understood TSPs are p53 and the retinoblastoma protein (pRb). p53 has been called the 'guardian of the genome' in light of its many varied roles in ensuring that cell growth and division does not continue unchecked as a consequence of DNA damage. Broadly, when a given cell is exposed to cellular stress and/or DNA damage, p53 is able to mediate cell cycle arrest followed by either DNA repair or programmed cell death if DNA repair proves impossible.

In contrast, pRb exerts its influence in late G1. If pRb is not phosphorylated it binds to and suppresses the E2F family of transcriptional activators. However, if pRb is phosphorylated it releases its inhibitory grip on the E2Fs allowing them to invoke the transcription of downstream genes whose actions are necessary for the cell to progress from G1 to S phase. Thus pRb is essential in preventing unregulated progression of cells from G1 to S. A notable product of downstream gene transcription is the expression of $p16^{INK4a}$ a protein, as will be seen below, whose expression is utilized to infer 'active' HPV infection.

It is via interactions with p53 and pRb that HPV exerts its primary oncogenic effects. Amongst other mechanisms, *E6* is able to bind p53 whilst *E7* binds pRb. In both cases this results in the degradation of both TSPs by the proteosome. Any cell losing the actions of these two key TSPs is well on the way to becoming a cancer. The effects of their loss will be subsequently augmented by a trend towards genetic instability and ultimately tumourigenesis promoted by the loss of their regulatory pathways (**Figure 13.4**).

HPV detection in clinical practice

HISTOPATHOLOGY

It has been well established that HPV+OPSCC presents with characteristic histopathological features. In contrast to HPV-SCCs which are typically moderately differentiated and keratinizing tumours arising from dysplastic epithelium, HPV-associated tumours are non-keratinizing, display a poorly differentiated predominantly basaloid morphology, are not associated with surface dysplasia but are associated with a high level of tumour infiltrating lymphocytes (TILs), the density of which have been shown to have prognostic value (**Figure 13.5**).[38] Although characteristic, these features are not diagnostic and a combination of molecular testing is required to establish a diagnosis of HPV-associated OPSCC in the oropharynx. Issues relating to the diagnosis of HPV+OPSCC is comprehensively reviewed in Robinson et al.[39]

MOLECULAR TESTING FOR HPV STATUS

It is insufficient to simply detect the presence of HPV DNA within a given tumour cell as a positive result may simply reflect a previous or bystander infection which resulted in inconsequential viral genome integration into the host genome or potential contamination with HPV DNA. Therefore, a necessary requirement for HPV testing is, in addition to demonstrating the presence of HPV DNA, to demonstrate some evidence of downstream HPV-driven biological activity. This is a particularly important issue when de-intensification of treatment – typically in the context of clinical trials (see later section) – is considered for patients with HPV+OPSCC.

TESTS FOR HPV DNA

Two types of diagnostic strategy are commonly used to detect the presence of HPV DNA within tumour cells.

In-situ hybridization (ISH)

This method relies on the use of a DNA probe labelled, for example, with a chromogen, the nucleotide sequence of which is complementary to the DNA sequence or gene under investigation. When applied to formalin-fixed paraffin embedded (FFPE) tumour samples, the probe will bind to the complementary sequence within the DNA of that tissue sample, thereby confirming its presence. The chromogen label allows the visualization of the bound probe by light microscopy. Kits are commercially available for the detection of HRHPV genotypes in FFPE tissue and are typically designed to detect the specific *L1* gene sequences, variations of which determine the specific genotype. A positive test result is confirmed by the presence of a blue dot under light microscopy (**Figure 13.6**). This technique allows localization of the HPV DNA to the host cell nucleus and whilst a punctate staining pattern is suggestive of HPV DNA integration it does not amount to categorical proof of this.

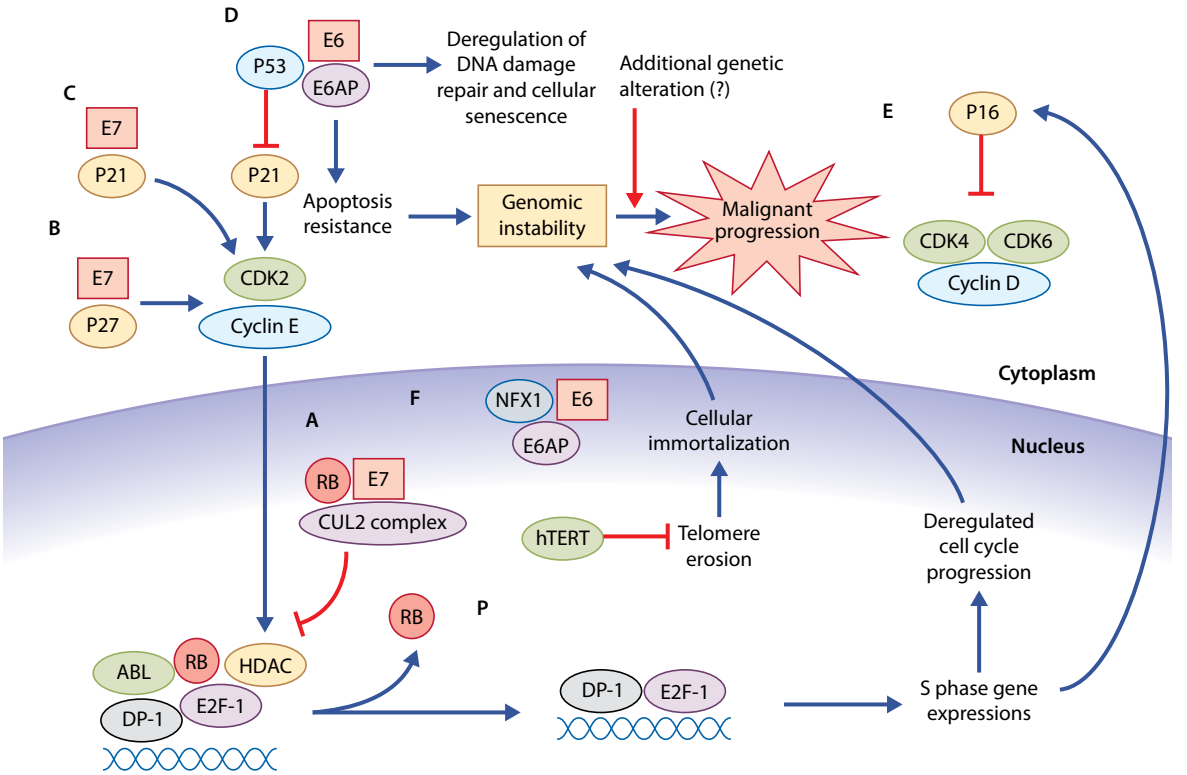

Figure 13.4 A schematic representation of the molecular pathways contributing to E6 and E7 mediated malignant transformation of normal keratinocytes. (A) Proteasomal degradation of retinoblastoma tumour suppressor protein (RB) as a consequence of binding by HPV oncoprotein E7 in association with the cullin 2 ubiquitin ligase complex. (B) Interaction between E7 and p27 resulting in inhibition of cell-cycle arrest. (C) Interaction between E7 and p21 resulting in inhibition of cell-cycle arrest. (D) Proteasomal degradation of p53 TSP as a consequence of binding by HPV oncoprotein E6 in association with the ubiquitin ligase E6AP. (E) Increased expression of $p16^{INK4A}$ as a result of loss of E2F repression which in turn results from RB degradation. (F) E6 and E6AP degradation of NFX1 resulting in the loss of repression of hTERT and a consequent reduction in telomere erosion thereby contributing to the development of cellular immortality. (Source adapted from Chung, CH & Gillison, ML.)[29]

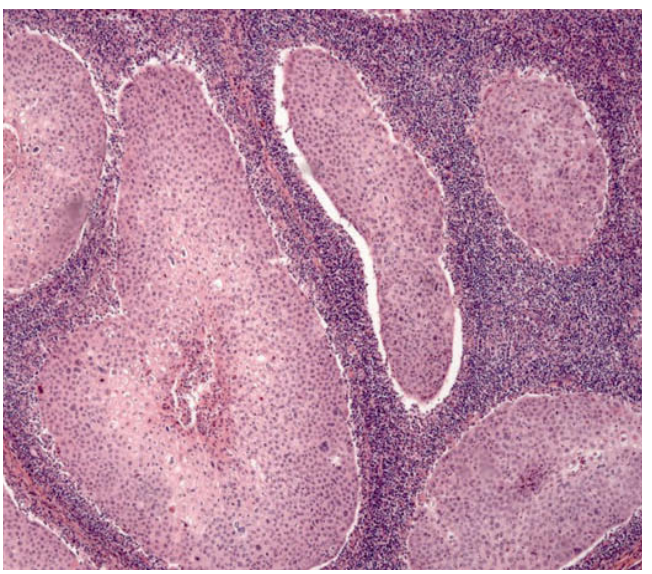

Figure 13.5 Image shows an H&E stained section of an oropharyngeal SCC. Tumour islands are surrounded by a dense infiltrate of lymphocytes. Magnification x50. By kind permission, Professor Gareth Thomas, University of Southampton.

Polymerase chain reaction (PCR)

This is a standard laboratory technique used to amplify short sequences of DNA. It is a highly sensitive technique which is able to augment a single copy of a given DNA sequence. Following the separation of double-strand DNA (dsDNA) into single-strand DNA (ssDNA), the presence of HPV DNA is detected using small targeted DNA sequences (primers) which are designed to bind to complementary DNA sequences on either side of the DNA segment (gene) under investigation: It is common to attempt to detect the presence of the HPV *E6* gene. Repeated cycles of the PCR will exponentially augment single copies of the specific gene under investigation allowing its detection with ease. This technique can be used on FFPE tissue although the best results are achieved using fresh tissue. Consensus PCR simply detects the presence of HPV DNA whilst real-time PCR is able to quantify viral load.

TESTS TO DETERMINE BIOLOGICAL ACTIVITY

Again two strategies are commonly used.

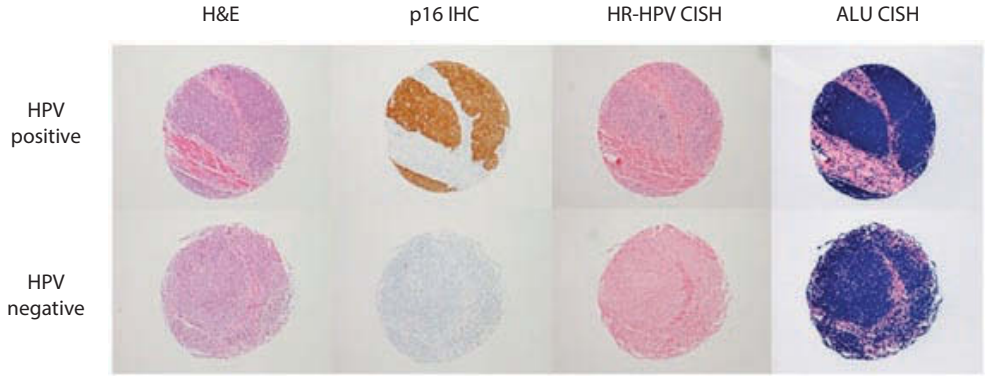

Figure 13.6 Panel of routine diagnostic tests applied for HPV status determination in OPSCC in the UK. **Columns from left**; Haematoxylin & Eosin (H&E), p16 immunohistochemistry (IHC), High-risk HPV chromogenic in situ hybridization (HR-HPV CISH), positive control (ALU CISH). **Top row** HPV positive OPSCC (p16 positive, high-risk HPV positive). **Bottom row** HPV negative OSPCC (p16 negative, high-risk HPV negative). (0.6 mm tumour cores). (By kind permission, Mr Andrew Schache, University of Liverpool).

Direct detection of E6 and E7 transcription

Quantitative Reverse Transcription – Polymerase Chain Reaction (qRT-PCR): Direct detection of E6 and E7 mRNA moves beyond merely detecting the presence of HPV DNA and aims to show HPV DNA is being transcribed resulting in the expression of E6 and E7 mRNA which have oncogenic properties and are presumed to be involved in tumorigenesis. The method most commonly used is quantitative reverse transcription PCR (qRT-PCR) by which complementary DNA (cDNA) is synthesized using the E6 or E7 mRNA transcript as a template. Thereafter, PCR, utilizing primers to the E6 and/or E7 cDNA sequence, is used to amplify the copy number of the cDNA transcripts. This technique is costly and labour intensive and has traditionally been restricted to frozen tissue. However, it constitutes the current gold standard assay for determining HPV biological activity.[24]

RNA-based Chromogenic In-situ-hybridization (RNA-ISH): This is a technique which also overcomes the dual testing requirements to firmly establish HPV status by detecting HPV specific E6/7 mRNA transcripts. This technique, which detects the presence of HPV E6 & E7 mRNA without the need for reverse transcription, is readily applied to the analysis of FFPE tissue. Therefore, in contrast to PCR techniques, it is potentially far easier to use in routine clinical practice. RNA-ISH performed on arrayed FFPE tissue cores has been shown to have a high level of sensitivity (97%) and specificity (93%) when compared with 'gold-standard' qRT-PCR performed on matched frozen tissue samples (**Figure 13.7**).[40] It is anticipated that RNA-ISH will become the routine standard for HPV testing in the foreseeable future. Commercial kits are readily available which contain probes for the E6 & 7 mRNA sequences of multiple HR HPV genotypes.

Surrogate markers

The surrogate marker most often used to detect HPV-induced transformation in the oropharynx is over-expression of $p16^{INK4a}$ using immunohistochemistry (**Figure 13.6**). It has been well established that the loss of $p16^{INK4a}$ is an early event in the development of tobacco and/or alcohol induced squamous cell carcinoma of the head and neck (SCCHN). However, by contrast, in HPV-associated SCCHN $p16^{INK4a}$ is typically intact. In non-transformed cells $p16^{INK4a}$ is negatively regulated by pRb. Consequently, when the effects of pRb are ameliorated by the actions of E7, $p16^{INK4a}$ levels are overexpressed.[41]

Immunohistochemistry to detect $p16^{INK4a}$ overexpression is easily performed on FFPE tissue samples. It is cheap, with well-established protocols and is widely available.

However, whilst its overexpression correlates well with clinical outcome[7] it is has low specificity for HPV infection as $p16^{INK4a}$ may also- be overexpressed by mechanisms other than the HPV-mediated inhibition of pRb in a minority (10–15%) of cases[24] for example Rb itself may be mutated.

Diagnostic algorithm

The Johns Hopkins Medical Institution diagnostic approach outlined by Westra[42] is one of the most widely accepted diagnostic algorithms in current use.

Using FFPE tissue, an initial screening of tumour tissue using IHC for $p16^{INK4a}$ is performed. Following this, all $p16^{INK4a}$ positive tumours undergo HPV-16 specific in-situ hybridization. All HPV-16+ / $p16^{INK4a}$+tumours are therefore designated as HPV-16+ve. The remaining minority of tumours which are $p16^{INK4a}$+/HPV-16 –ve then undergo further testing with an *in-situ* probe which is able to detect the presence of DNA of other HRHPV genotypes.

Such an algorithm is currently necessary in light of the variable sensitivity and specificity of the commonly employed individual tests and the need to demonstrate the presence of 'biologically active' HPV infection, and to ensure that tumours are correctly ascribed as being HPV+ve or not in the most cost effective and clinically convenient way.

CLINICAL PRESENTATION

Tumours which originate in the tonsil represent ~60% of all OPSCC tumours (**Figure 13.8**). In the context of HPV+OPSCC they are typically relatively small and

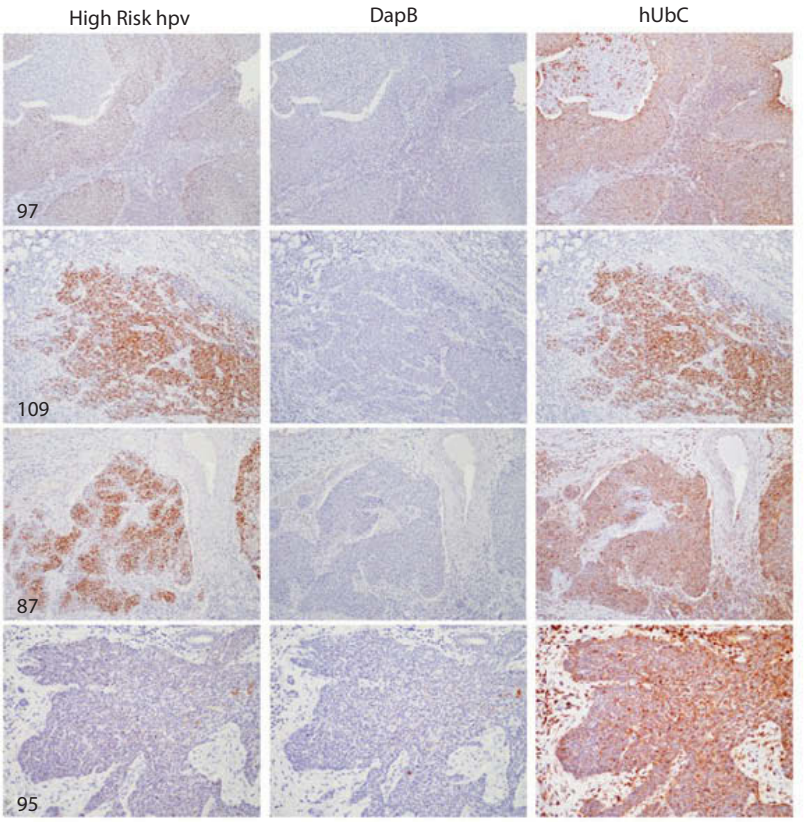

Figure 13.7 Photomicrographs of OPSCC stained using RNAscope with probes for high-risk HPV, dapB (negative control) and UBC (positive control). The cases demonstrate a range of positive staining patterns for high-risk HPV. Cases 109 and 97 showed strong and moderate staining, respectively, and contained HPV-16 E6/E7 mRNA by qRT–PCR. Case 87 showed strong staining and contained HPV-18 E6 mRNA by qRT–PCR. Case 95 showed weak staining and was negative for HPV-16 E6/E7 mRNA, HPV-18 E6 mRNA and HPV-33 E6 mRNA by qRT–PCR (false-positive result). Scale bars are equivalent to 200 mm for cases 109 and 87, and 50 mm for cases 97 and 95. (By kind permission, Mr Andrew Schache, University of Liverpool).

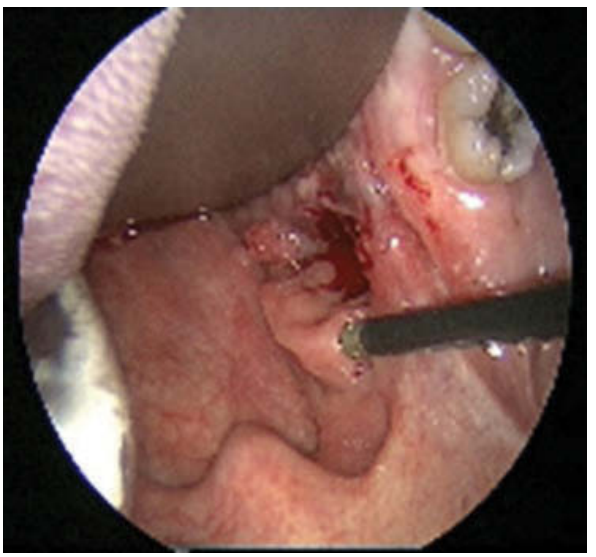

Figure 13.8 Intra-operative photograph of a T2 carcinoma of the right tonsil.

asymptomatic and patients present with cervical lymphadenopathy. They are also the most common site of primary tumours in the context of carcinoma of unknown primary origin (CUP).

As they enlarge, tonsillar tumours extend outside the confines of the tonsillar fossa. Their direction of local extension is unpredictable but can be cranial and medial onto the soft palate, caudal into the tongue base, posterolateral across the posterior pharyngeal wall, anterosuperior towards the retromolar trigone or laterally to involve the pterygoid musculature and other closely related structures in the neck, such as the carotid sheath. Disease which extends laterally and inferiorly may totally envelope the carotid sheath becoming contiguous with involved cervical lymph nodes. The extent of the local extension will obviously dictate the presenting symptoms which will range from being totally asymptomatic to having severe and intractable pain, often referred to the ipsilateral ear.

Base of tongue (BOT) make up ~30% of all OPSCC tumours. As with tonsillar OPSCC it is not unusual for BOT tumours to be asymptomatic or apparently occult, only coming to light during investigation of enlarged cervical lymph nodes. Local extension is typically towards and across the midline as well as into the intrinsic and extrinsic musculature of the tongue. Inevitably the greater the local extension the more likely symptoms relating to the tumour will be evident. Such symptoms can include odynophagia, persistent pain, including referred otalgia, dysphagia, altered speech, impaired tongue movement and bleeding.

Tumours of the oral surface of the soft palate make up the majority of the remaining 10% of OPSCC with posterior pharyngeal wall tumours presenting relatively rarely.

Soft palate OPSCC may present as a painful ulcerative lesion. Progression will result in involvement of the nasal surface of the soft palate, the superior tonsillar pole and/or the hard palate. These tumours not untypically present

as relatively small primary tumours with bilateral cervical lymphadenopathy. They are more likely to be HPV compared with OPSCC of the tonsil and BOT and accordingly typically behave in a more aggressive fashion with poorer outcomes.[3, 43]

Posterior pharyngeal wall tumours, which are also more likely to be HPV-, typically present late with symptoms of odynophagia, persistent sore throat and / or referred otalgia or dysphagia. They are notorious for presenting with widespread submucosal spread in all directions and as such are often underestimated on initial clinical assessment. The potential space between the pharyngobasilar and prevertebral fascia often acts as a barrier to deep spread and so tumour fixation as a consequence of deep spread to involve the prevertebral fascia is a very poor prognostic sign.

Patients presenting with oropharyngeal carcinoma present, broadly, in one of three ways:

- With symptoms related to the primary tumour with an enlarged cervical lymph node(s) which is/are usually painless and present at lymph node level II.
- With symptoms related to the primary tumour in the absence of an enlarged cervical lymph node(s) which is/are usually painless and present at lymph node level II.
- With an enlarged cervical lymph node(s) (usually painless and at level II) in the absence of symptoms related to a primary tumour (CUP).

It is well recognized that the presentation of patients with HPV+OPSCC differs significantly from the presentation of HPV-OPSCC.

HPV+OPSCC typically, although not exclusively, presents with a small primary tumour with multiple, enlarged, cystic cervical lymph nodes with a high prevalence of extracapsular spread (ECS). In contrast, HPV-OPSCC presents as a more typical head and neck cancer with larger primary tumours and relatively lower tumour burden in cervical lymph nodes.[6, 44, 45]

Symptoms relating to the primary tumour (soft palate, palatine tonsil, BOT or posterior pharyngeal wall) may vary quite considerably.

It is not unusual for patients to present with quite sizeable tumours in the absence of any obvious symptoms. In this patient group the primary tumour may be discovered incidentally following self-inspection or inspection of the mouth and oropharynx by a general medical or general dental practitioner, often in the context of seeking advice following a newly discovered neck lump. This is particularly the case for exophytic tumours of the palatine tonsil or BOT which have not invaded underlying musculature.

In contrast, ulcerative lesions which may be relatively small, may present initially with a sensation of sore throat with odynophagia. Larger lesions particularly of the BOT, posterior pharyngeal wall and tonsil may present with continuous pain exacerbated on swallowing and associated with referred otalgia and even dysphagia.

Incidental discovery of a painless enlarged cervical lymph node(s) whilst engaged in a routine task such as shaving or showering is a very common presentation for patients with OPSCC, especially HPV+OPSCC. If solitary, the presenting lymph node is almost invariably situated in lymph node level II whilst multiple lymph nodes will present typically as a chain extending from lymph node level II through III and IV, depending on the number and size of involved lymph nodes.

The presence of contralateral lymph nodes is not uncommon, especially if the primary tumour originates from the midline soft palate, midline BOT or midline posterior pharyngeal wall or is a non-lateralized tumour of the tonsil or BOT (i.e. a tumour encroaching or crossing the midline).

CLINICAL EXAMINATION

Oral cavity, pharynx and larynx

For patients presenting with signs and symptoms of an oropharynx cancer, a thorough examination of the head and neck should be undertaken as similar symptoms may result for tumours arising in one of several different anatomical sites of the upper aerodigestive tract (UADT).

The oral cavity should be carefully examined with the aid of a good light and tongue depressors. Inspection should include the buccal mucosa and lips, the palate, the tongue and floor of the mouth, all surfaces of the teeth and gums, opening and closing of the mouth and dental occlusion. Patients should be asked to elevate the tongue to the roof of the mouth and protrude the tongue towards both the right and the left. If tolerated by the patient, gentle intraoral palpation may be required to examine any swellings – this is particularly pertinent if a tumour of the BOT or tonsil is suspected as it is not unusual for tumours at these sites to be predominantly submucosal. Intraoral palpation may be combined with extra-oral palpation of the submental and submandibular lymph nodes and salivary glands to aid the characterization and/or localization of any swelling detected.

Following examination of the oral cavity, the oropharynx is then inspected with the tongue depressor placed firmly onto the dorsum of the tongue to depress it maximally. The anterior and posterior faucial pillars, the tonsil, retromolar trigone and posterior pharyngeal wall should all be inspected for colour changes, ulceration and swelling.

Pain and trismus arising as a consequence of pharyngolaryngeal or neck pathology may add to the difficulty of the examination but are significant clinical findings in their own right.

Following this initial inspection of the oral cavity and oropharynx, examination with a flexible fibre-optic endoscope passed through the nose, with or without topical anaesthesia, is essential. This will facilitate a high-resolution examination of the entire nasopharynx, oropharynx, larynx and often the hypopharynx. A camera attached to the endoscope permits the taking of high-quality photographs to record and present pertinent clinical findings.

Apart from the clinical scenario of an apparent CUP, an oropharyngeal tumour is usually readily detectable on clinical examination.

The neck

Even in the absence of an obvious neck node, it is essential to undertake a thorough examination of the neck if an oropharyngeal carcinoma is suspected. In order to do this the patient should be examined in the sitting position with the whole neck exposed so that both clavicles are clearly seen. The neck is inspected from the front and the patient asked to swallow, preferably with the aid of a sip of water. Movements of the larynx and any swelling in the neck are noted. The neck is then examined from behind with the chin flexed slightly downwards to remove any undue tension in the strap muscles, platysma and sternocleidomastoid muscles.

On examination for a lump in the neck, it is often helpful to ask the patient to point to any lump they have noticed first. Ask if the lump is tender. The neck is palpated bilaterally in a sequential manner comparing the two sides of the neck. All five palpable neck node levels (I-V) should be examined systematically as well as parotid and pre- and post-auricular nodes.

If a node is clinically obvious, either on inspection or on palpation, clinical examination should concentrate on ascertaining whether the node is solitary or whether there are multiple enlarged lymph nodes prior to estimating their size, determining their consistency (and whether they trans illuminate) and finally, whether they are mobile and therefore, by inference, amenable to surgical resection.

INVESTIGATIONS

1. **Patients presenting with a clinically evident primary tumour and an enlarged cervical lymph node(s) require the following investigations:**
   a. Ultrasound imaging of both sides of the neck followed by ultrasound guided fine-needle aspiration cytology (FNAC) of any neck nodes which are suspicious, on size and/or morphological criteria, of being involved with metastatic disease.
   b. Cross-sectional imaging (CT or MR) of the head and neck. Which imaging modality is employed is usually decided on the basis of local multidisciplinary team (MDT) preferences.
   c. A CT scan (or PET-CT scan) of the thorax and upper abdomen, in order to establish the absence (or presence) of a synchronous primary bronchogenic carcinoma or pulmonary and/or hepatic distant metastases.
   d. An examination under anaesthesia (EUA) of the UADT including a biopsy of the presenting primary tumour.

      Occasionally, it may be possible to biopsy an exophytic oropharyngeal tumour in the outpatient setting. Despite this, an EUA is still recommended if there are no contraindications in order to assess fully the extent and potential operability of the primary tumour.
2. **Patients presenting with a clinically evident primary tumour in the absence of enlarged cervical lymph nodes require the following investigations:**
   a. Cross-sectional imaging (CT or MR) of the head and neck. Which imaging modality is employed is usually decided on the basis of local MDT preferences.
   b. A CT scan (or PET-CT scan) of the thorax and upper abdomen, in order to establish the absence (or presence) of a synchronous primary bronchogenic carcinoma or pulmonary and/or hepatic distant metastases.
   c. An EUA of the UADT including a biopsy of the presenting primary tumour.

      As above, occasionally, it may be possible to biopsy an exophytic oropharynx tumour in the outpatient setting. Despite this, particularly if surgery is a treatment option and as long as there is no contraindication, an EUA is still recommended in order to assess fully the extent and operability of the primary tumour.
3. **Patients presenting with a clinically occult primary tumour with a clinically N+ neck (CUP), require the following investigations:**
   a. Ultrasound imaging of both sides of the neck followed by ultrasound guided FNAC of any neck nodes suspicious, on size and/or morphological criteria, of being involved with metastatic disease. This will, in most cases, confirm the diagnosis of metastatic SCC. If sufficient material is available, HPV testing of FNAC specimens is increasingly being advocated as detection of HPV in an enlarged metastatic cervical lymph node, strongly indicates that the primary site will be in the oropharynx – in particular the tonsil or BOT.[46, 47]
   b. In the absence of evidence of an obvious primary tumour on clinical examination, cross-sectional imaging (CT or MRI) of the head and neck is the usual next investigation of choice in many head and neck cancer centres.

      If the MRI scan confirms the presence of an obvious primary tumour then further investigation may proceed as outlined above with
   c. A CT scan (or PET-CT scan) of the thorax and upper abdomen, in order to establish the absence (or presence) of a synchronous primary bronchogenic carcinoma or pulmonary and/or hepatic distant metastases followed by
   d. An EUA of the UADT including a biopsy of the presenting primary tumour.

If, however, the MRI or CT scan of the head and neck does not delineate a likely primary tumour, then instead of proceeding with a CT scan of thorax and upper abdomen, a whole body PET-CT scan is the investigation of choice as has greater sensitivity for detecting primary tumour site,

whilst simultaneously investigating the presence of distant metastases.

If the PET-CT identifies, on the basis of increased FDG uptake, a likely primary site then and EUA should take place, to enable targeted examination and biopsy of the putative primary site.

In contrast, if PET-CT fails to identify a putative primary site an EUA should still be undertaken to allow a detailed inspection of the UADT taking particular note of the ipsilateral tonsil and BOT as these are the most likely sites of a small primary tumour. In the absence of an obvious primary tumour of the tonsil or BOT, the ipsilateral post nasal space and piriform fossa should be inspected.

If a primary tumour is still not revealed, at least the ipsilateral tonsil should be removed and either biopsies or a formal mucosectomy of the ipsilateral BOT should be performed and sent for histological assessment. Some clinicians would also advocate taking biopsies of the mucosa of the fossa of Rosenmüller and the ipsilateral piriform fossa.

Removal of the contralateral tonsil +/- a contralateral BOT mucosectomy is advocated by some clinicians.[48–50] However, this is a subject of much debate which revolves around the likelihood of detecting a tumour in the contralateral tonsil or tongue balanced against the morbidity of the procedures. To date, robust data do not currently exist to mandate this approach.

In all cases, biopsy of primary site tumours should be subjected to HPV testing. At the very least, this should involve immunohistochemistry for $p16^{INK4a}$ overexpression as described above as this has prognostic significance. If, however, as part of a clinical trial, de-intensified treatment is an option, then serious consideration should be given to additional testing for HPV DNA as outlined in the diagnostic algorithm above. Taking this dual testing approach minimizes the risk of de-intensifying treatment for the small proportion of patients who have tumours which overexpress $p16^{INK4a}$ but which are, in fact, HPV-.

Ultrasonography +/– fine needle aspiration cytology of a cervical lymph node

High-resolution ultrasound scanning (USS) has an established role in the contemporary management of head and neck cancer as the enumeration and characterization of cervical lymph nodes which contain metastatic tumour has a profound impact on outcome. It is common for USS +/- FNAC to be offered as part of a 'one-stop' neck lump diagnostic service in many head and neck centres.[51, 52]

Although USS and FNAC are operator-dependent and therefore should only be undertaken by specialists in the technique, it has been established that USS is more sensitive than palpation in the detection of enlarged cervical lymph nodes (97% vs 73%) and provides high specificity when combined with FNAC in the diagnosis of nodal metastases (93%). Moreover, ultrasound-guided FNAC is more accurate than non-image-guided FNAC.[53]

Magnetic resonance imaging (MRI)

MRI is used in many centres as the primary imaging modality of the head and neck. Continued development of MRI software and hardware ensure the ongoing improvement in MRI to distinguish pathology from normal anatomy. MRI is performed according to defined sequences. Three sequence parameters form the basis of head and neck imaging. T1-weighted images provide a high degree of spatial resolution of normal anatomy. T2-weighted images in contrast preferentially detect water content and therefore pathology. A short tau inversion-recovery (STIR) sequence also preferentially detects water content but in addition, suppresses the fat content of adjacent tissue to further enhance the contrast of pathological lesions. Intravenous gadolinium enhances the imaging of the vascular attributes of a tumour which adds to the contrast of a STIR sequence which may be of particular advantage when imaging apparently occult disease (**Figure 13.9**).

Accordingly, the soft tissue contrast features of MRI are superior to CT and therefore, in the absence of any contraindications (for e.g. inability to tolerate the increased scanning duration and/or intolerance to gadolinium), MRI is the preferred imaging option for oropharynx pathology.

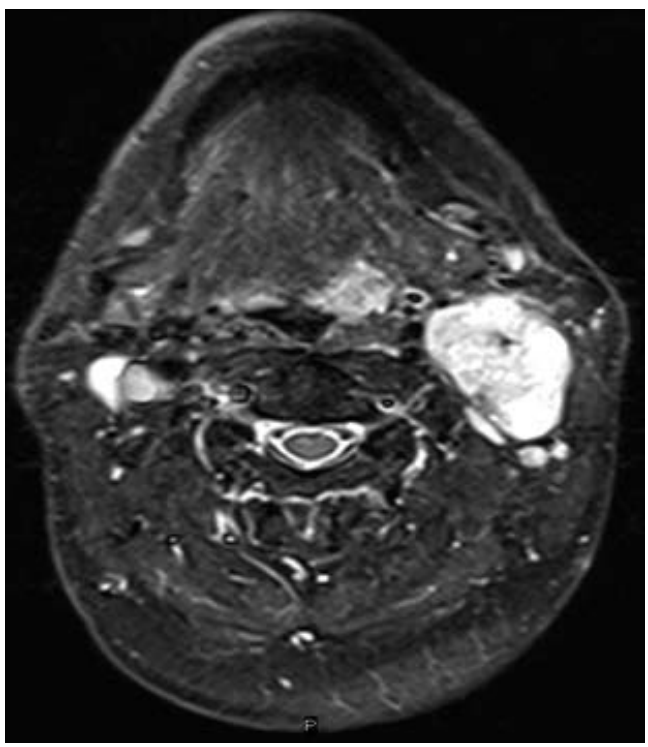

Figure 13.9 An axial short tau inverted-recovery (STIR) sequence magnetic resonance image (MRI) of a T2N2b carcinoma of the left base of tongue.

Computed tomography (CT)

Despite the widespread use of MRI in the staging of locoregional disease volume, CT is possibly the mainstay imaging modality for head and neck disease in most centres as it is widely available and its use in the staging of head and neck cancer is firmly established. It also facilitates imaging of the head and neck at one sitting which has obvious advantages for the patient and healthcare provider. Current imaging protocols ensure that imagine acquisition is rapid thereby reducing movement artefact as well as providing an advantage for patients unable to tolerate the more prolonged imaging sequence required for MRI. It is preferable to MRI if bone imaging is required but soft tissue resolution, particularly when staging soft tissue tumour extent, is comparatively inferior. Contrast-enhancement, using iodine-based contrast medium, based on a more rapid opacification of normal soft tissue than tumour provides added discrimination between tumour and normal. Contrast enhancement is contraindicated in patients with renal impairment. Contemporary CT software allows the high-resolution reconstruction of images to provide highly detailed 3D reconstruction which may be of considerable value when planning bony cuts, resection or reconstruction. The main downside of CT is the significant radiation dose incurred.

Positron emission tomography combined with CT (PET-CT)

The principle upon which this technique is based is the differential uptake, by cancer cells, of various labelled tracers, the pattern of which can then be fused with conventional CT images to create a functional map of the tumour. 18 fluoro-deoxyglucose (18-FDG) is the most commonly used tracer in clinical practice. Cancer cells rely preferentially on glycolysis, rather than aerobic respiration, for energy production (the Warburg effect). Accordingly, glucose derivatives, including 18-FDG, are preferentially transported into malignant cells and trapped. This differential transport is not exclusive to cancer cells as uptake is also greater in metabolically active cells such as inflammatory cells or active muscle. In light of this, PET-CT has to be undertaken in a quiet environment, when the patient is relaxed and preferably prior to the taking of diagnostic biopsies. Despite these precautions, PET-CT has a relatively low specificity with a high false-positive rate.[54, 55] Following administration and uptake, the labelled glucose tracer is detectable with a gamma camera. Metabolic activity is then accurately co-registered with the anatomical location defined by the CT images, thereby creating the functional map. In the context of OPSCC, PET-CT is most commonly used in the context of CUP, as recommended in the UK Royal College of Radiologists Guidelines published in 2013 (**Figure 13.10**).[56]

Examination under anaesthesia (EUA)

An EUA is highly recommended for all patients presenting with OPSCC, even if the primary tumour is evident on clinical examination in the outpatient department. The aims of EUA are typically threefold.

- To take a diagnostic biopsy of the primary tumour, and/or to assess the presence of a primary tumour in cases where a primary tumour is not immediately evident on clinical examination in the outpatient department.
  (A biopsy of the primary tumour is essential for subsequent treatment planning – surgical or non-surgical – even if a positive FNAC diagnosis of a cervical lymph node has been previously obtained. Only in the relatively rare cases when an EUA is contraindicated (usually on the basis of patient fitness) should treatment proceed on the basis of an FNAC result alone.)
- To assess the locoregional extent of the tumour and its relationship to adjacent anatomical structures. This is particularly pertinent if surgery is being considered.
- To exclude the presence of a synchronous second primary tumour.

Following anaesthetic induction, the patient is placed in a supine position with the neck extended assuming there is no contraindication. The sequence of events may vary depending upon operator preference but the following steps are mandatory.

1. Palpation of the BOT and vallecula if access is possible as well as palpation of the lateral walls of the oropharynx and postnasal space.

Figure 13.10 A fused axial section of an 18-fluoro-deoxyglucose (18-FDG) PET-CT scan showing increased 18-FDG uptake in the left tonsil and a left metastatic cervical lymph node.

2. An examination of the hypopharynx and cervical oesophagus, using rigid pharyngoscopes +/– a rigid fibre-optic light source.
3. A direct or rigid fibre-optic light source-assisted laryngoscopy.
4. Visual inspection of the oropharynx using an oropharyngeal gap and headlight.
5. A biopsy of any obvious or suspicious primary tumour.

Tonsil biopsy versus diagnostic tonsillectomy

If a primary tumour of the tonsil is evident then it is sufficient to take a representative biopsy to establish histological diagnosis.

If, however, following examination, it is considered that a likely primary tumour is contained within one tonsil a potential dilemma exists, particularly if transoral surgery is a primary treatment option. Traditional teaching would dictate that a diagnostic tonsillectomy is undertaken. However, this may compromise the reporting of surgical margins, complicate revision transoral surgery and adjuvant treatment decision-making. If transoral surgery is a primary treatment option then it may be preferable to either i) simply taking a representation diagnostic biopsy from the centre of the tonsil, avoiding the margins or ii) performing a tonsillectomy according the principles of TLM or TORS surgery. Adopting the former approach ensures that subsequent transoral surgery is not compromised whilst adopting the latter approach ensures that a diagnostic biopsy and appropriate resection are undertaken at the same time and adjuvant treatment decision making is not compromised.

In a third scenario, on EUA of a patient presenting with CUP, if the ipsilateral tonsil appears normal, undertaking the tonsillectomy according to TLM or TORS principles ensures that resection is appropriately completed in the context of a primary tumour being diagnosed on subsequent histological examination and appropriate adjuvant treatment decision-making can proceed unhindered following the completion of an ipsilateral selective neck dissection on a separate occasion.

STAGING

The staging of head and neck cancer will be dealt with in detail in Chapter 4, Staging of head and neck cancer. However, it is worth highlighting recent changes to the TNM staging recommendations published in the American Joint Committee on Cancer (AJCC) Cancer Staging Manual 8th edition[45] and the Union for International Cancer Control (UICC)[57] which are of particular importance to the staging of OPSCC. The changes and the rationale behind them are reviewed in detail in Lydiatt et al.[47]

1. In contrast to the AJCC 7th edition which considered staging of cancers of the naso-, oro- and hypopharynx in one chapter, the AJCC 8th edition divides pharyngeal cancers into three separate chapters which consider the staging of nasopharynx, p16+HRHPV associated OPSCC (p16+OPSCC)* and p16–non-HRHPV associated OPSCC (p16–OPSCC) together with hypopharynx cancers.
2. In the 8th edition, T stages for p16+OPSCC and p16–OPSCC remain the same apart from two exceptions for p16+OPSCC.
   a. The Tis classification has been removed because a premalignant lesion has yet to be identified in p16+OPSCC and because of the absence of a basement membrane in Waldeyer ring epithelium, the presence of which is essential for a diagnosis of Tis.
   b. T4b has been removed as the outcomes for T4a and T4b categories are indistinguishable when considering p16+OPSCC. Consequently a single T4 category remains in the 8th edition.
3. A T0 category is no longer assigned to p16–OPSCC and other non-HRHPV cancers for example larynx, oral cavity and hypopharynx as an exact primary site is, by definition, unable to be established and therefore cannot be assigned to a specific anatomical subsite. In contrast, cytology specimens following FNAC of an enlarged lymph node in which the presence of metastatic carcinoma is confirmed can be subjected to testing for HPV and Epstein—Barr virus (EBV) status. (In this context and in contrast to the recommendation above, both HPV ISH and p16 overexpression is necessary for the confirmation of HPV status whilst the presence of Epstein Barr Encoded RNA (EBER) determines EBV association.)

   It is considered that demonstration of HPV status or EBV status safely allows the primary site to be determined as oropharynx or nasopharynx respectively and therefore, classification systems for p16+OPSCC and nasopharynx maintain T0 categories. (As does salivary gland because primary site can be determined on cytological findings).
4. As p16+OPSCC may be treated with primary surgery or primary RT +/– chemotherapy, separate clinical and pathological staging systems have been stipulated.
   a. The clinical, or cTNM, classification is designed for patients before treatment (regardless of the intended form of treatment) and employs information from physical examination and imaging.

* Importantly and contentiously, HPV status determined according to the diagnostic algorithm described earlier in the chapter is not mandated as HPV-ISH is not widely available in centres throughout the world and its interpretation is often difficult. Instead, p16 overexpression as assessed by immunohistochemistry (>75% expression with at least moderate staining intensity) is considered sufficient to allow re-classification of OPSCC into p16+HRHPV associated OPSCC (p16+OPSCC) and p16 – non-HRHPV associated OPSCC (p16–OPSCC).

In this classification system, the presence of one or multiple involved ipsilateral cervical nodes, all < 6 cm, is classified as N1. The presence of bilateral or contralateral involved nodes < 6 cm, is classified as N2, whilst the presence of any node > 6 cm is classified as N3.

b. The pathological, or pTNM classification is designed only to patients managed with primary surgery. When surgical data were considered, lymph node size, even > 6 cm, or the presence of bilateral or contralateral lymph nodes was not discriminatory. Instead, the number of involved lymph nodes appeared critical. Accordingly, the presence of one to four lymph nodes is classified as N1 whilst five or more positive lymph nodes of any size are classified as N2.

Why the presence of lymph nodes > 6 cm is discriminatory in cTNM staging but not pTNM staging is not clear.

5. Consideration of T and N staging together has led to the publication of three separate stage groupings for OPSCC: separate clinical and pathologic groupings for p16+OPSCC and combined clinical and pathologic groupings for p16−OPSCC. The separate p16+OPSCC clinical and pathologic stage groupings each have three categories (I, II, III and IV) whilst the p16−OPSCC combined clinical and pathological stage grouping has six categories, as per the 7th edition, (I, II, III, IVA, IVB and IVC). Stage II and IVC are reserved for the presence of distant metastatic disease in each classification respectively.

It is important to stress that although the TNM 8th edition is useful for prognostication currently, it should not be used to inform treatment decision-making as its role in treatment allocation requires prospective evaluation in randomized clinical trials or similarly robust studies. Therefore, the management principles for OPSCC described in subsequent chapters have not been modified for TNM 8th edition.

MANAGEMENT

The management of oropharyngeal carcinoma represents an increasing clinical challenge, both because of its rising incidence, particularly in younger patients as a result of HPV infection, and because of the significant technological advances that have occurred in radiotherapy and surgery over the last 10–20 years which have increased treatment options for patients, with little robust evidence yet of their relative merits.

This situation is further complicated by the clinical paradox that has been created following the emergence of HPV+OPSCC. HPV status is highly prognostic in OPSCC patients treated with CRT. In a landmark study, Ang et al retrospectively analyzed the outcomes of patients with stage III/IV OPSCC treated with CRT in the RTOG 0129 study by HPV status: 3-year overall survival was 82.4% in HPV+patients, compared to 57.1% in HPV-patients ($p < 0.001$). Similarly high survival rates for HPV+OPSCC have been demonstrated in patients treated with primary RT/CRT and surgery.[7, 24, 58–62]

However whilst patients with HPV+OPSCC, in general, do better in survival terms than patients with HPV-OPSCC, it must also be borne in mind that a sub-set of patients with HPV+OPSCC also do badly. Whilst high T-stage and number of involved lymph nodes are associated with poor outcome in this subgroup, smoking habit, which is assumed to be a surrogate of underlying tumour mutational load and / or genetic instability, also appears to be of importance.[6, 7, 43]

Currently HPV+ and HPV- OPSCC are managed according to the same treatment protocols, but the improved prognosis associated with HPV-positivity has raised the possibility that they could be managed differently. In particular, there is a need to continually strive for novel intensified treatments which will enhance survival in patients with HPV-OPSCC and the subgroup of patients with HPV+OPSCC who will do badly, whilst potentially considering de-intensified treatment strategies for patients with HPV+OPSCC who will do well, with the aim of maintaining their current good survival outcomes whilst reducing the frequency and severity of short- and long-term post-treatment adverse events.

There is an absence of randomized studies comparing primary surgical and non-surgical approaches in the management of OPSCC, resulting in a global lack of consensus between surgeons and oncologists as to how these cancers should be managed. The options are:

- For T1-T2 N0: Radical radiotherapy or transoral surgery and neck dissection(with post-operative (chemo) radiotherapy if there are adverse pathological features on histology).
- For other stages: primary CRT or surgery and adjuvant (chemo) radiotherapy.

Open surgery and microvascular reconstruction followed by post-operative adjuvant treatment was the historic treatment of choice for OPSCC and is still offered by some units. However, a 2002 retrospective review of 6400 patients with OPSCC in 51 studies showed similar rates of locoregional control, overall survival and cause-specific survival for patients treated with open surgery and post-operative RT (PORT), compared with those treated with primary RT +/− neck dissection, but a significantly higher rate of severe or fatal complications in the surgery group, together with worse functional outcomes.[63] These data raised concerns regarding the continued use of this approach and when combined with high-quality level I and meta-analysis data confirming that benefit of radiotherapy +/− cisplatin-based chemotherapy[7, 64] in the management of OPSCC, a major shift away from open surgery to CRT in the developed world has occurred.

This shift is reflected in UK data from successive National Head and Neck Cancer (DAHNO) audits which confirm that by the 10th audit, CRT was given more than twice as frequently as RT alone.[65] Similarly, data from the US has shown a linear rise (from 20% to > 60% of cases) in the use of CRT for the management of OPSCC from

1998 to 2009 with a concurrent decrease in the use of surgery and radiotherapy alone.[66]

Radiotherapy (RT)/concurrent chemoradiotherapy (CRT)

The primary rationale for the use of RT or CRT in treating OPSCC is organ preservation and also, importantly, to preserve function whilst achieving high cure rates. Data from randomized trials, such as RTOG 0129,[67] comparing CRT schedules confirm that this approach can result in good oncological outcomes, particularly in HPV+ OPSCC. However, it is worth reiterating that high-quality data comparing surgical and non-surgical approaches do not exist, despite RT and CRT becoming the accepted standard of care in many centres throughout the world for early and late stage OPSCC respectively.

Early stage T1-T2 N0-N1 OPSCC can be effectively treated with RT alone.[68] For radical treatment, RT is commonly delivered at a total dose equivalent of 70 Gy in 35 fractions and this may be delivered as a hypofractionated schedule of 65–66 Gy in 30 fractions.

For more advanced T and/or N stage (stage III/IV, TNM 7th edition) OPSCC, CRT is the standard of care, with a RT dose equivalent of 70 Gy delivered in 35 fractions together with concurrent cisplatin at a dose of 100 mg/m^2 given on days 1, 22 and 43 of the RT schedule. The GORTEC 94-01 study demonstrated a ≥20% 3- and 5-year survival benefit for the addition of chemotherapy to RT, albeit in the setting of low overall survival figures (3-year overall survival 51% vs 31%, p = 0.02, disease-free survival 42% vs 20%, p = 0.04 and locoregional control 66% vs 42% p = 0.03).[69] Furthermore, meta-analysis data in 17 346 patients confirmed that, for HNSCCs as a whole, concurrent chemotherapy confers an overall survival benefit of 6.5% at 5 years (p < 0.0001), compared to RT alone.[64] The benefit of adding chemotherapy to RT for the management of OPSCC specifically was confirmed in an additional systematic review.[70]

Weekly administration of low-dose cisplatin (40–50 mg/m^2) is an alternative to 3-weekly high-dose cisplatin which has become increasingly used in clinical practice in an attempt to improve tolerance and compliance. A recent meta-analysis of 4209 patients in 52 studies concluded that there was no difference in treatment efficacy, as measured by overall survival or response rate, between the low-dose weekly and high-dose 3-weekly cisplatin regimens.[71] The weekly regimen was associated with a higher compliance rate and was significantly less toxic with regards to severe (grade 3–4) myelosuppression, nausea and nephrotoxicity. The authors concluded that the weekly regimen needed to be prospectively compared with the standard 3-weekly regimen before being adopted into routine clinical practice. In the meantime, clinicians will continue to choose between regimens, based on institutional protocols, personal experience and patient fitness. In patients for whom cisplatin is contraindicated, concurrent carboplatin chemotherapy (3-weekly at area under the curve (AUC) 5 or weekly at AUC 2) is an alternative that is associated with less ototoxicity and nephrotoxicity.

Concurrent weekly cetuximab (a monoclonal antibody targeting the epidermal growth factor receptor (EGFR) may be given with RT if there is a contraindication to platinum chemotherapy. In a randomized trial, the combination of cetuximab and RT improved median locoregional control (24.4 vs 14.9 months) and median duration of overall survival (49 vs 29.3 months) after a median follow-up of 54 months[72] and this survival difference was maintained on long-term follow-up. The addition of cetuximab to concurrent CRT did not improve outcome compared to CRT alone in a subsequent trial.[73] The results of randomized studies conducted in the USA (RTOG 1016: NCT01302834) and UK (DE-Escalate: NCT01874171) comparing the efficacy and toxicity profile of RT with concurrent cisplatin vs RT with concurrent Cetuximab in HPV+OPSCC are awaited and may change the future standard of care for the non-surgical management of this disease.

Radical RT may be given alone for patients with advanced disease who are not fit for concurrent treatment, particularly if >70 years of age when the benefits of concurrent chemotherapy and cetuximab are reduced.

Induction (or neoadjuvant) chemotherapy

The use of induction chemotherapy (IC) may be beneficial in selected patients. The MACH-NC meta-analysis[64] showed an overall survival advantage for cisplatin and 5-FU chemotherapy compared to local therapy alone for the management of HNSCC, and IC had a relatively more pronounced effect on distant metastasis rate than concurrent CRT. The benefits of using IC prior to concurrent cisplatin-based CRT have not been convincingly shown: a recent meta-analysis which included all types of HNSCC showed that IC increases toxicity and does not improve OS compared to CRT alone.[74]

In the context of OPSCC, including HPV+OPSCC, the use of IC has been advocated for patients with advanced (T4, N3, N2c) disease to reduce the risk of distant metastases.[44] High-quality prospective evidence of its efficacy in these indications is currently not available.

IC with the TPF regimen (taxotere, cisplatin and 5-FU) is recommended, based on a higher response and survival rates and reduced locoregional and distant failure rates compared to PF (cisplatin and 5-FU) in a meta-analysis of five studies.[75] The regimen is associated with higher acute toxicity (neutropenic sepsis and non-haematological toxicities) and therefore is only suitable for patients with good performance status and minimal comorbidity.

Radiotherapy planning and delivery

PRE-TREATMENT EVALUATION

All patients should undergo the following assessments before starting RT:

- **Dental assessment:** including orthopantomogram (OPT) for dentulous patients if the upper or lower jaw is likely to be in the radiation field. Dental treatment,

particularly extraction, should be carried out prior to starting RT (ideally 2 weeks before) to reduce the risk of osteoradionecrosis.

- **Nutritional assessment:** dietetic input prior to the start of treatment is important to start patients with pre-existing weight loss (>10%) on supplementary feeding prior to treatment and to identify patients who are likely to require a feeding tube to support their nutritional requirements during and after treatment. The choice between feeding gastrostomy tube (proactive or reactive) or nasogastric tube depends upon local preference, expertise and availability of resources.
- **Speech and swallowing assessment:** to assess speech and swallowing function and educate patients on proactive swallowing exercise to be repeated daily prior to and during treatment in order to minimize swallowing difficulties in the short and long term.

RADIOTHERAPY PLANNING

Intensity-modulated radiotherapy (IMRT) is now the accepted standard of care for RT treatment planning and delivery for OPSCC (**Figure 13.11**) – the conformal dose distributions achieved allow sparing of normal tissues and organs at risk, potentially reducing toxicities and improving quality of life (QOL). The UK phase III PARSPORT study demonstrated that parotid-sparing IMRT reduces the incidence of grade 3–4 xerostomia (dry mouth) compared to conventional RT, from 83% to 29% 24 months after treatment ($p = 0.0001$).[76]

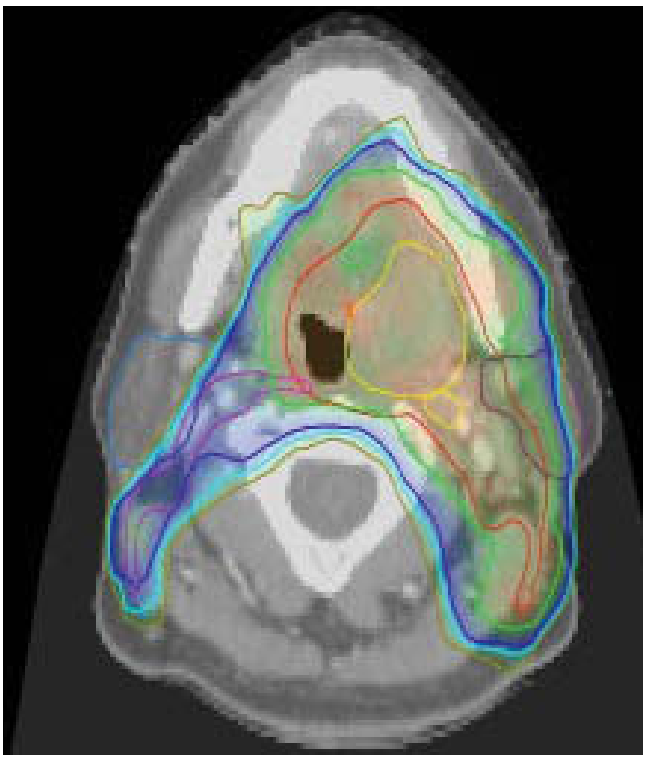

Figure 13.11 Intensity-modulated radiotherapy (IMRT) plan for left tonsillar carcinoma. Gross tumour volume (GTV) for left tonsillar primary and retropharyngeal node (yellow): Clinical target volume (CTV1) for radical dose RT (red): CTV2 for prophylactic dose RT (purple): 62.7 Gy, 51.3 Gy and 48 Gy isodose lines (shown in green, blue and mustard respectively).

Intensity modulation is delivered using a step and shoot technique or more recently, with dynamic arc therapy, either volumetric modulated arc therapy (VMAT) or tomotherapy.

Prior to target volume delineation, the primary tumour should be defined as lateralized or non-lateralized, depending on the site of the primary, T stage and extent of involvement of midline structures, as follows:

Lateralized tumour: tumour confined to the tonsillar fossa/lateral pharyngeal wall extending onto or into the adjacent BOT and/or soft palate by < 1 cm and with > 1 cm clearance from midline.

Non-lateralized tumour: tonsillar/lateral pharyngeal wall tumour that involves the adjacent BOT and/or soft palate by ≥ 1 cm or with ≤ 1 cm clearance from midline.

OR

A tumour that arises from a midline structure (BOT, soft palate or posterior pharyngeal wall primary tumour).

This will determine whether contralateral neck irradiation is required in cN0 cases (see 'Management of the neck' below).

Target volume definition

Patients will require a custom-made thermoplastic immobilization shell to ensure a reproducible position for accurate radiotherapy delivery. A 5-point immobilization system is normally used which includes the head, neck and both shoulders. Target volume delineation is carried out on a contrast-enhanced planning CT scan, often co-registered with the staging MRI and/or PET scan to enhance target volume definition. Target delineation requires a detailed knowledge of cross-sectional anatomy as well as detailed knowledge of tumour location and extent from the staging investigations. The following volumes are defined:

Gross tumour volume (GTV): the primary tumour (GTVp) and involved lymph nodes (GTVn) are delineated.

Clinical target volume (CTV): the CTV is a margin for microscopic disease and is usually divided into 2 or 3 volumes.

CTV1 (the high-dose CTV): typically, CTV1 includes a 1 cm isotropic margin around the primary and nodal GTVs and the whole of the involved nodal level in the neck. The isotropic margin may vary from 0.5 cm to 1.5 cm depending on local protocols and the certainty with which a tumour can be defined from the staging investigations.

CTV2 (the intermediate dose CTV): an optional volume which may include the whole involved nodal level in the neck (if not included in CTV1) and/or an additional isotropic margin around CTV1.

CTV3 (the prophylactic dose CTV): includes the 'at risk' nodal levels. For node negative OPSCC, this typically includes levels II–IVa. For node positive OPSCC, this typically includes levels Ib–V(b or c).

Internationally agreed consensus guidelines for the delineation of at risk nodal levels are used to guide outlining of the prophylactic CTV.[77]

Planning target volume (PTV): a margin (typically 3–5 mm) that is automatically added by the planning system to ensure the CTV is adequately covered on every day of treatment.

Organs at risk, including the spinal cord, brain stem, parotid glands and swallowing related structures are also outlined and also given a planning margin called the **Planning risk volume (PRV)**.

Defining the objectives for target volume coverage and constraints for the organ at risk doses, as well as the relative priorities of each, is then required prior to inverse treatment planning.

TOXICITIES OF RT/CRT

Radiotherapy can result in significant acute (< 90 days) and late (> 90 days after treatment) toxicities and late toxicities, particularly affecting salivary gland function, dentition and swallowing, may be permanent. CRT increases the risk of late toxicity[78, 79] and in the pre-IMRT era, up to 43% of HNSCC patients could develop grade 3–4 late toxicities following CRT.[80] The key late toxicity affecting QOL is swallowing dysfunction.[81] Swallowing is a primary concern for patients,[82] affecting their physical health and well-being, and is a major cause of distress and burden for family members[83] since dysphagic patients often require long-term supportive care.

Whilst the PARSPORT study demonstrated reduced rates of xerostomia in patients treated with IMRT compared to conformal RT, late dysphagia can still be an issue, even in patients treated with IMRT. Feeding tube dependence, a crude measure of swallowing dysfunction, has been reported in 8.6% of OPSCC patients at 1 year and 4.4% at 2 years after modern chemo-IMRT in a multi-institution pooled analysis.[84] Furthermore, a significant deterioration in patient-reported impairment in swallowing function, measured using the MD Anderson Dysphagia Inventory (MDADI), score, is seen in most patients 12 months after treatment and a deterioration of at least 20 points is still detectable in 15% of patients 24 months after treatment.[85,86] Aspiration, which can result in life-threatening episodes of pneumonia, may arise as a consequence. A US study identified > 3500 patients > 65 years who had been treated with CRT for head and neck squamous cell carcinoma (HNSCC) from the SEER-Medicare database (2000–2009) – it showed that > 25% of OPSCC patients had experienced at least one episode of aspiration pneumonia 10 years after treatment.[87]

Late dysphagia correlates with mean radiation dose to the swallowing-related structures (pharyngeal constrictor muscles, glottic and supraglottic larynx, oral cavity and cervical oesophagus), with the correlation being highest for the superior pharyngeal constrictors.[88, 89] The normal tissue complication probability curve for the pharyngeal musculature is sigmoidal in shape and increasing mean radiation doses between 50 and 60 Gy are in the critical range for late dysphagia.[88] The potential of dysphagia-optimized IMRT to reduce dysphagia rates, by reducing radiation doses to swallowing-related structures, holds significant promise and is being prospectively evaluated by a number of investigators and in an ongoing UK randomized controlled trial (RCT) (DARS ISRCTN: 25458988). Omitting chemotherapy could also potentially reduce the risk of dysphagia in selected patients, as concurrent chemotherapy increases late dysphagia rates compared with IMRT alone[89] and, as outlined above, the results of studies comparing the use of cetuximab instead of cisplatin with RT, in the context of good prognosis HPV+OPSCC, are awaited. Furthermore, prospective studies to determine whether intensity modulated proton beam therapy (IMPT) can reduce toxicity compared to IMRT by sparing non-target tissue in the head and neck are being planned.

Post-operative (adjuvant) RT/CRT for OPSCC

Evidence for the role of adjuvant RT after (open) surgery in head and neck cancers was provided by the RTOG 73-03 trial which showed that post-operative RT improved local control.[90] Subsequent studies helped to establish the optimum dose of post-operative radiation and recommended a minimum dose of 57.6 Gy to the primary site with up to 63 Gy to areas of ECS.[91] Prophylactic treatment for microscopic disease was established by a study showing that a dose of 50 Gy in 25 fractions was sufficient to control microscopic disease in over 90% of cases.[92] Patients should start their post-operative RT as soon as possible after surgery, ideally within 5 weeks (35 days) and no later than 6 weeks (42 days) to avoid reduced local control and survival due to protracted treatment beyond a total of 11 weeks (for surgery and RT combined).[93]

The indications for post-operative RT and CRT for OPSCC depend on pathological risk factors for recurrence common to most HNSCCs. These include: primary tumour factors (close (1–5 mm) or positive (< 1 mm) margins, T3–4 stage, perineural and/or lymphovascular invasion) and nodal factors (ECS of nodal disease and/or N2-N3 nodal stage). RCTs conducted by the RTOG and EORTC and a meta-analysis of their results confirmed that patients with ECS and/or microscopically involved (< 1 mm) surgical resection margins around the primary tumour experience significant benefit in terms of overall and disease-free survival from post-operative CRT compared to RT alone.[94] However, post-operative CRT results in significant toxicities (including a 2% death rate) and is not generally recommended in patients > 70 years of age and/or those with significant co-morbidities and poor performance status.

Transoral surgery

In light of accumulating retrospective data of efficacy and following the FDA approval of TORS for the management of OPSCC, there has been a resurgent interest in the transoral surgical management of OPSCC, with a 4.4% increase in the use of primary surgery in the US between 2009 and 2012,[95] a trend that is only likely to continue.

Transoral laser microsurgery (TLM) and transoral robotic surgery (TORS) are minimally invasive surgical techniques for OPSCC, which have the potential to excise T1-T3 tumours with considerably less long-term functional deficit than open surgery. Transoral surgery (TOS) of the primary tumour is usually performed in conjunction with a neck dissection, either carried out at the same time, or as a staged procedure. Although early stage (T1-T2 N0-N1) OPSCC can be effectively treated with surgery alone,[62] adjuvant treatment is required in most patients, usually due to advanced nodal disease.

It is important to note that whilst TLM and TORS employ a transoral approach for tumour resection, there are important practical and philosophical differences between the techniques which is often not appreciated by the uninitiated. The most important difference is that whilst the technique of TLM dictates that the extent of surgery, in an attempt to minimize the removal of uninvolved tissue adjacent to the tumour, is governed by the specific anatomy of the tumour and so differs from case to case, TORS is predicated on the advisability of undertaking a standard procedure avoiding transtumoral resection and attempts to adhere to the principles of traditional *en bloc* surgical resection.

Transoral laser microsurgery (TLM)

(For more information regarding the role of TLM in general, please see Chapter 22, Transoral laser microsurgery)

TLM is conducted according to the principles proposed by Wolfgang Steiner and Petra Ambrosch.[96]

As per the standard technique, tumours are removed in several (at least two) planned pieces following transtumoral resection. Transtumoral resection is necessary for two primary reasons: primarily, it eases the technical burdens of removing large tumours which is of particular importance when resection is taking place down a distending endoscope as is usual when resecting tumours of the BOT. In addition, it facilitates greater appreciation of the 3D orientation of the tumour allowing greater resection precision. In an attempt to confirm complete surgical removal representative marginal biopsies should be taken from the tumour bed and examined histologically.

Marginal biopsies should be taken from all peripheral mucosal regions when this is technically feasible, together with representative marginal deep biopsies from the tumour bed.

The technique of TLM resection for OPSCC is best described when considering resection of a primary tonsil tumour.

Most tonsil tumours considered amenable to TLM are T2 in size. Resection will typically involve removal in two parts, following an initial transverse laser cut through the centre of the tumour which divides it into superior (cranial) and inferior (caudal) halves. Thereafter, each half is removed separately. Following in continuity removal of a given half, it is usually orientated and pinned to a cork board. On removal of the other half, this too is orientated and pinned to the same cork board, to recreate the anatomical arrangement of the primary tumour.

It is from this pinned primary specimen that histological margins around the primary tumour will be determined.

Having removed the two halves of the primary tumour, marginal biopsies are then taken. Marginal biopsies, as far as anatomically possible, should maximally represent the mucosal regions adjacent to the primary tumour and the deep tumour bed (**Figure 13.12**). It is usual therefore to take up to eight marginal biopsies following a standard TLM of a tonsil tumour, namely:

- a superior marginal biopsy involving the mucosa adjacent to the superior pole of the tumour
- an anterosuperior marginal biopsy, from the mucosa anterior to the superior half of the tumour (in many cases this amounts to the mucosa covering the region of the anterior faucial pillar)
- a posterosuperior marginal biopsy, from the mucosa posterior to the superior half of the tumour (in many cases this amounts to the mucosa covering the region of the posterior pharyngeal wall)
- a superior deep marginal biopsy which includes a representative sample of constrictor muscle deep in the bed of the superior half of the tumour
- an inferior marginal biopsy involving the mucosa adjacent to the inferior pole of the tumour
- an anteroinferior marginal biopsy, from the mucosa anterior to the inferior half of the tumour (in many

Figure 13.12 A tonsillar carcinoma, resceted in two portions as per the TLM principles described by Steiner and Ambrosch. Each section is anatomically re-orientated and pinned to a cork board (orange needles). A mucosal marginal biopsy is also anatomically orientated adjacent to the superior edge of the superior specimen. The superior pole of the tonsil is marked with a blue needle.

cases this again amounts to the mucosa covering the region of the anterior faucial pillar)
- a posteroinferior marginal biopsy, from the mucosa posterior to the inferior half of the tumour (in many cases this too amounts to the mucosa covering the region of the posterior pharyngeal wall)
- an inferior deep marginal biopsy which includes a representative sample of constrictor muscle deep in the bed of the inferior half of the tumour.

The biopsies should be labelled as above prior to sending to the pathology laboratory. The taking of marginal biopsies around soft palate and BOT tumours is more difficult to mandate as, in keeping with the philosophy of TLM, to tailor the resection to the tumour extent, there is often no standard procedure for removing these tumours. However, the guiding principles of marginal biopsies – to maximally represent adjacent mucosal boundaries and the deep tumour bed of resected tumours – should be adhered to at all times.

If all marginal biopsies are free of microscopic disease, then resection of the primary tumour is considered to be complete and allocation of adjuvant treatment depends, *inter alia*, on the depth of the resection margin around the main tumour specimen(s).

Re-resection is usually undertaken in a case when one or more initial marginal biopsies are found to contain microscopic disease.

Transoral robotic surgery (TORS)

(For more information regarding the role of TORS in general, please see Chapter 80, Rhinoplasty following nasal trauma)

For tonsil and BOT tumours, it is usual for the neck dissection be performed prior to the TORS procedure, either during the same general anaesthetic or at a previous sitting, during which the ipsilateral lingual and facial arteries are identified and ligated in continuity.

The resection involves *en bloc* removal of the tumour as per the principles outlined in the da Vinci Transoral Surgery Procedure Guide, which can be accessed via the following link.[97] https://oto.med.upenn.edu/education/62-2/.

The resection is performed primarily with the monopolar cautery. Where facilities are available to couple a laser to the robotic arm, this may be used for the resection.

Tonsil tumours: Resectability of the tonsil tumour is confirmed based on imaging. Extension to the parapharyngeal space and pterygoid musculature are relative contraindications to the procedure. Retropharyngeal location of the internal carotid artery is also a contraindication for this procedure and the scans should be very carefully studied to ensure this is not the case. The resection specimen is essentially a lateral oropharyngectomy, where the constrictor muscles of the tonsil bed are removed along with the tumour. If any concerns arise regarding the adequacy of the margins during the resection, the margins can be extended. Following removal, the tumour is grossly inspected to ensure that adequate margins are obtained. This may involve cutting though the tumour with a blade if the expertise and facilities exist. If any concerns are raised about the margins following resection (this usually occurs at the inferior aspect, where the tonsil meets the tongue base), the areas are marked with methylene blue (to identify the surface of interest to the pathologist) and a further margin harvested. The specimen is orientated on a suitable mount and sent for histological examination.

Tongue base tumours: Resectability of the tongue base tumour is also confirmed on imaging. Tumour extending across the midline is a contraindication for the procedure. Resection of the ipsilateral tongue base is performed as described in the procedure guide above. If any concerns are raised about the margins following resection (this usually occurs at the deeper aspect of the BOT), the areas are marked with methylene blue (to identify the surface of interest to the pathologist) and a further margin harvested. The specimen is orientated on a suitable mount and sent for histological examination.

Tumours involving both the tonsil and BOT: These tumours usually do not involve the entire tonsil and thus, it is sufficient to cut through the tonsil and the constrictors at least 5 mm away from the tumour edge and proceed with the resection of the tonsil tumour in the usual fashion, leaving the cranial part of the tonsil. Once the tonsil tumour is completely mobilized down to the styloglossus, the tongue base cuts can be made and the entire tumour removed *en bloc*. As above, further margins are resected on the table if concerns exist. The specimen is orientated on a suitable mount and sent for histological examination.

As outlined above, in contrast to the principle of TLM, primary tumours are removed *en bloc* using TORS in the vast majority of cases. As a result, surgical margins after TORS can be assessed and measured using standard pathology reporting protocols and the taking of marginal biopsies does not apply to tumours resected in this way. However, transtumoral resection and the taking of marginal biopsies – as described for TLM - may also be appropriate when employing a TORS approach and in such cases the same criteria for assessing resection as outlined for TLM above, should be employed.

In the specific instance that *en bloc* resection has been attempted but histological examination confirms a positive (involved) resection margin or margins, the following recommendations apply.

- If the positive margin(s) is mucosal then further resection to confirm complete excision is permitted. In this case, risk group allocation will rely on the histological status of the re-resected mucosal margin(s).
- If the positive margin is deep, then in keeping with the principles of TORS, re-resection is not recommended due to the anatomical limitations of undertaking further resection lateral to the constrictor muscles or deep to the prevertebral fascia. In such cases, patients will automatically be categorized as pathologically high risk.

A retrospective US study of 204 patients with stage III-IV OPC treated with primary TLM and neck dissection reported 3-year rates of local control, overall survival and disease-free survival of 97%, 86% and 82% respectively,

which were higher in HPV+patients.[59] A retrospective series from Liverpool, UK of 153 patients with T1-T3 OPSCC (66% were HPV+) treated with TLM and neck dissection, reported 3-year rates of disease-specific survival, overall survival and disease-free survival of 91.7%, 84.5% and 78.2% respectively, again better in patients with HPV+ disease.[60]

Similarly good outcomes have been reported following TORS: a cohort study of 410 patients from 11 centres treated with TORS, +/- adjuvant RT/CRT, reported 2-year rates of locoregional control, disease-specific survival and overall survival of 91.8% (95% CI, 87.6–94.7%), 94.5% (95% CI, 90.6–96.8%) and 91% (95% CI, 86.5–94.0%) respectively.[98]

No randomized studies have yet compared outcomes following transoral surgery and RT/CRT for OPSCC. Nevertheless, a recent meta-analysis on early stage OPSCC reported comparable 5-year disease-specific survival rates of 90.4% (95% CI, 85.6–95.2%) for RT and 89.6% (95% CI, 81.8–97.3%) for TOS in early stage OPSCC.[27] Furthermore, a systematic review comparing the effectiveness of IMRT and TORS for T1-T2 OPSCC[28] reported similar survival outcomes in 1287 IMRT patients (2-year overall survival 84–96%) and 702 TORS patients (2-year overall survival 82–94%). A different profile of adverse events were reported for IMRT and TORS, which for IMRT included gastrostomy tubes (43%), oesophageal stenosis (4.8%) and osteoradionecrosis (2.6%) and for TORS as described below.

Transoral surgery for early and intermediate stage OPSCC is generally well tolerated, with a median length of hospital stay after surgery of approximately 4.4 days.[59] Acute complications include haemorrhage (2.4%) and fistula (2.5%). Temporary tracheostomy tubes are needed in 12% of patients at the time of surgery but most are decannulated prior to discharge.[99] Temporary nasogastric tubes are required in up to 47% of patients post-operatively but most patients can manage an oral diet without a tube by 4 weeks following surgery.[100, 101] Long-term functional outcomes after TOS appear favourable in small studies: in a study of 30 patients with early (mainly T1-2 N0-N1) OPSCC treated with TORS and neck dissection (without adjuvant treatment), all patients were taking a full oral diet without a feeding tube after a median follow-up of 2.7 years.[62]

However, in most reported series of TOS, the majority of patients also undergo adjuvant therapy, either with post-operative RT (PORT, 21–58% of cases) or post-operative CRT (POCRT, 16–62% of cases.[60, 61, 101–103] It is clear that adjuvant treatment increases acute and late toxicity associated with transoral surgery. In the largest TLM series,[60] adjuvant treatment doubled gastrostomy tube use from 17% to 33% and 19% of patients remained gastrostomy tube dependent 12 months after treatment. In 66 OPSCC patients treated with TORS,[101] 97% were tube free and managing an oral diet 4 weeks after surgery, but 27% (18/66) required a gastrostomy tube during their adjuvant therapy and 3 (4.5%) remained gastrostomy tube dependent more than 2 years after treatment. In 81 patients treated with TORS,[104] all patients were discharged post-operatively on full oral diet, but 13 (16%) required gastrostomy tube placement during adjuvant treatment; of these, five remained in place for over a year. Eating domain health related quality of life (HRQOL) scores were also significantly worse in patients who underwent adjuvant treatment compared to those who did not. Increasing age (>55 years) and extent of TORS resection predicted the need for a gastrostomy tube and high T stage (pT3/pT4) predicted the need for permanent tube feeding. Not surprisingly, functional outcomes following POCRT appear to be worse than after PORT. In 38 OPSCC patients, speech, diet and eating (PSS-H&N) scores at 6 and 12 months following treatment were significantly better following TORS alone compared to TORS followed by PORT which were, in turn, better than after TORS and POCRT.[105] Furthermore, a systematic review of TORS for OPSCC showed clear demarcation in swallowing outcomes across a variety of outcome measures in patients who received PORT compared to POCRT.[106]

It is clear that current adjuvant treatment protocols limit the use of TOS as a potential means of improving long-term function, whilst maintaining good oncological outcomes, in patients with OPSCC. This issue has been raised in particular in the context of HPV+OPSCC. However, adjuvant treatment decisions are based on pathological risk factors for recurrence established >20 years ago in studies which included a heterogeneous group of HNSCCs, most of which were treated with open (not transoral) surgery and none of which were tested for HPV[107, 108] and their relevance to the selection of adjuvant therapy regimens and doses in the context of HPV-positive disease have been questioned. A National Cancer Institute Head and Neck Cancer Steering Committee Clinical Trials Planning Meeting on transoral resection of pharyngeal cancer called for these parameters to be re-evaluated for HPV+ disease in controlled, prospective surgical trials with clinical-pathological correlation of outcomes.[109] US and UK clinical trials, ECOG 3311 and PATHOS (described in more detail later), are currently recruiting in an attempt to address this lack of data.

Management of the neck

The role of the neck dissection in the treatment of oropharyngeal cancer is well standardized and outlined in detail in the UK Head and Neck Cancer Multidisciplinary Management Guidelines 2016.[52]

CLINICALLY NO NECK

The prevalence of micrometastatic nodal disease in OPSCC patients presenting without clinical or radiological evidence of nodal disease is estimated to be between 10% and 30% accordingly, in most cases, elective treatment of the neck is recommended. Surgery, in the form of a selective neck dissection or radiotherapy, is a valid option. Which is chosen is typically predicated on the choice of treatment used for the primary tumour as the aim in early stage disease is for single modality treatment.

NECK DISSECTION

In patients with a lateralized tumour – see 'Radiotherapy planning' above for definition – an ipsilateral neck dissection suffices.

In patients with a non-lateralized tumour – see 'Radiotherapy planning' above for definition – then the contralateral neck should also be dissected if only for pathological staging purposes.

A selective neck dissection including the dissection of, at least, lymph node levels II and III and possibly level IV should be performed. There is also some evidence to recommend the dissection of level I in the case of anterior disease extension.[110] There is no evidence which mandates the dissection of level IIB in the context of clinically N0 disease.

Particularly when TORS is used for primary tumour resection, as described above, it is common for the neck dissection to be carried out as a staged procedure some 2 weeks prior to the primary resection. This is primarily recommended as a strategy to reduce the rate of pharyngocutaneous fistula (PCF) although in practice a staged approach is often dictated by local logistics relating to robot availability. The opportunity is taken, during the neck dissection, to ligate the branches of the external carotid artery which supply the lateral oropharynx (ascending pharyngeal, lingual and facial arteries). This is performed to reduce the local blood pressure with the aim of reducing major haemorrhage following primary tumour resection.

In contrast, when TLM is used for primary tumour resection, it is usual to perform the neck dissection, including the ligation of the external carotid artery branches, during the same anaesthetic. Which is performed first is a matter of personal choice. The risk of PCF is extremely small, especially if lymph node level I is not dissected. It the case where a PCF does occur, repair using local tissues such as the digastric or sternomastoid muscle, followed by a 5-day period of nasogastric feeding, is usually sufficient to allow successful PCF healing.

Although the goal for the treatment of early stage disease is single modality treatment, pathological findings (close or involved surgical margins, pN+ disease +/- ECS) following surgical resection may mandate the need for adjuvant RT +/- chemotherapy. It is for this reason there has been resistance to the use of surgery (to the neck and primary site) for the treatment of OPSCC, particularly in the HPV era. If adjuvant RT is required it should be planned according to the principles used for radical RT (see 'Radiotherapy' below), but a reduced dose of 60 Gy in 30 fractions is usually recommended.

RADIOTHERAPY

Prophylactic radiotherapy should be given to the ipsilateral cervical lymph nodes for lateralized (e.g. tonsillar) tumours and to both sides of the neck for non-lateralized tumours (see 'Radiotherapy planning' above). Radiotherapy to levels II/III/IVa is recommended; level Ib may also be included in cases with anterior extension of tumour and/or involvement of the anterior tonsillar pillar. Neck node levels should be outlined according to the DAHANCA, EORTC, HKNPCSG, NCIC CTG, NCRI, RTOG, TROG consensus guidelines and the associated on-line atlas.[76]

Treatment of the node positive neck

NECK DISSECTION

If the neck is considered operable and surgery is the primary treatment modality then an N+ neck should be treated by selective neck dissection including, at least, levels IIA, III and possibly IV. Additional nodal levels may be dissected as indicated by the volume and level of apparently involved lymph nodes. It is usual to dissect level IIb in the N+ neck and again, level I may be dissected in some instances where anterior extension of the primary tumour is marked. Whether, or which, adjuvant treatment – RT +/– chemotherapy – is required will be dictated by the surgical pathology although avoidance of adjuvant treatment, at least to the primary site, is highly unlikely in the context of T3 or T4 disease.

RADIOTHERAPY/CHEMORADIOTHERAPY (CRT)

The principles of radiotherapy outlining and planning are as described for earlier stage disease. Neck nodes should be included in the treatment fields depending on their probability of involvement and according to the DAHANCA, EORTC, HKNPCSG, NCIC CTG, NCRI, RTOG, TROG consensus guidelines and atlas which were updated in 2013.[77, 111] Radiotherapy to levels Ib–IVa, V(a,b) and the retropharyngeal nodes (level VIIa) at the level of the oropharynx is generally recommended in a N+ neck. The retrostyloid space (level VIIb) is included when level II is involved and the SCF (level IVb and level Vc) is included when level IVa or V are involved. The nodal levels to be included are summarized in **Table 13.1.** Radiotherapy should be given to at least the ipsilateral cervical lymph nodes for lateralized tumours and to both sides of the neck for non-lateralized tumours. The issue of whether the contralateral neck should be treated in patients with lateralized oropharyngeal tumours and advanced (N2+) nodal disease remains controversial and will depend on local practice.[111]

A recently reported phase III RCT that patients with N+ OPSCC can be effectively treated with CRT, without the need in most cases for a neck dissection. The PET NECK trial[112] confirmed that a post-treatment PET-CT surveillance policy, with neck dissection only being performed for patients who have FDG positive or equivocal residual nodal disease on PET-CT scanning at 12 weeks after completion of CRT, results in equivalent survival and regional control rates compared to a planned neck dissection, with a significant reduction in morbidity (by avoidance of surgery in 4 out of 5 patients) and improved cost effectiveness.

TREATMENT FAILURE

The landmark study by Ang et al,[7] which retrospectively considered outcomes of patients with stage III/IV OPSCC, treated with one of two CRT regimes and for whom HPV status had been established confirmed the improved survival outcomes seen for patients presenting

with HPV+OPSCC compared with patients presenting with HPV-OPSCC. The follow-up data also confirmed that significantly more patients in the HPV-OPSCC group had relapsed locoregionally than those in the HPV+OPSCC group (35.1% (95% CI, 26.4–43.8%) vs 13.6% (95% CI, 8.9–18.3%)), although the rate of distant metastasis did not differ significantly between the groups. Patients with HPV-OPSCC and a subset of patients with HPV+OPSCC also have less favourable outcomes in studies where patients were managed with primary surgery.[60, 61]

A retrospective cohort analysis of 185 patients with OPSCC treated with RT and cisplatin +/– tiranzapine by Rischin et al[113] also confirmed that locoregional recurrence was more likely in the HPV- group (14% vs 7%) although the rates of distant relapse were similar in each group.

Similar data were published by Posner et al[114] in a study of 111 patients with local advanced OPSCC. They, too, confirmed an increased rate of locoregional relapse in patients with HPV- tumours at 5 years compared with HPV+patients with similar rates in distant relapse in each group.

Huang et al,[115] in a study which included 624 OPSCC patients similarly concluded that locoregional relapse was statistically more likely in patients with p16- disease compared to those with p16+ disease (21% vs 6%), whilst distant relapse rates were similar.

Collectively these data confirm that locoregional relapse, in contrast to distant relapse, is statistically more likely in patients with HPV+OPSCC, but that the rate of relapse (locoregional and distant) in the HPV+ group is not insignificant and represents a subgroup of patients with HPV+ disease who do badly.

Although the rates of distant relapse appear similar between HPV+ and HPV- patient groups, other data[116, 117] reporting on the pattern of post-treatment distant metastatic spread at relapse in patients with OPSCC confirm obvious differences between HPV+ and HPV- groups.

Whilst the most common pattern of distant spread to the lung, bone and liver is similar between the groups, a subgroup (~30%) of patients with HPV disease develop metastases at unexpected anatomical sites including brain, skin and intra-abdominal lymph nodes. Moreover, it appears that these atypical patterns of spread are harbingers of aggressive tumour behaviour with patients experiencing rapid deterioration following diagnosis.

Despite this subgroup of patients with atypical spread which do extremely badly, overall patients with HPV+OPSCC still fare better after relapse than patients with HPV- disease although the magnitude of beneficial impact in the relapse setting is much smaller than the effect of HPV positivity in the primary disease setting.[115, 116, 118, 119]

Currently, predictive biomarkers of outcome are not available and so identification of the subgroup of HPV+patients destined for poor outcome is currently not possible. Furthermore, as things stand, it is unclear how best to treat patients at relapse and additional high-quality clinical trials designed to address this need are urgently needed.

THE FUTURE

Optimizing treatment for OPSCC: ongoing clinical trials

As explained previously, the emergence of HPV+OPSCC as a discrete disease entity has resulted in the need to identify novel de-intensified treatments for HPV+OPSCC which will maintain the current advantageous survival outcomes whilst reducing the acute and long-term adverse effects of current treatments. In contrast, the quest to identify tolerable intensified treatments for patients with HPV-OPSCC in an attempt to improve current modest survival outcomes, is ongoing. Moreover, there still remains an absence of level I evidence comparing surgical vs non-surgical treatment strategies.

Ongoing clinical trials are attempting to address these voids in our current clinical knowledge.

An EORTC phase III randomized study (EORTC 1420, 'Best-Of' NCT02984410) comparing late function (MDADI at 12 months following treatment) after TOS and IMRT in patients with (HPV+ and HPV-) T1-T2 N0 M0 OPSCC is currently recruiting in several European countries, including the UK and could inform future practice for early stage disease by providing much needed level I evidence following a head-to-head comparison of surgical vs non-surgical treatment.

Similarly, the currently recruiting Canadian ORATOR phase II clinical trial (NCT01590355) will attempt to address the same problem.

Patients with T3-4 OPSCCs, which are not transorally resectable, should undergo primary CRT as the standard of care. Dysphagia optimized IMRT, aiming to minimize radiation dose delivery to swallowing-related structures, and/or the use of cetuximab instead of cisplatin with RT, are being studied in ongoing UK clinical trials (DARS, ISRCTN: 25458988 and De-ESCALaTE-HPV, NCT01874171 respectively), as means of reducing toxicities in these patients.

In addition, The Quarterback Trial (NCT01706939): A Randomized Phase III Clinical Trial Comparing Reduced and Standard Radiation Therapy Doses for Locally Advanced HPV Positive Oropharynx Cancer, has completed recruitment and is in follow-up.

As an alternative approach, the UK phase II/III PATHOS study (ClinicalTrials.gov NCT02215265) (40), and the US study ECOG 3311 [NCT01898494]) are currently exploring transoral surgery (TLM or TORS) +/– de-intensified adjuvant as a potential means of improving long-term function, whilst maintaining good oncological outcomes, in patients with HPV+OPSCC.

PATHOS[120] (see **Figure 13.13** for trial schema) is currently recruiting patients with HPV+OPSCC who will undergo transoral surgery and a neck dissection. Post-surgical pathology will allow stratification into three distinct risk

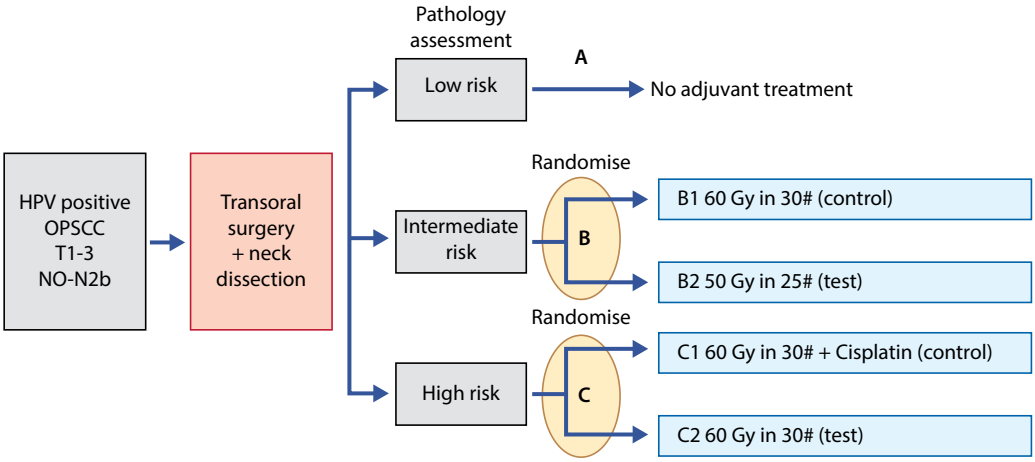

Figure 13.13 PATHOS (Post-operative adjuvant treatment for HPV+OPSCC study schema. Patients with T1-2 N0-N2b HPV+OPSCC undergo transoral surgery and a neck dissection before being stratified into groups (A, B and C) based on pathological risk factors. Group A (no risk factors) have no adjuvant treatment. Group B (N2, close margins, perineural /vascular invasion) are randomized to 60 Gy (control arm) or 50 Gy (test arm) of IMRT. Group C (ECS and/or high risk margins) are randomized to POCRT (control arm) or 60 Gy PORT only (test arm). Primary endpoint, Overall survival; Secondary endpoint, swallowing function, as measured by a multi-instrument swallowing panel, at 1 year post-treatment.

groups. Whilst a low-risk Group A will receive no adjuvant treatment an intermediate risk Group B will be randomized between standard and reduced dose adjuvant IMRT and a high-risk Group C will be randomized between adjuvant CRT and standard dose IMRT alone. A European phase III extension to the ongoing UK phase II is planned to investigate whether de-intensified adjuvant treatment schedules for patients with intermediate stage HPV+OPSCC, undergoing transoral surgery, results in non-inferior survival outcomes and improved swallowing function.

In contrast, poor prognosis OPSCC, including HPV+ current smokers[22] with advanced disease and patients with HPV-disease, may benefit from treatment intensification and an ongoing multi-arm, multi-stage (MAMS) UK study (COMPARE, UKCRN Study No: 18621) is exploring this possibility.

Translational research

What is clear is that many questions relating to the epidemiology and natural history of oral HPV infection and its relationship to the development of HPV+OPSCC remain. Some of the more pressing questions which are currently the basis of ongoing research include:

- Why do a small percentage of infected individuals fail to clear the initial HPV infection and why do a proportion of these then go on to develop HPV+OPSCC?
- Is the mechanism of infection and virally mediated transformation the same for OPSCC as for cervical cancer and why is HPV-16 the predominant genotype involved in OPSCC whilst HPV-18, together with HPV-16, has a more significant role in the development of cervical cancer?
- Why is OPSCC more responsive to treatment than cervical cancer despite presenting with clinicopathological features traditionally associated with poor outcome?
- Does an as yet undetected HPV+OPSCC premalignant lesion exist?
- Why is there a significant male:female gender bias?
- Why has this new discrete disease entity only emerged in the last 3–4 decades?

Moreover, there is an urgent need to identify robust predictive risk-stratifying biomarkers which will identify the subgroup of patients with HPV+ disease. The identification of such biomarkers is planned as a translational programme of research allied to several of the clinical trials highlighted above e.g. RTOG 1420, PATHOS, De-Escalate and COMPARE.

Following on from this, there is also an urgent need to identify novel treatments which will reduce rates of treatment failure and/or enhance life-expectancy in patients who relapse.

Of particular note in this context is the publication of the CheckMate 141 clinical trial.[121] This randomized, open-label, phase III clinical trial, randomized 361 patients with recurrent SCCHN, whose disease had progressed within 6 months of receiving platinum based CRT in a 2:1 ratio to receive nivolumab or standard single-agent systemic therapy. The primary end-point was overall survival. Overall survival was significantly longer in the group that received nivolumab compared with the group treated with standard systemic therapy (7.5 months vs 5.1 months: HR for death = 0.70; 97.7% CI 0.51–0.96%). A post-hoc exploratory analysis of 178 patients with OPSCC for whom p16 status was known confirmed that among the patients with p16+ tumours OS was 9.1 months in the nivolumab group vs. 4.4 months in the standard therapy group (HR for death = 0.56; 95% CI 0.32–0.99%), suggesting that PD-1 blockade may have a discriminatory advantage in patients with HPV+OPSCC in the recurrent / metastatic setting.

Prophylactic vaccination

Vaccination of girls against HPV has been implemented in many countries throughout the developed world with the aim of protecting women against cervical cancer. Gender-neutral vaccination for boys, with the aim of preventing HPV related cancers to which males are exposed, anal, oropharynx and penile, is more contentious. Currently, only the United States, Austria, Canada and Australia recommend vaccination for boys but only Australia has implemented a comprehensive nationwide vaccination programme for boys aged 12–13 years.

The main reason against widespread introduction of gender neutral vaccination is cost-effectiveness. Assessing cost-effectiveness is a relatively complex process as underpinning the successful protection of males is the effectiveness of herd-immunity which is predicated on vaccine take-up in girls. Modelling data confirm that if vaccine coverage in women exceeds 80% then herd-immunity will be sufficient to ensure the protection of males. This argument, however, is based on two main assumptions.

- A high level of vaccine coverage is uniform and sustainable in the long term across the whole female population being vaccinated.
- Males only have sex with vaccinated females.

If each of these assumptions are correct, then population-based vaccination of boys is arguably not cost-effective. Campaigners for the introduction of gender-neutral vaccines propose the following counter arguments:

- That uniform and sustainable vaccination of girls in any given country cannot be guaranteed and that there are areas and populations in all countries – London and certain ethnic and religious groups in the UK for example – where vaccination rates will be far less than 80% so that herd immunity is not guaranteed.
- In an increasingly globalized world men will not only have sex with women from countries where comprehensive vaccination programmes are in place and neither does this assumption take into account the men who have sex with men (MSM) – a group at particularly high risk of developing HPV-related cancers.
- Cancer inequalities will be augmented as males from more affluent backgrounds will be vaccinated privately.
- That choosing to vaccinate only one gender when it is known that the non-vaccinated gender is at risk of harm, albeit not to the same extent, is discriminatory.

Debates such as these are playing out in most developed countries in the world and certainly the proponents for gender neutral vaccination now have the support of high-profile scientific and medical opinion leaders.

Whatever the outcome, it is clear that any positive effect of prophylactic vaccination on the incidence of HPV+OPSCC is likely to be delayed for several decades and in the intervening time it is incumbent upon all involved to continue to strive to improve the outcomes for the patients unfortunate enough to develop this devastating condition.

KEY POINTS

- Globally, the incidence of oropharynx cancer is increasing rapidly in a geographically variable pattern.
- Most of this increase is attributable to a rise in Human papillomavirus related disease (HPV+) although non-HPV related disease (HPV-) appears also to be increasing in some countries.
- HPV+ oropharynx cancer (HPV+OPSCC), constitutes a discrete disease entity, presenting in patents who are younger, fitter and more affluent than patients presenting with HPV- disease.
- Despite presenting with clinicopathological features (N+ with ECS) usually associated with poor disease outcome, HPV+ tumours respond better to treatment.
- In light of this, attention has turned to the potential for de-intensified treatment strategies for HPV+OPSCC, in order to maintain advantageous survival outcomes whilst reducing treatment-related early and long-term toxicity.
- Despite a widespread perception that HPV+OPSCC is a defined sexually transmitted disease, this has yet to be confirmed.

SEARCH STRATEGY

The data in this chapter are based on searches of Medline, EMBASE and the Cochrane Library using the keywords: laryngeal cancer, squamous cell cancer, laryngeal dysplasia, diagnosis, treatment. The articles referenced by these authors were also reviewed. The data are supplemented by further searches of specialized books.

INTRODUCTION

Laryngeal carcinoma is the most common site of malignancy in the head and neck worldwide. The effects of the disease process and the treatment can have significant impact on voice and swallow function and quality of life. Recent advances in the surgical and non-surgical management options, with a burgeoning evidence base, have led to a sea change in the management of laryngeal cancer in the last decade. This chapter will deal with the principles of assessment, diagnosis and management of laryngeal precancer and cancer. The finer aspects of endoscopic, open and robotic surgery for laryngeal cancer merit detailed treatment and are dealt with elsewhere in the book.

EPIDEMIOLOGY

Worldwide, laryngeal tumours account for 156 000 new cases per year and 83 000 deaths. The incidence is higher in men worldwide, with an estimated 138 000 men being diagnosed each year compared to 18 000 women. There are significant variations in incidence across the world.[1] Laryngeal tumours are most common after the age of 60 and less common under 40.[2]

In the UK, the age standardized incidence of laryngeal cancer is estimated to be 3/100 000. Within the UK there are wide variations in incidence with the highest incidence in the north of the country. Overall, the incidence of laryngeal cancer has decreased by 20% since 1990 and appears to have plateaued between 2002 and 2006. This has largely been attributed to a reduced incidence of smoking. Yet other factors such as changes in the industrial landscape and decline in heavy industry could also have contributed. Concurrent with a drop in incidence, the survival following a diagnosis of laryngeal cancer has continued to improve in the UK; between 2002 and 2006 the figures improved from 82.75% to 85.33%. However, the 5-year relative survival rates have remained unchanged over the same period at 65% for the most recently diagnosed cases.[3]

Data from the United States also suggest that there are significant variations in incidence between racial groups, with the majority of tumours occurring in Caucasian patients.[4] A detailed treatment of epidemiology can be found in Chapter 3, Epidemiology of head and neck squamous cell carcinoma.

AETIOLOGY

Smoking remains the most common aetiological factor for cancers of the larynx, with alcohol an independent risk factor for developing laryngeal cancer in the absence

of smoking. The combination of smoking and alcohol appears to be a multiplicative risk.[5] The risk of developing laryngeal cancer is highest in current smokers and increases with the number of cigarettes smoked. There is a reduction in relative risk of developing laryngeal cancer after stopping smoking and drinking with the risk reduction reaching the level of never smokers after approximately 20 years.[5, 6]

While sexual behaviours and HPV infection have been strongly linked with tumours of the oropharynx, there is little epidemiological evidence linking these with tumours of the larynx.[7, 8] Unlike oropharyngeal cancer, existing retrospective studies do not identify a favourable prognostic impact for HPV positive laryngeal tumours.[9, 10]

Other known risk factors include occupational toxic agents such as asbestos, polycyclic aromatic hydrocarbons, wood dust, coal dust and cement dust.[11, 12] Lower socioeconomic status and manual 'blue-collar' occupations also experience a higher risk of developing laryngeal cancer.[11]

Certain genetic syndromes, such as Fanconi anaemia[13] and congenital dyskeratosis[14] are also associated with a higher risk of developing laryngeal tumours in addition to tumours in other parts of the body. A detailed treatment of aetiology of laryngeal cancer can be found in Chapter 2, Aetiology of head and neck cancer.

PATHOLOGY

The most common type of laryngeal cancer is squamous cell carcinoma; however, many other histological types of cancers can be seen in the larynx. A detailed discussion of the various pathological entities in the larynx can be found in Chapter 26, Head and neck pathology.

Optimal pathological assessment of specimens requires a co-ordinated approach between the pathologist and surgeon or oncologist. The Royal College of Pathologists in the UK have published guidelines for the dataset required to report cases. Important factors including the type, size and grade of the primary carcinoma, the pattern of invasion and proximity of carcinoma to resection margins. All have been shown to be important prognostic features.[15] It is crucial that small specimens resected via transoral approaches are oriented prior to pathological analysis to allow accurate reporting of the margins. Several options exist for mounting specimens, which is discussed in detail in 'Transoral laser microsurgery' below. To maintain clear lines of communication, the authors' preference is to send pictures of the resected, mounted specimen, which is then marked, to the pathology team. In cases where a total or partial laryngectomy has been performed, whole organ section analysis is usually performed to consider patterns of spread and resection margins. HPV testing is not considered routine but may be important in a subset of patients.

PATHWAYS OF CANCER SPREAD

Laryngeal squamous cell carcinoma has characteristic patterns of spread depending on the site of origin. Local spread is along tissue planes, while lymphatic spread is guided initially by the boundaries between embryological anlagen (arches III–VI), notably at the free edge of the glottis. Yet, despite long-held beliefs, there is no true anatomical barrier to check spread between the supra- and subglottis, as was shown as long ago as 1969 by Kirchner's laborious whole organ dissections.[16]

Historically, glottic cancer spreading to the anterior commissure (AC) was feared, because early invasion through Broyle's ligament directly into cartilage was thought inevitable. This was perceived to be due to the lack of an inner perichondrium in that area. However, recent work has shown that the ligament is in fact an effective barrier, but it is extension superiorly and inferiorly (via subglottic wedge and hence cricothyroid membrane) that worsens prognosis. Direct spread may continue via the AC to the opposite cord, or may extend posteriorly to invade the arytenoid cartilage. Glottic tumours may be confined to Reinke's space by the embryological boundary superiorly and the conus elasticus inferiorly. To reach the paraglottic space and thence gain an easy passage cranially and caudally, tumours need to transgress both the vocal ligament and vocalis muscle. The laryngeal skeleton is relatively resistant to invasion, though ossified areas appear less so. Nonetheless, external extension directly through the cartilages is regularly seen.

Lymphatic spread of glottic cancer is less common than at other subsites. It has been suggested that the lack of submucosal lymphatics in this area is responsible. However, detailed studies of mucosal cell trafficking have not yet been performed to confirm this. Spread, when it occurs, is to levels II, III, IV and VI. Estimates for the incidence of macroscopic lymph node metastasis by disease stage are: <5% (T1), 7% (T2), 14% (T3) and 33% (T4). The so-called 'Delphian' node (also known as the midline anterior metastatic node or Poirier's pre-laryngeal ganglia node) is very rare, but is thought to be associated with T3 or T4 tumours with significant subglottic extension.

Supraglottic cancers tend to remain locally confined (even with pre-epiglottic or nodal spread) to their subsite until relatively late. As a result, supraglottic laryngectomy is often a viable option even for bulky tumours. However, as noted above, there is no real anatomical barrier to inferior spread. Indeed, the routine use of angled Hopkins rods during staging procedures to examine the cavity of the laryngeal ventricle reveals a steady transmucosal progression of tumours similar to other subsites and permits the precise selection of patients suitable for supraglottic partial laryngectomy. Overall, several studies have shown that approximately 50% of supraglottic cancers spread to the glottic region. The presence of foramina within the epiglottic cartilage makes this less of a barrier to spread than that presented by the other cartilages. However, invasion of the hyoid is rare (2–4%), meaning that it can often be retained during operative clearance. 'Suprahyoid supraglottic' carcinomas tend to invade the pre-epiglottic space and the deep muscles of the tongue and spread mucosally into the piriform fossae rather than into the paraglottic space. Supraglottic tumours also have a propensity for bilateral nodal metastasis. In reports of

advanced disease, supraglottic carcinoma has a positive nodal rate of over 60%, compared with much lower rates of 20% in advanced glottic cases. This has a major influence on the decision to perform elective neck dissections for these patients (see Chapter 36, Clinical examination of the neck).

Subglottic carcinoma tends to extend caudally and circumferentially. Fifty percent invade the cricoid and 75% have already extended outside the larynx by the time of diagnosis. Despite this, clinically detectable nodal metastasis is surprisingly uncommon, although a microscopic incidence of one in three puts this disease into the category of requiring elective nodal dissection. Due to the propensity for inferior extension, nodal dissection for subglottic cancer should include the paratracheal/mediastinal nodes.

Transglottic cancer is defined by spread, both superficially and into the paraglottic space to span all three laryngeal subsites. True primary transglottic cancer is said to originate in the laryngeal ventricle, though in practice it is impossible to be precise about the original epicentre. It is, by definition, at least T3 at presentation and subsequent consideration will therefore be alongside advanced cancers.

Tracheal squamous cell carcinoma is exceedingly rare, with approximately eight cases per annum in the UK and one in Holland, despite being theoretically exposed to the same carcinogens as the larynx. Interestingly, the trachea has the highest density of immunologically active cells suggesting that mucosal immunosurveillance may be a crucial factor in defence against airway mutagenesis. A rule of thumb for spread in each site is given in **Table 14.1**.

Thyroid gland invasion has been studied in resected specimens and the incidence of this has been studied in a systematic review by Kumar et al.[17] Pooling data from 1287 patients, this study showed that the overall incidence of thyroid gland invasion is 10.7% (95% CI 7.6–14.2). Patients with primary subglottic tumours (relative risk 7.5; 95% CI 4.3–13.0) and disease extension into the subglottis (relative risk 4.3; 95% CI 2.5–7.2) have a significantly higher relative risk of thyroid gland invasion. Other sites did not confer this higher risk. As the overall incidence of thyroid gland invasion is low, thyroidectomy can be reserved for cases considered to be at risk as opposed to a being a routine measure for all total laryngectomies.

TABLE 14.1 Spread of laryngeal carcinoma

Primary site		Look for involvement of
Supraglottis	Epiglottis	Pre-epiglottic space
	Epiglottic petiole	Anterior commissure
	Intralaryngeal mucosa, false cords	Paraglottic space
	All	Vocal fold
		Laryngeal cartilage
Glottis	Anterior cord	Anterior commissure/ contralateral cord
	Posterior cord	Thyroid cartilage and cricothyroid membrane
	All	Arytenoid cartilage/ cricoarytenoid joint/ posterior commissure
		Paraglottic space
		Supraglottic/subglottic spread
Subglottis		Trachea
		Thyroid gland
		Cervical oesophagus

CLINICAL PRESENTATION

As with other cancers, laryngeal cancer may present with local symptoms or those due to metastatic spread to nodes or beyond. Occasionally, patients present with general systemic signs, such as weight loss or anaemia, but in laryngeal cancer these are rare in the absence of local symptoms. Paraneoplastic phenomena such as peripheral neuropathy and rashes are very rare. As a result, it is possible to provide primary care workers (and indeed the general population) with a fairly accurate idea of 'warning/red flag' symptoms that require urgent referral to an otolaryngologist.

Glottic cancer

It is fortunate that even the earliest glottic cancer alters the voice by affecting wave pattern forms over the vocal cord. Since normal voice production depends on the integrity of a six-cell thick epithelium and a delicate, jelly-like superficial lamina propria, even carcinoma *in situ* may produce significant voice change. Thus, any person with hoarseness persisting for 3 weeks or more (some would say even less time than this) should be referred urgently to an otolaryngologist for examination. The National Health Service in the UK has implemented a fast-track protocol to aid this. With increasing lesion size, maximum phonation time decreases and with the onset of cord fixation, breathiness may be superimposed, with variable degrees of aspiration. Advanced lesions may lead to airway obstruction causing progressive dyspnoea and stridor. Haemoptysis is usually associated with larger tumours. Referred otalgia (via the vagal complex) is a sinister sign suggesting deep invasion. Dysphagia and odynophagia are rare in uncomplicated glottic cancer. Neck nodes are rarely the presenting complaint; if present, they signify deep invasion and extension into the supraglottis.

Supraglottic cancer

Voice alteration is different in quality from that seen with glottic and subglottic cancer. Small supraglottic lesions not extending to the glottis may present with globus or foreign body sensation and parasthesia. If exophytic, they may cause haemoptysis. As tumour bulk increases, phonation is altered, with a 'hot potato' voice. If tumours extend to the cords, then hoarseness ensues as for glottic disease.

Further extension laterally may cause referred otalgia, odynophagia and true dysphagia. However, lesions may be asymptomatic until quite large and, as a result, first presentation with a neck lump due to cervical nodal metastasis is common.

Subglottic cancer

Again, early symptoms can be vague, with a feeling of 'globus' or foreign body sensation in the throat. Any involvement of the glottis or recurrent laryngeal nerves results in hoarseness. With paralysis, diplophonia may occur with a shortened maximum phonation time. Therefore, this diagnosis should always be considered in the possible differential causes of 'idiopathic' cord paralysis, especially in high-risk cases. Circumferential progression leads to progressive dyspnoea and stridor, with markedly shortened maximum phonation times and rapid vocal fatigue. Direct extension into the thyroid may mimic a thyroid isthmus lesion.

ASSESSMENT AND STAGING

Outpatient setting

In the outpatient setting, the larynx is best assessed using the flexible nasal laryngoscope. The procedure should be explained to patients beforehand, and in the authors' experience, the vast majority of adults tolerate the procedure very well. In most patients, a decongestant spray with a lubricated endoscope will suffice. If due care and attention is used while inserting the endoscope and the examiner ensures minimal contact with the nasal walls and stays in the lumen of the nose, the patient experiences minimal discomfort. Others may need topical anaesthetic spray to reduce the discomfort associated with the procedure. Significant information can be gained via endoscopy that will aid the decision-making process. The value of this examination should not be underestimated as this information is often complementary to what is gained during rigid endoscopy. The latter will not provide information such as cord mobility and a panoramic view of the larynx, and undue reliance should not be placed on the subsequent general anaesthetic procedure to examine the larynx.

Some centres prefer to perform outpatient endoscopy of the larynx using rigid telescopes for the superior view it provides. This requires special topical anaesthetic preparation and is less well tolerated. However, with the increasing availability of modern high-resolution flexible endoscopes that allow simultaneous recording, there is less need to use rigid telescopes for assessment. The outpatient endoscopic assessment can also direct the examiner towards additional investigations if necessary. For example, the finding of salivary pooling in the pyriform sinus in the setting of a small glottic tumour should trigger concern and prompt examination of the hypopharynx and upper oesophagus.

Laryngeal dysplasia (LD) is commonly seen in the glottis, but can be seen virtually anywhere in the larynx. The clinical appearance is that of an inflamed, erythematous larynx, with leukoplakia or erythroleukoplakia. However, clinically abnormal areas in the larynx do not always exhibit histopathological evidence of LD and LD can be detected under the microscope in clinically normal appearing epithelium. Cancers present as proliferative, infiltrative lesions or a mix of both. These are easily recognized as abnormalities on endoscopic examination. Uncommonly, malignancies, usually non-squamous cancers, can present as submucosal masses. The abnormality caused by these lesions can be subtle and may be missed on casual inspection.

Imaging

Imaging for laryngeal mass lesions should include as a minimum cross-sectional imaging for all tumour stages. Options include computed tomographic (CT) or magnetic resonance imaging (MRI), with the chest being imaged too. This is dealt with in greater detail in Chapter 37, Imaging of the neck. MRI scans have higher sensitivity than CT scans in assessing cartilage invasion. Both imaging modalities have their own advantages and drawbacks and this is also discussed in detail in Chapter 37, Imaging of the neck.

Assessment under general anaesthesia

Rigid endoscopic assessment should not only assess the extent of the tumour and take a biopsy, but also be done by a surgeon who can make the decision as to whether the tumour can be resected transorally. Anatomical constraints may make even small tumours not easily resectable. In addition, the judgement about whether special anaesthetic measures may be needed during the surgery (e.g. jet ventilation) will also need to be made and it is often helpful to do this with an anaesthetist who will be able to provide the service.

Submucosal and subglottic mass lesions can be difficult to biopsy. In these instances, an incision on the mass using microlaryngeal instruments, or preferably with a laser, will open into the abnormal tissue enabling a representative biopsy.

All excised samples should be appropriately labelled and if necessary, mounted on suitable media and orientated for the pathologist.

Staging

The staging of laryngeal cancer is discussed in detail in Chapter 4, Staging of head and neck cancer.

LARYNGEAL PREMALIGNANCY

LD has a reported incidence of between 2 and 10 lesions per 100 000 population.[18] The clinical significance LD, also known as laryngeal intraepithelial neoplasia, lies in its propensity for malignant transformation.

The 4th edition of the *World Health Organisation Classification of Head and Neck Tumours*, published in 2017, has adopted a two-tier system, based on

the morphological criteria of the amended Ljubljana Classification, where the lesions are called Squamous Intraepithelial Lesions (SIL): low-grade SILs and high-grade SILs.[19] Reported malignant transformation rates vary between 11% and 25%, but identifying which patients will transform is impossible. Given the above issues with clinical and pathological diagnosis, there is no universal consensus in the investigation and treatment of this condition. Therefore, management practices vary significantly.

The British Association of Otolaryngologists Head and Neck Surgeons have generated consensus on the management of this condition through a national survey and a joint meeting between surgeons and pathologists. The following sections will summarize these consensus guidelines, while recognizing that high-level evidence does not exist and that practices will differ based on local service arrangements and geography.

In larger centres, it is preferable if there is a nominated or a defined number of surgeons providing LD management service. It is also desirable that surgeons managing this condition have received appropriate training in laryngology. Severe dysplasia is preferably managed by personnel with expertise in head and neck cancer management.

All efforts should be made to reduce risk factors. Patients should be counselled regarding tobacco use, especially smoking in this setting. Patients who have symptoms of laryngopharyngeal reflux should also be counselled about anti-reflux measures; this may or may not include proton pump inhibitors.

LESIONS THAT HAVE NOT BEEN PREVIOUSLY TREATED

In patients who have been diagnosed to have LD following an initial biopsy, but have had no previous treatment, these are suggested management principles.

1. The overall appearance of the lesion (single, multiple or confluent) should be the most important factor in deciding management.
   - All visible single and multiple foci should be completely excised.
   - Widespread, confluent leukoplakia should be mapped using multiple biopsies. Following mapping, a staged resection should be offered if feasible. There should be a low threshold for re-biopsy in the presence of widespread disease.
   - All biopsies, including from multiple foci, should be mounted on suitable media for orientation before sending for pathological examination.
   - The general fitness of the patient will play a role in decision making.
2. Documentation in theatre
   - Intra-operative photographs should be performed before surgery and of the post-operative larynx.
   - Assessment during general anaesthesia should include palpation of the vocal cord.
   - Where possible, the intra-operative photographs should be shared with pathologists.
   - The details of type of biopsy (incisional or excisional; if mapping biopsies, identify them in the pictures) should be stated.
   - The technique and extent of resection should be documented.
   - The procedure should be categorized according to the European Laryngological Society classification.
3. Excision technique
   There is no gold standard in the tool used to resect the LD lesion. However, cold steel or laser resection is recommended over monopolar cautery
   - If laser excision is contemplated, carbon dioxide laser is recommended owing to the laser properties enabling minimal penetration, thus reducing collateral damage.
   - Laser ablation (i.e. laser used on the surface of the lesion to destroy the epithelium rather than excising it) is discouraged as no specimen will be available for diagnosis and there is a higher risk of damage to the voice.
   - Vocal cord stripping is not recommended at all owing to the high risk of damage to the vocal cord.
   - Radiotherapy should be offered only in rare circumstances for patients where there is very high risk/suspicion of conversion to malignancy and surgical resection is not possible owing to patient or tumour factors.
4. The histology should be studied in the context of the clinical findings post-operatively. If there is a report of severe dysplasia and the follow-up endoscopy shows a proliferative lesion, the patient should be re-biopsied at the earliest opportunity. The presence of dysplasia at the margins should not be of great concern, especially in mild dysplasia. This is not an indication for a repeat excision.

Figure 14.1 shows an algorithmic approach that summarizes the above points.

Management of persistent or recurrent lesions

The management of these lesions should follow the general principles and the treatment of the initial presentation as discussed above. Additional considerations are:

- Localized mild or moderate local dysplasia should be offered re-excision.
- Widespread mild or moderate widespread dysplasia may be observed or excised.
- The decision to excise should be based on a change in appearance (heterogenous texture; erythroplakia; proliferative features) or change in symptoms.
- The effect of further resections on the patients' voice should also be taken into consideration.
- Recurrent focal severe dysplasia should be managed as a T1 laryngeal carcinoma with surgical resection (e.g. cordectomy) where possible. Radiotherapy may

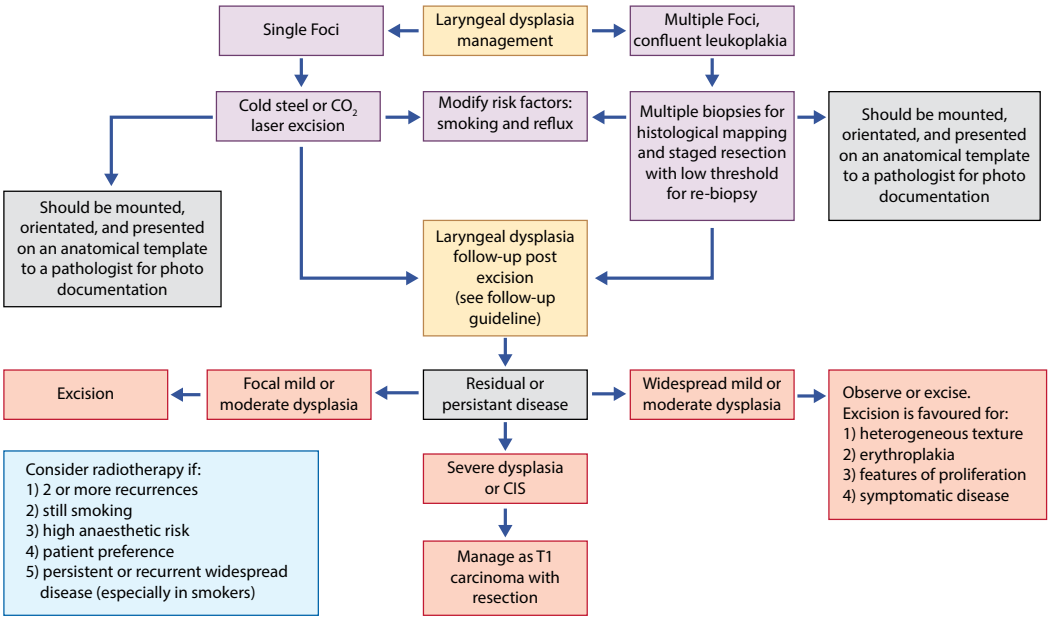

Figure 14.1 Algorithmic approach for the management of laryngeal dysplasia based on a multiprofessional consensus. (Redrawn from Cosway B, Paleri V. Laryngeal dysplasia: an evidence-based flowchart to guide management and follow up. *J Laryngol Otol*. 2015; **129**(6): 598–9.)

be considered in special circumstances only, on a case-by-case basis. Examples include patients who have had two or more recurrences, who continue to smoke, have high risk of anaesthetic complications or have poor access to the larynx.

- For persistent or recurrent widespread severe dysplasia, radiotherapy should be considered as an option.

Follow-up strategies

The recommended frequency and duration of follow-up is set out in **Figure 14.2**.

1. The ENT-UK guidelines recommend that all patients should be followed up as per the following standards:
   - Use of a flexible nasendoscope to view the larynx.
   - Colour photo documentation in the patient notes is essential.
   - Document continuing risk factors if present.
   - Stroboscopy is helpful if available, but is not necessary.
   - Follow-up of low-risk lesions can be performed by General ENT surgeons in peripheral clinics. High-risk lesions are preferably followed up by an ENT surgeon with a special interest in Head and Neck surgery or laryngology.
2. Outcomes should be assessed at baseline, 6 months and 12 months
   - Outcomes include recurrence and progression to cancer.
   - Voice outcomes should also be assessed using a patient-reported voice questionnaire.

LARYNGEAL MALIGNANCIES

Decision-making

As there is evidence base to support surgical and non-surgical treatment, all decisions for management are best made in a multidisciplinary setting. The benefits of multidisciplinary working are set out in Chapter 32, Multidisciplinary team working. A multidisciplinary discussion allows the entire treating team to assess the clinical findings, radiology and pathology, along with information provided by allied healthcare personnel about the patients' function, current quality of life, preferences, comorbidity and psychosocial context. In combination, all the above are invaluable in making the appropriate treatment choice.

Management of early stage laryngeal cancers

TREATMENT PHILOSOPHY

Function and survival

Although randomized data do not exist, most practising surgeons and oncologists believe that voice outcomes are comparable for T1 glottic cancers treated by either modality, and for mid-cord lesions, this should rarely be the basis for treatment selection. Even in patients who undergo resections that are type III cordectomy or more advanced, vocal function routinely returns to pre-operative levels following the initial healing period.[20] In a meta-analysis of 362 patients with a mean follow-up time of 47 months, where voice outcomes measured using the Vocal Handicap Inventory, no significant difference in post-treatment VHI scores were detected between radiotherapy and surgery.[21] Systematic reviews have identified no advantages in voice outcomes for patients with T1 glottic cancer treated by radiotherapy (RT) compared to transoral laser microsurgery (TLM).[21–23]

In the UK, the EaStER (Early Stage glottic cancer: Endoscopic excision or Radiotherapy) feasibility trial was set up to compare TLM with RT in laryngeal cancer staged T1, but failed to recruit the required number of patients. A detailed qualitative analysis[24] identified several reasons for failure. These included lack of consensus among investigators regarding the primary outcome, non-adherence to eligibility criteria and lack of equipoise in presenting trial information. However, the ultimate reason resulting in the failure to recruit was that patients declined to be randomized because of the largely practical benefits of TLM over RT. In particular, patients favoured TLM over RT as TLM was completed as a day-case procedure whilst RT involved several weeks of daily treatment. Moreover, recovery following TLM in T1 glottic cancers is rapid with no impact on swallowing, rapid return to normal activities and minimal impact on the voice. Given the above reasons, mid-cord lesions are largely excised by TLM and larger lesions, especially when the impact on voice is considered to be greater, are treated by RT.

It is commonly believed that in early cancers, surgery or RT as a single treatment modality, offer equivalent survival outcomes. As there is less anatomical disruption to the larynx following RT, the voice quality following treatment is superior, especially when the tumour involves the AC or extends across two sites. Thus, the choice of treatment is based on patient choices and the likelihood of advantageous voice outcomes following treatment. Warner et al.[25] updated their systematic review comparing RT, open surgery and endolaryngeal excision (with or without laser) for early (T1, T2a) glottic laryngeal cancer. Although one trial that satisfied inclusion criteria was identified, it was associated with a high risk of bias. The review concluded that all are presently accepted modalities of treatment and the published large case series of each treatment suggest that they confer similar survival advantages. In an assessment of voice quality after treatment of early vocal cord cancer, a randomized trial comparing laser surgery with radiation therapy concluded that overall voice quality between the groups was rated similar, but voice was more 'breathy' and the glottal gap was wider in patients treated with laser surgery than in those who received radiation therapy. Patients treated with radiation therapy reported less hoarseness-related inconvenience in daily living 2 years after treatment.[26, 27] The equivalence of the two modalities has been questioned by some new data. In a population-based analysis of 10 429 patients with localized laryngeal cancer (90% T1 and T2; 10% T3) from the SEER database between 1995 and 2009, Misono et al.[28] observed that while single modality treatment increased over the years (radiation or local surgery), combined modality treatment decreased, with these changes being statistically significant. Survival was analyzed by treatment modalities. Compared with radiation only, which was the reference category, patients who underwent 'local surgery only' or 'local surgery and radiation' had lower hazards of death ($P<.0006$ and $P<.0001$, respectively), with the survival differences persisting beyond 5 years of treatment. Whereas the 5-year disease specific survival rates for the 'local surgery' and 'local surgery and radiation' groups were 91% and 90% respectively, the 5-year survival rate for the 'radiation only' group was 83%.

Similar results have been produced in a database analysis for supraglottic cancers alone. Arshad et al.[29] analyzed outcomes in 2631 patients with early stage supraglottic cancer from the Surveillance, Epidemiology and End Results (SEER) database in the United States. In patients with T2N0 cancer, partial laryngeal surgery and neck dissection led to significantly better 5-year disease specific survival (86% vs 60%; HR = 0.31, $p<0.001$) and overall survival (77% vs 45%; HR = 0.36, $p<0.001$) compared to radiation therapy. These data go against the common perception that in early cancers, either modality offers equivalent survival.

Such retrospective reports, despite large numbers, have associated bias, but are hypothesis generating and clearly indicate the need to look for differences between these treatment methods in a controlled setting. However, it is highly unlikely that an adequately powered randomized controlled trial will be performed in the near future. Given the above data, the authors believe that if expertise is available and all else being equal, all patients should be offered

both treatment options with early stage cancers. The volume of data supporting better survival for the surgical arm is compelling and should be shared with patients.

ORGAN PRESERVATION AS AN ARGUMENT FOR PRIMARY SURGERY FOR EARLY LARYNGEAL CANCER

This is an important issue that is not often discussed during the decision-making process when treatment is planned for early laryngeal cancer, especially stage II. It should be recognized that T2 cancers, despite being categorized as 'early disease', have a significantly higher risk of local recurrence. This has been demonstrated in several studies. Organ preservation following the use of RT in a series of 260 patients with T2 laryngeal squamous cell carcinoma (LSCC) was 81% and 74% for T2a and T2b tumours respectively.[30] McCoul et al.[31] have shown in a meta-analysis of 21 studies (published between 1967 and 2007) that for T2a and T2b laryngeal tumours treated by radiation therapy, mean local control at 5 years was 76.2% (SD 10.2%) and 64.4% (10.2%) respectively. When four of the 21 papers from this study (n = 653) that were published in the last decade are considered separately, local 5-year control rates range between 70% and 80%, indicating no significant improvement in control rates. In a single centre[32] series of 1615 patients with laryngeal cancer of all stages, the 3-year risk of recurrence for T2 cancer was 27.3%. Thus, at least 25% and up to 30% of patients will suffer local disease recurrence when primary RT is used to treat T2 LSCC. These figures have been replicated in large population cohort studies.[33] In the patients who develop disease recurrence following RT, organ preservation is usually not feasible due to tumour and patient factors and total laryngectomy is often required, although open partial laryngectomy (OPL) (see 'Open partial laryngectomy (OPL) below) may be feasible in selected cases. Consequently, most patients who develop local recurrence of T2 LSCC following initial treatment with RT are treated with total laryngectomy, with the inevitable costs to voice and swallowing function as well as overall quality of life.

Prospective datasets suggest that between 7% and 15% of patients treated with transoral procedures for early laryngeal cancer will suffer local disease recurrence. Unlike in patients who recur following RT, a greater repertoire of re-treatment options is available (OPL, repeat TLM/TORS and/or RT) in an attempt to preserve a functioning larynx. This is demonstrated by three large case series with more than 100 patients each of T2N0 disease, with organ preservation rates of 84% to 96% are observed for T2N0 tumours.[33–35] As expected, survival rates are not different across the two modalities. A recent systematic review 48 papers pooled data from 1156 patients treated by TLM and 3191 treated with RT, showed similar local control rates.[36]

Similar high rates of laryngeal preservation are seen in series reporting the outcomes of surgery for T3 tumours of the larynx (73–83%)[35, 38] providing further support for the efficacy of this sequential organ preservation approach. As a result of these and other data, a recent review concluded that there was higher chance of laryngeal preservation if surgery was used as the initial treatment modality in T2 tumours.[39] While studies suggest that the voice outcome may be poor in surgically treated patients,[40] there is no doubt that the poorest voice results when a patient loses their larynx. It follows that the discussion to be had with the patient is whether an initial potential reduction in voice quality is acceptable to retain a fully functioning larynx.

HEALTH ECONOMICS AND EARLY GLOTTIC CANCER

Surgery for early stage laryngeal cancer has been shown to have superior cost-utility compared to RT in a meta-analysis.[41] A recent analysis compared TLM against RT in the management of early stage (T1a, T1b and T2) glottic cancer to identify the most cost-effective treatment modality within the UK National Health Service.[42] A Markov decision model was populated using data from updated systematic reviews and meta-analyses, with attributable costs from NHS sources. The study concluded that over a 10-year time horizon, RT as the initial treatment strategy was more expensive (£2654 vs £623) and less effective (quality adjusted life year (QALY) reduction of 0.141 and 0.04 in T1a and T1b-T2 laryngeal cancer respectively) than TLM. The dominance of TLM for T1a cancers was unchanged on sensitivity analysis in most modelled scenarios, while for T1b-T2 laryngeal cancers, RT became more cost-effective when TLM costs were increased and when a QALY gain was assumed for RT. In the UK, TLM is recommended as optimal treatment for T1a glottic tumours, unless robust contraindications exist.

A cost-effectiveness analysis considering the Canadian healthcare system[43] found TLM to dominate RT with higher QALYs and lower costs. A study of the itemized average costs of RT and TLM in the American healthcare system in 2001 showed RT to be 15.5 times more costly.[44] Using the 5-year survival rate as the 'effect' in a cost-effectiveness analysis, Diaz-de-Cerio et al.[45] found that TLM offered a saving of €1342.68 per year in the Spanish healthcare setting, concluding that TLM was the dominant option for T1 and T2 glottic cancers.

TREATMENT OPTIONS

There has been a significant expansion in the repertoire of surgical procedures used to treat early laryngeal cancer.

Transoral partial laryngectomy

Newer developments permit partial laryngectomy to be performed through transoral approaches. TLM is very commonly used for early cancer of the laryngeal glottis and the supraglottis, with widespread expertise and has also been shown in several controlled series to provide excellent oncological and functional outcomes,[35] comparable to OPL.[46] Centres with expertise in this procedure have moved to a stage where they offer patients with this stage of disease only surgery, with consistently excellent long-term results.[35, 47, 48] TLM is discussed in detail in Chapters 22, Transoral laser microsurgery and 23, Anatomy as applied to transoral surgery. The other

method to perform transoral partial laryngectomy is with the assistance of a robot, used primarily for supraglottic cancers; transoral robotic surgery is dealt in greater detail in Chapter 29, Applications of robotics in head and neck practice.

Open partial laryngectomy (OPL)

Although OPL has been in use in Europe (especially France and Spain) for many years, this procedure has not gained wide acceptance in many countries. Reasons include easier access to radiation therapy services and concerns about post-operative function, which has consequently led to loss of expertise. However, recent publications confirm good to excellent long-term functional and oncological outcome for these procedures,[49] and refinement of the procedure[50] that leads to consistent results. A more detailed treatment of OPL can be found in Chapter 27, Open conservation surgery for laryngeal cancer.

RADIATION THERAPY

RT as a single modality offers an alternative to organ preserving surgical options in the treatment of early LSCC (glottic and supraglottic). The long-term local control rates for early glottic carcinomas are similar to organ preserving surgical approaches (TLM). RT is preferred in most centres in the UK and the United States, where the tumour involves AC and in T2 glottic tumours, largely due to better functional outcomes and to a lesser extent due to the low availability of surgical expertise. This modality is also the preferred option in patients with poor access for surgery and/or high risk for general anaesthesia.

The long-term local control rates following RT alone for early supraglottic carcinomas are also similar to surgery with 5-year local control rates of 100% for T1 and 86% for T2.[51] With increasing expertise in minimal access surgery, the proportion of patients treated with surgery is likely to increase.

TREATMENT PRINCIPLES

Transoral laser microsurgery

Glottic cancers: The standard of care for surgical treatment of mid-cord glottic cancers is TLM. For mid-cord lesions staged T1a, TLM excision has a very high cure rate[23,27] with the undeniable advantage of higher laryngeal preservation rates[27,52] and is commonly recommended in most MDTs where expertise exists. TLM to excise T1a lesions is easily taught and learnt, and the treatment process is rapid and preferred by patients,[24] with health economic benefits.[42]

TLM is less commonly used for T1 cancers that involve the AC and for T2 cancers as the impact of surgical resection on the voice is considered to be greater, although cure rates are at least equivalent, if not higher than those achieved by radiation therapy (**Tables 14.2** and **14.3**). The suitability of AC lesions for TLM has been debated in the literature, with some reports suggesting that AC location has an impact on prognosis,[53–56] while others do not.[57] A systematic review[58] of T1b tumours treated by either modality showed a trend towards improved local control when treated with RT, with the caveat that this finding was based on a limited number of published outcomes (n = 194).

All glottic cancers resected by the TLM approach should be classified as per the European Laryngological Society (ELS) system,[59] which describes six types of cordectomy based on the extent of resection of the vocal cord and the adjoining structures (**Table 14.4**).

It is well recognized that AC lesions can exhibit cartilage invasion in up to 20% of cases at presentation.[60,61]

It is important that the resection specimens are orientated for the pathologist; small specimens sent in a fixative solution can cause shrinkage and curling of the tissue hindering accurate histological interpretation. The techniques used to orientate larger specimens are not effective and thus should be mounted and orientated on suitable media. A popular

option is to use dehydrated cucumber as a mount with the specimen anchored to it by tissue glue (**Figure 14.3**).[72]

It should be recognized that for the specimens resected by TLM will have much smaller margins than traditional open surgery, with margins of the order of a millimetre being appropriate, which should not be misinterpreted as close or positive margins. Thus, the pathologist should be fully apprised of the nature of the resection and there should be clear channels of communication between the surgeon and the pathologist for appropriate reporting of the resection margins. The authors cannot emphasize enough the importance of clinico-pathological correlation in transoral resections. This is often an area of contention and guidelines for management after TLM have been published by the British Association of Otolaryngologists — Head and Neck Surgeons.[73] These are summarized in **Box 14.1**.

Supraglottic cancers: All supraglottic cancers resected by a transoral approach should be classified as per the ELS system,[74] which describes four types of supraglottic laryngectomy based on the extent of resection (**Table 14.5**). As stated earlier, it is important that all resections be orientated for the pathologist. Unlike glottic cancer, where possible, a conscious effort should be made to achieve surgical margins of at least 5 mm during resection. Further patient side biopsies can be sent for confirmation of the margin status.

Unlike glottic cancers, patients following transoral resections for supraglottic tumours can be expected to have significant swallowing dysfunction in the early stages, even up to 6 weeks at times. Appropriate swallow assessment, therapy and supplemental feeding may be necessary. However, the author's experience and the literature suggest that the swallow outcome is invariably favourable and patients achieve very good functional swallow.[75, 76]

Open partial laryngectomy

There is little debate about the oncological efficacy of OPL as primary treatment for early laryngeal cancer. The relatively poor functional outcome has been the deterrent to wide use of this procedure. A systematic review by Thomas et al.[49] on the outcome of surgically treated laryngeal cancer showed a pooled local control rate at 24 months from 5061 patients to be 89.8% (95% CI 88.3–91.2), a pooled overall survival of 79.7% (n = 3967; 95% CI 76.5–782.8) and pooled mean disease-free survival of 84.8% (n = 2344; 95% CI 80.6–88.7). These figures are comparable to any other treatment modality, despite the fact that a substantial proportion of the cohort in the study had T3 disease. Some of the studies with large cohorts from high-volume centres are

TABLE 14.4 European Laryngological Society classification of cordectomies for glottic carcinomas[59]

Definition	Type	Description
Subepithelial cordectomy	I 	Resection of the vocal fold epithelium passing through the superficial layer of the lamina propria
Subligamental cordectomy	II 	Resection of the epithelium, Reinke's space and the vocal ligament
Transmuscular cordectomy	III 	Resection of the vocal fold down through vocalis muscle
Total cordectomy	IV 	Resection of the cord, which extends form the vocal process to the anterior commissure. The depth of the surgical margins reaches or includes the internal perichondrium of the thyroid ala
Extended total cordectomy	Va 	Resection includes the contralateral vocal fold and the anterior commissure
	Vb 	Resection includes the arytenoids

	Vc 	Resection includes the subglottis
	Vd 	Resection includes the ventricle and false cords
Anterior commissurectomy	VI 	Resection of the anterior commissure with bilateral anterior cordectomy; may include the subglottic mucosa and the cricothyroid membrane

summarized in the table below. OPL has been used in the past for supraglottic cancers with significant success rates.[49] It is recommended that the ELS system of classification of open horizontal laryngectomy be used by surgical practitioners to collate data and report on this technique.[77] However, as the procedure involves disruption of the neck musculature and also sensory supply to the pharynx, functional outcomes were even less predictable than with resections for glottic cancer. With the emergence of transoral approaches, OPL is less used as a primary procedure.

Transoral robotic surgery (TORS)

Glottis: Early experience with this modality suggests equivalent oncologic control rates as for TLM.[78, 79] However, the advantages of a TORS approach for glottic tumours are yet to be defined.

Supraglottis: TORS has been a useful addition to the surgical armamentarium in the management of supraglottic tumours. The high-definition three-dimensional vision of the operating field, wristed movement with 7 degrees of freedom and the ability to work without the target

BOX 14.1 Post-resection management following cordectomy for early laryngeal cancer

1. All specimens must be orientated and mounted for histological analysis.
2. Terminology such as 'complete excision', 'close margins' and 'incomplete excision' are misleading. It is advisable for the pathologist to precisely specify the sites on the orientated specimen where the margins are less than 1 mm. This will help in planning a second look and during follow-up.
3. Based on the pathologist's report, the following actions are recommended:
   (i) If the resection margins are considered surgically adequate and are clear by a millimetre or more on histology, no second look is warranted. Routine clinical monitoring will suffice.
   (ii) If the surgical margins are not in doubt but the histology shows tumour at the margins, a second look is recommended 6–8 weeks later.
   (iii) If the surgeon has concerns about resection margins and residual tumour is confirmed on histological analysis, the feasibility of further TLM resection should be considered.

Future management should be discussed at the MDT meeting and careful consideration given to alternative non-endoscopic treatment options.

being in line of sight (as for laser microsurgery) has made robotic supraglottic laryngectomy a procedure that can be taught and learnt with greater ease than TLM procedures (**Figure 14.4**). As for TLM procedures, support systems for the post-operative swallowing dysfunction should be in place. As **Table 14.7** suggests, outcome data are comparable to those performed by the established TLM techniques.

Neck management

T1 glottic cancer usually presents with no metastatic lymphadenopathy and the risk of occult nodes are very small. Thus, treatment for the primary site alone will suffice. T2 tumours also are less prone to metastatic spread, but given the risk of occult spread of ~7%, there is no consensus on whether the neck should be treated in this setting.

With supraglottic, unlike glottic cancers the neck will almost always need to be addressed even if there is no clinical or radiological evidence of disease. The incidence of occult neck metastases is well over 15%. Exceptions to this rule might be small cancers of the tip of the epiglottis with minimal invasion, or for salivary malignancies in this region.

Radiation therapy

Glottic carcinoma: RT is delivered using megavoltage photons (4 to 6MV), the target volume encompasses the primary tumour. The regional lymph nodes are not treated due to low risk of lymph node metastasis. The treatment is usually delivered using two lateral fields covering the laryngeal skeleton from thyroid notch superiorly to the inferior border of cricoid. The field size ranges from 4 × 4 cm to 5 × 5 cm, with larger field size for T2 tumours, depending on the extent of tumour. The most commonly used fractionation regime in the UK is 50 to 55 Gy in 16 to 20 daily fractions over 3 to 4 weeks. Yamazaki et al. reported a prospective randomized trial in patients with T1N0M0 glottic carcinoma receiving definitive radiation treatment. The study compared two different doses per fraction (2 Gy/fraction Vs 2.25 Gy/fraction). The 5-year local control rates were 77% after 2 Gy per fraction and 92% after 2.25 Gy per fraction with no difference in either acute or late toxicity.[84]

Supraglottis: The target volume for radiation treatment encompasses the primary tumour and lymph nodes bilaterally (Level II–IVa) due to high risk of microscopic lymph node metastasis. The at risk nodal levels are treated to a reduced dose (prophylactic dose). The fractionation regime commonly used is as for glottic carcinomas. Alternatively, a regime of 65 Gy in 30 fractions over 6 weeks is used.

Management of T3 laryngeal cancer

TREATMENT PHILOSOPHY

Functional issues

Physicians treating laryngeal cancer have always assumed that laryngeal preservation is a priority for all patients. In 1981, when total laryngectomy was the standard of care, McNeil et al. published a landmark study[85] scrutinizing the trade-off between quantity and quality of life faced by patients diagnosed with locally advanced laryngeal cancer. The utility analysis was performed on 37 healthy volunteers based on the assumption that RT was associated with a poorer survival, but a better voice outcome, while laryngectomy achieved an improved survival at the expense of an artificial voice. The study showed that not everyone valued survival at any price and that survival may not be the most important outcome for all patients. This study has no doubt contributed to the organ preservation

TABLE 14.5 European Laryngological Society classification of transoral resections for supraglottic carcinomas[74]

Definition	Type		Indication and Description
Limited excision	I		Excision of small superficial tumours anywhere on the supraglottis
Medial supraglottic laryngectomy with partial resection of the pre-epiglottic space	IIa		Tumours of laryngeal surface of epiglottis located above the hyoid bone: resection includes the suprahyoid epiglottis
	IIb		Tumours extending below the hyoid: resection includes a total epiglottectomy
Medial supraglottic laryngectomy with resection of the pre-epiglottic space	IIIa		Tumours extending to petiole of epiglottis: resection must include the pre-epiglottic space
	IIIb		Tumours of the infrahyoid epiglottis extending to the ventricular fold: resection includes ventricular folds dissected from the thyroid cartilage

trials in the 1990s and the first decade of this millennium (see below). Although quality-of-life comparisons between patient groups treated with total laryngectomy or chemoradiation show differences in functional subscales, the overall QOL scores of both groups seem similar.[86, 87] Clearly significant clinical experience has been accrued since the organ preservation protocols have been implemented across the world. When Laccourreye et al.[88] polled 163 otorhinolaryngologists about the percentage chance of cure that they would be prepared to trade-off to preserve their larynx when faced with advanced stage laryngeal cancer, the professionals were almost equally

divided between total laryngectomy and larynx preservation. These authors[89] also performed a similar questionnaire survey on 269 patients attending the otolaryngology service for various problems and concluded that laryngeal preservation is not a major objective of treatment shared by patients filling a questionnaire devoted to the choice of treatment when facing an advanced laryngeal cancer.

Hamilton et al.[90] replicated the work by McNeil et al.[85] in a more robust fashion. They developed four health state descriptors representing total laryngectomy or chemoradiotherapy with either optimal outcome or with complications. They recruited 114 participants demographically matched to the head and neck cancer population, and asked them to rank the outcome scenarios, assign utility values to each health state using time trade-off and rate the importance of survival on treatment choice. This study concluded that the functional outcome of treatment was a greater determinant of a laryngeal cancer health state utility value than treatment modality and that in many individuals, larynx preservation may not be the primary consideration for treatment selection. This puts in perspective the discussion in the next section on treatment choices for these patients.

RECURRENCE, SURVIVAL AND CONTROVERSY AROUND TREATMENT CHOICES

In the latter part of the 20th century, the standard treatment for T3 laryngeal cancer was total laryngectomy. Indeed, no study has shown improvements in local control and survival compared to total laryngectomy. The landmark Veterans Affairs study[91] compared induction chemotherapy followed by radiation to total laryngectomy and is to date the only study to have compared surgical management with non-surgical management. The study recruited 332 patients with stage III or IV laryngeal squamous carcinoma who were randomized to either three cycles of chemotherapy followed by RT or surgery and RT. In the non-surgical arm there was an assessment after two cycles of chemotherapy. Patients who did not clinically respond crossed over the surgical arm and were treated by total laryngectomy. The study reported comparable survival in both groups of 68% at 2 years. Overall the laryngeal preservation group was 64% in those treated in the non-surgical arm. This study was the first to suggest that non-surgical treatment was a valid option for stage III and IV laryngeal tumours. The Veterans Affairs study had a higher proportion of supraglottic tumours compared to glottic tumours (208 vs 124). The majority were T3 (216) tumours, with a Karnofsky score of >80 in 253 of the patients. Patients who eventually needed a laryngectomy in the non-surgical arm had glottic tumours, fixed vocal cords, gross cartilage involvement and stage IV or T4 cancers. The above factors should be taken into consideration when interpreting the results.

The Intergroup Radiation Therapy Oncology Group (RTOG) 91–11 trial[92] randomized 547 patients to one of the three study groups, which included RT only, induction chemotherapy followed by radiation (ICRT) and radiotherapy with concurrent cisplatin (CRT). The study found that at 2 years, a statistically higher proportion of patients who received CRT had an intact larynx after RT (88%) compared to ICRT (75% P = 0.005) or RT (70%, P<0.001). The rate of locoregional control was also significantly better with CRT (78 percent, vs 61 percent with ICRT and 56 percent with RT only). This trial showed that in suitably selected patients, the addition of chemotherapy concurrently to RT enhanced chances of laryngeal preservation significantly, while not showing a decrease in the overall survival. Subsequently, longer term outcomes for this study with a median follow up of 10.8 years have been published.[93] The long-term study confirmed that both chemotherapy regimens significantly improved organ preservation. Although overall survival did not differ significantly across the groups, there was a trend towards a worse outcome with CRT relative to ICRT. In addition,

the study also demonstrated a statistically significant higher percentage of deaths not attributed to larynx cancer or treatment in the CRT arm (30.8%) than the ICRT (20.8%) or the RT arm (16.9%). The toxicity of the CRT was not insignificant. The CRT arm experienced a 43% rate of severe late complications, including an 18% rate of pharyngeal dysfunction, a 25% rate of laryngeal dysfunction, a 7% rate of death due to the treatment protocol and a high rate of complications following salvage laryngectomy.

Since the publication of the above two studies, several commentators have expressed concerns about the generalization of the trial results to all patients with advanced laryngeal cancer[94, 95] without a full appreciation of the caveats of this approach. The undoubted advantages to organ preservation should be placed and understood in the context of the inclusion criteria to this trial, which have been discussed in an elegant editorial.[96] Over 40% of the patients in the two studies had mobile vocal cords (48% in the VA study and 42% in the RTOG 91–11 study); it is well recognized that cord fixity has an adverse prognosis compared to mobile cords and these patients would have needed a total laryngectomy anyway. The trial participants included a proportion of T2 patients, who could potentially be treated by partial laryngectomy, thus avoiding a permanent stoma. The lack of a surgical arm has been a drawback of this trial, especially given the long-term follow-up data suggesting more causes of non-cancer deaths in the CRT arm. It is important to recognize that several studies[47, 49, 97, 98] showing comparable mature outcomes in patients with T3 cancer who received open or transoral partial laryngectomy as the primary management.

Large database analyses have suggested that a primary non-surgical treatment may have an adverse effect on survival. Hoffman et al.[99] analyzed data from 158 426 cases of laryngeal squamous cell carcinoma (excluding verrucous carcinoma) diagnosed between the years 1985 and 2001 from the US National Cancer Data Base. This review of data showed decline in the 5-year relative survival between the 1985–1990 period and the 1994–1996 period among glottic and supraglottic cancers classified as T3N0M0. Initial treatment of T3N0M0 laryngeal cancer (all sites) in the 1994–1996 period resulted in poor 5-year relative survival for those receiving either chemoradiation (59.2%) or irradiation alone (42.7%) when compared with that of patients after surgery with irradiation (65.2%) and surgery alone (63.3%); there was no difference during this period for the subset of T3N0M0 glottic cancers initially treated with either chemoradiation or surgery with irradiation. In a subsequent SEER analysis, Chen et al.[100] showed that between 1985 and 2007, the use of CRT increased from <7% to 45%, whereas the use of total laryngectomy decreased from 42% to 32% in patients with advanced staged cancer. The 4-year survival rates for patients with advanced laryngeal cancer treated with total laryngectomy, CRT, and RT were 51%, 48% and 38% respectively despite patients receiving CRT being used in younger patients from higher socioeconomic groups.

Megwalu et al.[101] studied a cohort of 5394 patients who received a diagnosis of stage III or IV laryngeal squamous cell carcinoma between 1992 and 2009. Data were extracted from the Surveillance, Epidemiology, and End Results (SEER) Database in the US. They found that patients who received surgical therapy had better 2- and 5-year disease-specific survival (70% vs 64% and 55% vs 51%, respectively; $P < .001$) and 2- and 5-year overall survival (64% vs 57% and 44% vs 39%, respectively; $P < .001$) than patients who received non-surgical therapy. The difference in DSS and OS between treatment groups remained statistically different after stratification by year-of-diagnosis cohorts. Multivariate analysis showed non-surgical patients to suffer worse hazard of disease-specific survival (1.33 [95% CI, 1.21–1.45]) and overall survival (1.32 [95% CI, 1.22–1.43]) after adjustment for other variables. The authors concluded that surgical therapy leads to better survival outcomes than non-surgical therapy for patients with advanced laryngeal cancer. A further analysis[102] of 487 patients with T3 laryngeal tumours alone from the SEER registry and Medicare databases showed adjusted hazard ratio for OS of 0.68 (95% CI, 0.49–0.94) for patients receiving surgery alone vs non-surgical management and 0.75 (95% CI, 0.57–0.98) for patients receiving surgery plus adjuvant treatment vs non-surgical management.

The above analyses could be considered to favour surgery on the basis of less comorbidity in the surgical group. However, in an investigation into the prevalence of comorbidity in surgical vs non-surgical patients in 16 489 cases of advanced laryngeal cancer from the national cancer database, Zhu et al.[103] found that patients with comorbidity were less likely to receive chemoradiation than subtotal or total laryngectomy, with a risk ratio (RR) of 0.84 (95% CI, 0.81–0.87) for patients with one or more comorbidities compared with those without any comorbidity, after controlling for factors such as tumour stage, age, race/ethnicity, insurance and socioeconomic status. A recent systematic review[104] echoes the above points about heterogeneity in staging, anatomical subsite and heterogeneity in patient cohorts, concluding that CRT should not be used as a 'One size fits all' approach for T3 cancers.

The above discussion brings to the fore the question that surgery has not been directly compared to various forms of primary non-surgical therapy. Organ preservation can only be considered for an organ which is fulfilling its functions. Thus, a dysfunctional larynx where the airway is compromised, or where the tumour bulk causes significant dysphagia needing tube feeding are circumstances where organ preservation strategies should not be considered, even if the tumour stage and extent makes it suitable. These are echoed by the recommendations of the Larynx Preservation Consensus Panel.[105]

While the VA trial showed no improvement in survival following primary surgery for patients with stage III and IV laryngeal cancers, there is broad consensus in the literature that primary surgery for T3 tumours offers the best chance for locoregional control. Two single centre studies[106, 107] of stage III or IV laryngeal SCC with

substantial numbers have shown that surgical treatment was associated with statistically significant superior locoregional control rates (16% to 20%), but not in overall survival with a primary surgical option. In a single-centre large series of 1615 patients with laryngeal cancer of all stages,[32] the 3-year risk of recurrence was highest for T3 (35.8%) laryngeal cancer. Of the 368 patients with recurrent disease, 271 (74%) were managed by RT as primary treatment.

However, a meta-analysis[108] of outcomes following primary surgery vs non-surgical treatment for advanced-stage laryngeal cancer arrived at different conclusions. Data from 16 retrospective studies involving 8308 patients (4478 in the TL group and 3701 in the non-surgical group) showed that TL had better 2- and 5-year overall survival (OR 2.79, 95% CI 1.85–4.23 and OR 1.52, 95% CI 1.09–2.14). Interestingly, there were no significant differences between TL and NOP for 5-year local control. This indicates the heterogeneity in the patient population that is categorized as T3 laryngeal cancer. There is an acute need to re-evaluate treatment options for T3 laryngeal cancer. The authors would favour an individualized approach to the management of these patients and advise caution in advocating a primary non-surgical approach to all patients with this disease stage.

TREATMENT OPTIONS (TABLE 14.9)

Non-surgical treatment

Radiation therapy in combination with systemic therapy with either concurrent chemotherapy or Cetuximab (monoclonal antibody which competitively inhibits the cell-surface Epidermal Growth Factor Receptor-EGFR) or alone offers organ preservation in a proportion of appropriately selected patients without compromising survival. The landmark VA study[91] showed that in patients responding to induction chemotherapy, the laryngeal preservation rate was 64% at 2 years with similar survival rates at 2 years (68%) compared to surgery followed by RT. Salvage laryngectomy rates were significantly lower for T3 compared to T4 disease (29% vs 56%). A higher proportion of patients with glottic cancer (those with fixed cord) compared to supraglottic cancer underwent salvage laryngectomy.

A subsequent trial by the Intergroup RTOG 91-11[92] demonstrated that laryngeal preservation rates with concurrent chemoradiotherapy (CRT) was superior to sequential induction chemotherapy followed by RT and to RT alone (88% vs 75% vs 70%) with similar survival rates. The use of concurrent CRT in advanced laryngeal cancer is also supported by the tumour site specific meta-analysis and offers a 5.4% absolute benefit with the addition of chemotherapy at 5 years.[109] This benefit decreases with age and is non-significant above 70 years of age and therefore less appropriate in patients above this age. Combined modality treatment is associated with significant toxicities. The grade 3/4 toxicities related to treatment were 24% in ICT arm, 30% with CRT and 36% for RT arm with treatment related death of 3% in the ICT and RT arm and 5% in the CRT arm.[93] Robust data relating to laryngeal function preservation following CRT are lacking. The consensus panel now recommends the primary end point to be survival and function for future studies. A meaningful functional end point defined is laryngo-oesophageal dysfunction-free survival at 2 years.[105]

It must be emphasized that in the 91–11 trial the radiation therapy delivery was mostly unplanned or using 3D forward-planning technique whilst most centres now use the modern state of the art radiation therapy delivery intensity-modulated radiation therapy (IMRT) or volumetric modulated arc therapy (VMAT) which allows to conform the radiation doses to the target volume, minimize hot spots and spare dose to adjacent normal structures thereby potentially reduce the associated toxicities.

Standard concurrent chemotherapy regimens include cisplatin (100 mg/m^2) on day 1, 22 and 43 of RT and carboplatin/5 FU on weeks 1 and 5 during RT. In patients where chemotherapy is contraindicated, cetuximab, monoclonal antibody could be considered as an alternative in patients with performance status 0 or 1 during RT. The addition of cetuximab during RT has been shown to improve local control (3-year LRC 47% vs 34%) and 5-year overall survival by 10% (46% vs 36%) compared to RT alone (27% of patients are advanced laryngeal cancer).[111] The toxicities associated with cetuximab include acne form skin rash and hypersensitivity reactions and does not increase the rate of radiation induced mucosal toxicities.

Induction chemotherapy regimens include combination cisplatin and 5FU (PF) given every 3 weeks to a total of 2 to 3 cycles. This in selected patients may improve survival and reduce distant metastasis but its role is not proven prior to concurrent CRT. The addition of docetaxel to above drugs has shown a higher overall response rate and larynx preservation rate compared to PF in patients with stage III/IV laryngeal cancer and may improve survival.[111–115]

Standard fractionation RT alone may be used as a single modality treatment in patients over 70 years of age or where comorbidity precludes the use of concurrent chemotherapy or cetuximab. The outcomes are suboptimal compared to CRT and should only be considered in patients who are selected or chose to receive RT alone.

Altered fractionation regime improves local control and survival at the cost of higher mucosal toxicities but the outcomes are better than RT alone but are still suboptimal compared to concurrent CRT. Altered fractionation with hypoxic modifiers, namely nimorazole, is currently being studied in a UK clinical trial, NIMRAD (a randomized placebo-controlled trial of concurrent nimorazole vs RT alone in patients with locally advanced squamous cell carcinoma not suitable for concurrent chemotherapy or cetuximab).

The potential role of concurrent chemotherapy and dose-escalated RT in laryngeal and hypopharyngeal cancer has been studied in a phase III trial, ART DECO. The early results demonstrated no improvement in local control in the dose-escalated arm and an increased incidence of acute toxicities in the dose-escalated arm.

Primary non-surgical treatment with concurrent CRT remains the preferred treatment option in patients with the following: good performance status, minimal or no comorbidity, disease is limited to the confines of larynx with no cartilage invasion, functioning larynx with no airway compromise to achieve the best possible outcome of organ and function preservation.

Radiation Technique: Most centres in the UK and US routinely use IMRT for treatment (**Figure 14.5**). This allows the dose to be conformal around the target and minimize dose to the adjacent normal structures. This technique also allows the delivery of differential dose to the primary site, involved nodes and uninvolved at risk nodal levels simultaneously. Centres use either two- or three-dose levels for definitive treatment. The two-dose levels are 65-66 Gy for gross disease and 54 Gy for microscopic disease in 30 fractions. A dose of 60 Gy is used for regions at high risk of microscopic disease in centres where three dose levels are used.

In a node-negative patient, the nodal levels at risk for microscopic spread are bilateral level II to IVa and are treated to prophylactic dose of 54 Gy in 30 fractions. The levels are outlined using consensus guidelines.[116]

In a node-positive neck, in addition to level II to IVa, level Va, Vb are also at risk. In patients with level IIa involvement, level Ib and level VIIb (retrostyloid space) are at risk of microscopic spread and are treated to a prophylactic dose as above.

The management of residual neck nodes in patients with higher neck stage (N2b, N2c and N3) following CRT is guided by the results of PET scan done at 10–12 weeks post CRT. A salvage neck dissection is done in patients with positive or equivocal PET uptake.[117]

Open partial laryngectomy (OPL) and Transoral partial laryngectomy

As discussed above, several studies[47, 49, 97, 98] show comparable mature outcomes in patients with T3 cancer who received OPL or transoral partial laryngectomy as the primary management. In the systematic review by Thomas et al,[49] pooled local control rate at 24 months following primary open partial laryngectomy for 5061 patients; 832 patients had T3 or T4 cancers; despite this the LC and DFS rates were excellent. There will be an inevitable selection bias when these treatments are offered, and these are often single-centre series where pockets of expertise exist. A recent systematic review[104] of surgical and non-surgical organ preserving options showed that both OPL and TLM seem to be efficient organ preserving methods for the treatment of T3 squamous cell laryngeal cancer. However, comparisons between surgical and non-surgical treatments were not feasible in this study due to population heterogeneity; recognizing the above bias, some of the best organ preservation and survival rates and lowest recurrence rates were seen with OPL. The authors do not recommend organ preservation surgery for T3 cancers outside of a registered institutional protocol.

Total laryngectomy

Total laryngectomy is a bona fide treatment for T3 laryngeal disease, especially in patients who have laryngopharyngeal dysfunction or a fixed cord. For endolaryngeal tumours with no pathological evidence of neck disease, a total laryngectomy with adequate margins will be all that will be needed. These patients will not need reconstructive interventions as adequate pharynx will be available to create an adequately wide neopharynx.

T4 disease

There is general agreement that laryngeal cancer which extends outside the framework of the larynx should be treated by primary surgery.[118] The reasons for this consensus are that tumours invading the cartilage do not respond well to radiation, and even if tumour control is achieved, patients may be left with a non-functional larynx (poor airway with aspiration) and chondronecrosis, both of which will need surgery for management. There is also a high risk of gastrostomy dependence if this group of patients is treated with CRT.[119, 120] As discussed above, these hark back to the contraindications for organ preservation as discussed by the Larynx Preservation Consensus Panel (**Table 14.9**).

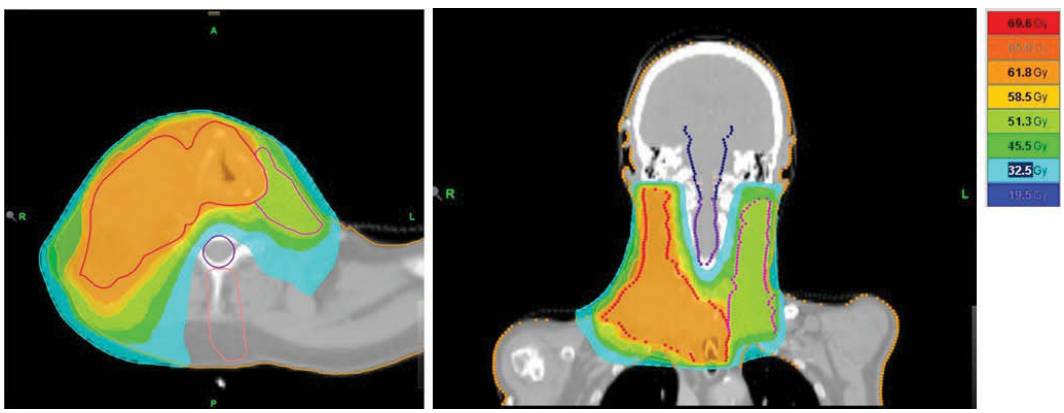

Figure 14.5 Axia and coronal section of an IMRT plan for a patient with T2N2b disease. The prescription dose (orange) encompasses entire larynx and involved nodal levels. The contra lateral at risk nodal level is treated with a prophylactic dose (green).

In an analysis of patients in the United States National Cancer Data Base diagnosed from 2004 to 2012 with T4N0 laryngeal cancer, Stokes et al. showed that overall survival among patients undergoing surgery with adjuvant radiation therapy (n = 1559) was superior to that of patients treated with concurrent CRT (n = 1597)[121] and single-centre reports support this position.[119]

Surgery usually takes the form of total laryngectomy, but for smaller selected tumours, open partial laryngectomy may be an option.[49] There are also reports supporting TLM resection for these tumours with good control rates,[122] but these have not been reproduced outside of experienced hands. Professional opinion on managing this disease is in favour of primary surgery followed by adjuvant therapy. Virtually all these patients will need the neck addressed based on the extent of neck disease; N0 necks will need bilateral levels II-IV neck dissection.

Adjuvant treatment

Post-operative RT to the tumour bed and/or neck in patients at risk of locoregional recurrence can improve locoregional control and survival. The risk factors are pT4 tumours, close or involved resection margins, involved node measuring more than 3 cm, multiple positive nodes and extracapsular spread. Other relative factors are perineural invasion and vascular invasion.

Concurrent chemotherapy and post-operative RT improves locoregional control and disease-free survival compared to post-operative RT in patients with risk factors for locoregional recurrences at the expense of increased mucosal and haematological toxicity. It improves overall survival in patients with positive resection margin and/or extracapsular spread and should be considered in patients with these risk factors for relapse.[123, 124]

TABLE 14.9 Recommended treatments for advanced laryngeal cancer

T stage	1st choice	2nd choice	3rd choice
T3	CRT	OPL/TLM/TORS*#	TL*#
T4a	TL#	CRT	OPL/TLM*#

* based on patient choice, local expertise, tumour and patient factors.
# may need adjuvant radiation based on pathological findings.

RECURRENT LARYNGEAL CANCER

Recurrent early laryngeal cancer

Residual or recurrent laryngeal cancer (hereafter referred to as recurrent cancer) following RT is a difficult clinical problem as the disease is more aggressive and carries a poor prognosis. Although several treatment options exist for patients with laryngeal cancer at first presentation, options for those with recurrent cancer will be limited based on the initial treatment received and the stage of the recurrent disease. Cancers that recur after radiation therapy often demonstrate aggressive behaviour, arise in a field where lymphatic drainage is unpredictable, and are associated with poor control rates. Salvage total laryngectomy (STL) is an often recommended option, even for early radiorecurrent cancers, because it is technically easy, and the outcomes are predictable.[124–126] Recognizing that recurrent head and neck squamous cell carcinoma has an aggressive course, and concerns about the higher incidence of complications in the irradiated neck, surgeons have been reluctant to adopt less radical procedures. However, total laryngectomy has far-reaching consequences for the patient in terms of function and quality of life.

OPL

OPL in recurrent cancer has withstood the test of time in instances where the tumour extent and patient are suitable for the procedure, and has been demonstrated to have very good outcomes in the recurrent setting too (**Figure 14.6**). Paleri et al.[128] performed a systematic review and a meta-analysis to study the role of open conservation (partial) laryngeal surgery in radiorecurrent laryngeal cancers. The pooled estimates of oncological outcomes were as follows: local control rate at 24 months for 560 patients was 86.9% (95% CI, 84%–89.5%), the disease-free survival rate for 352 patients was 91.2% (95% CI, 88.2%–93.9%), and the overall survival rate for 360 patients was 83.1%

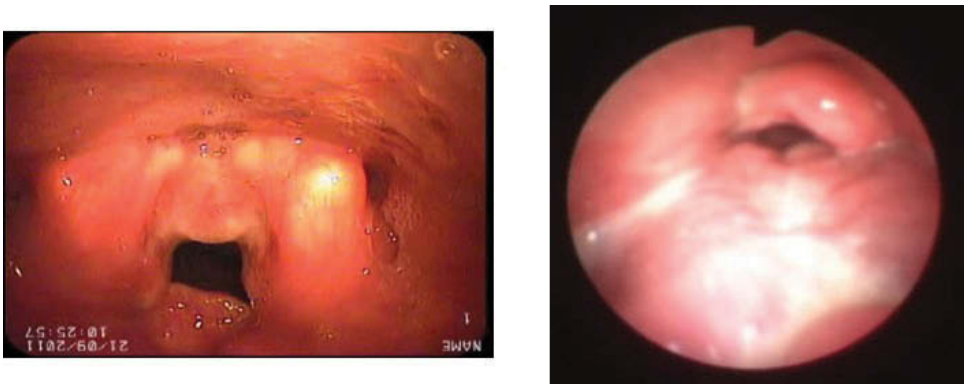

Figure 14.6 Two examples of salvage supracricoid laryngectomy. The patient on the left had both arytenoids and epiglottis preserved, while the one on the right had removal of epiglottis and the right arytenoid. In carefully selected patients and meticulous attention to operative detail, excellent function can be achieved.

(95% CI, 79.1%–86.7%). Since the review, further studies have demonstrated the efficacy of this approach in the radiorecurrent setting.[129]

TLM

As shown above, TLM has a well-defined and proven role in the management of primary laryngeal cancer with several advantages. It is therefore intuitive to try and exploit these advantages to early recurrent laryngeal cancer. However, there are several caveats to this approach. The conventional margins employed during TLM resection in the treatment of primary laryngeal cancer may well not be applicable in the radiorecurrent setting.[130] There is considerable difficulty in identifying peri-operative tumour margins accurately in a previously irradiated larynx, even in the most experienced hands. This is borne out by de Gier et al.[131] who reported a 58% recurrence rate after the first laser resection. Steiner et al.,[132] whose series included recurrent advanced tumours, reported only 38% remained free of disease after the first laser procedure. This improved to 71% following repeat TLM. Studies by Roedel et al.[133] and Ansarin et al.[134] revealed that recurrent tumour was typically clinically understaged and was later found to display a higher stage on pathological examination. This has also been demonstrated in other studies where whole organ sectioning has been employed, where pre-treatment clinical and radiological staging accuracy for recurrent tumour is around 50%, with more than 90% being understaged.[130] Ramakrishnan et al.[135] performed a systematic review of the use of salvage TLM and identified that although it was oncologically sound with a high larynx-preservation rate, there was a distinct trend towards inferior local control rates compared to OPL. The pooled mean estimate of local control at 24 months after first TLM (n = 249) was 56.9%, a full 30% less compared to the 24-month local control rates for OPL in recurrent cancers. This remained the case even when the improved LC following repeat TLM is taken into consideration. The relatively lower mean larynx preservation rate of 72.3% for TLM vs 84% for OPL[128] is a reflection of the higher locoregional failure following TLM and the lower threshold for resorting to a total laryngectomy. The authors believe that where suitable, patients should be offered OPL in preference to TLM for recurrent tumours, unless the cancer is limited to the mid cord and there is little concern about submucosal spread. In cases not suitable for OPL due to patient factors, total laryngectomy should be offered.

Recurrent advanced laryngeal cancer

Patients who recur following CRT are rarely candidates for anything less than a total laryngectomy. Recurrent T3 and T4 cancers with partial or limited erosion of the thyroid cartilage may be suitable for OPL, and there are data to support the oncological efficacy of this approach in carefully selected patients.[128]

Pharyngocutaneous fistulae (PCF) are known to occur in nearly a third of patients after STL.[127] PCF has severe impact on duration of admission and costs, quality of life and can even cause severe complications such as bleeding, infection and death. Paleri et al.[136] performed a meta-analysis of the benefit of vascularized tissue repair in reducing the risk of PCF following STL. Using data from 591 patients across 7 studies, the pooled incidence of PCF for 332 patients who underwent flap reconstruction was 22.2% (95% CI 17.9 to 26.8%), but 31.2% (95% CI 25.8 to 36.9%) in 259 patients who underwent primary closure. The absolute risk reduction in PCF rates of 9% indicates that 11 patients will need a flap to prevent one fistula. The pooled relative risk derived from 591 patients was 0.63 (95% CI: 0.47 to 0.85), indicating that patients who have flap reconstruction/reinforcement reduced their risk of PCF by a third. Another study by Sayles et al.[137] on the same subject, albeit with different inclusion criteria, published almost concurrently, arrived at similar conclusions. They concluded that relative risk of fistula was 0.57 (95% CI 0.37–0.85, $P < 0.001$) for STL with flap reinforced closure compared to primary closure of the pharynx alone and the number needed to treat to prevent one fistula was 6. These pooled analyses suggest that there is a clear advantage in using vascularized tissue from outside the radiation field in the laryngectomy defect (**Figure 14.7**).

Neck management in recurrent laryngeal cancer

A handful of studies have specifically looked at the utility of offering neck dissection to patients who present with recurrent laryngeal cancer.[138–145] Current imaging techniques to assess the post-treatment neck offer a high-negative predictive value (~96%) increasing clinical confidence. Given the increased complications associated with neck dissection in the salvage setting,[142] consideration should be given to conservative management of the neck

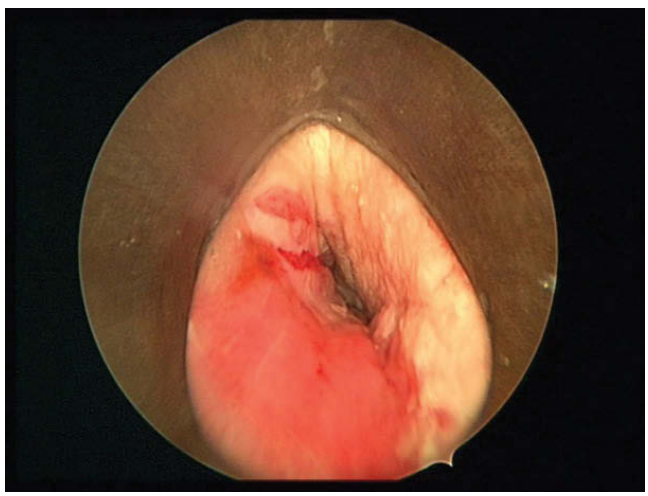

Figure 14.7 Endoscopic view of pharyngeal lumen augmented using a free cutaneous flap in a patient who underwent salvage laryngopharyngectomy.

in clinically node-negative patients, especially in patients who have received elective irradiation to the nodal basins. It should be noted that a similar philosophy has significant support in the post chemoradiated neck, where surgical salvage treatment is planned based on imaging findings. Following a comprehensive review of the question, Sanabria et al.[146] offered some recommendations on the subject. In patients with glottic tumours classified originally as early cancer (T1–2) and who recur with tumours of similar stages (rT1–2), an observation policy for the untreated neck is appropriate, if the imaging shows no neck disease. For recurrent early supraglottic cancers, it is very likely that the neck would have been previously treated and a neck dissection is not warranted if there is no clinical or radiological evidence of neck disease. For more advanced laryngeal tumour recurrences (rT3–4), the recommendation was for elective neck dissection (bilateral for supraglottic cancers), particularly if previous radiation fields did not include the lateral neck. It should be noted that if a free-flap reconstruction is to be performed for pharyngeal reinforcement or augmentation, limited dissection of at least one side of the neck may be necessary to site the microvascular anastamosis.

RARE CANCERS (SW)

While the majority of tumours of the larynx are squamous cell carcinomas a number of other pathologies can occur in the larynx. These include neuroendocrine, connective tissue, salivary gland, epithelial cell, malignant melanoma and immune cell derivatives. In a review of these in both the supraglottis and glottis the majority were in men in their 7th decade of life. In the supraglottis, neuroendocrine, small cell and lymphomas predominated. While in the glottis spindle cell, sarcomas and small cell tumours were more common. Limited data exist due to the relative rarity of these tumours to guide treatment.[147]

Neuroendocrine tumours are the most common non-squamous tumours of the larynx. Current consensus classifies them into paraganglioma, typical carcinoid tumour, atypical carcinoid tumour and small cell neuroendocrine carcinoma. Precise diagnosis is essential as natural history treatment and prognosis vary depending on the category. Surgery is the mainstay of treatment for typical and atypical carcinoid. Atypical carcinoid is considered more aggressive and therefore elective neck dissection is advocated, and adjuvant CRT should be considered. Paraganglioma is a benign entity and can typically be treated with surgery alone with an excellent prognosis. Small cell neuroendocrine carcinoma carries a poor prognosis (<5% 5-year survival) and surgery has been shown to offer no benefit when compared to CRT alone.[148]

Primary laryngeal lymphoma is extremely rare, and there is debate in the literature as to whether it constitutes an unusual presentation of non-Hodgkin lymphoma rather than being a separate disease entity. Treatment is targeted at the histological subtype of the lymphoma rather than the site at which it presents, and therefore surgery has a very limited role.

Laryngeal small-cell carcinoma is a subtype of the extrapulmonary small-cell carcinomas (EPSCC) carrying a generally poor prognosis when compared to pulmonary small cell carcinoma. EPSCC is usually a fatal disease, with a 13% 5-year survival rate. In a small percentage of patients, surgery can be curative if the tumour is small and confined to the organ of origin. Because of the poor overall outcome, one needs to consider the possible use of adjuvant chemotherapy in appropriate circumstances if surgery is to be employed. In most patients with limited disease, the combination of chemotherapy and radiation as the primary treatment can be as effective as surgery. EPSCC is responsive to commonly employed regimens for small-cell lung carcinoma; however, the responses are short-lived. The extent of disease at diagnosis represents the most sensitive predictor of survival.[149]

LARYNGEAL CANCER IN YOUNG AGE GROUPS

Laryngeal cancers in young people are much less common. In the US it is estimated that 26% of laryngeal cancers present under the age of 40.

There are a number of studies considering head and neck cancer in young adults, typically defined as younger than 45. In general, this age group has a lower proportion of alcohol drinkers and or smokers. For many subsites there appears to be an inverse relationship with fruit and vegetable intake.[150, 151] HPV infection may be more important in this age group, although epidemiological studies thus far have not shown a strong link as they have in oropharyngeal cancer.

A higher proportion are associated with genetic abnormalities, such as Fanconi's anaemia (FA), than in the older cohort. FA is a rare autosomal recessive inherited cancer syndrome is associated with defects in DNA repair. It is clinically characterized by congenital malformations, progressive bone marrow failure, and increased incidence of malignancies, especially acute myeloid leukemia and squamous cell carcinomas of the head and neck (HNSCCs). On a cellular level, typical features of the disorder are a high degree of genomic instability and an increased sensitivity to bi-functionally alkylating agents. Cisplatin-based chemotherapy, in combination with RT cannot be used in FA patients due to their propensity for increased toxicity. Surgery is the most important treatment option for HNSCC in FA patients, who also merit frequent screening for early detection of malignancies.[152]

Infection with the human immunodeficiency virus (HIV) has been positively linked with rare malignancies of the head and neck, such as Kaposi's sarcoma (KS), non-Hodgkin lymphoma, and more commonly squamous cell carcinoma. Head and neck involvement of KS is not unusual. However, laryngeal involvement is rare. Most patients have had AIDS-related KS, although HIV-negative persons with laryngeal KS have also been

noted. Of the AIDS cases reported, the majority (91%) were males of mean age 35 years (range 24–56 years), with advanced HIV disease, that were antiretroviral naïve. This may explain why many afflicted persons also had oropharyngeal, as well as cutaneous and visceral KS. Care should be taken when performing biopsy of these lesions as they are very vascular and can be associated with brisk, potentially fatal bleeding. Therapeutic options for this scenario include low-dose local irradiation, intralesional chemotherapy or laser ablation, and systemic therapy, particularly if there is disseminated KS. For laryngeal KS lesions producing acute or impending airway obstruction urgent intervention is necessary. However, depending on the location of the KS lesion, tracheostomy may contribute to mortality as a result of fatal haemorrhage. Therefore, cricothyroidotomy has been recommended by some authors as an alternative approach to life-threatening emergencies in this setting.[153]

It is rare to see these cancers in children (those under 18), however cases do occur, particularly in those with a genetic cause. Management will be multidisciplinary and should additionally involve the paediatric oncology teams. Treatment principles however are generally the same, and should be led by tumour histopathological type and subsite, as for adult patients.

KEY POINTS

- A binary grading system for laryngeal dysplasia is currently espoused.
- Management of laryngeal precancer is driven by consensus and logistics as high-level evidence is lacking.
- Transoral laser microsurgery is the preferred option for most T1a and some T1b lesions, based on clinical and cost-effectiveness analysis.
- For locally advanced tumours that have not caused laryngeal dysfunction, radiation therapy allows organ preservation, which is supported by high-level evidence.
- Good evidence exists to support local laryngectomy for T4a disease.
- Management of the neck should be based on the site and the stage of the primary tumour, the presence or absence of disease in the neck, with the treatment modality influenced by the treatment planned for the primary site.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: surgical voice restoration, laryngectomy and tracheo-oesophageal speech.

INTRODUCTION

Enormous advances in the treatment of cancer of the larynx have occurred since Theodor Billroth performed the first successful laryngectomy in Vienna in the year 1873.[1] Whilst removal of the malignancy and preservation of life remain the primary goal, attention is now directed at achieving functional outcomes for breathing, swallowing and speech to provide optimal quality of life. Management decisions are best made within designated head and neck units by the multidisciplinary team (MDT) of professionals who pool their individual specialist knowledge for the benefit of the patient. The weekly MDT meeting provides the forum for discussion of cases allowing all members to contribute to patient management.[2] Core MDT members include the surgeon, clinical oncologist, pathologist, plastic surgeon, staff nurse, dietician, speech and language therapist (SLT), clinical nurse specialist (CNS), physiotherapist and psychologist.

BACKGROUND

In the presence of advanced disease or recurrence following initial treatment with radiotherapy or chemoradiotherapy, total laryngectomy is often the only available treatment option, with the intent to remove the entire larynx and the cancer. This is major life-changing surgery and the news is almost never welcome. Patients and their close relatives need time and the opportunity to ask questions, and should be offered counselling to understand the considerable implications of a total laryngectomy;[3] these include the formation of a permanent neck stoma, changes to breathing, swallowing and of course the loss of the vocal cords and normal voice production (**Figures 15.1** and **15.2**). This role generally falls to the SLT, the CNS or both. It can take repeated explanations aided by information sheets, diagrams, photos and videos before patients absorb the information. They should be offered the opportunity to also meet other carefully selected laryngectomies. Hence, the rehabilitation starts prior to surgery and enables patients to have realistic expectations.

In addition to the above, counselling should also include detailed information about the various options for voice production. These are oesophageal speech, the artificial larynx and surgical voice restoration (SVR). The latter involves the creation of a tracheo-oesophageal puncture (TEP) at the time of primary surgery or at a later date. The TEP is a fistula through the posterior tracheal wall into the oesophagus. This TEP is stented open with a Foley catheter or a one-way valve made of medical grade silicone. Air can pass into the oesophagus for voice production when the stomal exit is temporarily covered, but food and fluid are not aspirated (**Figure 15.3**).

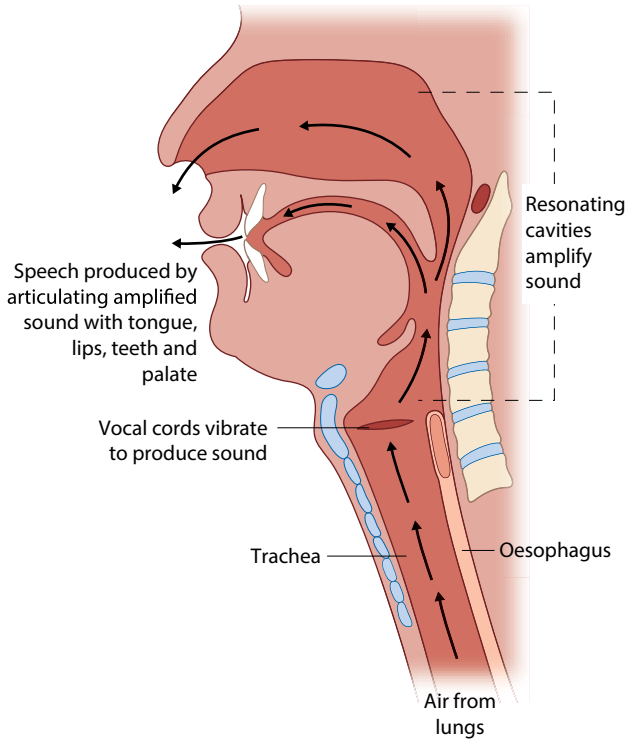

Figure 15.1 Laryngeal voice production.

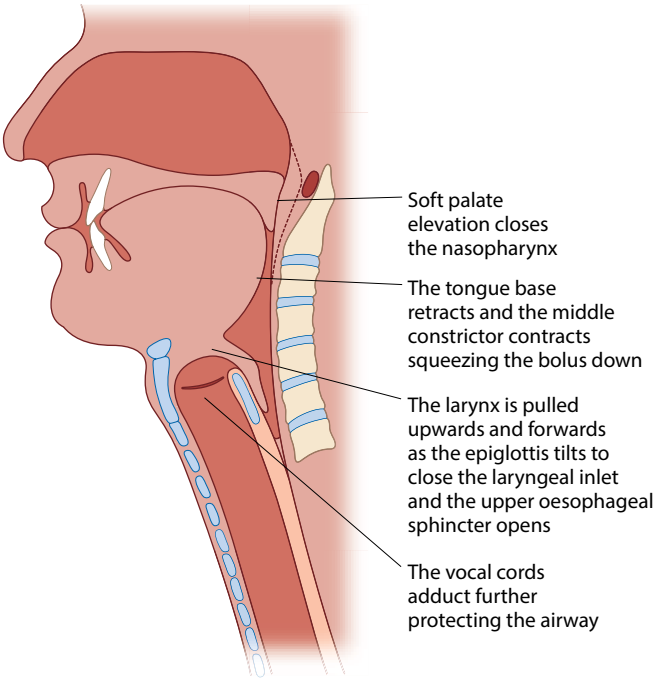

Figure 15.2 Normal laryngeal swallow.

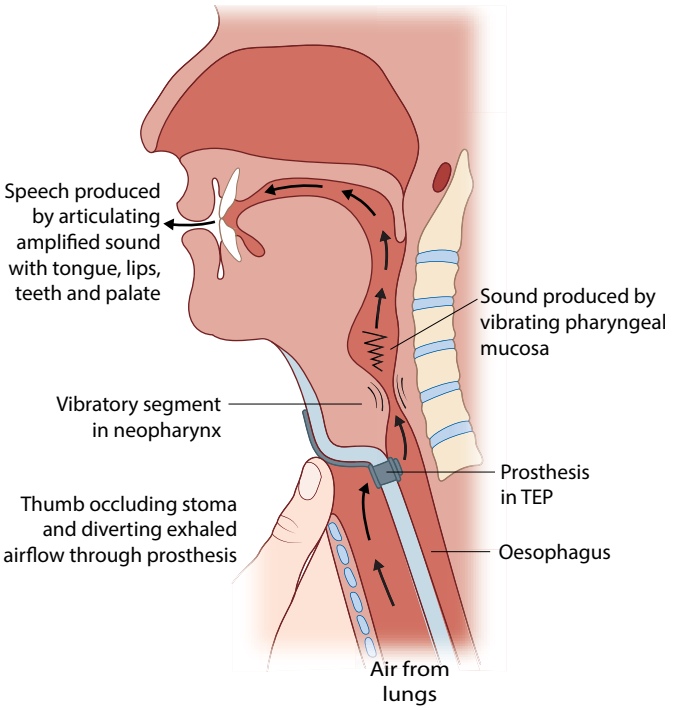

Figure 15.3 Surgical voice production.

SURGICAL TECHNIQUE TO OPTIMIZE SPEECH AND SWALLOW

Tumour resection

Of prime importance is the need to resect all diseased tissue to provide good oncological results. There are, however, a number of fundamental steps that improve the voice and swallowing results and these should be undertaken if they do not compromise the oncological resection.

The laryngectomy is carried out in the usual fashion conserving as much pharyngeal mucosa as possible, particularly over the postcricoid region, the piriform fossae and the valleculae, provided safe clearance from the tumour is obtained. The thyropharyngeus and cricopharyngeus muscles should be dissected off the thyroid laminae on both sides preserving as much muscle as possible (**Figure 15.4**). For hypopharyngeal tumours the mucosa of the uninvolved piriform fossa is carefully preserved to minimize the need for flap reconstruction. Ideally a transverse, unstretched mucosal width of at least 6 cm at the narrowest point is necessary to enable adequate swallowing and effortless tracheo-oesophageal speech. Augmentation of the pharynx with a flap is preferable if the residual mucosal strip is less than 6 cm to avoid pharyngeal stenosis and functional impairment. Irrespective of the available mucosal width, vascularized tissue reconstruction is preferred in the setting of the salvage laryngectomy after chemoradiotherapy, as this strategy reduces the risk of pharyngocutaneous fistula formation by a third.[4]

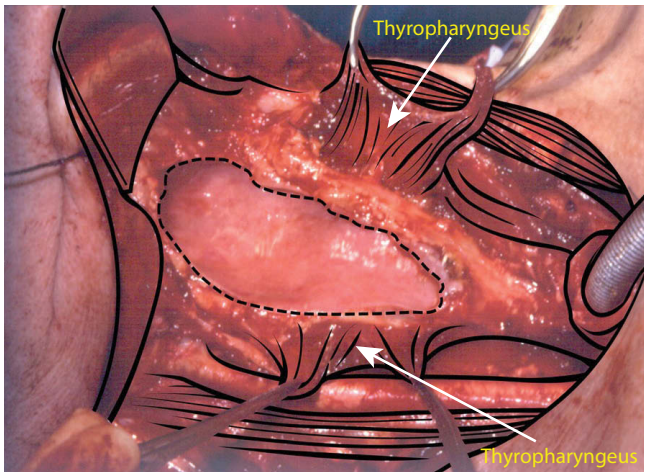

Figure 15.4 Preservation of thyropharyngeus for later muscle repair.

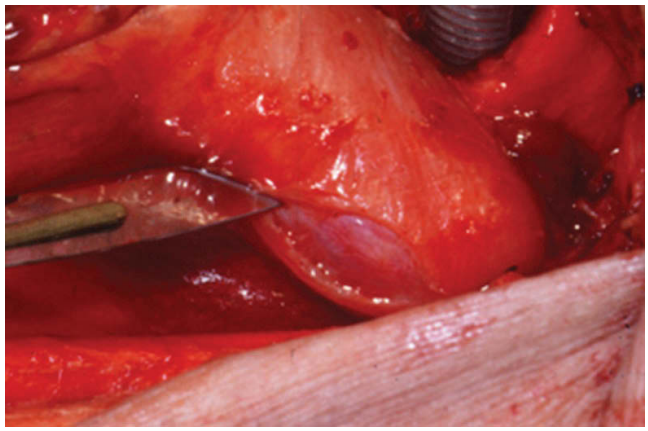

Figure 15.5 Myotomy through upper oesophageal muscles to underlying mucosa.

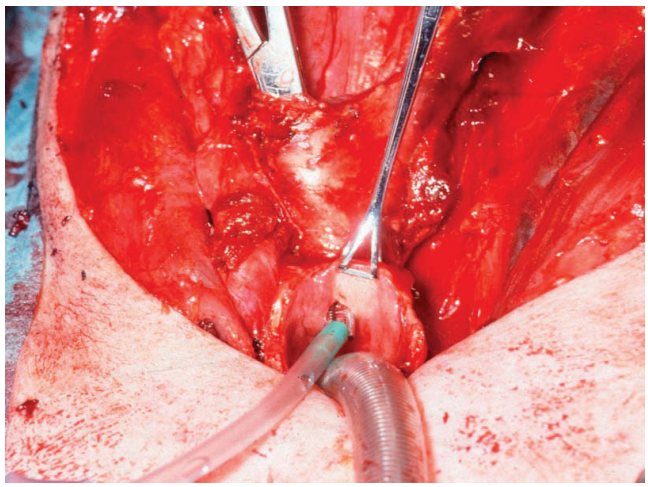

Figure 15.6 Tracheo-oesophageal puncture.

Cricopharyngeal myotomy

Once the larynx is removed, a myotomy of the upper oesophageal sphincter is carried out. This is important to avoid hypertonicity and spasm of these muscles during attempted phonation, and to allow expansion of the upper oesophagus providing an air 'reservoir' below the pharyngo-oesophageal (PE) segment. Hypertonicity or spasm will interrupt the flow of air to a varying degree, restricting or completely stopping voice production. This spasm appears to be caused by reflex contraction of cricopharyngeal and constrictor muscles when the upper oesophagus is distended with air, and is a cause of TEP speech failure in 10–12% of patients.

A short posterior midline myotomy is carried out with a scalpel over a distance of 4–5 cm starting from just below the level of the TEP site, extending cranially into the fibres of the thyropharyngeus. This divides the circular muscle fibres in the upper oesophagus and the cricopharyngeus. It is important that all muscle fibres are cut (**Figure 15.5**). It is unclear whether assessment of the upper oesophageal sphincter with a finger can predict the development of spasm and there seems little contraindication to doing a myotomy on all patients as it may also improve swallow. One of the conclusions of the European multicentre audit of speech and swallowing results after laryngectomy was that myotomy improved voice outcomes.

A unilateral pharyngeal plexus neurectomy has been advocated in the past as an alternative method of constrictor relaxation. Three to five branches of the plexus entering the lateral wall of the pharynx are exposed and identified with a nerve stimulator before division with cautery. This technique has not gained widespread use.

Tracheo-oesophageal puncture

The puncture is positioned in the midline about 10–15 mm below the cut edge of posterior tracheal wall. The tip of a pair of curved artery forceps is inserted through the pharyngeal defect and advanced into the upper oesophagus just as far as the puncture site, tenting up the mucosa. A scalpel is used to incise minimally and horizontally through the mucosa and muscle onto the tip of the forceps, which are then advanced into the tracheal lumen and opened to grasp the tip of a 14 NG tube or Foley catheter (**Figure 15.6**). The forceps and the catheter are then withdrawn through the fistula tract and the tip of the catheter is passed distally down the oesophagus. The catheter is anchored to the skin above the stoma at the end of the procedure. Absorbable sutures between the oesophageal wall and the posterior aspect of the trachealis on either side of the proposed position of the puncture secures the party wall and avoids inadvertent separation. An alternative technique is to insert a valve at the time of surgery through the newly created puncture.

Pharyngeal closure

The pharyngeal defect can be closed using an interrupted or continuous absorbable mucosal suture; A horizontal closure is considered to produce a wider pharynx above

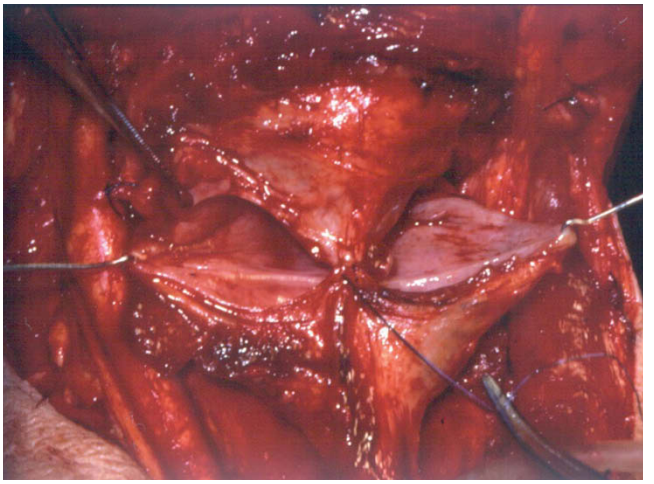

Figure 15.7 Horizontal pharyngeal closure.

the PE segment and may improve resonance for speech (**Figure 15.7**).[5] An alternative technique is the 'T' closure.

Based on how much constrictor muscle is available, an interrupted closure of the muscle is appropriate It is hypothesized that the constrictor muscle closure creates a suitable, 'tonic' PE segment at the optimal site in the pharynx with a good reservoir below it and a wide resonating pharyngeal segment above.[6] Whilst the upper oesophagus needs to be relaxed so that it does not respond to air being injected through the valve by going into spasm, the neopharynx or PE segment needs to provide an area where the mucosa is in apposition to allow it to vibrate efficiently and produce strong voice. Repairing the thyropharyngeus provides this vibratory segment. Conversely, if the muscles or PE segment wall are hypotonic (e.g. after total pharyngolaryngectomy and reconstruction or if thyropharyngeus is not repaired) the voice will be weak because there is minimal or absent muscle in the wall to create a PE segment. However, others[7] have recommended 'half-muscle closure technique', where only one side of the remnant constrictor muscles is used to reinforce the primary closure, with the advantage of reducing pharyngoesophageal spasm. Significant resection of the hypopharynx will necessitate a flap reconstruction.

Repair of the suprahyoid muscles

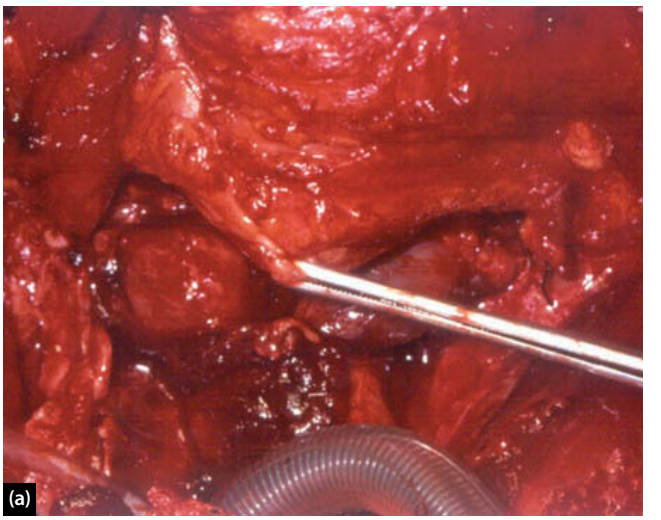
Following repair of the thyropharyngeus it is important to suture the suprahyoid muscles down to the thryopharyngeus. This strengthens the mucosa above the repair, so avoiding a pseudoepiglottis and anterior pouch that may affect swallow, and also reattaches the middle constrictor and other suprahyoid muscles which are important in the swallow reflex (**Figure 15.8**).[8]

Stoma reconstruction

The size, shape and contour of the stoma and surrounding skin are important to aid digital occlusion of the stoma and help ensure optimal adhesion of the base plate for the tracheostoma valve housing. In order to avoid unnecessary tracheal retraction, care should be taken during the laryngectomy not to transect the trachea too low; if necessary, the margins of the trachea can be sutured to the medial margins of the sternomastoid muscle to secure it near the skin. If the tendons of the sternomastoid muscle are prominent, they can be safely divided to ensure a flatter area around the stoma for better base plate adhesion.

Post-operative care

Post-operatively the patient must be fed enterally either naso-gastrically or via a catheter placed through the TEP or the prosthesis, and then directed into the stomach. After an appropriate healing period, which may be significantly longer after chemoradiotherapy, oral feeding is reintroduced, beginning with water and quickly building



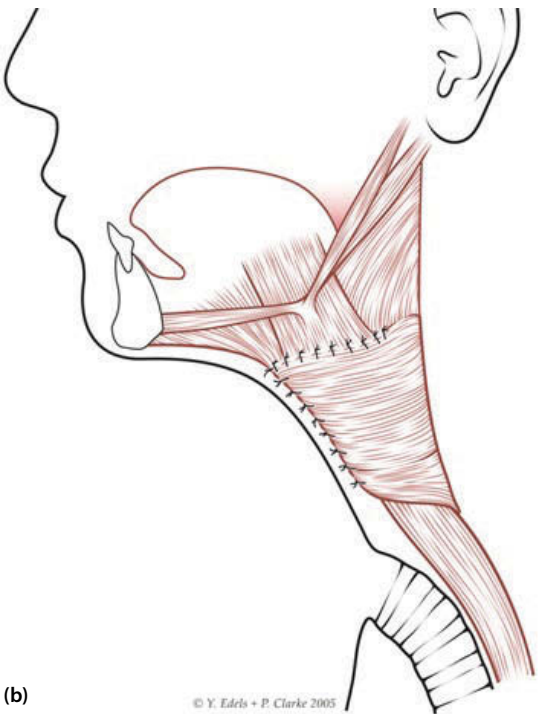


Figure 15.8 Closure of the suprahyoid muscles.

to pureed food, soft food and ultimately a normal diet. Work on voice production begins when adequate healing has taken place. If phonation begins too early, excess pressure during voicing can lead to suture line breakdown.[9] Patients not yet fitted with a voice prosthesis must be sized and fitted at this point. There is increasing support for early feeding, commencing as early as the second post-operative day in patients who have undergone laryngectomy as the primary treatment, as there is no good evidence that this increases the risk of pharyngocutaneous fistula formation.[10]

SECONDARY VOICE RESTORATION

The technique of TEP with prosthetic valve and voice restoration was originally developed for those patients who had failed to achieve adequate oesophageal speech. However, present day indications are mainly for patients who have complex resections and reconstructions, or those undergoing salvage surgery.

Laryngectomies need a tonic PE segment to provide a satisfactory vibratory source for tracheo-oesophageal speech. The first step in assessing patients who present for secondary voice restoration after laryngectomy, when they have failed oesophageal speech acquisition, should be an assessment of PE segment tonicity. A preliminary videofluoroscopy will determine whether it is necessary to inject botulinum toxin into the cricopharyngeus. If the end tracheostoma is too narrow for valve maintenance, a stoma revision may also be indicated at the time of the TEP. The patient should be judged to have adequate lung function to open the valve and produce voice.

Timing of valve placement varies, with the choices being placement of a sterile prosthesis either during surgery or post-operatively once healing has occurred. Either way, the length of the TEP must be carefully measured with a sizing gauge and the overall form and function of the site assessed before selecting an appropriate prosthesis from the extensive range available. One size does not fit all; thus the Blom-Singer and Provox prostheses range include valves of different diameters, lengths, opening pressures and design as well as custom-made varieties, so rarely is it not possible to find an appropriate one. Ex-dwelling prostheses can be self-changed by the patient or carer, freeing the patient from regular hospital attendance, while indwelling prostheses are to be changed by the healthcare professional only, and can remain *in situ* over extended periods.

HEAT AND MOISTURE EXCHANGE

Essential areas for rehabilitation include respiration, swallowing and voice production. Nasal functions of air humidification, filtration and warming are lost when air is taken in via the stoma.[11] The loss of the height from nose to stoma reduces air resistance within the lungs leading to less optimal gaseous exchange. A heat and moisture exchanger (HME), works as an artificial nose, reducing mucus over-production due to loss of nasal humidification, warming and filtering the air thus reducing coughing and assisting sleep. The HME consists of a small filter contained in a cassette, attached in front of the stoma either by a base plate stuck to the parastomal skin or inserted into a laryngectomy tube. Different designs exist, with specifications for daily activity, sleep and exercise. Ideally, an HME should be provided within a few days of surgery to minimize the risk of becoming accustomed to the reduction in respiratory pressure, which can be difficult to re-educate later. Failure to use an HME is mostly related to getting it to attach and remain attached. Difficulties may be due to post-treatment effects on the neck tissue or because the sternocleidomastoid muscles were not divided at laryngectomy to provide a flattened parastomal area for successful attachment. The increased need for pedicled or free flap reconstruction of laryngectomy defects after chemoradiotherapy also distort the anatomy around the stoma making the use of standard base plates difficult. Products exist to clean, moisturize and assist with better base plate attachment, often after a certain amount of trial and error. Several randomized studies have shown clear benefit from HME use in reducing pulmonary symptoms and improving lung function.[12, 13]

SWALLOW

Removal of the hyoid bone and larynx during laryngectomy and separation of the trachea and oesophagus into discrete systems destroys the normal sequential muscular swallow sequence. All laryngectomies have a modified swallow, and the differences between laryngeal and alaryngeal swallow are identified in **Table 15.1**. The key aspects of pharyngeal reconstruction that contribute to a good swallow are discussed above.

SPEECH

Oesophageal speech requires air to be taken into the top of the oesophagus either by injection or inhalation,[14] and then forced out again causing the newly reconstructed pharynx, the PE or vibratory segment, to vibrate in response to the flow of air and produce sound. As in normal laryngeal voice production, this sound is amplified by the resonating cavities above and modified into speech by the articulators, tongue, teeth, lips and soft palate. The electrolarynx produces a sound that is then transmitted into the resonating cavities either by direct pressure of the machine against the skin of the upper neck or through a tube directly into the oral cavity. SVR has largely replaced these other methods, being easier to learn and producing better quality voice (**Table 15.2**).

SVR voice is produced when the stoma is temporarily sealed by a finger placed in front of it or over the HME cassette. Later, the patient may use an adjustable tracheostoma valve (ATSV) allowing hands free speech (**Figure 15.9**). The ATSV seals when the expiratory breath

TABLE 15.1 Differences between laryngeal and alaryngeal swallow

	Oral	Pharyngeal	Laryngeal	Top of oesophagus	Oesophagus
Laryngeal swallow	Lips seal. Teeth, tongue, hard and soft palate form bolus and pass it to the back of the mouth	Soft palate elevates to close nasal port. Back/base of tongue and posterior pharyngeal wall close together. Stripping action propels bolus onward. Swallow sequence fires	Suprahyoid's contract, elevating and tilting larynx forwards and tucking it under the tongue. This action also pulls on the cricopharyngeal muscles helping them to relax and open the top of the oesophagus. The epiglottis biomechanically tilts over, sealing the tracheal entrance and the laryngeal sphincters close together to protect the airway.	Oesophageal entrance opens. Negative pressure created as oesophagus widens helps to draw the bolus in. The bolus enters the oesophagus.	Gravity and the sequential peristaltic wave carry the bolus to the stomach. Lower oesophageal sphincter relaxes and opens to allow bolus to pass.
Alaryngeal swallow	Lips seal. Teeth, tongue, hard and soft palate form bolus and pass it to the back of the mouth.	Soft palate elevates. Tongue back/base approximates posterior pharyngeal wall. Partial/reduced stripping action of posterior pharyngeal wall due to surgery and denervation. Bolus transits pharynx under gravity and power created here. Swallow sequence follows.	Reattached suprahyoids contract, pulling on the top edge of the reconstructed thyropharyngeus muscles and possibly also helping to lift the reconstructed pharynx. Reconstructed thyropharyngeus (and possibly cricopharyngeus) are stretched and relax, helping to open the entrance to the oesophagus. Bolus, under reduced pressure from tongue base/posterior pharyngeal wall contraction, exerts pressure from above. Reduced stripping action together with gravity move bolus on.	Oesophageal entrance opens. Bolus under pressure from above and gravity enters the oesophagus.	Gravity and the sequential peristaltic wave carry the bolus to the stomach. Lower oesophageal sphincter relaxes and opens to allow bolus to pass.

TABLE 15.2 Comparison of speech production before and after laryngectomy

Physical requirements	Normal laryngeal voice production	Oesophageal speech production	Surgical voice production
Initiator	Moving column of air from the lungs	Moving column of air from the oesophagus	Moving column of air from the lungs
Vibrator	Vocal cords	Vibratory/pharyngo-oesophageal (PE) segment	Vibratory/pharyngo-oesophageal (PE) segment
Resonators	Resonating cavities: nose, mouth, pharynx	Resonating cavities: nose, mouth, pharynx	Resonating cavities: nose, mouth pharynx

is strong enough to close its valve and remains shut as long as this pressure is maintained. Once the air pressure falls the ATSV reopens and a new breath is taken in. Regardless of method, once the stoma is sealed, air passes via the voice prosthesis into the oesophagus making the walls of the vibratory segment (i.e. the area between the top of the oesophagus and the base of the pharynx) vibrate to produce sound. This basic tone is again amplified by the resonating cavities above (pharynx, nose and mouth) and modified into speech by the articulators. Outcome measures for post-laryngectomy speechg are evaluated by Deore et al.[15]

TONICITY

For optimal outcomes, the newly created reconstructed/vibratory segment must dilate on swallow and vibrate for voice. This area must be surrounded by tonic muscles to produce optimum voice.[16] If the neopharynx is too loose (hypotonic), the swallow is functional but voice quality is low, weak, whispery and often wet; if it is too tight (hypertonic), swallowing requires increased pressure and the voice is high pitched, effortful and difficult or impossible to maintain.

Hypotonicity is managed using digital pressure against the outside of the neck, artificially increasing the tone. Less severe hypertonicity is managed with a low opening pressure prosthesis but when insufficient, other measures must be considered.

Stretch receptors located within the muscles at the top of the oesophagus respond to being dilated by clamping down, preventing the free passage of air for voice production.[6, 17] By interfering with this mechanism hypertonicity and spasm can be avoided. This is effectively managed at the time of surgery by performing a myotomy[18–20] or neurectomy.[21] A myotomy should cut through all the muscles in the lower third of the reconstructed segment extending down to the level of the puncture (**Figure 15.10**). The upper two-thirds of the vibratory segment is spared leaving these muscles tonic for good voice production.

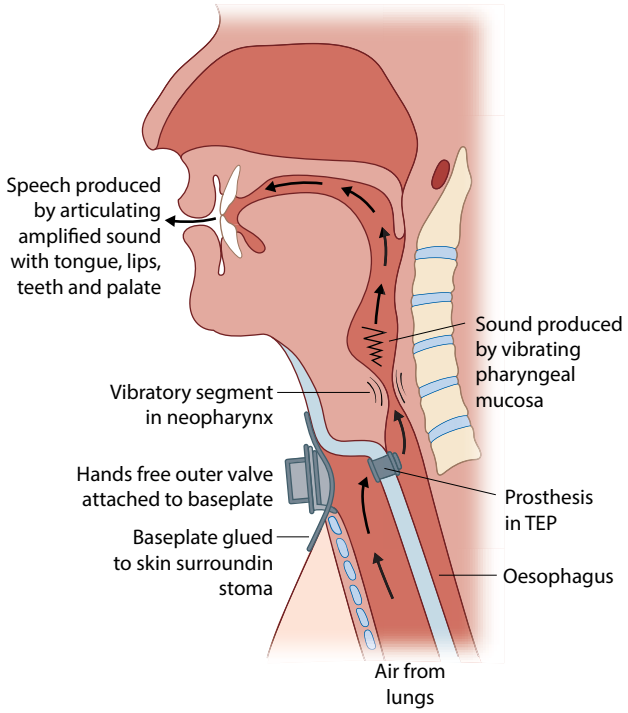

Figure 15.9 Hands-free surgical voice production.

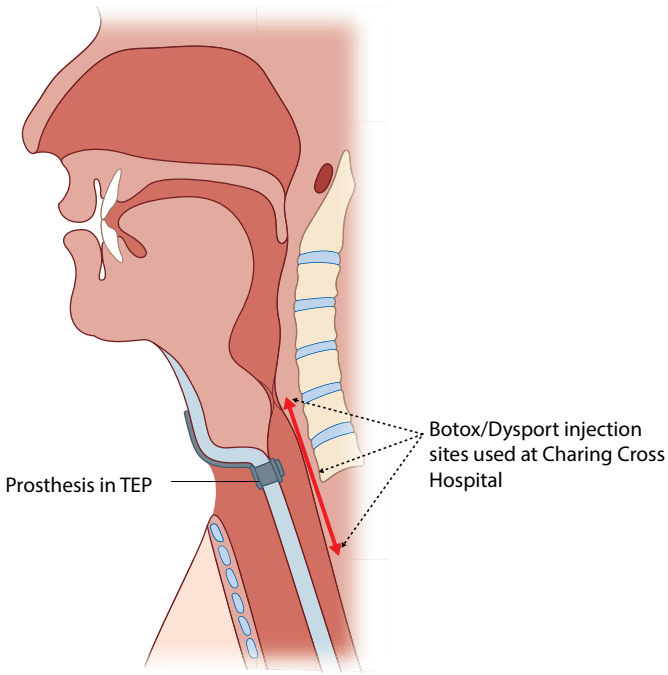

Figure 15.10 The myotomy is made posteriorly from the level of the cricopharyngeus down to below the level of the tracheo-oesophageal puncture. Botox/Dysport injection sites used at Charing Cross Hospital.

Hypertonicity/spasm that develops post-operatively can be managed with an open myotomy or chemical neurectomy. Since the introduction of botulinum toxin,[22] myotomy involving reopening the neck and dividing all the muscles including those of the reconstructed/vibratory segment is rarely performed, as it may cause hypotonicity and involves the risk of perforation.

A full videofluoroscopic assessment of swallow and voice should be carried out followed by a lignocaine injection to confirm the diagnosis.[23] Botulinum toxin is injected unilaterally at three sites along the same short myotomy line (**Figure 15.10**). The dosage administered is influenced by the degree of hypertonicity, neck fibrosis and stricture, whether a primary myotomy was performed and the surgical reconstruction. Injection of botulinum toxin can be repeated, though a single treatment is often sufficient to allow continued tonic voice.

PROBLEM-SOLVING

Problems occur both with the TEP and prosthesis.

Candida albicans

Candida spp. thrive in warm moist environments with a pH near 6.5 (e.g. oesophagus).[24, 25] A voice prosthesis acts as a foreign body within the TEP, becoming covered by a biofilm of bacteria and yeasts, forming plaques (**Figure 15.11**). *Candida albicans* interferes with the prosthesis valve mechanism, causing leakage and aspiration or increasing airflow resistance such that the prosthesis becomes non-functional.[24, 26–28] *Candida* spp. can also develop on the outside of the prosthesis burrowing into local tissue and causing an allergic type reaction (granulation tissue; see 'Granulation' below) (**Figure 15.12**).[24]

Figure 15.11 New prosthesis and one covered in a biofilm bacteria and yeats.

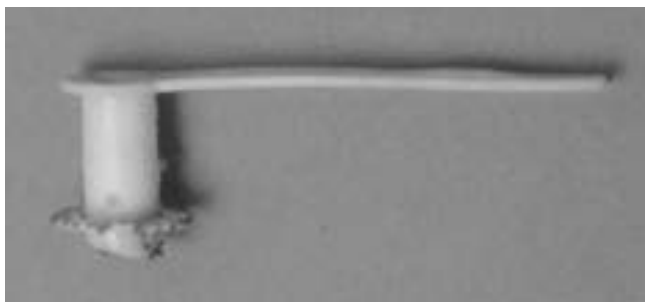

Figure 15.12 Candida species adherent to prosthesis.

Patients should brush and flush their prosthesis daily *in situ*,[29] possibly including a liquid antifungal (e.g. nystatin).[30] Exdwelling prostheses should be regularly removed, washed and sterilized overnight in 3% hydrogen peroxide.[31] If the estimated prosthesis lifetime[32] is too short, the prosthesis should be sent for mycological analysis and the results will indicate the appropriate antifungal to prescribe. Prostheses impregnated with antifungals are available at a cost. Fungal resistant materials are being developed;[33] meanwhile, dietary adjustment including the addition of probiotics should be considered.[34–36]

Granulation

Granulation is connective tissue thought to occur as an acute inflammatory response to a complex interaction between the prosthesis, *Candida* spp and the patient's tissue.[24] Removal of the voice prosthesis can cause bleeding and the open wound acts as a source for further infection. Small areas can be cauterized using a silver nitrate stick but larger areas require surgical removal (**Figures 15.13** and **15.14**). Prosthesis function may be disturbed and lead to TEP closure. Managing the *Candida* colonization is essential to prevent it recurring.

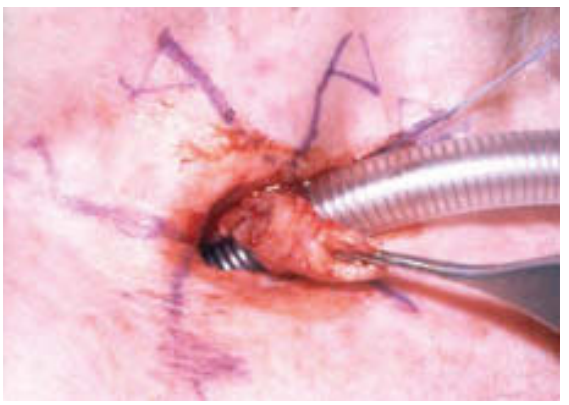

Figure 15.13 Excess granulation tissue being removed from tracheo-oesophageal puncture site.

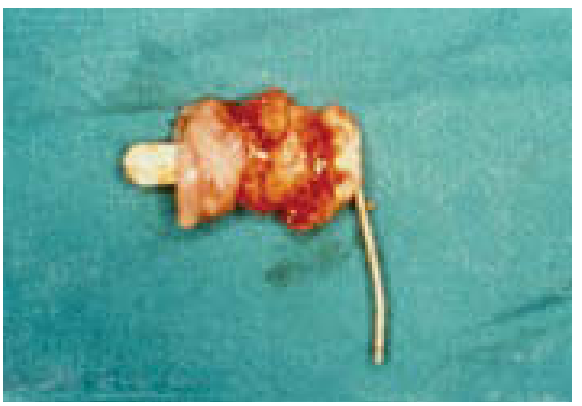

Figure 15.14 Granulation tissue removed from around prosthesis.

Reflux

Reflux causes oesophagitis and heartburn, and encourages *Candida* spp growth, granulation tissue formation and TEP dilation.[25] Its influence has been under-recognized.[25] Management of reflux is discussed in detail in Chapter 77, Reflux disease.

Central leakage

Candida interfering with prosthesis valving function is the most common cause of prosthesis central leakage.[27] This results in aspiration and increases the risk of chest infections. Other causes include prosthesis fouling against the posterior oesophageal wall while swallowing or negative pressure created within the oesophagus leading to inappropriate valve opening. Alternative prostheses with more appropriate sizes should be selected.

Peripheral leakage

This happens when the tissue around the TEP no longer beds down snugly onto the prosthesis barrel and allows saliva or liquid to penetrate around the prosthesis and hence aspirated into the trachea causing coughing or chest infections. Peripheral leakages should be managed prophylactically, anticipating and preventing this problem.

Reported reasons for peripheral leakage include:

- an oversized prosthesis pistoning within the TEP, suctioning the bolus through[31]
- a thinned or weakened party wall (below 8 mm), associated with a wider diameter prosthesis *in situ*[37, 38] often in patients with concurrent comorbidity (e.g. diabetes).[39]

Prevention can be achieved by the following measures:

- minimizing trauma by avoiding dilation of the TEP[37] and reducing the number of changes
- when changing the prosthesis, one option is to cut the *in situ* prosthesis in half, removing the anterior portion and allowing the posterior portion to pass out through the patient[40]
- hand-load the prosthesis into a smaller gel cap for placement.

Additional options include:

- injecting a filler to bulk the party wall[39, 41]
- using successively smaller diameter catheters to shrink the TEP (e.g. from a 20 FG to 16 FG)[42]
- using a snugly fitting extended flange prosthesis to cover the gap (**Figure 15.15**)[39]
- purse string suture procedures, reported to have poor success rates.[43]

Figure 15.15 Extended flange prosthesis and pushing device to help placement into the gelcap.

KEY POINTS

- Management decisions about rehabilitation after laryngectomy should be made within dedicated head and neck units by the multidisciplinary team.
- Surgical voice restoration should be offered to patients undergoing laryngectomy.
- Attention to surgical detail and long-term speech and language therapist input is required to optimize speech and swallowing after laryngectomy.
- Patients should commence wearing heat and moisture exchange devices as soon as possible after laryngectomy.

SEARCH STRATEGY

A search of PubMed with MeSH headings hypopharynx, piriform fossa, postcricoid,posterior pharyngeal wall, tumour, cancer, squamous cell carcinoma, gastric pull up, free jejunal graft, radiotherapy, chemotherapy,Trans Oral Videoendoscopic Surgery,Transoral Laser surgery, pharyngectomy, laryngopharyngectomy, near total laryngectomy in various combinations was carried out.

INTRODUCTION

Hypopharynx is the caudal part of the pharynx, also called laryngopharynx, extending from the hyoid bone to the lower margin of the cricoid cartilage. It is a dynamic conduit between the oropharynx and oesophagus and has three subsites – pyriform sinus, post-cricoid area and posterior pharyngeal wall. Laryngeal and hypopharyngeal cancers are often clubbed together due to their anatomic proximity. However, hypopharyngeal cancers are distinctly different from laryngeal cancers in terms of presentation, management and prognosis.

EPIDEMIOLOGY

Hypopharyngeal cancers are rare, and account for less than 0.5% of all cancers and 3–5% of head and neck cancers.[1–3] They have a large geographical variation, being relatively rare in Eastern Asia, Africa and Northern Europe (incidence under 0.5:100,000) and more common in India, Brazil, Central and Western Europe (incidence of 2.5:100,000). The incidence in India and France are substantially higher at 8–15 cases per 100,000 population in males.[4]

Hypopharyngeal cancers occur in individuals above 50 years of age, with a peak incidence in the sixth and seventh decades.[5] The most common site of origin is the pyriform sinus followed by the posterior pharyngeal wall and the postcricoid area. Pyriform and posterior pharyngeal wall lesions are more common in males, whereas postcricoid cancers are predominant in females.[6–9] The most common histology at this site is squamous cell carcinoma.

SURGICAL ANATOMY

The hypopharynx lies below and behind the base of tongue and larynx. It extends from the level of the hyoid bone to the lower border of the cricoid cartilage. It is comprised of three subsites: pyriform sinus, postcricoid area and posterior pharyngeal wall.

The pyriform sinus is a funnel-shaped lateral channel on either side of the larynx beginning at the level of the pharyngoepiglottic fold. It has a lateral wall which is contiguous with the posterior pharyngeal wall, a medial wall that forms part of the aryepiglottic fold converging into the postcricoid mucosa medially, and opens posteriorly into the lumen of the pharynx.

The pyriform sinus is bound laterally by the thyrohyoid membrane and medially by the aryepiglottic fold. The tumours tend to spread through this membrane beyond the larynx without cartilage destruction, keeping the laryngeal function somewhat intact. This is relevant in treatment planning.

The pyriform apex lies at the junction of the medial and lateral walls, deep and inferior within the pyriform sinus. It is related laterally to the thyroid cartilage, medially to the cricoid cartilage and lies inferior to the paraglottic space. Tumours involving the pyriform apex can easily spread superiorly into the paraglottic area causing vocal cord fixity. Tumours of the pyriform apex are in close proximity to the cricoid cartilage and oncological removal necessitates removal of the cricoid cartilage. This has implications when considering conservation laryngeal surgery. Tumours from the pyriform apex can also escape via the cricothyroid membrane early on beyond the laryngeal framework and need careful evaluation.

The postcricoid area lies behind the larynx and is located below the level of the arytenoid cartilages and extends to the inferior border of the cricoid cartilage. It continues below into the cricopharynx which lies at the upper end of oesophagus. Tumours in this region often involve the cricoarytenoid joints causing vocal cord fixity and/or aspiration. Being a junctional region, obstruction to the passage of food occurs early on and tumours often extend into the oesophagus inferiorly, mandating evaluation of the lower extent of tumour spread.

The posterior pharyngeal wall is the part of the hypopharynx between the lateral walls of the pyriform sinuses extend from the hyoid above to the level of the arytenoids below. It is separated from the prevertebral muscles by the prevertebral fascia. Tumours in this region can spread in either direction and even involve the prevertebral fascia and muscles early on in their spread.

The wall of the hypopharynx consists of four layers – 1) lining formed by non-keratinized stratified squamous epithelium; 2) pharyngobasilar fascia; 3) muscular layer formed by the lower fibres of the middle constrictor and the inferior constrictor muscles and 4) buccopharyngeal fascia. The hypopharynx derives its major blood supply from the superior thyroid arteries along with collaterals from the lingual and ascending pharyngeal vessels. Care should be taken not to devascularize the remnant pharynx during surgery to avoid pharyngocutaneous fistulae. Motor and sensory supply is provided by the pharyngeal plexus, formed by branches of the glossopharyngeal and vagus nerves. The vagus nerve via Arnolds nerve provides sensory innervation of the external auditory canal and is responsible for referred otalgia in hypopharyngeal cancers. Further description of the hypopharyngeal anatomy can be seen in Chapter 58, Anatomy of the larynx and tracheobronchial tree.

The hypopharynx has a rich lymphatic drainage (**Figure 16.1**). The pyriform sinuses drain to the deep cervical chain – the jugulodigastric and jugulo-omohyoid nodes. The pyriform sinus apex as well as postcricoid area drain into the paratracheal nodes while the posterior pharyngeal wall drains into the retropharyngeal nodes.[10] Careful evaluation of the tumour location and its draining lymph nodes is important in treatment planning in context of lymph node dissection and radiation therapy planning (**Figure 16.1**).

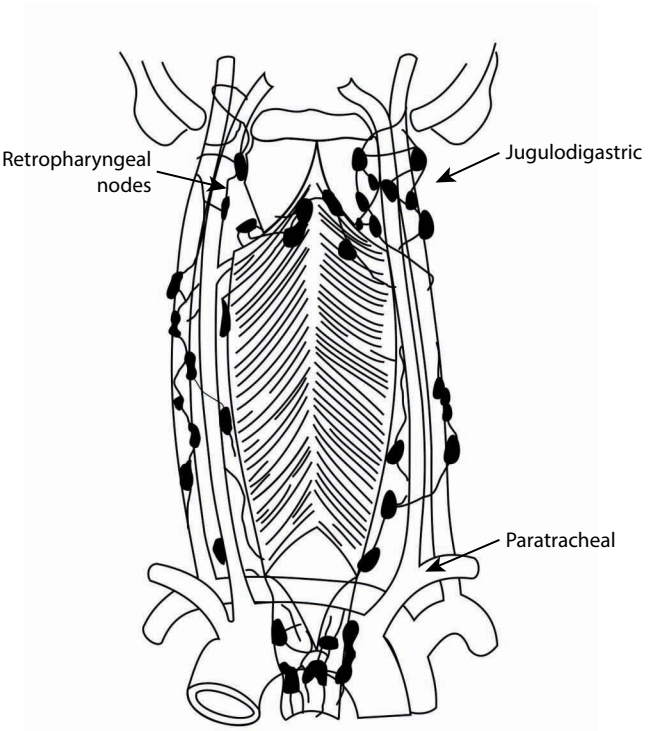

Figure 16.1 Lymphatic drainage of the hypopharynx.

AETIOLOGY

Hypopharyngeal cancers have multifactorial aetiology, predominantly associated with tobacco and alcohol usage. Air-cured tobacco is associated with a higher risk than the flue-cured one of developing laryngo-pharyngeal cancer.[11] Current smokers have a 8.53 higher incidence rate as compared to never smokers.[12] Early initiation of smoking and increase in the number of cigarettes consumed per day increases the cancer risk.[4] There is also a dose–response relationship with bidi smoking;[13] a multicentric case-control study showed bidi smoking to be a strong risk factor for developing hypopharyngeal cancer (odds ratio – 6.8) and supraglottic cancer (odds ratio – 7.5).[14] Smoking cessation is important as it decreases the risk of developing head and neck cancers.[15] Alcohol consumption with direct and indirect carcinogenic actions is also associated with hypopharyngeal cancers. Alcohol not only acts as a solvent for carcinogens like tobacco but also makes the mucosa more permeable to them. Wine, beer and liquor have similar risk of developing head neck cancers.[13, 16–18] There is a dose–response relationship between alcohol intake and

hypopharyngeal cancer[19] with a meta-analysis showing heavy drinkers (>4 drinks/day) having a relative risk of 9.03 compared to occasional or non-drinkers.[20] Those consuming dark liquors have been found to have 4.4 times relative risk compared to light liquors.[21]

HPV related cancers, though more common in the oropharynx, are seen in 10.9% of hypopharyngeal cancers with pyriform fossa having the highest association.[22, 23]

Diet and weight have a bearing in development of cancers. Lower body mass index (BMI) (<18.5) is associated with a greater risk of developing hypopharyngeal cancers.[24] and this seems to be particularly strong among current smokers.[25] Fruits, raw vegetables, and whole grain and dietary fibre intake have an inverse relationship with pharyngeal cancer while higher meat and fried food intake seem to increase the risk of developing hypopharyngeal cancers.[26–29] Post-cricoid tumours are commonly seen in women and are associated with sideropenic dysphagia (Paterson–Brown–Kelly syndrome/Plummer–Vinson syndrome). Certain occupations such as construction workers, potters, butchers, barbers and those exposed to formalin fumes, coal dust, steel dust, iron compounds and fumes are at a higher risk of developing hypopharyngeal carcinoma.[16, 30, 31]

MOLECULAR BASIS OF HYPOPHARYNGEAL CANCERS

Molecular changes causing hypopharyngeal cancers are similar to those at other head and neck sites. However, there are certain specific molecular factors that impact the prognosis of hypopharyngeal cancers. The hypopharynx cancer-specific literature identifies a correlation with amplification of oncogenes (*CCND1*, *FGF3* and *FGF4*) in the region of 11q12, and surprising lack of correlation with loss of tumour suppressor gene.[32] On the contrary, *p53* overexpression was seen in 66% of hypopharyngeal tumours and the overexpression or stabilization of *p53* was significantly associated with improved survival.[33] Cyclin D1 overexpression, apart from being predictive of multiple neoplasms, correlates with advanced clinical stage, tumour extension and relapse prediction after primary radiotherapy and survival.[34] Ki-67, a marker of cell proliferation, is indicative of poor survival.[35, 36] Amongst various factors such as p53, p21, Rb and Cyclin D1 studied in laryngeal and hypopharyngeal cancers, only Cyclin D1 has independent prognostic value for cancer-specific survival.[37] Amongst the growth factor receptors, EGFR was found to be overexpressed in 30% of hypopharyngeal cancers.[38] These may translate into biomarkers for early detection or treatment planning in the quest for personalized medicine.

HISTOLOGY

Most cancers of the hypopharynx are squamous cell in origin and tend to be moderately or poorly differentiated tumours, especially in the pyriform sinus. Non-squamous malignancies are rare and tend to arise from the minor salivary glands (mostly adenoid cystic carcinomas) or are mesenchymal in origin.

ROUTES OF SPREAD

Due to the lack of well-defined spaces as in the larynx, tumours of hypopharynx do not have a very well-defined pattern of spread within the laryngopharynx. With absence of barriers these cancers tend to grow and disseminate long before the patient is symptomatic.

Local extension

Tumours involving the lateral wall of the pyriform sinus most often invade the thyroid cartilage, with ossified cartilages being more prone to tumour invasion. Tumours involving the medial wall of the pyriform sinus extend antero-medially into the paraglottic space and impede vocal cord movement either by mass effect or by invasion of the intrinsic muscles. The apex of the pyriform sinus being inferior to the paraglottic space, tumours tend to involve the paraglottic space early causing cord fixity. Tumours at the pyriform apex can also escape through the cricothyroid membrane and involve the thyroid gland (**Figure 16.2**).[39] Tumours at the pyriform apex do not lend themselves to any form of partial laryngo-pharyngectomy that preserves speech as well as nasal respiration, since the oncological resection would entail removal of the cricoid cartilage. The proximity to the intrinsic laryngeal muscles, the cricoarytenoid joint and the recurrent nerve leads to early impairment of the vocal cords by the tumours.[40, 41]

Post-cricoid area tumours tend to invade the cricoid and tracheal cartilages,[42] thus involving the airway and causing obstruction. The tumour may infiltrate the posterior cricoarytenoid muscle and cricoarytenoid joint causing cord fixity and even precipitate aspiration. Post-cricoid tumours also tend to extend exolaryngeal through the cricothyroid membrane to involve the thyroid gland (**Figure 16.4e**).

Figure 16.2 Right hypopharyngeal cancer with thyroid gland invasion presenting as a thyroid mass.

Anterolateral spread from a predominantly submucous infiltrative post-cricoid cancer may present with a swelling in the region of the thyroid and may be misdiagnosed as goitre, especially in cases where the dysphagia is minimal. It must be pointed out that both these conditions, i.e. post-cricoid cancer and goitre, are commonly seen amongst young females. There have been instances when such mistaken diagnosis has led to exploration of the neck for thyroidectomy causing a lot of embarrassment to the surgical team (**Figure 16.2**).

Post-cricoid lesions have significant submucosal spread which is more pronounced inferiorly than superiorly.[43] The extension of the disease into the cervical oesophagus is common with occasional skip lesions in the oesophagus due to the submucosal lymphatic plexus. This mandates careful pre-treatment evaluation and planning as it can alter the treatment plan.

Lateral spread (parapharyngeal) is in the vicinity of the carotid sheath and extralaryngeal spread from the hypopharyngeal and supraglottic cancers often encases the carotid vessels which needs careful evaluation to differentiate from nodal disease (**Figure 16.3**).

Posterior pharyngeal wall tumours are relatively less common and have not been studied extensively. The tumours tend to be exophytic and are frequently large at the time of diagnosis. In spite of this, invasion of the prevertebral fascia occurs late. The tumour usually involves adjacent areas when first diagnosed. The tumour may extend superiorly to the base of the tonsil and laterally to the oropharyngeal wall, or spread inferiorly into the post-cricoid region and cervical oesophagus. Synchronous tumours along the pharyngeal wall should be evaluated due to the continuous mucosa and extensive lymphatics.

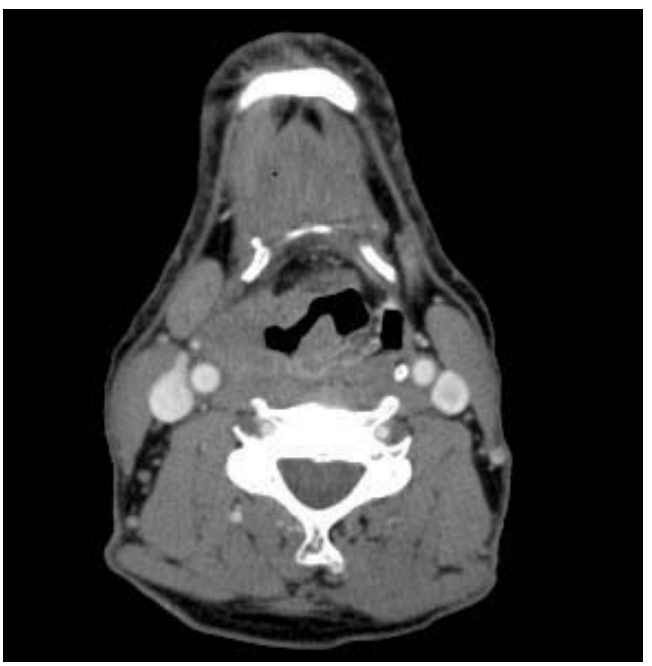

Figure 16.3 Right hypopharyngeal cancer demonstrating extralaryngeal extension.

Regional spread

Hypopharyngeal tumours have the highest propensity for early lymph nodal metastases. Up to 70% of patients may have lymph nodal metastases particularly to levels II and III at presentation and there is a high incidence of occult nodal metastases, which will influence the investigations, staging and treatment.[44] Paratracheal and paraoesophageal i.e. level VI metastases are more common in lesions involving post-cricoid or pyriform sinus apex while retropharyngeal nodes can be involved in posterior pharyngeal wall cancers.[45, 46] When patients have unilateral clinically positive neck disease, the incidence of contralateral occult lymph node metastases is at least 50%.[47] Bilateral occult lymph node metastases in patients with clinically negative neck are most frequently associated with cancers of the pyriform sinus (**Figure 16.1**).[47, 48] In patients with clinically positive neck disease, more than 20% have involvement of the lower nodal stations (level IV and V).[48]

Distant spread

Among all head and neck cancers, hypopharyngeal primaries have the highest incidence of distant metastases at presentation (17–24%)[49, 50] and during follow-up, with more than 50% of failures due to distant metastases.[51] Pulmonary metastases are most common followed by skeletal and liver metastases. The average survival is usually less than 1 year once distant metastases have been diagnosed.[52] Development of distant metastases at some time following initial treatment is associated with tumour recurrence locoregionally.[53]

CLINICAL PRESENTATION

Symptomatology

Hypopharyngeal tumours are detected late as the patients are asymptomatic in the early stages, especially those involving the pyriform sinus. The cardinal symptoms are odynophagia, dysphagia, hoarseness, otalgia, weight loss or a neck lump. The earliest symptom may be that of mild non-specific throat discomfort. In fact, globus sensation may be the only presenting complaint with normal clinical findings.[54] Dysphagia to solid food may be an early presentation in post-cricoid cancers, but is generally seen late in pyriform cancers. Significant weight loss is especially seen in post-cricoid area and oesophageal tumours. Unilateral referred otalgia, is another common symptom and may indicate involvement of Arnold's nerve (X) as explained before. Occasionally, in advanced cases, where the disease extends superiorly to involve the tongue base, referred otalgia may be present deep in the ear, mediated via the glossopharyngeal nerve, the pharyngeal plexus and the Jacobson's nerve in the middle ear. Hoarseness of voice may be a late presentation in pyriform and post-cricoid cancers while 'hot potato' speech signifies involvement of the base of the tongue. As discussed before, a significant

proportion of patients may present to the clinic with palpable neck lymphadenopathy as the only complaint on initial clinical examination.

Clinical examination and signs

A careful and detailed history taking and examination of the patients with suspected hypopharyngeal cancers must be done in the clinic. Most of these patients tend to be elderly males except those with post-cricoid tumours, which is seen predominantly amongst females. A history of tobacco and alcohol consumption must be elicited and recorded with respect to quantity and duration. Counselling services must be offered for tobacco and alcohol cessation, if the patient is continuing with the habit. Patients with advanced disease may look unwell, with significant weight loss. Halitosis may be present. The patients may appear to attempt swallowing with discomfort frequently and a noticeable lump may be present in the neck on inspection. Hoarseness of the voice and history of aspiration must be recorded in every case. In advanced disease, there can be airway compromise with stridor on presentation.

On examination, the presence of exolaryngeal spread with widening of the thyroid cartilage must be assessed. Loss of laryngeal crepitus (Trotter's sign) and restriction of neck extension may imply involvement of the prevertebral fascia. The neck must be carefully palpated for nodes and their size, level of involvement and laterality recorded meticulously. In case of large nodes, movement of the node in vertical and horizontal axis, fixity to the carotid sheath and consistency of nodes (solid or necrotic) must be noted. Skin and platysma involvement must be documented. The root of neck at the suprasternal space of Burns needs to be evaluated for tracheal displacement as well as palpable disease or lymph nodes which would suggest unresectability.

On laryngeal examination, either with a Hopkins rod telescope or mirror, the presence of a growth should be observed. Pooling of saliva may obscure the growth especially in pyriform cancers. If a growth is noted, the extent of disease and involvement of hemi-larynx should be noted. A fibre-optic endoscopic examination under local anaesthesia would give additional visualization and help document the disease extent especially in posterior pharyngeal and pyriform growths. Additionally, a biopsy may be taken with use of the flexible forceps passing through the biopsy channel. However, the flexible endoscope may not be adequate to visualize the inferior extent of the disease, particularly the apex of pyriform sinus and post-cricoid area. In these cases, rigid pharyngoscopy should be performed under general anaesthesia. Treatment decisions are guided by the tumour map, which highlights the importance of a good clinical and laryngoscopic evaluation. In case of circumferential lesions of post-cricoid going down into the cervical oesophagus, a flexible oesophagoscopy may be better than a rigid oesophagoscopy to document the inferior extent of disease as well as to look for a second primary in the oesophagus. A checklist used at the time of the evaluation is important to avoid missing details and has implications for treatment planning (**Table 16.1**).

DIAGNOSIS AND STAGING

Investigations

Barium oesophagogram is an effective screening tool for hypopharyngeal cancers and synchronous cancers in the oesophagus. Barium swallow helps determine the lower limit of a post-cricoid cancer, information that is very vital in the treatment planning.[55] Current practice in most centres involves a flexible transnasal oesophagoscopy to map the lesion, determine its lower limit and proximity to the cricopharynx, assess oesophageal involvement and evaluate synchronous primaries in the oesophagus. This supersedes barium imaging.

Direct laryngoscopy under general anaesthesia helps obtain a biopsy and assess the extent of the lesion for treatment planning. In case of a palpable neck node, biopsy confirmation may be obtained with fine-needle aspiration cytology (FNAC). Open biopsy must be avoided.

Compared to endoscopy or manual examination, CT imaging has higher sensitivity for defining the T stage of the primary tumour (size of tumour, relationship to critical deep structures). Adequate imaging includes contrast enhanced CT (CE-CT) performed with a multidetector CT scanner with bone window reformats (for cartilage assessment).[56] For assessment of cartilage invasion, MR imaging seems to be more sensitive than CT (sensitivity up to 96%). However, CE-CT is the first choice for imaging with MR reserved for trouble shooting. Both CT and MRI over diagnose posterior tumour spread in advanced hypopharyngeal disease and should be correlated clinically. The imaging reporting should be synoptic to avoid missing critical information. The synoptic essentials are covered in **Table 16.2**. **Figure 16.4** illustrates the range of radiologic findings in hypopharyngeal primaries.

A chest X-ray should be performed as a part of screening for distant metastasis while a CT chest is indicated in all patients with advanced stage tumours and/or bulky neck disease.[57] In borderline-resectable disease, positron emission tomography (PET) along with CT scan (FDG-PET/CE-CT) as a single-staging investigation may be considered for evaluation of the primary disease status and excluding any occult distant disease.[58–61] FDG PET/CE-CT is a useful imaging modality in the assessment of laryngeal and hypopharyngeal cancers, especially in post-radiation residual/ recurrent disease where it is often very difficult to prove the presence of active disease and differentiate it from post-radiation oedema.[62]

Staging

Staging of hypopharyngeal cancer is carried out according to the TNM classification, (**Table 16.3**). For the larynx and hypopharynx the only change from the previous staging has been the renaming of T4a resectable as T4a (moderately advanced) and T4b unresectable as T4b (very advanced).

TABLE 16.1 Checklist for direct laryngoscopy under anaesthesia

Subsite evaluated during endoscopy	Disease status	Implication
Oropharynx		
Vallecula /base tongue	Involved / free If involved lateralized or crossing midline	If lateralized resectable If crossing midline, decision-making for glossectomy with laryngectomy vs. chemoradiation
Inferior tonsil pole	Close / involved / free	Close – resectable but will need pharyngeal reconstruction Involved – to evaluate for resectability with superior and lateral extent of lesion into parapharyngeal space
Hypopharynx		
Pyriform apex	Involved / free	No conservation laryngeal procedure feasible as cricoid cannot be oncologically preserved
Cricoartyenoid joint	Involved / free	
Arytenoid cartilage	Involved / free	If cricoarytenoid joint is mobile, consider replacing posterior glottic bulk if conservation laryngeal procedure is planned
Cricopharynx	Free / involved / extending to oesophagus	Involvement indicates circumferential pharyngeal resection requiring reconstruction with free jejunum or free radial artery flap Oesophageal involvement indicates need for gastric pull-up
Lateral pyriform wall	Involved / free	Pharyngotomy approach and pharyngeal reconstruction
Posterior pharyngeal wall	Involved / free If involved lateralized or crossing midline	Crossing midline – pharyngeal reconstruction needed
Pharyngeal mucosa	Mobile / fixed	Mobile – consider TLM / RT Fixed – non-surgical modality
Post-cricoid	Involved / free	Near-total laryngectomy is not feasible and may require patch pharyngoplasty
Glottis / supraglottis		
Vocal cords	Mobile / impaired / fixed	Mobile cords – TLM/TORS,/OPL/ RT Fixed cords – organ preservation
Pre-epiglottic space	Involved / free	Free TLM/TORS/ OPL / RT Involved – organ preservation
Paraglottic space	Involved / free	
Anterior commissure	Cords mobile and pre-epiglottic space free	Supracricoid laryngectomy/hemipharyngectomy
Subglottis	> 1 cm anteriorly	No conservation laryngeal surgery possible
	< 5 mm posteriorly	
Inter-arytenoid	Involved	Conservation laryngeal surgery and near-total laryngectomy not feasible.

TABLE 16.2 Synoptic radiological report

- Tumour volume
- Locoregional extent of the disease
  - Superior – Oropharynx
  - Inferior – Cricopharynx, oesophagus
  - Transglottic
  - Crossing midline – anterior commissure, post cricoid
- Pre-epiglottic space and paraglottic space
- Exolaryngeal spread – thyrohyoid membrane, cricothyroid membrane, straps muscles
- Thyroid and cricoid cartilage involvement
- Cricoarytenoid joint
- Visceral spaces (prevertebral fascia, carotid space)
- Metastatic lymph nodes - Levels II-V, Paratracheal, Retropharyngeal

FACTORS DETERMINING TREATMENT IN HYPOPHARYNGEAL CANCER

Treatment decisions in cancer are guided by the biology of the disease and the peculiarities of the organ affected. Tumour and nodal factors, performance status (PS) of the patient, resources and available technical expertise dictate the management.

Tumour factors: Squamous cell cancers are biologically more aggressive in the hypopharynx due to its rich vascularity and lack of barriers to the spread of tumour. Hypopharyngeal tumours uniquely have substantial submucosal spread well beyond the mucosal limits of the tumour and are seen up to 20 mm.[63] Whole organ studies of hypopharyngeal cancer specimens showed submucosal spread in 60%, most being in the inferior direction followed by lateral and superior. The submucosal spread is not obvious macroscopically and is more often seen in post-irradiated patients.[64] Surgical margins should be critically assessed to contain this submucosal spread.

Proximity of hypopharynx tumours to the larynx causes them to affect laryngeal functions.[65] Surgical organ preservation procedures should be planned based on structural and functional integrity of the larynx without compromising oncologic safety.

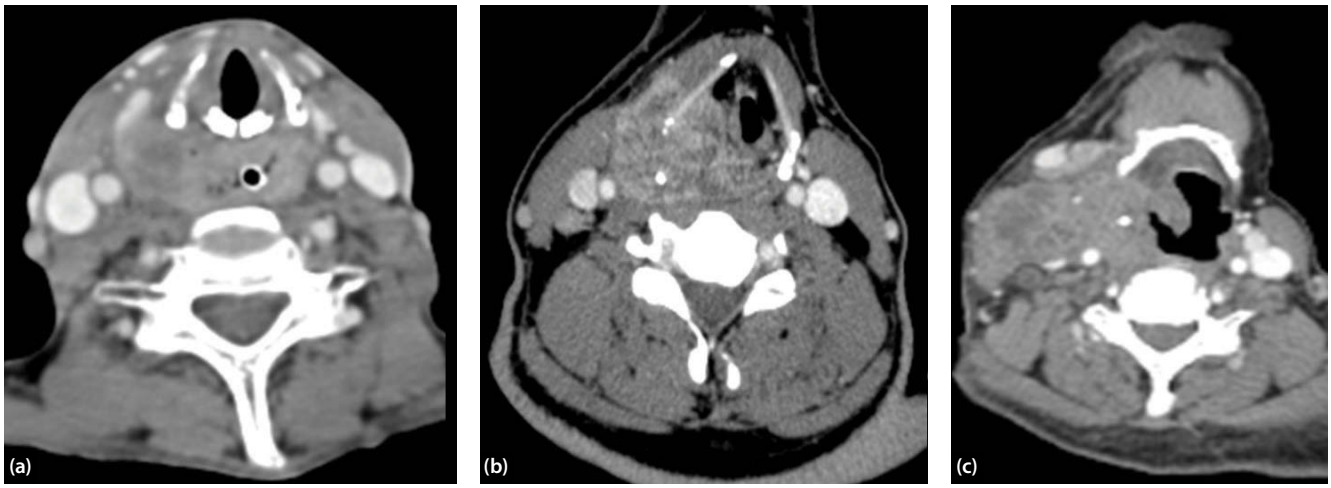

Figure 16.4 **(a)** Extension into post-cricoid region with extralaryngeal component: T3. **(b)** Involving the outer cortex of thyroid cartilage with extralaryngeal spread that surrounds less than 180° of the carotid artery. **(c)** Extralaryngeal spread with involvement of prevertebral fascia and splaying of carotid vessels: T4b.

Nodal factors: Hypopharynx is rich in lymphatics with a high incidence of metastasis to the jugular paratracheal and retropharyngeal group of lymph nodes even in early stages of the disease which may result in the nodal disease as the primary manifestation in 65% to 80% and occult metastasis in 30% to 40% of N0 necks.[43, 48, 66–68] Hence treatment of neck nodes is mandatory in all hypopharyngeal cancers.[69]

Performance status: PS is a measure of general condition of the patient. It takes into account their general wellbeing and ability to carry on daily life activities. Usually the PS scales are the Karnofsky score or the WHO / ECOG / Zubrod scale.

PS in hypopharyngeal cancers is important estimate of treatment outcomes:

- Conservative surgery both open and transoral methods will alter laryngeal anatomy and physiology, resulting in alteration of laryngeal protection mechanisms, thus increasing the probability of aspiration and dysphagia. PS is an important estimate of the ability of the patient to withstand sequelae of the surgery.
- More than 75% of patients present in advanced stages III and IV and will go on to receive multimodality treatment. If PS is low, the possibility of withstanding and completing treatment is lower.
- In the palliative care setting, PS helps determine if the patient will benefit from either chemotherapy or radiation or is best suited for only supportive care.

Resources and technical expertise: Transoral surgery in select cases is technically demanding as well as resource heavy. Transoral laser and robotic surgery require intensive training and mentorship. The goal is to reduce morbidity of multimodal therapy without compromising oncological outcomes; hence achieving proper clearance of disease through transoral access is paramount. Resources such as a fully equipped microlaryngeal setup with laser or a transoral robotic setup are required and may not be feasible at all centres.

Partial laryngopharyngeal resection requires proper case selection and training in laryngeal conservative surgery and reconstructive techniques.

Radiation therapy and chemotherapy are challenging in patients who are nutritionally depleted, who will experience higher grade toxicity with concomitant chemotherapy regimes, resulting in noncompliance with treatment schedule and poorer outcomes. Expertise in delivery of these technically demanding therapies is required for optimal outcomes.

TREATMENT OF EARLY HYPOPHARYNGEAL CANCERS

Early cancers are potentially curable and the goals of treatment should be maximizing chances of cure with function preservation. In hypopharyngeal cancers, these goals are impeded by the proximity of the larynx and occult metastatic nodes, even in early staged tumours.

Treatment of T1 and T2 hypopharyngeal cancers can be with either radiation therapy or conservation surgery. Decision-making in early hypopharyngeal cancers depends on the tumour location and the ability of the patient to withstand treatment. Oncological safety and functional preservation are important decision-making criteria while choosing treatment.

Larynx conservation surgery

Surgical considerations are similar to those in laryngeal cancers where preservation of speech and larynx protection mechanisms is paramount. Patient age and respiratory function are very important selection criteria because hypopharyngeal resection combined with partial laryngectomy alters voice and increases risk of aspiration and airway compromise. Hence patients with tumours involving

TABLE 16.3 UICC staging 8th edition

Primary tumour	
T1	Tumour limited to one subsite of hypopharynx and/or 2 cm or less in greatest dimension
T2	Tumour invades more than one subsite of hypopharynx or an adjacent site, or measures more than 2 cm but not more than 4 cm in greatest dimension without fixation of hemilarynx
T3	Tumour more than 4 cm in greatest dimension or with fixation of hemilarynx or extension to oesophagus
T4a	Moderately advanced local disease. Tumour invades thyroid/cricoid cartilage, hyoid bone, thyroid gland, or central compartment soft tissue (includes prelaryngeal strap muscles)
T4b	Very advanced local disease. Tumour invades prevertebral fascia, encases carotid artery, or involves mediastinal structures
Regional lymph nodes (N)	
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension without extranodal extension
N2a	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension without extranodal extension
N2b	Multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension without extranodal extension
N2c	Bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension without extranodal extension
N3a	Metastasis in a lymph node, more than 6 cm in greatest dimension without extranodal extension
N3b	Metastasis in a single or multiple lymph nodes with clinical extranodal extension*

Stage grouping

Group	T	N	M
0	Tis	N0	M0
I	T1	N0	M0
II	T2	N0	M0
III	T3	N0	M0
	T1, T2, T3	N1	M0
IVA	T1, T2, T3	N2	M0
	T4a	N0, N1, N2	M0
IVB	T4b	Any N	M0
	Any T	N3	M0
IVC	Any T	Any N	M1

* Presence of skin involvement or soft tissue invasion with deep fixation / tethering to underlying muscle or adjacent structures or clinical signs of nerve involvement is classified as clinical extranodal extension. Midline nodes are considered ipsilateral nodes.

the pyriform apex or post-cricoid area and those with poor pulmonary function should not be considered as candidates for partial pharyngolaryngectomy. Gastrostomy tube and tracheostomy tube dependence is also a real possibility with alteration of laryngopharyngeal anatomy with surgery and post-operative radiation therapy.

The larynx conservation surgery for early hypopharyngeal cancers can be via two approaches: conventional external and transoral approaches.

EXTERNAL APPROACH – PARTIAL LARYNGOPHARYNGECTOMY

Indications

Conservation surgical procedures are considered for early lesions of the hypopharynx:

- Tumours less than 4 cm (T1–T2)
- Pyriform apex and post-cricoid mucosa free of disease
- Mobile vocal cords
- No erosion of the thyroid cartilage
- No paraglottic spread.

Types

The choice of conservation surgical techniques depends on the location and the spread of the tumour. Depending on the proximity of the lesion to the larynx the procedure can be either partial pharyngectomy, or partial pharyngolaryngectomy.

Partial pharyngectomy: When the tumour arises on the pharyngeal component of the hypopharynx and spares the medial wall of the pyriform sinus and the apex, it is suitable for partial pharyngeal resection. Approached through a lateral pharyngotomy, the involved pharyngeal wall is resected and reconstructed with either pectoralis major myocutaneous flap or free flap. The pharyngeal reconstruction restores continuity of the upper aerodigestive tract and with it, normal speech and swallow.

Partial pharyngolaryngectomy: When the tumour involves the medial wall of the pyriform sinus and extends onto the supraglottic structures of the larynx it necessitates partial resection of the hypopharynx and the larynx. Partial pharyngectomy can be either an extended supraglottic partial laryngectomy or supracricoid hemilaryngopharyngectomy. It is a functional procedure involving resection of the hemilarynx above the level of the cricoid and the medial aspect of pyriform sinus and the ipsilateral supraglottic structures (**Figure 16.5a**). The laryngeal functions are impeded with loss of sensation due to resection of superior laryngeal nerve and removal of supraglottic structures. These need to be reconstructed to prevent aspiration, stridor and dysphagia.

RECONSTRUCTION FOLLOWING PARTIAL LARYNGOPHARYNGECTOMY

Following partial laryngopharyngectomy, the goals of reconstruction are to restore not only the anatomical continuity but also the functionality of the larynx viz airway protection, airway preservation and the ability to voice. The pharyngeal defect is reconstructed with either the pectoralis myocutaneous flap or the free flap usually the radial forearm flap (**Figure 16.5b**). The laryngeal

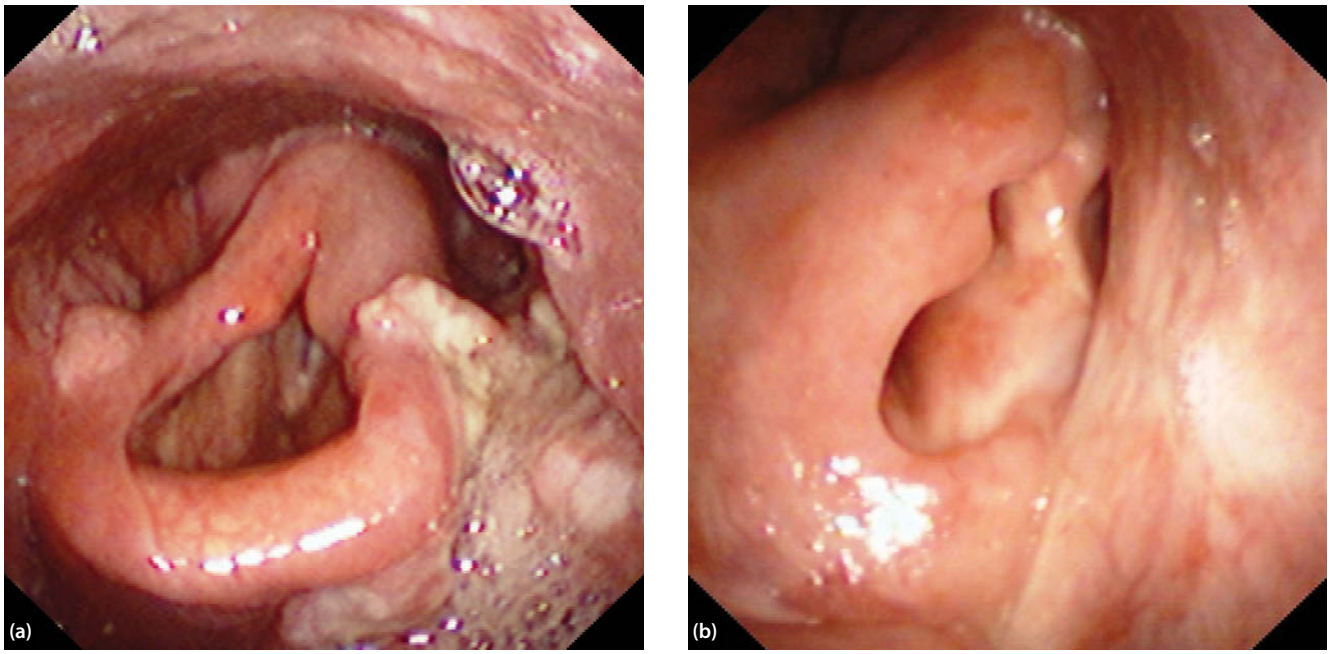

Figure 16.5 **(a)** Early hypopharngeal tumour treated by open partial laryngopharyngeal resection and free radial forearm flap reconstruction, **(b)** shows a healthy pyriform at two years with minimal disruption of anatomy. Note lack of pooling indicating good swallowing function (Courtesy of Prof. Rudolf Hagen, Germany).

structures will be reconstructed ingeniously using parts of the epiglottis and hyoid. Microvascular free-flap expertise has tremendously improved outcomes as compared to the 1960s and 1970s with lower rates of morbidity.

Oncological outcomes

Several studies analyzed the results obtained with partial surgery in patients with early pyriform sinus carcinoma.[49, 70, 71] with 5-year overall survival rates ranging from 55% to 59%. The local control rates have often been excellent ranging from 77% to 97% while regional recurrences occur in 15–23% and distant metastases in 28%. In most series, the incidence of distant metastasis increases as the local control rates improve. Survival is better in patients with T1 disease, those with good surgical margins and in those receiving post-operative radiation.[72–74] Extension to the apex of the pyriform sinus is fraught with local failure while distant metastases occur in patients with two or three wall involvements.[49] Amongst the contemporary series, Chung et al[75] reported 58 patients who underwent partial pharyngectomy with reconstruction, showing 5-year overall and disease specific survival rates of 78% and 77.6% respectively. Level VI metastasis confirmed by histopathological analysis, close (< 5 mm) histologic margins, advanced nodal stage and posterior pharyngeal wall tumours were significant independent factors associated with poor disease-specific survival.

Functional outcomes

Conservation surgery entails removal of structures involved in laryngeal protection. The long-term functional issues are aspiration, tracheostomy and gastrostomy. The published literature suggests that the majority of patients achieve deglutition without aspiration. However, there is a real possibility of aspiration leading to pulmonary infection and death. Even from experienced centres a 3.7% post-operative mortality is reported.[76] Aspiration-free swallowing is generally restored in two-thirds of cases by the end of the first month and in the rest up to 1 year after surgery. However, 3–5% of cases either die of aspiration or undergo completion total laryngectomy or a permanent gastrostomy. With microvascular free-flap reconstruction, the contemporary series show better results. Chung et al[75] in their series of 58 patients reconstructed the pharynx in 72%, majority with free-radial forearm flap. Post-operative pharyngocutaneous fistula developed in 10.3% of which two required PMMC reconstruction for closure. Oral feeding was achieved in 86.2% patients within a mean of 26 days while 13.8% required percutaneous endoscopic gastrostomy tube. Eighty-eight per cent could be decannulated within a mean of 44 days post-operatively. Hence proper patient selection and use of appropriate reconstruction of the laryngopharyngeal defect is important to succeed with the intended functional laryngeal preservation.

TRANSORAL APPROACHES

The transoral approach for surgical resection of the hypopharyngeal cancers can be undertaken either with transoral laser microsurgery or transoral robotic surgery. A new technique, transoral videoendoscopic surgery, has recently been described.

Indications are similar to the open approaches

- tumours less than 4 cm (T1–T2)
- pyriform apex and post-cricoid mucosa free of disease

- good exposure
- mobile vocal cords.

Contraindications:

- oral submucous fibrosis
- full thickness involvement of the pharyngeal muscles
- thyroid cartilage involvement
- base tongue and arytenoid involvement
- cervical oesophagus involvement.

Advantages over open approach:

- avoid disruption of laryngeal skeleton and soft tissues
- avoid tracheostomy
- preservation of innervation
- prevention oro-cervical fistula formation.

Transoral laser microsurgery (TLM)

This transoral approach uses CO_2 laser coupled to the microscope to resect hypopharyngeal tumours. The advantages of laser are precise resection with minimal collateral thermal damage. With minimum alteration of anatomy, there is negligible aspiration and early restoration of oral feeding. Case selection for organ conservation in hypopharyngeal cancers is based on the amount of margin possible with preservation of structures to retain a functional larynx. Besides the larynx, the pharyngeal resection should not expose neck structures requiring additional surgery.

Oncological outcome

The efficacy of TLM in hypopharyngeal cancers should be analyzed in terms of organ preservation and local control. In Steiner's series,[77] transoral CO2 laser surgery was performed on 172 patients, of whom 33 were stage I and II pyriform sinus carcinoma. The 5-year local control was 84% for T1, 70% for T2, 75% for T3 and 57% for T4a tumours. The 5-year recurrence-free survival was 73% in stage I and stage II disease, 59% in stage III disease and 47% in stage IVa disease. Rudert et al[78] in their series of 29 hypopharyngeal cancer patients treated with TLM reported a 5-year overall survival of 71% in stage I and stage II tumours and 47% in stage III and stage IV tumours. In these series, the highest local control rate was achieved in tumours involving the lateral hypopharyngeal wall. In the final analysis, the outcome is significantly dependent on the lymph node involvement as in most head and neck squamous cell cancers. While deciding on the treatment options, functional preservation and oncological safety are important considerations, especially when a lesser morbid treatment option is available. TLM of hypopharynx shows comparable results with open surgical procedures and is superior to radiotherapy alone in terms of organ preservation and local recurrence rate.

Functional outcomes

Post-operative recovery following endoscopic resection of even large hypopharyngeal cancers is surprisingly smooth. If the arytenoid is preserved, most patients are on oral feeds from the first post-operative day. Aspiration depends on preservation of structures and innervation. The healing process is rapid and usually is not a major problem. Hence the procedure is feasible even in the elderly and those with chronic obstructive pulmonary disease (COPD). Mild to moderate discomfort on swallowing may persist for about a week.

Following resection of a large tumour, the resultant raw area necessitates tube feeding for a few days. If the arytenoid is resected, aspiration may be a problem in the post-operative period. In most series[79, 80] functional preservation was seen in 80% of patients. More than one-third of patients do not need nasogastric feeding following TLM, while in the rest the tube feeding remains for around 10–14 days. Post-operative aspiration pneumonia is seen in less than 12% of patients and the need for tracheostomy arises in 5% of patients.

Steiner and Ambrosch report two patients out of 129 cases of pyriform sinus cancer where oral feeding could not be resumed because of persistent aspiration.[77] Pradhan et al[81] have reported persistent aspiration necessitating a feeding gastrostomy in two patients where the arytenoid was resected out of 109 cases of early hypopharyngeal and supraglottic tumours. Both these were cases of recurrent disease in the pyriform sinus 5 years and 13 years following treatment with radiation therapy.

Transoral robotic surgery (TORS)

Another transoral approach which has evolved in the past decade is TORS. It is technologically improved on the standard microscopic and endoscopic techniques in terms of 3D-vision, magnification and ability to operate outside the line of sight. The TORS facilitates two- to four-handed surgery without tremors and improved dexterity. A transoral resection is performed with electrocautery tip similar to open surgery with the added advantage of transoral route with minimal anatomical changes.

TORS is currently done with the da Vinci robotic system® with three arms, one for the camera which has full HD capability with two endoscopes and a 10 x magnification (**Figure 16.6**). TLM is limited with the need for line of sight for firing the laser beam. This is overcome with angled vision and the degrees of freedom for the wristed robotic arms. There is also the advantage of active control of larger blood vessel bleed with use of electrocautery and two-handed approach. The use of TORS for hypopharyngeal cancers has begun recently and long-term results are awaited.

Park et al[82] from Yonsei University, Seoul, Korea published their results of 23 patients managed by TORS with an overall survival of 89% and disease-free survival of 84% at 3 years. On objective evaluation, serious aspiration or delay of swallowing was not observed during the pharyngeal stage of the swallowing process. Overall, 96% of the patients showed favourable swallowing abilities.

There are also reports of combining fibre CO_2 laser with the robotic arm to get that additional advantage of reduced collateral thermal damage as compared to the electrocautery. However, it remains to be seen if the TORS

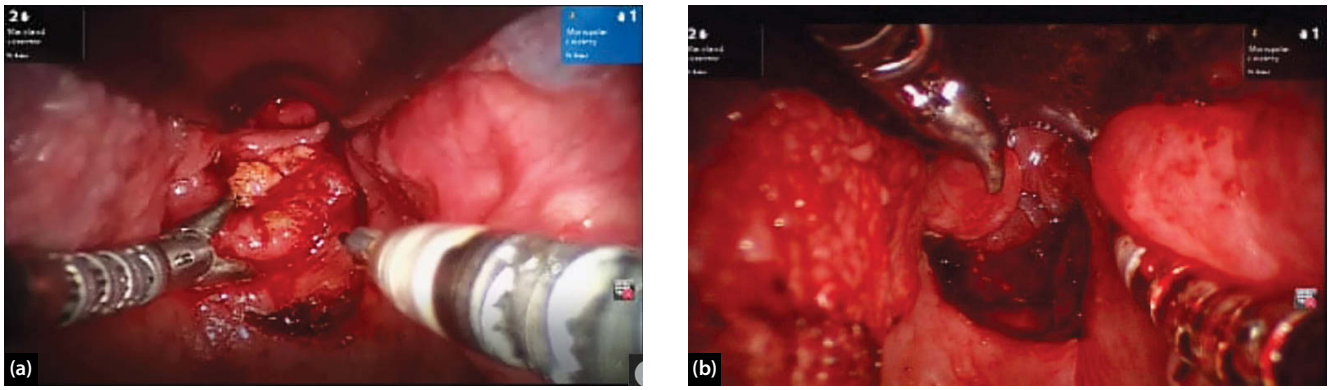

Figure 16.6 Transoral robotic resection of a posterior pharyngeal wall tumour **(a)** the defect is left to heal by secondary intention **(b)** (Image courtesy of Prof. Vinidh Paleri, London).

scores over TLM in oncological and functional outcomes besides ease of surgery and the morbidity of the procedure.

Transoral videoendoscopic surgery (TOVS)

TOVS uses flexible video endoscope to visualize the lesion through a suspended larynx similar to microlaryngoscopy (**Figure 16.7**). The difference is the utilization of the video endoscope to visualize the lesion and use of curved instruments with electrocautery for resection. The inspiration for TOVS comes from the endoscopic mucosal resections carried out in the oesophagus by the gastrointestinal surgeons, which, akin to early cancers of the hypopharynx, are predominantly mucosal diseases. The procedure is relatively new and early results are promising. The Japanese series show promising early results with technical feasibility, use of available equipment and outcomes. The long-term oncological outcomes are awaited with early reports from Shiotani et al showing 95% 3-year disease-free survival[83, 84] and good voice and swallowing outcomes.[85, 86]

MANAGEMENT OF THE NECK

All patients should be assessed with CT scan and ultrasonography (USG) as complementary tools to discern metastatic nodes. Patients with pT_1N_0 tumours are either followed up with a wait and watch policy for the neck, with regular US every 2–3 months in the first 2 years, then every 6 months or undergo ipsilateral selective neck dissection of levels II, III and IV. In patients with suspected occult metastatic neck nodes on imaging, unilateral or bilateral neck dissection is performed, depending on the imaging and site of primary. The neck dissection is usually a selective neck dissection of levels II, III and IV and evaluated on frozen section; if disease is found to be positive a modified radical neck dissection is performed. Where facilities for frozen section do not exist, further adjuvant treatment is based on histological report of the neck dissection specimen. In patients with larger tumours (T3–T4) Martin et al[87] recommend a bilateral neck dissection.

In open partial surgery, with the neck exposed for access, the ipsilateral levels II and III that are at the highest risk of occult metastasis are dissected. If they are obviously metastatic or on frozen section they appear involved, then a comprehensive neck dissection of levels II to V is carried out. In case of clinically palpable cervical lymph node metastasis, bilateral comprehensive neck dissection is performed.

ADJUVANT THERAPY FOLLOWING TRANSORAL APPROACHES IN EARLY CANCER

Following resection of T1/T2 hypopharyngeal cancer adjuvant radiation therapy is advised for tumour factors

such as positive margins, where re-resection is not suitable and for metastatic neck node disease. Fields of radiation include the primary tumour as well as both sides of the neck.

It must be highlighted here that TLM of hypopharyngeal cancer should not be performed to merely debulk the tumour. The intent must always be to achieve a complete resection with tumour-free margins.

Radiation therapy in early hypopharyngeal cancers

The goal of radiation therapy as a single modality in early hypopharyngeal tumours is to achieve an oncological cure with minimal toxicity, preserving both organ and function. Conventional external beam radiotherapy (EBRT) is usually delivered over a period of 6–7 weeks, with daily fractionation, 1.8–2 Gray (Gy) per fraction, 5 days a week, over a period of 6–7 weeks. Conformal radiotherapy with 3D planning or intensity-modulated radiation therapy (IMRT) is preferred to minimize radiation to normal structures and reduce xerostomia (**Figure 16.8**).

An analysis of 101 patients with T1–T2 carcinoma of the pyriform sinus treated at the University of Florida[88] with radiotherapy (RT) with or without a planned neck dissection for organ preservation demonstrated 5-year local control rates of 90% for T1 cancers and 80% for T2 lesions. The absolute survival rates for stage I and II were 57% and 61% respectively. Moderate to severe long-term complications developed in 12% of patients. RT alone or combined with a planned neck dissection can result in local control with larynx preservation in a high proportion of patients. The chance of cure is comparable to that observed after conservation surgery, and the risk of major complications is low.

A multi-institutional Japanese study[89] of 115 patients (39 Stage I and 76 Stage II) was carried out where 98 patients were treated with conventional fractionation RT and twice-daily RT in 17 patients. Chemotherapy was combined with RT in 57 patients. With a median follow-up of 47 months the 5-year overall and disease-specific survival rate for 95 patients without synchronous malignancies was 66.0% and 77.4% respectively. The 5-year disease-specific survival rate was 95.8% for T1 and 70.1% for T2 disease. Local control with laryngeal voice preservation was achieved in 87% of T1 lesions and in 73.6% of T2 lesions. Synchronous or metachronous cancers developed in 56.5%. Early hypopharyngeal cancers tend to have a good prognosis with RT. However, second malignancies have an adverse effect on the overall outcomes of patients with early hypopharyngeal cancer.

TREATMENT OF ADVANCED HYPOPHARYNGEAL CANCERS

Advanced hypopharyngeal cancers pose a challenge for the treating oncologists. Many of them present with severe dysphagia, weight loss and malnutrition that needs active intervention by insertion of feeding tubes and dietary supplementation, prior to starting any therapy. It is important to make a proper assessment of the patient's PS and ability to tolerate and withstand major surgery and/or chemoradiation. The choice of initial therapy is based not just on age, PS, medical comorbidity but also on tumour characteristics such as extent of disease, presence of aspiration,

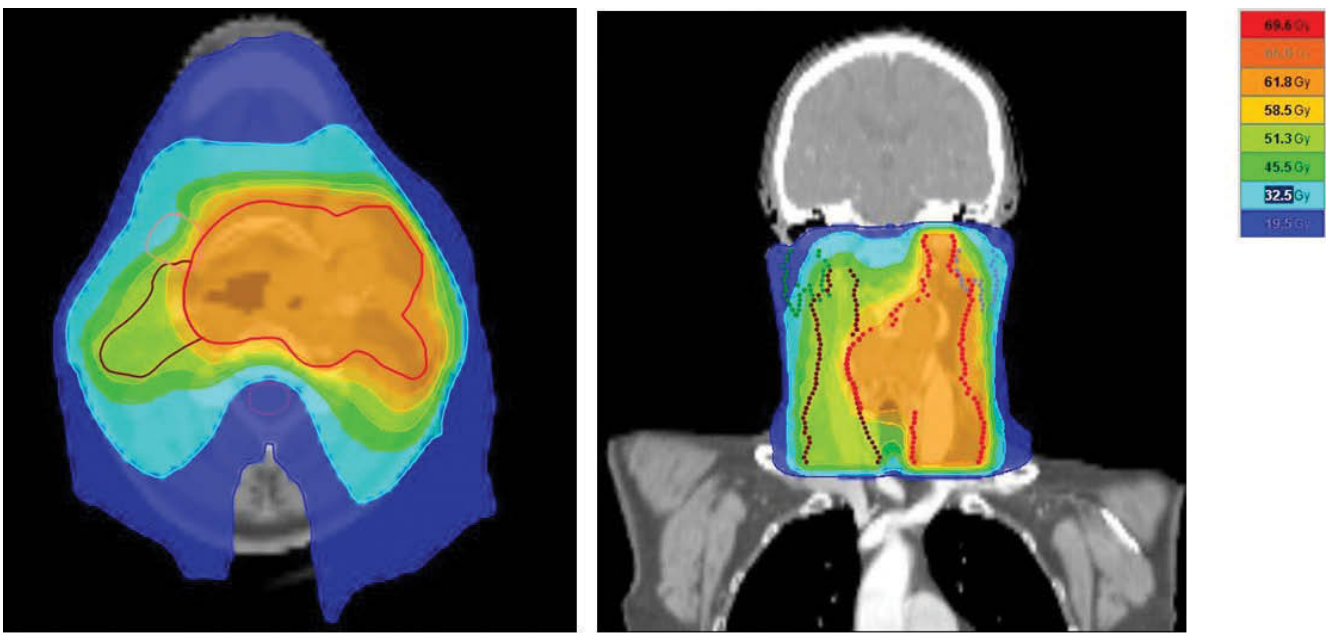

Figure 16.8 Axial and coronal section of an IMRT plan for a patient with T3N2b disease of the left pyriform fossa. The prescription dose (orange) encompasses entire larynx and involved nodal levels. The contralateral at-risk nodal level is treated with a prophylactic dose (green).

function of vocal cords as well as technical expertise and availability of treatment facilities. A multidisciplinary approach should involve surgical, radiation and medical oncology experts as well as speech and language therapists. The patient and caregivers must be counselled about available treatment options. The treatment is based on patient preference and tailored accordingly.

In advanced hypopharyngeal cancers with cord fixity and/or cartilage erosion (T3/T4a), the main issue is treating the disease whilst preserving the laryngeal form and function. In patients with good PS, no comorbidities as well as intact laryngeal framework and function (T1-3N0-2c) the standard of care is concurrent chemotherapy with radiation. In patients with compromised laryngeal framework (T4a) or function, the standard treatment is a total or near-total laryngectomy with a partial or circumferential pharyngectomy along with adjuvant radiation therapy. Lastly, in those patients with intact laryngeal function but exolaryngeal spread through the membranes without cartilage involvement, neoadjuvant chemotherapy with response assessment may be considered for chemoselection for organ preservation.

Surgery for advanced hypopharyngeal cancers

Surgery for hypopharyngeal cancer involves the larynx as well as the hypopharynx. The larynx is usually entirely removed unless the lesion is lateralized. The pharynx is usually resected either partially or circumferentially and most patients will need appropriate reconstruction to restore pharyngeal continuity. Adjuvant radiation / chemoradiation is an essential part of the multimodal therapy for treatment of stage III / IV hypopharyngeal cancers treated surgically.

INDICATIONS

- good general condition
- compromised laryngeal function
- involved laryngeal framework
- salvage surgery following radiation or concurrent chemoradiation.

CONTRAINDICATIONS

- poor general condition
- disease extension
  - Involvement of root neck
  - Prevertebral involvement presents with inability to extend the neck and absence of laryngeal crackle
  - Superior extension into the oropharynx
  - Lateral extension involving carotid artery
- Metastatic disease

Types of surgical procedures

- near-total laryngectomy with partial pharyngectomy
- total laryngectomy with circumferential pharyngectomy
- total laryngo-pharyngo-oesophagectomy (TLPE) with gastric pull-up (GPU).

Near-total laryngectomy with partial pharyngectomy (NTLP)

Voice conservation procedures preserve voice as well as nasal respiration while total laryngectomy sacrifices both functions on the other extreme. The near-total laryngectomy (NTL) falls midway, preserving voice but not nasal respiration.

Indications for NTLP are advanced but lateralized hypopharyngeal cancers where the lesion does not involve the post-cricoid mucosa or the interarytenoid region; the contralateral vocal cord and arytenoid can be preserved and used to form a biological shunt between the trachea and the neopharynx.

This innervated laryngotracheal remnant is fashioned into a tube which, though inadequate to serve as an airway for breathing, is large enough to act as a dynamic shunt by diverting air from the trachea to the pharynx for voice production. The patient therefore has a permanent tracheostome for breathing as in a total laryngectomy which when occluded diverts air through the shunt to produce speech. The innervated dynamic shunt with its sphincteric action protects the airway, preventing aspiration.

The procedure of NTLP offers preservation of excellent lungpowered speech and may be suitable in almost 20% of advanced, operable, pyriform cancers – the most common site amongst hypopharyngeal cancers.

NTL is contraindicated in the following situations:

- Interarytenoid or post-cricoid involvement, which makes preservation of the contralateral arytenoid oncologically unsafe.
- Mucosal involvement of more than one-third the length of the contralateral cord. This does not allow preservation of sufficient laryngeal remnant for shunt formation.
- Prior radiation therapy is a relative contraindication especially if the tissues are oedematous.

Total laryngectomy with partial pharyngeal resection

In hypopharyngeal lesions involving the inter-arytenoid and post-cricoid mucosa, the entire larynx needs to be sacrificed along with the involved pharynx preserving part of the pharynx after adequate resection.

Total laryngectomy with circumferential pharyngeal resection

Indicated in hypopharyngeal lesions involving the post-cricoid mucosa where there is no option of preserving any pharyngeal mucosa. The lesion should however be limited above the level of the cricopharynx ensuring that the cervical stump of oesophagus is normal.

Total laryngo-pharyngo-oesophagectomy (TLPE)

In post-cricoid lesions or hypopharyngeal lesions extending beyond the cricopharynx, an oncological safe margin

requires total laryngopharyngectomy with removal of the entire oesophagus.

RECONSTRUCTION OF PHARYNX FOLLOWING PHARYNGEAL RESECTION

After partial pharyngeal resection, the remnant pharynx is evaluated for mucosal adequacy at the oropharynx, mid-pharynx and the cricopharynx as well as its texture and vitality. If the width is less than 3 cm unstretched or the remnant pharynx is not pliant and oedematous a reconstruction should be considered. The long-term study from Queen Mary Hospital, University of Hong Kong, by Hui et al, showed that a 3 cm unstretched pharyngeal remnant ensures a normal swallow in patients.[90] There are three varieties of defects created:

Partial pharyngeal defects

This requires reconstruction with a pliant tissue similar in thickness of the pharynx. For partial defects, radial artery free flap or anterolateral thigh free flap are suitable. Alternatively, pectoralis major myocutaenous (PMMC) pedicled flap can be used.

Circumferential defects

In our experience, circumferential pharyngeal defects are ideally reconstructed with free jejunal graft. Skin-lined tubed reconstruction, if done, should preferably be a free radial forearm flap. Tubed PMMC is a possible but poor alternative.

Gastric pull-up (GPU)

Following a TLPE, the defect is reconstructed by mobilizing the stomach along with a segment of the duodenum which allows the stomach to be brought into the neck and is sutured to the oropharynx at the fundus. GPU offers a reliable, single-stage vascularized reconstruction with anastomosis in the neck, minimizing the risk of stricture, fistula and post-operative mediastinitis. The GPU is however fraught with higher morbidity in the post-operative period.

MANAGEMENT OF NECK

In stage III and IV either the patient has manifest neck nodes (N1-N3) or has advanced primary (T3/T4) tumour. With manifest neck nodes the surgical plan will usually be bilateral neck dissection levels II–V. In patients with advanced primaries and no neck nodes, the surgical plan will entail bilateral levels II to IV neck dissection.

FUNCTIONAL OUTCOMES

In advanced hypopharyngeal cancers treated surgically, the functional outcomes are related to swallowing and speech. The pharyngeal remnant and the effect of adjuvant radiation will determine the ease of swallow. Generally, patients undergoing primary closure with an adequate pharyngeal width (more than 3 cm unstretched) will experience swallow outcomes close to normal. During neopharynx formation, only mucosal closure vs mucosal and overlying pharyngeal muscle closure has been shown to affect swallowing. Propulsion of the bolus with pharyngeal muscle approximation is more effective while the amount of bolus swallowed is better with only mucosal closure. Thus, during closure the surgeon should ensure that the pharyngeal remnant is adequate and avoid a tight pharyngeal muscle closure. Swallowing is similar in NTLP to TLP with a pharyngeal stenosis rate of 10% caused either by a narrow pharyngeal remnant or radiation-induced stenosis.[91] The pharyngeal reconstruction with a vascularized patch does not alter the function of swallowing and speech in a major way. The only issue remains the amount of functional pharyngeal remnant which can preserve peristalsis. Disordered motility can cause stasis and is more common when the major part of the pharynx is reconstructed.[92] The main concern in gastric pull-up is the gastric emptying. The patient would have to remain upright for fear of regurgitation on lying down after eating. The issue is less with a proper pyloroplasty and most patients have good swallowing albeit with reduced food volume and occasional regurgitation within the first 3 months.

Speech is determined by the pliability of the pharyngo-oesophageal segment. With a remnant pharyngeal mucosa, the speech restoration with tracheo-oesophageal prosthesis is successful in more than 90% of patients. When the laryngeal remnant is preserved as in a NTLP the patients acquires an intelligible, lung-powered speech. Almost every patient will speak following this procedure unless there is a shunt breakdown or stenosis, which is uncommon and is usually technique related, which can be minimized with experience. Results from most published series demonstrate success rates ranging from 74% to 100%.[93–97] Occasionally, a patient may not develop speech or may have to strain while talking. The commonest cause of this is NTL shunt stenosis. This can be overcome by dilatation of the tract using simple gum elastic bougies.

ONCOLOGICAL OUTCOMES

In properly selected cases, the locoregional control rates with near-total laryngectomy are comparable to those with total laryngectomy. In our own series consisting predominantly of T3 / T4 cancers, local recurrence rate is less than 7% with a median survival of 57%.[91] A national analysis of over 1500 patients in the UK showed a 5-year survival of 57% for those treated with pharyngolaryngectomy.[98]

MORBIDITY

The morbidity of surgical treatment in hypopharyngeal cancers is related to the integrity of the neopharynx. Salivary leaks occur more commonly in patients who undergo primary pharyngeal closure for hypopharyngeal cancer surgery compared to those for laryngeal cancers[94]

and may be related to the remnant pharyngeal width. The pharyngeal leak rates are higher in post-irradiated patients, seen in almost 50%. Salvage surgery following concurrent chemoradiation tends to have a higher chance of salivary leak, the incidence rates of which can be reduced by a third using vascularized tissue to reconstruct the defect.[99] In circumferential pharyngo-oesophageal defects, reconstruction with free anterolateral thigh flap seem to have higher success rate (96% vs 93%) compared to free jejunal flap reconstruction, achieving best functional outcome with minimal donor-site morbidity.[94]

The mortality in surgically treated hypopharyngeal cancers is a reality. Nouraei et al have reported the average hospital mortality rate for laryngopharyngectomy around 6% with the gastric pull-up group having the highest incidence at 11%. Those that have had a reconstructive failure tend to have an odds ratio of 6:2 for in-hospital death as well as a worse prognosis.[98]

ADJUVANT THERAPY

Following surgery in advanced stage III and IV hypopharyngeal cancers, adjuvant therapy with either radiation therapy or concurrent chemoradiotherapy is an essential part of the treatment protocols. The factors warranting adjuvant treatment are advanced primary cancer (T3/T4), close- or positive-cut margins, presence of perineural invasion (PNI), lymphovascular embolii (LVE), extension/invasion to adjacent structures like cartilage, muscle, soft tissues, multiple nodal involvement and finally the presence of extra-capsular extension (ECS) in the nodes. There is conclusive evidence for use of concurrent chemotherapy with radiation in cases with positive margins and extra-capsular spread.[100, 101]

Non-surgical organ preservation strategies for advanced hypopharyngeal cancers

Non-surgical organ preservation aims for good locoregional control with function preservation i.e. no aspiration or need for tracheostomy and feeding tubes after completion of treatment. However, careful patient selection is essential to ensure optimal results.

CHEMORADIATION FOR ADVANCED HYPOPHARYNGEAL MALIGNANCIES

The evidence for concomitant chemoradiation in hypopharyngeal cancers comes from the recent update of the MACH-NC with subgroup specific analysis. In the MACH-NC update including 87 trials and 16485 patients, Pignon et al compared locoregional treatment with or without chemotherapy.[102] The hazard ratio of death was 0.88 ($p < 0.0001$) with an absolute benefit for chemotherapy of 4.5% at 5 years and a significant interaction ($p < 0.0001$) between chemotherapy timing (adjuvant, induction or concomitant) and treatment. Concomitant chemotherapy was found to be better than induction chemotherapy. For the 50 concomitant chemoradiation trials, the hazard ratio was 0.81 ($p < 0.0001$) and the absolute benefit was 6.5% at 5 years. The meta-analysis showed benefit for concomitant chemotherapy irrespective of type of radiation (conventional or altered fractionation). The study also concluded that multi-agent chemotherapy did not provide a significant benefit over single-agent cisplatin in the concurrent setting and compared to any other chemotherapeutic agent, platinum-based chemotherapy was significantly efficacious. There was a decreasing effect of chemotherapy with age suggesting that this strategy may be less beneficial in patients over the age of 70 years.[102]

In the MACH-NC comprehensive analysis by tumour site[103] there were 2767 patients with hypopharyngeal cancers. The study suggested that addition of chemotherapy has an absolute 5-year overall survival benefit of 3.9% in the definitive setting with concomitant chemoradiation, both with conventional and altered fractionation.

Non-surgical treatment is used in resectable advanced hypopharyngeal malignancies for organ preservation and when medical comorbidities preclude surgery. Chemoradiation is generally accepted as the gold standard of treatment in advanced laryngeal cancers without frank cartilage erosion. This has been extrapolated to hypopharyngeal cancers despite there being greater risk of both acute and chronic toxicities.[104]

Larynx preservation with concomitant chemoradiation

Chemoradiation scores over surgery with its ability for larynx preservation. However, there have never been any randomized trials comparing chemoradiation vs surgery followed by radiation in hypopharyngeal cancers. The only evidence we have today are single-arm studies, which

TABLE 16.4 MACH-NC UPDATE [Hypopharynx subset] Hazard Ratio of death and 5-year OS

	Timing of chemotherapy			Test of interaction	OS Hazard ratio
	Adjuvant	Neoadjuvant	Concomitant		
HR [95% CI]	1.06 [0.82; 1.38]	0.88 [0.75; 1.02]	0.85 [0.75; 0.96]	$p = 0.31$	*0.88*
5-year abs benefit [CI]	–2.3% [–13.7 9.1]	+5.3% [–0.8; 11.4]	+4% [–1.1; 9.1]		

have shown encouraging results with respect to larynx preservation.

In a study by Huang et al[105] on 33 patients with advanced resectable hypopharyngeal cancers treated with IMRT and concomitant chemotherapy, the laryngeal preservation rate was 67% with a 5-year overall survival (OS) of 44%. A similar study by Liu et al[106] on 27 patients showed laryngeal preservation rates of 63% and 5-year OS rates of 35%. The only randomized controlled trial[107] comparing induction chemotherapy followed by radiotherapy to concomitant chemoradiotherapy for laryngeal preservation in T3M0 pyriform sinus carcinoma, found significantly better laryngeal preservation rate of 92% at 2 years in the concomitant chemoradiation arm as compared to 68% for the induction chemoradiotherapy group.

INDUCTION CHEMOTHERAPY FOR ADVANCED HYPOPHARYNGEAL MALIGNANCIES

When induction chemotherapy is used in conjunction with concurrent chemoradiation in HNSCC, the treatment is referred as sequential chemoradiation. The rationale underlying the use of induction chemotherapy is based on the expectation that drug delivery is better in untreated well-vascularized tumour, and the eradication of micrometastatic disease may be achieved because of high response rate and better tolerance to induction chemotherapy in treatment-naive HNSCC patients.[106]

The approach generally used is to use two to three cycles of induction chemotherapy followed by response assessment. Responders are continued with definitive chemoradiotherapy whereas non-responders are offered surgery. The earliest randomized evidence in favour of induction chemotherapy came from the EORTC 24891 trial[108] conducted in patients with tumours that would require total laryngectomy. This trial randomly allocated patients to induction chemotherapy with cisplatin and 5-florouracil (5-FU) followed by definitive radiation vs primary surgical resection and post-operative radiation. With a median follow-up of 10 years, this trial demonstrated no significant difference in 5- or 10-year OS or progression-free survival.[109] Of note, two-thirds of living patients in the chemoradiotherapy arm were able to retain their larynxes. Thus, PF became the standard induction chemotherapy regime. This is the only randomized controlled study for hypopharyngeal cancer patients and it needs special emphasis that the organ preservation rate in this study was 42% at 3 years with no difference in overall survival.[109]

The only randomized trial comparing induction chemotherapy followed by radiotherapy to concomitant chemoradiotherapy in T3 pyriform cancers showed larynx preservation rates which were lower for the induction arm (68% at 2 years), but there was no difference in the event free survival rates.[107]

The MACH-NC data showed no benefit of multiagent chemotherapy regimes. However, this was a meta-analysis of earlier trials.[102] The later studies evaluated the addition of docetaxel (T) to the backbone of cisplatin and 5FU (PF) to facilitate organ-preservation in locally advanced laryngeal or hypopharyngeal cancers. A randomized French study on 213 patients demonstrated that TPF induction chemotherapy (compared to PF induction) results in superior tumour response rates (80% vs 59%) as assessed by laryngoscopy and CT or MRI.[110] Those with response to induction chemotherapy were treated with organ-preserving (chemo)radiotherapy, while non-responders received laryngectomy and post-operative (chemo)radiation. The higher response rates in the TPF arm allowed for higher rates of laryngeal preservation (70% vs 57% at 3 years), without a detriment in OS (60% at 3 years in both arms). The superiority of TPF was reconfirmed in their long-term follow-up with 10–year larynx preservation at 70.3% vs 46.5% ($p = 0.01$) in the TPF vs PF arm respectively.[111] However, no difference was seen in overall survival, disease-free survival or locoregional control rates between the two arms.

The TAX-324 study utilized similar induction chemotherapy arms (TPF vs PF), followed by concurrent chemoradiotherapy with carboplatin in locoregionally advanced cancers.[112] Five-year survival in the TPF arm was 52% vs 42% receiving PF, while no increased rates of gastric feeding tubes or tracheostomies were noted between groups. A subgroup analysis of larynx and hypopharynx patients demonstrated improved survival in these patients, as well as higher rates of laryngectomy-free survival.

Thus, for advanced hypopharyngeal cancers which have intact laryngeal framework and function, induction chemotherapy (multi-agent TPF) followed by chemoradiation in responders seems to be superior in preservation of larynges and triaging out patients for surgery. Morbidity of the therapy is high and should be kept in mind while selecting a suitable patient for organ preservation.

ALTERED FRACTIONATION FOR ADVANCED HYPOPHARYNGEAL MALIGNANCIES

Another method of organ preservation is by intensification of radiation therapy. Altered fractionation radiotherapy modifies the dosage or fractionation schedules of conventional fractionated radiotherapy. Altered fractionation has been found to improve locoregional control with a potential for organ preservation. A meta-analysis of radiotherapy in carcinomas of the head and neck (MARCH) established the survival benefit of altered fractionation, especially with hyperfractionation having an 8% absolute benefit at 5 years over conventional radiotherapy.[113] A multicentric randomized control trial, comparing accelerated (6 days per week) compared to conventional (5 days per week) showed a 12% 5-year locoregional control advantage.[114] However, there were few hypopharyngeal cancers in most of these studies.

There are a few retrospective series looking at the role of altered fractionation in hypopharyngeal cancers. Niibe et al[115] reported the results of 42 patients with

hypopharyngeal carcinoma who were either inoperable or refused surgery treated with curative intent radiation therapy. Hyperfractionated radiation therapy was used in 23 whilst 19 were treated with conventional fractionation. They found significantly better 3-year local control rates (61.5% vs 18.4%), pharyngolaryngectomy-free-survival rates (64.7% and 5.3%) and a relatively better overall survival rate (69.3% and 31.6%, $p = 0.075$) with hyperfractionated RT with acceptable toxicity. Kawashima et al[116] used a 'chemotherapy enhanced accelerated radiotherapy' regimen to improve control rates in T2–T4 hypopharyngeal cancers; 35 patients received 40 Gy/4 weeks to the entire neck followed by boost RT administering 30 Gy/2 weeks (1.5 Gy twice-daily fractionation). Cisplatin and 5 fluorouracil were administered concomitantly only during the boost RT. They reported encouraging results with overall survival and local control rates at 3 years being 91% and 88% respectively, without significant effects on swallowing.

Salvage surgery after organ preservation

The premise of offering organ preservation is based on the ability to salvage if the treatment does not succeed. This is critical in the counselling of the patient whilst planning treatment.

RESIDUAL LOCAL DISEASE

The hypopharynx is at the highest risk for locoregional and distant failure following standard treatment protocols. Organ preservation strategies for advanced hypopharyngeal cancers are generally applied in Stage III/IVa cancers. However, control rates after primary radiotherapy/chemoradiation are low, with around 30–50% of patients having residual/ local recurrences.[117–119] Most of these patients tend to be unresectable with recurrences involving the prevertebral fascia or carotid artery. When salvageable, the surgery for most cases would be a laryngopharyngectomy with pharyngeal reconstruction.[120–122] In a retrospective study,[119] the successful salvage rate was 17.1% (7/41 patients who recurred locally after radiotherapy). None of the patients who had a primary T4 disease could be successfully salvaged. In a similar study on salvage laryngectomy post-chemoradiation for laryngeal and hypopharyngeal cancers, only 10% of patients with recurrent hypopharyngeal carcinoma underwent salvage surgery.[123]

Salvage laryngopharyngectomies have an increased rate of complications especially pharyngocutaneous fistulae which may occur in up to 50%.[117] Concomitant chemoradiotherapy with radiation doses more than 64 Gy increase this risk considerably. Pharyngocutaneous fistulae in turn increase the incidence of carotid artery blowouts. With a low salvage potential and high rate of complications it is imperative to carefully choose patients for organ preservation, and the surgical team should have a low threshold for using vascularized tissue from non-radiated areas to reconstruct or buttress the pharyngeal repair.

RESIDUAL NECK DISEASE

Limited neck disease (N1) tends to respond well to chemoradiotherapy. Large volume nodal disease (N2 or N3), however, has a poor response despite chemoradiation. In case of palpable or radiologically obvious remnant neck node, salvage neck dissection is done. Generally, a modified neck dissection levels II–V is performed. In case neck nodes are not palpable but picked up on PET-CT scan at 12 weeks in the surveillance scan, a neck dissection is performed on those findings.[124] Larger neck nodes have a reduced salvage potential and increased morbidity and the same caution should be exercised before deciding on organ preservation.

MANAGEMENT OF RECURRENT AND METASTATIC DISEASE

Patients with recurrent disease should be triaged into locoregional and distant metastasis. The management of recurrences depend on recurrent staging, interval between completion of treatment and recurrence (disease-free interval), patient's PS, presence of comorbidities, patient's willingness for further treatment, 'salvageability' potential and durability of control.

Prior treatment has an immense bearing on the salvage treatment. Potential for durable response to treatment improves if surgical salvage is followed by adjuvant radiation/chemoradiation received. In a previously irradiated patient the fields of radiation and the potential for re-irradiation should be discussed prior to salvage surgery.

Many patients with hypopharyngeal cancer develop distant metastases at some point in their clinical course. When this occurs, long-term survival is rare and the treatment intent is palliative in nature. The median overall survival for patients with metastatic head and neck cancer is 6–10 months. Palliative treatment should be planned to improve the remaining quality of life and includes symptom control with appropriate pharmacological interventions, radiation therapy, chemotherapy and best supportive care.

Pain alleviation with narcotic pain medication is invaluable. Palliative radiation therapy is suitable in patients with local pain or bleeding. Palliative chemotherapy can be considered in patients with good PS and disseminated disease. Single-agent cisplatin has been shown to improve overall survival in head and neck cancer patients.[125] Historically, combinations of cytotoxic chemotherapies do not improve survival in comparison to cisplatin alone and are not used routinely. Recent randomized evidence supports the use of a triple drug regimen (cisplatin or carboplatin, 5 fluorouracil and the anti-epidermal growth factor receptor monoclonal antibody cetuximab) in recurrent or metastatic head and neck cancer,[126] with addition of cetuximab to platinum and 5FU significantly improving OS from 7.4 to 10.1 months. However, patients with poor PS should be offered best supportive care and pain medications.

FOLLOW-UP OF PATIENTS

Patients treated for hypopharyngeal cancers should be followed up to check their functional status as well as look out for recurrence. Functional status includes swallowing and speech apart from morbidity related to surgery and radiation therapy.

Follow-up schedule

The standard follow-up schedule is bimonthly for the first 2 years, quarterly in the third year and biannually in the fourth year. From the fifth year, annual check-ups are done with a high index of suspicion for second primary cancers.

Speech

Patients treated with radiation/chemoradiation should undergo periodic speech assessment and therapy to counter the effects of radiation on the vocal cords. Over time the muscle tends to atrophy and the patients are counselled to do regular speech therapy. The speech therapy should be initiated during the treatment itself to inculcate proper vocal 'hygiene' habits in the patients. This includes vocal exercises, vocal naps, hydration and taking care of gastro-oesophageal reflux.

In those rehabilitated with a tracheo-oesophageal prosthesis, careful evaluation for any signs of leakage either through or around the puncture site is carried out. Care of the prosthesis with antifungal application as well as regular cleansing is to be reiterated. This will be further elaborated in the chapter on speech rehabilitation Chapter 34, Speech voice and swallow rehabilitation after chemoradiation.

Swallowing

During radiation/chemoradiation active swallowing and speech therapy is advocated. This must be evaluated at every follow-up appointment. Proactive intervention during the treatment process and continuation thereafter may prevent the fibrosis that sets in which impedes restoration of a normal swallow. Use of saliva substitutes improves swallowing.

A consult with the speech and language pathologist prior to treatment initiation is important. The patients should be counselled to persist with the oral swallowing to reduce the amount of radiation induced fibrosis. On treatment completion the patients are evaluated for signs of aspiration and pharyngeal stenosis which needs dilatation and active therapy.

Dental check-up

Dental check-up for carious teeth and damaged crowns should be done diligently prior to radiation. During follow-up, fluoride gel application is advised regularly to strengthen the enamel and prevent dental carries. Hydration and its importance in preventing halitosis, periodontitis should be impressed on the patients.

Thyroid status

The thyroid gland is either removed partially or completely during surgery and/or radiated following surgery. In either case the patient may turn hypothyroid following treatment for hypopharyngeal cancer. The thyroid function tests should be done when symptomatic or routinely at 6 months following completion of radiation. Thyroxine replacement is started if hypothyroidism sets in and replacement is based on body weight at 1–2 mcg per kg.

Disease surveillance

The patients should be monitored for second primary cancers in the upper aerodigestive tract which are seen in up to 50% of patients. The risk of new cancer development increases by 1% annually. The patients who continue to abuse tobacco and alcohol have a 15–20% increased recurrence risk and should be counselled to desist.

PET-CT scan should be done between 10 and 12 weeks for optimum benefit following radiation in those treated with organ preservation. The negative predictive value of PET-CT is above 95% and is an important indicator of disease control.

SUMMARY

Hypopharyngeal cancer is a high-risk cancer. There are fewer barriers to spread of disease and a good lymphatic network yields a high incidence of occult nodal metastasis. The chance of synchronous tumours is 15% and distant disease at presentation is known. The long-term overall survival in stage III & IV cancers is low. Treatment of hypopharyngeal cancers is fairly morbid affecting speech and swallowing and is requires multidisciplinary planning. Careful evaluation of laryngeal and pharyngeal function in treatment planning is of paramount importance. Organ preservation in advanced hypopharyngeal cancers requires careful case selection. Surgery with adjuvant therapy still remains the gold standard in the management of advanced hypopharyngeal cancers.

KEY POINTS

- Accurate staging is essential. Workup should include evaluation for synchronous primaries and distant metastasis.
- Laryngeal function should be accurately evaluated prior to treatment especially while considering organ preservation.
- Radiation therapy is recommended for Stage I and II disease.
- Multimodality treatment is recommended for Stage III and IV disease.
- The overall 5-year, tumour-specific survival is less than 30%, although the survival of treated patients rises to 50%.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search as well as the websites Cancerlit and Cancer Net using the keywords: neck mass, carcinoma of occult primary (COP), carcinoma of unknown primary (CUP), head and neck neoplasm, imaging, and focusing on diagnosis, surgery and management. The evidence in this chapter is mainly levels 3–4 with some level 2 evidence. The clinical recommendations are predominantly B and C.

INTRODUCTION

Head and neck squamous cell carcinoma (HNSCC) that presents as carcinoma of unknown primary (CUP) represents a difficult challenge for the practising clinician. With improvements in diagnostic techniques such as cross-sectional imaging, molecular diagnostics, robotics and positron emission tomography (PET) scanning, clinicians are now able to identify a higher proportion of primary sites in patients presenting with CUP than before. The most common presentation of CUP in the head and neck is in the context of human papillomavirus (HPV)-associated oropharynx (HPV+OPSCC) carcinoma. As the year-on-year numbers of HPV+OPSCC are increasing in the developed world, it is likely therefore that the incidence of CUP is also increasing.[1–3]

DEFINITION AND HISTORICAL BACKGROUND

The term carcinoma of unknown primary (CUP) represents a heterogeneous disease entity characterized by the presence of clinically overt metastatic disease in the absence of a clinically or radiologically obvious primary tumour. In the head and neck, the definition of a true unknown or occult primary carcinoma is the presentation of metastatic neck lymphadenopathy without the development or manifestation of an index primary tumour within a subsequent 5-year period.

CUP is diagnosed in a patient who presents with biopsy-proven squamous cell carcinoma (SCC) in one or more cervical lymph nodes and in the absence of an obvious primary tumour despite rigorous clinical examination, appropriate cross-sectional imaging and examination under anaesthesia including an ipsilateral tonsillectomy and biopsy of tongue base mucosa (or formal mucosectomy) +/– biopsy of the mucosa of the post nasal space and/or ipsilateral piriform fossa.

It is important to distinguish between true CUP cases in which a primary site tumour never becomes evident and the case where, on initial presentation, a primary tumour is present but remains undetected.

In the latter case, it is presumed that there has been early metastasis from a small primary tumour following which the growth of the cervical metastasis has proceeded at a considerably faster rate than that of the primary tumour. It is inevitable that, left untreated, the primary tumour would eventually become clinically evident. However, as will be seen later, the sites at highest risk of harbouring a

primary tumour are often treated in any case such that the primary tumour never becomes clinically evident.

It follows therefore, that quantification of the true rate of CUPs is not possible with any accuracy.

One of the first explanations of CUP was suggested by Volkmann in 1882 and widely accepted until the 1940s. He believed that the neck mass resulted from the degeneration of a 'branchiogenic cyst' into carcinoma. In 1940, Martin and Morfit revisited this hypothesis in a study of 55 CUP patients; as only eight met Volkmann's criteria, this theory was dismissed.[4–9] Since then several theories have been proposed in an attempt to explain this clinical phenomenon.

Two hypotheses currently predominate, although neither are proved. In the first hypothesis proposed, as explained above, the microscopic primary tumour lies undetected in the mucosal folds of Waldeyer's ring and is too small to be detected by conventional diagnostic methods and is ultimately successfully treated either by design or coincidental (by inclusion in radiation fields designed primarily to treat the neck).

The second hypothesis, which attempts to explain the existence of 'true' CUPs, supposes that the primary tumour is removed by the patient`s innate or adaptive immune system, but not before early metastasis to the cervical lymph nodes has occurred with subsequent evasion of the host immune response.[10–13]

INCIDENCE

The incidence of CUP in HNSCC has reduced significantly over the last two decades (**Table 17.1**). In the 1970s and early 1980s, prior to the universal availability of cross-sectional imaging, the incidence ranged between 10% and 30%. Many of these historical cases may have been incorrectly diagnosed as CUP as they represented distant metastases from lung and abdominal primaries.[14]

The incidence reported in the literature subsequently plateaued over the last decade to around 5% of HNSCC due to standardized diagnostic protocols.[15–28] Our own single-centre experience at Guy's & St Thomas' NHS Trust has also seen a reduction in the incidence of CUP over the last 10 years from 8% to 4% of new HNSCC cases.[29] It is increasingly recognized that high-risk HPV related HNSCC tends to present with regional disease and clinically unrecognized primary focus, and most patients with CUP presentation will have a primary site in the oropharynx.

NOMENCLATURE

The staging of head and neck cancer is dealt with in detail in Chapter 4, Staging of head and neck cancer However, recent changes to the TNM staging system published in the American Joint Committee on Cancer (AJCC) 8th edition Cancer Staging Manual and the Union for International Cancer Control (UICC) included changes which involve the staging of CUP.

A T0 category is no longer assigned to p16 – OPSCC and other non-HR HPV cancers e.g. larynx, oral cavity and hypopharynx. This is because, in these tumours an exact primary site is, by definition, unable to be established. In contrast, cytology specimens following fine-needle aspiration cytology (FNAC) of an enlarged lymph node in which the presence of metastatic carcinoma is confirmed can be subjected to testing for HPV and Epstein–Barr virus (EBV) status.

It is considered that demonstration of HPV or EBV status safely allows the primary site to be determined as oropharynx or nasopharynx respectively and therefore, classification systems for p16 + OPSCC and nasopharynx maintain T0 categories (as does salivary gland as primary site can be determined on cytological findings). The molecular biological and pathological aspects are discussed in Chapters 6, Introducing microbiology of head and neck cancer and 26, Pathology of head and neck malignancies respectively. The management of HR HPV oropharyngeal cancer can be found in Chapter 13, Oropharyngeal tumours.

EVALUATION AND DIAGNOSIS

Clinical assessment

Patients presenting with metastatic lymphadenopathy with an occult primary should undergo a structured diagnostic workup, as recommended by evidence-based guidelines. A thorough history is essential. A history of excessive alcohol consumption and heavy smoking may suggest a primary tumour outside the nasopharynx, while a history of multiple sexual partners and orogenital contact may suggest a primary tumour within the oropharynx.[14] Clinical examination should include fibre-optic nasolaryngoscopy with special attention to sites where a small primary focus can be missed, such as the nasopharynx, tongue base, the infrahyoid epiglottis and the pyriform sinus. The site of the node is an indicator of the primary site. For instance, level I nodes are almost never seen with nasopharyngeal primaries

TABLE 17.1 Treatment recommendations by ENT-UK Multidisciplinary Treatment Guidelines (2016)

Stage	Surgery	Radiotherapy	Chemotherapy
T0N1M0 (No ECS)	SND or MRND	No unless for mucosal sites	No
T0N1M0 (ECS)	SND or MRND	Yes to neck	Should be considered
T0N2M0	SND or MRND	Yes – ipsilateral but contralateral should be considered	Should be considered
T0N3M0	MRND or RND	Yes – ipsilateral but contralateral should be considered	Should be considered

and level V nodes never with laryngeal cancer. Based on epidemiological data and lymph node distribution, nomograms have been created to predict the primary site.[30]

Novel endoscopic techniques, used in the clinic setting, have shown use in this scenario. Narrow band imaging (NBI) is based on the modification of the standard white light endoscope in which white light is transmitted through optical filters absorbing all but two wavelengths; one band centred at 415 nm and another at 540 nm. The former wavelength penetrates the superficial mucosa and highlights submucosal capillaries as a brown colour while the latter penetrates through the submucosal layer and identifies prominent vessels as cyan in colour. As SCCs arising from the upper aerodigestive tract mucosa are accompanied by neoangiogenesis, NBI identifies neoplastic tissue at an earlier stage than conventional endoscopy. A meta-analysis[31] of four studies where NBI was performed on 115 patients with CUP demonstrated a high level of diagnostic accuracy(sensitivity (74.1%; 95% confidence interval [CI] 52.5%–100%) and specificity (94.1%; 95% CI 5 23.7% –100%)).

This should be followed by cross–sectional imaging such as multi-planar computed tomography (CT) or and magnetic resonance imaging (MRI) and FDG PET-CT before the patient is subject to an assessment under general anaesthesia.[32] If the primary is not identified following the above sequence of investigations, then the patient should undergo pandendoscopy under general anaesthesia which should include biopsies based on the results of the core biopsy and imaging. Sites to be sampled include the nasopharynx, tongue base and ipsilateral tonsillectomy.[33] Using this protocol, most CUP cases turn out to be either tonsil or tongue base primary cancers.[14, 29]

RIGID ENDOSCOPY GUIDED BIOPSY OF THE NASOPHARYNX

Blind biopsies of the nasopharynx have proven to be unsatisfactory as they often provide a poor yield of primary site diagnosis.[30] It is therefore recommended that biopsies on this site should be guided using rigid telescopes,[14] especially where abnormalities have been noted on imaging. In instances where high-resolution imaging does not identify pathology, even telescope-guided biopsies are unlikely to pick up a malignant focus.

BILATERAL TONSILLECTOMY

There is evidence from selected series that bilateral tonsillectomy should be employed as the primary resides in the contralateral tonsil in up to 10% of cases.[34–36] In the high-risk HPV era, there is greater recognition that these tumours can be multifocal at presentation,[37] providing further basis for a bilateral tonsillectomy (**Figure 17.1**). It has been suggested that bilateral tonsillectomy could reduce the need for bilateral irradiation to the neck, thus leading to reduced morbidity. In patients who have undergone previous tonsillectomy but they have tonsillar remnants, the search for the primary should also include the excision of the remnants as primary tumours can be found within them.[38, 39]

TONGUE BASE BIOPSIES

Blind biopsies of the base of tongue (BOT) are often unsatisfactory as occult carcinomas rarely arise from the mucosal surface. It is therefore advisable to target the deep tissue of the BOT. The superior manoeuvrability and access provided by transoral robotic techniques have led to the design of the procedure called tongue base mucosectomy (TBM, **Figures 17.2** and **17.3**). This procedure samples the entire tongue base mucosa and has been shown to identify a primary site in over 50% of patients who are PET negative and have no primary site in the tonsil. Interestingly, around 10% can be contralateral foci. However, the morbidity of this procedure cannot be underestimated, with the risk of bleeding, need for tube feeding and the very small risk of pharyngeal stenosis.[40, 41]

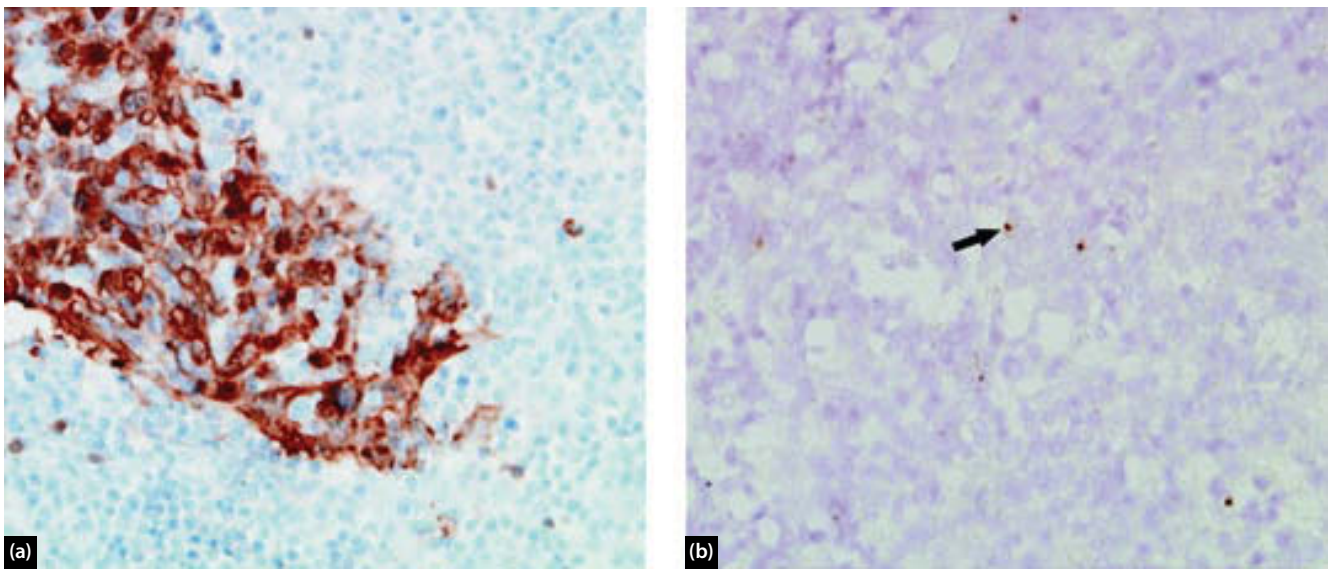

Figure 17.1 Photomicrograph showing immunohistochemistry positivity to p16 in a lymph node of a patient with metastatic HNSCC of unknown primary suggesting a tonsil origin. (a) P16 positivity in the tonsil **(b)** identified malignant cells in the tonsil.

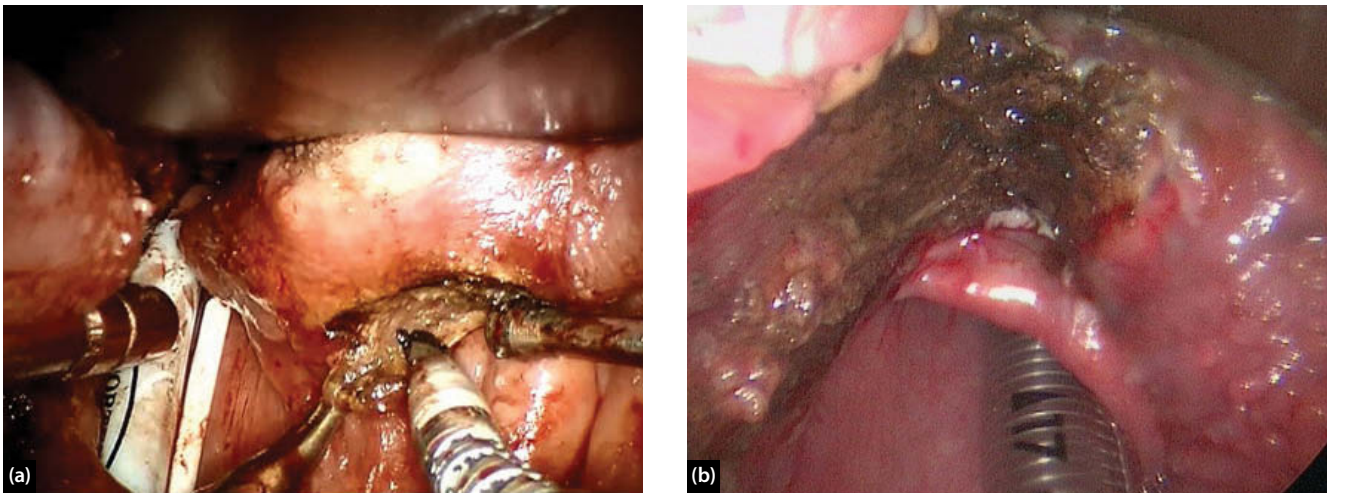

Figure 17.2 (a) A robotic tongue base mucosectomy in progress and **(b)** completed procedure.

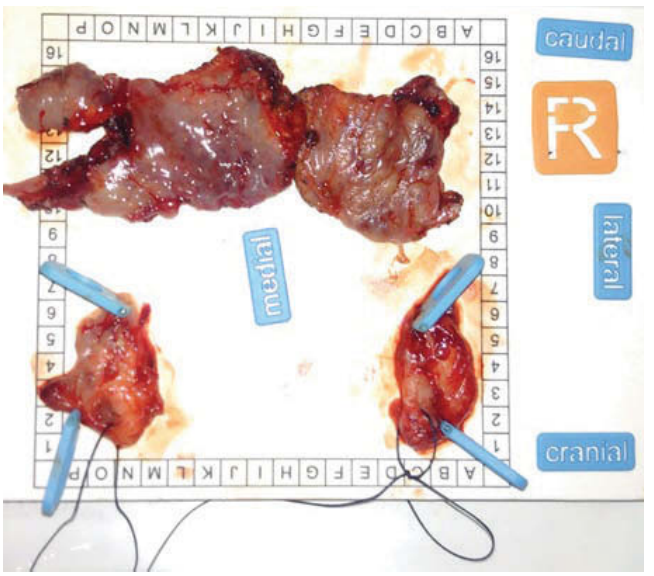

Figure 17.3 A bilateral tonsillectomy and robotic tongue base mucosectomy specimen orientated and mounted for pathological examination.

POSITRON EMISSION TOMOGRAPHY (PET) SCANNING

Fluorodeoxyglucose[18] (G) positron emission tomography (FDG-PET) scanning is now a key modality in the evaluation of the unknown primary. It is combined with a CT scan to provide anatomical localization of the avid lesion (fusion or co-localized PET scanning).

A recent meta-analysis of FDG-PET-CT from the Netherlands has reported data from 11 studies including 433 patients with CUP. Overall primary detection rate was 37%, with equal sensitivity and specificity of 84%. A negative PET-CT result does not preclude the requirement for panendoscopy and multiple site biopsies.[42, 43] Other studies have identified the sensitivity and specificity of PET scanning in identifying the primary in HNSCC to be as high as 87% and 92% respectively.[32–39]

It should be noted that this investigation is only useful if it is performed before the panendoscopy and biopsies, as the post-biopsy inflammatory response may increase the uptake of the FDG tracer, causing a false positive result (**Figure 17.4**).

NICE RECOMMENDATIONS

The pathways for assessment of neck lumps vary across different healthcare settings. Based on low- to high-quality evidence from retrospective studies, an original systematic review, meta-analysis of diagnostic parameters and the experience and opinion of an expert panel, the National Institute for Health and Care Excellence (NICE) made the following recommendations for people with a neck lump that is thought to arise from a head and neck cancer[44] (NICE terminology uses 'offer' to reflect a strong recommendation and 'consider' for a recommendation where the evidence of benefit is less certain):

1. Consider adding ultrasound guidance to fine-needle aspiration cytology or core biopsy.
2. Consider having a cytopathologist or a biomedical scientist to assess the adequacy of the cytology sample.
3. Consider a FDG PET-CT scan as the first investigation to detect the primary site.
4. Consider using NBI (in clinic or during general anaesthetic assessment) in cases where PET-CT has filed to identify a primary site.
5. Offer surgical diagnostic assessment if the FDG PET-CT does not identify a primary site, including guided biopsies, tonsillectomy and TBM.

These have been summarized in an algorithmic fashion in **Figure 17.5**.

CLINICAL MANAGEMENT

Management of CUP continues to generate controversy in multidisciplinary tumour board and scientific meetings.

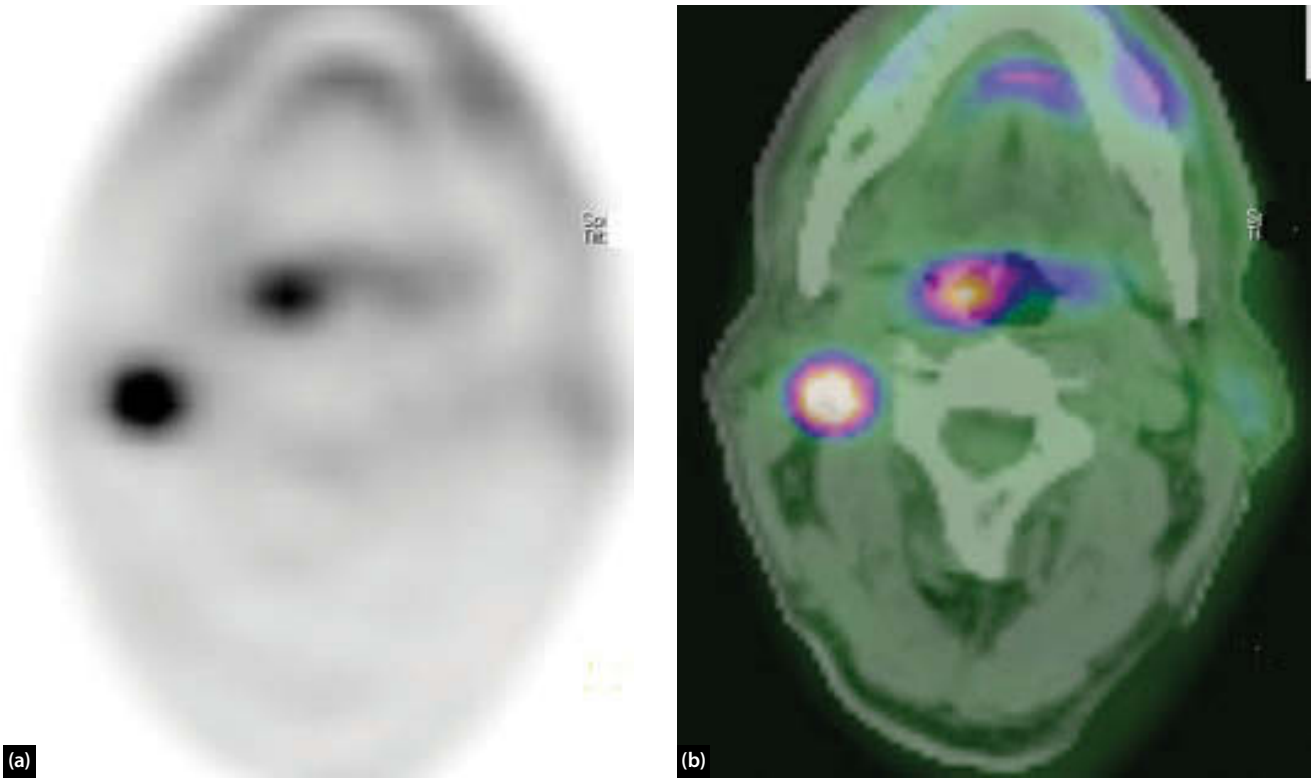

Figure 17.4 FDG-PET-CT scan demonstrating uptake tracer in the right oropharynx in a patient presenting with metastatic SCC of the right neck performed before panendoscopy and biopsy.

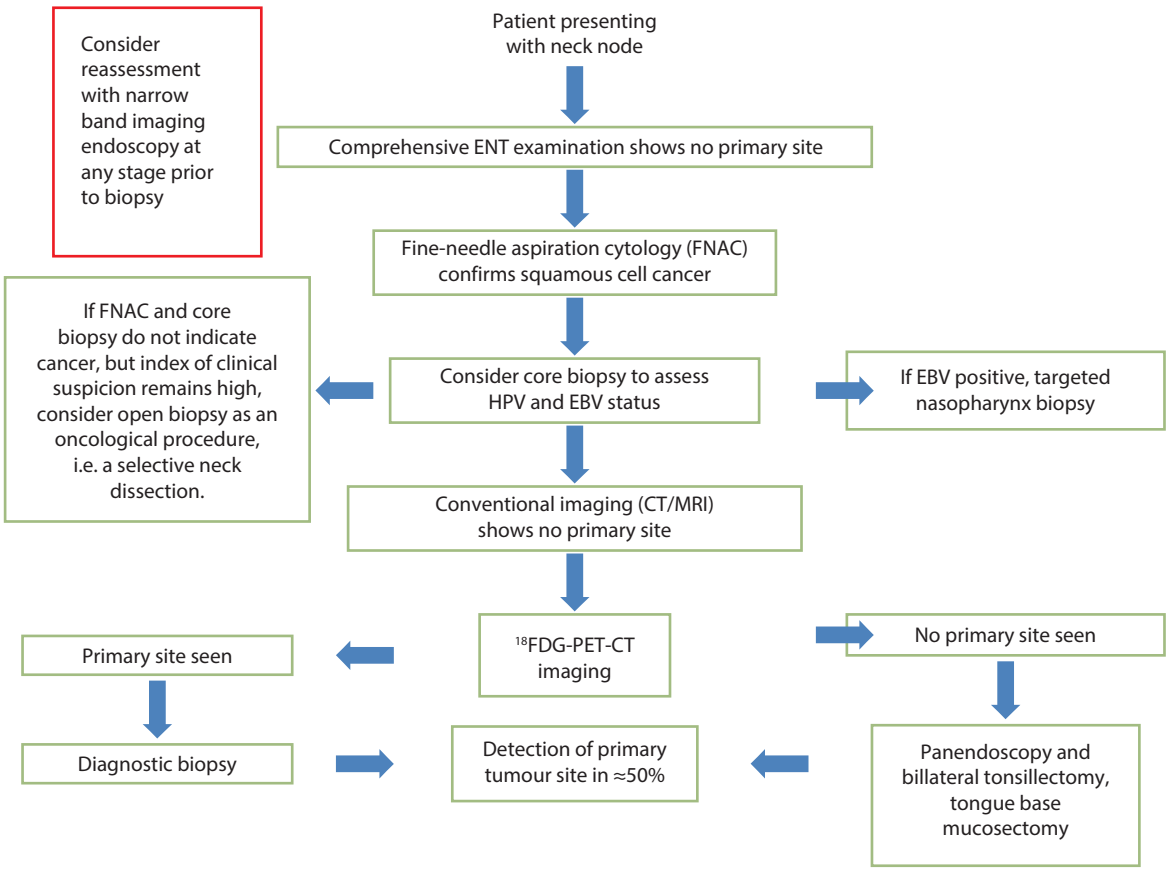

Figure 17.5 Suggested algorithm for the management of the unknown primary.

CUP management can be organized into the treatment of early disease (N1 with no extracapsular spread) and advanced disease (extracapsular spread, N2 and N3).[42, 43] In early disease, single-modality therapy can be considered in the form of neck dissection alone or radiotherapy alone. Radiation therapy alone has been reported for small N1 stage disease with some success and can be considered in patients with comorbidities that can pose a high surgical risk.[40] Similarly, some authors have adopted neck dissection surgery alone without radiotherapy for N1 neck disease with a 'watch & wait' approach to the primary.[41] Advanced cases require combined modality therapy.[45–47] In the absence of high-level evidence, management is largely based on institutional protocols.

Surgical management of the neck

Traditionally, either radical neck dissection or modified radical neck dissections have been employed in the management of CUP. Selective neck dissection has been suggested as a valid option for patients with N2a and N2b disease as the risk of metastases in levels I and V has proven to be rare in patients with CUP unless they present with N3 neck disease.[29, 44]

Traditionally, most units favour neck dissection upfront followed by either RT or chemoradiotherapy (CRT) as indicated. This allows adequate pathological staging of the neck and therefore tailoring treatment accordingly. There is also an advantage of performing surgery in a non-irradiated neck and therefore minimizing morbidity. This approach could potentially cause a treatment delay if any unexpected complications from the surgery occur. Primary RT or CRT will reduce the need for but may render surgery difficult and with an increased risk of complications.

However, recent randomized trials[48] have reported that PET-CT-guided active surveillance after radical CRT showed similar survival outcomes to upfront neck dissection followed by CRT and lead to considerably fewer NDs, fewer complications and lower costs. Although this is in the setting of the known primary, the data is robust enough to warrant a re-examination of current approach for primary surgery in CUP, especially when a firm diagnosis of the neck lump can be established by non-surgical means.[45, 46]

Management of the violated neck

In the past many patients underwent excisional and incisional biopsies as first-line diagnosis. Earlier reports identified poor prognosis in these patients, which has been attributed to inadequate definitive treatment and advanced stage at presentation. With current, centralized, multidisciplilnary team (MDT) driven practices, smaller numbers of patients with lateral neck masses undergo open surgical interventions for diagnosis, primarily due to non-diagnostic FNAC or owing to suspicion of non-SCC pathology such as lymphoma. In the era of adequate surgical management of the neck and good (chemo)radiation practices, open cervical biopsy does not signify a poorer prognosis provided adequate and timely treatment is given.[49] A high proportion of HPV positive oropharyngeal tumours may also explain the favourable outcomes observed.[50] The treatment of the violated neck can be upfront surgery or CRT followed by PET-CT surveillance and surgery as needed.

Branchial cyst carcinoma

The evidence for the existence of branchial cyst or branchiogenic carcinoma is tenuous. Many reported series have failed to meet the criteria set by Hayes Martin and in many cases elective tonsillectomies were not performed. Many patients with CUP may present with lateral neck cystic masses mimicking branchial cysts. There is enough evidence to recommend that all patients over the age of 35 years with lateral cystic masses must be presumed to have cancer until proven otherwise. The authors recommend that these people should be entered into a CUP investigation protocol even if the FNAC is not suggestive of metastatic SCC.[51]

Radiation therapy to the neck and the putative primary site

The external beam radiotherapy (EBRT) fields recommended remains controversial, with some centres offering unilateral radiation to the neck and ipsilateral likely primary sites, whilst others propose bilateral neck treatment, so-called 'total mucosal irradiation'.

Results for bilateral neck irradiation tend to show improved local control rates and disease-free survival compared to unilateral neck treatment. The improvement on overall survival however is not always seen.[43, 45–50]

Unfortunately, the superior survival results seen with bilateral EBRT are at the expense of increased morbidity in terms of pain, xerostomia and long-term dysphagia with increased feeding tube dependence.[46]

Intensity-modulated radiotherapy treatment (IMRT) with bilateral neck radiation has the potential for reduced acute and late toxicity as the parotid glands may be spared, with robust data to suggest that IMRT significantly reduces morbidity.[52, 48] IMRT is currently the standard of care for head and neck cancers in several countries. For CUP patients receiving total mucosal radiation, IMRT appears to provide improved radiation coverage of the mucosa including the nasopharynx with significant reduction of dose to the parotid gland contralateral to the involved neck and therefore reducing the risk of severe xerostomia.[53]

RECOMMENDED TREATMENTS[47, 54]

bcT0N1M0

cT0N1M0 WITHOUT ENE FOUND ON HISTOPATHOLOGICAL OR RADIOLOGICAL STUDIES

Patients can be treated with single-modality treatment either with selective neck dissection or involved field

radiotherapy alone. If treated surgically, the upper aerodigestive tract mucosa should be carefully inspected during surveillance visits.

PT1N0M0 WITH ENE

Patients should be treated with post-operative RT if ENE is identified.

T0N2M0 AND T0N3M0

Patients should be treated with primary CRT followed by PET-CT guided surveillance or combined modality treatment including neck dissection followed by RT or CRT.

TREATMENT OUTCOMES

Most series show improved overall and disease-free survival with combined modality treatment. Survival results are dependent upon the N stage at presentation with worsening outcome observed with increased stage. The outcome and survival of patients with CUP has been variable as the published series are mainly retrospective and represent diverse patient populations. We would however expect a 5-year survival of between 70% and 100% for N1 stage cancers and 30% and 60% for stage N3.

The overall 5-year survival for all stages of HNSCC with unknown primary site would be in the range of 52% and 75%.[39–49] A 10-year single-centre uncontrolled retrospective case series of 25 patients with complete records, from the authors' institution, showed an excellent overall survival for N1 disease of 100% and a 60% survival for patients with N2 and N3 neck disease.[29] (**Figure 17.6**)

In a recent series of patients with CUP treated with IMRT by the Memorial Sloan Kettering Cancer Center showed 2-year regional progression-free survival, distant metastases-free survival and overall survival of 90%, 90% and 85% respectively.[55]

PATTERNS OF FAILURE

The pattern of failure largely depends on the initial treatment protocol. If EBRT is used, disease recurrence is usually in the neck and in form of distant metastasis. Recurrent disease is often difficult to diagnose and it often shows extracapsular spread and presents in advanced stages. FDG-PET-CT scan is probably the best method of detection and diagnosis of recurrences. Distant metastases often occur within a year of treatment completion and are most common in the lung.[51, 52] The incidence of recurrence in the potential primary sites is extremely variable and may occur from 0% to 66%. It occurs mainly in those patients treated initially with surgery alone. The emergence of a primary tumour often occurs within the first 24 months and usually presents in the oral cavity, oropharynx and nasopharynx.[53]

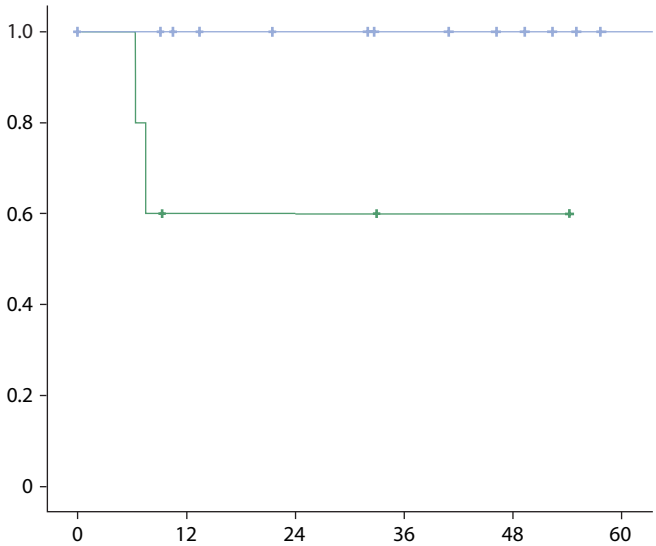

Figure 17.6 Kaplan – Meier Survival Curve for Guy's & St Thomas' series of patients with occult primary carcinoma of the head & neck *n* = 25 (2000 to 2011).

CONCLUSION

The unknown primary in HNSCC is becoming an increasingly rare entity due to better diagnostic protocols and now accounts for fewer than 5% of cases. However, the raw numbers may be on the increase owing to the higher number of HPV-positive cancers. The diagnostic workup should include panendoscopy, bilateral tonsillectomy, biopsies of nasopharynx, tongue base and any other potential suspicious lesions in the upper aerodigestive tract. Investigations should employ cross-sectional imaging CT and or MRI as well as PET-CT imaging; the latter must be performed before the biopsies are taken. Recent modalities being used in the clinical and operative setting allow for a higher primary pickup rate. Most of these cases identify the primary in the oropharynx.

Treatment of CUP should be based on the stage of the disease process, with single modality sufficing for patients with early stage disease. A combination of neck dissection and EBRT may be needed for patients with advanced disease. Bilateral neck irradiation increases overall and disease-free survival at the expense of increased morbidity.

Molecular analysis of the metastatic cervical neck nodes can potentially locate previously occult oropharyngeal or nasopharyngeal primaries.

The survival outcomes are generally good for early and late-stage disease but whether less intensive or single-modality therapy could be adequate in patients who are HPV-positive is yet to be determined.

BEST CLINICAL PRACTICE

- ✓ There is no level 1 evidence for guidance in the management of CUP. Data are at best level 2.
- ✓ PET-CT has shown to have a key rode in the management of patients with CUP and should precede multiple biopsies.
- ✓ Primary surgical management of the neck is preferred to radiotherapy in patients with operable disease.
- ✓ Post-operative selective or total mucosal radiotherapy is indicated for most patients with advanced operable disease.
- ✓ Strategies for the use of new treatment technologies, IMRT and modified radiation fractionation, are largely based on extrapolation of data accumulated for the treatment of known sites of HNSCC.

FUTURE RESEARCH

The management of CUP remains controversial. With the current lack of adequate randomized controlled clinical trials and the decreasing incidence due to improved diagnostic tools, the management of patients with CUP will continue to be challenging.

Most of the current evidence is provided by retrospective single institution studies. With increasing data to suggest that HPV related cancers can be multifocal, further work is needed to define this problem better.

Several questions in the aetiology and management of CUP remain unresolved. These include:

- ➤ Is definitive neck dissection sufficient for patients with N1, N2a and selected N2b disease, avoiding the need for elective total mucosal irradiation?
- ➤ Should definitive RT or CRT should be offered as a primary modality of treatment with salvage neck dissection for persistent disease?
- ➤ Which extent of neck dissection patients should have for each stage?
- ➤ What are the optimal fields for elective irradiation? Ipsilateral, versus bilateral vs total mucosal unilateral or bilateral irradiation.

KEY POINTS

- CUP is an increasingly rare clinical scenario and accounts for only up to 5% of patients with head and neck malignancy.
- Involvement of nodal levels I to IV is almost exclusively associated with occult upper aerodigestive tract primary SCC with level II being the most common site
- Patients should be evaluated with CT, MRI or FDG-PET-CT prior to biopsy in order to guide biopsy site and to avoid imaging artefacts or false positive results with PET-CT.
- FDG-PET-CT has now a clear role on the management of CUP and should be employed whenever possible.
- The only tumour marker of clinical value is Epstein–Barr virus serology as will indicate origin from the nasopharynx. HPV16 status can be determined in tumour cells aspirated from the necks of patients with metastatic HNSCC and its presence is a reliable indicator of origin from the oropharynx.
- Bilateral tonsillectomy may be recommended as diagnostic tool in the evaluation of CUP. Transoral laser and transoral robotic mucosectomies of the tongue base have showed promising results in detecting primary tumours at this site.
- Definitive neck dissection should be performed in all patients with CUP. The extent of the neck dissection requires further evaluation especially on those patients with N1, N2a and limited N2b disease where selective neck dissection could be considered.
- Total mucosal irradiation has demonstrated a reduction in primary site recurrence without any improvement in overall survival. Associated mucositis and xerostomia rates are high.
- Radiotherapy-related morbidity can be reduced if selective mucosal irradiation is undertaken, most commonly by exclusion of nasopharynx especially in patients presenting with II to IV nodal disease.
- IMRT should be considered as the optimal technique for radiation dose delivery.
- For total mucosal irradiation, a dose of 50 Gy in 25 daily fractions, five fractions per week is sufficient for control of occult primary disease.
- Nodal stage is the most important risk factor for local recurrence.
- CRT in patients with CUP should be considered in N3 disease and in those patients with definitive ECS or when resection margins are positive for example around the common carotid artery.

SEARCH STRATEGY

Data in this chapter may be updated by a search on Pubmed and Medline using the keywords: neck nodes, cervical lymphadenopathy, metastatic lymphadenopathy, neck dissection, occult neck metastases, neck levels and radiation therapy to the neck.

INTRODUCTION

One of the most important prognostic factors in head and neck cancer is the presence or absence, level and size of metastatic neck disease. Many tumours of the head and neck will at some stage metastasize to lymph nodes and a number of factors control the natural history and spread of disease.

Several controversies exist about the management of malignant neck disease, with varying practices on choice, timing and combination of treatment modalities. This is primarily due to the paucity of high-level evidence to many treatment paradigms, but this trend has been reversed with randomized controlled trials and systematic reviews published more recently. However, many organizations have generated guidelines following rigorous evidence gathering exercises, suggesting best management practices based on available evidence in many countries.

This chapter identifies the evidence base and discusses the principles of management of metastatic head and neck squamous cell carcinoma (HNSCC) at initial presentation, residual and recurrent neck disease. It also outlines major clinical controversies regarding the management of the neck in relation to when to treat, how much to treat and which modality to use. It reviews the various rationales for assessment as well as methods for elective and therapeutic treatment and focuses on quality-of-life (QOL) issues. The management of tumours other than HNSCC (i.e. salivary gland and thyroid tumours) are not covered in this chapter.

CLINICAL IMPLICATIONS OF METASTASES

The presence of regional lymph node metastases acts as an indicator of the ability of the primary tumour to metastasize locally and to distant sites, rather than acting as an instigator of distant metastases on their own. This is because lymph node involvement indicates a host response which is permissive for the development of metastases, not only in the regional lymph nodes but also to distant sites. (The molecular mechanisms that promote or prevent metastases is discussed in greater detail in Chapter 6, Introducing the molecular biology of head and neck cancer.) Therefore, the degree of lymph node involvement should be regarded as an indirect index of the systemic tumour burden. Elective removal of regional lymph nodes

serves as a staging procedure to ascertain whether or not metastatic disease is present and to identify high-risk patients who might benefit from systemic adjuvant therapy, but is not expected to diminish the metastatic potential. Akin to breast cancer, tumour-free survival depends more on the biology of the tumour present at the operation rather than at the extent of surgery. This explains why patients with metastatic lymph nodes in HNSCC have a significantly reduced chance of survival when compared with those who have no lymph node metastases.[1]

It has long been recognized that systemic spread can occur early in many solid tumours and this includes HNSCC. Traditional teaching has been to offer wide margin radical surgery to the neck, with the premise that patients who have a large number of occult positive nodes achieve better survival since these nodes are discovered earlier. This philosophy is now being questioned as locoregional disease can be cured with locoregional treatments in a greater proportion of patients, who are now living longer only to die more frequently of second primaries or distant metastases. Overall survival has not changed.

It becomes clear from the above discussion that the spread of HNSCC to the regional lymph nodes indicates an aggressive tumour where the tumour–host balance has swung in favour of the tumour. While there are structural and immunobiological mechanisms that may affect tumour lysis within the lymph node itself, in a certain proportion of cases, systemic spread occurs early on. This can take place by lymphatic or haematological routes. These processes of spread and tumour arrest can be affected by previous treatment. As the systemic immunosuppressive effects of multimodality head and neck cancer therapy are taken into consideration, both the number and the complexity of modalities that are used become ever more important.

NECK LEVELS

It is useful to introduce the concept of neck levels here. The Memorial Sloan-Kettering Hospital published, in 1981, a number of levels or regions within the neck which contain groups of lymph nodes representing the first echelon sites for metastases from head and neck primary sites.[2] These levels have been widely accepted and currently six neck levels are recognized, with level VII being outside the neck and referring to the chain of paratracheal nodes below the suprasternal notch to the level of the innominate artery. These neck node levels (**Figure 18.1**) along with their respective boundaries are described in **Table 18.1**.[3] Levels I, II and V can be further subdivided into (a) and (b). These subdivisions were introduced to recognize certain areas in the neck that have a biological significance independent of the larger zone that they lie in. For instance, Level Ia is rarely involved in malignant processes excluding the lip, anterior floor of mouth and midface. The prognostic significance of level Vb involvement is grave and thus merits the subdivision. The rationale behind subdivision of level II is discussed in 'Elective surgery' below.

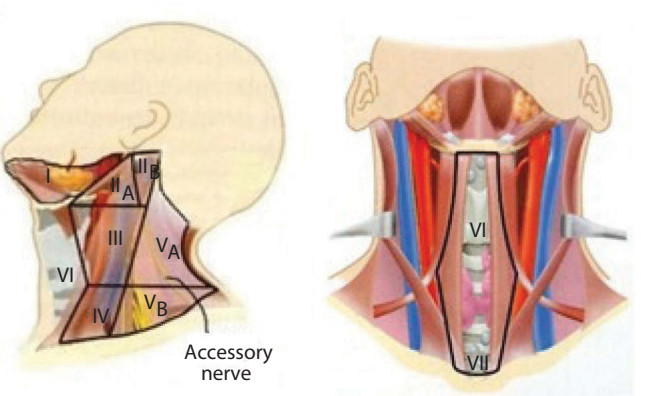

Figure 18.1 The lymph node levels of the neck.

NECK DISSECTION TERMINOLOGY

Standardized neck dissection terminology that was first produced by the American Academy of Otolaryngology and Head and Neck Surgery in 1991 has been updated by the Committee for Neck Dissection Classification of the American Head and Neck Society in 2002 and is widely used (**Table 18.2** and **Figure 18.2**). There is an increasing trend to divide neck dissections into two broad types with subdivisions: comprehensive (removal of levels I–V) and selective (SND) (less than five levels).

The previous division of SND into named subtypes has been superceded by recommendations that the levels or sublevels removed during SND be precisely stated in the operation notes.[4] The term elective neck dissection (END) is used to describe any type of neck dissection that is performed on the clinically and radiologically negative neck (cN0, see below). However, a neck dissection may not fall into one of these standard types, especially in the salvage setting. Recognizing that the current neck dissection terminology will not be appropriate in several post-treatment scenarios, the International Head and Neck Scientific Group has proposed a new classification system for neck dissections.[5]

REGION SPECIFIC LYMPHATIC DRAINAGE

There are approximately 150 lymph nodes on either side of the neck. The normal range in size is from 3 mm to 3 cm but most nodes are less than a centimetre. Within the upper deep cervical nodes in level II, the largest node is often called the jugulo-digastric node and is situated within the triangle formed by the internal jugular vein, facial vein and posterior belly of the digastric muscle. It is important because it receives lymph from a wide area which includes the submandibular region, the oropharynx and oral cavity. The jugulo-omohyoid nodes are situated at the junction between the middle and lower cervical group (low level III/high level IV) where the omohyoid muscle crosses the internal jugular vein and receives lymph from a wide area which includes the anterior floor of mouth, oropharynx and larynx. It is important to realize that contralateral

TABLE 18.1 Neck levels as defined by the American Academy of Otolaryngology-Head and Neck Surgery[6]

Level	Clinical location	Surgical boundaries	Radiological boundaries
Ia	Submental triangle	S: Symphysis of mandible I: Hyoid bone A (M): Left anterior belly of digastric P (L): Right anterior belly of digastric	Nodes above the level of lower body of hyoid bone, below mylohyoid muscles and anterior to a transverse line drawn through the posterior edge of submandibular gland on an axial image
Ib	Submandibular triangle	S: Body of mandible I: Posterior belly of digastric A (M): Anterior belly of digastric P (L): Stylohyoid muscle	
IIa	Upper jugular	S: Lower level of bony margin of jugular fossa I: Level of lower body of hyoid bone A (M): Stylohyoid muscle P (L): Vertical plane defined by accessory nerve	Superior and inferior limits as described under surgical boundaries Nodes posterior to a transverse plane defined by the posterior surface of submandibular gland and anterior to a transverse line drawn along the posterior border of the sternomastoid. NOTE: Nodes lying medial to the carotids are retropharyngeal and not level II
IIb	Upper jugular	S: Lower level of bony margin of jugular fossa I: Level of lower body of hyoid bone A (M): Vertical plane defined by accessory nerve P (L): Posterior border of SCM	
III	Mid Jugular	S: Level of lower body of hyoid bone I: Horizontal plane along inferior border of anterior cricoid arch A (M): Lateral border of sternohyoid muscle P (L): Posterior border of SCM or sensory branches of the cervical plexus.	Superior and inferior limits as described under surgical boundaries Nodes anterior to a transverse line drawn on each axial scan through the posterior edge of the SCM and lateral to the medial margin of the common carotid arteries
IV	Lower jugular	S: Horizontal plane along inferior border of anterior cricoid arch I: Clavicle A (M): Lateral border of sternohyoid muscle P (L): Posterior border of SCM or sensory branches of the cervical plexus.	Superior and inferior limits as described under surgical boundaries Nodes anterior to a transverse line drawn on each axial scan through the posterior edge of the SCM and lateral to the medial margin of the common carotid arteries
Va	Posterior triangle	S: Convergence of SCM and trapezius muscles I: Horizontal plane along inferior border of anterior cricoid arch A (M): Posterior border of SCM or sensory branches of the cervical plexus P (L): Anterior border of trapezius muscle	
Vb	Posterior triangle (supraclavicular)	S: Horizontal plane along inferior border of anterior cricoid arch I: Clavicle A (M): Posterior border of SCM or sensory branches of the cervical plexus. P (L): Anterior border of trapezius muscle	Nodes posterior to a transverse line drawn on each axial scan through the posterior edge of the SCM
VI	Anterior compartment	S: Hyoid bone I: Sternal notch A (M): Common carotid artery P (L): Common carotid artery	
VII	Superior mediastinum	S: Sternal notch I: Innominate artery A (M): Common carotid artery P (L): Common carotid artery	

S = superior; I = inferior; A = anterior; P = posterior; L = lateral; M = medial; SCM = sternocleidomastoid.

TABLE 18.2 Classification of neck dissection techniques

Radical neck dissection (RND)	Removal of levels I–V, accessory nerve, internal jugular vein and SCM
Modified radical neck dissection (MRND)	Removal of levels I–V dissected; preservation of one or more of the accessory nerve, internal jugular vein or SCM (types I, II, III respectively)
Selective neck dissection (SND)	Preservation of one or more levels of lymph nodes.
Extended radical neck dissection (ERND)	Removal of one or more additional lymphatic and/or non-lymphatic structures(s) relative to a radical neck dissection, e.g. level VII, retropharyngeal lymph nodes, hypoglossal nerve

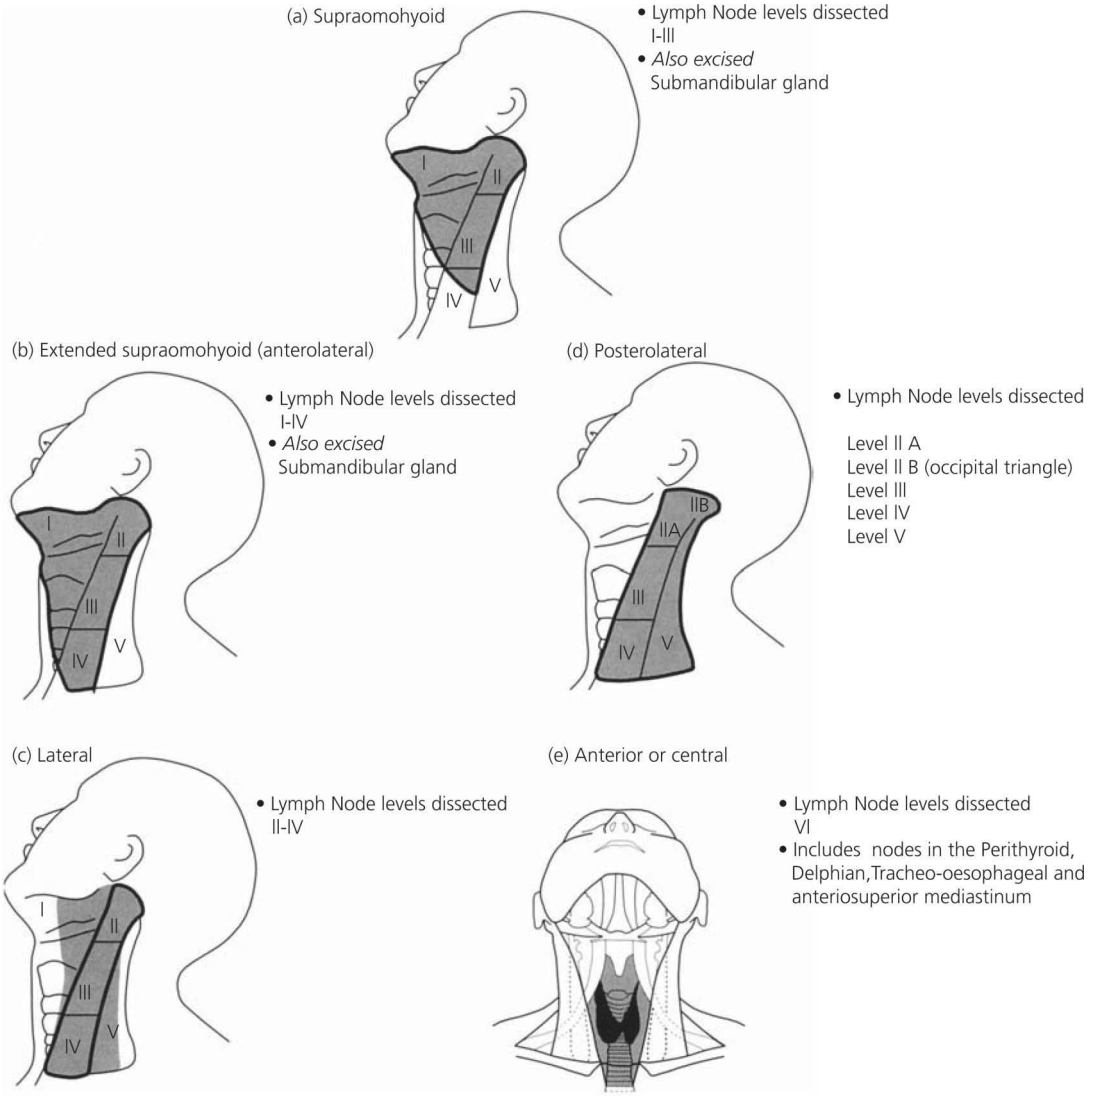

Figure 18.2 Types of selective neck dissection **(a)** Levels I-III (supraomohyoid); **(b)** levels I-IV (extended supraomohyoid; **(c)** levels III-IV (lateral); **(d)** levels III-IV (posterolateral); **(e)** level VI-VII (anterior/paratracheal).

neck spread may occur early in those tumours situated in or near the midline.

- The nasopharynx, nasal cavities and sinuses drain via the junctional nodes into the upper deep cervical nodes (levels II and III) having passed through retropharyngeal or submandibular lymph nodes.
- The oropharynx similarly drains into the upper, middle and lower deep cervical nodes (levels II, III and IV) again either directly or via the retropharyngeal nodes. Within these areas of deep lymph node collections in the neck, certain nodes can reach quite large proportions.
- The oral cavity has a wide area of drainage and this is important because there is often free communication between the two sides of the tongue. The posterior parts of the oral cavity either drain directly into the upper deep cervical nodes (level II/III) or indirectly via the submandibular nodes (level Ib). More anterior parts of the oral cavity and tongue also drain to these nodes but, in addition, may drain to the submental nodes (level Ia) or directly to the jugular nodal chain (levels II to IV). The tongue especially is known to cause 'skip metastases' to level IV.
- The larynx drainage is separated into upper and lower systems based on their embryological origins, with a division that occurs at the level of the true vocal cord. The supraglottis drains through vessels which accompany the superior laryngeal pedicle via the thyroid membrane to reach the upper deep cervical nodes (levels II/III), with a greater tendency for bilateral nodal drainage. The lower system drains directly into the deep cervical nodes (levels III/IV) through lymphatics which pass through or behind the cricothyroid membrane and also into the prelaryngeal, pretracheal or paratracheal nodes (level VI) before reaching the deep cervical nodes. Because the vocal cords are relatively avascular, they have an extremely sparse lymphatic drainage and, as such, lymph node metastases from small carcinomas at this site are uncommon.

- The hypopharynx is similar to the supraglottic larynx, and both may have contralateral spread, particularly in those areas that are either close to the midline or have significant communications across the midline such as the epiglottis, posterior pharyngeal wall and post-cricoid region. Drainage is to levels III, IV, VI and VII.

The region-specific drainage translates well into clinical practice and it is possible to predict the site of a primary tumour based upon the distribution of cervical metastases and vice versa. In a landmark study of 1155 patients with previously untreated HNSCC published by Lindberg in 1972,[6] the topographical distribution of clinically evident cervical metastases was set out. This identified distinct patterns of spread to the neck based on the primary site. Histological proof of this concept was produced in 1990 by Shah[7] in a series of 1119 neck dissections.

It is widely accepted that patterns of subclinical microscopic metastases follow a similar distribution. The high incidence of occult metastases in tumours of the oral cavity, pharynx and the supraglottic larynx forms the basis for SND and removal of the echelon lymph nodes which are the most likely sites of initial metastatic deposits. The echelon nodes for each site are as follows: levels I, II and III for the oral cavity, levels II, III, IV for the oropharynx, larynx and hypopharynx and levels IV, VI and VII for the thyroid gland. For the parotid gland, the first echelon lymph nodes are the pre-auricular, periparotid and intraparotid lymph nodes along with those in level II, III and the upper accessory chain (level Va). For the submandibular and sublingual gland, the echelon lymph nodes lie in levels I, II and III.

METASTATIC BEHAVIOUR IN THE PREVIOUSLY TREATED NECK

Treatment modalities can affect tumour–host equilibrium in unpredictable ways and these include surgery, radiotherapy and chemotherapy.

Surgery can undoubtedly mechanically alter the locoregional tumour environment. Considerable gaps between lymphatics mean that collateral channels form, and the ability to do this relates to the nature of connective tissue through which the lymphatics must grow. These mechanical effects can alter patterns of lymphatic metastatic spread and divert lymph flow to the contralateral neck and sometimes even cause retrograde spread. Surgical scarring can trap tumour cells although this may not always ultimately lead to established local recurrence.[8] It seems sensible to suggest that gentle handling of cancer tissues may decrease the amount of exposure that a surgical wound gets to free cancer cells and as such minimize the potential for any growth.

There is evidence in the literature that the systemic cellular immune response is significantly compromised following locoregional radiation therapy (RT) in head and neck cancer patients.[9] Radiation is associated with changes in the regional lymph nodes and lymphatics in general. Thus, within a few days of starting RT, there is a decrease in the numbers of lymphocytes within lymph nodes and thickening of the walls of both lymph nodes and blood vessels can be noted. Some of these changes explain why previous RT can cause lymphatic obstruction and shunting of lymph both into the subdermal vessels and also to the contralateral neck. All of the above lead to unpredictable changes in the pattern of lymphatic drainage, and thus, the echelon levels described above for the various sites will not be applicable to disease recurrence following treatment.

OCCULT NODAL DISEASE

The term occult disease is used to describe the presence of metastases in the neck nodes that cannot be clinically or radiologically identified. This falls into two categories: occult metastases that can be identified on light microscopy and micrometastases measuring less than 2mm that need special histological techniques (immunohistochemistry, step serial sectioning and molecular analysis) for identification. The incidence of occult disease as assessed by routine histological examination varies by the site and stage of tumour (**Table 18.3**), but use of molecular techniques to look for metastatic disease will increase the incidence rates.

TABLE 18.3 The probability of cervical metastases (N) related to primary (T) staging in patients with HNSCC

Primary site	T-Stage	N0%	N1%	N2–N3%

	T_4	26	15	58

The natural history and the clinical significance of occult metastases is an important, yet largely unanswered question. Neck dissection may arrest progress of some cancer cells. However, a lymph node may be negative on examination because either cancer never reached it or if it did, it was not retained or indeed was destroyed. This has led to several controversies in the management of the occult neck. It is important to address this question because this affects whether or not the disease needs to be treated and by what method. Observational data suggests that the conversion rate from the N0 to the N+ neck without neck treatment is similar to the incidence of pathological positive nodes in END specimens (around 30%).[8] There is no doubt that occult neck disease does have the potential to manifest itself, but it is impossible to predict with reasonable certainty in individual patients. This is one of several arguments that justify the elective treatment of the occult neck. The clinical significance is discussed in depth in 'The N0 neck' below.

MICROMETASTASES

Micrometastases are deposits of cancer cells less than 2 mm in size.[10] Presence of micrometastases upstages the neck status. One of the many goals of translational research in cancer has been to refine disease prediction by detecting tumour-specific molecular alterations in histological normal tissues either at resection margins or identifying 'sub-pathological' metastases in regional lymph nodes. Specific clonal genetic changes seen in tumour cells can be used as molecular markers for their detection in lymph nodes. However, the heterogeneity seen in HNSCC, like other solid cancers, precludes the use of a single tumour specific marker. Thus, these studies are dependent on the amplification of less specific epithelial genes or a panel of their transcripts.

Several molecular markers have been used to identify the presence of 'sub-pathological' metastases in lymph nodes. Using immunohistochemistry, micrometastases can be detected in between 5% and 25% of tumour-positive ENDs of clinically N0 necks,[11, 12] with upstaging occurring in up to 12% of patients.[13, 14] Using techniques such as quantitative reverse transcriptase-polymerase chain reaction (QRT-PCR) results can be obtained within two hours of tissue harvesting. An isolated tumour cell is a further category of micrometastases; equating to single cells or clusters of cells no more than 0.2 mm in size. Where identified, they are still classified as N0. However, isolated tumour cells are classified as N1 in cutaneous malignant melanoma and Merkel cell carcinoma.[15]

The clinical significance of micrometastases is undetermined. Prospective studies have used different markers and techniques to assess micrometastases and have arrived at diametrically opposite conclusions. In the absence of a universally acceptable marker or a battery of markers, it will be difficult to design clinical trials. Because of the unknown prognostic significance of micrometastases or indeed implications for additional post-operative treatment, the extra work involved in discovering it on a routine basis is not currently justified.

CYSTIC NECK METASTASES

Cystic neck metastases are usually of oropharyngeal origin, with the most common sites being the tonsil or tongue base. Human papilloma virus (HPV) related tumours are more often associated with cystic metastases than HPV negative tumours.[16] These lymph node metastases tend to have a better prognosis than their non-cystic counterparts. This has been reported as branchiogenic carcinoma in the past. Any diagnosis of branchiogenic carcinomas should be viewed with scepticism.[17, 18] The majority of branchiogenic carcinomas are in fact cystic metastases from oropharyngeal carcinoma and not true carcinomas arising in a branchial cleft cyst. Given the exponential rise in HPV positive oropharyngeal carcinoma throughout the world, any cystic level II neck mass in an adult should be considered as a potential metastasis and should be investigated as recommended in Chapter 17, Neck metastases from an unknown primary, that deals with the investigation and management of carcinoma from an unknown primary.

PROGNOSTIC NODAL FEATURES

There are a number of features of metastatic cervical nodal disease which indicate a poor prognosis (**Box 18.1**). However, much of the data used to arrive at these conclusions is retrospective and readers should consider whether primary surgical or non-surgical treatments were used in the descriptive observational case series. Surgery accurately stages disease and primary radiotherapy will not upstage occult neck disease or define extranodal extension (ENE), previously known as extracapsular spread. Lefebvre et al[19] looked at the impact of various regional factors on regional recurrence and distant metastases. This study with 1330 patients showed that irrespective of T staging, ENE, three or more positive nodes and positive level IV nodes doubled the risk of regional recurrence and trebled the risk of distant metastases. In the era of HPV-induced oropharyngeal SCC (OPSCC), there is emerging evidence that the number of involved nodes may have greater prognostic significance than ENE.[20] Matted nodes identified on pre-treatment imaging, defined as three nodes abutting one another with loss of an intervening fat plane replaced by ENE, is another factor that may confer a worse prognosis for patients with HPV OPSCC undergoing CRT.[21]

Extranodal extension

ENE occurs when the cancer has penetrated and infiltrated beyond the lymph node capsule. There is a consensus that the presence of ENE in a lymph node is associated with a poor prognosis.[8, 22–26] Both prospective and retrospective evidence

BOX 18.1 Prognostic nodal features

- Site, size and number
- Low neck nodes
- Extracapsular spread / Matted nodes
- Morphology
- Bilateral and contralateral spread (N2c disease)

suggests that ENE decreases survival rates by approximately half compared to those patients whose tumour was confined to the nodes. Also, patients who have occult involvement of nodes but ENE statistically do worse.[8, 27] A recent meta-analysis concluded that perinodal spread adversely affected 5-year survival, with a summarized odds ratio of 2.7.[28] Some workers have noted that invasion of the soft tissues of the neck by tumour lowers treatment success rates by 80%. Other studies show that patients with ENE are at increased risk of local recurrence, distant metastases and that the time to recurrence is shorter. Indeed, it has been suggested that stratification of disease by the presence or absence of ENE would offer a more accurate prognosis than the current TNM system.[29] It is likely that ENE may have a differential impact depending on the primary sites. For instance, Oosterkamp et al[30] showed that ENE adversely affected survival in laryngeal cancer by increasing the risk of metastases nine times, compared to a three times greater risk in patients without this finding.

Currently, it is not clear whether or not ENE represents increase in tumour burden or an increase in tumour aggressiveness. Toker[31] demonstrated that a primary rest of tumour emboli within the node capsule may lead to ENE occurring quite early in the metastatic process and as such may represent an anatomical variation rather than an aggressive tumour. In addition, not all nodes within a neck dissection specimen show ENE and there may be a threshold volume of ENE above which the prognosis is poor.

The literature almost universally recommends that the standard treatment if ENE is detected following surgery is to add post-operative radiotherapy or chemoradiation, even for those who have only one node involved.[8, 32, 33] In the presence of ENE, there is level 1 evidence in support of concomitant cisplatin with post-operative radiotherapy for patients fit enough to receive this.[33] However, there are some questions raised over how this evidence relates to the particular population of patients with HPV related OPSCC, following primary surgical management. This is discussed below.

Retropharyngeal nodes

Tumours that are associated with these nodes include primary disease of the oropharynx, paranasal sinuses and pyriform sinus as well as advanced primary tumours at any site together with massive unilateral or bilateral neck disease, which presumably involves retropharyngeal nodes due to shunting from obstructed lymphatic ducts or channels. Retropharyngeal node invasion is almost always a radiological diagnosis (**Figure 18.3**). There are a number of reports in the head and neck literature that associate the presence of retropharyngeal nodes with a very poor prognosis,[8, 34, 35] but a study of 51 patients concluded otherwise.[36]

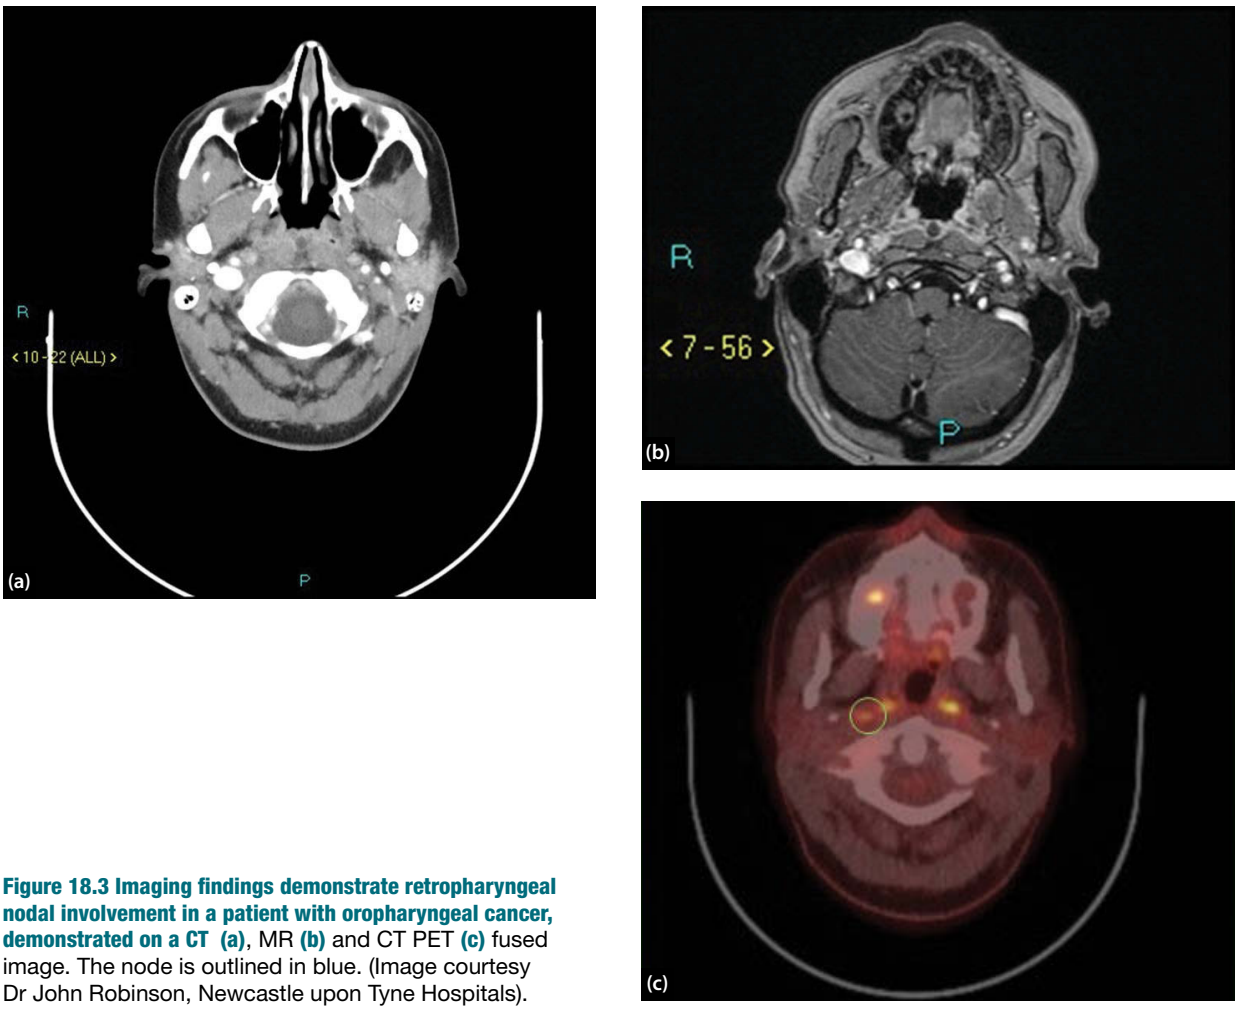

Figure 18.3 Imaging findings demonstrate retropharyngeal nodal involvement in a patient with oropharyngeal cancer, demonstrated on a CT (a), MR **(b)** and CT PET **(c)** fused image. The node is outlined in blue. (Image courtesy Dr John Robinson, Newcastle upon Tyne Hospitals).

CLINICAL STAGING

A classification system is essential for documentation of disease extent, comparisons of results between centres and stratifying patients for inclusion into trials. This is based not only on the presence or absence of cervical lymphadenopathy but also the size, number and laterality of the lymph nodes. The joint UICC and AJCC classifications for regional cervical lymphadenopathy have had substantial changes made to them, in the latest 8th edition (**Tables 18.4–18.6** and **Figures 18.4** and **18.5**). They now take into account ENE status

TABLE 18.4 Clinical N staging for cervical metastases[5, 15]

N category	Criteria
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension and ENE-negative
N2a	Metastasis in a single ipsilateral lymph node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE-negative
N2b	Metastasis in multiple ipsilateral lymph nodes, none larger than 6 cm in greatest dimension and ENE-negative
N2c	Metastasis in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension and ENE-negative
N3a	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE-negative
N3b	Metastasis in any node(s) and clinically overt ENE-positive

ENE = Extranodal Extension. Defined as: The presence of skin involvement or soft tissue invasion with deep fixation/tethering to underlying muscle or adjacent structures or clinical signs of nerve involvement is classified as clinical extra nodal extension.

TABLE 18.5 Clinical N stage for Human Papillomavirus (p16) positive associated oropharyngeal carcinoma[5, 15]

N category	Criteria
NX	Regional nodal status cannot be assessed
N0	No regional lymph node metastases
N1	One or more ipsilateral lymph nodes, none larger than 6 cm
N2	Contralateral or bilateral lymph nodes, none larger than 6 cm
N3	Lymph node(s) larger than 6 cm

TABLE 18.6 Pathological N stage for Human Papilloma virus associated oropharyngeal carcinoma[5, 15]

P category	Criteria
NX	Regional nodal status cannot be assessed
N0	No regional lymph node metastases
N1	Metastasis in 4 or fewer lymph nodes
N2	Metastasis in more than 4 lymph nodes

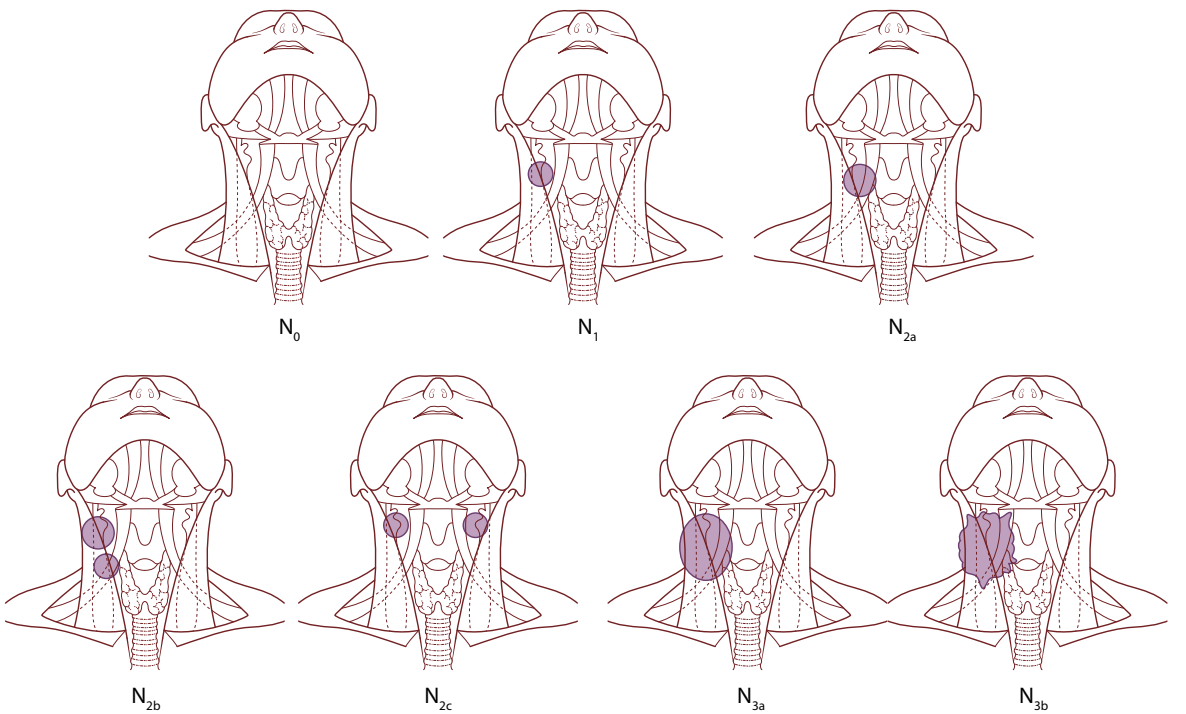

Figure 18.4 Clinical N staging for non-human papillomavirus associated oropharyngeal carcinoma.

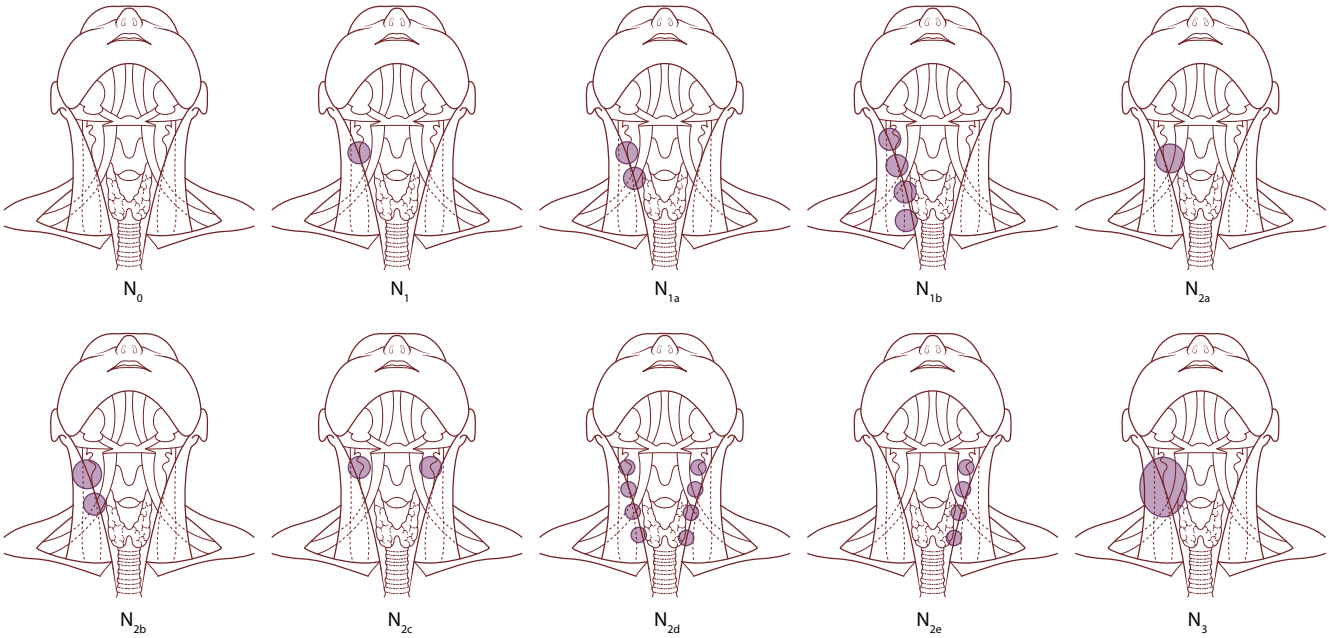

Figure 18.5 Clinical N staging for human papillomavirus associated oropharyngeal carcinoma.

and HPV (P16) status, and split the staging into distinct clinical and pathological classification. This is covered in detail within Chapter 4, Staging of head and neck cancer.

A retrospective analysis of 1190 patients between 1985 and 2007 demonstrated that the inclusion of ENE status in addition to the N-stage offered more accurate survival prognosis than the previous TNM staging system.[29] The 8th edition of the TNM staging recognizes a clinical staging group for ENE in p16 negative SCC, called N3b, diagnosed unambiguously on clinical examination alone (e.g. invasion of skin, infiltration of musculature/dense tethering to adjacent structures, or dysfunction of a cranial nerve, the brachial plexus, the sympathetic trunk, or the phrenic nerve) and supported by radiological evidence (**Figure 18.4**). This represents far more advanced disease than many patterns of ENE identified in neck dissection specimens.

The International Collaboration on Oropharyngeal cancer and Network for Staging (ICON-S) has developed[37] and validated[38] a model for HPV related OPSCC, with neck disease resembling the N-staging for nasopharyngeal carcinoma, but without the lower neck disease variable. This work has shaped the 8th edition of the TNM staging systems. There was recognition that 5-year overall survival was similar for N1, N2a and N2b subgroups, the rationale for these stages being grouped together as N1 disease (**Figure 18.5**). The separate TNM staging system for p16 positive cancers is due to the more favourable prognosis of HPV OPSCC, with previously defined advanced disease now being more appropriately classified to fit with the prognostic evidence. There is an anticipated psychological benefit for these patients, in which many previously stage IV tumours will now be stage I.[39]

CLINICAL PRESENTATION OF NECK DISEASE

The pattern of spread of malignant disease to the neck depends upon both patient and tumour factors. These are identified in **Box 18.2**. The site of the primary tumour is important with some sites having a higher incidence of metastases, both palpable and otherwise, at presentation (**Table 18.3**). Neck metastases usually present as neck masses, usually firm to hard on palpation. They may be mobile or fixed to surrounding structures, usually determined by the degree of ENE.

ASSESSMENT OF CERVICAL LYMPHADENOPATHY

Any patient with a head and neck primary tumour requires careful assessment of the neck. This begins with a full clinical examination which may be supplemented by an examination under anaesthetic. Further assessment of the neck with fine needle aspiration / core biopsy cytology and radiological imaging can help confirm or refute the diagnosis. Occasionally, an open biopsy may be required.

BOX 18.2 Factors implicated in pattern of metastatic nodal disease

- Tumour site
- Tumour size
- Tumour thickness
- Previous treatment
- Tumour recurrence

Clinical examination

Clinical examination remains an important initial method of assessing regional lymph nodes and is covered in more detail in Chapter 36, Clinical examination of the neck. Clinical examination of the neck has a variable diagnostic accuracy.[40, 41] Based on a systematic review,[42] physical examination has a sensitivity of 74%, specificity of 81% and an overall accuracy of 77%. This can be particularly difficult in necks that are difficult to examine i.e. following radiotherapy, previous surgery or in short, stocky necks. Nodes in these instances may go unnoticed until they reach a considerable size. In addition, some regions are inaccessible such as the retropharyngeal area.

Fine needle aspiration cytology

In the presence of palpable disease and a proven primary, treatment will usually be directed towards the assessment of the neck disease rather than confirming that a metastasis is present by fine-needle aspiration cytology (FNAC). Few surgeons would ignore a clinically palpable node in the presence of proven primary disease even if the FNAC shows no evidence of malignancy. The technique is particularly useful in the assessment of a palpable node when searching for an unknown primary as the cytological aspirate (which may require a core biopsy according to institutional practice) can be subjected to tests that may help in the search for the primary tumour. For example, evidence of HPV or Epstein–Barr virus transcripts (or their surrogate markers) will point to a primary site in the oropharynx or nasopharynx respectively. The possibility of anaplastic carcinoma or lymphoma usually makes a core-biopsy or open biopsy mandatory. The FNAC technique is easy to perform, can be reported immediately (particularly if a cytopathologist is present in the outpatient clinic) and has overall accuracy rates exceeding 90%.[43] There is, however, a well-recognized learning curve associated with the technique.

Ultrasound scan

This technique can detect the presence of malignant cervical lymph nodes with sensitivity rates between 70% and 90%. When combined with FNAC, this figure increases to 90%. However, the technique requires an expert ultrasonographer to be present in the outpatient clinic, is operator dependent and labour intensive. The addition of power Doppler to assess vascular flow[44] and molecular analysis of the aspirate[45] does improve on these figures. It should be noted that there are no absolute criteria for differentiating benign from malignant disease, but absent hilar echoes and increases in short axis length are generally considered to be features of metastatic neck nodes. Sonoelastography is a new imaging technique where low-amplitude, low-frequency shear waves are propagated through internal organs, while real-time Doppler techniques are used to image the resulting vibration pattern.

The decrease in vibration amplitude caused by the presence of inhomogeneity, such as a tumour within a region of soft tissue, is measured. This has shown promise in the evaluation of neck nodes.[46] There is also an increasing vogue for adding ultrasound with or without guided FNAC to follow up neck disease in patients after chemoradiation.[47]

CT

The diagnostic accuracy of CT scanning in detecting malignant cervical lymphadenopathy is higher than clinical examination. The range of non-malignant cervical lymphadenopathy is 3 mm up to 3 cm, but most authors recognize that nodes greater than 1 cm in size on CT may contain metastatic disease. The criteria used for categorizing metastatic deposits include lymph nodes with short axis diameter larger than 1 cm, cluster of three or more borderline enlarged nodes larger than 0.8 cm, and nodal necrosis or patchy enhancement within the nodes.[48–50]

A meta-analysis of CT vs physical examination with 647 neck dissections showed CT to have a sensitivity of 83% with a specificity and overall accuracy of 83%.[42] This figure has remained stable in a more recent meta-analysis.[51] The detection of malignant disease is based on the fact that as cancer invades the lymph node, its size, shape and characteristics change so that as it enlarges, its centre dies and appears necrotic and there is a thin rim of inflammation around the edge which shows up on scanning as rim enhancement.

It is important to realize that the two most difficult areas in imaging head and neck cancer are the detection of low-volume neck disease and residual and recurrent disease following surgery and irradiation. Based on the above imaging criteria, it is possible to miss a metastatic deposit in an 8 mm cervical lymph node, at which stage, the lymph node would contain 10^8 malignant cells. With increasing use of organ preservation modalities, conventional imaging (CT and MRI) and nuclear medicine imaging have assumed an important role in the assessment of treatment response after chemoradiation.

However, it is important not to rely on imaging alone and management decisions must be made after correlating the clinical findings. Indications for neck imaging are set out in **Box 18.3**.

MRI

This technique can detect cervical lymphadenopathy with overall similar accuracy rates to CT although meta-analyses have found CT to perform better than MRI.[51, 52]

BOX 18.3 Indications for anatomical neck imaging

- Primary tumour assessment
- Careful monitoring of N0 necks (Ultrasonography more likely)
- Assess treatment response
- Assess the difficult neck
- Re-staging recurrent tumours

However, MRI may be better in evaluating the N0 neck and in the presence of deep invasion. Similar criteria for malignancy are used in both techniques. Initial experience with ultrasmall paramagnetic iron oxide-enhanced MRI has shown this modality to have superior diagnostic efficacy compared to conventional imaging.[53, 54]

PET with CT

PET using [18F]-2-fluoro-2-desoxy-d-glucose (^{18}FDG) as a radioactive tracer has proven efficacy in the functional imaging of solid tumours. Tumour cells metabolize more glucose compared to normal tissue and the increased uptake of the glucose analogue FDG can be imaged. However, the major drawback of this technique is the limited morphological information, making the exact anatomical localization of an area of increased glucose metabolism difficult. On its own, ^{18}FDG-PET has inferior sensitivity and specificity compared to conventional imaging,[55] but has been shown to have the ability to change the management in up to 15% of patients when used prior to commencing treatment.[56, 57]

Co-registered anatomical and functional imaging techniques using dual modality PET-CT scanners lead to accurate image fusion, thus harvesting the advantages of both techniques. With relevance to metastatic neck disease, PET-CT has been investigated in the following settings: initial staging, radiotherapy planning, and evaluation of response to radiation or chemoradiation.

There are calls for using this modality in routine practice to stage patients prior to treatment planning, as apart from diagnosis, this may have an impact on the treatment; for example, the presence of distant metastases otherwise not detected on conventional scanning may be picked up on PET imaging, leading to a more palliative approach. For this reason in the UK, recent national guidelines have recommended offering patients PET-CT staging for all T4 hypopharynx and nasopharynx disease, and all N3 neck disease.[58] This can help more treatment resources to be directed to those who are more likely to do well following locoregional treatment.[59] High sensitivity (90–95%) and specificity (95–99%) rates have been observed in the pre-treatment setting.[60–62] PET-CT detection rate for nodes less than 1 cm is reported at 71%.[63] Thus, this modality has poor detection rate (0–30%) in the setting of the N0 neck.[64–66]

Currently the widespread role of PET-CT is confined to detecting the occult primary, detecting unknown distant metastases in certain clinical settings, and for assessment of residual and recurrent disease following irradiation. If a primary site is not immediately apparent on clinical examination, all efforts must be taken to identify the primary site. A detailed discussion of the assessment of the unknown primary can be found in Chapter 17, Neck metastases from an unknown primary.

It is worth noting that false positive results with PET-CT are common in the first few weeks after primary chemoradiation treatment and scans should be deferred until at least 10–12 weeks after completion of treatment.[67] The scan has a high sensitivity (100%) and negative predictive value (98–100%)[68, 69] in the evaluation of the post-treatment neck, and these figures are consistent on meta analyses.[70] Based on this finding, its use has been recommended to avoid salvage neck surgery (see below).

Open biopsy

In general, this diagnostic procedure is best avoided as an initial diagnostic modality. However, in situations where FNAC is not available, equivocal or non-diagnostic, or when the results suggest either a lymphoma or an anaplastic carcinoma, it may be necessary. When a primary site cannot be identified through exhaustive investigations and diagnostic cytology cannot be achieved from a suspicious neck node (most commonly a cystic lesion), the open biopsy should be performed as an oncological procedure, namely as a SND. There is no evidence in the literature that an open biopsy alters the prognosis, as long as correct treatment is instigated within 6 weeks.[32] Any incision should be made to facilitate the removal of the scar via a subsequent standard neck dissection incision and previous surgery may mean that vital structures such as the sternomastoid muscle may have to be sacrificed due to scar tissue.

Sentinel node biopsy

The sentinel node biopsy (SNB) is a diagnostic technique used to assess the presence of occult metastatic disease in the N0 neck. The SNB concept is based on the principle that identification of the echelon nodes and assessing them for metastatic spread will provide information regarding the status of the rest of the neck. Using radioactive probes and/or blue dye around the tumour site, the first to third echelon nodes are identified with the help of gamma cameras and peri-operative hand-held probes; these nodes are subsequently harvested and analyzed for tumour deposits. From a pathological point of view, these nodes undergo a much more comprehensive analysis (step-serial sectioning, immunohistochemistry) as missing a small deposit in the node could result in a wrong decision to not treat the neck. The assumption here is that if these echelon nodes are negative for secondary deposits, it is unlikely for the rest of the neck to have metastases, thus avoiding further treatment to the neck.

It has been shown in patients with early-stage malignant melanoma that selective lymphatic dissection performed after confirmation of positive sentinel node(s) is therapeutically equivalent to elective lymphatic dissection. Although the technique is considered standard for melanoma, breast cancer and other and non-head and neck sites, there have been some concerns regarding the technique in the head and neck. The head and neck lymphatic drainage can be variable with skip metastases, collateral channels are often present and the technique potentially involves the violation of oncologic principles. In addition, the technique is operator dependent with a recognized learning curve[71, 72] and there is an inherent risk of facial nerve damage when assessing parotid nodes. Its role would

appear to be mainly in the treatment of disease within the oral cavity and oropharynx. Injection of the tracer around laryngeal tumours may be cumbersome and satisfactory injection all around the tumour is difficult. Despite these concerns, meta-analysis shows very good sensitivity of SNB for this difficult site.[73] When considering the SNB evidence, the sensitivity of the test would seem most valuable, indicating the risk of false negative results which could lead to under treatment of neck disease. A pooled meta-analysis of non-randomized trials demonstrated that SNB had a sensitivity of 93% for oral cavity cancer.[71] The implications of this are discussed in the section on management of N0 disease below.

Pathology

The head and neck pathologist has the final say in the assessment and staging of cervical lymphadenopathy. Following neck dissection, the specimen should be pinned out on a board and orientated as to the levels, or the specimen separated into respective levels before presenting it to the pathologist. It will then be examined to assess the total number of lymph nodes in the specimen, the number that are positive, the levels that are involved along with the presence or absence of ENE, neural, vascular and lymphatic permeation. Standardization of pathological reporting is essential in order to compare data across centres and to facilitate comparative audit and there is currently a standardized reporting form, which has recently been updated by the Royal College of Pathologists. A detailed treatment of the pathological aspects can be found in Chapter 26, Pathology of head and neck malignancies.

DRAWBACKS IN THE LITERATURE WHEN ASSESSING TREATMENT OUTCOME

The majority of papers published in the literature which relate to HNSCC are retrospective, and because of this some of the controversies that existed fifty years ago have yet to be resolved. Retrospective data suffers from several biases. These include variation in treatment protocols caused by factors relating to the patient, the tumour and treating physician. Diagnostic and treatment expertise varies between centres and therapeutic schedules applied in various ways and at various times. Data collection may require perusal of the notes, which are often incomplete and studies that report different end points are not strictly comparable. For example, survival is the usual end-point reported by head and neck surgeons but when studying the efficacy of any type of neck treatment, locoregional control is more important.

When assessing any single or combination treatment with regards to the control of neck disease, it is important that the study meets the requirements set out in **Box 18.4**. Prospective randomized therapeutic trials control for all these variables but unfortunately there is a paucity of surgical trials in the current head and neck literature, although this situation is improving with several recently published trials and many trials registered and recruiting currently.

BOX 18.4 Prerequisites for studies reporting outcomes of treatment for neck disease

- Homogeneity in disease presentation (untreated necks, recurrent disease, etc)
- Method of treatment should be standardized
- The primary site should be controlled
- Nodal status verified by rigorous histological examination where possible
- Standardized assessment of treatment response
- Clear presentation of regional control rates and disease specific survival
- Adequate follow-up period

TREATMENT OF METASTATIC NECK DISEASE

After controlling for patient and tumour factors, the treatment of metastatic neck disease is usually decided by the stage of neck disease as identified by the joint UICC and AJCC classifications for regional cervical lymphadenopathy.[5, 15] The following section discusses treatment of neck disease for each N stage. It is worthwhile identifying the broad areas where there is a lack of high-level evidence and controversy exists (**Box 18.5**). Most of these topics are being actively investigated and the treatment paradigms are evolving.

It is worth reiterating a few important general principles regarding neck spread when discussing the surgical management of metastatic neck disease. 1) In the untreated neck, patterns of spread may be predictable. 2) In the N0 neck, occult disease is usually found within the first echelon lymph node drainage basin. This permits the principle of SND. 3). Previous treatment alters drainage patterns significantly. 4) Patients with palpable neck disease are more likely to have non-palpable spread in other levels.

BOX 18.5 Controversies in the management of metastatic neck disease

- Significance of occult disease in cervical lymph nodes
- Clinical significance of micrometastases
- Treatment of the N0 neck: elective vs therapeutic
- Role of selective neck dissection in N1 disease
- Role of the sentinel node biopsy in N0 disease
- Role of chemoradiation in advanced neck disease
- Role of superselective neck dissection in the irradiated neck
- Role of neoadjuvant chemotherapy in neck disease
- Optimal treatment for suspected or established bilateral neck disease
- Management of the difficult, inoperable or untreatable neck
- Use of salvage surgery and re-irradiation in recurrent neck disease
- Quality of life following single and multimodality treatment for neck disease

The N0 neck

Historically, evaluation and treatment for the N0 neck has been one of the great dilemmas in head and neck surgery and its treatment today is still controversial. The problem that faces the head and neck oncologist is whether or not to treat the neck electively. The rationale for elective treatment to the N0 neck is the finding of high incidence of subclinical disease in elective RND specimens at the following subsites: the oral cavity, pharynx and supraglottic larynx. As shown in **Table 18.3**, the likelihood of there being involved nodes depends not only on the site of the primary disease but also on tumour size and histological differentiation. The controversy extends to when and how the N0 neck should be treated.

There are a number of treatment options for the N0 neck. These include the following:

- elective surgery
- elective radiotherapy
- adopting a policy of 'wait and see'
- elective neck investigation.

ELECTIVE NECK TREATMENT

Proponents of elective neck treatment maintain it prevents some cancer-related deaths because untreated neck disease can shed tumour into the vascular or lymphatic system and produce distant metastases. Unfortunately, only distant metastases which are seeded from developing nodal disease can be prevented by elective neck treatment and since spread can occur by other routes, or at inception of tumour, then quite clearly the argument for elective treatment is weakened. The evidence for elective neck treatment vs observation is discussed.

Oral cavity

Early stage oral cavity SCC is a common tumour for head and neck surgeons to encounter. There is no controversy; primary surgical management is the treatment of choice for the primary tumour.[75] There has always been great interest in the question of END for cT1-2 N0 oral cavity disease. The other common early stage tumour, glottic cancer, is rarely associated with cervical metastases and as such elective neck treatment is not considered. A recent large RCT has provided significant evidence in support of END for early oral cancer, and is the basis for the UK NICE guidelines recommending END or SNB for this disease.[58] In 2015, D'Cruz et al published outcomes for 500 patients in the New England Journal of Medicine.[76] Patients were randomized into END (level I–III with levels IV and V cleared for obvious or frozen section proven disease) or observation of the neck with therapeutic neck dissection (MRND) for regional recurrence. The primary outcome measure of 3-year overall survival was 80% for the END group and 68% for the therapeutic ND group (p = 0.01). Disease-free survival was also significantly different at 3 years: 70% vs 46%. Ultrasound was used to stage the neck disease pre-operatively. Suspicious disease was noted in less than 1%, indeterminate nodal disease in 7–8% and normal nodal structure found in approximately 92%, with similar results in both treatment groups. The rate of occult nodal disease in the END group was 30%. It could be argued that this is a reason for END in itself, but the authors rightly point out the disparity in ultrasound findings and occult disease. Improved pre-operative imaging could have the potential to correctly identify more patients with involved nodes. Nodal relapse in the therapeutic ND group was 45%, markedly higher than the 30% occult nodal rate in the END, and nodal relapse was more advanced and was associated with a higher rate of ENE in the therapeutic ND group. The authors reasonably suggest the benefit of END could be higher for a population of patients who may not be as rigorously followed up as in this trial. Subgroup analysis suggested the benefit of END may not exist for tumours with a depth of 3 mm or lower.

Prior to this major publication the evidence was less clear; four randomized prospective trials that have examined the issue of elective neck treatment are summarized in **Table 18.7**. Three compared surgical clearance of the neck,[77–79] and one elective neck irradiation,[80] with observation. Only one trial[78] favoured elective neck treatment. Careful 5-year follow-up detected no difference in survival between the two groups in the French trial,[77] but in the delayed treatment group, tumour problems or the patient's general condition precluded an operation when nodes were palpable in two patients, one of the objections to adopting a policy of

TABLE 18.7 Randomized controlled studies in management of the N0 neck

Study	Treatment arms	Number of patients	Positive necks	Disease-free survival	Follow-up (years)	Difference
Pointon and Gleave[80]	ENI	100	–	80%	2	NS
	OBS	105	–	65%		
Vandenbrouck et al[77]	END	39	19	NA	5	NS
	OBS	36	19	NA		
Kligerman et al[78]	END	34	7	72%	3	p = 0.04
	OBS	33	13	49%

	OBS	40	23	52%		
D'Cruz et al[76]	END	245	81	70%	3	p < 0.001
	OBS	255	146	46%		

ENI = Elective neck irradiation; OBS = Observation; END = Elective neck dissection; NA = Not available; NS = Not significant.

'wait and see' for N0 disease. In addition, more than 50% of patients in both arms received radiation, which may have contributed to the lack of difference. Although the trial by Fakih et al[79] showed no difference in control rates between the arms, it must be noted that the results reported were 1-year survival data, despite median follow-up period of 20 months. Careful perusal shows that patients who underwent elective treatment did well in all comparisons, without achieving statistical significance. It must also be noted that all these studies are not adequately powered. Many retrospective studies and recently, other prospective non-randomized studies, including an evidence-based review,[32] that have looked at the treatment of the N0 neck in oral cavity carcinomas,[81–85] suggested improved outcome when the neck was electively treated. A recent large multicentre trial of 415 patients showed the sensitivity was 86%.[86] Patients with early stage T1-2N0 appeared to have no oncological compromise, despite only 94 of the 415 undergoing neck dissection. The evidence base pertaining to both END and SNB were assessed by the National Institute for Health and Care Excellence in 2016. Based on a systematic review and an original health economic model, the NICE guidelines made two explicit recommendations pertaining to the management of N0 disease in T1 and T2 oral cavity cancer:

- surgical management of the neck should be offered to all patients
- sentinel lymph node biopsy should be offered instead of END unless they need cervical access at the same time (for example, free-flap reconstruction).[58]

Other head and neck primary sites

A 'wait and watch' policy will result in 25–35% of patients presenting with overt disease, needing therapeutic neck treatment, although the results from the randomized trials quoted above suggest a much higher conversion rate. Control rates in this scenario approximate 30–50%, leading to around 15% of patients who have progressive disease. This figure is still higher than the widely accepted 5–7% failure rate where the neck is electively treated. In the absence of high-level evidence for a watch and wait policy, the general consensus in the literature is to err on the side of caution and it is prudent to treat the neck when the risk of occult spread is more than 15–20%. This figure is derived from a rather simplistic decision analysis model performed in the 1990s[87] which showed that at a threshold occult metastatic rate of 20%, the morbidity of treatment is offset by its benefit, and is widely accepted. It must be noted that the surgical treatment considered in the model was radical neck dissection (RND). Many surgeons and oncologists would perform elective neck treatment for lesser probability (5–15%) of occult metastases.[88] The Scottish Intercollegiate Guidelines Network and UK National Multidisciplinary Guidelines also espouse elective treatment of the neck in this scenario.[67, 89]

Currently both END and irradiation are viewed as prophylactic treatments. If one recognizes the significance of occult neck disease as a marker of the ability of any individual tumour to metastasize, thereby providing a significant prognostic indicator of eventual distant metastases and the possible need for systemic adjuvant chemotherapy, then only surgery can provide the histological data to give this information.

BOX 18.6 Indications for elective neck treatment

- 15–20% chance of subclinical neck disease
- Vigilant follow-up not possible
- Clinical evaluation of the neck is difficult
- Access to the neck for reconstruction

CHOICE OF TREATMENT MODALITY FOR THE N0 NECK

Although there are no prospective trials, retrospective data from studies with large numbers suggest that END and irradiation are equally effective in controlling subclinical disease.[90] The choice of treatment modality is dictated by numerous factors including physician and patient choices, QOL issues and how the primary site is managed. When the primary tumour is being treated with radiotherapy, then elective treatment should be with radiotherapy to at least the first echelon lymph nodes (or the whole neck) and where midline extension occurs, treatment should be bilateral. If the primary tumour is being treated with interstitial brachytherapy then the neck may be treated electively with either surgery or irradiation. When the primary tumour is treated with surgery, then elective neck surgery should be carried out since it provides further information for clinical staging, lymph nodes in the area are cleared to give access to vessels for reconstructive purposes, local recurrence rates may be reduced and survival enhanced. The appropriate levels to be dissected out in an SND are based on the site of the primary tumour and this is discussed later. **Figure 18.6** summarizes our recommendations for management of the ipsilateral N0 neck.

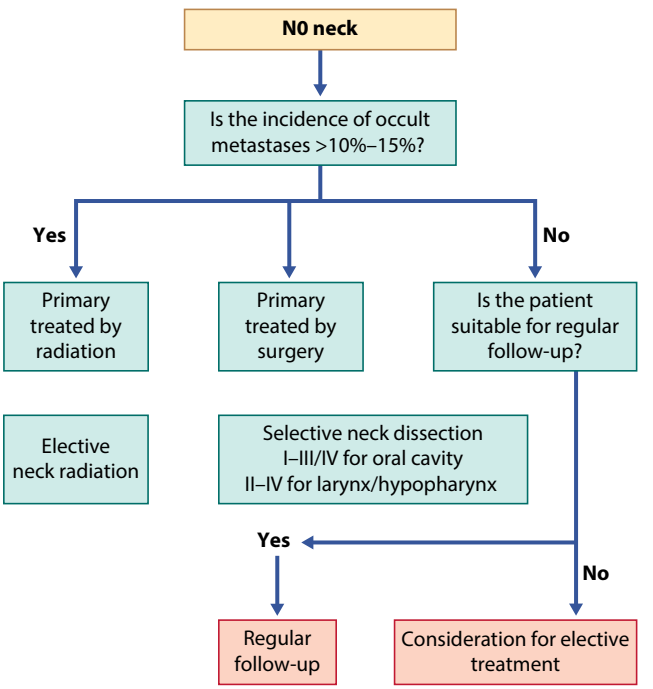

Figure 18.6 Algorithm for management of the N0 neck.

Elective surgery

The pros and cons of elective neck surgery are set out in **Box 18.7** and **Box 18.8** below.

The concept of therapeutic equivalence of SND and comprehensive neck dissection for elective treatment of the neck is widely accepted[91] and based on prospective studies, there is little justification for a comprehensive neck dissection in this setting.[92, 93] Levels II–IV need to be cleared for laryngeal and hypopharyngeal cancer.[93] For patients with oral cavity cancer, SND of at least levels I–III should be carried out, with the addition of level IV for tongue cancers.[92] Levels II–IV are recommended for oropharyngeal cancers.[94] There appears to be little advantage in dissecting level V for any of the mucosal primaries electively.[95–97] Excellent local control rates can be obtained with SND, with recurrence rates around 5% with the primary controlled.

Current work focuses on selecting the levels that need to be dissected in the elective setting. For example, clearance of level IIb during SND involves dissection in a relatively narrow field and significant retraction of the sternomastoid muscle is needed. It is likely that the accessory nerve can be subjected to traction injury and segmental devascularization, causing shoulder dysfunction. Prospective studies[98] have shown that SND causes a small but significant impairment to the shoulder function. The incidence of isolated metastases in this level is very low at 0.3%.[99] Prospective studies have shown little oncological benefit in clearing this level in laryngeal cancer as the occult metastatic rate is low at 0.4%,[99, 100] but higher incidence rates are seen in oral cavity (3.9%) and oropharyngeal (5.2%) cancer. Whether preservation of level IIb necessarily leads to improved shoulder outcomes needs to be verified in prospective studies.

END can undoubtedly serve to pathologically stage the neck, and offer a subsequent indicator of the risk of systemic disease. Local neck and distant metastases are manifestations of the same process and represent the ability of the tumour to metastasize in an individual host.

BOX 18.7 Arguments for elective neck surgery

- The high incidence of occult metastatic disease
- Selective neck dissection has a low morbidity and mortality
- Routine clinical follow-up will not detect the earliest conversion of the neck from N0 to N1 in all patients
- Untreated neck metastases can increase the incidence of distant metastases
- The control rate for neck dissection is decreased if gland enlargement occurs or multiple nodes appear
- Elective neck surgery can be performed during primary surgery
- Anatomical reasons preclude proper neck examination
- Patient compliance for follow-up cannot be assured
- The pathological neck node status from pathology can be used to prognosticate
- The presence of multiple occult metastases will dictate adjuvant irradiation

BOX 18.8 Arguments against elective neck surgery

- Control rates are no lower when a 'wait and see' policy is followed and therapeutic neck dissection is performed
- Careful clinical follow-up combined with imaging has the potential to detect early conversion from N0 to N1
- Radiation is as effective as neck dissection for non-palpable disease
- Elective neck dissection results in a large number of unnecessary surgical procedures associated with inevitable morbidity
- Elective neck dissection removes the barrier to the spread of disease and may have a detrimental immunological effect
- Elective neck dissection can cause a scarred, hypoxic field that can reduce radiation kill.

Elective neck irradiation

Retrospective evidence suggests that external beam radiation of approximately 40–50 Gy to the clinically N0 neck will control occult metastases in up to 90–95% of cases.[101, 102] In addition to the prospective study identified,[80] other retrospective studies evaluating its role in the treatment of patients with SCC of the oral cavity and tongue[103] did show that elective neck irradiation improves locoregional control and may prolong survival in some cases. This is based on the observed rate of conversion of N0 to N+ necks after elective neck irradiation (3–15%) and the expected rate of appearance of nodes when the neck is observed, based on a 20–40% histological incidence of occult neck disease. However, this assumes that all occult lymph node cancer deposits are clinically significant and evidence from other studies suggests this is not necessarily the case.

Elective neck investigation

Another option in the N0 neck is to consider elective neck investigation. Could a radiological investigation such as CT, MRI or ultrasound demonstrate malignant cervical lymphadenopathy at the subclinical stage and if so, could a treatment plan be adopted based on these scans?

It would seem that many of the arguments levelled against neck dissection could be levelled against elective neck imaging.[104] If false positive results are inevitable in the presence of inflammatory neck nodes and false negatives do occur, then imaging could play no role in the routine evaluation of the N0 neck. Treatment should be based upon the understanding of the natural history in question and currently it is probably cheaper and as effective to offer elective treatment to those high-risk patients who need it and 'wait and see' in the others. This will avoid large numbers of unnecessary CT scans and subsequent inevitable inappropriate surgery. It is perfectly reasonable to adopt a policy of 'wait and see' in low-risk necks, i.e. carcinoma of the glottis or the gingiva, but for those that are high risk, waiting for the neck to develop from N0 to N1 may have a detrimental effect on the patient should not to be recommended in current clinical practice.

One recent study[105] evaluated the outcome of observing the clinically N0 neck in high-risk patients (mainly oral carcinoma) using ultrasound-guided FNAC (US-FNAC) for follow-up after transoral excision. Patients were followed up for between 1 and 4 years using palpation and US-FNAC. The high salvage rate (71%) was attributed to a strict follow-up policy using US-FNAC and concluded that a policy of 'wait and see' was justified. Although the authors did not identify the T staging of the primary tumour, some neck failures might have been prevented by elective treatment rather than elective investigation.[106, 107]

THE CONTRALATERAL N0 NECK

In the setting of a unilateral primary and ipsilateral metastases, traditional data suggest that the contralateral neck has a very high incidence of occult metastases, between 30% and 70%, especially in supraglottic,[108–110] hypopharyngeal[111–114] and oropharyngeal tumours.[94, 115] In the presence of advanced primaries at high risk of occult spread, contralateral neck treatment is warranted. Recurrence in the untreated contralateral neck has been shown to be the commonest cause of failure in supraglottic cancer, with improved local control and 2-year survival when dissected.[116–119] There is no benefit in clearing level IIb in the contralateral N0 neck.[99, 120]

The management of the contralateral cN0 neck has again gained prominence as a discussion point, with the rise in popularity and interest in transoral surgical techniques in managing oropharyngeal carcinoma. This technique particularly lends itself to the common scenario observed in HPV positive OPSCC; small-volume lateralized primary tumours, with ipsilateral nodal disease. With this clinical presentation of disease, the most common treatment modality would be primary chemoradiotherapy. Radical treatment dose would be given to the primary site and ipsilateral neck, with prophylactic dose (commonly 54 Gy) to the contralateral neck. The authors offer transoral robotic surgery for this disease and have routinely performed a contralateral staging SND as part of the surgery. They have observed a lower than expected rate of contralateral occult nodal disease in this population. Only 5 out of 60 patients were found to have occult nodal disease, upstaging them to N2c and altering their adjuvant radiotherapy dosage (currently unpublished data). Adjuvant radiotherapy to the contralateral neck was avoided in 55/60 patients. Three of the five patients had HPV negative disease, and it would appear that the risk of occult contralateral nodal disease is higher in the HPV-negative setting. It must be stressed, that the patients treated in this way had lateralized OPSCC, more than 1 cm lateral to the midline of the tongue base, and were highly selected. Nevertheless, these data would suggest that the traditional risk of contralateral occult disease in OPSCC may not be so relevant to this common clinical pattern of disease. Head and neck clinicians should consider how reduced morbidity of treatment can be achieved by avoiding radical treatment to the contralateral neck. Options could consider a staging SND as described, sentinel lymph node biopsy, or serial monitoring with US.

The N+ neck

Management of the N+ neck is continuously evolving as more and more data are accrued. Traditionally, advanced neck disease has needed a combination of surgery and RT for control of disease. The treatment offered to the neck often depends on the modality used to treat the primary site, as seen in the suggested algorithms for patients undergoing primary chemoradiation (**Figure 18.7**) and primary surgery (**Figure 18.8**).

SINGLE PALPABLE METASTASIS IN THE IPSILATERAL NECK LESS THAN 3 CM IN DIAMETER (N1)

Similar to the N0 neck, the choice of modality is usually dictated by the treatment to the primary site. Where the primary is treated with irradiation, the neck is covered as well in the field. ENE is less common in this stage and since the survival figures are good, conservation neck surgery is feasible. In palpable neck disease, traditional teaching is for all five levels to be dissected to clear occult disease; however, it is rare for level I to be involved in primary sites other than the oral cavity. In most cases, the accessory nerve can be preserved, enabling MRND. Based on assessment of the best available evidence,[32] there is no evidence that RND achieves better survival figures than MRND.

It is widely accepted that single-treatment modality gives good control rates for N1 neck disease,[121] although review of large databases suggest that there may be survival advantage in offering adjuvant RT following surgery even for N1 necks.[122] As approximately 50% of clinically N1 necks are upstaged after pathological assessment, many patients subsequently require post-operative radiation. Single modality usually suffices to control N1 neck disease, with both radiation and surgery having equivalent control rates.

Selective neck dissection in the N1 neck as primary treatment

The role of SND in the N+ neck is controversial. There is no doubt that the morbidity of a neck dissection arises largely from level V dissection and there is a low incidence of nodal involvement at this level unless two or more levels (especially level IV) are involved.[32, 123] There is a clear pathological basis for SND in N1 and N2a disease. The proponents for a 'less than five level' neck dissection for N1 disease argue that the distribution of metastases within first echelon lymph nodes in non-palpable disease can be applied to early palpable disease. However, this sort of surgery requires considerable expertise and is not recommended for the trainee surgeon. With experience, a 'conservative MRND' can be performed for N1–N2b to include the entire levels II–IV, with dissection under sternocleidomastoid (SCM) to pull through a significant volume of level V, and to encompass any level IB nodes superficial to the submandibular gland. Careful preservation of the marginal mandibular nerve, the accessory nerve, and

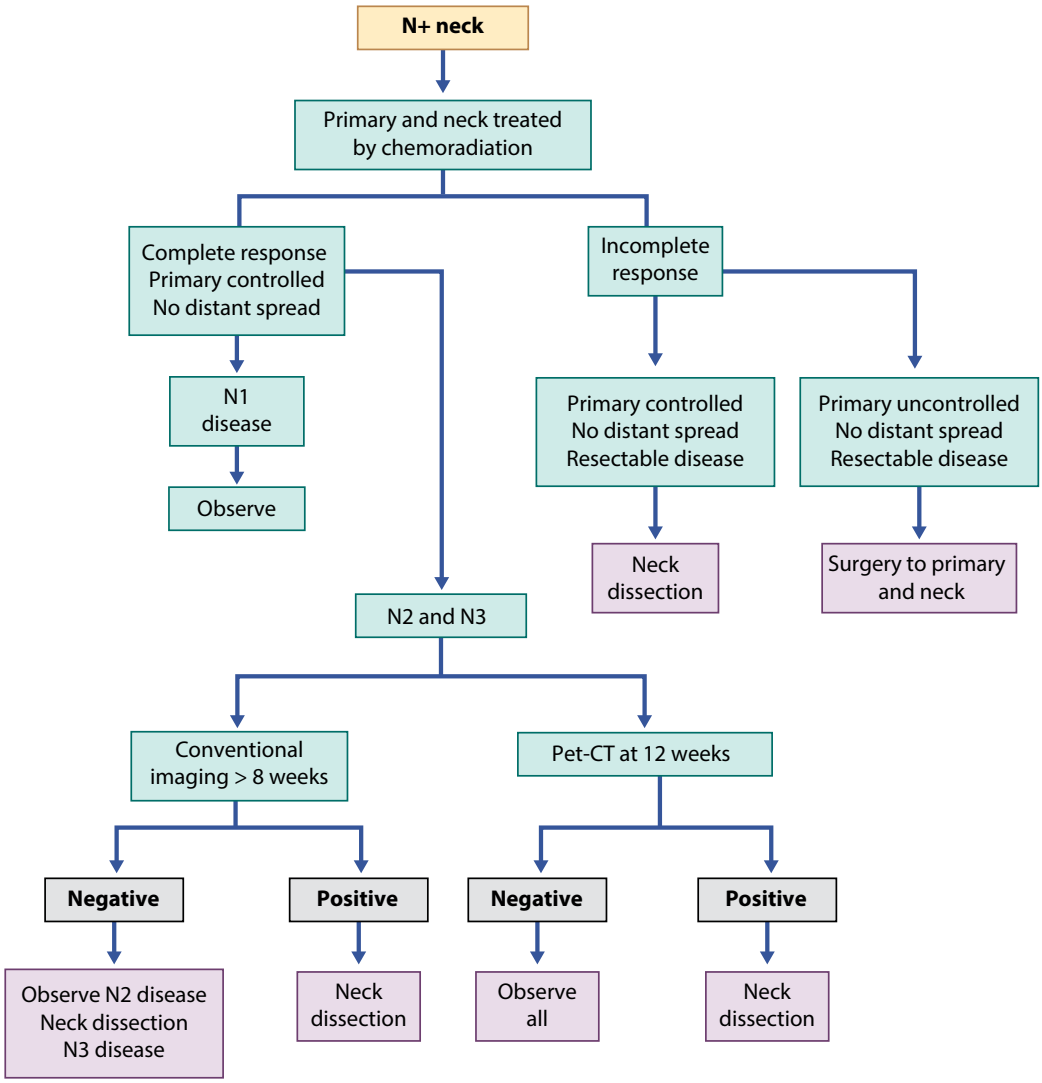

Figure 18.7 Algorithm for management of the N+ neck when chemoradiation is the primary modality.

importantly the small cervical plexus branch that joins to the accessory nerve lateral to the posterior border of the SCM should be performed if considering a conservative approach such as this. Whilst unproven, this sort of conservative approach over a traditional MRND for tumours with predictable nodal metastatic spread may be reasonable, especially if adjuvant therapy can be anticipated to the neck.

Byers et al[124] looked at the outcomes of SNDs in 517 patients. They found that recurrence rates in patients with N1 disease were 5.6% and 35.6% with and without post-operative radiation respectively. Other retrospective studies also vouch for the efficacy of the SND alone in the N1 neck, as long as adjuvant treatment is provided if the disease is upstaged following surgery or other adverse factors exist.[125–130]

Prospective studies are yet to be performed to evaluate this further, but on the basis of a large body of retrospective evidence, it can be concluded that SND may be sufficient treatment for N1 disease confirmed on pathological examination. We recommend that where there is doubt regarding the spread and extent of disease, it is better to perform a comprehensive procedure the first time around.

Concurrent chemoradiation therapy for the N1 neck

Concurrent chemoradiation (given for treating the primary site) offers excellent control rates.[131, 132] No treatment is required in the event of a complete response, but partial responders merit a neck dissection. The type of neck dissection for partial responders is discussed below.

IPSILATERAL LARGE NODE (>3 CM TO 6 CM; N2A) OR MULTIPLE UNILATERAL NODES (N2B)

The treatment depends on the management of the primary and if deemed operable, the neck should be treated with comprehensive neck dissection. If possible, an MRND sparing the accessory nerve gives equivalent control rates to a RND.[32, 133, 134] Larger neck nodes are at a greater risk of ENE, and following primary surgery

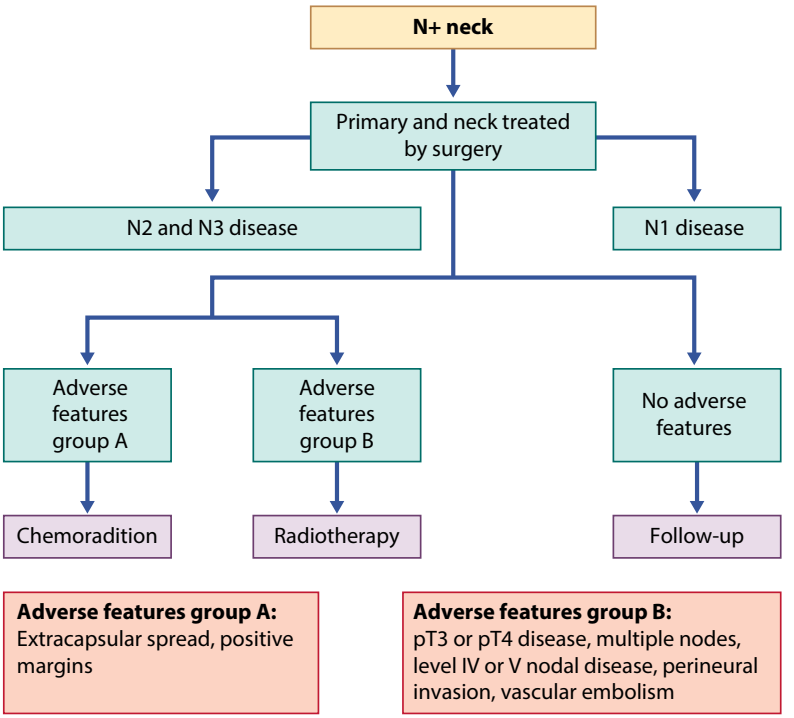

Figure 18.8 Algorithm for management of the N+ neck when surgery is the primary modality.

are best treated by post-operative adjuvant treatment. Analysis of large databases show that adjuvant RT confers a 10% absolute increase in 5-year cancer-specific survival and overall survival for patients with lymph node-positive HNSCC compared with surgery alone.[135] Recent randomized controlled trials performed in Europe and the United States confirm the clear benefit provided by adjuvant chemoradiation in the presence of ENE.[33, 136, 137] If the primary site is being irradiated, and incomplete response ensues, a neck dissection is warranted. Patients who achieve a complete response do not need surgical salvage and the rationale behind this is discussed in more detail in the section on the chemoradiated neck. This group represents advanced disease and retrospective and prospective studies clearly show that if primary surgery is performed, post-operative adjuvant therapy is required to achieve good regional control rates.

BILATERAL AND CONTRALATERAL NODES (N2C)

Patients with bilateral neck nodes are uncommon and occur overall in about 5% of head and neck cancers. As discussed above, N2c disease is more common if the primary sites involved are the tongue base, supraglottic larynx and hypopharynx. Conventionally, the presence of bilateral neck disease was thought to be a grave prognostic sign and this was indicated historically in its staging. However, subsequent careful pathological studies have shown that, in certain instances, this is not so. The prognosis is determined more by the size, number of nodes and by the presence or absence of ENE within the neck rather than by pure laterality. This is particularly true for the supraglottic larynx and in those patients where the bilateral nodes do not feature massive and multiple nodes, treatment can be worthwhile using conventional surgery[138] or chemoradiation. Conservation neck surgery may be possible on the less involved side and post-operative radiotherapy will usually be administered.[1, 139] The decision to treat will often be helped by the location and size of the primary site. Laryngeal tumours with extralaryngeal spread and bilateral nodes are often eminently treatable with laryngectomy and appropriate neck dissection. Patients with bilateral nodes when one side is fixed are usually incurable.

BOX 18.9 Indications for postoperative adjuvant treatment

- Extracapsular spread
- Two or more positive nodes
- N2–3 stages
- Residual disease

MASSIVE NODES (GREATER THAN 6 CM; N3)

The presence of massive nodes is again an uncommon event occurring in patients with head and neck cancer. Only 5% of all patients will present with N3 neck disease in the UK. It is important to realize that many nodes that do reach 6 cm in size are often fixed to the skin and/or underlying structures. The decision whether or not to operate depends upon the stage and site of the primary site, presence or absence of fixation, what the node is fixed to, the experience of the surgeon and the needs of

the patient. The incidence of true fixation of neck masses is often difficult to determine from the literature and varies from series to series with figures from 23%[140] going up to 30%.[141] Fixation to the mandible, sternomastoid muscle or muscles in the midline may not represent as much of a problem as fixation to the brachial plexus or carotid artery. These patients are at high risk of distant metastases and may present a special group where PET-CT scans may be warranted to fully evaluate this problem. Long-term control rates are poor and the benefit of treatment must be carefully weighed against the morbidity caused by it, including the chances of control at the primary site. In many patients, palliation will be the best option. Combined modality therapy leads to better control rates.[142]

THE DIFFICULT NECK

The scenarios that present a difficult neck are set out in **Box 18.10.**

Careful clinical assessment with mandatory radiological imaging will help to assess operability and some of these patients will be helped by extended RND. Fixation to the skull base and brachial plexus is certainly a contraindication to surgical treatment, but fixation to the skin may be treated by wide resection and flap repair.

BOX 18.10 The difficult neck

- Difficult to assess
- Short stocky neck
- Retropharyngeal nodes
- Recurrent disease
- Involvement of vital structures

Carotid invasion: In current day practice, most tumours that present with clinical and radiological signs of carotid invasion are likely to be radiorecurrent.[143] Indications for considering carotid resection include clinical evidence of fixation of the tumour to the carotid, invasion confirmed on imaging, and encroachment of tumour which encompasses more than 270 degrees of the vessel wall. Luminal invasion is rare and pathological evidence of invasion, limited to the adventitia, is seen in only 40–50% of resected arteries.[144–146]

The plan to resect the carotid should always be a pre-operative decision and almost never should a situation arise where this is contemplated for the first time peri-operatively. Pre-operative work up is essential to plan the resection. Balloon occlusion of the artery with single photon emission computer tomography (SPECT) is performed to prognosticate the possibility of neurological deficit following resection. If the test shows adequate cross-flow and does not cause symptoms, there is a lesser need to shunt the artery during resection. If the cross-flow is inadequate, the internal carotid artery should be shunted for the duration of the resection. In all cases, we recommend reconstruction of the artery using an appropriate graft to reduce chances of neurological complications. Most studies report using the saphenous vein graft (**Figure 18.9**). Intra-operative ligation without reconstruction is fraught with a high risk of complications owing to the haemodynamic instability that can occur. This is likely even in those patients who demonstrate good cross-flow and a stump pressure of more than 70 mmHg.

A high-operative morbidity (33% hemiplegia) and mortality (12%) has been quoted from work done in the 1980s, but recent studies where resection and reconstruction of the carotid artery is performed have shown much lower figures.[147, 148] A review of 148 patients published between

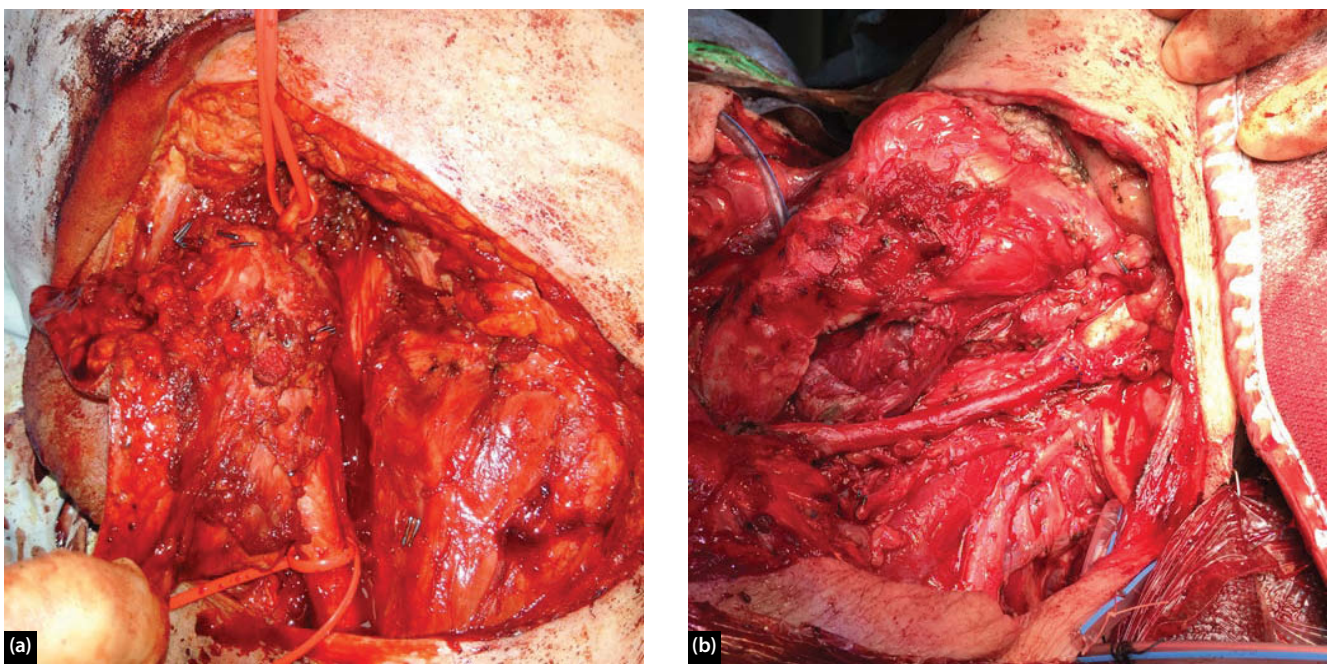

Figure 18.9 (a) A carotid resection in progress. **(b)** The artery has been replaced by a saphenous vein graft.

1987 and 1998 demonstrated combined major neurological morbidity and mortality rates of 10%.[149]

It is well recognized that in untreated patients with HNSCC, the carotid artery may not often be involved even when massive disease is present in the neck and that neck dissection may be possible. However, in the presence of radiological evidence of invasion, surgeons have traditionally opted to resect the carotid. In a review of 90 patients with documented radiological evidence of invasion, Ozer et al[143] showed that this need not be the case and in over 70% of cases dissection of the carotid is feasible and the tumour can be removed without recourse to carotid resection.

Traditionally, carotid resections were regarded to be unrewarding in HNSCC from the point of either achieving locoregional control or improving survival. A review of the literature in 1992[146] reported a 2-year survival rate of 22% following carotid artery resection. This study has been criticised for failing to identify those patients who had been treated previously, for not distinguishing between the treatment of isolated neck recurrence compared with recurrent disease at the primary site as well as the neck. Aggressive disease in a radiated neck may be associated with residual tumour following resection and there is high risk of systemic disease; thus resection of the carotid artery was thought not to affect the natural history of the disease. Papers published in the last decade suggest that poor outcomes are especially seen in patients who have had previous radiation. Those patients with demonstrable carotid invasion who undergo primary surgical resection with or without reconstruction of the carotid may have a much superior outcome, with control rates between 30% and 50% at 5 years.[143, 148–150] There may be a subgroup of patients who present with bulky neck disease and carotid invasion, who are best managed by primary resection and reconstruction with adjuvant radiation.

This is often a difficult scenario and decision should be made after careful consideration of the morbidity and mortality of the procedure, patient expectations and the expertise of the treating team.

THE IRRADIATED N0 NECK WITH RECURRENCE AT THE PRIMARY SITE

Very few studies[151–153] have addressed this question, but they have arrived at the same conclusion. There appears to be no increased risk of occult metastases in this setting and SND is oncologically adequate to clear the neck.

MANAGEMENT OF THE NECK FOLLOWING PRIMARY CHEMORADIATION

Organ preservation protocols have established a firm place in head and neck oncological practice. Using concurrent chemoradiation, they aim to avoid resection and thus sacrifice of the organ where the primary is sited, even for advanced primaries. The following discussion assumes that the primary site has been controlled in all instances.

Although histological evidence of nodal residual disease has been demonstrated in only 40–45% of partial responders, few centres would argue against salvage neck surgery in this setting. The extent of the procedure remains a point of controversy as it is rare to find viable disease in levels that are clinically negative.[154, 155]

Until recently, there had been no universal agreement on how the advanced neck should be dealt with following chemoradiation when a complete response is obtained. Pathological examination of neck dissection specimens has revealed residual disease in up to 25% of patients who have achieved a complete response,[131, 156] but the presence of tumour cells does not indicate that they are viable. Some studies show a clear benefit in regional control when planned neck dissection is undertaken even in the presence of complete response.[131] However, prospective studies of patients with a complete response as assessed radiologically have mature long-term clinical follow-up and show very low regional relapse rates that are comparable to the regional failure rates reported in planned neck dissections series.

Several studies have demonstrated the high sensitivity and negative predictive value of PET-CT imaging to assess residual disease in complete,[68, 157, 158] and partial responders,[68, 69] performed at least 8 weeks after treatment. Earlier scanning increases false positive results and is not recommended. A meta-analysis showed that highest sensitivity results are seen in studies performing PET-CT 10 weeks after treatment.[70] This has been used as a decision-making tool in recommending neck dissection after chemoradiation, with surgery being limited to cases where there is evidence of uptake (**Figure 18.10**). The literature has slowly shifted towards non-surgical management for patients who experience a complete response[159–161] with some international groups endorsing this in consensus statements.[162] Emerging data suggest some role for an SND or even a lesser procedure (superselective neck dissection) in this setting when a complete response is obtained.[163–166]

In 2016, Mehanna et al published the primary outcome results of the PET-NECK trial;[167] 564 patients were randomized to have either an END following CRT, or surveillance of the neck with PET-CT 12 weeks following completion of CRT. Patients were included with N2 or N3 disease at presentation, with primary nasopharyngeal disease excluded from entry to the trial. Patients in the PET-CT surveillance arm underwent ND for residual disease. The trial demonstrated equivalent overall survival between the groups at two years (85% in the surveillance group and 82% in the END group), with fewer neck dissections in the surveillance group (54 vs 221) and a cost saving of approximately £1500 ($2200) per patient undergoing PET-CT surveillance.

The authors make a very important comment following their analysis in suggesting it would be reasonable to monitor residual enlarged neck nodes following CRT, if they are PET-CT negative, in HPV-positive disease. They suggest that in HPV-negative disease, equivocal but enlarged nodal disease on PET CT at 12 weeks should undergo neck dissection (**Figure 18.11**).

In light of this recent level 1 evidence, we recommend that necks staged N2 and N3 undergo PET-CT imaging at 12 weeks (the TNM 8th edition clinical staging[5, 15] does

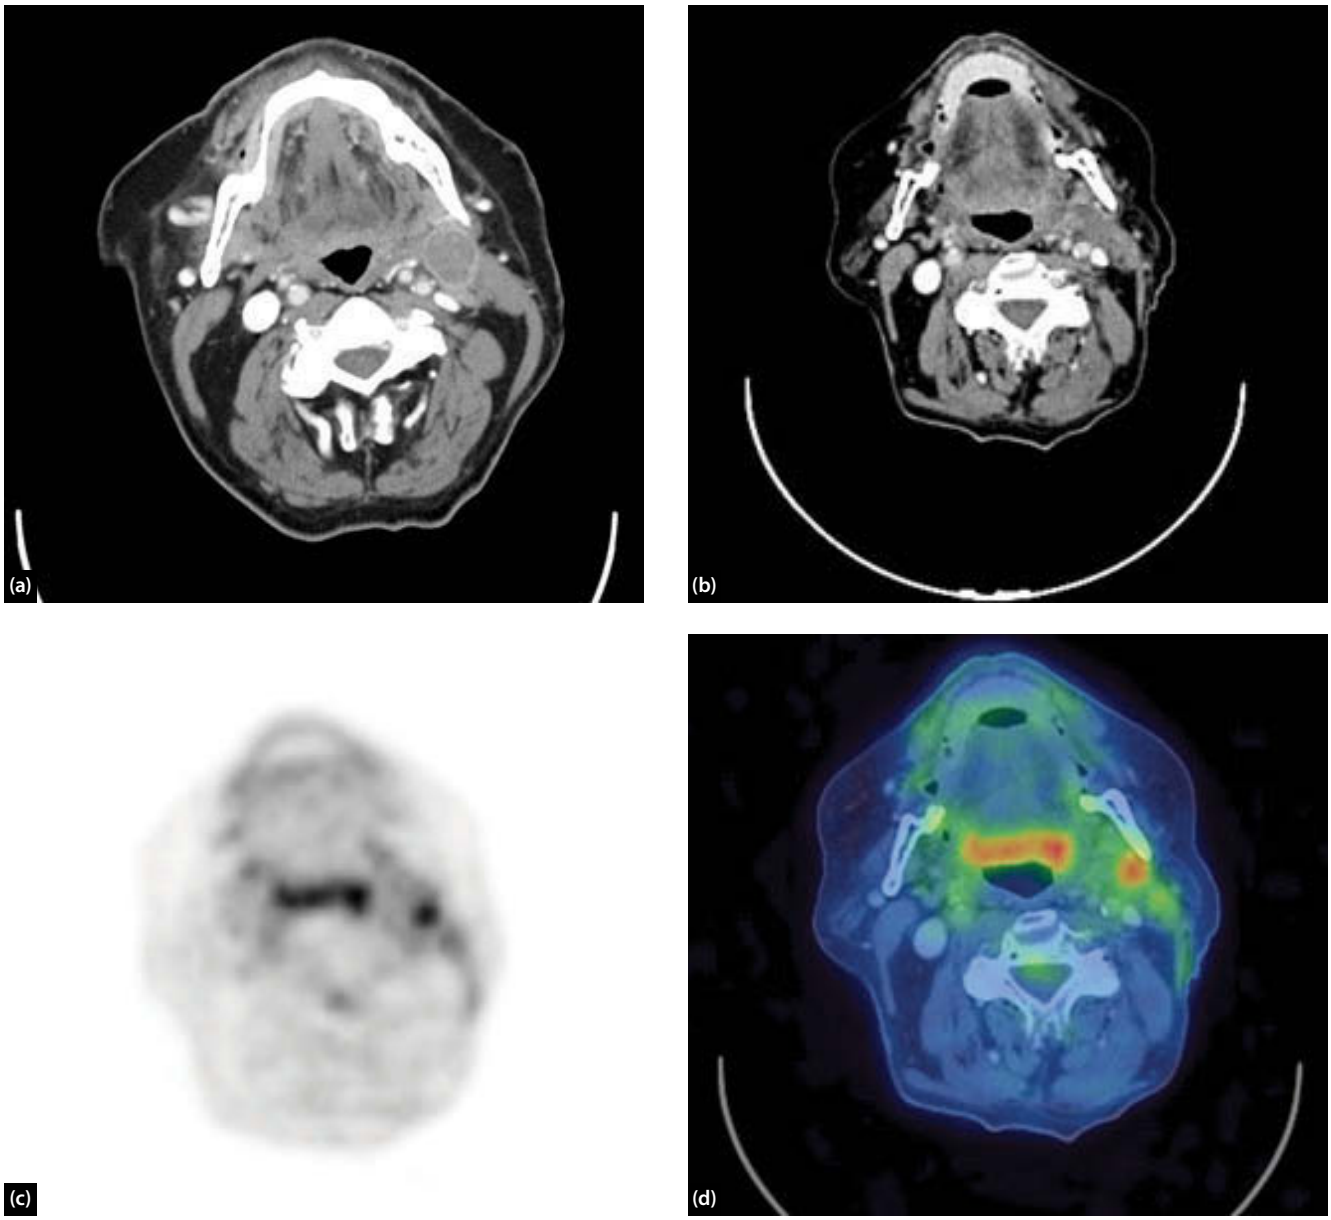

Figure 18.10 **(a)** The pre-treatment CT scan demonstrating a cystic metastasis. Post-treatment CT component of PET-CT scan **(b)** at 14 weeks shows residual nodal swelling that is avid on the PET **(c)** and the fused PET-CT images **(d)**, indicative of residual disease. This patient underwent a neck dissection that confirmed residual disease (Image courtesy Dr Tamir Ali, Newcastle upon Tyne Hospitals.

not allow distinction of a single <3 cm HPV positive node – hence all N1-3 disease should undergo PET-CT imaging at 12 weeks). Complete responders can be observed. Where there is no access to PET-CT, conventional imaging should be performed at 12 weeks. Salvage neck dissection should be considered for residual enlarged nodes.

The PET-NECK trial data has now clarified that complete neck responders can be safely observed.[167] Patients with equivocal PET-CT uptake will be considered partial responders and should be offered neck dissection. Of course, not all of these patients will have pathologically viable tumour. It is the authors' experience that many equivocal neck findings on PET-CT will ultimately turn out to be negative on pathological examination. As discussed above, there has been a move towards SND or even super-SND following CRT, with the recognition that neck morbidity is reduced with less levels dissected. For equivocal responders on PET-CT or more concerning residual findings on PET-CT, what should the extent of neck dissection be? The evidence for this question predates the emergence of PET-CT scanning as a reasonable predicator of response, and comes from series in which many more patients more routinely offered post-CRT neck dissection. However, the series of 177 post-CRT neck dissections described by Robbins et al[166] offers convincing data to support a limited SND in patients with residual disease. Having utilized CT imaging post-CRT, of the 54 patients with pathological residual disease, only two

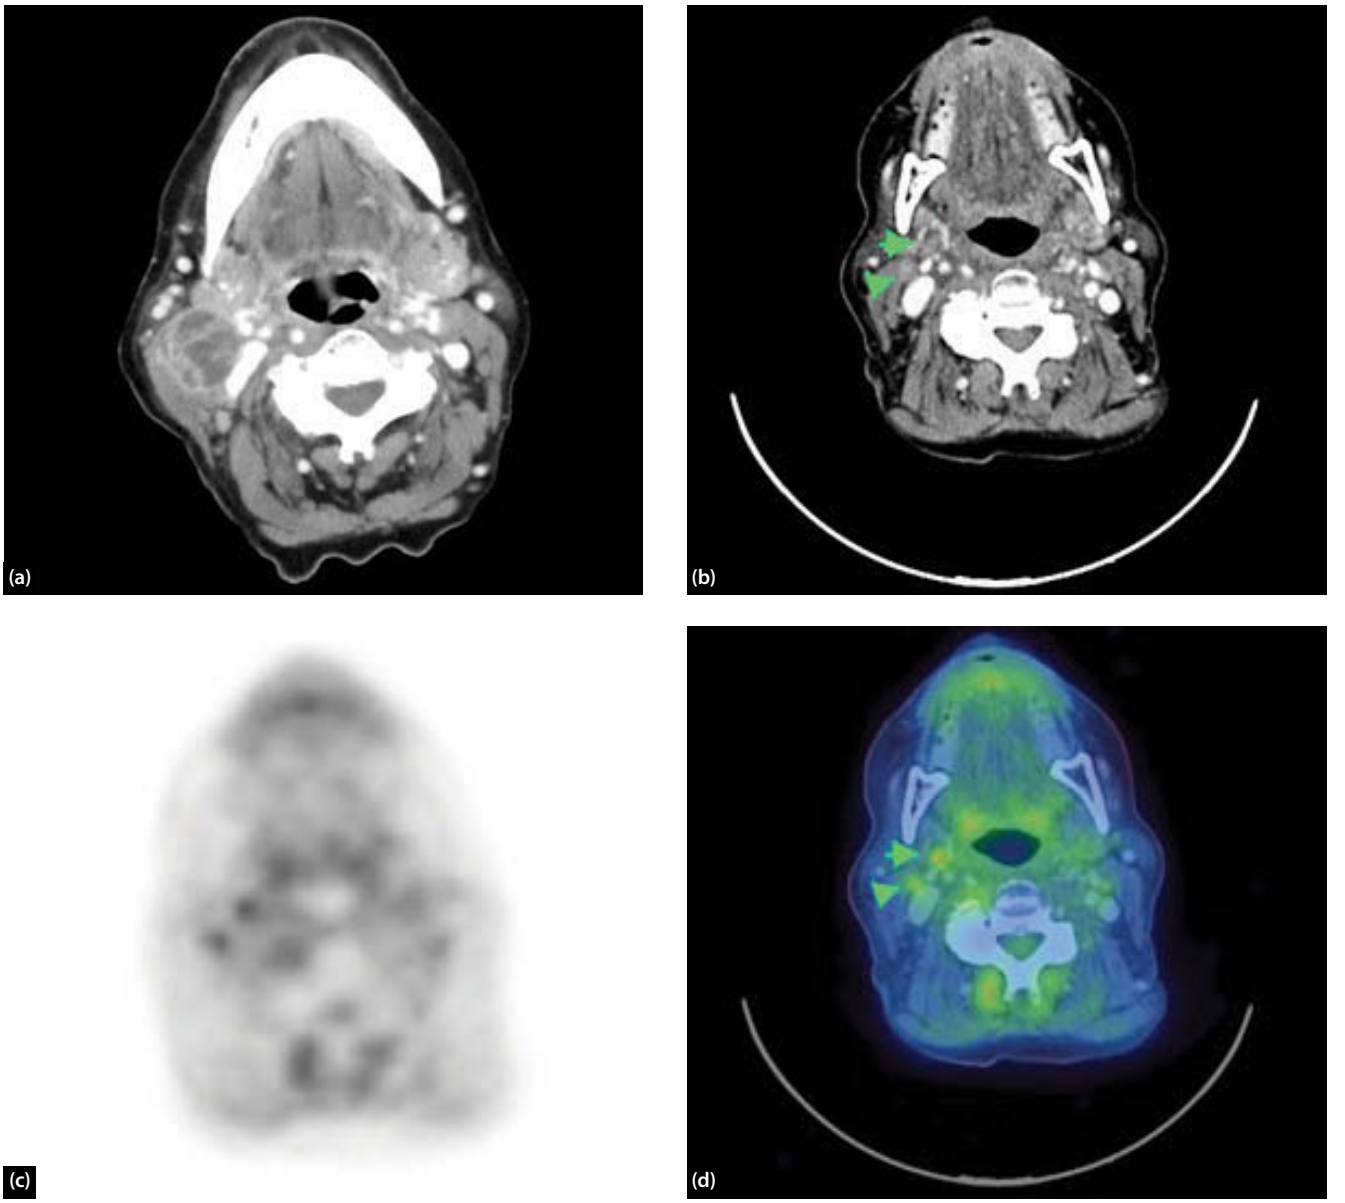

Figure 18.11 **(a)** The pre-treatment CT scan demonstrating a metastatic node in the right side of the neck. Post-treatment CT component of PET-CT scan **(b)** at 12 weeks shows small residual nodal swelling (green arrowheads). The PET **(c)** and the fused PET-CT **(d)** images show equivocal standard uptake values. The decision was made to follow up this patient without surgical intervention (Image courtesy Dr Tamir Ali, Newcastle upon Tyne Hospitals).

patients had disease beyond the clinically predicted single neck level. Only one of these patients would not have had their disease appropriately removed with a limited SND.

The timing of neck dissection after chemoradiation has not been systematically assessed. Nodes tend to regress at variable rates after irradiation. Bataini[168] suggested an interval of at least 8 weeks for nodes 6 cm and less and longer periods (16–20 weeks) for those more than 6 cm. Pathological studies have shown that metastatic disease can be demonstrated in 30% of necks after chemoradiation despite clinical and radiological evidence of complete response, but this does not correlate with the clinical outcome of low (5%) recurrence.[169–172] This may be due to non-viable cells and the fact that many of the neck dissections were done 4–6 weeks after treatment. The neck is best assessed between 8 and 12 weeks as discussed above and salvage offered following this. Surgical procedures on necks after chemoradiation necks are associated with more complications.

NECK DISEASE ASSOCIATED WITH HUMAN PAPILLOMAVIRUS

Enormous research interest lies in head and neck cancer caused by HPV, as it continues to increase in incidence in many parts of the world and as it represents a distinct type of head and neck cancer. The overwhelming majority of HPV-induced cancer is found in the oropharynx.

Most patients who present with HPV-induced OPSCC, do so with advanced disease, often with nodal metastases. Currently, there is no recommendation that HPV-induced OPSCC should be treated any differently to all other non-HPV-induced head and neck cancer with nodal disease. The recognition that patients with HPV-induced OPSCC have better survival outcomes has led some to question whether their management can be better tailored to reduce treatment-related morbidity, whilst maintaining treatment efficacy. As many patients with HPV-induced OPSCC present with small volume, discrete primary tumours, lacking field cancerization change, in combination with nodal metastases, there has been a growing interest in offering transoral surgery to these patients. However, the major stumbling block in offering transoral surgery over primary non-surgical management is the debate around management of the neck disease. Patients with HPV-induced OPSCC have a high rate of ENE within nodal metastases. Based on the current level 1 evidence, any patient with ENE found in their neck dissection, completed as part of their primary surgical management, should be offered adjuvant chemoradiotherpy.[33] There are arguments against such aggressive adjuvant therapy for this particular group of patients: whilst the evidence in support of adjuvant chemoradiotherapy is incontrovertible for ENE, especially for OPSCC, the data on which the conclusions are drawn are somewhat dated and may pre-date the rapid rise in HPV-induced OPSCC. As such, it is possible that only a minority of patients in the two RCTs had HPV-induced OPSCC.[136, 137] We have no data to demonstrate what the survival advantage may be for patients with HPV disease who receive chemotherapy in addition to adjuvant radiotherapy. A large multicentre study assessing the outcomes of transoral laser surgery in 204 patients with advanced stage OPSCC demonstrated no survival difference using multivariate analysis in those patients with or without ENE.[173] In this series, 74% had HPV-induced disease, 63% had ENE and only 16% received adjuvant chemoradiotherapy. A further study of patients undergoing primary surgery demonstrated that whilst ENE was an independent factor in disease-specific survival in oral cavity cancer, ENE did not affect disease specific survival in the 133 OPSCC patients (57% p16 positive). A phase II randomized trial is currently recruiting in the UK to assess the functional outcomes of a reduction in adjuvant therapy, prior to the proposed phase III study to assess survival, for patients with HPV-positive OPSCC treated with primary transoral surgery and neck dissection. Within this trial, patients with ENE are randomized to either adjuvant radiotherapy alone or adjuvant chemoradiotherapy.[174] A similar randomized trial is ongoing in the USA.[175]

TREATMENT OUTCOMES

Regional control rate in the pN0 neck is consistently good with failure rates between 3% and 7%, largely irrespective of the modality of treatment. Recurrence rates following therapeutic neck treatment will vary depending on other factors such as control of the primary site, ENE and the stage. Where the primary tumour has been controlled, overall recurrence rates range from approximately 10% for N1 disease without ENE, 20–30% for N2 disease and up to 85% for N3 disease although some small series quote better results,[1, 142, 176] In many cases of N3 disease, the primary site remains uncontrolled.[8]

Recurrent neck disease

Recurrence in the neck following previous treatment carries a poor prognosis. However, there will be instances in which further treatment is appropriate to control the disease and relieve symptoms, accepting the ultimate lack of curative intent. In accordance with the natural history of HNSCC, the majority of recurrences occur within the first 2 years of treatment. Various considerations including status of the primary site, extent and nature of recurrence, distant metastases and comorbidity dictate the treatment. Thus, a comprehensive investigation of the general status of the patient and distant metastases should be performed. Many of these masses will be fixed to vital structures which will negate extensive surgery. In patients who present with unresectable disease, re-irradiation with or without chemotherapy should be considered, particularly in those who present more than 2 years since their previous treatment. Evidence of partial repair of RT-induced spinal cord subclinical damage and newer RT delivery techniques (IMRT, tomotherapy, protons) that allow better sparing of neurological structures at risk make this a realistic option in a larger number of patients. If surgery is possible, wide resections should be undertaken and post-operative re-irradiation considered. About one-third of patients will be untreatable at presentation.

RECURRENCE IN THE IPSILATERAL UNTREATED NECK

In this situation, neck dissection is usually the preferred treatment with or without post-operative radiotherapy based on the histology. This group of patients do relatively well and local control rates between 50% and 60% can be expected. Alternatively, irradiation with surgical salvage may be used along the principles described above.

RECURRENCE IN THE CONTRALATERAL UNTREATED NECK

A proportion of patients in whom metastases occur on the untreated contralateral side of the neck sometime after a dissection on the other side may be salvaged, provided there is no recurrence at the primary site. In a retrospective review of 2550 patients, Spector et al[177] concluded that delayed metastases occurring on the untreated contralateral side were associated with significantly better salvage rates (42.5%) than the ipsilateral previously treated neck (17%).

RECURRENCE IN THE PREVIOUSLY TREATED NECK

Radical radiotherapy can be used if there is recurrent disease in the neck developing after previous surgery, which was not followed by post-operative irradiation. Owing to scarring from previous treatment, the neck stage is often N2a or more at presentation and ENE occurs in the vast majority of patients.

A multi-institutional review[178] studied 77 patients with cervical recurrence on the treated side, in the setting of a controlled primary. The review found that attempting salvage was useful in selected patients, giving a 33% control rate at 3 years. Results were better when surgical salvage was performed, but this probably reflects the low disease volume. Salvage rates were significantly better in the previously irradiated neck rather than the neck treated by previous surgery, with disease-free intervals being 46 months and 8 months respectively. The use of a pedicled pectoralis major flap or free flap should be seriously considered when embarking on salvage neck dissection, to reduce wound healing complications.

NODAL RECURRENCE AFTER COMBINATION TREATMENT

The prognosis is extremely poor in those patients who suffer a neck recurrence following previous surgery and radiotherapy, with median disease-free intervals of 4 months.[178] This clinical situation is often associated with distant metastases. However, the presence of such disease in the neck causes distressing symptoms such as pain or bleeding, together with offensive fungation and in selected cases further treatment may be appropriate. This includes wide excision of the tumour and the overlaying skin, flap reconstruction and brachytherapy. In very selected cases, re-irradiation may be an option. Evidence of partial repair of RT-induced spinal cord subclinical damage and newer RT delivery techniques (IMRT, tomotherapy, protons) that allow better sparing of neurological structures at risk make this a realistic option in a larger number of patients.

IMPACT OF NECK TREATMENT ON QUALITY OF LIFE

The issues that relate to quality of life (QOL) and the treatment of metastatic neck disease are discussed below.

Elective surgery versus irradiation of the N0 neck

There are no studies comparing (QOL) between these two treatments and there is very little morbidity associated with a well-executed SND. This is because vital structures are preserved and level V is not usually dissected. In contrast, a strategy of uniformly irradiating both sides of the neck to try and decrease the likelihood of occult cancer growth may be associated with numerous problems since radiation does not always control occult neck cancer, the fate of recurrent cancer in an electively irradiated neck is much more difficult to salvage and isolated recurrence in the contralateral neck is extremely unlikely.[8] In addition, treatment options for second primary tumours are diminished when wide-field radiotherapy has been applied to both sides of the neck and there are no prospective randomized studies which demonstrate a survival disadvantage when the N0 neck is observed. In summary, the QOL issues relating to elective irradiation appear less transparent than those for elective surgery and should not be underestimated when prescribing its use. Further studies are awaited.

Impact of neck treatment on the shoulder

Neck surgery for node positive disease usually involves a 5-level dissection and there are QOL issues that relate both to the extent of the dissection and which tissues are sacrificed (i.e. accessory nerve, sternomastoid muscle and the internal jugular vein). Shoulder problems are greater in patients undergoing a RND as opposed to a MRND.[179, 180] Despite preserving the accessory nerve in MRND, dysfunction occurs due to the nerve being devascularized and stretched. The least problems are seen in patients undergoing an SND.[98] It is noteworthy that SNDs that clear levels II– IV can also affect the shoulder by stretching the accessory nerve during dissection of the submuscular recess (level IIb).[181] Quite clearly if level V is not dissected, this may improve QOL. However, it must be noted that the trade-off for not dissecting all five levels may be the subsequent morbidity of post-operative radiotherapy, which does contribute to shoulder dysfunction.[126]

The use and extent of radiotherapy to the neck

While the effects of neck surgery are confined to the neck, radiotherapy fields often include the salivary glands and some of the viscera, leading to side effects such as mucositis and xerostomia. Use of intensity-modulated radiation therapy (IMRT) has allowed parotid-sparing techniques. Results from randomized controlled trials indicate that IMRT does improve quality of life, at least in the early years.[182] In addition, the evidence that both sides of the neck need to be irradiated in well lateralized primaries post-operatively is flimsy since the incidence of contralateral neck disease is relatively uncommon in certain tumours, as discussed earlier.[8] Unfortunately, many oncologists continue to routinely prescribe bilateral post-operative radiotherapy to the neck.

In our efforts to improve quality of life and reduce the traumatic psychosocial impact, a number of specialist centres are now in the process of balancing science with ethics and the human experience with a surge of QOL research and, hopefully, an evidence-based rationale to guide us in the future. Until a major therapeutic breakthrough takes place, reducing physical treatment morbidity, improving patients' overall QOL and minimizing the psychosocial impact of therapy will continue to present our greatest challenge in the practice of head and neck surgery.

FUTURE RESEARCH

The quality and quantity of randomized trials for metastatic neck disease is acknowledged to be limited, but this has improved significantly in recent years. Particularly in the UK, the improved structure of research trial coordination has led to the successful completion of a number of surgical trials, most notably the PET-NECK trial. As a result of this successful trial a number of clinical trials have been funded and are now recruiting well. Further research should involve the integration of modified randomized trials with prospective audit and quality control studies.[183] The following are areas where further work needs to be addressed.

- Imaging of low volume disease
- Significance of occult cancer in the neck
- Molecular detection of occult neck disease and its significance
- Sentinel node biopsy for occult neck cancer, in non-oral cavity cancer
- Selective neck dissection for palpable disease
- Superselective neck dissection for residual disease after chemoradiation
- Management of the contralateral neck
- Quality of life should be investigated following various treatment modalities
- Centralization with specialization and appropriate data collection should improve research, audit and quality control.

KEY POINTS

- Head and neck squamous cell cancer is a systemic disease.
- Tumour-host interaction has a major role to play in the outcomes of treatment.
- Metastatic cervical lymphadenopathy is the most important prognostic factor in head and neck squamous cell carcinoma.
- Patterns of neck metastases are altered by previous treatment.
- Subclinical neck disease is not early cancer.
- Selective neck dissection is adequate in the management of N0 necks.
- Elective neck dissection should be considered for all T1-2 N0 oral cavity SCC, and should be performed for tumours with a depth of over 3 mm.
- Modified radical neck dissection is as good as radical neck dissection in regional control.
- Adjuvant radiotherapy or chemoradiotherapy is indicated for surgically managed N2 and N3 disease and for N1 disease with poor prognostic features.
- Where there is access to it, PET-CT should be performed 12 weeks after primary chemoradiotherapy for N2 and N3 disease. The results should guide the need for subsequent neck dissection.
- In selecting treatment options, QOL issues are important considerations.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline Search using the following keywords: head and neck, radiotherapy, intensity-modulated radiotherapy, linear quadratic equation, therapeutic ratio and radiobiological modelling.

INTRODUCTION

Radiotherapy as a single modality or combined with synchronous chemotherapy is capable of high rates of tumour control. A local control rate of 90% at 5 years would be expected both when radiotherapy is administered as the sole treatment for a T1-glottic carcinoma and when HPV-associated oropharyngeal cancer is treated with synchronous chemoradiation in patients without a significant smoking history.[1–6]

However, these high rates of local control come at considerable cost to the patient. Acute side effects can include mucositis which often requires the use of strong opioid analgesia, taste disturbance, hair loss, acute xerostomia, dysphagia requiring the use of temporary tube feeding and skin reactions. Long-term side effects can include the risk of osteoradionecrosis, xerostomia and the risk of stricture formation and fibrosis necessitating long-term tube feeding. There is no strong evidence that prophylactic treatment of these side effects is effective other than the use of intensity modulated radiotherapy to avoid late xerostomia.[7–10] On the contrary an adverse effect on local control was observed in one study when patients were randomized to receive prophylactic granulocyte-colony stimulating factor (G-CSF) during irradiation with no improvement in the rate of acute mucositis, a finding with possible implications for prophylactic G-CSF use during chemoradiation.[11] Death during or within 8 weeks of completion of treatment, when actually reported in randomized trials, occurs in 0–7% of patients undergoing radiotherapy alone and 0–14% with chemoradiation. Deaths definitely ascribable to treatment are reported in 0–3% and 0–5% of patients respectively.[11–23]

It is therefore essential that this therapeutic ratio i.e. the benefit to the patient (altered chance of cure) vs the detriment to the patient (altered chance of mortality/morbidity) is considered in detail when any modification to the radiotherapy or chemoradiotherapy schedule is made.[24–28] In this chapter the physical, chemical and biological processes involved in radiotherapy delivery will be briefly considered to enable an appreciation of the way in which these processes have already been or may be modified in the future to affect this ratio. The radiobiological modelling of such modifications will then be considered.

Basic physical, chemical and biological processes

Photons for use in head and neck radiotherapy, normally of energy of 6 megavolts (MV), are produced in a linear accelerator by accelerating electrons into a target. The photon beam produced can be shaped by using a series of collimators in the head of the machine (multi-leaf collimators) which are able to move permitting intensity-modulation between the delivery of multiple beamlets (step and shoot

intensity-modulated radiotherapy (IMRT)) or during the delivery of the beam (dynamic IMRT). The gantry of the linear accelerator can also move around the head of the patient to deliver photons from different beam angles. If the IMRT is only delivered while the gantry is stationary from a number of set-beam angles (normally 5 or 7 in head and neck IMRT) the treatment is known as fixed-beam step and shoot IMRT. If the IMRT is delivered while the gantry is rotating about the patient the treatment is known as dynamic arc IMRT.[24, 29, 30] Intensity Modulated Proton Therapy (IMPT) may be considered in the future for certain head and neck tumours due to the ability to reduce the 'low dose bath' with this modality (**Figure 19.1**).

Photons cause ionization in normal tissue resulting in the formation of secondary electrons which cause further ionization resulting, in the presence of oxygen, in free-radical formation. The principal target of radiotherapy at a cellular level is deoxyribonucleic acid (DNA). Radiation causes cell death primarily through single- or double-strand breaks in DNA. Single-strand breaks are mostly due to the effects of hydroxyl radicals (OH^-) formed as described above. Double-strand breaks are directly proportional to the dose of radiation delivered and may result from direct interaction by the photons or secondary electrons with the DNA double strand.[31–34]

In general it is the double-strand breaks that are crucial for the lethal effects of radiation. Irreparable DNA damage causes sterilization of the tumour cell with loss of proliferative capabilities, also known as cell kill.[35] However, single- and even double-strand breaks can be repaired by complex repair processes.[36, 37] It must be remembered that both tumour cells and the varied normal tissues which surround the tumour are affected by radiation. It is the differential response between tumour and normal tissues in their ability to repair DNA lesions and their response to the amount of radiotherapy delivered per treatment (fraction size) which the head and neck radiation oncologist utilizes in order to maximize the therapeutic ratio.[25]

Radiobiological modelling

There have been many randomized studies of altered fractionation in head and neck cancer and thus it has been possible to test in the clinical setting models of tumour cell kill and normal tissue response originally derived from the irradiation of cell lines.[38–45] An understanding of the relatively straightforward calculations involved in such modelling together with an appreciation of the limitations of such models is essential for radiation oncologists and helpful for other members of the multidisciplinary team.

Linear quadratic equation and biologically effective dose (BED)

Since 1989 the linear quadratic equation and the concept of BED has been proposed as a model for comparing the biological effects from different dose schedules in radiotherapy:[46–49]

$$E = \alpha nd + \beta nd^2$$

Where:

- E = biological effect
- n = number of fractions of radiotherapy in a course
- α = linear component of cell kill or intrinsic radiosensitivity or lethal hit component of cell kill in units of $Gray^{-1}$ (Gy^{-1}). One Gray (Gy) is equivalent to 1 Joule of energy deposited per kilogram of tissue.
- β = quadratic component of cell kill or component of cell kill resulting from combined sublethal hits in units of Gy^{-2}
- d = dose per fraction

In the mode of action of radiotherapy discussed above the alpha component of cell kill might be considered to be related to the number of double-strand breaks and the beta component related to the number of combined single-strand breaks. The beta component is inversely

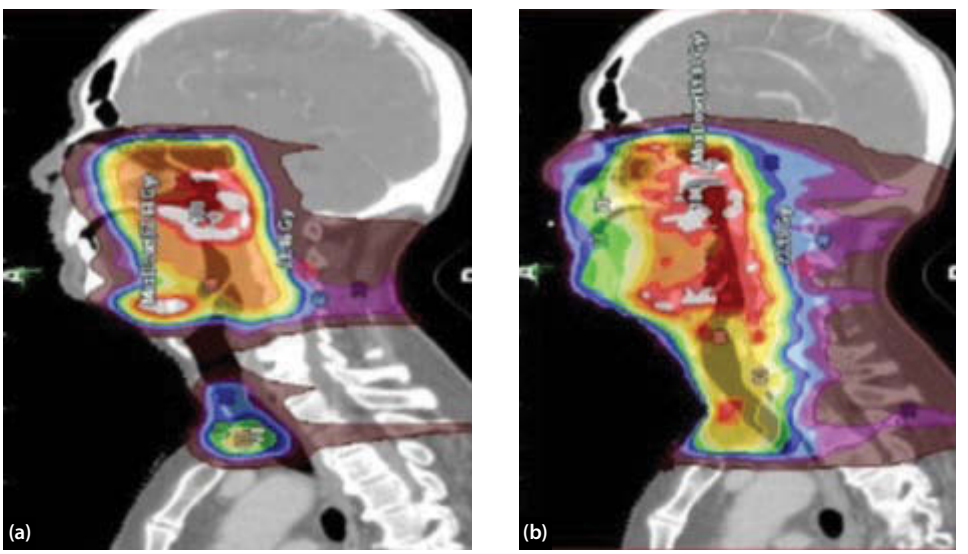

Figure 19.1 Sagittal plane of **(a)** an Intensity Modulated Proton Therapy (IMPT) plan and **(b)** an Intensity Modulated Radiotherapy (IMRT) plan illustrating potential sparing of the posterior fossa of the brain and posterior cervical musculature (Images courtesy of Mr. Trevor Williams).

proportional to the repair ability of the tumour or tissue under consideration. To make this model useful clinically, the concept of BED has been defined. This permits the comparison of different dose fractionations. Two different dose fractionations which result in the same specific biological effect in a defined tissue (which might be a particular tumour or normal tissue) will have the same BED.[46]

BED is derived by dividing the above equation by the intrinsic radiosensitivity parameter alpha:[46–48]

$$\frac{E}{\alpha} = BED = \frac{\alpha nd}{\alpha} + \frac{\beta nd^2}{\alpha} = nd + \frac{\beta nd^2}{\alpha} \tag{19.1}$$

Factorizing gives:

$$BED = nd\left(1 + \frac{\beta}{\alpha}d\right) = nd\left(1 + d\Big/\frac{\alpha}{\beta}\right) \tag{19.2}$$

Number of fractions (n) times the dose per fraction (d) = D = total dose:

$$BED = D\left(1 + d\Big/\frac{\alpha}{\beta}\right) \tag{19.3}$$

Where $\frac{\alpha}{\beta}$ is known as the alpha beta ratio and reflects the sensitivity of different tumours or normal tissues to changes in the dose per fraction d or fraction size. For example the $\frac{\alpha}{\beta}$ for squamous cell carcinoma of the head and neck is considered to be around 10 Gy and for the acute musocal reaction seen during radiotherapy also around 10 Gy but for late mucosal damage around 3 Gy.[50–52] From the above equations, it can be seen that the lower the $\frac{\alpha}{\beta}$ of the tissue the greater the sensitivity to changes in fraction size.

If two treatment regimes used for squamous carcinomas, 55 Gy in 20 fractions (#) and 70 Gy in 35# are considered in terms of likely late mucosal toxicity it is possible to calculate the BED for late mucosal toxicity for both regimes using equation 3. In this example it is necessary to use an $\frac{\alpha}{\beta}$ of 3 Gy. For the first regime with total dose (D) of 55 Gy and dose per fraction (d) of 2.75 Gy, the BED is 105 Gy. For the second regime with D = 70 Gy and d = 2 Gy the BED is 117 Gy i.e. higher rates of late mucosal damage might be expected with the second regime. Although there is a higher dose per fraction in the first regime, the decreased total dose offsets this. In calculations such as these the BED may be reported as $105\,Gy_3$ and $117\,Gy_3$, the subscript reflecting that the dose has been calculated using an $\frac{\alpha}{\beta}$ of 3.[53, 54]

Equivalent dose in 2 Gy fractions (EQD2)

Often BED is converted into equivalent dose in 2 Gy fractions (EQD2) as in the conformal era normal tissues and tumours often received a homogenous dose. Therefore, radiation oncologists were used to working with both tumour doses and normal tissue tolerance in 2 Gy per fraction.[47, 51, 52, 54] This is less relevant in the IMRT era as both total doses and dose per fraction differ greatly between tumour and normal tissues. If needed the conversion can be made:

$$EQD2 = \frac{BED}{\left(1 + 2\Big/\frac{\alpha}{\beta}\right)} \tag{19.4}$$

A similar calculation can be performed for the response of tumour using an $\frac{\alpha}{\beta}$ of 10 Gy. For the two regimes considered above this results in tumour BEDs of $70\,Gy_{10}$ and $84\,Gy_{10}$ and EQD2s of $58\,Gy_{10/2}$ and $70\,Gy_{10/2}$ (the subscripts now indicating that the calculations have been made for a tissue (in this case a tumour) of $\frac{\alpha}{\beta}$ of 10 Gy but that the dose is quoted as if it were delivered in 2 Gy fractions).

The effect of time on biologically effective dose

From the above calculation it would be expected that the second regime (70 Gy in 35) would be associated with a higher rate of tumour control but, in reality, control rates seen with these regimes are similar. In several studies prolonging the overall treatment time over which a fractionated course of radiotherapy is delivered for squamous cell carcinoma of the head and neck results in reduced tumour control.[55–58] This is thought to occur due to an increase rate of cell proliferation in surviving cells once radiotherapy has commenced. In most recent radiobiological studies this accelerated repopulation is modelled to commence at around 21 days known as the kick off time or T_k.[58–62] For squamous cell carcinoma during radiotherapy, the cell turn over time or T_p is modelled at 3 days. A modified equation for BED to take into account overall treatment time has been derived for overall treatment time (T):[51–52]

$$BED = D\left(1 + d\Big/\frac{\alpha}{\beta}\right) - \left(\frac{\ln 2}{\alpha} * \frac{(T - T_k)}{T_p}\right) \tag{19.5}$$

Repeating these calculations for the two regimes above having T of 25 days and 46 days respectively, using a value for alpha of $0.3\,Gy^{-1}$, gives BEDs of $67\,Gy_{10}$ and $65\,Gy_{10}$ suggesting more similar tumour controls. The reliability of these models for tumour control will be discussed in 'Altered fractionation' below.

Such calculations are useful not only in the design of randomized studies but for devising revised schedules when an unintended gap in treatment occurs.[63–66] Such gaps should be avoided where possible but may be compensated for by altered fractionation following the gap. It is important to note that for late side effects such as late mucosal damage or neurological damage there is no correction for time when calculating BED. Late responding tissues appear dependent on total dose and fraction size only and typically have a low $\frac{\alpha}{\beta}$ ratio.[67]

The same calculations as performed for tumour can be performed for BED with respect to the rate of acute grade 3 ucosal reactions which has been considered the dose limiting acute toxicity in head and neck cancer. Tolerance models for the acute mucosa for different radiotherapy schedules have been devised.[50, 68, 69] When calculating BED for acute mucosa the values for $\frac{\alpha}{\beta}$, α, T_p and T_k used are 10 Gy, 0.35 Gy^{-1}, 2.5 days and 7 days. In the simplest of three published models based on published studies of radiotherapy as sole modality in head and neck cancer, Fowler et al. suggest that schedules with an acute mucosal BED (amBED) greater than 61 Gy_{10} were unlikely to be tolerable due to severe acute mucositis.[51] Such models should again inform the design of future randomized studies although it is important to note that they are based on data from the conformal era and that mucosal sparing achievable with IMRT or IMPT may not be taken into account.[70, 71] A recent study has suggested that these tolerance models may be used in the chemoradiation setting (**Figure 19.2**).[72]

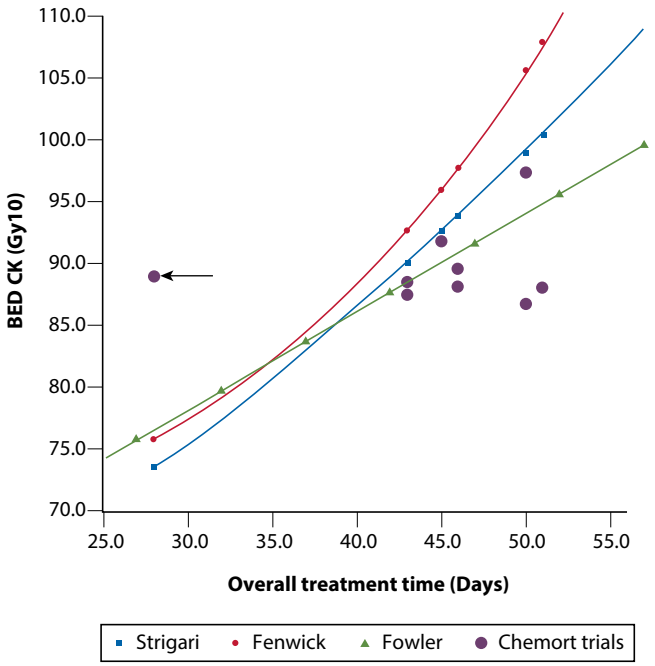

Figure 19.2 Plot of biological effective dose cell kill (BED CK) including contribution from chemotherapy against overall treatment time to illustrate how radiobiological modelling can predict mucosal tolerability. The arrowed trial is predicted to be above the levels of tolerability of 3 published models and indeed was shown to have a grade 3–4 mucositis rate of 77%.

CLINICAL PROCESS FOR A PATIENT UNDERGOING CHEMORADIATION FOR HEAD AND NECK SQUAMOUS CELL CARCINOMA

Radiotherapy for head and neck cancer offers numerous possibilities for modifications to the treatment schedule which might affect the therapeutic ratio. Before considering these and the ways in which their effect might be modelled, a typical patient pathway will be outlined. If the example of a locally advanced squamous carcinoma with p16 positivity invading the base of tongue to midline with no neck nodes or distant metastases in a patient without a significant past smoking history is taken, this patient might expect to be treated in the following way:

Preparation: The patient's case will have been discussed in a multidisciplinary meeting with surgeons, radiation oncologists, histopathologists, radiologists, dieticians, speech therapists and clinical nurse specialists present. The acute and late side effects of the treatment would be discussed with the patient and the patient would give consent. The patient would be offered a choice between having a prophylactic or a reactive feeding tube placed. Dental assessment would be arranged.

Immobilization: The patient's head and shoulders would be immobilized in an immobilization device known as a shell or mask which is subject to regular departmental audit. The data from such audit would be used to inform the planning target volume (PTV) margins below.

Imaging: The patient would have 2 mm slice CT scanning with intravenous contrast in the immobilization device with diagnostic MRI imaging fused to these images.

Target volume definition: The head and neck radiation oncologist would define the GTV based on MRI and CT. A small margin to allow for microscopic spread and the limitations of fusion and the imaging employed (5–10 mm) would be added to form the high-dose clinical target volume (CTV) to receive 70 Gy in 35 fractions. Adjacent areas of oropharynx and nodal regions felt to be at high risk of harbouring microscopic disease may be included in a prophylactic CTV to receive 56 Gy in 35 fractions. PTV margins based on in-house data derived from audit of image guided radiotherapy (IGRT) normally 3–5 mm are added to both CTVs.

Organs at Risk definition: The minimum organs at risk defined for a case such as this would include the spinal cord, brainstem, contralateral parotid, brain and mandible. Other organs that might be contoured but constraints would normally be achieved with ease include lens, optic nerves, chiasm. Other volumes which may be contoured in an attempt to reduce toxicity include oral mucosal volume, laryngeal framework, brachial plexi, cochlea and swallowing muscles.

Peer review of contours: The CTV defined by the radiation oncologist should where possible be peer reviewed particularly in complex cases (skull base, post-operative and following neoadjuvant chemotherapy).

Treatment planning: The departmental dosimetrists would produce an IMRT plan which is reviewed quantitatively and qualitatively by the radiation oncologist and then subjected to rigorous quality assurance.

Delivery: The above plan would be delivered over 7 weeks (number of treatment days 35 but overall treatment time 46 days). Each day the patient would be imaged using cone

beam CT scanning or megavoltage imaging to check positioning and assess any changes in contour due to weight loss or tumour shrinkage which might affect dosimetry (IGRT).

Chemotherapy: Provided the patient was less than 70 and there were no contraindications the patient would receive cisplatin 100 mg/m^2 on the Monday of week 1, 4 and 7 of radiotherapy.

Supportive care: The patient would be reviewed weekly during treatment and till the mucosal reaction has settled by a multidisciplinary team of radiation oncologist, radiographers, speech therapists, dieticians and nurses.

At nearly every point of the example pathway described above there are alternatives or points of controversy. Many of these will be discussed in detail in other chapters. From the literature it is clear that for the most fundamental component of radiotherapy delivery, target volume definition, there is considerable heterogeneity between clinicians.[73, 74]

Altered fractionation

As an illustration of how the linear quadratic model can be used both to model changes in the therapeutic ratio and to clarify terminology associated with radiotherapy fractionation schemes, altered fractionation as an alternative to chemoradiation will be considered.

Although 70 Gy in 35 fractions (overall treatment time 46 days (7 weeks)) has been defined as the standard above, prior to chemoradiation being accepted as standard treatment several different fractionation schemes had been the subject of randomized studies.[39–45] In describing such schemes certain definitions need to be understood. Acceleration is a reduction in the overall treatment time below the standard 46 days. Hyperfractionation is the use of less than 2 Gy per fraction. Conversely hypofractionation is the use of more than 2 Gy per fraction. Dose escalation is an increase in the total physical dose above 70 Gy. The schedules tested in randomized trials include hyperfractionated dose escalated schedules e.g. 84 Gy in 70# over 46 days with 2 fractions delivered twice a day. In this case, dose escalation is made possible because the fraction size is reduced and thus late side effects which depend only on total dose and dose per fraction are not enhanced (late BED for 84 Gy in 70# is 118 Gy_3; for 70 Gy in 35# is 117 Gy_3 (equation 3). Other examples include pure accelerated schedules e.g. 68 Gy in 34# delivered over 38 days (DAHANCA schedule) where the total dose is only dropped minimally and overall treatment time is reduced.[43] Finally, very accelerated schedules were tested such as the CHART regime 54 Gy in 36 fractions over 12 days where 3 fractions a day were administered over 12 continuous days (no weekend breaks).[41] To make very accelerated regimes tolerable to the acute mucosa it was necessary to drop the total dose. A meta-analysis of trials of altered fractionated grouped trials into these three groups as described above and found that an overall survival benefit was only found in the hyperfractionated dose escalated group.[38, 75] This survival benefit is approximately the same as that seen with the addition of synchronous chemotherapy to standard radiotherapy. Unfortunately, this benefit was not seen in patients aged over 70 and so dose-escalated hyperfractionated radiotherapy is not an evidence based alternative to chemoradiation in this cohort.

Using the randomized trials considered in this meta-analysis, one study has shown a strong correlation between BED calculated for each regime using the parameters described above and the proportional change in local control, rate of acute grade 3 mucositis and late mucosal damage seen between study arms.[67] Studies indicate a 1.2% change in local control for a 1% change in BED in the dose range considered. This finding supports the use of the linear quadratic equation as a guide to predicting both tumour and toxicity endpoints in radiotherapy studies.

The therapeutic ratio: dose-escalated radiotherapy or synchronous chemoradiotherapy

The addition of synchronous chemotherapy to radiotherapy has been associated with an 8% survival advantage.[76] As the same benefit can be achieved with dose escalation of radiotherapy alone, modelling studies have looked at the effect on the therapeutic ratio of the addition of synchronous chemotherapy.[24, 77, 79] Initially such studies calculated the effect of chemotherapy on local control as an additional radiotherapy dose in terms of BED using knowledge of the dose response. Such studies suggest that the addition of chemotherapy to radiotherapy is equivalent to the addition of three–four 2 Gy fractions in terms of local control.[24, 77–79] A similar calculation can be performed for the rate of grade 3 mucositis and an approximate mucosal sparing of two 2 Gy fractions for the use of synchronous chemotherapy rather than dose escalated hyperfractionated radiotherapy was proposed.[24] That is, synchronous chemotherapy is beneficial to the therapeutic ratio if the principal benefit of local control and the principal dose limiting side effect of grade 3 mucositis are considered.

However, two recent trials of accelerated fractionation chemoradiation versus conventional fractionation chemoradiation have cast doubt on such modelling.[80, 81] In both these studies the expected increase in local control with accelerated chemoradiation predicted both by previous radiobiological modelling and meta-analysis was not observed.[82] One hypothesis for the lack of benefit for acceleration in these studies is that accelerated repopulation may be compensated for by synchronous chemotherapy. Alternative modelling has been proposed where the dose lost from accelerated repopulation is reduced when synchronous chemotherapy is used by increasing the value of T_p for both tumour and mucosa in equation 19.5 above.[83, 84] Interestingly, a therapeutic loss is predicted for the addition of chemotherapy when this modelling is employed.

While the above serves as an example of how radiobiological modelling can be employed, such an analysis of the therapeutic ratio is limited as it ignores overall survival and the many other early and late toxicities experienced

by patients. It is also largely based on data from the conformal radiotherapy era and toxicity sparing from IMRT is not taken into account.

CONCLUSION

A basic understanding of the mechanism of action of radiotherapy, the radiotherapy preparation and delivery process, the linear quadratic equation and the rationale for the use of chemoradiation or altered fractionation radiotherapy as described above can be beneficial to all members of the multidisciplinary team treating head and neck cancer patients.

KEY EVIDENCE

- Parotid sparing radiotherapy reduces late xerostomia.
- Dose-escalated hyperfractionated radiotherapy increases overall survival by 8% at 5 years compared with conventionally fractionated radiotherapy alone.
- The addition of synchronous chemotherapy to radiotherapy increases survival by 8% at 5 years compared with conventionally fractionated radiotherapy alone.
- Two randomized trials have failed to show evidence for a survival benefit of synchronous chemotherapy and accelerated radiotherapy over synchronous chemotherapy and conventionally fractionated radiotherapy.

KEY POINTS

- Prolonging the overall treatment time reduces the efficacy of radiotherapy.
- The Linear Quadratic Equation can be used to predict the results from future randomized studies.
- The Linear Quadratic Equation can be used to devise compensation schedules following unscheduled gaps in radiotherapy.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: Quality of Life, head and neck cancer, patient reported outcomes, questionnaires and survivorship.

INTRODUCTION

The aim of this chapter is to outline important aspects of quality of life and survivorship following head and neck cancer. The chapter is divided into five sections that take the reader from the definition and measurement of quality of life through to survivorship.

There are two million people living with or beyond cancer in the UK. This figure is set to rise to four million by 2030. It is a cause for celebration that more people than ever are surviving after diagnosis, but we know the impact of cancer does not suddenly stop when treatment is over.[1] There is considerable focus on survivorship through programmes such as the National Cancer Survivorship Initiative – improving the ongoing services and support for those living with and beyond cancer.[2] Survival is improving following oral cancer[3] and with advances in medical care, refinements in treatments and changes in the clinical characteristics of head and neck cancer patients, improved survival is expected in head and neck cancer (HNC) patients. Survivorship focuses on the health and life of a person with cancer from the completion of treatment until the end of life. It covers the physical, psychosocial, and economic issues of cancer, beyond the diagnosis and treatment phases (**Figure 20.1**). Survivorship includes issues related to access to healthcare and follow-up treatment, late effects of treatment, second cancers, and quality of life. It is recognized that family members, friends and caregivers are also part of the survivorship experience.[4] Quality of life

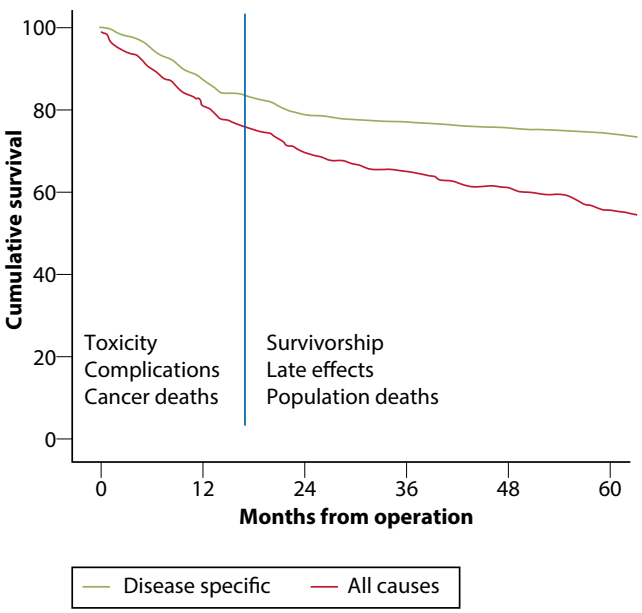

Figure 20.1 Transition from early post-treatment to longer term survivorship following HNC.

(QoL) for HNC patients is a crucial field in which interest has developed in the last two decades and there is now a considerable body of information available to clinical teams concerning QoL outcomes. There are several review articles summarizing the issues related to QoL.[5–9]

WHAT IS HRQoL AND HOW IS IT MEASURED?

Quality of life (QoL) is considered as a multidimensional concept. The World Health Organisation (WHO) defines quality of life as an '*individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns*'.[10] QoL is present in both the positive and negative aspects of different life domains. There are different theoretical models to help explain how QoL is constructed (**Figure 20.2**).[11, 12] In a simplistic model, cancer and its treatment has a consequence. The detrimental extent of this 'consequence' has a direct bearing on 'quality of life', for example, loss of tongue function after surgery or dry mouth following radiotherapy. How patients respond to that 'consequence' has many influences such as their ability to adapt and cope; however, the perceived consequence will influence the patient's ability to accept the situation. This has a direct bearing on their experienced QoL. Finally, in this theoretical model the patients' sense of cure and control over the cancer will impact on their perception of QoL. Hence, if patients are cured this has a positive impact on their QoL.

Health-related quality of life (HRQoL) is regarded as a subcategory of QoL and its coverage can be categorized into four areas related to physical functioning, psychological functioning, social functioning and symptoms from the disease and treatment.[9] The cross-cultural aspects and wide applicability of HRQoL has resulted in the availability of various validated translation questionnaires. Translations have to be carefully undertaken as it is possible that words or phrases differ between languages and cultures.[13] HRQoL is not usually considered to include expected acute toxicity.

HRQoL should not be limited to an outcome in research, but should make a vital contribution in the treatment and management careplan involving both patients and healthcare professionals.[8] HRQoL has a major role in treatment decisions in several but not all situations. For example, when different treatments have a good chance of cure, HRQoL will influence decison-making. The priority given to the best chance of cure often outweighs HRQoL outcomes for indiviual patients, treatment protocols and trial designs. Patients set cure and survival as priority and there is individual patient variability related to the side effects of treatment.[14–17] Another area where HRQoL has an important role is when treatments have equivalent survival outcome but the HRQoL outcomes are different. There might be a trade off with the degree of dry mouth, trismus, pain and swallowing difficulties depending on the modality of treatment used. Also, when the cancer treatment is very unlikely to be curative or the intention of treatment is palliative, there is a strong focus on treatments that maintain HRQoL for the remaining time available. Finally, some treatments result in such a poor HRQoL that even if cure is possible, the adverse impact on the patient HRQoL is too great to consider such treatment. Studies show that long-term survivors of advanced HNC accept major surgical procedures, with over 90% of 273 patients stating that 'I would undergo the same treatment'.[18] There is also strong agreement between patients, their companions and members of the multidisciplinary team (MDT) with regards to priorities in HNC outcomes and low post-treatment regret for patients and their companions. These results suggest that the patients' companions and members of the MDT are able to exercise good judgement when it comes to supporting patients in decision-making.[17] In spite of the enormity of the diagnosis and treatment, relatively few patients feel that they regret treatment. This, of course, may not reflect the reality of the personal experience that can be hidden from the healthcare profession.

HRQoL is usually measured by a patient's self-completed questionnaire. Questionnaires can be complemented by objective measures such as swallowing, speech and shoulder movments. There is no gold standard questionnaire that is best.[7, 19] The choice of questionnaire will depend on the context in which it is being used, based on the hypothesis being tested, such as general cancer issues (pain, depression), HNC-specific items (shoulder, appearance) or function-specific assessment (xerostomia, swallowing, speech).[20] **Table 20.1** gives common examples of the different questionnaires by group. The choice of questionnaire will be influenced by whether they are used in audit or research. The British Association of Head and Neck Oncologists and the British Association of Otorhinolaryngologists Head Neck Surgeons both recommend that HRQoL should be longitudinally recorded. Questionnaires are one of the ways to measure HRQoL and give a structured insight into the patients' point of view.[21] The most commonly used questionnaires[22] are the European Organization for Research and Treatment for Cancer (EORTC),[23] and the University of Washington quality of life (UW-QoL).[24]

TREATMENT DECISIONS AND OUTCOMES IN THE CONTEXT OF HRQoL AND SURVIVORSHIP

The epidemiology of HNC in the UK is changing. The oral cavity is now the most common subsite and there has been a 51% rise in human papillomavirus (HPV)-related oropharyngeal cancers between 1989 and 2006[25] (The HPV-related cancers appear to affect younger people and may respond better to chemoradiotherapy with or without surgery.[25, 26] Organ-preserving therapies are favoured for laryngeal cancer.[27] The choice of treatments available is also changing. These choices are informed by recommendations made in MDTs and following discussion with patients.[28] It is desirable that treatment decision-making should be shared between patients and doctors.[29] Shared decisions involve the doctor learning about the patient, in particular the extent of their understanding, their circumstances and ultimately their wishes, and the patient learning from the doctor about the nature of the treatment and the prognosis.[30, 31] The patient may have to make a decision early in their treatment path which could have important implications for their HRQoL.[32] Shared decision-making improves patients' satisfaction with the consultation, leading to better quality of life.[33–35] Related to shared decision-making is the process of informed consent where an autonomous person has understanding of the treatment and intentionally authorizes the proposed action.[36–38] The view of what a 'reasonable patient' might expect outweighs standards being set from a 'reasonable doctor's view point'.[39] The exchange of information underpins both informed consent and shared decision-making, and there is evidence that patients want detailed information on the effect treatment will have on survival and quality of life.[40] QoL may include specific issues such as the effect on speech and swallowing as well as general issues including pain, fatigue and anxiety.[15, 41, 42] Information needs to be defined by the individual patient and not by the diagnosis or treatment.[36–38, 43, 44] Too much information can result in reduced recall and anxiety, too little information and it is unlikely that patients will be able to reach understanding.[31] Healthcare professionals need to disclose a core set of information about a treatment.[43] The development of a core information set for informed consent will improve the effectiveness of these processes for both patients and doctors.

As with 'Core Disclosure Sets', there is an increasing need for the development of 'Core Outcome Sets' to

enable standardization of outcome reporting in clinical trials. These would define a minimum set of outcomes that should be measured in clinical trials for any given condition. The purpose of core outcome sets is to improve the quality of research by emphasizing the importance of including relevant stakeholders, especially patients, in decisions about which outcomes should be measured and reported and reducing reporting bias by clear definition of outcomes.[45] Outcomes used in clinical trials of head and neck HNC frequently focus on objective measures of function and survival outcomes, but little is known about which outcomes are important from the patients' and carers' perspective.[44] Prognosis research in cancer often fails to report suffering from symptoms, functional status and QoL. Mortality may not be the most important outcome to the patient, nor is it necessarily a good proxy for other outcomes. A range of outcome predictors should be considered: the social and healthcare environment, psychosocial factors and health behaviours as well as biological factors.[46]

HRQoL AND SURVIVORSHIP

The MDT need to be aware that some patients will tend to report a much worse HRQoL. These patients might be helped by additional support through treatment and into survivorship. The types of patients most at risk of poor HRQoL outcome are given in **Table 20.2**.[8,47] Poor HRQoL has been identified as an independent predictor of survival[48–50] but this association may be influenced by various cancer-related, personal, biological, psycho-behavioural, physical, lifestyle-related and social factors.[51]

The main inflences of HRQoL are site, stage and treatment.[5–9, 52] There are much smaller differences by age and gender and these tend to be item-specific such as appearance. Older patients cope remarkably well[53, 54] and with careful selection and support, their expectations are less than younger patients and they can adapt remarkably well to the deficits after cancer therapy. Younger patients can experience more negative impacts related to family, employment, finance, and the the gap between the reality of what they have as a consequence of the cancer and the hopes and expectations for their lives. However, patients' ability to adapt and cope cannot be underestimated.[55]

TABLE 20.2 Common factors associated with worse HRQoL outcomes

Alcoholism: Pre exiting comorbidity and poor coping mechansim
Age: Young patients have much more to lose in terms of life expectation, finance.
Combined treatments: Surgery and radiotherapy, Chemoradiotherapy
Deprivation: Lower socio-economic background
Personality: Negative, nihilistic
Pre-existing distress: Anxiety related conditions, mental health
Single: Lack of support
Site: Oropharynx and hypopharynx
Stage: Advanced disease
Unknown: What clinical experience gives clinicians

SITE

Thyroid

A better understanding of HRQoL following thyroid cancer has developed over recent years and thyroid cancer-specific questionnaires are now available.[56] Awareness of these specific determinants of HRQoL could help healthcare practitioners to provide better supportive care. Long-term thyroid cancer survivors experience more symptoms and deteriorated HRQoL compared to the normative population. Thyroid cancer-specific neuromuscular, sympathetic, concentration and psychological symptoms are stronger associated with HRQoL than clinical and sociodemographic factors alone.[57]

Surgical, radiotherapy and hormonal aspects have been considered.[58–61]

Oral cavity

In most institutions, oral cancer tends to be treated by primary surgery. Conventional surgery with or without adjuvant treatment gives better HRQoL across most domains compared to chemoradiotherapy for oral cavity squamous cell carcinoma[62] including those issues considered most important to patients: chewing, swallowing, saliva and speech.

The HRQoL is better in patients treated with laser excision or primary closure compared to free tissue transfer reconstruction.[63] However, the extent of tumour ablation and the need for reconstruction will depend on the stage of disease. Reconstruction of the tongue and floor of mouth using local methods can provide good function outcomes and shorten operating time, and surgical morbidity.[64] There are a variety of soft tissue free flaps for reconstruction and the choice of flap has relatively little influence on most HRQoL domains. There will be differences in donor site morbidity.[65] For example, with mandibular resection, the need for adjuvant radiotherapy is a more important influence on HRQoL rather than whether a segmental or rim resection is performed or a composite free flap is used.[66] The survival advantage needs to be balanced against increased treatment toxicity. Post-operative radiotherapy (PORT) can be associated with reduced global health status, increased xerostomia and marginally increased levels of fatigue at 6 months post treatment for oral cavity cancer.[67] Adjuvant radiotherapy has a significant effect on HRQoL mainly because of dry mouth.[68] The patients' ability to cope with oral cancer is remarkable; the HRQoL in people who survive more than 5 years, when assessed with the SF-36 questionnaire was similar to those of the general population, even exceeding these reference values in some dimensions.[69]

Maxilla

Debate continues around the importance of obturation or free tissue transfer on HRQoL for the maxillectomy defect.[70] Obturator prosthesis is a highly positive and non-invasive approach to improve the quality of life of patients with maxillectomy defects.

There is an element of patient preference, however, with the large complex resections (palate, maxilla, sinuses, orbital content) HRQoL outcome is arguably better with microvascular reconstuction.[71] It is likely that edentulous obturated patients have worse outcomes than dentate patients, and although the size of the maxillectomy defect might have relatively little bearing, adjuvant radiotherapy results in worse mouth opening and self-reported oral and swallowing problems.[72]

Oropharynx

The oropharynx site brings into focus the debate around organ 'preservation' (non-surgical treatments) and surgery combined often with radiotherapy.[73] The stage[74] and treatment[75, 76] are key determinants of HRQoL outcomes. There is some evidence that there is a tendency for improved HRQoL among patients with oropharyngeal carcinoma treated surgically compared to advanced stages of disease managed with primary chemoradiotherapy.[77] There has been considerable interest in HRQoL as treatment affects aspects of social function for the patients such as speech and swallowing. There have been different treatments advocated such as transoral laser surgery, transoral robotic surgery with risk stratified adjuvant radiation or chemoradiotherapy. With radiotherapy, there is a body of evidence developing in support of intensity-modulated radiotherapy (IMRT). The association with HPV has raised the possibility of treatment de-escalation with better HRQoL and equivalent survival. T stage, tumour involvement of the tongue base, professional status and emotional and social functions can be considered as the main determinants of HRQoL,[78] while HPV status itself is not a main determinant.[79] Early disease can be treated with high long-term HRQoL by surgery alone. Primary surgery with PORT in selected patients with limited primary tumours and advanced neck disease renders excellent HRQoL. IMRT is superior to former radiation techniques with regard to HRQoL, and should be considered as standard of care in patients undergoing RT for oropharyngeal squamous cell carcinoma (SCC).[79] Further efforts to reduce swallowing dysfunction are likely to yield additional gains in HRQoL.[80]

Larynx

The outcomes of patients with early stage glottic cancer report significantly better HRQoL and function specific patient-reported outcome measures (PROMs) than those with more advanced stage disease. When attempting to make comparison between voice handicap and QoL after radiotherapy versus endoscopic laser resection (ELR) for T1a-glottic carcinoma, results should be interpreted in light of the biases inherent in retrospective studies. There is little difference with T1-laryngeal disease treated with ELR and radiotherapy.[81] Laoufi et al.[82] concluded that long-term subjective voice-related quality of life was worse after ELR, with no difference in other domains and larger T2 tumours might have better speech outcome with primary radiotherapy. However, T2 tumours, in particular T2b, and continuing smoking after radiotherapy correlated significantly with poor local control and worse voice handicap index.[83]

Partial laryngectomy procedures such as vertical or horizontal partial laryngectomies, have a role in attempting to optimize function and hence HRQoL. Modified supracricoid laryngectomy seems to improve quality of voice and QoL in patients with early laryngeal cancer.[84] The HRQoL benefits for extended vertical hemilaryngectomy and reconstruction with a neovascularized tracheal autograft for advanced unilateral laryngeal tumours need further evaluation.[85]

TOTAL LARYNGECTOMY

Following laryngectomy, areas that tend not to recover to baseline level are physical functioning, role functioning, social functioning, fatigue, dyspnoea, appetite loss, financial difficulties, senses, speech and social contact. Rather than age, sex, education and tumour site predicting HRQoL outcome, it is tumour stage, recurrent disease, radiotherapy and mental health.[86] Patients can be more accepting of, and find less troublesome, anticipated sensory impairments, cough and dyspnoea, than more general side effects such as constipation and nausea/vomiting.[87] Despite common belief, many patients who have undergone total laryngectomy (TL) maintain a good overall QoL.[88] There are potential difficulties in returning to work after TL. Influencing factors include age < 50 years, being self-employed or a clerical employee, good physical functioning, good speech intelligibility, high motivation to go back to work, and support from colleagues.[89] There is evidence around the impact on HRQoL and primary and secondary tracheo-oesophageal puncture (TEP).[90] Primary TEP provides almost immediate and satisfactory voice rehabilitation. Chemoradiotherapy and patient age do not seem to affect voice quality with either procedure.[91]

Comparison between TL and concurrent chemoradiation for function and long-term QoL outcomes in pharyngolaryngeal carcinoma patients shows no significant difference concerning feeding-tube, oral supplements and respiratory related HRQoL items. Differences are encountered in aspects such as smell and taste (surgical) and with dry mouth and weight loss (with chemoradiation).[92]

Skull base

There is a relative lack of HRQoL outcome data related to skull-base cancer. The development of an Anterior Skull Base Surgery Questionnaire (ASBS-Q) has improved our understanding of the PROM following skull-base cancer.[93] The overall QoL of patients

following endoscopic extirpation of skull-base tumours is good. Endoscopic skull-base surgery is considered a minimally invasive surgical modality with less morbidity and patient discomfort. It appears that endoscopic approaches are not associated with a detrimental long-term effect on sinonasal-related QoL. Short-term impairments of sinonasal-related QoL are predictable and self-limited.[94] Comparison of the impact of the open and endoscopic skull-base surgery on HRQoL revealed that patients who have endoscopic surgery reported significantly better scores in the physical function and impact on emotion domains than the patients who have open subcranial surgery.[95]

STAGE

Stage of disease is consistently one of the main influencing factors for HRQoL outcomes.[5, 9] Stage is related to the extent of the cancer, radicality of treatment, and associated functional deficits. The clinically meaningful significant differences in HRQoL between early stage and late stage HNC is reflected in most papers on this subject. The implication of this finding is that promoting early cancer presentation would make a significant difference not only on survival (patients' first priority) but also HRQoL.

TREATMENT

In general, single modality treatment, radiotherapy or surgery alone, confers much better HRQoL.[96] Transoral robotic surgery might be a way of preserving functional anatomy without compromising surgical resection margins and could have a positive impact on HRQoL,[97, 98] The advantage of less invasive surgery on HRQoL (e.g. transoral resection versus open resection and free-flap reconstruction[63] or rim mandibulectomy versus segmental resection)[66] is lost if primary surgery has to be followed by adjuvant radiotherapy. Avoiding radiotherapy after primary surgery has substantial benefits for patients in terms of HRQoL as long as optimal survival is maintained.[68, 99] There is evidence that reducing the dosage of radiotherapy can make a substantial difference.[100] In addition, IMRT has much better HRQoL outcomes compared to 3D-conformal radiotherapy (3D-CRT).[101]

Outcomes for overall HRQoL are similar for surgery with reconstruction compared to radical radiotherapy,[102] and for radical surgery and radiotherapy compared to chemoradiotherapy. There are functional differences in these comparisons such as greater impairment of speech and shoulder function after surgery whereas after chemoradiation, patients suffer from greater pain, xerostomia, difficulty swallowing and problems chewing.[103] Although the short-term side effects of treatment may differ between the groups, long-term QoL is remarkably similar whether the patients choose primary chemoradiation or surgery with post-operative radiation.[104, 105] Global QoL scores might be associated with slightly better functional outcome with surgery, and from the perspective of functional outcomes, either surgery or chemoradiation seem appropriate treatments for advanced HNC[106] but better long-term HRQoL scores are seen in patients undergoing concurrent chemoradiation.[107] Osteoradionecrosis (ORN) of the mandible is a severe complication of radiation therapy and has a detrimental impact on HRQoL. Surgery for ORN can result in an improved HRQoL; however, lack of improvement, despite the restoration of an intact mandible, relates to the persistent effects of chemoradiotherapy.[108, 109]

Treatment intent

To date there is a relative paucity of information concerning HRQoL in patients treated with palliative intent and further clinical outcomes research is needed.[110, 111] The published studies have tended to be qualitative in design due in part to the absence of a suitable HRQoL questionnaire specific to palliative care in HNC.[112]

Clinical trials

In the literature the evidence base concerning HRQoL is limited in respect to clinical trials. HRQoL questionnaires are a component of a clinical trial often included as a secondary outcome, and not explicitly driven by hypothesis.[113, 114] In the future there will be an increasing number of trials and interventions specifically aimed at evaluating HRQoL differences such as a study to assess the effect of low-level laser therapy on PROMs of oral mucositis and QoL in HNC patients receiving chemoradiotherapy.[115] IMRT will continue to be the subject of trials' research for the foreseable future until it becomes a standard of care (see 'Xerostomia below').

HRQoL ISSUES

There is a diverse range of patient and carer needs and concerns after completion of HNC treatment.[106, 116, 117] The variety of HRQoL issues are reflected in **Table 20.3** and will be mentioned individually below. Issues include pain, skin reactions, mucositis, nutritional status, swallowing, voice and speech, hyposalivation and xerostomia, dental health, trismus, shoulder and tissue fibrosis, sleep, fatigue, anxiety and depression, body image and social isolation, taste and smell, cognitive function and work status. However, the most frequent issue that patients wish to talk about is fear of recurrence (FoR).[116, 118–124]

Carer support

The benefit of carer support is a key issue in terms of patients' HRQoL. The use of support services differs over time. During the treatment phase and in the early period following interventions, there is a need for a wide range of supportive care expertise, including dental hygienists, physical therapists, specialist dietician and speech

TABLE 20.3 The vast array of different aspects to HRQoL following HNC

Alphabetical list
Carer: positive carer support
Coping: social support seeking good, avoidance bad
Dental status: eating- social interaction-coping
Disfigurement: appearance, body image, intimacy
Emotion: anxiety pre-treatment, depression is treatable, mood
Fatigue: common in year 1, poor sleep, low energy
FoR: does not lessen over time
Financial / work: employment, benefits, retirement
Information: various amounts, in various ways, at various times
Nutrition: low weight, diet, PEG feeding
Oral rehabilitation: chewing / eating – expectations + trade-off
Pain: need for opiates, poor sleep, depression
Personality: optimism and HRQoL + survival, high neuroticism
Self-esteem: low self-esteem associated with poor QoL
Sociodemographic: children, social support, ethanol abuse,
Speech: laryngeal speech / isolation
Swallowing: presence of feeding tube most significant
Shoulder: shoulder discomfort and neck tightness – selective
Trismus: poor difficulty in mouth opening – diet/social/intimacy
Xerostomia: profound impact on social function, IMRT
Unknown: clinical art of the individual not a precise science

therapists; long-term supportive care is more focused on aspects such as dental hygiene, speech therapy and physical therapy. Patients pecieved HRQoL deficits will influence their need for supportive care services.[125] Increased social isolation may be a risk factor for poorer physical recovery from, or adjustment to, treatment-related side effects. Social support may be an important target for psychosocial interventions for patients who face challenging treatment side effects.[126] Patients might view themselves as not being a burden to their carers but there is evidence emerging as to the demanding role placed on carers and family.[127] Carers see the patients as they are 'day-to-day' and not just at the review clinic episode. They are often more able to identify needs than the patient themselves recognize.[128] There are potentially many unmet supportive care needs and changes to the needs before and after treatment.[129, 130] Family caregivers report significant stress and needs themselves,[131] and the need for more information and healthcare services support. There is merit in devloping a tool to identify carer needs and caregiving training programs.[132]

Coping

The types of coping strategies patients adopt are important in terms of HRQoL recovery and adaptation.[133–135] Negative coping strategies need to be avoided as they are associated with poorer psychological state (higher incidence of depression, anxiety or low mood) and a reduced HRQoL. Post-laryngectomy avoidant coping strategies (both cognitive and behavioural escape) were among the strongest predictors of poor HRQoL.[136] To enable patients to implement positive coping strategies such as fighting spirit, coping with emotions and benefit finding is important.[137] Coping is part of a complex psychological construct linking QoL, coping styles, optimism and anxiety and depression.[138] Self-efficacy is also shown to positively influence social distress. Formal or informal support for HNC patients on how to cope effectively with disease can increase their resilience and perhaps reduce their reliance on a support network.

Dental status

Chewing and eating are part of social interaction. The significance of dental function cannot be underestimated with patients reporting chewing and eating being one of the most common issues they wish to discuss in clinics irrespective of the site (larynx, oropharynx, oral) or stage (early, advanced) of cancer.[122] The value of oral rehabilitation is not just in chewing, but also in self-esteem and well-being.[139] Oral rehabilitation is discussed in detail below.

Deprivation

Deprivation influences the incidence and outcome of patients with HNC. The more deprived the background of the patient, the worse the HRQoL outcome.[140] The relationship between deprivational and HRQoL is complex and is influenced by social support, lifestyle, comorbidity and coping strategies.

Disfigurement

Disfigurement embraces concepts such as appearance, body image and intimacy. It can be associated with shame and stigma[141] and social and emotional distress.[142, 143] The issue of body image disturbance has been addressed in a review by Rhoten et al.[144] There is a need to screen for appearance problems so that suitable advice and interventions can be offered.[145]

Emotion

The emotional impact of being diagnosed and treated for cancer cannot be underestimated, and certainly not least in HNC.[146]

There is a range of emotional distress syndromes but the main two components are anxiety and depression.[147–149] Anxiety is highest pre-treatment compared to depression, whilst depressive symptoms peak at the end of treatment and persist into survivorship for a proportion of patients.[150–152] Poorer survival has been associated with anxiety, depression, and worse HRQoL.[153] It is possible to screen for anxiety and depression in routine clinics[154, 155] and then to access a variety of interventions.[156, 157]

Fatigue

Fatigue, poor sleep and low energy are well-recognized symptoms during and following treatment, particularly in the first year. Depression and fatigue symptoms correlate negatively with HRQoL.[158] Fatigue-related items are common to several head and neck questionnaires but recently a Modified Brief Fatigue Inventory has been developed to measure intensity and frequency of fatigue specifically in HNC patients.[159] Comorbidity, cancer stage and adjuvant radiotherapy were associated factors. The excess fatigue reported in the IMRT cohort may, at least in part, be attributed to the dose distribution to the posterior fossa, cerebellum and brainstem.[160] Post-treatment hypothyroidism or subclinical hyperthyroidism induced by levothyroxine is associated with alterations in the HRQoL, reduction in the muscle function of upper limbs, and higher degree of fatigue.[59] The benefit of exercise is still to be defined in HNC, whereas it might be of benefit in other cancer sites.[161]

Fear of recurrence

FoR following treatment is common and significantly influences HRQoL.[116, 162] FoR is a major patient concern but is infrequently discussed in outpatient settings and may cause significant detrimental effect on the patient's psychological well-being.[118] Some patients experience intermittent and consistent levels of significant FoR, which do not improve with time and it is difficult to predict those based on clinical characterists.[163] There is merit in screening as this can lead to both informal and formal interventions.[164, 165]

Finance

Financial, work, employment benefits and retirement are factors in HRQoL for this patient group. For some, the cancer can be a time of positive readjustment moving to a slightly earlier retirement that planned. However, for those employed and with financial commitments the treatment and aftermath of cancer can be a substantial cause for concern and stress. Return to work is influenced by the type of job with 'white collar workers' such as professional, managerial, or administrative more likely to return than 'blue collar workers' (BCWs) for example involved in skilled or unskilled manufacturing. Considerably more severe impairments were reported in the self-administered questionnaires for BCWs and a poorer HRQoL.[166] Singer et al.[167] report that only a few laryngectomees return to work and they stress that return to work is important for many patients. Patient consultations should consider possibilities to support vocational rehabilitation before offering to apply for retirement. Survivors who perceived greater negative consequences of their cancer and worse physical functioning took longer to return.[168] In a study by Rogers et al,[169] 57% had suffered financially since diagnosis and QoL had decreased in 53% as a result of the financial impact of the disease. This was most common in the unemployed (64%), and in those whose work was affected by cancer (83%). Two-thirds had applied for benefits after diagnosis. Patients with worse physical and emotional functioning experienced more notable financial burden, more difficult life circumstances in the past month, greater financial difficulty and loss of income due to their condition in the previous week, more dissatisfaction with how well they took care of their own financial needs and were more likely to have sought statutory benefits.[170]

Gastrostomy

Although gastrostomy tube and swallowing, nutrition and function are covered in other parts of this chapter, this deserves individual mention because of the significant association with HRQoL.[171, 172, 173] Clinical stage, tumour site, patient age and nutritional parameters are all associated with the gastrostomy tube placement.[173] Patients with gastrostomies reported multiple deficits in HRQoL and a much poorer QoL. The presence of a feeding tube interferes with family life, intimate relationships, social activities and hobbies, in additon to the practical considerations of local discomfort, leakage or blockage. Permanent gastrostomy is a suitable surrogate indicator for HRQoL outcome.

Information

Patient and their carers need differing amounts of information, delivered in various ways, and at various times. Anxiety and supportive care needs are paramount during the diagnostic phase of the cancer journey.[174, 175] Anxiety and unmet needs are highest in those patients who experience a delay in diagnosis, treatment commencement, poor information and lack of psychological support.[175] Information provision needs to be tailored and include material about illness, treatment, side effects, function, physical fitness, impact on functioning, duration of recovery time, impact on QoL, support groups, where to go for financial advice and the long-term effects of treatment on ability to work.[41, 176] The internet has an important role for patients in providing information and support about their cancer, although other sources are still very important especially in the elderly and those early school leavers.[177]

Intimacy

Problems with sexuality and intimacy in HNC are under reported and have a detrimental imapct on HRQoL. Around one-third of those willing to answer intimacy and sexuality questions report substantial problems with sexual interest and enjoyment, and one-quarter problems with intimacy. The problem is particularly common in the under 55-year old age group.[178] The issue is complex and involved concepts such as 'personal identity', 're-establishing social networks' and 'intimate relationships', and is related to patients' perceived changes to self-esteem and image.[179] There is scope for intervention and pscho-sexual counselling but the concern is difficult to identify in clinical practice as discussion of this tends to be taboo.[180]

Nutrition

Malnutrition is common among HNC patients and negatively impacts on survival and QoL.[181] Unintended weight loss of more than 10% seems to be the most reasonable definition of malnutrition. More than 10% weight loss during and directly after radiotherapy has a significant impact on social eating, social contact, and HRQoL.[182] Chemotherapy and low body mass index at diagnosis are strong predictors of malnutrition.[183] Individualized dietary counselling on nutritional status is beneficial, compared to no counselling or standard nutritional advice and makes a positive impact on HRQoL. The effects of oral nutritonal supplements and tube feeding seem inconsistent in the literature.[184] Nutritional advice is still necessary years after chemoradiation.[185] Novel ways to encourage appetite should be considered.[186.]

Oral rehabilitation

Oral rehabilitation is a basic consideration for all HNC patients due to the importance that chewing, teeth and oral function have on HRQoL and well-being.[121, 139] Oral function influences swallowing, appearance, chewing, trismus, drooling and food clearance.[187] Oral rehabilation improves masticatory efficiency and this impacts positively on both food choice and social life. Consumption of solid, semisolid and overcooked food can be considerably better with the prosthesis.[188] After rehabilitation there is less worry about maxillary prostheses falling out, less embarrassment while conversing, less worry about losing self-confidence from embarrassment caused by dentures and fewer drooling problems.[189] The positive treatment outcome of oral rehabilation is not always predictable as some local effects following soft-tissue resection or radiotherapy cannot be significantly improved by prosthetic rehabilitation leading to functional and emotional disability.[190]

Pain

Pain is a major factor that influences a patient's QoL in relation to HNC. It is a common item in most HRQoL questionnaires.[7] Pain levels relate to HRQoL, the need for opiates, poor sleep and depression.[191] Different questionnaires are used to measure the extent and intensity of pain; however, further research needs to be undertaken to create a better objective, validated pain-related questionnaires.[192] Screening for pain in clinic can allow for intervention and when necessary, onward referral to a specialist pain team.[193]

Personality

Personality, ways of coping, mood and distress all have a bearing upon HRQoL. High neuroticism, avoidance focused coping, drinking to cope and high alcohol consumption are associated with worse distress.[135, 194, 195] Moreover, personality types and coping choices can correlate to survival.[196] The link between HRQoL and coping means that clinicians should be aware of the various positive and negative coping strategies and enlist the help of a clinical or health psychologist.[197]

Self-esteem

Low levels of self-esteem are linked to poor HRQoL and are influenced by issues such as shame and stigma,[141] oral function,[139] intimacy,[179] disfigurement,[142] support needs and family.[132] There are significant differences in anxiety and depression between those patients who have high self-esteem compared to those with low self-esteem. Ideally, patients with low self-esteem need pre-treatment and ongoing intervention.[198] The evidence relating to psychosocial interventions is considered later in this chapter.[157]

Sociodemographics

In a study by Rodriguez et al,[199] the most important contributor of overall HRQoL for people recently diagnosed with advanced cancer was social support. It was followed by general health perceptions, energy, social function, psychological function and physical function. In another study, patients with more support reported less anxiety and depression and better HRQoL in the mental health domain, independent of demographic and medical variables.[200] The degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate healthcare decisions (health literacy) is important. Beitler et al.[201] found that patients who underwent TL had a high chance of being lost to follow-up as well as having inadequate healthcare literacy. When assessing the impact of treatment in respect to HRQoL outcomes it is essential to consider the individual, his or her background and their context for the cancer and survivorship.

Shoulder

The morbidity associated with radical neck dissections and the impact of shoulder dysfunction and pain is well recognized.[202, 203] Where possible selective neck dissections should be performed as the function and HRQoL is much better.[204] There is little subjective morbidity associated with shoulder dysfunction after a unilateral 3 or 4 level neck dissection compared with patients undergoing primary surgery without a neck dissection.[205] Also following selective dissection, patients usually rate poor shoulder function of less importance than other items such as swallowing, speech, dry mouth, chewing and appearance.[206] If level IIb can be safely spared there is some evidence that the accessory nerve function is better.[207] Identifcation of a 'sentinel node' offers potentially the least morbid approach and early reports show HRQoL benefit, for example, less appearance dysfunction related to marginal mandibular nerve weakness and scarring.[208, 209]

Speech and voice

Speech is one of the main HRQoL issues following HNC[121] as it impacts on social function,[210] and contributes to isolation.[5] Radical treatment can have a significant impact on speech, voice and communication outcomes. The assessment is complex and lends itself to specific questionnaires.[211–215] Voice and speech impairment are prevalent;[216] for instance, over two-thirds of surviving oropharyngeal cancer patients will have speech impairment. The main clinical correlates associated with adverse patient and observer-rated speech and voice outcomes are tumour stage, combined treatment (surgery and radiotherapy) and free-flap reconstruction.[217] Local flaps (pharyngeal flap) can improve function and HRQoL in more than half soft-palate resections.[218] Following endoscopic resection or radiotherapy for early glottic cancer HRQoL and voice appear similar despite the two different treatments,[219] and based on functional outcome, patients can have a choice of treatment for early glottic cancer.[220] Voice restoration following TL is an important part of patients' rehabilitation and long-term QoL. Primary TEP provides almost immediate and satisfactory voice rehabilitation. However, it may not be ideal in all clinical scenarios and secondary TEP may be needed. Chemoradiotherapy and patient age do not affect voice quality with either procedure.[91] Voice-related quality of life (V-RQoL) outcomes for patients using tracheo-oesophageal speech had similar V-RQoL outcomes compared to oesophageal speech (ES), and both performed significantly better than electrolaryngeal speech (ELS). For ELS, the total V-RQoL score was better with longer time after surgery and older age.[221]

Swallowing

The importance of swallowing in HRQoL outcomes cannot be underestimated. In this chapter there is only space for a cursory summary of key concepts. The link between nutrition, social function and carers is important and there is the association of permanent gastrostomy with poor HRQoL.[171, 222] It is essential that patients and caregivers attend pre-treatment clinics to discuss nutritional support via the artificial route; their QoL can be enhanced if guided through a specialist support pathway based at the clinical site where they initiated their care, with links to key agencies.[223] Prophylactic gastrostomy insertion can be associated with significantly earlier start and longer use of enteral nutrition, fewer malnourished patients over time, and improved HRQoL at 6 months after start of treatment but there has to be a drive to assist the patient to achieve an adequate swallow to allow the feeding tube to be removed wherever possible.[224] Advanced T-stage, free-flap reconstruction, younger age and base of tongue tumours have a negative impact on post-treatment swallow function and related HRQoL in these patients.[100, 225–228] Swallowing dysfunction following chemoradiation is a major cause of morbidity and reduced HRQoL related to early and late toxicity.[229] More clinical outcomes research is a priority in this area through prospective and randomized studies, robust cohort studies comparing types of feeding and treatment, and interventions.[230, 231] Screening in clinic allows the opportunity for patients and carer support.[232] For more detailed assessment, questionnaires should be accompanied by objective measures and there can be differences between the two evaluations.[232] Long-term dysphagia is influenced by mean radiation doses to the constrictor muscles and there is potential advantage in reducing the RT dose to swallowing structures to avoid severe dysphagia.[233–235]

Taste

Alteration of taste (dysgeusia) is a relatively common complication of head and neck radiotherapy and has a detrimental effect on HRQoL.[236, 237] Taste alteration can influence patients' enjoyment and choice of foods[238] and their dietary energy intake.[239] Consumption of sugary foods (cariogenic) places dentate patients at risk of radiation related caries.[240]

Trismus

Trismus (limited mouth opening) is a common symptom and the incidence is in the region of one-tenth at presentation, one-third at 6 months and one-quarter at 1 year after treatment.[241] The incidence can be higher depending on the criteria used to define trismus.[242, 243] Trismus severely impairs HRQoL through issues such as pain, eating, chewing, taste, saliva, social functioning, social contact and dry mouth.[241–243] Structured exercise with jaw mobilizing devices can improve mouth opening on trismus and have a positive effect on trismus symptomatology and HRQoL.[244]

Xerostomia

As previously mentioned, the severity of of xerostomia correlates with oral discomfort, difficulty chewing/swallowing/speaking, altered taste and low mood.[245] Sticky saliva and profund dryness at night can be major issues.[246] Prevention is better than measures aimed at symptom control; hence there have been technological advances in the delivery of radiotherapy and this has led to less salivary gland hypofunction with sparing of the partoid glands and a potential improvement in HRQoL.[247, 248] IMRT is a technique that allows delivery of lower doses of radiation to normal tissue, while maintaining or increasing the tumour dose, compared with two-dimensional radiotherapy (2DRT) or 3D-CRT. Patients treated with IMRT experience statistically significant improvements in several important HRQoL domains.[249] IMRT had significantly better outcome in various scales such as global QoL, physical functioning, swallowing, senses (taste/smell), speech, social eating, social contact, teeth, opening mouth, dry mouth, sticky saliva and feeling ill.[101, 250] Adaptive head and neck radiotherapy (ART) is a new concept in which there is dose avoidance to anatomical structures. A timed

replan can achieve dosimetric improvement and needs further outcomes research.[251]

Unknown

In spite of the many issues impacting on HRQoL reflected in this chapter, there is still a lot we do not know. HRQoL is a clinical art of the individual and not a precise science. The patient response is not all negative and it is possible, from their experience, to get a different perspective and have a profound influence on the person's QoL.[252] Survivors benefited from support and understanding offered by family, friends and healthcare professionals. This difficult situation can serve as a catalyst for deeper human change. In spite of the major changes such as following laryngectomy, the support of family, friends and healthcare professionals can encourage a successful transition to recovery.[253]

HRQoL IN FOLLOW-UP

Routine assessment

It is very important to adopt a holistic approach to patients' care throughout their follow-up. Patients can report distress at differing time points. Distress negatively impacts on HRQoL.[254] HRQoL screening may permit early identification of problems that influence HRQoL outcomes and may also facilitate timely intervention.[255] HRQoL questionnaires are limited for holistic assessment in routine clinic.[193] Consequently, some of the patients' concerns will be under-recognized and this will lead to unmet needs, poor communication, delayed recovery, further distress and dissatisfaction. The Patient Concerns Inventory (PCI) has been developed to help patients raise issues in their consultation that would otherwise be missed and also to request the opportunity to see or be referred on to other members of the MDT.[256] Despite the PCI comprising of 57 items, it has been shown not to delay the consultation, as there is evidence that both the clinician and the patient focus on what they wish to say in the consultation more efficiently.[257, 258] As an indicator of quality of care and helping to reflect the patients' experiences, the PCI has been included in the national HNC mandatory audit (DAHNO).[259] Advances in information technology and patients' familiarity with computers and the internet will in the future allow for a much more integrated approach to HRQoL assessment and intervention.[260, 261]

Interventions

As our understanding of the HRQoL outcomes of patients has increased in recent decades this has led to a focus on intervention. There are many different interventions reflecting the scope of HRQoL in the post-treatment patient. Semple et al.[157] published a review of psychosocial interventions. Evidence for interventions is limited by the small number of studies, methodological problems and poor comparability. Future interventions should target HNC patients who screen positive for clinical distress and be integrated into standard care.[156] Certain groups of patients might be more suitable for targeted interventions, such as those having chemoradiotherapy, where the HRQoL outcomes are worse.[262] A nurse-led intervention around the time of discharge from hospital, based on informational needs, has potential benefits to HRQoL and satisfaction.[263] Early provision of psychotherapy might reduce post-traumatic stress disorder, anxiety and depressive symptoms, and prevent chronic psychopathology.[264] Interviewing patients to allow them to express their concerns has merit.[265] In the work stemming from the PCI, FoR has been found to be the commonest concern that patients wish to talk about at outpatient consultations.[118] The AFTER (Adjustment to the Fear, Threat or Expectation of Recurrence) intervention has been developed [266, 267] and needs further evaluation. Acupuncture as an intervention has been evaluated. It has been used in the prevention and treatment for radiation-induced xerostomia.[268] When given concurrently with radiotherapy and compared with sham acupuncture it significantly reduced xerostomia symptoms and improved HRQoL.[269] In a randomized crossover study by Simcock et al.[270] eight sessions of weekly group acupuncture compared to group oral care education showed significantly better relief of symptoms in patients suffering from chronic radiation-induced xerostomia. Holistic alternative approaches have also been investigated; examples include intra-oral low-level laser therapy for patients receiving radiotherapy and complementary and integrated therapies (CIT) such as relaxation massage.[271, 272] There is scope for other interventions such as for secondary lymphoedema to help in the management of associated symptom burden, functional loss and psychosocial impact.[273]

Lifestyle

There is a risk associated with continued smoking and alcohol consumption after diagnosis and this affects survival outcomes.[274, 275] Patients with HNC are at considerable risk for other chronic conditions, such as coronary heart disease, causing around one-quarter of deaths. Also, secondary cancers are prevalent.[276] Comorbidity impacts on survival[277, 278] and HRQoL,[279–281] hence it is important to include staging and outcome analysis.[282]

CONCLUSION

HRQoL is now an integral part of the management of the head and neck patients and their carers. In the future, it is likely that enhancements in information technology will allow HRQoL to be routinely integrated into the patient pathway. Also, as our understanding of the patients' perspective of outcome increases, so treatment selection will become more refined and aftercare determined by the needs of the patient.

KEY POINTS

- HRQoL is an essential component when reporting outcomes following head and neck cancer.
- HRQoL is usually measured by questionnaires. The choice of questionnaire is an important consideration and depends on the reason for collecting the patient reported outcomes.
- Many factors impact on HRQoL and relate to the physical/functional, social and emotional consequences of treatments.
- HRQoL questionnaires can be augmented by using prompt lists such as the Patients Concerns Inventory in order to give a more holistic approach to clinical care.
- Advances in computer technology will make a substantial difference in helping to collect HRQoL outcomes and allow this to be use on an individual patient basis for interventions.

THE ROLE AND CHALLENGES IN PROVIDING PALLIATIVE CARE TO HEAD AND NECK CANCER PATIENTS

Head and neck cancer accounts for around 8000 cases per year in England and Wales and up to half of all these patients will die from their illness and will require palliative support.[1] The World Health Organisation (WHO) defines palliative care as being the 'total active care of patients whose disease is not responsive to curative treatment'.[2] The fundamental principle of palliative care is that it should 'offer a support system to help patients live as actively as possible until death and....help the family cope during the patient's illness and in their own bereavement'.[3] The care should be both patient-focused and family-centred and encompass physical, psychological, social and spiritual aspects of care.

With this holistic approach to care and treatment, the overall goal is the achievement of the best quality of life for patients and their families, a parameter recognized to be as important to patients as actual survival and avoidance of recurrence.[4, 5] Patients with head and neck cancer represent a complex group, in part related to the unique properties of the disease itself and the impact the illness and treatments have on different organ systems essential for human functioning e.g. communication, swallowing and breathing.[1, 4] The resulting functional deficit and symptoms that arise can be challenging to treat[6] and can have an impact on the patients' psychological well-being due to resulting social isolation and depression.[4] Additionally, the focus and type of treatment can contribute to the care challenges; those who undergo potentially curative surgery for advanced or recurrent cancer can still have significant morbidity and a limited prognosis and may be considered by some to be palliative.[7] The concept surrounding the terms 'radical' and 'palliative' treatment are challenged when caring for head and neck cancer patients.[8] An ideal palliative treatment is defined as one which provides symptom relief without producing significant morbidity; radiotherapy doses given to induce tumour regression and relieve symptoms are in the range used for cure and can cause painful mucositis and xerostomia; surgical intervention can be accompanied by disfigurement and functional loss.[8] The diagnostic difficulties raise a further challenge; sometimes, due to previous treatments, it can be difficult to obtain histological confirmation of disease recurrence causing uncertainty regarding appropriate referral for palliative care input.

Since the inception of the modern hospice movement by Cicely Saunders in the 1960s, palliative care has expanded.[9] Specialist palliative care units (or hospices) traditionally operated outside the National Health Service (NHS) and were funded by voluntary donations. Since the 1980s however, this situation has been changing with many hospices entering into financial partnerships with the NHS. Palliative Medicine became a recognized speciality in the UK since 1987[10] and increasing numbers of multidisciplinary palliative care support teams have been established within hospitals and the community. Multidisciplinary teams (MDTs) both within hospices and as advisory teams are an integral and key part of specialist

palliative care services and aim to bring together different healthcare professionals with the knowledge and expertise to ensure the appropriate treatment and care is given to each individual patient.[2]

Generally, when assessing the need for palliative care input and support, the decision for referral should be based on need rather than diagnosis, although clear explanations to both the patient and palliative care colleagues may be required regarding roles and responsibilities. Within the last decade, there has been recognition of the need to move palliative care 'upstream' in the disease trajectory and integrate more with curative and rehabilitative therapies rather than the more traditional involvement immediately prior to death (**Figure 21.1**).[9, 11]

Timon and Reilly[13] estimate that approximately 20% of head and neck cancer patients would qualify for palliative care input at the time of initial diagnosis, with an average survival of 5 months within this cohort. Shuman et al[11] suggest the following situations for review regarding the need for palliative care:

- unresectable locoregional disease and/or distant metastasis at initial presentation
- patients with recurrent unresectable locoregional disease and/or distant metastasis after treatment
- patients unable to have anticancer treatments due to disease stage, comorbidity, functional status and/or individual preference.

While this is a useful principle, it may not always be as clear-cut in practice as symptom burden or needs may indicate that palliative care involvement would be beneficial. Many principles of palliative care management are applicable earlier in the course of the illness, often in conjunction with anticancer treatment.[8] Generally, improved patient outcomes can be achieved by a proactive approach with the involvement of palliative care colleagues for advice about symptom control, joint discussion and decision-making and advanced care planning. There is a lack of data, evidence and outcomes regarding the needs and management of end-of-life for patients with head and neck cancer.[6] Further research is needed in this area to guide patient management and improved outcomes.

COMMON PALLIATIVE PROBLEMS IN HEAD AND NECK CANCER

Common symptoms that arise with head and neck cancer patients include pain, dysphagia, fatigue, weight loss and breathing difficulties[6, 14] although many other symptoms and concerns can arise (**Table 21.1**). A retrospective review of 93 terminal head and neck cancer patients showed that patients had a mean number of 4.7 (+/– 2.67) symptoms in the last 6 months of life.[14]

Within this section, an overview will be provided of the following issues: pain, respiratory tract secretion management, communication difficulties, and emergencies including terminal haemorrhage and airway obstruction. For more specific details about other symptoms and specific medications, reference to specialist palliative care textbooks such as the *Oxford Textbook of Palliative Medicine*[18] and the *Palliative Care Formulary*[19] is advised.

Pain

In head and neck cancer patients, pain is a common symptom with studies estimating the prevalence to be between 62% and 99% (**Table 21.1**). Pain can be sub-divided into two main categories:

- Nociceptive pain: arising due to ongoing activation of primary afferent nerves by noxious stimuli (nociceptors)[20]
- Neuropathic pain: due to dysfunction or disease affecting the peripheral and/or central nervous system.[21]

Within clinical practice, there can often be a mixture of both nociceptive and neuropathic pain which can arise either due to the cancer itself (local compression or invasion) or related to previous treatments.

The principles of effective pain management are governed using the WHO pain ladder which remains a useful, practical approach to managing cancer pain (**Figure 21.2**).[22] This step-wise approach advocates the use of non-opioids first-line (e.g. regular paracetamol); then the addition of a weak opioid such as codeine; then proceeding on to substitute the weak opioid for a strong opioid. Generally, the opioid of choice for moderate to severe pain remains morphine.[24]

The concept and understanding of opioid-induced neurotoxicity has become increasingly recognized due to accumulation of opioid metabolites.[25] Clinically, the patient will present with symptoms such as myoclonus, peripheral shadows, hallucinations, confusion and drowsiness. In this situation, the following should be considered:

- Can the current dose of the opioid be reduced (if pain is controlled)?

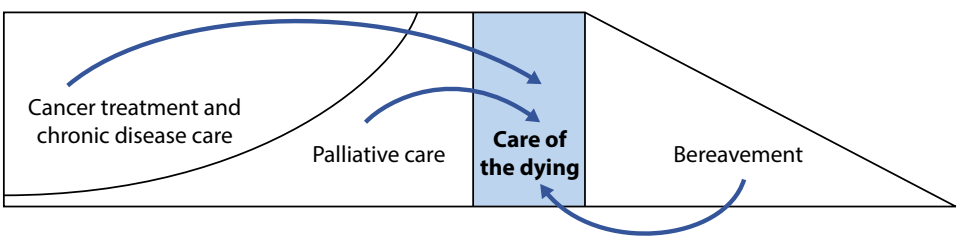

Figure 21.1 Involvement of palliative care within disease trajectory.[12]

TABLE 21.1. Symptom prevalence in advanced head and neck cancer

Author	Talmi et al.[15]	Price et al.[14]	Ethunandan et al.[16]	Ying-Li et al.[17]	Forbes[8]
Year	1995	2009	2005	2011	1996

Feeding difficulties	22 (32)	Not reported	Not reported	84 (89)	28 (74)
Bleeding	6 (9)	13 (14)*	5 (16)	30 (32)	18 (47)

* This includes bleeding from tumour; haemoptysis; mucosal bleeding and bleeding from stoma.
** Problems with secretions.

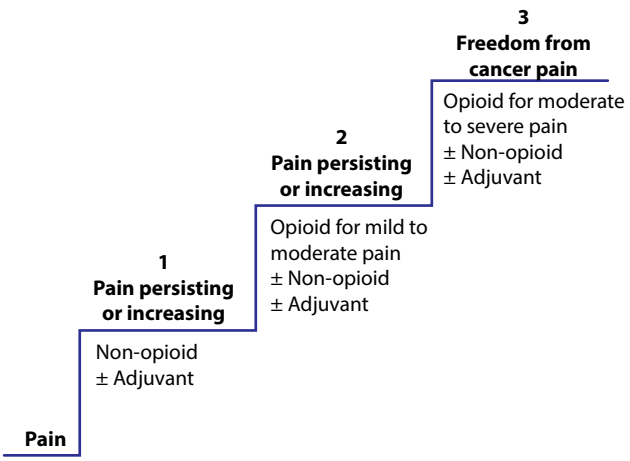

Figure 21.2 WHO pain relief ladder[23]

- Is the patient's renal function stable (as metabolites are more likely to accumulate if opioid is renally excreted)?
- Does the patient require an opioid switch?

In the latter situation, the current opioid medication should be switched to an alternative such as morphine to oxycodone or hydromorphone. If there is evidence of renal impairment, using opioids which are not excreted by the kidneys is beneficial e.g. alfentanil.[26]

In terms of addressing neuropathic pain, in addition to using the WHO ladder, the first-line approach to treatment is either using an anti-convulsant (e.g. gabapentin) or anti-depressant (amitryptiline) medication. If there is evidence of nerve compression, a trial of corticosteroids (dexamethasone) could be considered. Other therapeutic interventions would include the use of methadone, ketamine and potentially interventional pain procedures, and the involvement with specialist palliative care teams would be beneficial for this advice.

There have been more recent developments in the concept of 'breakthrough pain'. The Association of Palliative Medicine within the UK defines this as 'a transient exacerbation of pain that occurs either spontaneously, or in relation to a specific predictable or unpredictable trigger, despite relatively stable and adequately controlled background pain'.[27] Usually, in this situation a short-acting preparation of morphine is given e.g. oramorph or oxynorm. There are newer formulations of strong opioids (fentanyl) which can be administered via sublingual, buccal and intranasal routes, for this type of pain. They have been shown to have equal efficacy compared with traditional oral medications,[28] quicker onset of action but are more expensive. In practice, they tend to be reserved for pain related to a particular event e.g. movement or pain that is sudden in onset and short-lived. It is noteworthy that prior to use, patients should be on at least 60mg of oral morphine or the equivalent.

Particular challenges that arise for patients with head and neck cancer include the route of administration as often the oral route cannot be used. Where a gastrostomy tube is in place, medications can be given this way. It is particularly noteworthy, however, that sustained release preparations of opioids should not be crushed or opened when administered via this route. There are modified-release granules (Zomorph) and suspension (MST Continus) that can be used safely.

The transdermal method of delivery remains an alternative way of delivering opioid medication e.g. fentanyl

patch but it is important to be mindful of the following key messages related to their use:

- transdermal patches should only be used when pain control has been established and is generally stable
- transdermal patches tend to be changed every 72 hours so they do not have as much flexibility in terms of dose titration
- some forms of the buprenorphine patch (e.g. BuTrans) have a maximum dose range (up to 20 mcg which is equivalent to just under 50 mg oral morphine.[29]

The administration of subcutaneous medication given via a continuous infusion (CSCI) is often associated with care of a dying patient. They can be used, however, earlier in the disease trajectory for head and neck patients and this would include as a temporary measure until a gastrostomy is inserted.

Respiratory tract secretion management

When considering the use of anti-secretory medications, the three main drugs are glycopyrronium, hyoscine hydrobromide and hysocine butylbromide. Comparison of these drugs has mainly been undertaken in studies looking at their efficacy in managing retained respiratory tract secretions associated with the last days of life. There is a lack of conclusive evidence about comparable efficacy, although due to the reduced likelihood of agitation and sedation, glycopyrronium may be preferred.[30] The balance needs to be reached between trying to reduce the amount of secretions and not making them too tenacious. If the oral route is not available and a gastrostomy (or equivalent) is not in place, transdermal hyoscine hydrobromide (Scopoderm) patches could be considered.

Communication difficulties

For patients with head and neck cancer, as the disease progresses, there can be increasing difficulties with speech. Alternative methods to aid communication can be using devices for artificially generated speech or using written communication, but the loss of the subtleties of communication can have a profound psychological effect on patients.[8]

Generally, it can be challenging to discuss the complexities of care and decision-making at any time, but with the additional impact of head and neck cancer on communication, this is even more heightened. It also highlights that advance care planning is even more pertinent for these patients while they are able to do so. Having open-ended discussions about the goals of care, potential future complications and issues and being proactive in screening for unmet information needs is an important principle to adopt within the management of these patients.[8]

Terminal haemorrhage

Care for head and neck cancer patients is especially challenging in the terminal phase of illness (the last weeks and days of life) due to the perceived risk of acute catastrophic events such as having a terminal haemorrhage[1, 11] or 'carotid blow out'. The actual occurrence of a terminal haemorrhage (defined as 'bleeding from an artery which is likely to result in death within a period of time that may be as short as minutes')[31] is low with rupture of the carotid artery system occurring in an estimated 3–5% of patients who have undergone major head and neck resections.[32] However, the anxiety and distress associated with the risk of this potential event should not be underestimated. With the increasing numbers of patients who wish to be able to die in their own home, there is the potential for terminal haemorrhage to occur in this setting.[33] Although it is important to be able to prepare the patient and family for this possibility, the benefit and burdens of such discussion need to be carefully balanced in order to avoid unnecessarily escalating distress about an event that may not occur.[33]

Certain factors can increase the risk of a terminal haemorrhage occurring including:

- tumour-related factors – proximity to carotid artery
- treatment-related factors – previous radical neck dissection and radiotherapy; post-operative healing problems
- systematic factors – coagulopathy; age >50 years; 10–15% loss of body-weight; and comorbidities e.g. diabetes mellitus.[33]

Sometimes there can be a herald or warning bleed which precedes the life-threatening haemorrhage or evidence of a ballooning or visible pulsation of arterial vasculature.[34] Trying to minimize the risk of terminal haemorrhage occurring is important. This includes reviewing the patient's current medication to ensure that anti-coagulants (warfarin, heparin) are stopped and other medications which effect platelet function or the coagulation pathway are reviewed and potentially discontinued e.g. non-steroidal anti-inflammatory medications, aspirin, selective serotonin reuptake inhibitor (SSRI) anti-depressants. In several cases arterial embolization by interventional radiologists following a sentinel bleed can delay a bleed or abrogate an ongoing bleed.

Ubogagu and Harris[33] published guidelines about the management of terminal haemorrhage. Although these were specifically for patients at risk of a terminal haemorrhage in their own home, the principles apply for other settings. The key principles include:

- somebody should stay with the patient (and family if present) to help reduce the anxiety and distress associated with the event
- dark towels should be used to reduce the visibility of blood
- an anxiolytic should be given e.g. 10 mg of midazolam given via deep intra-muscular injection due to its rapid onset and short duration of action.

The midazolam should be pre-emptively prescribed, although often in view of the rapidity of the event it is not needed, and certainly is secondary to the need to stay

with the patient. The aim of giving the midazolam is to reduce the patient's awareness and hence distress of the event. Additionally, it provides retrograde amnesia so that if the patient did recover, they would not have recollection of the event. Opioids are generally not needed in this situation unless the haemorrhage is not terminal and the patient is reporting pain. Providing sufficient support to both the family and the healthcare professionals involved is a key factor after the event.

Management at home is more challenging and ideally needs to include a full MDT discussion so that the community healthcare professionals are involved in care planning, the ambulance service are prepared (as they may provide acute support during immediate distress of the event) as well as having appropriate discussions with the patient and family.

Airway obstruction

A further complication that can lead to an acute catastrophic event is airway obstruction. Compromise of the airway can arise due to retention of secretions or by tumour encroachment into the airway or tracheostomy. Preparation for the patient, family and healthcare professionals that this event could occur is of key importance[11] although again the likelihood is thought to be rare. Decision-making about the appropriate level of escalation of treatment in the event of an acute airway obstruction is pertinent. Palliative surgical options include tracheostomy or debulking of the tumour within the airway if deemed appropriate.[35] In the palliative situation, pre-emptive prescription of an anxiolytic, such as midazolam, is appropriate for a terminal event. If there is clinical evidence of stridor, high dose (8 to 16 mg) dexamethasone[36] given via subcutaneous injection may be beneficial.

HOLISTIC CARE FOR THE HEAD AND NECK CANCER PATIENT

Spiritual issues

Spirituality can be interpreted as how an individual finds meaning, purpose and value in their life.[37] Although this meaning may be found within a religious context, it can also relate to achieving life goals, being at peace with oneself[38] or finding particular aspects of life worthwhile.[37]

As a routine part of the palliative care consultation, issues relating to this should be explored. For example, asking questions such as 'how are you coping?'; 'what gives you hope and strength?'; and 'do you ever question "why" this illness has happened to you?' This will enable a patient to share key concerns and the healthcare professional to explore the patient's priorities and wishes for their future care.

Depression

Depression is common in head and neck cancer patients, and as it can independently predict poorer quality of life, requires prompt diagnosis and treatment.[39] Additionally, head and neck cancer patients are noted to have a disproportionately higher suicide risk compared with the cancer population as a whole.[40] Part of this may be due to the higher prevalence of head and neck cancer among male patients and the association with tobacco and alcohol consumption, all of which have been associated with depression and suicide. Additionally, these patients may have more limited social support networks, impacting on their ability to cope.[11]

Brief screening measures can be useful for identification of depression in particular asking about anhedonia (loss of interest or pleasure in doing things) and low mood[41] as many of the traditional physical symptoms associated with depression occur commonly with advanced cancer e.g. weight loss, fatigue, reduced appetite. Treatment with both psychotherapy and anti-depressant medications should be discussed with patients and medication commenced where appropriate. Generally, SSRIs are often considered first line compared with tricyclic anti-depressants due to the latter often being poorly tolerated.[42] It is noteworthy, however, that SSRIs do have the potential to increase the risk of bleeding from the gastrointestinal tract which is a particular consideration for head and neck cancer patients. Mirtazepine is a noradrenergic and specific selective serotoninergic anti-depressant and may be associated with weight gain and sedation. Both of these may be acceptable side effects for cancer patients, particularly if the medication is taken at night.

Ethical issues

The four general principles of ethical decision-making include:[43]

- respect for autonomy – the individual's right to decide what is best for them
- beneficence – duty to act in a way that provides benefit
- non-maleficence – duty to act in a way that does not cause harm
- justice – the fair use and distribution of resources.

These principles form a useful framework to guide decision-making and care planning. Key to good practice is ensuring patient-centred decisions are made and providing explanations about the burdens and benefits of treatments to the patient. Particular ethical issues that arise for head and neck cancer patients include decisions relating to the provision of nutrition and hydration, especially those approaching end of life. Healthcare professionals should consider the individual values and wishes of patients and their families when undertaking decision-making. In view of the likely communication difficulties already highlighted, forward planning and discussions about these issues is pertinent to patient-centred care. Advanced care planning is defined as a 'process of discussion between an individual, their care provider, and often those close to them about future care' and most patients welcome the opportunity to have these types of discussions.[44] Ideally, these should be serial discussions, over a period of time and at intervals when the patient's

condition is relatively stable. Detailed evidenced-based national guidelines have been published within the UK.[45]

The General Medical Council (GMC) within the UK provides specific guidance about decision-making about hydration and nutrition by focusing on both patients 'approaching the end of life' (defined as those likely to die within the next 12 months), and those for which death is thought to be imminent and expected within a few hours or days.[46] A Cochrane review of clinically assisted hydration (CAH) (defined as providing fluids via the intravenous or subcutaneous route) in palliative care was unable to provide any firm recommendations about the use of CAH in dying patients due to the lack of good quality studies.[47] There is limited evidence that CAH may improve sedation and myoclonus,[48] but no evidence to suggest it will improve thirst, delirium or fatigue. Again, although the evidence is limited, CAH may exacerbate symptoms caused by fluid retention e.g. peripheral oedema and ascites. Overall, the review concluded that clinical decisions regarding CAH in the care of dying patients needed to be directed by the perceived benefits and harms on an individualized basis. Additionally, although CAH is regarded in law as a medical treatment,[49] many patients and families consider CAH to be a principle of basic care. This potentially creates tension and a point of ethical contention when making a decision to engage, withhold or withdraw fluids.

In practical terms, patients with advanced head and neck cancer often have a gastrostomy inserted as part of their earlier treatment and, if appropriate, this can be used as a route for hydration and nutrition. If the patient's overall condition deteriorates, the volume of fluid and feeds should be reviewed. For patients who are actively dying (i.e. in the last hours or days of life), often the desire for food or fluid reduces and is seen as a part of the dying process.[44] For those able to take sips of fluid, this should be continued and for all patients good oral hygiene promoted, appreciating that access may be more limited if there is local malignant disease. For most patients, CAH or nutrition is not required at this stage of their illness but a discussion with the patient (if able) and family members is often required to explain that they are dying from their illness rather than from a lack of hydration or nutrition. If concern is raised about this decision, the subcutaneous route can be used to provide fluids and is less burdensome compared with the intravenous route. It is not without complications, however, and these include local site reactions (pooling of fluid or cellulitus) and potentially more systemic problems with symptoms of fluid retention including retained respiratory tract secretions. If a decision is made to commence fluids in this way, regular daily review of the burdens and benefits of the treatment should be considered.

CARE OF THE DYING FOR HEAD AND NECK CANCER PATIENTS

Prognostication i.e. predicting when death will occur remains extremely difficult, with doctors often tending to overestimate prognosis in those with an incurable illness.[50] The recognition and documentation of particular disease trajectories has aided this process e.g. cancer tends to have a comparatively predictable trajectory with a steady decline and a recognized terminal phase (**Figure 21.3**).[48] Patients with head and neck cancer challenge this trajectory to an extent, however, as there is the risk of different modes of death occurring, e.g. acute complications such as terminal haemorrhage or from comorbidities such as chronic obstructive pulmonary disease (COPD).

End-of-life care policies for a number of countries focus on trying to enable more people to die in their preferred place of care which generally is at home.[51, 52] The majority of patients, however, continue to die within the acute hospital setting [53–55] and it is likely that patients with head and neck cancer are no exception to this trend. The provision of palliative care within the acute hospital sector, however, is not without its shortcomings. A recent national survey

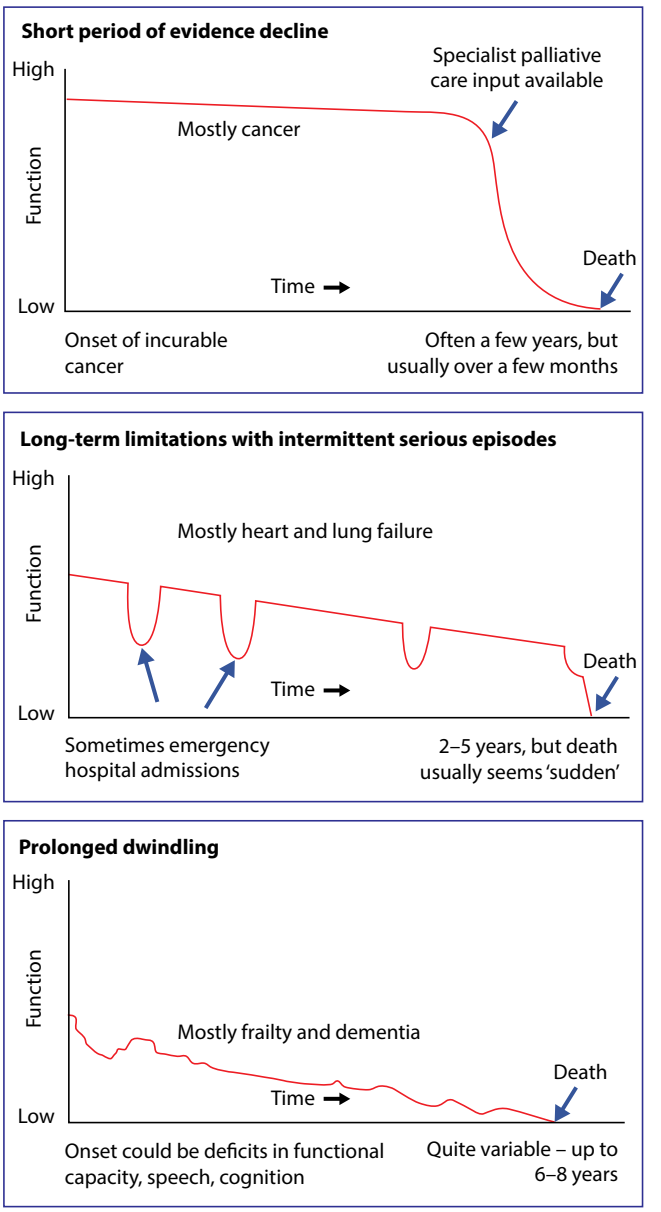

Figure 21.3 Typical illness trajectories for people with progressive chronic illness.[47]

BOX 21.1 The Priorities for Care are that, when it is thought that a person may die within the next few days or hours[58]

1. This possibility is recognized and communicated clearly, decisions made and actions taken in accordance with the person's needs and wishes, and these are regularly reviewed and decisions revised accordingly.
2. Sensitive communication takes place between staff and the dying person, and those identified as important to them.
3. The dying person, and those identified as important to them, are involved in decisions about treatment and care to the extent that the dying person wants.
4. The needs of families and others identified as important to the dying person are actively explored, respected and met as far as possible.
5. An individual plan of care, which includes food and drink, symptom control and psychological, social and spiritual support, is agreed, co-ordinated and delivered with compassion.

of bereaved people in the UK perceived that the quality of care for dying patients was not as high as the level provided at home, within the hospice or care home setting.[56] Recommendations have included increasing accessibility to specialist palliative care teams and mandatory training about care for dying patients for all healthcare professionals.[56] The most recent National report for 'End of Life Care Audit – Dying in Hospital' based on data collected in 2015, however, demonstrated that there were improvements compared with a similar audit undertaken in 2013: a higher proportion of patients were appropriately recognized to be dying in a timely manner and for 95% of these, there was a documented discussion about this recognition with those individuals identified as important to the patient.[57]

In terms of national guidance within the UK about the principles of providing care for those who are dying, the 'One chance to get it right' report identified five 'priorities for care'.[58]

'Individualized end-of-life care plans' are recommended and the subsequent publication of the NICE guidelines for end-of-life care has helped provide a framework for best clinical practice.[59]

Issues specifically related to care of head and neck cancer patients who are actively dying include the provision of adequate pain control. It is not generally recommended that transdermal fentanyl patches are commenced at this stage due to difficulty with titration. If the patient is already established on this method of analgesia, however, it should be continued and in the first instance, as needed injections of opioid used to help control pain. Depending on the amount of extra opioid needed, a continuous subcutaneous infusion (CSCI) should then be commenced in addition to the fentanyl patch.[60]

CONCLUSION

Caring for patients with advanced head and neck cancer is a complex area which raises unique challenges compared with other malignant diseases. Close collaborative working between head and neck cancer teams and specialist palliative care teams is important in addressing patients' needs and achieving high quality of care for the patient and their family. A pro-active approach to management of physical and psycho-social symptoms is needed to best meet patients' changing needs and providing best supportive care.

KEY POINTS

- Head and neck cancer patients have especially complex needs due to the impact the illness and treatment have on communication, swallowing, and breathing.
- Patients often have multiple symptoms including pain, fatigue, retained respiratory tract secretions as well as psychological distress causing depression.
- Advance care planning is important due to the potentially different modes of deterioration and subsequent death from this illness.
- Individualized care plans, incorporating a holistic assessment of needs, should support those who are actively dying.

SEARCH STRATEGY

The initial search strategy involved PubMed, EMBASE, and Google Scholar database enquiries using the search term *transoral laser microsurgery*. The Cochrane database of systematic reviews was also searched for relevant articles. Additional articles were identified by manually searching reference lists.

INTRODUCTION

Transoral laser microsurgery (TLM) is a minimally invasive surgical approach to functional organ preservation for cancer of the upper aerodigestive tract. It involves tumour resection using specialized endoscopic instruments, microscopes and lasers, with the wound bed often left to heal by secondary intention.[1] The term TLM was first coined by John Salassa of Mayo Clinic in the 1990s to distinguish this technique from the more generic endoscopic laser surgery by virtue of using an operating microscope to closely examine the host-disease interface following principles established by Wolfgang Steiner.[2] This affords the advantage of binocular vision and stereoscopic depth perception, combined with the superb optics of modern microscopes, making it truly a microsurgical technique. In contrast to non-surgical radiation and chemoradiation-based protocols, TLM places no limit on treatment options in the event of recurrent, persistent or second primary disease and avoids the long-term iatrogenic sequelae of definitive radiotherapy. TLM differs from traditional surgical oncology by departing from the classic Halstedian principle of *en bloc* resection. Instead, tumour is often divided with the laser and the tumour margin followed under the microscope, with frozen-section control, allowing piecemeal resection via the endoscope. The aim is to ensure a tumour-free margin in all dimensions with minimal excision of normal tissue. TLM also has a diagnostic element, as it precisely defines tumour extent at the time of surgery and provides maximal tissue for pathological assessment. Transoral minimally invasive techniques will likely become more widespread in the future as advances in technology continue to improve endoscopic access to the pharynx and larynx. This chapter describes the current state of surgical laser technology, its application to head and neck cancer, and provides a framework for the TLM approach to tumours at each major head and neck subsite.

LASERS

Production of laser light

An appreciation of the quantum physical basis of electromagnetic radiation is important for any surgeon wishing to understand the adjustable parameters of laser equipment. 'Laser' is an acronym for light amplification by stimulated emission of radiation. A laser consists of three key components: the lasing medium (e.g. carbon dioxide [CO_2]); an excitation source (e.g. alternating electrical current); and a resonant chamber with a mirror at either end to create positive optical feedback.

Laser energy is the result of electrons in the lasing medium transitioning from high to low energy states. Electrons are negatively charged subatomic particles that can be thought of as orbiting around a nucleus of protons and neutrons. Each orbit can be thought of as an 'energy level'. Electrons transition between discrete energy levels by either absorbing (low-to-high energy transition), or emitting (high-to-low energy transition) a packet of energy. Energy is emitted as a 'photon' of light, the wavelength of which may or may not be in the visible part of the spectrum. Electrons prefer to be in the lowest possible energy level, known as 'ground state'. The transition of an electron from a high energy level to ground state either occurs spontaneously or is stimulated by the collision of the atom with an incident photon. In the stimulated case, one photon collides with an atom and a second photon is emitted. The first photon is not absorbed and continues on its path. Therefore, the total number of photons is increased and the light is amplified.

The lasing medium is contained within the resonant chamber with a mirror at either end. The lasing medium is first excited ('pumped') with an input energy, usually an electrical current. This energy promotes electrons from their ground state to an excited state. Some electrons will then spontaneously fall back to ground state, emitting photons of light with a characteristic wavelength dependent on the lasing medium. These photons are reflected from the mirrors at the ends of the resonant chamber, back into the chamber. The photons will then collide with the lasing medium, producing stimulated electron transitions to ground state, and therefore stimulated photon emission. The stimulated emission has the same wavelength and travels in the same direction as the incident photon. For there to be net amplification of light, there needs to be more lasing medium molecules in the excited state than in the ground state at any one time. This state is known as 'population inversion' and is achieved by pumping with input energy. At one end of the resonant chamber the mirror is partially reflective and partially transmissive. Thus a portion of the light can escape the chamber as a 'laser beam'. The remaining light remains in the chamber, stimulating more photon emissions. The chamber rapidly reaches an equilibrium and the process continues as long as the excitation source maintains population inversion. The result is a beam of light that is monochromatic (of a single wavelength), collimated (travelling in one direction), and both temporally and spatially coherent (photons oscillate in phase, and are distributed equal and parallel across the wave front) (**Figure 22.1**).

Laser parameters

The adjustable parameters of surgical laser systems relate to the laser power, the size and shape of the focused beam (the 'spot'), the power output pattern (continuous wave (CW) or pulsed), and in some cases the equipment allows the user to specify a penetration depth. It is important to realize there is no single 'best' set of parameters: the most appropriate settings vary widely according to the clinical situation, the preferences of the individual surgeon, and between different laser delivery systems.

WAVELENGTH

The wavelength of laser light is dependent on the lasing medium. The CO_2 laser has been the workhorse of TLM since the inception of this approach to treating laryngeal carcinoma because of the excellent tissue cutting and coagulation properties.[2, 3] Other lasers such as Thulium-YAG and Holmium-YAG have been used for TLM and transoral robotic surgery.[4, 5] Each laser has a different wavelength and in turn different absorption characteristics in living tissues. The wavelength of the CO_2 laser is relatively long at 10.6 µm, placing it in the mid-infrared part of the electromagnetic spectrum. Therefore, CO_2 laser light is invisible. It is usually combined with a co-axial He-Ne red aiming beam. The CO_2 laser has a high coefficient of absorption by water, and its action is independent of

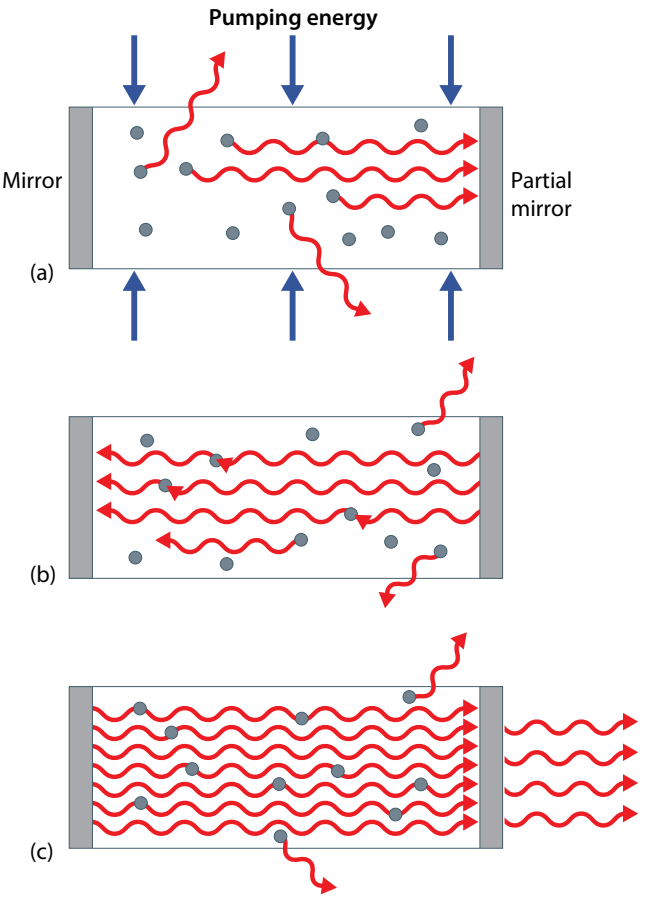

Figure 22.1 Laser physics. **(a)** Pumping of the CO_2 and start of the population inversion. **(b)** The reflected photons traverse the cavity and stimulate other CO_2 molecules to emit photons: the beam is amplified. **(c)** Almost the complete medium contributes to the stimulated emission. The laser beam is transmitted via the partially reflective mirror.

tissue colour. The energy of the CO_2 laser is therefore absorbed by all water-containing tissues.

POWER

Laser power (in watts) is a measure of energy (in joules) emitted per second. Increasing the power increases the amount of energy transferred to the target tissue per second. However, to predict the effect of a given power, the size of the focused beam and the pattern of power output must be known. That is because for a given power the effect on target tissues will be greater if the beam is focused onto a smaller spot (i.e. the energy is more concentrated in space). For this reason, it is sometimes useful to talk about 'power density' (in watts per cm^2) rather than power *per se* as means of comparing different laser set-ups. Similarly, for a given total amount of energy the effect is greater if it delivered over a shorter time period (i.e. the energy is more concentrated in time). Fluence (in joules per cm^2) is power density multiplied by the exposure time, and measures the *total* amount of energy delivered per unit area of exposed target tissue; the 'dose' of electromagnetic radiation. Some laser systems allow the user to specify a penetration depth. It is crucial to realize this is based on the *average* absorption of CO_2 laser light by living tissues. Based on this assumption of average energy absorption and knowing the size of the focused beam, the software calculates the power output required to make the selected incision depth. Therefore, by selecting an incision depth, the user is allowing the software to vary the laser power to produce a predicted surgical effect. The user should be aware that the system is by no means measuring the depth of the incision made, and the actual depth cut will depend on a variety of factors unique to each case.

FOCUSED BEAM 'SPOT' SIZE

The laser beam is passed through a lens to focus the energy on a spot which is typically 0.2–2.0 mm in diameter. The diameter of the focused beam exists over a range of distances around the focal length of the lens, the 'depth of focus'. By defocusing the beam the spot size at the target surface is increased and the laser energy is spread over a wider area. This effect can be exploited for haemostasis of small vessels up to 1 mm in diameter.[6] Larger vessels require careful identification and endoscopic clip application and/or cautery. As well as the manual microscope-mounted micromanipulator laser beam used in a standard 'dot-to-dot' approach, some surgeons use the AcuBlade™ system (Lumenis Inc., Santa Clara, CA., USA). This automatic scanning micromanipulator system produces either linear or curvilinear incisions or circular areas of tissue ablation by rapidly scanning the laser beam back and forth along a pre-determined path.[7]

POWER OUTPUT PATTERN

Lasers energy can be delivered through intermittent pulses, repeated pulses, as a continuous wave (CW) or as very rapid (< 1 ms) pulses in the form of UltraPulse of SuperPulse mode. CW mode produces surrounding tissue damage from thermal spread of laser energy. To produce the desired effects of cutting and coagulation with adequate haemostasis of small vessels and limited char formation, specialized CO_2 laser pulsed modes have been developed: SuperPulse and UltraPulse. These are used with the laser in CW mode, with the energy output pattern modulated into a SuperPulse or UltraPulse pattern. Pulsed modes deliver high peak power density in repeated short duration (< 1 ms) pulses. The difference between SuperPulse and UltraPulse is subtle and clinical outcomes are largely equivalent, although incisions are marginally finer with UltraPulse mode.[7] Superpulse has higher peak energy, less total energy per pulse and more rapid pulse repetition compared to UltraPulse.[6]

Delivery systems

Until relatively recently the CO_2 laser was limited to line-of-sight delivery via a reflecting mirror driven by a micromanipulator mounted on an operating microscope in the manner first used by Strong and Jako in 1971.[3] Restrictions in the physical workspace available via the transoral route, and/or in laryngeal exposure limited the circumstances in which the CO_2 laser could be used. Hollow waveguide systems have been developed to allow the CO_2 laser to be delivered via flexible guides to an increased range of upper aerodigestive tract subsites. These flexible waveguides can be used freehand using a variety of hand pieces, linked to a transoral robotic system, or used via flexible endoscopes in an outpatient setting.[8–15] The first hollow core flexible waveguide system was developed by OmniGuide (Boston, MA., USA) using a photonic band-gap fibre assembly, and is now marketed as BeamPath™. Subsequently, Lumenis (Santa Clara, CA., USA) have developed the FiberLase™ system.

Laser interaction with tissues

When laser light hits tissues, a proportion of the energy is reflected from the surface, a proportion is scattered, a variable amount is absorbed, and the remainder is transmitted. Reflected energy is effectively lost for the surgical purpose of cutting and coagulation and can cause unwanted thermal injury to adjacent tissue. Scattering is dependent on the optical properties of the tissue and the wavelength of light. Shorter wavelengths are scattered more than long wavelengths; hence the commonly used CO_2 laser in TLM is only minimally scattered. Absorption requires a chromophore (a molecule to absorb energy at a particular wavelength). In the case of the CO_2 laser the chromophore is water. The intensity of laser energy decreases exponentially from the tissue surface, hence the absorption (and therefore the heat generated) is maximal at the tissue surface. The thermal penetration of the CO_2 laser is much shorter than other lasers; several micrometres compared to several millimetres for Nd-YAG, Argon, or KTP-YAG lasers.[16, 17] Laser energy is rapidly converted

to heat, resulting in tissue vaporization and precise cutting. Compared to other lasers, the CO_2 laser causes much less thermal spread to adjacent tissues.[18] It is important to maintain appropriate tissue traction and counter-traction when working with the CO_2 laser, to allow visualization of the cut tissue surface and to avoid excessive char formation. In contrast to tumour excision by cutting with a CO_2 laser, there has been some early success with photoangiolytic therapy for early glottic carcinoma.[19–22] In this technique, a KTP laser or other angiolytic lasers that use haemoglobin as a chromophore are exploited to selectively destroy the microvasculature of early glottic cancers.

OPERATING ROOM SET-UP

Trans-oral techniques require a number of highly specialist pieces of equipment including the operating microscope, endoscopes, lasers and endoscopic graspers, diathermy probes and clip applicators. The arrangement of the room is an important consideration since the microscope and laser are bulky and there are specific safety concerns regarding the laser and operating room personnel. **Figure 22.2** is a schematic representation of the typical operating room set-up. It is important to have a selection of endoscopes available (**Figure 22.3**). A good endoscope has a wide proximal aperture to allow instruments to be introduced and manipulated to achieve optimal tumour exposure and tissue retraction. Some endoscopes have inbuilt smoke extraction ports whilst others require an additional smoke extraction unit to be mounted. For oropharyngeal and some hypopharyngeal tumours, the Feyh-Kastenbauer retractor (Invotec) may be used (**Figure 22.4**). This is a highly versatile system, and provides excellent exposure in the majority of cases. Several laser delivery systems are available, each with their own specific advantages and disadvantages over others. The most commonly used systems include the microscope-mounted micromanipulator and more recently flexible hollow core delivery systems (**Figure 22.5**). In all cases, the back table is set up with a selection of endoscopic graspers and diathermy probes (**Figure 22.6**). For dental protection, we prefer to use customized guards for each patient, made from thermoplastic (**Figure 22.7**).[23]

HANDLING THE PATHOLOGIC SPECIMEN

A fundamental concept in TLM that distinguishes it from traditional surgical oncology is resection by tumour division. There is now extensive clinical and experimental evidence showing no compromise of local oncologic control with a systematic TLM piecemeal resection compared to the traditional *en bloc* approach.[2, 24–26] The host–disease interface is carefully examined under the operating microscope and the tumour removed piecemeal through the endoscope. For early glottic carcinoma, UK TLM surgeon consensus agreement is for circumferential or *en bloc* resection where feasible with the philosophy of a second-look surgery in the event of uncertain or positive margins.[27] As the indication for TLM evolves to include larger tumours in more inaccessible subsites the paradigm for dealing with resection margins is also changing. The complete excision of tumour to negative histopathological margins at the primary site is key to local disease control.[28, 29] Positive margins on permanent section at the end of TLM are associated with significantly increased rates of local recurrence, distant metastasis, and necessity for salvage surgery, as well as lower overall survival rates.[26, 30] However, an advantage of TLM is that there is usually no need to reconstruct the surgical defect, so the tumour bed is left exposed and readily accessible for second or even third resections to achieve negative margins. There is no negative effect on local recurrence or survival if the negative margin requires two or more attempts.[28, 29]

Hinni et al. recently coined the term 'margin mapping' to describe their approach to the pathological specimen in a series of 128 TLM oropharyngeal cancer resections.[31] This technique involves the surgeon inking the margins of each section of the tumour removed in the operating theatre followed by careful pathological assessment of the margin by intra-operative frozen section. Overall, the positive deep margin rate in the permanent section was 1% for previously untreated palatine tonsil squamous cell carcinoma. There were no local recurrences in the previously untreated group. The piecemeal removal of tumour in the lateral oropharynx is therefore oncologically sound. This is despite what some would term 'close' margins, with the mean smallest margin of 1.98 mm. Hinni et al. relate the size of the deep margin to the width of the lateral oropharyngeal wall musculature in healthy volunteers as assessed by magnetic resonance imaging and conclude

Figure 22.8 The tongue is non-compressible. Illustration of the difficulty of endoscopic exposure imposed by a large tongue, here using a tennis ball as the 'tongue'.

that since the superior constrictor width is 2.4 mm, it is unlikely that larger margins would be obtainable. They point out that inferiorly in the tonsillar fossa, deep to the superior constrictor muscle, is a space between styloglossus and stylopharyngeus muscles filled with parapharyngeal fat. This fat is unlikely to represent a barrier to tumour spread and is of no use as a frozen section margin. It should be emphasized that this detailed microscopic 'margin mapping' approach requires close collaboration between the surgeon and pathologist for intra-operative frozen section analysis and reporting. In some institutions limited resources mean this is simply not practicable.[32] It is also important to remember that frozen sections do not always correlate with permanent pathology.[33]

OPERATIVE TECHNIQUE

General considerations

The optimal patient for TLM is edentulous, with a wide mandible and no limitation of neck extension. Patient selection is key to the success of the technique, as inadequate endoscopic access to facilitate satisfactory oncologic resection is the main contraindication to TLM. It is important to realize that it is often necessary to adjust the set-up at least once during the procedure. Be prepared to change the endoscope and to move position to facilitate tumour exposure and extirpation. The tongue can be a source of significant difficulty in achieving the optimal exposure, as it is non-compressible (**Figure 22.8**). In addition, prolonged retraction and compression of the tongue can result in post-operative complications such as lingual and hypoglossal nerve palsies, and tongue oedema necessitating tracheostomy. In short, the usual caveats of endoscopic exposure apply to the TLM technique: think of the five Ts, Tongue, Trismus, Teeth, Tumour and Tilt (neck extension). To some extent, the development of flexible hollow-core waveguide systems for CO_2 laser delivery has allowed the endoscopic surgeon to work around corners; however, the microscope-mounted laser is limited to line-of-sight view. Therefore, appropriate tissue retraction and positioning of endoscope blades is essential for efficient and effective surgery. The optimal technique involves retracting the tumour into the field of view, applying tension to the specimen and cutting with the laser along the host–disease interface. The use of robotic techniques partially obviates this limitation, but sacrifices the magnification benefits of the TLM procedure.

As with any technique, experience is an important factor in the outcome. In particular, the ability to operate on larger tumours with the TLM approach is experience-dependent. There is a significant learning curve that affects both oncologic outcome and the incidence of operative complications.[34, 35] The authors recommend gaining experience on small tumours before attempting more complex resections using TLM. Locally-advanced hypopharyngeal tumours are often beyond the surgical expertise of even the most experienced TLM surgeons.

Laryngeal carcinoma

The aim of TLM is to preserve as much normal tissue as possible, thereby maximizing the potential for functional recovery. Small superficial T1a glottic tumours may be excised *en bloc* with the CO_2 laser.[27] More complex glottic and supraglottic tumours (T1b, T2-T3) benefit from an initial cut through tumour to assess depth of invasion (**Figure 22.9, Figure 22.10,**). The way in which the laser cuts through normal tissue and tumour is very different and can be appreciated under the operating microscope Normal tissues under tension will spring apart with a 'clean' appearance. Tumour tends to be firmer, less elastic and chars more when cut with the laser. Once the deep margin of the tumour is identified, the host–disease interface is followed with the laser and the tumour removed piecemeal. For large exophytic tumours, the authors recommend initially debulking the tumour to allow accurate assessment of the tumour footprint and its interaction with the host tissues. Assessment of the tumour should take into account the functional consequences of resection.

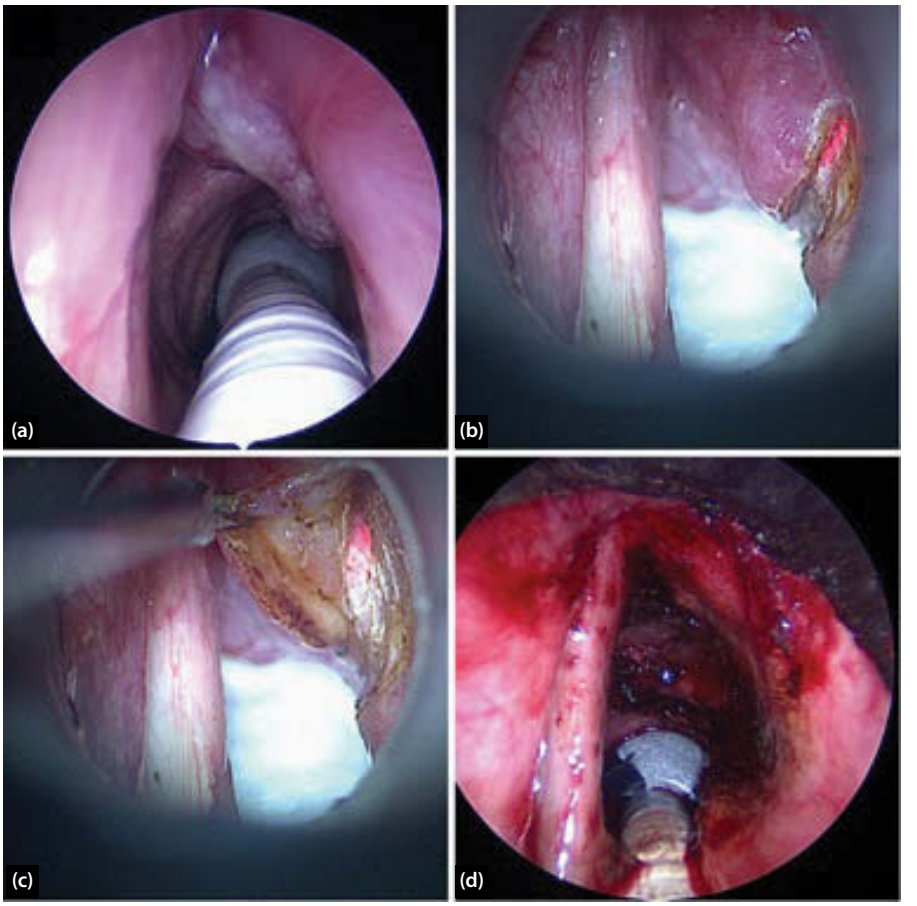

Figure 22.9 TLM for T1a N0 glottic carcinoma. **(a)** Tumour is confined to the right vocal cord. **(b)** The tumour is first divided with the laser to assess the depth of invasion. **(c)** The deep margin of the tumour is followed with the laser, applying tension to the specimen. **(d)** Appearance at completion of resection.

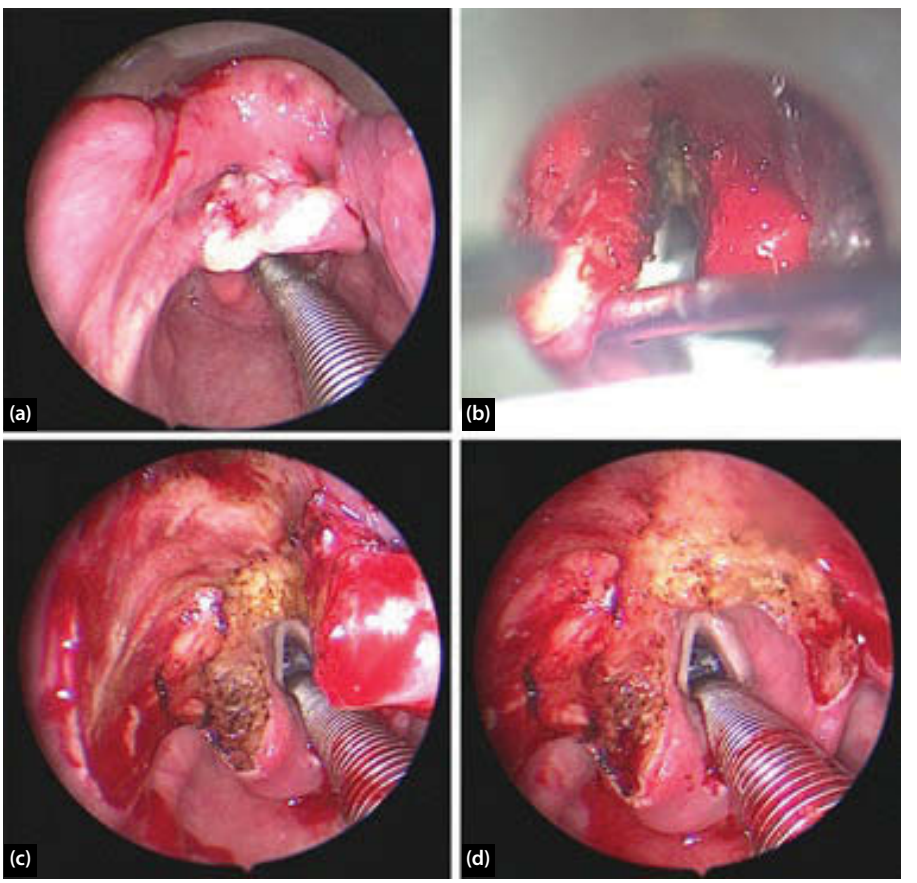

Figure 22.10 TLM for T2 N0 supraglottic carcinoma. **(a)** T2 tumour involving the epiglottis. Both arytenoids are free of tumour. **(b)** The epiglottis is first divided vertically to split the tumour in two to assess depth of invasion. **(c)** The left supraglottis is removed first. The arytenoid is spared. **(d)** Appearance at completion of resection.

To prevent significant functional impairment at least one competent arytenoid complex should be preserved.

The major limiting factor in TLM is surgical access. It has been the experience of the authors that laser excision of the false cord is useful for endoscopic access to the underlying glottis in some cases. Almost any laryngoscope can be used, and several different scopes may be needed during one resection. Very small diameter scopes such as the Hollinger laryngoscope may afford only a monocular view. Deployment of the laser in this situation is difficult. Laryngoscopes with matt finishes are preferable, as this limits reflections from the microscope. For glottic and supraglottic laryngeal carcinoma TLM, the authors prefer the use of suspension with the Göttingen table (Karl Storz). This modular system allows great flexibility and is ideal for laser laryngeal surgery (**Figure 22.11**).

Oropharyngeal carcinoma (OPC)

The use of TLM as a treatment for OPC was first reported by Steiner et al;[36] however, its use was been widely adopted until recently when evidence emerged of its potential benefits in treating OPC with the aim of achieving improved post-treatment swallowing function.[37–39] This is particularly pertinent in this era of HPV16 + OPC as TLM has the potential to contribute favourably to treatment de-intensification strategies. (See Chapter 13, Oropharyngeal tumours)

Transoral access to the lateral oropharynx and the soft palate is relatively straightforward using either a standard Boyle Davis tonsillectomy gag or, more usually, a Feyh-Kastenbauer retractor (**Figure 22.4**) or equivalent. In contrast, access to the tongue base is challenging. Access, if secured at all, is usually achieved using a bivalved distending oropharyngoscope (**Figure 22.3a**). Even then, due to the line-of-sight constraints, complete exposure of the tumour is not the norm and tumour resection has to proceed in a superficial to deep direction, appreciating the 3D orientation of the base of tongue and vallecula. In addition, it may be difficult, even for experienced surgeons, to distinguish tumour from normal base of tongue lymphoid tissue. In such cases, frozen section assessment may be helpful.

Figure 22.11 Göttingen suspension table. Adjustable laryngoscopy suspension table used for TLM resections. This offers maximal flexibility.

When resecting a tonsil carcinoma, following adequate exposure, it is usual to start by transecting the tumour in the axial plane at the mid-point, immediately separating the tumour into a superior and inferior portion.

Each portion is then resected completely, paying particular attention to the mucosal and deep margins whilst considering the trade-off between normal tissue resection and complete tumour removal.

It is important to appreciate, as highlighted above, that there is an anatomical limitation to the extent of deep resection margin that can be achieved in many cases.

Following resection of the main tumour specimen – which is typically orientated and pinned to a cork-board – and in the absence of frozen section availability, representative marginal biopsies are taken from the mucosal edges and deep tissues of the tumour bed. These marginal biopsies are separately assessed for the presence of residual tumour. There should be a zero tolerance for positive marginal biopsies and further resection should be mandated for the infrequent cases where one or more marginal biopsies are positive for tumour.

Similar resection margins are taken following the resection of tongue base tumours although the position from which the marginal biopsies are taken is less proscriptive and is tailored to the position and extent of the primary tumour resection. Despite this, the same zero tolerance for positive marginal biopsies should be maintained.

Hypopharyngeal carcinoma

The same principles of TLM apply when using it to treat cancers of the hypopharynx. As highlighted above, the management of large hypopharyngeal tumours using TLM is contraindicated in all but the most experienced hands. However, TLM removal of smaller tumours (T1/2) is often surprisingly straightforward and results in highly favourable swallowing function outcomes. Assuming there are no anatomical limiting factors relating to the jaw and dentition, access to tumours in the hypopharynx, using a distending oropharyngoscope, is often more straightforward than accessing the more constricted and anteriorly placed larynx – particularly if the tumour is anteriorly placed within the larynx.

An absolute contraindication to TLM in the hypopharynx includes tumour invading through thyroid cartilage into the tissue of the neck and relative contraindications include large tumours, the resection of which will also include the hemilarynx.

COMPLICATIONS

As the indications for TLM to treat laryngeal and pharyngeal malignancies have increased, so too has the number

of complications.[35] Although there are many advantages of TLM over traditional open surgical approaches, such as a decreased need for tracheostomy and gastrostomy with improved post-operative speech and swallowing function, it is not without risk of significant intra-operative and post-operative complications. Routine laser safety precautions are observed to reduce the risk of inadvertent burns to the patient and operating theatre staff. The patient's eyes and face must be covered with wet towels soaked in saline and all operating theatre personnel (with exception of the operating surgeon) must wear protective eye-glasses. It is common practice to display notices outside the operating theatre to warn staff the laser is being used.[40] The major procedure-associated risks are intra-operative airway fire, post-operative haemorrhage and aspiration pneumonia.

Upon contact with living tissue the energy in the CO_2 laser is immediately converted to heat, reaching temperatures up to 450 °C. The incidence of airway fire in large series is 0.4–1.5%.[41] The time to ignition of fat when lasing in oxygen concentrations of > 50% and with a power greater than 5 W is less than 5 seconds.[41] TLM is typically performed with FiO_2 < 30%, especially if an open ventilation system such as high-frequency jet ventilation is used, to avoid significant risk of airway fire.[6, 41, 42] It is routine practice to use laser-compatible endotracheal and jet ventilation tubes, and to cover the cuff of the endotracheal tube with saline-soaked patties to reduce the chance of tube damage and airway fire.[43] Smoke exhaustion should always be used, as the combustible particles in smoke significantly increase the chance of ignition at the site of lasing.[41] In the event of an airway fire the endotracheal tube is removed, the airway re-secured, bronchoscopy is performed and the procedure is terminated.

The most worrisome post-operative complication following TLM is catastrophic haemorrhage in the presence of impaired swallowing and airway protection. In this scenario patients are at risk of death from both torrential aspiration and exsanguination.[35, 44, 45] Rates of post-operative bleeding in large series are 1.4–10%.[1, 44, 46] The majority of bleeds occur within 7 days of surgery, but late secondary haemorrhage occurring up to 17 days post-operatively has been reported.[44] Bleeding is more likely in lateral pharyngeal wall and supraglottic resections compared to resections limited to the endolarynx or oral cavity.[44] Post-operative haemorrhage after TLM highlights the need for modern head and neck surgeons to be familiar with neck vascular anatomy from an inside-out perspective, in contrast to the traditional outside-in view (**Figure 22.12**). Larger vessels should be carefully identified, and clipped and cauterized before division. Vessels identified as the source of major post-operative secondary haemorrhage include the superior laryngeal artery, lingual artery and anterior facial artery.

It is preferable for the TLM surgeon to manage any post-operative haemorrhage. The principles are those of securing and preserving the airway and controlling the source of bleeding. If a surgeon other than the TLM surgeon is managing the emergency situation it may be safer to tie off the external carotid system in such cases, or consider endovascular embolization. Small bleeds should be considered sentinel bleeds. A careful and thorough endoscopic examination under anaesthesia in theatre by the TLM surgeon with equipment available to deal with a major haemorrhage (large clip applicators, large-bore suction, and monopolar and bipolar diathermy) may be required.

ADDITIONAL CONSIDERATIONS

Compared to traditional open surgery, TLM greatly reduces the need for tracheostomy and tube feeding.[47, 48] Temporary tracheostomy may occasionally be necessary for some patients undergoing extensive resections in whom significant aspiration is expected in the immediate post-operative period and who have marginal pulmonary function. Other indications for tracheostomy in TLM cases include patients with high risk of post-operative haemorrhage, and those who have received prior radiotherapy and undergo concurrent neck dissection at the time of TLM resection. Tracheostomy may also be necessary on occasion to improve endoscopic access to the tumour by obviating the oro-tracheal tube. It must be borne in mind, though, that tracheostomy impairs swallowing function in the immediate post-operative period. In the setting of post-operative complications necessitating a return to the operating room, it may be preferable to perform a tracheostomy, to avoid trauma to the healing surfaces by intubation and subsequent extubation by an oro-tracheal route.

Feeding tubes are generally not required in TLM resections. In some extensive oropharyngeal and supraglottic resections it may be necessary to place a nasogastric tube temporarily. This is best done by the operating surgeon under direct vision at the time of TLM resection. In the presence of large open wounds with multiple vascular clips the patient should remain nil by mouth for a period after surgery to reduce the risk of post-operative haemorrhage. In patients requiring post-operative radiation therapy and predicted to require a feeding tube for a prolonged period, the naso-gastric tube should be converted to a percutaneous gastrostomy tube if possible. Early involvement of a specialist speech and language therapist is of benefit for patients with swallowing impairment.

Other considerations include elective intensive care unit admission and the use of antibiotic prophylaxis during healing. Generally, ICU admission should be considered in patients at high risk of post-operative haemorrhage and those requiring tracheostomy. Some TLM surgeons favour the use of post-operative antibiotics in selected cases. It is our routine practice to avoid the use of antibiotics in the majority of patients.

CONCLUSIONS

The continued development of endoscopic and laser equipment has enabled significant advances in minimally invasive surgical approaches for head and neck cancer. TLM offers an alternative to traditional open surgical approaches, with minimal reconstruction (and the associated morbidity)

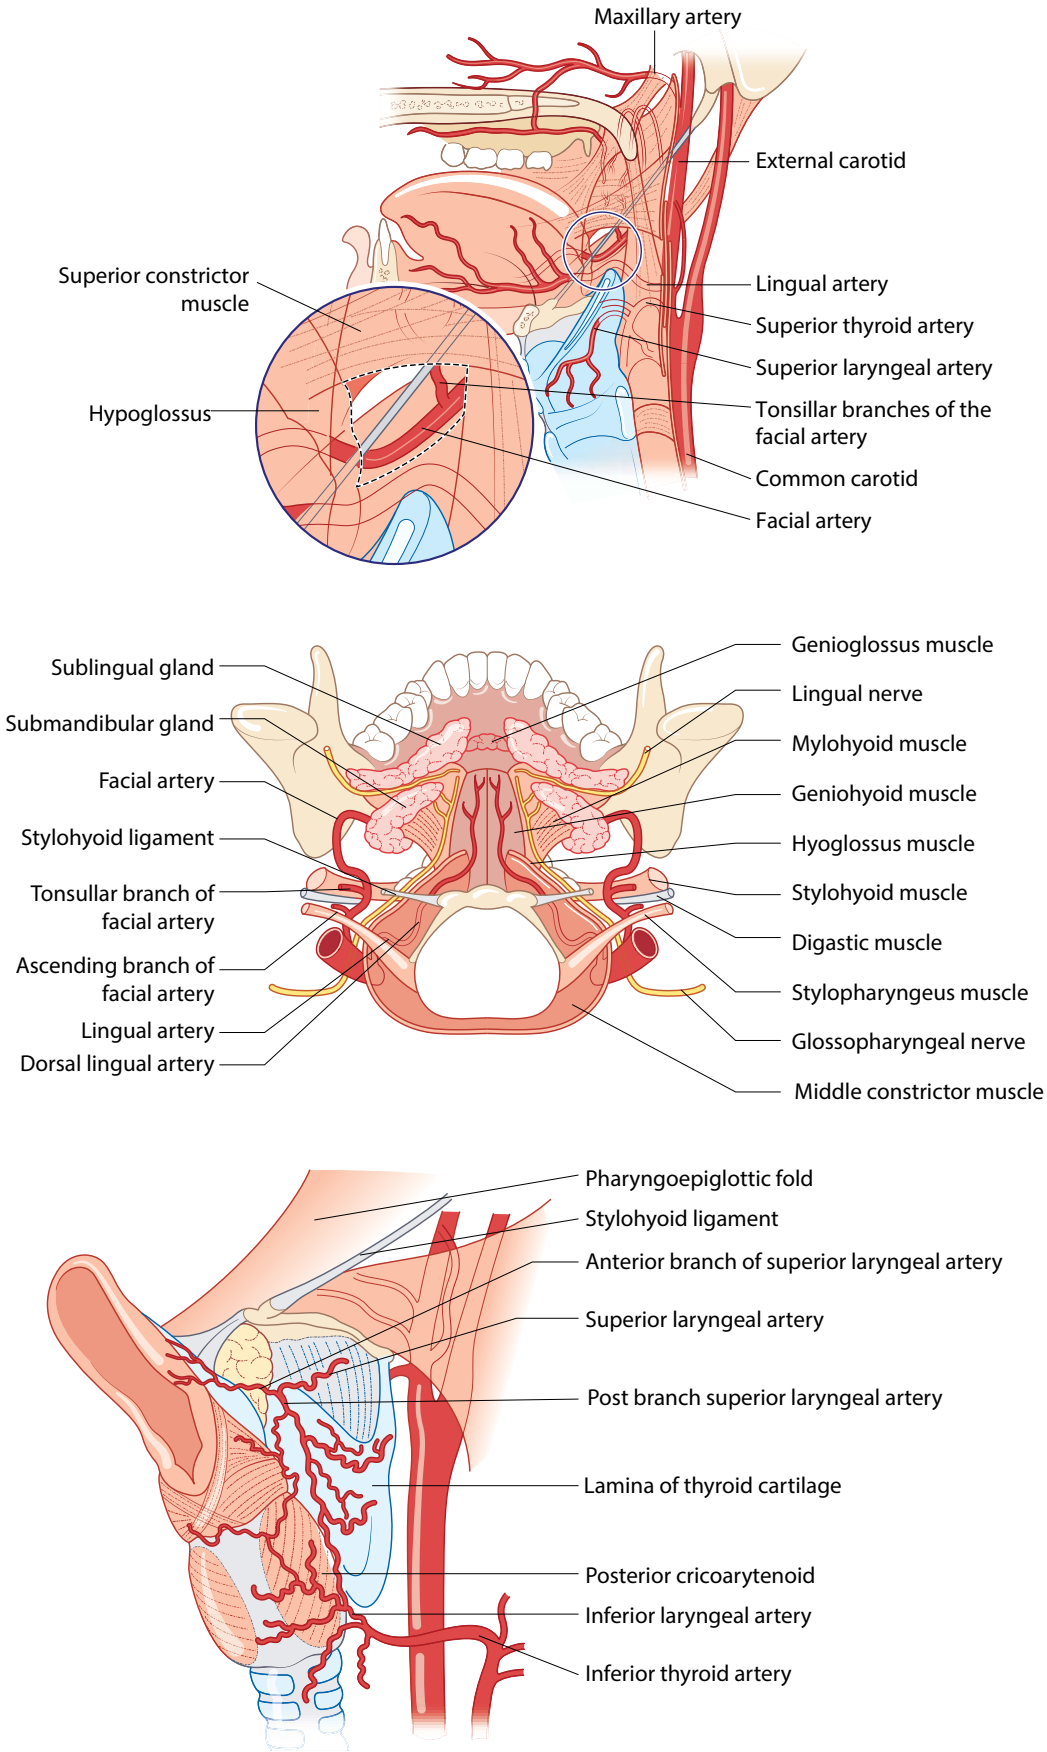

Figure 22.12 Vascular anatomy for TLM.

required in the majority of cases. Since its introduction in the 1980s the use of TLM has expanded to include all head and neck subsites. This is the result of technological advances in both endoscopic access and methods of delivering laser energy to the tumour site, combined with a developing surgical experience and expertise throughout Europe and North America. An understanding of the equipment required to achieve optimal surgical access and the pertinent factors influencing patient selection are key for the practice of TLM. Surgeons of the future need to familiarize themselves with the operating room set-up and operative technique of TLM throughout their training to offer this approach as part of a modern and integrated multidisciplinary head and neck cancer service.

KEY POINTS

- Transoral laser microsurgery is a proven technique in the management of the primary site for a variety of cancer subsites in the upper aerodigestive tract.
- This technique offers significantly less morbidity compared to open approaches.
- The technique requires surgeons to have an excellent appreciation of the anatomy from inside out.
- Significant research is ongoing on transoral surgical techniques with improvements in instrumentation and increased experience.

SEARCH STRATEGY

The data in this chapter is supported by a Medline search using the keywords: transoral surgery, tongue, pharynx, and larynx.

INTRODUCTION

Anatomy is traditionally taught through an outside-to-inside approach. Transoral laser microsurgery (TLM) and transoral robotic surgery (TORS) challenge this classical view, necessitating a 3-dimensional appreciation of the relevant anatomy from a counter-intuitive, inside-out approach. This is particularly important as tumour and/or surgical instrumentation such as retractors or endoscopes distort the normal anatomy. While other chapters within this reference text offer the conventional anatomic approach, the aim of this chapter is to focus on head and neck anatomy relevant for TLM and TORS, with special relevance to the vascular anatomy as seen from a transoral perspective.

TONGUE BASE

The tongue base refers to the posterior portion of the tongue (oropharynx), separated from the anterior, oral cavity segment by the terminal sulcus. This area is derived from the second, third and fourth branchial aches. The tongue base contains the lingual tonsils and the pharyngoepiglottic and glossoepiglottic folds (**Figure 23.1**).

Muscles

The tongue is composed of intrinsic and extrinsic muscles, the muscles on each side are separated by a dense fibrous midline band. The intrinsic muscles from superficial to deep are: superior longitudinal, inferior longitudinal, transverse and vertical. These muscles generally serve to alter the shape of the tongue, the intrinsic muscles are all innervated by the hypoglossal nerve.

The intrinsic and extrinsic muscles of the tongue and their relationship with the oral cavity can be appreciated in **Figure 23.2**.

There are four extrinsic tongue muscles, originating from outside the tongue and inserting within the substance of the tongue. They are styloglossus, hyoglossus, genioglossus and palatoglossus. These are paired muscles which move the main body of the tongue. A detailed breakdown of the actions of the muscles is in the **Table 23.1** below.

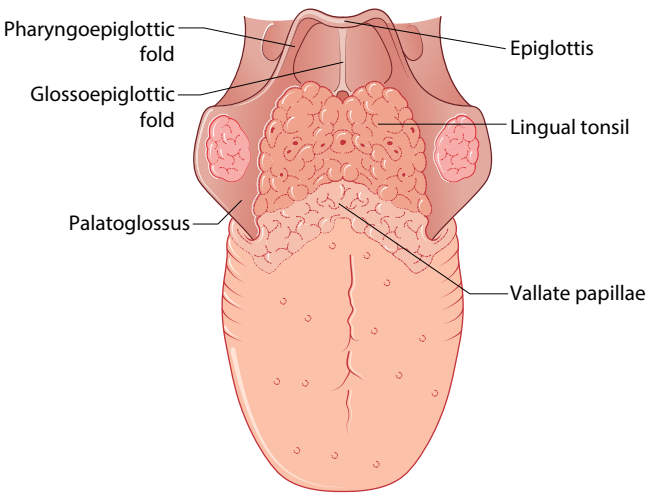

Figure 23.1 Tongue surface anatomy.

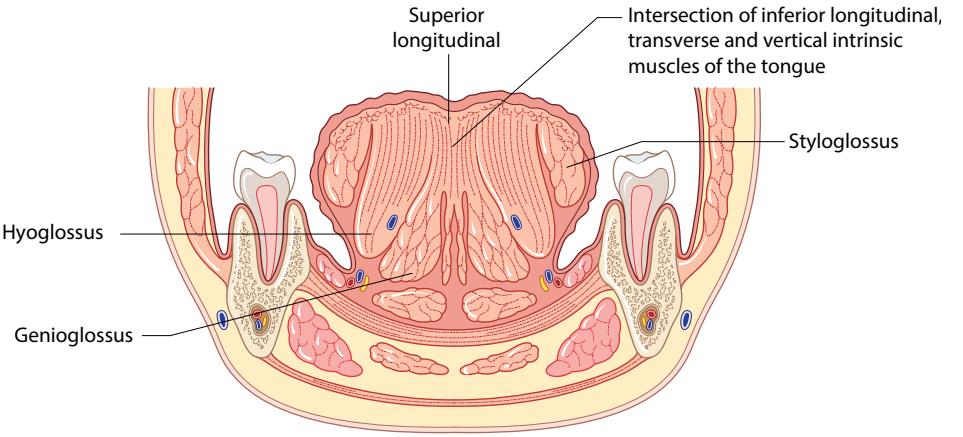

Figure 23.2 Cross-sectional anatomy of the tongue highlighting the muscles of the tongue.

TABLE 23.1 Anatomy, innervation and action of tongue muscles

Muscle	Type	Origin	Insertion	Action
Superior Longitudinal	Intrinsic	Lingual septum and submucous fibrous layer	Margins of tongue	Elevates tip and sides of tongue; shortens tongue
Inferior longitudinal	Intrinsic	Body of hyoid and base of tongue	Apex of tongue	Curls tip inferiorly; shortens tongue
Transverse	Intrinsic	Lingual septum	Submucous fibrous layer	Narrows and lengthens tongue
Vertical	Intrinsic	Superior surface of the tongue	Inferior surface of tongue	Flattens and broadens tongue
Genioglossus	Extrinsic	Mental spine of mandible	Lateral and inferior tongue	Depresses and protrudes tongue
Hyoglossus	Extrinsic	Body and greater horn of hyoid	Lateral and inferior tongue	Depresses and retracts tongue
Styloglossus	Extrinsic	Styloid and stylohyoid ligament	Lateral and inferior tongue	Retracts tongue
Palatoglossus	Extrinsic	Palatine aponeurosis	Lateral tongue	Elevates posterior tongue

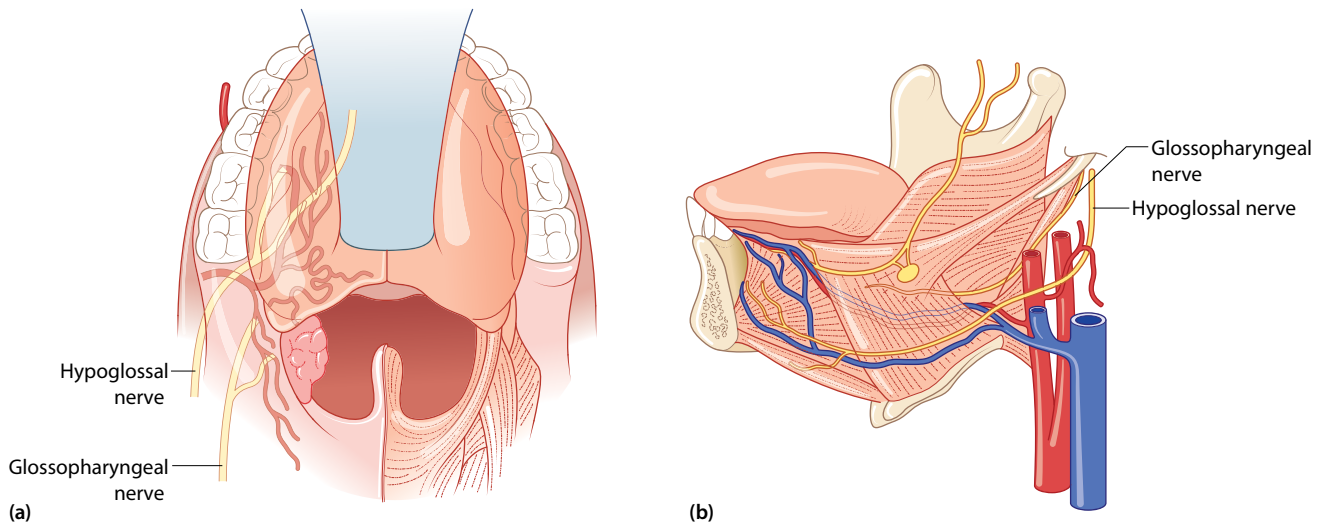

Figure 23.3 Transoral and lateral view of the nerves of the tongue.

Nerves

All the tongue muscles are innervated by the hypoglossal nerve apart from the palatoglossus, which is supplied by the pharyngeal plexus.

The hypoglossal nerve passes through the hypoglossal canal travelling alongside fibres from C1–2, then passing over the internal and external carotid arteries. It is seldom seen during transoral surgery for tongue base pathology (**Figure 23.3a** and **b**). It passes deep to the lingual nerve, along the genioglossus towards the tip of the tongue, and small off-shoots supply the intrinsic and extrinsic muscles apart from palatoglossus.[1]

The glossopharyngeal nerve supplies taste to the posterior 1/3rd of the tongue via the lingual branch. These fibers travel to the inferior glossopharyngeal ganglion and ultimately to the pons/hypothalamus.

Vascular

The principal artery encountered during transoral surgery of the tongue base is the dorsal lingual artery which arises from the common lingual artery. The common lingual artery is usually a branch of the external carotid artery (78%) but in 20% of cases it may arise from a common lingo-facial artery trunk.[2]

The artery has been divided into four segments by Shangkuan et al,[2] the original segment, the segment within the hyoglossus, the ascending and the horizontal segments (**Figure 23.4**).

The original segment consists of the root of the lingual artery which ascends medially then descends anteriorly, it consistently lies 3 to 4 mm supero-lateral to the greater horn of the hyoid bone. This artery is encountered when skeletonizing the greater horn of the hyoid bone deep to hyoglossus muscle.

The segment within the hyoglossus passes obliquely from posterosuperiorly to anteroinferiorly under the posterior border of the hyoglossus muscle and medial to the hypoglossal nerve; prior to entering the intrinsic muscles of the tongue, it runs lateral to the genioglossus.[1] The dorsal lingual artery, the first branch of the lingual artery arises approximately 0.7 cm from the anterior border of the hyoglossus. The vascular territory of the dorsal lingual artery stretches from the root of tongue, 5 mm behind the terminal sulcus, to the glossoepiglottic folds, the glossopalatine arch and the epiglottis.

The ascending segment of the lingual artery ascends in a tortuous manner along the anterior border of hyoglossus. The sublingual artery arises 0.8 cm above the hyoid bone at the origin of the ascending segment passing forward between genioglossus and the sublingual gland. The vascular territory of the sublingual artery includes the ventral side of the tongue, the anterior and lateral floor of the mouth and the vestibular and lingual gum.

The horizontal segment of the lingual artery becomes the deep lingual artery which runs forward with many upward and downward tortuosities between the longitudinal muscle of tongue and the genioglossus of each side, extending to 1cm from the tip of the tongue. The vascular distribution includes the dorsal side of the tongue, the lateral side and part of the ventral side.[3]

VASCULATURE ENCOUNTERED DURING SURGERY FOR TONGUE BASE TUMOURS

The position of the lingual artery within the tongue base is 2.7 cm inferior and 1.6 cm lateral to the foramen cecum (**Figure 23.5**). Dissection within the intrinsic muscles of the tongue tends to be safe, the main trunk lies on the lateral surface of the genioglossus muscle.[4] Intra operative and post-operative bleeding can be controlled with electrocautery or haemostatic clips. More severe bleeding may require transcervical ligation of the lingual and facial arteries.[5]

The veins of the tongue mirror the arteries in name and in their passage through the tongue.

LATERAL PHARYNGEAL WALL

The pharynx is a musculomembranous tube shaped like an inverted cone. It extends from the cranial base to the lower border of the cricoid cartilage, where it becomes continuous with the oesophagus.

Muscles

The muscles of the pharynx are three circular constrictors and three longitudinal elevators. The constrictors may be thought of as three overlapping cones which arise from

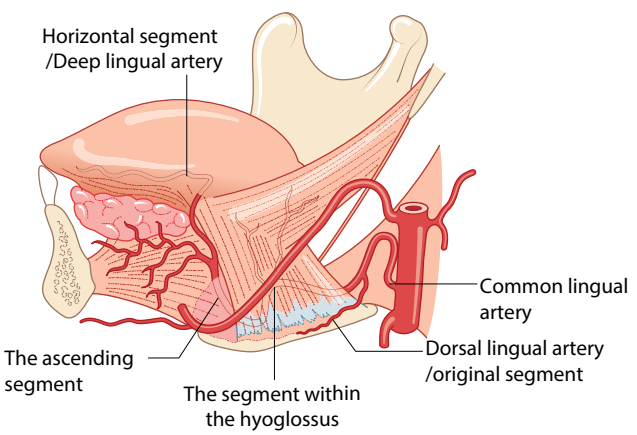

Figure 23.4 Blood vessels of the tongue.

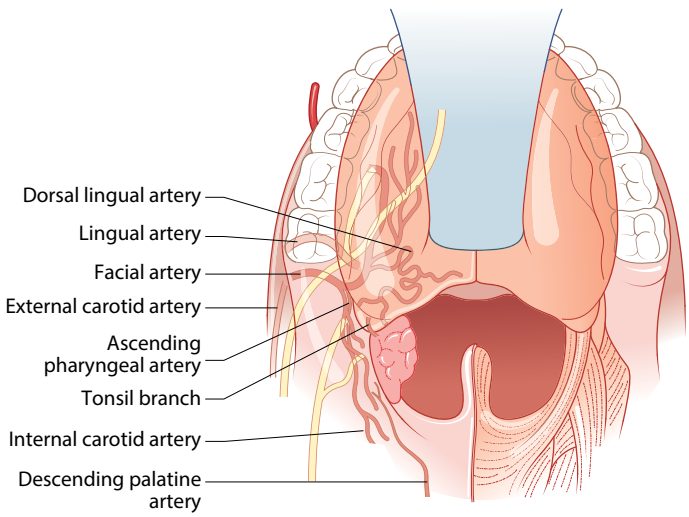

Figure 23.5 Transoral view of the blood vessels of the tongue.

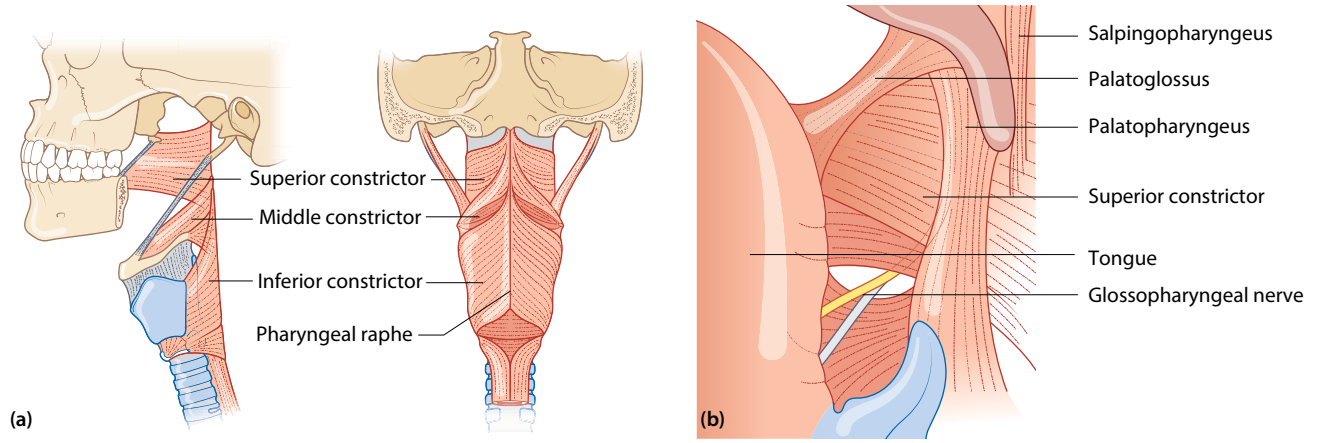

Figure 23.6 **(a)** Pharyngeal constrictors **(b)** Anatomy of the Superior lateral pharyngeal wall.

structures at the sides of the head and neck and pass posteriorly to insert into a midline fibrous band, the pharyngeal raphe (**Figure 23.6a**).

The tonsil is the most medial structure of the lateral pharyngeal wall. It lies between the palatoglossus (anterior faucial pillar) and palatopharyngeus (posterior faucial pillar) muscles. Superiorly these muscles unite with the levator and tensor palatine muscles; inferiorly they are attached to the tongue and pharyngeal wall respectively merging with the superior constrictor.

Deep to the tonsil lies the first of the circular constrictor muscles, the superior constrictor, which originates from the posterior midline pharyngeal raphe and attaches to the pterygomandibular raphe. The constrictors (superior, middle and inferior) overlap each other and all attach to the pharyngeal raphe posteriorly. They act in unison to propel the food bolus into the oesophagus by contracting the lumen.

Continuing to move laterally through the neck the two muscles encountered are styloglossus and stylopharyngeus (**Figure 23.6b**). The styloglossus, an extrinsic tongue muscle, is located superior-anteriorly compared to the stylopharyngeus. These are longitudinal muscles that shorten and widen the pharynx, and elevate the larynx during swallowing.

Nerves

The pharyngeal plexus is responsible for the majority of the innervation of the pharynx. The pharyngeal plexus is comprised of branches of; the glossopharyngeal nerve (CN IX), the vagus nerve (CN X) and sympathetic fibres of the superior cervical ganglion.

The sensory supply to the oropharynx is via the glossopharyngeal nerve (CN IX) and the laryngopharynx is supplied by the vagus nerve (CN X). The glossopharyngeal nerve is located between the styloglossus and stylopharyngeus which in turn lie between the superior and middle constrictors. The glossopharyngeal nerve is consistently identified at the junction of the posterior tonsillar pillar and the tongue base.

The motor supply for all the muscles of the pharynx is the vagus nerve except for stylopharyngeus, which is innervated by the glossopharyngeal nerve.

Vascular

The vascular supply for the lateral pharyngeal wall originates from the external carotid. The upper part of the pharynx receives blood from the pharyngeal branch of the ascending pharyngeal artery and descending branches of the lesser palatine arteries. The lower part of the pharynx is supplied from inferior thyroid artery and superior thyroid artery. The rest of the pharynx receives blood from the ascending palatine and tonsillar branches of the facial artery as well as from the maxillary artery (**Figure 23.7**).

The vascular supply to the tonsil is via tonsillar branches of the ascending pharyngeal and facial arteries, occasionally there may also be a branch from the lingual artery. The tonsillar vessels are commonly found on the medial surface and running through the superior constrictor.

Vasculature encountered during surgery for tonsil tumours

The space between the stylopharyngeus muscle and the superior constrictor muscle contains an irregular and complex venous network called the pterygoid venous plexus, which is partly hidden behind the belly of the stylopharyngeus muscle. Beyond the pharyngeal plexus antero-medially along the superior constrictor the ascending pharyngeal artery and the ascending palatine artery, a branch of the facial artery can all be visualized. The facial, lingual and ascending pharyngeal branches of the external carotid artery lie approximately 5–8 mm deep to the styloglossus.[6,8]

Venous drainage of the superior aspect of the pharynx is via the retromandibular and facial veins which drain into the internal jugular vein. The inferior aspect of the pharynx venous drainage is through the pharyngeal plexus. The pharyngeal plexus can drain either into the internal jugular vein or brachiocephalic vein via the inferior thyroid vein (**Figure 23.8**).

LARYNX

The main laryngeal framework is composed of the hyoid bone, the thyroid cartilage; a fusion of two quadrilateral shaped laminae, and the cricoid cartilage (**Figure 23.9**). The larynx is suspended from the hyoid bone by two membranes (also termed ligaments), the medial and lateral thyrohyoid membranes.[1]

Cartilages

The thyroid cartilage attaches anteriorly to the cricoid cartilage through the cricothyroid membrane and posteriorly through the cartilaginous cricothyroid joints. Inferiorly the lower border of the cricoid cartilage is attached to the trachea by the cricotracheal ligament. The medial and lateral thyrohyoid membranes along with the cricotracheal

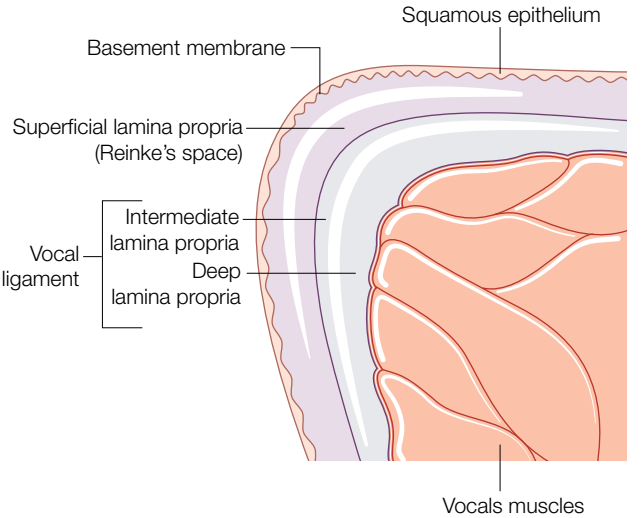

Figure 23.10 The superficial and deep layers of the true vocal cords

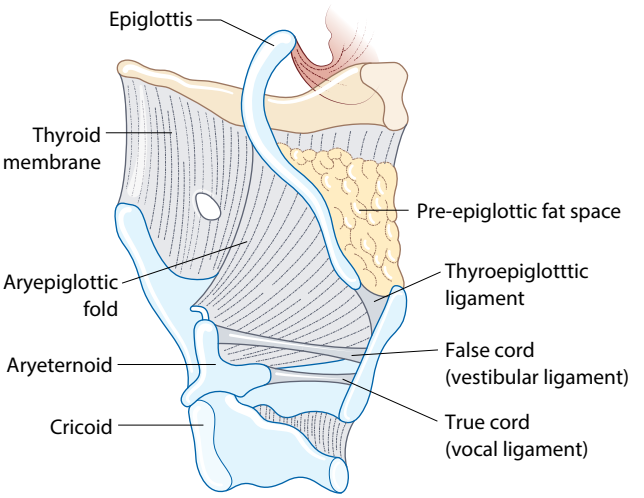

Figure 23.11 Schematic diagram of the larynx in the sagittal plane demonstrating the pre-epiglottic space.

membrane are termed extrinsic ligaments of the larynx. Within the thyroid cartilage, the endolarynx is supported by intrinsic ligaments which lie beneath the laryngeal mucosal membrane forming an internal framework and connecting the internal laryngeal cartilages together.[2] There are two intrinsic fibro-elastic membranes divided by the laryngeal ventricle; the quadrangular membrane, stretching from the arytenoid cartilage to the epiglottis, the free superior border being named the aryepiglottic fold, and the inferior free border forming the ventricular or false vocal fold. The inferior membrane, called conus elasticus, has attachments below to the upper border of the cricoid cartilage, to the mid-point of the thyroid prominence of the thyroid cartilage anteriorly and the vocal process of the arytenoid posteriorly. The free superior edge of the conus elasticus forms the true vocal ligament.

The true vocal cords extend from the angle of the thyroid cartilage to the vocal processes of the arytenoid cartilages. The vocal cords are layered structures with a surface layer of non-keratinizing, stratified squamous epithelium (**Figure 23.10**).

The fusion of the two vocal cords anteriorly produces the anterior commissure tendon. The anterior commissure is an important area for transoral surgery as the epithelium reaches within 1 to 2 mm of the cartilage, there is no perichondrium at this site, and it is a difficult area to expose during surgery. Superior to the anterior commissure the thyroepiglottic ligament attaches the epiglottis to the thyroid cartilage. The epiglottic cartilage extends superiorly and posteriorly forming an important anatomical space within the larynx, the pre-epiglottic space. The pre-epiglottic space is bounded anteriorly by the thyrohyoid ligament, the hyoid bone, and posteriorly by the epiglottis, and superiorly by the hyoepiglottic ligament, connecting the epiglottis to the hyoid bone (**Figure 23.9**).

Posteriorly the vocal cords attach to the vocal process of the arytenoid cartilages (see **Figure 23.11**). The arytenoid cartilages are pyramidal in shape, having a forward projection already mentioned, the vocal process, and a lateral projection, the muscular process to which the posterior cricoarytenoid and lateral cricothyroid muscles attach. These paired cricoarytenoid units are the main functional elements of the larynx involved in speech and swallowing and thus at least one unit must be preserved if meaningful laryngeal function is to be maintained. Two corniculate cartilages articulate with the apices of the arytenoid cartilages. Within the aryepiglottic folds sit two small cuneiform cartilages.

Between the vocal and vestibular ligaments there is a horizontal slit which opens into a recess, the laryngeal ventricle. A diverticulum of the laryngeal ventricle termed the laryngeal saccule extends vertically between the vestibular ligament and the thyroid cartilage. The saccule contains numerous mucous secreting glands to keep the vocal cords lubricated.

The vestibular folds are thick mucus membranes enclosing the vestibular ligament; this being the lower border of the quadrilateral membrane, the superior edge being the aryepiglottic fold (**Figure 23.12**).

Another important anatomical space in laryngeal oncological surgery is the paraglottic space which lies laterally to the conus elasticus and medial to the thyroid cartilage, having the pyriform sinus mucosa as a posterior border (**Figure 23.13**).

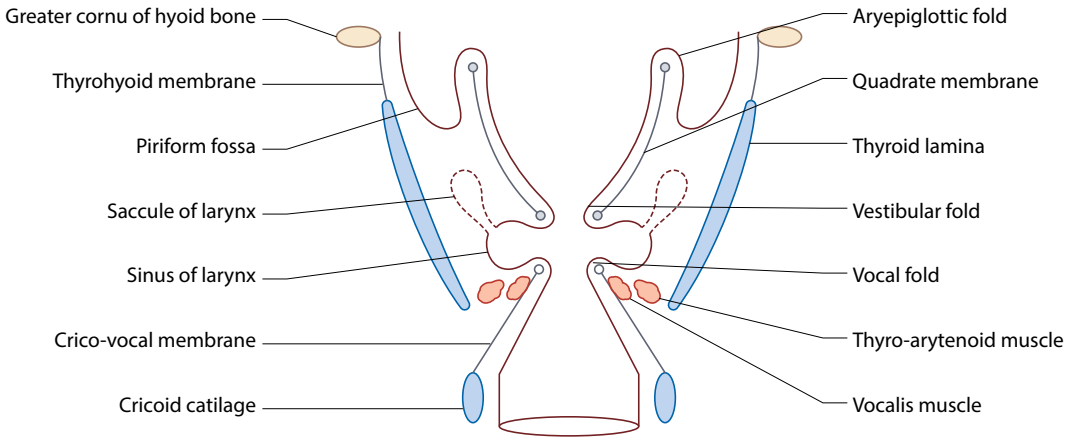

Figure 23.12 Schematic illustration of the endolarynx with the intrinsic membranes, the vestibules and the saccules.

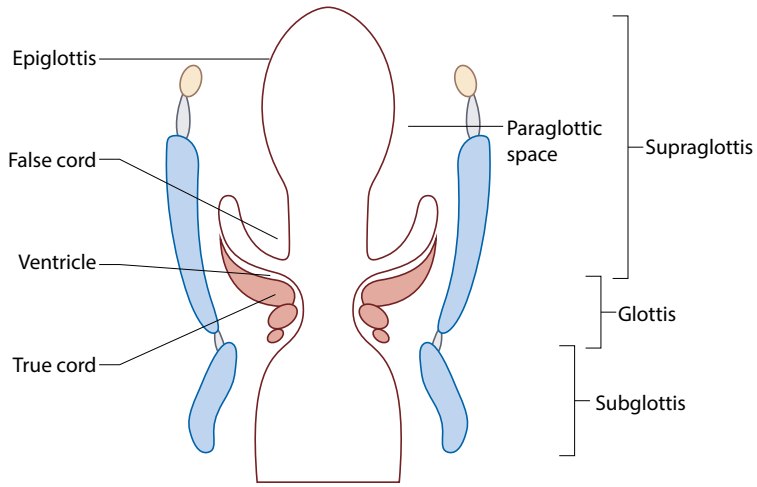

Figure 23.13 Schematic diagram of the larynx demonstrating the paraglottic spaces.

Muscular

The internal laryngeal muscles move the laryngeal cartilages relative to one another, affecting tension and position of the true vocal cords. The thyroarytenoid muscle is a broad flat muscle lying deep to the free edge of the vocal ligament, originating from the thyroid prominence and cricothyroid ligament and inserting in to the vocal process and anterolateral surface of the arytenoid cartilage. The medial portion of the thyroarytenoid muscle is termed the vocalis muscle. The extrinsic portion of the thyroarytenoid muscle inserts anteriorly in to the anterior commissure as thick fibrous tissue known as Broyle's ligament. The intrinsic muscles of the larynx are depicted in **Figure 23.14**.

Vascular

The blood supply to the larynx is derived from the superior and inferior thyroid arteries. The superior laryngeal artery (a branch of the superior thyroid artery) is the artery of main concern regarding post-operative bleeding in TLM / TORS. The superior laryngeal artery courses deep to the thyrohyoid muscle and pierces the thyrohyoid membrane along with the internal branch of the superior laryngeal nerve to enter the larynx.

RELEVANT VASCULATURE ENCOUNTERED DURING SURGERY FOR SUPRAGLOTTIC TUMOURS:

The pharyngoepiglottic fold is important in transoral surgery due to the presence of the neurovascular bundle, comprised of the superior laryngeal artery, superior laryngeal vein and the internal branch of the superior laryngeal nerve (**Figure 23.15**).[3] The artery travels within the pharyngoepiglottic fold to then divide in to five branches:[4] an ascending branch supplies the epiglottis which anastomoses with branches from the lingual artery within the vallecular,[5] other branches supply the ventricle, post-cricoid region, false vocal cords and the thyroarytenoid muscle (**Figure 23.16**). There is a consistent branch of the superior laryngeal artery which runs from posterior to anterior within the undersurface of the false cord. The superior laryngeal artery can generally be found in the superior portion of a triangle formed by the anterior commissure, the vocal process of the arytenoid cartilage, and the attachment of the aryepiglottic fold to the epiglottis.[6,7] Variations of the anatomy of the superior laryngeal artery course exist with a potential for this named vessel being found within the paraglottic space.

The inferior laryngeal artery arises from the inferior thyroid artery and courses with the recurrent laryngeal nerve on the trachea, entering the larynx beneath the

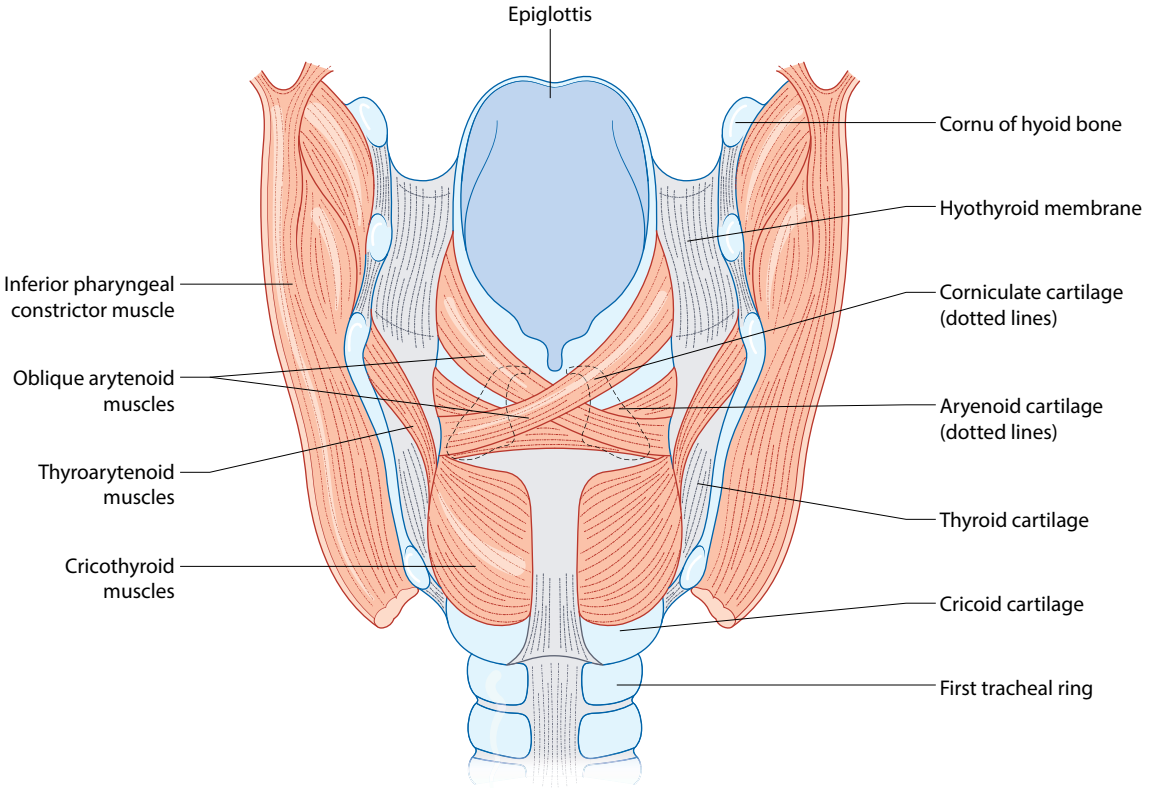

Figure 23.14 A posterior view of the larynx showing the intrinsic muscles of the larynx.

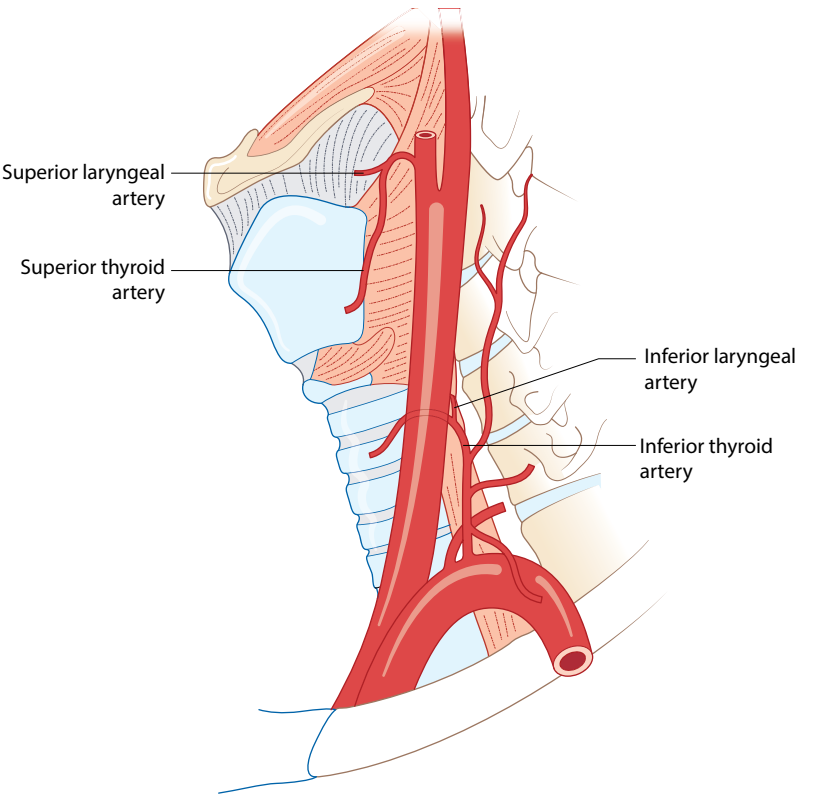

Figure 23.15 The origin and course of the superior laryngeal artery.

lower border of the inferior constrictor. The cricothyroid artery is a branch of the superior thyroid artery and passes across the upper part of the cricothyroid ligament.

Neurological

The motor and sensory supply to the larynx is derived from the vagus nerve. At the level of the greater cornu of the hyoid bone, the superior laryngeal nerve divides in to internal and external laryngeal nerves. The internal branch pierces the thyrohyoid membrane just above where the superior laryngeal artery enters the membrane. The internal laryngeal nerve gives sensory and secretomotor supply to the larynx above the level of the vocal cords (**Figure 23.17**). The branch terminates by piercing the inferior constrictor and uniting with an ascending branch of the recurrent laryngeal nerve; this anastomosis is termed Galen's anastomosis. The internal branch of the superior laryngeal nerve is intimately associated with the superior laryngeal artery and this is an important consideration in oncological resection. This nerve generally splits in to two branches; one which supplies the mucosa above the ventricle and one which supplies the mucosa below the ventricle.[7] If the mucosa superiorly is to be removed as in excision of a supraglottic lesion then preservation of the superior branch is irrelevant. Preservation of the inferior branch which supplies the mucosa below the vestibule along with the hypopharynx could potentially help with the cough reflex preventing aspiration.

KEY POINTS

- A detailed knowledge of the oropharynx, hypopharynx and larynx is essential for all head and neck surgeons.
- The complexities of trans oral surgery turns the conventional anatomy 'inside out', this alternative viewpoint needs to be appreciated before embarking on transoral surgery.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: chemotherapy, induction chemotherapy, concurrent chemotherapy, radiosensitizers, targeted biological agents, recurrent head and neck cancer, metastatic head and neck cancer and EXTREME trial.

INTRODUCTION

Chemotherapy alone cannot cure head and neck cancer. It is used in conjunction with other treatments, surgery and radiotherapy, to improve outcomes such as better local control, organ preservation with continued organ function and decrease the incidence of subclinical micrometastatic spread. Chemotherapy is given for its direct tumouricidal effect, at both the local primary and distant metastatic sites. If given with radiotherapy it can have a radio-sensitizing effect, making cancer cells more susceptible to radiotherapy and increasing the cancer cell kill.

If the cancer has already caused organ destruction and there is no future option to maintain organ function, then surgery with or without adjuvant radiotherapy may give the best chance of cure and long-term survival. Organ preservation is pointless if the patient is left with a non-functioning organ, especially if it may lead to future problems such as aspiration. Chemotherapy can be used in this situation as well. It may be used as induction chemotherapy to shrink the advanced primary tumour or shrink and render fixed cervical nodes mobile, potentially enabling technically easier surgery.

In locally advanced head and neck cancer, chemotherapy can be used at different points in the patient pathway. Chemotherapy is not given routinely for early primary T1/T2 disease, without nodal involvement. It can be used as induction or neoadjuvant treatment before the primary treatment, be that surgery or radiotherapy; but if used for induction this is almost always before radiotherapy rather than surgery as its use would inevitably delay surgery. However, the preparatory processes before radiation therapy, such as manufacturing an immobilization device and creating a radiotherapy plan, consume time and these can take place while the patient is having induction chemotherapy, thereby bringing forward the initial treatment start date.

If induction chemotherapy is used, further chemotherapy is usually given with subsequent radiotherapy, and this is known as concomitant chemotherapy, which is more commonly used; only a minority of patients receive induction regimens.

Adjuvant chemotherapy, which is treatment given after the principal treatment, is not used as a sole modality after radiotherapy, as it has not been shown to have benefit in this setting; however, when given with adjuvant radiation, it has been shown to improve local control and increase survival where primary surgery has been the definitive treatment. This benefit is seen in patients who have a higher risk of recurrence with positive surgical margins, nodal involvement, especially multiple nodes involved or extra capsular spread.

CHEMOTHERAPY AND HPV-POSITIVE TUMOURS

Human papillomavirus (HPV) is known to have an aetiological role in introducing head and neck cancers, especially in the oropharynx where HPV infection may be linked to 50–80% of tumours. There is also some growing evidence for HPV associated non-oropharyngeal tumours.[1] HPV-positive and -negative head and neck cancers are thought to represent distinct diseases with differing natural histories and prognosis. There is evidence from several studies, for example RTOG 0129, that outcomes are better following treatment in patients with HPV-positive tumours.[2] However, much of this evidence is retrospective, with completed trials being re-interrogated for patients' HPV status, often without complete data being available for all patients entered into these trials. As prospective evidence builds, HPV-positive patients do appear to have better outcomes following treatment when compared to HPV-negative patients. There is also growing evidence that continuing to smoke negates the benefit of the better prognosis given by HPV positivity.

Despite this growing evidence that HPV-positive patients have better outcomes, at present there are not enough robust data to alter chemotherapy or indeed radiotherapy treatment regimens depending on the patient's HPV status, outside of the context of a clinical trial.

There is considerable interest in reducing treatment for patients with HPV-positive tumours and multiple trials are underway worldwide addressing this question.[3–5]

INDUCTION (NEOADJUVANT) CHEMOTHERAPY

As interest in organ function preservation grew, induction chemotherapy was considered to have the potential for several benefits.

If induction chemotherapy could shrink primary tumour volumes before the principal treatment of radiotherapy or chemoradiotherapy, this might allow better blood flow into the tumour allowing a greater tumouricidal dose of drugs to be delivered and decrease the volume of hypoxic areas, which would decrease the radioresistance that hypoxic cancer cells show. If induction chemotherapy could improve local control, there would be a greater chance of functional organ preservation. Since surgery and radiotherapy are both locoregional treatments, induction chemotherapy could theoretically treat distant subclinical metastatic disease.

The response to neoadjuvant chemotherapy could give important prognostic information, as it can act as a surrogate marker for response to later treatment. This latter advantage was used in one of the earliest trials of neoadjuvant chemotherapy for organ preservation, the Veterans trial, in which the patients were given two cycles of cisplatin and 5-fluorouracil followed by response assessment; if there was a response to chemotherapy, patients went on to have chemotherapy and radiotherapy but if there was no response, the patients went directly to laryngectomy.[6]

Most patients who have had induction chemotherapy go on to have concurrent chemotherapy as well. There is a risk that patients undergoing induction chemotherapy may be more at risk of not completing or having breaks in the subsequent definitive radiotherapy treatment because of the morbidity induced by induction chemotherapy, which would result in poorer outcomes.

One of the main evidence sources for the use of chemotherapy in head and neck cancer is the meta-analysis of chemotherapy in head and neck cancer (MACH-NC), which was originally published in 2000 and updated in 2007 and 2009.[7–9] These overviews reviewed more than 90 trials containing data on more than 16 000 patients, with overall survival as the primary endpoint. The analysis failed to show an overall survival benefit from the use of induction chemotherapy when compared to primary surgery or radiotherapy alone, although cisplatin and 5-fluorouracil (5-FU) as a combination did show some benefit. However, these reviews did suggest that induction chemotherapy may reduce the incidence of distance metastases, more effectively than concurrent chemotherapy.

There is still debate as to whether induction chemotherapy followed by concurrent chemoradiotherapy is more beneficial than concurrent chemoradiotherapy alone. Some large trials have shown no benefit[10] while others have shown some.[11] Interest was rekindled in induction chemotherapy when two trials, one European and one from North America, 'TAX 323' and 'TAX 324' showed benefit by including a taxane, such as docetaxel or paclitaxel in the induction chemotherapy regime in addition to cisplatin and 5-FU.[12, 13] Response rates and survival outcomes were higher with taxane-containing regimens but toxicity was considerably higher and chemotherapy-related deaths were also increased with these regimens. Such sequential regimens are offered to patients with good performance status and fewer comorbidities, and those with bulky nodal disease, stage N2b and above, and where surgery is not appropriate.

CHEMOTHERAPY REGIMENS USED IN INDUCTION CHEMOTHERAPY

The standard regimen was formerly cisplatin 100 mg/m² and 5-fluorouracil, 1 g/m² per day for 4–5 days via a chemotherapy infusion bottle. This was given 3-weekly for two to three cycles, before definitive treatment. The definitive treatment is almost always concurrent chemoradiotherapy, except in a few cases where induction chemotherapy can be used in the hope of converting inoperable locoregional disease to more surgically manageable disease.

The European TAX 323 and the North American-based TAX 324 trials[12, 13] produced evidence that adding a taxane, such as docetaxel or paclitaxel to cisplatin and 5-FU (i.e. TPF vs PF) did improve survival in the TPF arm, but at a cost of much higher toxicity, both

haematological with myelosuppression and neutropenia and non-haematological, especially increasing mucositis.

In TAX 323, no concurrent chemotherapy was given with subsequent radiotherapy and in TAX 324, concurrent carboplatin was used. This has led to some criticism that the most optimal concurrent chemotherapy available was not given in the studies. The TPF doses were also different in each of these trials. Both studies did show TPF gave better overall survival than cisplatin and 5-FU alone.
