The results for stapling and laser division are similar. Stapling has the theoretical advantage of reducing the risk of perforation and mediastinitis, whereas the laser permits a better view when there is limited access.

Cricopharyngeal myotomy as a sole procedure has a role in the treatment of the very small pouch. There remain some indications for pouch excision. The experience of the surgeon appears to be of the utmost importance. At times, pouch surgery can be difficult and the complications life-threatening. Surgeons who have developed an interest in pouch surgery sufficient to publish large series have the best results.

BEST CLINICAL PRACTICE

- ✓ When operating, strive to obtain a good view.
- ✓ Treat tissues with great respect.
- ✓ Carry out a biopsy for abnormal mucosa.
- ✓ If there is significant trauma, insert a nasogastric tube.
- ✓ For a small perforation, use an endoscopic suture.
- ✓ For a large perforation, open the neck and repair.
- ✓ Post-operative contrast studies are unhelpful.

FUTURE RESEARCH

- ➤ The very small pouch is difficult to treat endoscopically. Changes in the design of the stapling device might help resolve this problem, namely a device that cuts and staples along the whole length of its jaws.
- ➤ Access is difficult in 20% of patients. Improvements in endoscopes and viewing telescopes may reduce the degree of difficulty.

- The recurrence rate for all types of pouch surgery is high and may be related to persistent gastric reflux. Aggressive treatment of the gastro-oesophageal reflux may be appropriate but the evidence is lacking.
- Following all types of pouch surgery, patients are rarely completely asymptomatic and it would be useful to have a method for treating these residual symptoms, which are probably due to an underlying neuromuscular incoordination.
- Randomized controlled trials comparing new techniques with established treatments are justified.
- In the UK, virtually all pharyngeal pouch surgery is now performed by ENT surgeons. Subspecialization is slowly happening and is to be encouraged so that, within each major centre, only ENT surgeons with a special interest in pouch surgery should manage pouch patients.

KEY POINTS

- Cricopharyngeal dysphagia results from the failure of the cricopharyngeal muscle to relax. It can occur with or without the formation of a pharyngeal pouch.
- Pharyngeal pouch occurs in elderly, sometimes frail, patients.
- Incidence is one per 100 000 per year.
- Diagnosis is made with a barium or video swallow.
- Surgery improves quality of life.
- Endoscopic resection with a stapling device or laser is generally considered the first-line treatment for most pouches.
- Recurrence is easily treated with endoscopic techniques.
- Carcinoma is rare but vigilance is required.
- Surgeons with a special interest in pouch surgery should treat all patients.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: gastro-oesophageal reflux disease, Barrett's oesophagus, oesophageal motility, oesophageal achalasia, oesophageal cancer, oesophageal perforation, oesophageal disruption, Boerhaave's, oesophageal foreign body, eosinophilic oesophagitis. The fifth edition of the textbook *Oesophagogastric surgery* was also consulted in preparing this chapter.[1]

INTRODUCTION

A broad spectrum of benign and malignant conditions affects the oesophagus. This chapter concentrates on the main conditions dealt with by upper gastrointestinal surgeons and some gastroenterologists, recognizing that some patients present first to the ENT surgeon depending on the predominant symptoms. Malignant disease and several of the less common benign conditions are managed in specialist oesophagogastric centres in order to improve knowledge, achieve standardization of treatment and, most importantly, improve outcomes.

GASTRO-OESOPHAGEAL REFLUX

Gastro-oesophageal reflux disease (GORD) is extremely common, with symptoms triggered by food, gastric acid or bile from the duodenum travelling back up into the oesophagus.

Presentation

The most common symptoms include retrosternal pain, heartburn, dyspepsia, waterbrash, pain on swallowing, regurgitation and vomiting. Symptoms typically become apparent after meals or when lying supine. A small minority of patients present with atypical symptoms related to proximal reflux. These include voice changes, coughing, sore throat, throat clearing or even sinusitis. Reflux and micro-aspiration might account for worsening of respiratory symptoms in patients with underlying lung disease.

Risk factors include being overweight, smoking, overeating and leaving only a short interval between meals and sleeping. Spicy foods and alcohol are commonly recognized as substances that precipitate symptoms. The underlying mechanisms for developing reflux can include the presence of a sliding hiatus hernia, a reduction in lower oesophageal sphincter pressure, an increase in the number of lower oesophageal sphincter relaxations, abnormal oesophageal peristalsis that fails to clear any refluxate, poor gastric motility and excessive gastric acid production.

Investigation

All patients over 40 with new onset reflux or a change in long-standing reflux symptoms should be referred for urgent flexible endoscopic assessment. This is not only to identify signs of reflux disease but also to exclude malignancy. Endoscopy should be performed while patients are not on any acid-lowering treatment. Appearances might demonstrate oesophagitis, the presence of a sliding hiatus hernia that would predispose to reflux disease, bile reflux or acid-related strictures or they might be normal (**Figure 53.1**).

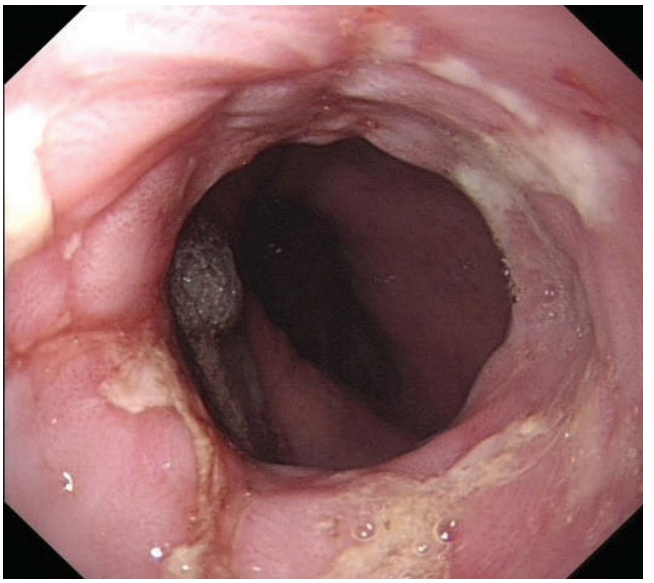

Figure 53.1 Endoscopic view of moderate oesophagitis above a sliding hiatus hernia.

Further investigation is only required in a minority of patients where endoscopic appearances are equivocal in supporting the diagnosis (particularly in cases where non-acid reflux is suspected), if surgery is being contemplated, or in cases of suspected proximal reflux.

Oesophageal manometry assesses the adequacy of peristalsis and can identify any underlying motility disorders. A fine catheter placed in the oesophagus records pressures at rest and during the passage of 10 swallows at various levels along the oesophagus and the oesophagogastric junction. Conventional manometry uses eight channels and displays results as a line graph (**Figure 53.2**). Developments in catheters and software has allowed the introduction of high-resolution manometry, where up to 32 channels can be used to give more detailed information and produces images with contrasting colours to represent differential pressure levels (**Figure 53.3**).

Oesophageal 24-hour ambulatory pH monitoring will reveal whether the oesophagus is exposed to acid content for a pathological length of time (pH<4 for more than 5% of the 24-hour period) and allows for correlation with

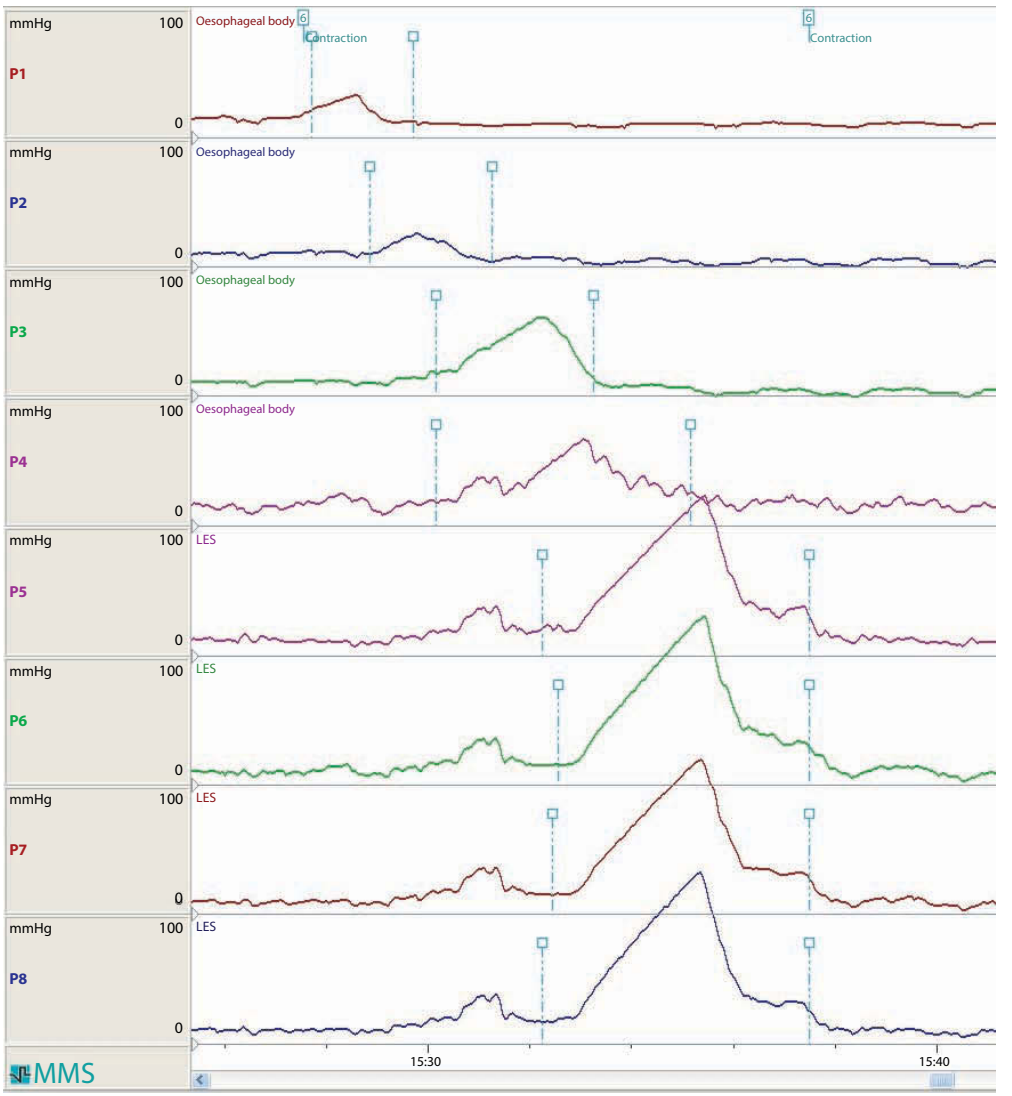

Figure 53.2 Conventional eight-channel manometry demonstrating normal peristalsis within the oesophageal body.

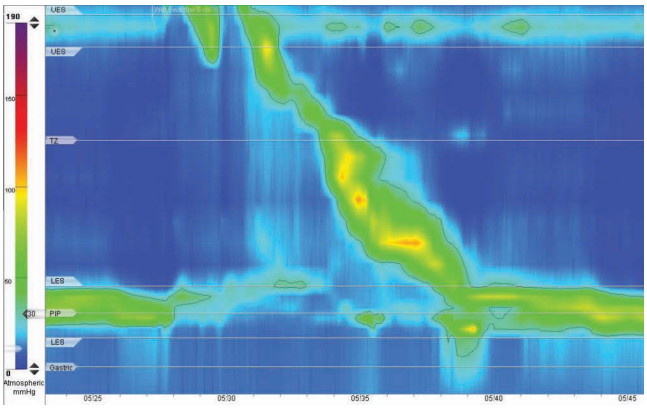

Figure 53.3 Appearances of high-resolution manometry in a normal oesophagus.

any symptoms the patient experiences. Impedance studies are required only in cases of suspected proximal reflux or when non-acid reflux is implicated as the underlying cause. Bile reflux monitoring is possible although is not commonly used. Contrast radiology in the form of a barium swallow can be useful to exclude underlying dysmotility and may also demonstrate reflux.

Management

The overwhelming majority of patients with reflux disease will be managed successfully by addressing risk factors and simple antacids, with proton pump inhibitors required in those with more severe symptoms. The few patients who fail this treatment strategy can be assessed for anti-reflux surgery once the additional investigations have excluded dysmotility and shown evidence of oesophagitis on endoscopy or abnormal acid exposure during 24-hour pH monitoring.[2, 3] Appropriate patient selection is crucial to achieving successful outcomes from antireflux surgery as the potential effects of fundoplication in the wrongly selected patient are disabling.

The standard operation involves a fundoplication where the fundus of the stomach is wrapped around the gastro-oesophageal junction. This is performed laparoscopically in most centres because of reduced post-operative pain and length of hospital stay (often day case) although open surgery perhaps improves the longevity of the fundoplication.[4] A floppy Nissen fundoplication involves a loose, posterior 360-degree wrap combined with tightening of the crura, although variations are practised.[5–8] Whether tailoring of the wrap improves outcomes is not conclusive.[9] Complications from surgery include dysphagia, retrosternal pain, gas bloat, excess flatus and oesophageal perforation. Revisional antireflux surgery is challenging and includes patients with short-term as well as long-term symptom recurrence.[10] Resumption of proton pump inhibitor treatment will suffice in many cases although revisional fundoplication is an option. Subtotal gastrectomy and a roux-en-y reconstruction is reserved as a definitive procedure to relieve intractable symptoms. Newer endoscopic and robotic antireflux techniques remain unproven.[11, 12]

Reflux disease appears to accelerate the development of bronchiolitis obliterans in some lung transplant recipients.[13] This has led to antireflux surgery being considered in such patients.[13] Ongoing research is needed to determine which of these patients are most likely to benefit and to decide upon the optimal timing of such procedures. This mechanism is being extrapolated to patients with other respiratory diseases who do not exhibit symptoms traditionally associated with reflux. In future antireflux surgery might be beneficial in preventing reflux-associated lung damage from microaspiration in this group of patients.

KEY POINTS

- Reflux symptoms are common.
- Upper respiratory tract symptoms are rarely due to reflux.
- Patients over 40 with recent onset reflux symptoms need an endoscopy.
- Most patients with reflux disease are managed with lifestyle modification and proton pump inhibitors.
- Only a minority of patients will require surgery (floppy Nissen fundoplication).

BARRETT'S OESOPHAGUS

Barrett's oesophagus develops when the normal oesophageal lining changes from stratified squamous to columnar epithelium (**Figure 53.4**). It is common in the Western world and has an increasing incidence. It occurs as a result of chronic inflammation secondary to acid, alkaline and bile reflux.[14–16] Genetic factors might also increase an individual's predisposition to this condition and its progression.[17] This metaplastic epithelium increases the risk of developing adenocarcinoma of the oesophagus.[18–20] A formal diagnosis of Barrett's requires the reporting of two separate specimens from a specialist gastrointestinal pathologist. Dysplastic changes within the Barrett's epithelium can occur, subclassified as either low-grade or high-grade. Confirmed low-grade dysplasia increases the risk of progression on to high-grade dysplasia or adenocarcinoma although some will not progress.[21, 22] High-grade dysplasia poses a significant risk of developing adenocarcinoma and, given the subjectivity of biopsies, might indicate that there is adenocarcinoma already present. Patients with a diagnosis of low- or high-grade dysplasia within Barrett's oesophagus should be referred to specialist centres for management.

Surveillance

Enrolment of patients in to an endoscopic surveillance programme improves identification of dysplastic changes before the onset of adenocarcinoma and potentially allows less invasive treatment.[23] Despite the logical advantage of surveillance on an individual basis, definitive evidence of benefit has not yet been produced. A randomized study comparing endoscopic surveillance versus symptomatic presentation designed to determine whether surveillance improves survival in patients with Barrett's oesophagus

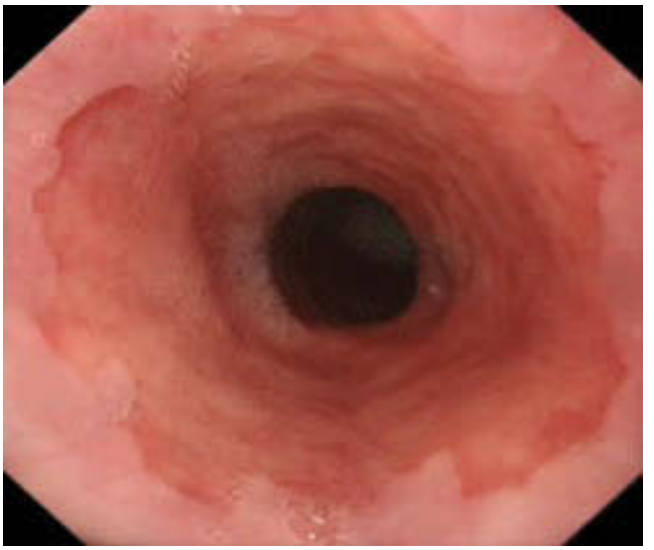

Figure 53.4 Macroscopic appearance of circumferential Barrett's oesophagus.

completed recruitment in 2012. Research using less invasive screening devices that could perhaps identify patients needing endoscopy is ongoing.

Management

The development of Barrett's oesophagus does not require treatment other than addressing risk factors for reflux disease, prescribing proton pump inhibitors to reduce acid reflux and endoscopic surveillance. There is no evidence to suggest that antireflux surgery, which will prevent both acid and alkaline reflux, is superior to medication at preventing progression of the condition.[24, 25]

The development of high-grade dysplasia within Barrett's oesophagus requires full staging to exclude an underlying malignancy with computed tomography (CT), flexible videoendoscopy and endoscopic ultrasound (EUS). Endoscopic mucosal resection (EMR) to obtain a more substantial biopsy might be required (see below). The confirmation of dysplasia will trigger consideration of further treatment.

Radiofrequency ablation

Radiofrequency ablation (RFA) is a newer endoscopic treatment used to destroy dysplastic epithelium.[26] It is indicated in high-grade dysplasia when complete assessment and staging have shown an otherwise normal oesophagus with a flat mucosal lining and an underlying adenocarcinoma has been excluded. It is often used following EMR of a nodular area of Barrett's. Long-term results from this treatment are lacking and there remain concerns about occult neoplasia developing beneath the ablated epithelium.[27] Repeated treatment applications are often required with potential complications of perforation and stricture formation. Intensive endoscopic surveillance is required following treatment to detect any recurrence or new dysplasia that require repeat application or repeat staging. Long-term follow-up of this treatment is awaited and prospective registration of all cases should ensure accurate data.[28] Indications for RFA are likely to expand to include low-grade dysplasia to prevent progression.

Surgery

Oesophagectomy still remains the gold standard for high-grade dysplasia in Barrett's oesophagus as it provides definitive cure. It is indicated when nodal disease is evident on staging suggesting undiagnosed invasive adenocarcinoma, the length of Barrett's oesophagus is extensive or multifocal, the oesophagus is otherwise abnormal or the patient is young. Morbidity and mortality have reduced considerably in oesophagectomy and can be performed with a low mortality and acceptable morbidity. In cases of high-grade dysplasia in Barrett's oesophagus, mortality appears even lower, with one review showing a 1% mortality in 530 patients.[29] More limited resection techniques have also been used.[30]

KEY POINTS

- Barrett's oesophagus increases the risk of developing oesophageal adenocarcinoma.
- Endoscopic surveillance should be offered to patients with Barrett's oesophagus.
- High-grade dysplasia within Barrett's oesophagus indicates the need for full staging and referral to a specialist centre.
- Radiofrequency ablation is a new alternative to surgery to treat high-grade dysplasia in selected cases but long-term results are awaited.
- Oesophagectomy remains the gold-standard treatment for high-grade dysplasia in Barrett's oesophagus.

OESOPHAGEAL CARCINOMA

Incidence

Oesophageal carcinoma is the eighth most common cancer worldwide, with an estimated incidence of 480 000 in 2008.[31] The two predominant types are adenocarcinoma and squamous cell carcinoma. Adenocarcinoma and squamous cell carcinoma differ in several of their risk factors, predominant location within the oesophagus, response to chemotherapy and radiotherapy, and overall survival. Rare cancer types include small cell carcinoma, primary melanoma, malignant stromal tumours and leiomyosarcoma.

The incidence of oesophageal carcinoma increases considerably after the age of 40, with a peak between 70 and 74 years of age for men and a continual rise for females. The cancers have a strong preponderance in affecting males more than females in a 2–4 : 1 ratio.[31]

OESOPHAGEAL ADENOCARCINOMA

This histological subtype predominates in the Western world, accounting for over two-thirds of all oesophageal cancers diagnosed (**Figure 52.5**). The incidence of adenocarcinoma in the Western world is continuing to increase and is the source of concern.[32] These cancers have a

Figure 53.5 Appearance of an oesophageal adenocarcinoma after fixation of the specimen.

tendency to occur in metaplastic columnar epithelium of the middle and lower thirds of the oesophagus or at the oesophagogastric junction. There are concerns that adenocarcinoma might increase in the Far East as Western lifestyles and habits spread.[33] There has also been an increase in the number of oesophagogastric junction adenocarcinomas, seemingly a result of oesophageal cancers migrating distally and gastric cancers migrating proximally over time.

The main risk factors include obesity, reflux disease and the presence of Barrett's oesophagus.[18, 34–36] Smoking, excessive alcohol consumption, a family history of gastrointestinal cancer and diets low in fresh fruit and vegetables are all also implicated in increasing risk of developing oesophageal adenocarcinoma.

OESOPHAGEAL SQUAMOUS CELL CARCINOMA

In contrast squamous cell carcinoma of the oesophagus still predominates in the Far East. These cancers tend to occur in the cervical oesophagus and the upper parts of the thoracic oesophagus. Smoking, high alcohol intake, low socioeconomic status, hot drinks and diets low in fresh fruit and vegetables are strong risk factors in developing squamous cell carcinoma.

Presentation

Presentation often occurs late as many of the early symptoms are non-specific and patients often do not seek medical advice. Attempts at increasing awareness of risk factors and symptoms are important as early disease improves chances of offering curative treatment. Many of the symptoms overlap with benign reflux disease and dysmotility (**Box 53.1**). Early flexible videoendoscopy is essential to capture the patients that have cancer as the underlying cause. Respiratory symptoms can occur due to more proximal reflux and microaspiration from obstruction. Surveillance of patients with Barrett's oesophagus and those with significant family history is designed to identify premalignant changes or early disease.

BOX 53.1 Symptoms suggestive of oesophageal cancer

- New onset or worsening heartburn or reflux in patients aged over 40
- Dysphagia
- Early satiety
- Loss of appetite
- Unexplained weight loss
- Vomiting or haematemesis (less common)
- Voice changes or a persistent cough (less common)

Diagnosis and staging

Diagnosis is made by flexible videoendoscopy, following which patients require fitness assessment, staging investigations and formal discussion at a specialist oesophagogastric multidisciplinary team (MDT) meeting (**Figure 53.6**). These are coordinated through centralized units. This MDT meeting involves oesophageal surgeons, medical and clinical oncologists, radiologists, pathologists, specialist nurses, dieticians, palliative care nurses and a coordinator.

Fitness investigations require a thorough history and examination of the patient, an electrocardiogram, spirometry and a timed exercise test. Formal cardiopulmonary exercise testing (CPET) has been introduced to help objectively measure a patient's fitness in order to quantify risks of treatment.[37, 38] CPET can identify undiagnosed cardiorespiratory comorbidity that might be amenable to treatment before any potential surgery although its precise value is yet to be determined.

Oesophageal cancer and oesophagogastric junction cancers that predominantly involve the oesophagus are staged using the seventh edition of the tumour, node, metastasis (TNM) classification[39, 40] (**Table 53.1**).

Precise identification of the location and depth of the primary cancer, the location and numbers of lymph nodes involved, and the total length of disease taking into account involved lymph nodes will determine available treatment options. Staging investigations as a minimum will include endoscopy, and a gastric protocol CT of the chest, abdomen and pelvis (**Figures 53.7**).

Most patients require additional investigations (**Box 53.2**). EUS is better than CT at identifying local nodes and depth of invasion (**Figure 53.8**). Tumours that demonstrate invasion into the muscular layers of the oesophagus (T3) or involvement of nodes require

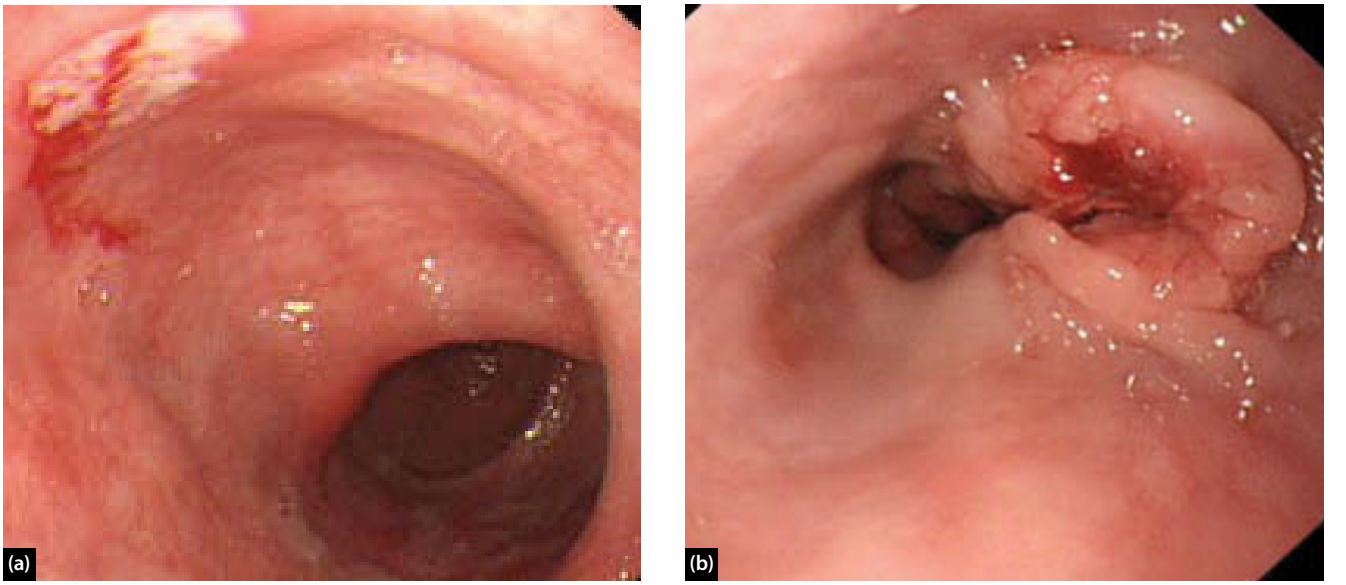

Figure 53.6 The endoscopic appearances of two different oesophageal cancers.

TABLE 53.1 TNM classification of oesophageal cancer

additional staging with either bone scan or positron emission tomography (PET-CT) (**Figure 53.9**).

EMR is often required to obtain a more substantial biopsy for small lesions that have inconclusive histology. It may provide a therapeutic option (see below). Neck ultrasound is useful at diagnosing suspicious nodal disease in the neck and can guide fine-needle aspiration cytology. Bronchoscopy and endobronchial ultrasound are occasionally required. Staging laparoscopy is required in patients who have evidence of gastric involvement in locally advanced cancers.

Management

Management is determined by the patient's fitness to undergo radical treatment, the patient's wishes, the stage of the disease and the histological type of cancer.[41, 42] Early cancers include those that are limited to the mucosa,

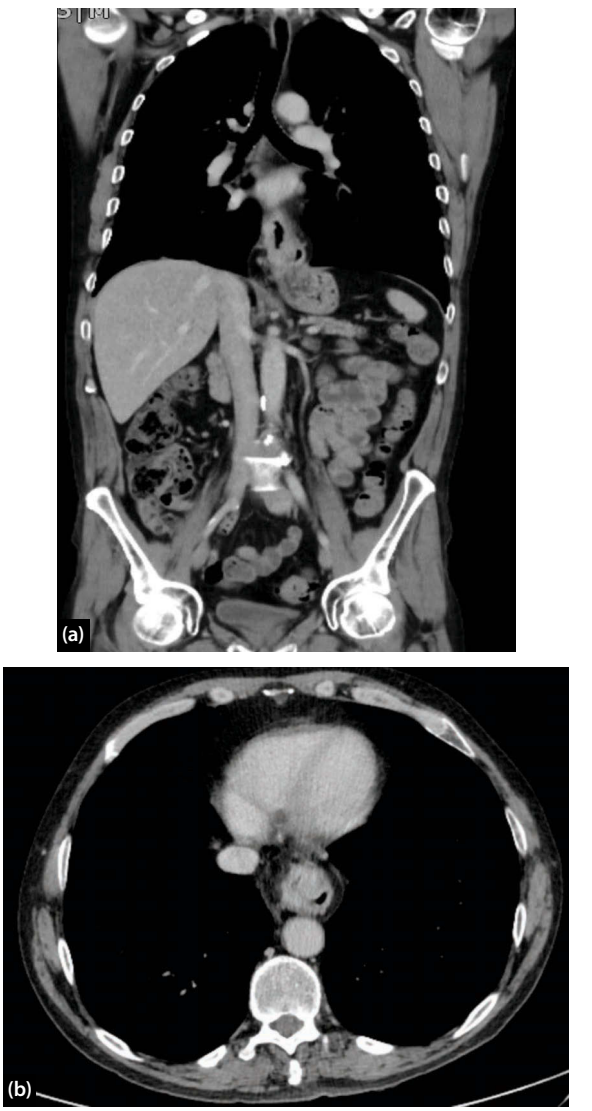

Figure 53.7 CT images demonstrating the presence of a polypoidal tumour in the lower oesophagus and a hiatus hernia.

BOX 53.2 Staging investigations in oesophageal cancer

All patients require endoscopy and CT. The majority also require endoscopic ultrasound and bone scan or PET-CT. Other investigations are selected on an individual case basis.

- Flexible videoendoscopy
- CT chest, abdomen, pelvis (gastric protocol)
- Endoscopic ultrasound
- Bone scan
- Positron emission tomography (PET-CT)
- Neck ultrasound +/– fine-needle aspiration
- Bronchoscopy
- Endobronchial ultrasound
- Staging laparoscopy
- Endoscopic mucosal resection

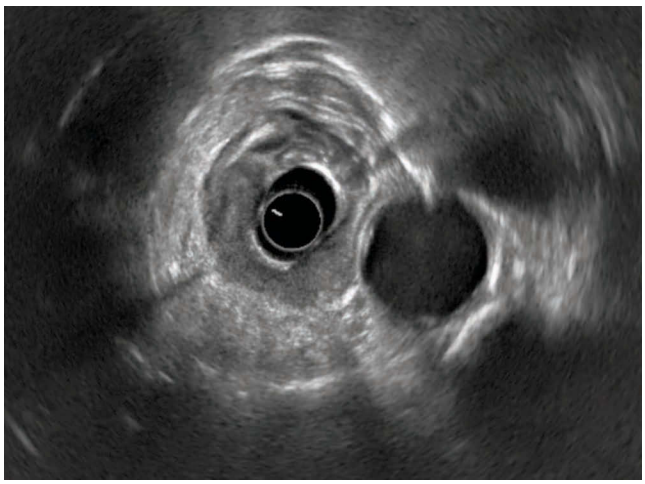

Figure 53.8 Endoscopic ultrasound image demonstrating a T3 oesophageal cancer posteriorly.

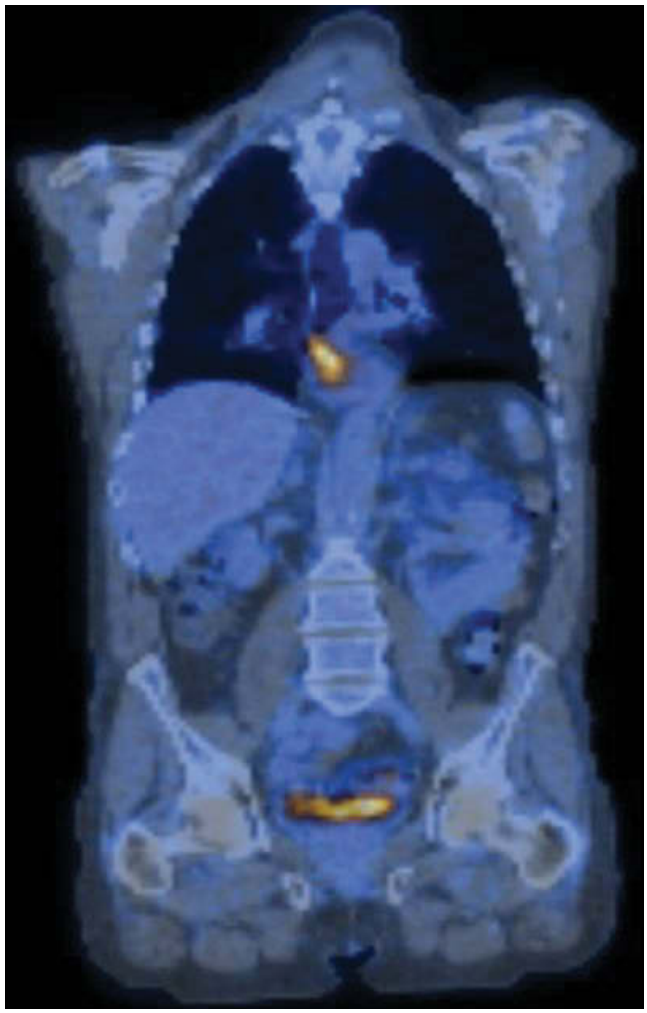

Figure 53.9 A PET-CT image demonstrating high uptake of FDG in a cancer of the lower oesophagus.

submucosa or to the muscularis propria where there is no evidence of nodal involvement on clinical staging (*c*T1/2 N0). Locally advanced cancers can be considered those cancers where there is evidence of lymph node involvement within surgically resectable fields or within the scope of radical radiotherapy in relevant cases of squamous cell carcinoma such that treatment is of curative intent.

NEOADJUVANT AND ADJUVANT CHEMOTHERAPY

For oesophageal cancer that is clinically staged as either reaching adventitia (T3/4) or with nodal involvement (N1-3), neoadjuvant chemotherapy or chemoradiotherapy followed by restaging and surgery is the recognized treatment pathway, with adjuvant chemotherapy then considered following surgery.

The benefit of chemotherapy was originally demonstrated by the Medical Research Council (MRC) OE02 study in which patients were randomized to receiving surgery alone or two cycles of cisplatin and 5-fluorouracil followed by surgery.[43] The patients who received neoadjuvant chemotherapy demonstrated an overall survival advantage of 6% at 5 years.[44] This regimen is currently still used in squamous cell carcinoma in the UK although is likely to be superseded by neoadjuvant chemoradiotherapy based on a similar chemotherapy regimen supplemented with neoadjuvant radiotherapy.

In oesophageal adenocarcinoma, neoadjuvant chemotherapy in the UK is based on the MRC adjuvant gastric infusional chemotherapy (MAGIC) trial that evaluated the benefit of administering three cycles of epirubicin, cisplatin and capecitabine in the neoadjuvant setting followed by a further three cycles in the adjuvant setting.[45] This trial was originally designed for gastric adenocarcinoma but included lower-third oesophageal and oesophagogastric junction adenocarcinoma. It demonstrated a 13% survival advantage at 5 years. A further study (OE05) comparing two cycles of neoadjuvant cisplatin and 5-fluorouracil to four cycles of epirubicin, cisplatin and capecitabine completed recruitment in 2011. A recent meta-analysis has confirmed the benefit of neoadjuvant chemotherapy.[46]

Current trials are assessing whether anti-angiogenic agents confer additional survival advantage, and preliminary investigations evaluating agents targeting growth factor receptor antagonists have also started.

NEOADJUVANT CHEMORADIOTHERAPY

Chemoradiotherapy in the neoadjuvant setting was previously reported in the UK but was abandoned in favour of neoadjuvant chemotherapy after reports of increased morbidity and mortality. Other countries continue to use neoadjuvant chemoradiotherapy, although regimens in each country differ. Newer chemoradiotherapy regimens do not appear to affect morbidity as in the past. Although there are few randomized trials comparing neoadjuvant chemotherapy to neoadjuvant chemoradiotherapy, a recent meta-analysis and a randomized trial suggest there is an additional survival advantage without an increase in morbidity.[47, 48] Squamous cell cancers are recognized as being more sensitive to chemoradiotherapy and most of the benefit highlighted in the recent trial was in patients with squamous cell carcinoma. Neoadjuvant chemoradiotherapy is likely to become the standard for squamous cell carcinoma. Whether the same occurs for oesophageal adenocarcinoma will depend on the outcomes of future appropriately powered studies designed to evaluate whether neoadjuvant chemoradiotherapy offers a survival advantage without additional morbidity to patients over neoadjuvant chemotherapy.

Surgery

The principles of oesophagectomy were established many years ago. Surgery is only undertaken with curative intent, when a complete (R0) resection is expected based on the staging investigations. There is no role for oesophagectomy in a palliative setting. An en bloc resection is performed with a radical two- or three-field lymphadenectomy.[49, 50]

LYMPHADENECTOMY

Current radiological staging investigations are not accurate enough to predict the lymph node status following resection in all patients. A standardized, radical lymphadenectomy is therefore performed in all patients to offer the best chance of cure. Evidence has accumulated that the extent of lymphadenectomy improves disease staging but more importantly improves overall survival and reduces locoregional recurrence rates.[51, 52] Patients in whom there is no evidence of nodal disease within the resection specimen are perhaps overtreated by the lymphadenectomy but this observation can only be made once all the lymph nodes have been examined by a pathologist. Patients with extensive nodal involvement are at high risk of having occult metastases and developing early recurrence. However, without the full lymph node resection for pathological analysis this cannot be determined. It must be remembered that for any given individual it is impossible to predict long-term outcome. The contribution of radical lymphadenectomy to the morbidity of oesophagectomy is difficult to quantify although the overall reduction in morbidity from resection and the improvements in lymph node yields suggest that in the majority of patients the lymph node dissection can be performed without additional burden.

In-hospital mortality following oesophageal resection has reduced to 2.9% in the UK while other major centres in the world also report improvements in mortality.[53, 54] This reduction is the result of a number of factors including earlier diagnosis, improvements in pre-operative patient assessment and selection, peri-operative care, and post-operative recognition and management of complications. Specialist oesophagogastric centres have been established that concentrate expertise and increase hospital and surgeon volume, with good evidence to suggest this approach improves outcomes.[55]

SURGICAL APPROACH[1]

The stomach is the preferred organ to use as the conduit following oesophagectomy. Colon is used in patients with previous gastric surgery rendering the stomach unsuitable or when there is extensive gastric involvement with the cancer. Either the right colon or transverse colon can be used. Colon is not considered as the primary choice owing to its functional deterioration over time. Jejunum can also be considered in certain circumstances.

Open surgery

Several different approaches can be used. For middle- and lower-third cancers, a two-stage transthoracic resection is the preferred approach. An upper midline incision is used, to allow for gastric mobilization with preservation of the right gastroepiploic and right gastric arteries and veins. A pyloroplasty or pyloromyotomy is performed to improve post-operative gastric emptying and reduce the risk of aspiration. Insertion of a feeding jejunostomy is also good practice and can be performed with a low additional complication rate. It allows enteral nutrition access during the recovery period but more importantly in the event of any anastomosis or conduit problems that delay the resumption of oral intake.

A posterolateral right thoracotomy is performed through the fourth or fifth intercostal space. The thoracic duct is removed en bloc along with all tissue dissected from the aorta, pericardium, pleurae, bronchi and right side of the trachea including all the mediastinal lymph node stations (**Figure 53.10**). A supra-azygous dissection is performed for middle-third oesophageal cancers or when staging investigations identify nodes above this level. It is not routinely required in lower-third cancers. The stomach is delivered into the chest, taking care not to twist the conduit. The stomach is divided to excise the cardia and proximal lesser curve with the oesophagus resection ensuring an appropriate margin from the primary tumour. The conduit must not be made too narrow as this will interrupt intramural vascular arcades and increase the risk of ischaemic necrosis of the anastomosis or conduit. The anastomosis is completed with a circular stapling device before closure of the gastrotomy. Hand-sewn anastomoses can also be used and there is no evidence to suggest either method is superior to the other.[56, 57]

A routine three-phase procedure with a neck dissection is not required unless the oesophageal lesion is in the upper

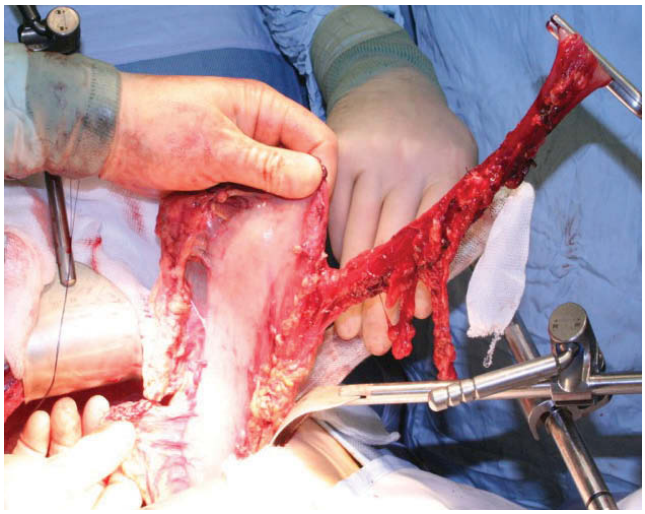

Figure 53.10 *En-bloc* resection of the oesophagus with delivery of the stomach into the chest prior to gastric division.

third or upper part of the middle third of the oesophagus. Routine three-field lymphadenectomy compared to two-field does not outweigh the potential increase in morbidity of the procedure from the extra thoracic dissection and neck dissection. Only minimal additional longitudinal resection is gained by this approach. Proponents highlight that cervical anastomotic problems cause less morbidity than intrathoracic leaks, although considerable reductions in overall anastomotic problems indicate that any such differences account for few patients. A left- or right-sided neck incision or a collar incision can be used to deliver the oesophagus and stomach into the neck and fashion an oesophagogastrostomy. Most surgeons use hand-sewn anastomoses in the neck although stapling techniques are also described.

Localized carcinoma of the hypopharynx or cervical oesophagus can be treated with pharyngolaryngo-oesophagectomy incorporating a radical neck dissection and a transhiatal oesophageal resection. Intraepithelial carcinomas of the upper oesophagus can also be considered for this approach.

Some surgeons approach lower- and middle-third cancers utilizing a left-sided thoracoabdominal incision. This route does not afford optimal access for either the formal abdominal lymph node dissection or the complete mediastinal lymphadenectomy. The transhiatal approach has a role in a selected group of patients. Some surgeons use this approach routinely although the ability to perform a radical mediastinal lymphadenectomy is considerably reduced. The technique has evolved from blind mediastinal dissection to several descriptions of dissection under vision.[58] Randomized trials comparing transhiatal and transthoracic resection have demonstrated improved survival in patients with oesophageal adenocarcinoma undergoing transthoracic resection, particularly in patients with limited nodal disease on histology.[30, 59]

Vagal-sparing resections and limited resections with jejunal interposition have been proposed as suitable alternatives for early disease on clinical staging.[30]

Minimally invasive oesophagectomy

Experience in minimally invasive oesophagectomy (MIO) techniques has increased over recent years, although publication of very few long-term results prevent definitive comparisons with open approaches.[60] It must be remembered that all the same oncological principles apply whether the adopted approach is open or minimally invasive.

Totally minimally invasive techniques involve laparoscopic gastric mobilization with thoracoscopic mediastinal dissection and oesophagus mobilization. Hybrid procedures utilize an open gastric mobilization and thoracoscopic mediastinal dissection, or a laparoscopic abdominal procedure followed by a conventional thoracotomy. The anastomosis can be performed in the chest through a mini-thoracotomy although is more commonly performed in the neck. The belief is that smaller incisions lessen the burden of the surgery on the patient, with less post-operative analgesia requirements, increasing mobilization and reductions in post-operative respiratory complications. One small, randomized trial has demonstrated a reduction in post-operative respiratory complication although it was not powered sufficiently to draw firm conclusions.[61] The UK national audit showed similar complication levels for open and MIO techniques.[54]

There are a few high-volume centres with experienced surgeons who achieve excellent results but this has not been reproduced countrywide. Complications specific to the MIO approach have been recognized including an increased risk of anastomosis and conduit problems. This has led to a refinement in techniques and an increase in the understanding of which patients are potentially suitable for such approaches. Overweight and obese patients create a particular challenge for laparoscopy due to the intra-abdominal fat obscuring tissue planes and the vascular arcade that requires preservation.

Robotic surgery has also been used in a few centres for oesophageal resection although such procedures remain in the remit of trials.[62] It will take many years to decide whether such techniques confer benefit in the recovery period without compromising long-term survival.

Endoscopic mucosal resection

Limited intramucosal disease where there is no evidence of nodal disease on CT or EUS can be resected using EMR. EMR is often performed as a diagnostic procedure but, provided depth of invasion is confined to the mucosa and both deep and lateral margins are clear, it can be considered a curative treatment. The procedure is performed under sedation. The submucosal layer is injected with Volplex®, indigocarmine dye and adrenaline. This lifts the lesion from the underlying muscle layer. The lesion is then removed either by applying suction and cautery with a cap device attached to the flexible endoscope, or by applying suction and a band below the lesion before excision (**Figure 53.11**).[63, 64]

Intensive endoscopic surveillance every 3 months is required with targeted biopsies at the EMR site to diagnose any dysplasia or recurrence as this is a relatively

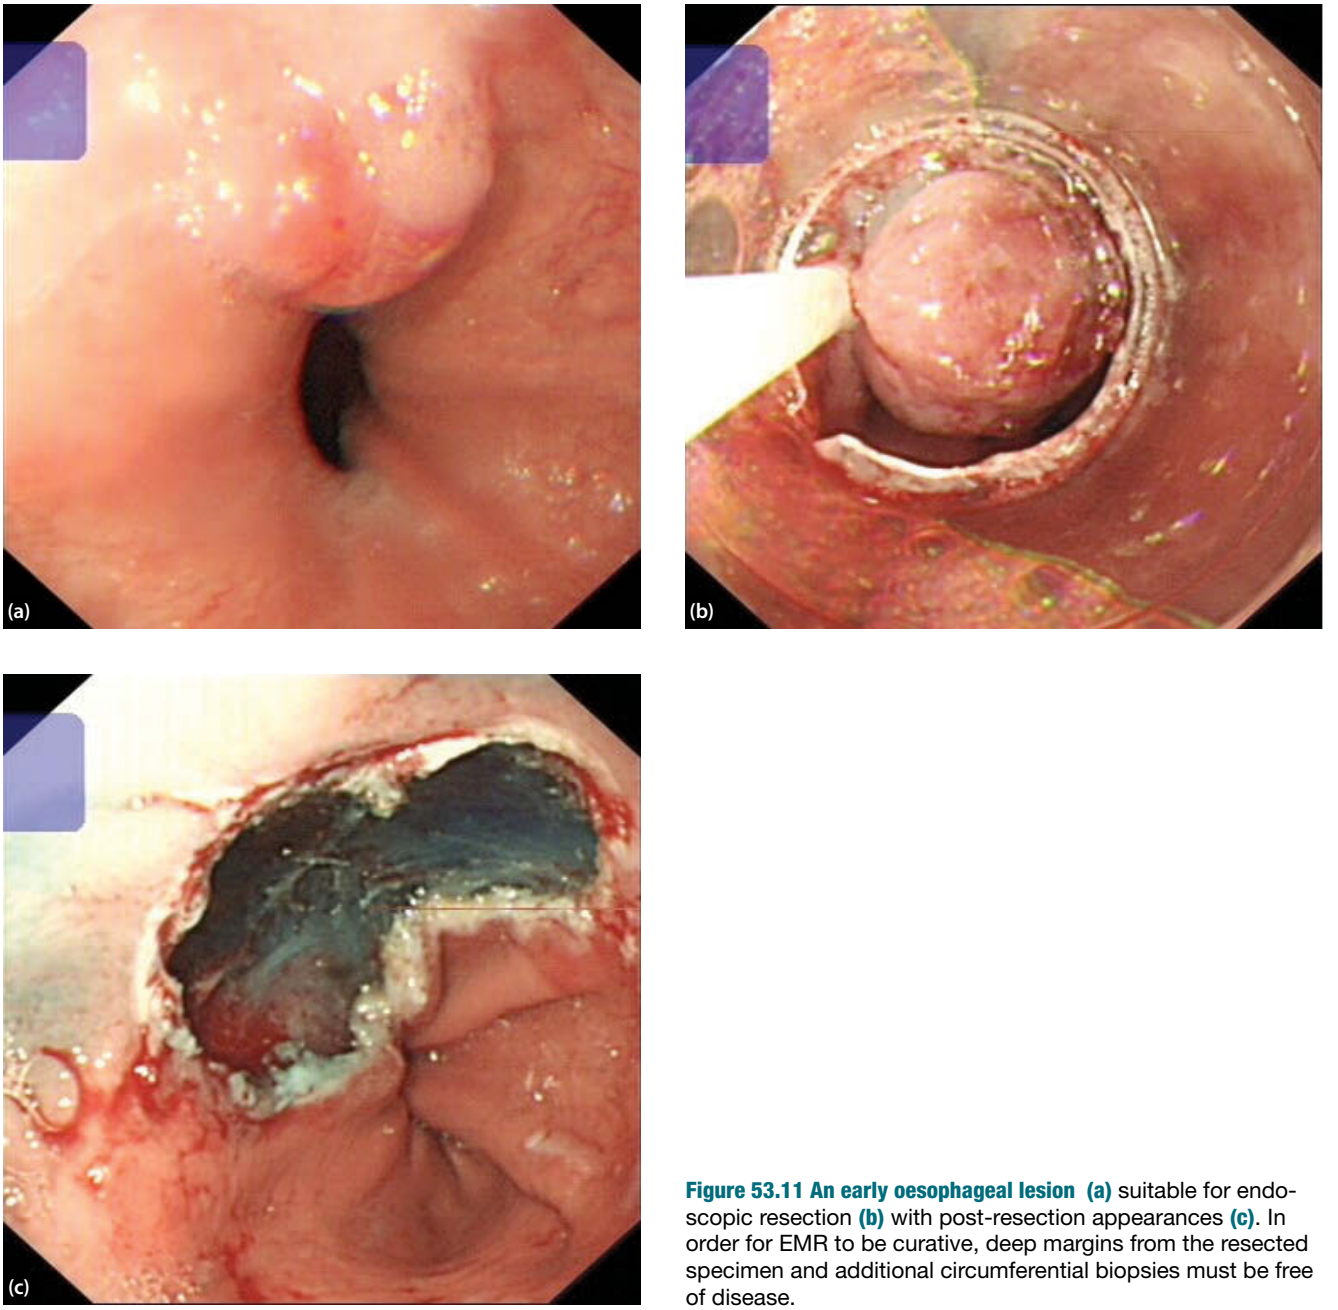

Figure 53.11 An early oesophageal lesion (a) suitable for endoscopic resection **(b)** with post-resection appearances **(c)**. In order for EMR to be curative, deep margins from the resected specimen and additional circumferential biopsies must be free of disease.

new treatment strategy and long-term results are few.[65] Evidence shows that the risk of lymph node metastases in the context of mucosal disease is negligible which is why this strategy has become feasible.[66, 67] If margins are positive, repeat EMR can be performed although surgery should also be considered. If circumferential margins are positive for dysplasia only (low-grade or high-grade) and all visible disease has been removed, the remainder of the oesophagus can be treated with RFA. Surgery should still be considered in young patients with high-grade dysplasia at the margins and in patients where there is evidence of multifocal high-grade dysplasia. Surgical resection is recommended because of the higher risk of lymph node involvement for oesophageal cancer with submucosal involvement although endoscopic submucosal dissection is technically feasible.

Definitive chemoradiotherapy

Definitive treatment with radical, concurrent chemoradiotherapy has been used with curative intent in oesophageal squamous cell carcinoma where total disease length does not exceed 10 cm. The evidence to compare this strategy to neoadjuvant treatment and surgery is sparse. No substantial evidence exists to support such an approach for adenocarcinoma. Often the choice of definitive chemoradiotherapy depends on the local expertise and the discussions between patient, clinical oncologist and surgeon. Patients who are not fit enough to undergo surgical resection might still be fit enough to tolerate definitive chemoradiotherapy. Studies have failed to identify conclusively for which particular patients definitive chemoradiotherapy might be a suitable curative option.

Salvage oesophagectomy remains an option in selected patients treated with definitive chemoradiation who fail to respond completely or demonstrate evidence of locoregional recurrent disease on follow-up.

Palliative treatments

Palliative chemotherapy and chemoradiotherapy can be used in patients with non-curative oesophageal adenocarcinoma and squamous cell carcinoma. External beam or endoluminal radiotherapy can be delivered to reduce tumour burden. Oesophageal stents are inserted to palliate dysphagia in patients with non-curative disease who are unsuitable for or opt against chemoradiotherapy.[68, 69] Stents should not be inserted in operable tumours because of the risks of perforation that would render the cancer incurable and also because of the transmural inflammation that inevitably results.

KEY POINTS

- Oesophageal adenocarcinoma continues to increase in incidence and accounts for the majority of oesophageal cancers in the Western world.
- Centralized units coordinate complete endoscopic and radiological staging with assessment of patient fitness through timed walking tests and cardiopulmonary exercise tests.
- Intramucosal disease might be suitable for endoscopic mucosal resection with follow-up endoscopic surveillance.
- Most patients with potentially curative disease have evidence of nodal disease or at least T3 depth of disease at presentation and receive neoadjuvant or peri-operative chemotherapy prior to surgery.
- Two-stage oesophagectomy with a radical lymphadenectomy has been shown to improve outcomes for lower-third adenocarcinoma.
- Experience with minimally invasive surgery techniques is increasing although a definite benefit has not been demonstrated and long-term outcomes are yet to be reported.
- Definitive chemoradiotherapy is an option in squamous cell carcinoma.
- Palliative treatments include chemotherapy, internal or external beam radiotherapy and endoluminal stents.

OESOPHAGEAL PERFORATION

Oesophageal perforation remains a rare condition and still has high mortality.[70] Spontaneous perforation (Boerhaave syndrome) occurs in an otherwise normal oesophagus.[71] Iatrogenic perforation can occur in a variety of procedures, particularly therapeutic flexible endoscopy, diagnostic or therapeutic rigid endoscopy or during revisional antireflux surgery. Increasing chances of a successful outcome depends upon a high index of suspicion, prompt resuscitation and investigation, with early transfer to a specialist oesophageal unit. The degree of pleural and mediastinal contamination in conjunction with the presence of systemic sepsis determines whether patients require surgery or can be managed non-operatively. Perforations of the cervical oesophagus are more likely to have successful non-operative management provided there is no mediastinal contamination. Non-operative approaches require intensive observation and reassessment of the patient (**Box 53.3**). A feeding jejunostomy can be inserted via a mini-laparotomy and is the preferred option for enteral nutrition access although a nasojejunal tube could also be considered.

BOX 53.3 Non-operative management of oesophageal perforation

- Nil by mouth
- Intravenous fluids
- Intravenous proton pump inhibition
- Intravenous antibiotics
- Intravenous antifungals
- Opiate analgesia
- Prophylactic low molecular weight heparin
- Nasogastric decompression (endoscopically or radiologically placed)
- Consider intercostal chest drain
- Enteral nutrition (feeding jejunostomy or nasojejunal tube)
- Regular reassessment in high-dependency environment

Surgery for perforation involves repair of the oesophageal defect following thorough debridement and lavage of mediastinal and pleural contamination of the mediastinum and pleura. Repair over a T-tube provides a controlled oesophagocutaneous fistula and is a good option in most, although primary repair has been used in some cases with success. Intercostal muscle flaps can be used as reinforcement. Oesophageal stents of varying types have been reported with varying success.[72] Stents are unlikely to hold position in an otherwise normal oesophagus, as there is not a stricture to hold the stent in place. Stents expose patients to complications of migration, bleeding and later stricture formation. They should not be inserted routinely in perforations as there is a lack of evidence to suggest healing rates and outcomes are improved. Many of the publications report on stent use in the context of adjunct drainage procedures. It is difficult to assess whether the control of sepsis through drainage or the stent contributes more to the healing in these situations.

KEY POINTS

- Recognizing oesophageal perforation requires a high index of suspicion.
- Prompt resuscitation, investigation and referral to a specialist centre are advised.
- The choice between non-operative and operative management depends on the degree of contamination and the presence of sepsis.
- Placement of oesophageal stents remains unproven and controversial.

FOREIGN BODY INGESTION

Ingested foreign bodies and food boluses can impact in the oesophagus. Foreign body ingestion is most commonly seen in children but also in patients with psychiatric conditions. Food bolus obstruction can occur in

any patient group. It is sometimes associated with an underlying Schatzki ring, peptic stricture or eosinophilic oesophagitis and occasionally is the first presentation of a malignant stricture. Initial investigations include antero-posterior and lateral plain radiographs, although some radiolucent objects will not be identifiable. CT can also be considered. Airway difficulties, absolute dysphagia, ingestion of sharp objects or button batteries, and prolonged impaction are indications for intervention. Rigid oesophagoscopy in experienced hands is appropriate to locate and retrieve impacted objects in the pharynx and cervical oesophagus. Care must be taken to avoid iatrogenic oesophageal perforation. Flexible endoscopy is the investigation of choice and allows for therapeutic intervention. It has a lower risk of perforation compared to rigid oesophagoscopy. Pushing a food bolus distally without having first passed the endoscope beyond the bolus should be avoided as it increases the risk of perforation.

MOTILITY DISORDERS

Achalasia

Achalasia is an uncommon condition with an annual incidence of 1 in 100 000. It is seen in both men and women, most frequently in middle and older age groups. Achalasia results from degeneration of the ganglionic neurons within the myenteric plexus and is characterized by a failure of relaxation of the lower oesophageal sphincter on swallowing with absence of peristalsis in the oesophagus. This can be associated with a higher resting tone in the oesophagus. Primary achalasia is idiopathic in aetiology while secondary achalasia occurs in Chagas' disease and following antireflux surgery with creation of a fundoplication wrap that is too tight.

PRESENTATION

Patients most often present with dysphagia to liquids and solids. Some present with symptoms of regurgitation or recurrent chest infections resulting from aspiration of stagnant oesophageal content. Retrosternal chest pain is a feature of a specific type of achalasia (vigorous achalasia) as a result of simultaneous, strong peristaltic contractions. Weight loss is a feature of long-standing achalasia.

INVESTIGATION

Investigation should start with a flexible endoscopy. It is important to exclude cancer as the underlying problem as many of the symptoms are common to both diagnoses. Endoscopic appearances in early achalasia can be completely normal. Features supporting a diagnosis of achalasia include a tight oesophagogastric junction, a dilated oesophagus or food within the oesophagus. A barium swallow in advanced cases will demonstrate delay in passage of barium across the oesophagogastric junction, possibly within a dilated oesophagus that fails to show any peristaltic activity (**Figure 53.12**). Confirmation of the diagnosis is provided by oesophageal manometry (**Figure 53.13**).

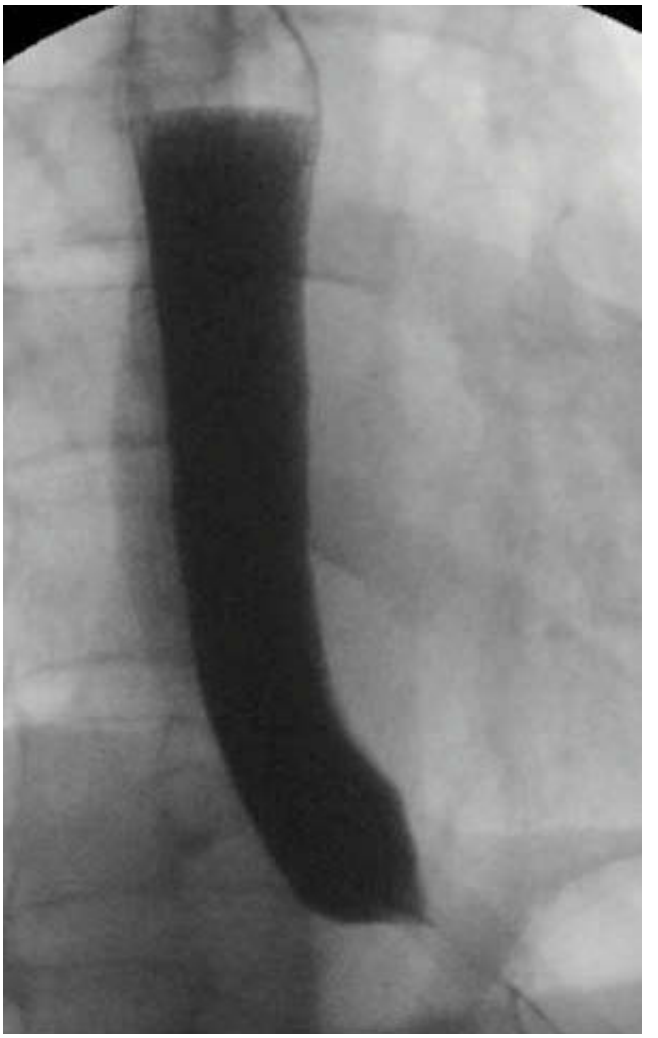

Figure 53.12 Barium swallow showing the classical bird's beak appearance in achalasia with a dilated, non-peristaltic oesophagus tapering towards a lower oesophageal sphincter that fails to relax.

Recent results with high-resolution manometry suggest there are several subtypes of achalasia that may respond differently to treatment.[73]

MANAGEMENT

The two main treatment options are endoscopic balloon dilatation or cardiomyotomy.[74–76] Results from a European multicentre randomized trial did not demonstrate differences in treatment efficacy at 2 years (93% balloon dilatation versus 90% laparoscopic cardiomyotomy) or in the occurrence of gastro-oesophageal reflux after treatment.[77]

Successful and safe balloon dilatation requires experienced endoscopists. The procedure is performed under sedation as a day-case procedure with image intensification used to ensure complete effacement of the balloon waist. The balloons are of fixed diameter with initial dilatation performed with a 30 mm size. Sequential dilatation can be performed if necessary after several weeks with a 35 mm and a 40 mm balloon. The main risk is of perforation and this risk increases with the larger diameter balloons.

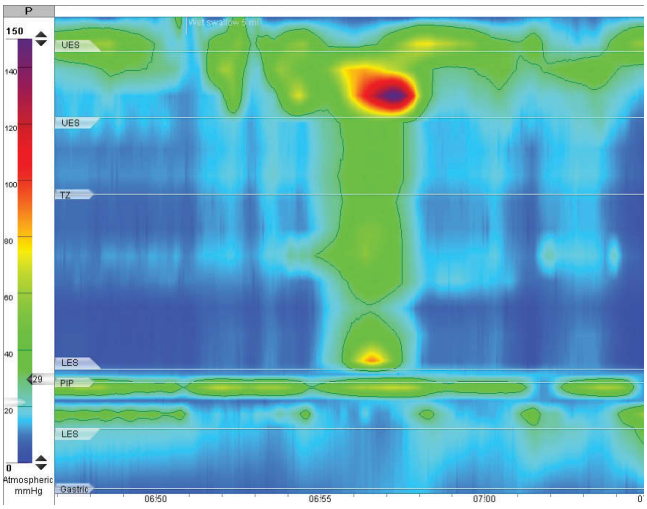

Figure 53.13 High-resolution manometry appearances of achalasia (type 2) with oesophageal compression. Pan-oesophageal pressurization can be seen in the oesophageal body between the higher pressure bands of the upper and lower oesophageal sphincters. The lower oesophageal sphincter fails to relax with swallowing.

Cardiomyotomy is performed laparoscopically and some surgeons combine this with a partial fundoplication intended to reduce the incidence of post-operative reflux.[78] The muscles are split for 5 cm along the oesophagus with the myotomy extended into the cardia for 3 cm. There is a risk of mucosal perforation with the procedure but this can be managed conservatively in most cases.

A newer technique of endoscopic myotomy has been developed in Japan and is being evaluated in randomized trials against balloon dilatation and cardiomyotomy.[79–81] It is performed under general anaesthesia and involves creation of a submucosal tunnel with an endoscope before division of the fibres in the circular muscle layer.

Endoscopic injection of botulinum toxin into the lower oesophageal sphincter is not a long-term solution. It has significant early failure rates and should be considered only in frail patients unsuitable for the other treatment modalities.[82]

SURVEILLANCE

Patients with achalasia should be enrolled on endoscopic surveillance programmes because of the increased risk of developing both squamous cell carcinoma and adenocarcinoma.[83, 84] Whether successful treatment alters this risk is currently not known.

KEY POINTS

- Achalasia requires investigation with endoscopy, barium swallow and manometry.
- Results from balloon dilatation and laparoscopic cardiomyotomy are equivalent so treatment depends on the available expertise.
- Achalasia patients should undergo endoscopic surveillance because of an increased risk of developing oesophageal cancer.

Diffuse oesophageal spasm

Diffuse oesophageal spasm is a rare condition characterized by non-peristaltic high-pressure contractions of increased duration. These occur in the smooth muscle of the lower two-thirds of the oesophagus. Symptoms are predominantly of severe retrosternal pain during swallowing and can occur in conjunction with dysphagia.

INVESTIGATION

Non-oesophageal causes of these symptoms need to be excluded. The diagnosis is evident on manometry when high-amplitude simultaneous contractions are measured within the oesophagus following an apparent normal swallow. This does rely upon patients experiencing symptoms during the 10 swallows of the investigation. Further investigation with ambulatory manometry might be required.[85] Occasionally evidence of such spasm is identified during a barium swallow.

MANAGEMENT

Treatment options aim to induce smooth muscle relaxation and include calcium channel blockers such as nifedipine, nitrates and botulinum toxin although results are variable. Surgery is rarely undertaken in these patients but one option is to perform a long oesophageal myotomy.[86]

Nutcracker oesophagus

This is a rare condition characterized by severe retrosternal pain during swallowing similar to diffuse oesophageal spasm. The diagnosis is made by demonstrating normal peristalsis with higher than normal amplitude contractions on manometry.

Eosinophilic oesophagitis

Eosinophilic oesophagitis is an increasingly recognized condition. Clinical symptoms relate to oesophageal dysmotility. Endoscopic features can include fixed oesophageal rings, luminal narrowing, furrows or exudates evident on flexible endoscopy.[87] Biopsies show eosinophilic infiltration within the oesophageal epithelium. Reflux disease should be excluded as the underlying cause. Treatment strategies are evolving and include topical steroids, avoidance of any identifiable food allergens and cautious dilatation of strictures.

Oesophageal diverticulae

Diverticulae are infrequently found in the oesophagus on flexible endoscopy. These are mostly asymptomatic. Congenital diverticulae are rare. Of acquired diverticulae, these are mostly of pulsion type where incoordinated peristalsis and functional obstruction lead to increased pressure at a specific point in the oesophageal wall. Most such diverticulae occur in the lower parts of the oesophagus and rarely need any specific treatment.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: pharynx, pharyngeal disease, neurological disorders and nervous system. Articles are included that are systematic reviews and meta-analyses of systematic reviews from four medical journals: *British Medical Journal*, *Lancet*, *New England Journal of Medicine* and *Journal of the American Medical Association*.

INTRODUCTION

A wide range of neuromuscular diseases can affect the pharynx. The primary function of the pharynx is swallowing. Different phases of swallowing are affected by different conditions, depending on which of the cranial nerves are involved. These diseases can also manifest as difficulties with breathing and speaking. Symptoms may arise in conjunction with anatomical variations, from congenital or acquired diseases.

ANATOMY AND PHYSIOLOGY

The reader is referred to a detailed discussion of the relevant anatomical details and physiology of swallowing in Chapter 47, Anatomy of the pharynx and oesophagus, and Chapter 48, Physiology of swallowing. A good understanding of these concepts is a necessary prelude to understanding management of neurological diseases of the pharynx.

SYMPTOMS

The principal symptoms of neurological dysfunction affecting the pharynx include:

- dysphagia
- odynophagia
- aspiration
- coughing
- choking
- throat clearing
- nasal regurgitation
- 'wet' voice.

Dysphagia is the principal symptom and can be due to a structural problem as well as a neurological one. History taking and physical examination are accompanied by endoscopy. Details of chronology, the effect of different food consistencies, exacerbating and improving factors and particularly past medical history help the clinician formulate a diagnosis. Oral cavity and cranial nerve examination are important in assessing neurological disease of the head and neck. Examination of the face and limbs can elicit muscle wasting and fasciculation.

EXAMINATION

General examination of the patient can yield information about the likely underlying pathology for the reported swallowing difficulties. Paucity of facial expression suggests Parkinson's disease whereas facial weakness and grade of this suggests a stroke and the time elapse since onset. Inspecting for mobility aids (walking stick, walking

frame, wheel chair) and a tracheostomy also provides an indication of disease severity that may relate to the degree of swallowing dysfunction.

Patients' gait patterns may correspond to certain neurological diseases. A festinating gait can be characteristic of Parkinson's disease as can a broad-based gait in cerebellar dysfunction. Fatigability can accompany advanced Myasthenia gravis, though will also be present in patients with advanced osteoarthritis and those with intermittent claudication secondary to peripheral vascular disease.

Certain distinctive patterns of speech may be present in those patients with advanced cases of neurological disease. Dysarthric (slurred) speech is the commonest speech pattern present in neurological disease and is associated with cerebrovascular accidents, cerebellar disease, Parkinson's and motor neurone disease. 'Wet' or 'moist' speech can develop in patients with Parkinson's disease due to poor oral phase control, though this does develop in cases of head and neck trauma and presbyphagia. It is usually associated with aspiration. Patients' suffering with bulbar palsy (affecting the IXth, Xth, XIth and XIIth cranial nerves) can develop a nasal quality to their speech. The aetiology of this condition is primarily a lesion of the medullar oblongata, though local tissue infarction and demyelinating diseases are also causes. Those with pseudobulbar palsy may demonstrate 'Donald Duck' speech due to alaryngeal vocalization using the buccal area.

Formal neurological examination may or may not elicit the signs described later in this chapter. Cranial nerve examination, particularly of the lower cranial nerves, provides the most useful and familiar assessment to the otolaryngologist in this area. Unilateral or bilateral fasciculation or even wasting of the tongue or soft palate, secondary to progressive deinnervation of the muscles will affect the oral and pharyngeal phases of swallowing. Flexible nasolaryngoscopy is useful in identifying these changes in the pharyngeal constrictor muscles and identifies other abnormalities including vocal cord palsy, polling within the pyriform fossae and laryngeal penetration that contribute to the overall assessment of patients' swallowing abilities.

INVESTIGATIONS

Swallowing assessment and endoscopy

Swallowing assessment is complemented by functional endoscopic evaluation of swallowing (FEES). The pharynx and larynx are visualized through an endoscope while boluses of different volumes and consistencies are swallowed. These endoscopies may be performed at bedside, if tolerated by the patient, limiting the need for transport to a radiology department, possibly in a different hospital.[1] Images may be recorded and transferred for discussion and review. FEES may be performed by appropriately trained speech and language therapists. Views of bolus and saliva retention in the hypopharynx can be achieved, which may not be possible in videofluoroscopy.[1] The disadvantages are obstruction of the operator's view due to food and fluid in the pharynx and when the pharynx closes, limiting assessment of the pharyngeal phases of swallowing. The oesophageal phase cannot be viewed either, though the upper oesophageal lumen can be visualized.

Videofluoroscopy

Videofluoroscopy is the gold-standard investigation in assessing neurological disease of the pharynx. Videofluoroscopy was initially developed in 1965 and involves recording fluoroscopic images that appear on a monitor of a patient ingesting a radio-opaque bolus.[2] This demonstrates the dynamics of the swallowing mechanism and allows speech and language therapists to assess swallowing problems and identify techniques for a safer swallow for the patient.

The investigation can identify nasal regurgitation, poor pharyngeal contraction, retention of the food bolus within the vallecula and pyriform sinus, and problems with opening of the upper oesophageal sphincter. Videofluoroscopy is particularly useful in identifying 'silent' aspiration, pre-, intra- and post-deglutitory.[1]

The patient is placed in an anterolateral position and anatomical landmarks are identified. Administration of the bolus begins with minimum quantities to avoid the risk of inhalation and may be increased as the consistency of the patient's swallow is assessed. Liquid, semi-liquid and solid boluses can be provided. An anteroposterior image recording can assess for asymmetry in movement or stasis of the bolus.[1]

Radiation exposure is limited in videofluoroscopy and the recorded images can be viewed repeatedly and transferred between clinicians and centres.[1] It supplements the clinical examination in those patients with reflex mandibular closure and aids treatment planning.[3] 'Reflex mandibular closure' is different from the gag reflex and is a sign of neurological disease, whereby patients are unable to maintain mouth opening, rather than reacting to oropharyngeal stimulation. No direct view of the passage of the food bolus is provided, however, and videofluoroscopy cannot be performed at the patient's bedside, requiring transfer to a radiology department. The general physical state of the patient may prevent investigation and compliance with instructions. Interpretation of the images recorded may vary considerably.[1]

ACQUIRED CONDITIONS

NEUROMUSCULAR DISEASE

Multiple sclerosis

Multiple sclerosis results from inflammatory demyelination of neurons within the central nervous system. Progressive and relapsing–remitting forms of the disease have been identified, the former of which generally has a poorer prognosis. The greatest incidence is in younger adults, particularly those of Western European origin and in areas between latitudes 40°N and 40°S. Definite diagnosis requires evidence that two or more areas of the central nervous system are affected on different occasions.

Cerebrospinal fluid testing may reveal oligoclonal bands of immunoglobulin G.

Dysphagia results when the brainstem and/or the corticobulbar tracts are affected. Dysphagia typically presents in advanced cases of the disease, while choking is more a feature of the earlier stages. Percutaneous gastrostomy feeding may therefore be required. Videofluoroscopy reveals a delayed swallowing reflex and loss of pharyngeal peristalsis.

Management includes corticosteroid medicines and β-interferon. While multiple sclerosis itself is not a terminal condition, many sufferers succumb to pneumonia due to poor coughing mechanisms and uraemia as a result of urinary retention and renal failure.

Parkinson's disease

Parkinson's disease results from degeneration of the substantia nigra in the zona compacta, leading to a reduction in the neurotransmitter dopamine within the brain. Symptoms develop around 45–65 years of age. The disease is overwhelmingly idiopathic without any aetiological cause, though manganese, carbon monoxide and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) narcotic can be implicated in its development. Diagnosis is based primarily on the clinical features displayed by patients including rigidity, bradykinesia, tremors and poor posture stability.

Swallowing initiation slows and bolus stasis in the pyriform fossae results.

Levodopa remains a mainstay of treatment as do anticholinergic agents and dopamine agonists. Selegiline and amantadine inhibit dopamine metabolism and improve milder symptoms, respectively. Catechol-O-methyltransferase (COMT) inhibitors reduce levodopa metabolism, prolonging the effect. Deep brain stimulation surgery is available.[4]

Myasthenia gravis

Myasthenia gravis results from autoimmune IgG antibodies developing against acetylcholine receptors at the end plate of the neuromuscular junction. Nerve impulse conduction is slowed and weakened as a result. Voluntary muscle weakness develops with diplopia and ptosis in cases of orbital muscle involvement. Classically symptoms are reported to improve following periods of rest and worsen with periods of repetitive action. Patients may present with dysphagia, dysphonia or nasal regurgitation alone having previously been well and deterioration in symptoms correlates with advancement of the disease. Electrophysiology testing reveals muscle fatigue following stimulation and serum acetylcholine receptor antibodies may be detected.

Videofluoroscopy reveals reduced pharyngeal mobility and aspiration.

Management includes cholinesterase inhibitors, edroponium, corticosteroids and other immunosuppressive agents. Thymus excision may benefit those patients with a thymoma because of the causative effect of the tumour.

Motor neurone disease

Motor neurone disease describes a collection of diseases that affect motor nervous fibres, including progressive bulbar palsy, pseudobulbar palsy, primary lateral sclerosis, amyotrophic lateral sclerosis and progressive spinal muscle atrophy. Difficulties in swallowing, chewing, coughing, talking and breathing develop in addition to limb weakness, limb stiffness, muscle wasting and fasciculation. Motor neurone disease is progressive with death most commonly resulting from pneumonia.

Dysphagia and aspiration result if the corticobulbar tract is affected. The disease is aggressive (death from the amyotrophic lateral sclerosis results within 5 years of symptom onset) and early gastrostomy insertion should be considered to prevent aspiration pneumonia, as dysphagia develops within months of diagnosis or may be the presenting symptom.

Guillain Barré syndrome

Guillain Barré syndrome, also described as acute idiopathic polyneuropathy, results from multifocal demyelination of the cranial nerves and immune cell-mediated damage to nerves, usually following a preceding infection or immunization. Both motor and sensory function deteriorates, usually in an ascending and symmetrical pattern with peripheral regions of the body being affected initially. Motor function deterioration is usually more prominent. Respiration and swallowing function can be affected, though not universally.

Cerebrospinal fluid analysis reveals high protein concentrations. The prognosis is generally good though recovery may be prolonged. Up to 20% of sufferers may be left with residual disability.

Muscular dystrophy

Muscular dystrophy is a collection of myopathic disorders that result in muscle wasting. This leads to continued muscle contraction following withdrawal of the initial nerve impulse producing further muscle weakness. Duchenne muscular dystrophy has the worst prognosis with rapid progression; death results within 15 years of symptom onset due to respiratory failure and pneumonia when the respiratory muscles become affected. Other types are more benign with slower rates of progression. Muscle biopsy and electromyography confirm the myopathic nature of the disease.

The soft palate is usually affected with regard to swallowing, producing dysphagia and nasal regurgitation. Sensation is maintained. Videofluoroscopy reveals muscle paralysis leading to nasal regurgitation and aspiration. No treatment for muscular dystrophy exists though physiotherapy and speech and language therapy maintain function and slow symptom progression.

STROKE

Cerebrovascular events are the commonest neurological disorders of the pharynx. Patients may suffer with

both dysphagia and aspiration. Nerve injury results from infarction or, less commonly, haemorrhage. Patients typically present with sudden onset of neurological deficits, the signs of which reflect the area of the brain affected. Patients commonly have a past medical history of atherosclerosis, hypertension, diabetes mellitus or heart valve disease. Infarction risk is uniform throughout the cerebral vasculature.

Dysphagia can be the sole symptom of an event affecting the brainstem, with videofluoroscopy demonstrating asymmetrical movement and poor bolus transit. CT imaging of the head distinguishes between an infarction and haemorrhage. Management involves anti-platelet therapy and control of risk factors to prevent reinfarction in particular, including statin use to reduce blood cholesterol levels.[5–7] Thrombolysis has an increasing role in treating ischaemic strokes that present sufficiently early. Patients may be suitable for carotid artery surgery if symptoms are transient, which may be offered as an urgent or emergency operation.[8] The overall prognosis for survival is better for those suffering an ischaemic than a haemorrhagic stroke, though the risk of recurrence is greater in such patients, as is the risk of myocardial infarction.

INFECTIOUS DISEASE

Polio

Polio is caused by poliovirus that destroys neurons within the anterior horn cells of the spinal cord. The brainstem may also be affected. Dysphagia develops slowly and steadily when the pharyngeal muscles are affected, often years after the original infection. The disease is rare in the developed world but remains endemic elsewhere, such as in parts of Asia and Africa.

Herpes zoster

Herpes zoster results from *Varicella zoster* virus infection, which remains in the dorsal root ganglia and cranial nerve ganglia in a latent state. Reactivation can lead to palsies of the lower cranial nerves. Disease manifestation is commoner in patients over 60. Treatment includes famciclovir or acyclovir antiviral agents. The disease has equal prevalence throughout the world.

Diphtheria

Diphtheria results from *Corynebacterium diphtheria* bacterial infection, which produces a neurotoxin that can ultimately lead to pharyngeal weakness. Infection of the pharynx may also cause airway obstruction. The treatment includes antitoxin and penicillin antibiotics. A vaccination based on the toxin is available. The disease is commoner in the developing world.

Rabies

Rabies is caused by a viral infection residing in feral animals. The virus infects the neurons of the central nervous system, through which it spreads. Laryngopharyngeal spasm can result as can fasciculation of the pharyngeal muscles. This severely limits the patient's ability to swallow, leading to aspiration. Rabies has been eradicated in much of the developed world but is endemic elsewhere. It can be successfully treated with vaccination and specific immunoglobulin administration.

Botulism

Botulism results from bacterial toxins released from *Clostridium botulinum* that weaken the muscles supplied by the lower cranial nerves. Patients present with dysphagia. The disease can be successfully treated with a specific antitoxin.

NEOPLASTIC DISEASE

Nasopharyngeal carcinomas and particularly skull-base tumours compress and invade the lower cranial nerves producing a variety of symptoms. MRI and CT scanning of the anterior cranial fossa, brain and temporal bone should follow the appropriate clinical examination. Surgery or radiotherapy can then be considered. A variety of jugular foramen syndromes exist, described in **Table 54.1**. A small number of paraneoplastic syndromes have been associated with neurogenic dysphagia including squamous cell carcinoma of the skin, transitional cell carcinoma of the bladder, ovarian cancer, prostate cancer and chronic lymphocytic leukaemia.[9–13]

MISCELLANEOUS ACQUIRED CONDITIONS

Trauma and surgery

Blunt or penetrating trauma to the pharynx can injure the nervous supply as well as cause structural abnormalities through muscle injury. Iatrogenic surgical injury in thyroid, cardiothoracic, anterior cervical spine, carotid and oesophageal surgery can injure branches of the vagus nerve in particular.

TABLE 54.1 Jugular foramen syndromes

Syndrome	Cranial nerves affected	Aetiology
Vernet's	9, 10, 11	Aneurysms or tumours at the jugular foramen
Collet–Sicard	9, 10, 11, 12	Parotid tumours, chemodectomas or metastases at the posterior laterocondylar space
Villaret's	9, 10, 11, 12 Horner's syndrome	Parotid tumours, chemodectomas or lymphadenopathy at the posterior retroparotid space
Jackson's	10, 12 Corticospinal tract	Chordomas, metastases or schwannomas

Glossopharyngeal neuralgia

Glossopharyngeal neuralgia presents with stabbing pain in the oropharynx region innervated by the glossopharyngeal nerve. The cause is unknown but the symptoms may be attributed to Eagle's syndrome. Investigation for skull-base lesions may be required and, while surgery to remove an enlarged styloid process may treat the condition in cases of Eagle's syndrome, symptom control is usually achieved with carbamazepine.

Medication

Medications whose side effects result in depression of the central nervous system can make any dysphagia worse.

Old age

The oral phase of swallowing increases in old age and the first two stages become 'uncoupled', leading to the food bolus passing into the vallecula prior to laryngeal elevation. The food bolus volume necessary to stimulate pharyngeal swallowing may need to increase up to five times. Both these factors increase the risk of aspiration.

CONGENITAL CONDITIONS

A small number of neurodevelopmental disorders affect the function of the pharynx. Compression of nervous tissue is the principal cause of pharyngeal dysfunction.

In Klippel–Feil syndrome, the cervical vertebra fuse during growth, compressing the brainstem and injuring the nuclei of the lower cranial nerves, with concurrent shortening of the neck. In Dandy–Walker syndrome, cerebrospinal fluid flow out of the ventricular system is obstructed, leading to a cyst developing in the posterior cranial fossa that compresses the cortex and brainstem. Compression of the brain by an Arnold–Chiari malformation can cause brainstem herniation and injury. In syringomyelia, a cystic cavity remains in the medulla or upper spinal cord that enlarges to compress and injure the nerve tracts.

TREATMENT

The treatment of neurological disease of the pharynx centres on accurate diagnosis of the underlying cause and treatment of that cause. Specific otolaryngological interventions for those chronic conditions that cannot be treated centres on avoiding aspiration, with resulting pneumonia, and maintaining feeding. Both require a multidisciplinary approach and a crucial role is provided by speech and language therapists.

A variety of techniques can be deployed to these ends. Solid food chewing is preferable to liquid foods that are more easily aspirated. Neck flexion both aids swallowing and protects the airway. The Mendelsohn manoeuvre aids the opening of the pharyngo-oesophageal segment and coughing immediately after swallowing clears food from the laryngeal inlet, preventing aspiration. More detail on the subject of rehabilitation is presented in Chapter 55, Rehabilitation of swallowing disorders.

Support to control sialorrhoea medically is available.[14] Hyoscine (usually in patch form), glycopyrrolate (usually as oral solution) are most commonly used in the United Kingdom and are anticholinergic medications that antagonise the effects of acetylcholine at the muscarinic receptors. Other medications used are atropine, tropicaimide, hyoscyamine and tricyclic antidepressants, which all have anticholinergic properties.[14] Common side effects include xerostomia, urinary retention confusion and sedation and anticholinergic use is contraindicated in glaucoma and in those patients with established dementia.

Botulinum toxin (type A or type B) can be injected into the major salivary glands to reduce saliva production by inhibiting acetylcholine release from axonal endings at cellular neuromuscular junctions.[14] The dosage and duration of effect are variable but can be repeated. Ultrasound guidance improves gland localization, particularly in those that undergo atrophy with age or from repeated injection, and the accuracy of delivery.

Those patients who cannot tolerate swallowing safely will require a feeding tube to be placed. Short-term feeding needs can be satisfied with insertion of a nasogastric tube but patients with chronic or deteriorating swallowing problems with little hope of recovery will benefit more from a gastrostomy placement. Feeding usually takes place overnight for convenience to the patient.

Anxiety and depression must be recognized in patients at every stage of their problems and should be treated accordingly.

There is a specific role for surgery to 'normalize' the phases of swallowing. Vocal cord medialization techniques can aid airway closure in swallowing while cricopharyngeal myotomy or botulinum toxin injection into the muscle will treat spasm of the cricopharyngeus muscle. Tracheostomy insertion abates the risk of aspiration but interferes with the normal process of swallowing by fixing the position of the larynx. Rarely, total laryngectomy may need to be considered to eliminate intractable aspiration.

KEY POINTS

- The aetiology of neurogenic dysphagia and the clinical features of different neurological diseases should be considered when managing swallowing disorders.
- FEES assessment and videofluoroscopy are complementary in the assessment of patients' swallowing function.
- The management of neurogenic dysphagia is multidisciplinary and includes treatment of the principal aetiology, early speech and language therapist input to improve swallowing function and ensure a 'safe' swallow and consideration of additional interventions to prevent aspiration and maintain satisfactory feeding and nutrition.

SEARCH STRATEGY

Data in this chapter are based on several independent literature searches of the PubMed, Scopus and Google Scholar databases, which involved relevant keywords describing each intervention (e.g. effortful swallow, transcranial magnetic stimulation, transcranial direct current stimulation etc.) and outcome measure (e.g. pharyngeal pressure, motor evoked potential etc.). Furthermore, the reference lists of identified studies were searched for additional relevant publications.

INTRODUCTION

The clinical management of swallowing disorders has evolved over the last four decades to include ongoing development of compensatory and rehabilitative interventions designed to increase swallowing efficiency and safety. Initially, the clinical approach to managing swallowing disorders was largely characterized by strategies to compensate for impaired peripheral motor function. Many of these techniques remain a valuable asset in the clinical armamentarium for the short-term management of disordered swallowing. Since then, multidisciplinary clinicians and researchers have developed ever-increasing sophistication and specificity in the diagnosis and treatment of dysphagia. As diagnostic specificity is increasing, we are no longer applying traditional treatment approaches to patients in a 'one size fits all' approach.

Increased specificity will ultimately lead to improved rehabilitative outcomes, for two reasons. First, with greater diagnostic specificity we will be able to tailor compensatory and rehabilitative efforts to directly address the underlying impairment of any given patient. One example of this is the clinical application of a technique known as thermal–tactile application (TTA) of the faucial pillars. This technique was originally developed to facilitate initiation of pharyngeal swallowing[1] and was applied to any patient presenting with preswallow pharyngeal pooling. It stands to reason that only patients presenting with pharyngeal pooling secondary to sensory impairment would benefit from this sensory-based technique, not those presenting with underlying motor impairment. Thus, careful scrutiny of the underlying impairment and consequent selection of the right treatment for the right problem is likely to increase the rehabilitative effectiveness of TTA.

Second, increasing diagnostic precision will improve patient outcomes by decreasing the likelihood for causing harm. For example, the technique of effortful swallow, historically applied as a compensatory technique to facilitate bolus clearance during swallowing,[2, 3] is now increasingly being used as a rehabilitation approach.[4, 5] Repeated swallowing with effort is presumed to strengthen pharyngeal contraction, much like repeatedly lifting weights will increase arm muscle strength. However, studies have now demonstrated that effortful swallowing may in fact impair, not facilitate, anterior hyoid movement during swallowing in some patients due to an imbalance of anterior and posteriorly oriented forces acting on the hyolaryngeal complex during swallowing.[6] A subsequent case study has documented the potential for effortful swallowing to impair movement patterns at the base of the tongue, resulting in nasal redirection.[7] Similarly, the Mendelsohn manoeuvre was originally designed to increase airway protection through volitionally prolonging swallowing-related suprahyoid contraction at the point of maximal hyolaryngeal excursion.[3, 8] Recent evidence obtained using high-resolution pharyngo-oesophageal manometry demonstrates that, while pharyngeal bolus passage may be aided by increased and prolonged pharyngeal pressure generation, proximal oesophageal peristalsis is significantly decreased

during Mendelsohn manoeuvre swallows.[9, 10] Meticulous evaluations of both short- and long-term effects of these manoeuvres, and others, are required.

Our current state of the art in dysphagia rehabilitation is quickly broadening from an almost exclusive approach of peripheral muscle strengthening to incorporate techniques designed to maximize central control mechanisms. This chapter provides a cursory introduction to the established muscle-strengthening techniques for which a supportive evidence base has been reasonably established. Then we look ahead with a preview of exciting new developments in cortical modulation that are likely to move into clinical application once a supporting evidence base is available.

CURRENT REHABILITATION APPROACHES

Oral motor exercises

Speech pathology has a long history of therapeutic efforts aimed at increasing the strength and efficiency of oropharyngeal movements. Originally, these were developed for improving articulatory precision related to speech. Subsequently, these exercises were logically expanded and transferred to swallowing rehabilitation, with the goal of improving oral phase movements and facilitating tongue-driving forces involved in pharyngeal phase swallowing. Although these techniques have been around for decades, only recently has their efficacy for improving functional swallowing been systematically investigated. The development of a handheld manometric device, known as the Iowa Oral Performance Instrument (IOPI), facilitated the evaluation of oral motor exercise (OME) in swallowing rehabilitation. Regular OME using this device and performed prophylactically by healthy elderly individuals can increase swallowing and isometric peak pressures following a 9-week exercise regimen.[11] This was accompanied by an increase in lingual volume. Of note, the beneficial effects of regular OME do not necessarily rely on using the IOPI for training; they can also be achieved by standard tongue strength exercises using a tongue depressor.[12] A study evaluating the effects of OME in patients documented that an 8-week isometric lingual exercise regimen using IOPI as biofeedback modality increased isometric and swallowing pressures for some bolus conditions in patients presenting with dysphagia following stroke.[13] It has also been demonstrated that tongue strength measured using the IOPI is significantly correlated with oral phase dysphagia following stroke[14] and longer meal times in residential age care.[15]

Effortful swallow

First introduced as a compensatory technique by Kahrilas and colleagues,[2, 3] the instructions for this technique are simply to 'swallow hard'. With increased effort resulting in increased pressure on the bolus, this technique was routinely applied to reduce pharyngeal residue in patients with pharyngeal motility disorders. A considerable body of research has documented the potentially positive effects of increased pharyngeal pressure associated with effortful swallowing.[6, 9, 10, 16–24] However, subsequent research now demonstrates that simply 'swallowing hard' is not as benign as it may seem.

A potential complication of the effortful swallow was documented to be decreased anterior hyoid movement during swallowing.[6] Biomechanically, this observation is likely linked to the relative imbalance in the opposing muscles that act on the hyoid during swallowing. Anterior pull of the relatively small floor of mouth muscles may be outweighed by posteriorly oriented forces exerted by the much larger pharyngeal constrictors and suprahyoid muscles (posterior belly of digastric, stylohyoid). Due to the synergistic coordination of the oropharyngeal swallowing process, it is likely that during effortful swallowing, **all** muscles involved in swallowing exert a greater degree of contraction. With regard to the movement of the hyolaryngeal complex, this would lead to a biomechanical imbalance resulting in a stronger net posterior hyoid displacement compared to non-effortful swallows. A further single case study of a young patient with brainstem tumour resection experienced increasing nasal redirection on initiation of effortful swallowing that subsided when the technique was discontinued.[7] In young healthy women, effortful swallowing was shown to increase sympathetic cardiac modulation, a sign of cardiac overload.[25] These studies require replication but should prompt clinicians to understand that, if a technique is powerful enough to effect a positive change, it may also be powerful enough to effect a negative change. It is critical to understand which direction our interventions take on not only the physiological feature of interest but other biomechanical and (neuro-)physiological processes as well.

Mendelsohn manoeuvre

Another technique, which was originally introduced as a compensatory technique but which is now being employed as a rehabilitative approach, is Mendelsohn manoeuvre.[8] Following initiation of swallowing, peak hyolaryngeal excursion is maintained for several seconds before relaxing and completing the swallow. The presumed benefit of this manoeuvre is prolonged suprahyoid contraction, which subsequently results in prolonged upper oesophageal sphincter (UOS) opening for improved bolus flow into the oesophagus. Repeated performance of this manoeuvre is now thought to result in improved cricopharyngeal compliance. In 1990 Logemann and Kahrilas[8] were the first to report the biomechanical effects of the Mendelsohn manoeuvre in a single case report of a patient presenting with dysphagia following lateral medullary infarct. Swallowing efficiency improved greater than twofold over other techniques in this patient. Subsequent basic research identified increased duration of anterior and superior hyolaryngeal excursion that resulted in delayed UOS closure on videofluoroscopic swallowing study. Miller and Watkin[22] later identified similar results using real-time ultrasound, and a further study employing manofluorography suggested that not only the duration but also the

intensity of pharyngeal contraction is increased during this manoeuvre.[26] McCullough and colleagues documented that, following 2 weeks of treatment, 18 patients with dysphagia following stroke demonstrated increased duration of hyoid excursion[27] and increased hyoid elevation,[28] which were not maintained after a subsequent 2-week, non-training period. Of note, two studies employing high-resolution pharyngo-oesophageal manometry in healthy volunteers demonstrated that, while pharyngeal pressures and bolus transfer were increased during Mendelsohn manoeuvre swallows, proximal oesophageal peristalsis was reduced.[9, 10] This phenomenon requires consideration in clinical populations with impaired pharyngo-oesophageal peristalsis and warrants further investigation.

Masako manoeuvre

The Masako, or tongue-hold manoeuvre, is the first potential rehabilitation exercise that was designed to directly address a specific underlying symptom. Fujiu and colleagues initially documented significantly increased anterior bulge of the posterior pharyngeal wall in patients who had undergone base of tongue resection for cancer treatment. [29] The Masako manoeuvre was designed to mimic this disorder by instructing individuals to 'protrude the tongue maximally but comfortably, holding it between the central incisors'.[30] In healthy participants, this manoeuvre resulted in videographically assessed increased anterior bulging of the posterior pharyngeal wall.[30] This manuscript provided a caution, however, about using this technique during bolus ingestion as the anterior tongue placement leaves the airway in a relatively unprotected, vulnerable position. When the technique was translated to a small population of three patients with base-of-tongue resection, the manoeuvre resulted in increased base-of-tongue to posterior pharyngeal wall contact pressures. This finding is remarkable considering that the posterior pharyngeal wall was required to compensate for the anteriorly resected base-of-tongue structures. In a group of 40 healthy individuals, however, oropharyneal and hypopharyngeal pressures did not differ during manoeuvre conditions, while UOS relaxation pressures were significantly reduced.[31] Using high-resolution pharyngeal manometry and intramuscular electromyography, it was similarly demonstrated that, in the absence of posterior tongue movement during tongue-hold swallows, activation of the superior pharyngeal constrictor was increased, resulting in stable pharyngeal pressures.[32]

Head-lift (Shaker) exercise

The Shaker exercise was originally introduced by Shaker et al.[33] and was designed to target floor-of-mouth muscle contraction outside the context of swallowing with the aim of increasing UOS opening during ingestion. Individuals are instructed to lie flat on their back and to raise their head until they can see their feet, without raising their shoulders off the bed. As such, this exercise is purely a muscle-strengthening exercise for the floor-of-mouth muscles involved in both the oral phase (lowering the jaw during chewing) and pharyngeal phase (contraction of floor-of-mouth musculature and subsequent anterior displacement of the hyolaryngeal complex) of swallowing. Importantly, this exercise does not strengthen other muscles involved in swallowing, as is the case with the effortful swallow or Mendelsohn manoeuvre. Research has documented that the Shaker exercise induced signs of fatigue in the floor-of-mouth muscles[34] and increased EMG amplitude during exercises,[35] suggesting an active involvement of these muscle during the exercise. In their initial study, Shaker et al. documented that this exercise resulted in increased laryngeal excursion, increased width and duration of UOS opening and consequently decreased UOS intrabolus pressure in healthy elderly individuals. Similar findings were reported in a subsequent study of stroke patients and patients with specific impairment of UOS opening.[36] After 6 weeks of exercise, all were able to resume oral feeding. Clinically, it is conceivable that this exercise may be a suitable addition to training with the effortful or Mendelsohn manoeuvres as it specifically targets the swallowing musculature and may hence counteract any biomechanical imbalance potentially induced by the latter two manoeuvres (as discussed above).

Expiratory muscle strength training

Expiratory muscle strength training (EMST) is quickly emerging into more widespread clinical practice and is a promising approach for pharyngeal swallowing impairment and airway protection. EMST emerged from the area of respiratory medicine and has since been adapted for speech and swallowing rehabilitation. EMST is designed to strengthen the contraction of the expiratory musculature by directing expiratory airflow through a one-way, spring-loaded valve that remains open in the presence of positive airflow. The resistance of the valve can be adjusted so that increasing valve resistance requires increasing expiratory airflow. Initial work by Sapienza et al.[37] demonstrated that EMST resulted in significantly increased expiratory airflow in young, healthy participants. Proof of concept for a potential application of EMST in swallowing rehabilitation was provided by a study that documented increased activation of floor-of-mouth muscles during EMST. As outlined above, these muscles play a critical role of providing anterior pull on the hyolaryngeal complex during swallowing which biomechanically facilitates UOS opening. Based on the promising early results, several studies of the effects of EMST in neurological populations have since documented that EMST may help recover respiratory muscle weakness in Parkinson's disease[38, 39] with a further study demonstrating greater hyoid movement and penetration–aspiration (P–A) scale scores following a period of EMST training.[40] Positive effects have also been reported in patients with multiple sclerosis on speech production and, importantly, strength of voluntary cough in patients with moderate disability.[41, 42] Similarly, EMST has been shown to increase maximum expiratory pressure and maximum hyoid displacement during swallowing in amyotrophic lateral sclerosis.[43]

EXPANDING THE INTERVENTION REPERTOIRE

As outlined in the previous section, the majority of interventions available for swallowing rehabilitation have traditionally focused on facilitating the recovery of swallowing function through biomechanical modifications that are largely driven by increased muscle strength. The assumption has persisted that, by increasing peripheral muscle strength, there would be consequent increased biomechanical force, which in turn would facilitate effective pharyngeal bolus clearance and airway protection. This approach may well be appropriate in some presentations of swallowing impairment; however, it may also well be inappropriate in others. By focusing solely on peripheral, biomechanical (dys)function, there has been little regard for the central neurological networks that drive human sensorimotor function. This represents a significant shortcoming in common management practices for patients with neurological impairment.

Increased understanding of swallowing neural control – particularly the role of the cerebrum in swallowing neural networks – has brought about a significant paradigm expansion in our collective approach to addressing swallowing impairment. Recent research favours the assumption that, if we can modify the underlying neurological substrates of swallowing, the changes in swallowing biomechanics will be more permanent and robust than what is seen following peripheral muscle exercise alone. Behavioural and non-behavioural techniques for neural modulation are currently under development and provide promise for new approaches to rehabilitation of swallowing impairment. These are briefly outlined below, accompanied by a discussion of ethical and practical challenges that may accompany their transition into routine clinical practice.

Behavioural, cortical modulation: skill training paradigms

Stevenson and Allaire[44] comment that a process of encephalization underlies the ability to modify the reflexive swallowing response seen in infancy to the more mature and variable response seen in adult-like, ingestive swallowing. Inherent in this comment is the suggestion that the 'skill' component of swallowing is acquired through cortical expansion and modulation of the primitive brainstem generated response. Quite unlike our current strength-based, peripheral approaches, relearning or modifying the complex sequence of swallowing events at the level of central control is gaining increasing recognition as a type of skill-based training following neurological impairment.

DEFINITION AND REQUIREMENTS OF SKILL TRAINING

Much of the conceptual research related to skill training derives from physiotherapy. In very brief summary, this research suggests that task-oriented skill-training programmes produce more favourable rehabilitative effects on recovery of motor impairments than strength-training programmes due to greater neuroplastic adaptation in the motor cortex,[45] greater corticomotor excitability,[46] greater functional movement improvements[47] and greater strength gains.[48]

Skill training can be defined as the acquisition of skill through functional repetition and refinement of movement patterns. However, fundamental knowledge of neurorehabilitation demands that mere repetition of a task will not improve skill; several additional criteria must be met. First, skill-based training must incorporate task-specificity to ensure cortical plasticity.[49] Thus any repetitive exercise must replicate the desired task – in this case swallowing. Second, there must be an element of task challenge and problem solving[50] to activate different brain circuits which underlie motor learning, neural and behavioural change.[51] Finally, extrinsic visual and intrinsic kinaesthetic feedback regarding task performance allows for evaluation of movement accuracy and correction on subsequent exercise trials.[52, 53]

EARLY ATTEMPTS AT TRANSLATING TO SWALLOWING RESEARCH

Translated to clinical routines, some of our traditional strength training approaches may indeed satisfy the task-specificity requirement by incorporating repetition of exercise into the context of functional swallowing; this would be the case with effortful swallowing, Mendelsohn manoeuvre, or tongue-hold swallowing. The adaptation required for task execution lends support for their application in skill-based training regimes with the focus on initiation and modulation of volitional swallowing rather than strengthening. Inclusion of ingestive swallowing in the treatment paradigm also meets the criteria for task specificity. However, there is likely to be very little therapeutic benefit from ingestion of a safely tolerated diet as it merely repeats a task with no challenge. The newly described McNeill Dysphagia Therapy Program[54] could be considered a type of skill training as it meets the requirement of task challenge. This protocol uses a hierarchical approach to bolus size and texture, thus systematically challenging oral intake in a controlled therapeutic environment. Another approach using surface electromyography as a biofeedback device has recently been described.[55] Although historically used to provide valuable feedback regarding increased strength of contraction, recent research suggests great benefit of this modality for increasing skill and precision of movement using a targeted, skill-based rehabilitation protocol[55] This protocol meets the characteristics of skill training by requiring repeated execution of skilled swallowing movements, progressive and challenging aims for timing and degree of muscle contraction, and ongoing and delayed feedback regarding task performance.

Proof of concept research in a sample of patients with dysphagia secondary to Parkinson's disease has documented significant improvements in quality of life and functional swallowing after two weeks of daily skill training. Other skill training approaches have been explored using manometry as a biofeedback device to alter timing characteristics of the pharyngeal response[56] and respiratory related feedback to improve swallowing respiratory coordination.[57]

Our past rehabilitation attempts that have focused on strength training may well have inadvertently facilitated recovery by increasing skill, more so than strength. Only recently have clinicians and clinical researchers focused specifically on therapeutic tasks to increase swallowing skill with the exclusion of potential imbalance in the biomechanical system through muscle strengthening. In doing so, rehabilitative outcomes are likely to improve as we develop greater specificity in treatment options.

Non-behavioural or behaviourally augmented central modulation: stimulation paradigms

The development of brain imaging and stimulation techniques has significantly expanded our understanding of the neurophysiological mechanisms of swallowing. Approaches designed to improve swallowing function through extrinsic modulation of central neuronal circuits involved in swallowing motor control have received increasing interest by researchers and clinicians alike. Approaches designed to improve swallowing function through extrinsic modulation of central neuronal circuits involved in swallowing motor control have received increasing interest by researchers and clinicians alike. A growing body of evidence now suggests that harnessing the brain's ability to reorganize its synaptic connections using stimulation techniques may in the future provide superior rehabilitation outcomes in some patient groups compared to 'traditional' behavioural intervention.[58, 59] Techniques developed to assess and promote neuroplastic reorganization in the human motor cortex, including transcranial magnetic stimulation (TMS), transcranial direct current stimulation (tDCS) and pharyngeal electrical stimulation (PES) will be briefly outlined below. At present, none of these techniques has been sufficiently evaluated in order to be applied in routine clinical practice; however, their evidence base is continuously expanding. Once optimal treatment paradigms have been developed and evaluated, it is highly likely that some, if not many, of these techniques will be available to the judicious clinician.

The reader is directed to Doeltgen and Huckabee[60] for a discussion of some of the practical and ethical considerations that accompany the transition of these techniques into routine clinical application. It is worth noting that several brain stimulation devices are already available for anyone to purchase over the internet.[61] This is likely to speed up the transition of some of these techniques into clinical practice and may challenge their application in an evidence-based framework.

TRANSCRANIAL MAGNETIC STIMULATION

Perhaps the most researched non-invasive brain stimulation technique in the field of swallowing rehabilitation is that of transcranial magnetic stimulation (TMS). Employing a strong but short-lasting electric current that is discharged through a coil of wires placed over a targeted cortical area, usually the primary motor cortex, a magnetic field is generated that painlessly penetrates the intact skull. At sufficiently high intensities, TMS transynaptically activates descending motor output neurons that in turn will generate descending volleys of action potentials. These can be measured at the periphery as a single motor-evoked potential (MEP) using surface electromyography. In its basic application, single-pulse TMS therefore allows assessment of the excitability of targeted motor circuits. Rapid application of up to several hundred TMS pulses, known as repetitive TMS (rTMS), can under certain circumstances modulate the trans-synaptic excitability of the targeted motor circuits and this effect may outlast the stimulation period by several hours.[62] The nature of the neuroplastic changes induced by rTMS heavily depends on its stimulation parameters, including frequency, intensity and stimulus pattern.

Conventional rTMS is applied in rhythmical trains of single stimuli. When applied at low inter-stimulus frequencies of less than 1 Hz, rTMS reduces corticospinal or corticobulbar excitability, whereas higher rTMS frequencies of greater than 1 Hz increase it. For example, in healthy research participants, 1 Hz rTMS applied over the motor projections to the pharyngeal musculature reduces the corticobulbar excitability of these projections, which is accompanied by a reduction in swallowing reaction time of normal and fast swallowing.[63] Although significant in its own right due to its proof of principle nature, this finding may be particularly important for future studies developing this paradigm into a rehabilitation approach for patients who present with delayed onset of swallowing, such as following stroke. Interestingly, when facilitory 5 Hz rTMS was applied to the non-dominant hemisphere, the inhibitory effects of the previous 1 Hz rTMS could be reversed, an effect that was shown to restore swallowing function.[64]

In a group of patients presenting with dysphagia following stroke, 5 Hz rTMS applied over the contralesional hemisphere was shown to increase pharyngeal motor cortical excitability, which was accompanied by a reduction in aspiration scores and pharyngeal residue.[65] In contrast, low-frequency 1 Hz rTMS applied over the ipsilesional hemisphere clinically increased swallowing response time for liquids and reduced aspiration for liquids and residue for paste on videofluoroscopy.[66] Applied at 3 Hz over the lesioned representation of the oesophageal musculature, rTMS resulted in improved clinical presentation of swallowing impairment in cortical stroke patients[67] and patients presenting with lateral medullary stroke or brainstem stroke.[68] Taken together, the findings of these studies suggest that rTMS may hold the potential to assist the recovery of swallowing function in various patient groups, although at present the variability in stimulation paradigms is reflective of the infancy of this approach.

TRANSCRANIAL DIRECT CURRENT STIMULATION

Although it has been developed over a century of invention and research,[69, 70] electrical stimulation of the human

central nervous system has only recently been rediscovered in the form of transcranial direct current stimulation (tDCS). Unlike its relatively painful relative, transcranial electrical stimulation, tDCS employs low-intensity electrical direct currents that modify the excitability of large neuronal assemblies mainly through changes in the transmembrane potential during stimulation. In general, anodal current flow applied over the primary motor cortex increases the excitability of its motor representations, whereas cathodal stimulation has the opposite effect. Originally demonstrated in the corticospinal motor system,[71] the bidirectional effects of tDCS have now also been demonstrated in the corticobulbar motor system involved in the control of swallowing. For example, cathodal tDCS at 1.5 mA intensity for 10 minutes reduced pharyngeal motor excitability, whereas 10 minutes of 1.5 mA or 20 minutes of 1 mA of anodal tDCS increased it.[72] When applied in a cohort of patients presenting with cortical stroke, 2 mA contralesional anodal tDCS applied for 30 minutes combined with effortful swallowing on 5 consecutive days increased functional swallowing based on clinical presentation.[73] Likewise, ipsilesional application of 1 mA anodal tDCS for 10 days[74] or 5 days[75] improved clinical ratings of swallowing function.

Several systematic reviews come to the conclusion that both rTMS and tDCS may hold a promising potential to assist the recovery of swallowing function. The reader is directed to these reviews for an in-depth discussion of the currently available evidence.[76–79] It is worth noting that in these clinical trials researchers evaluated the effects of the various tDCS paradigms on clinical outcome measures that were based purely on observational, clinical rating scales. Future studies are warranted to evaluate neurophysiological and biomechanical outcome measures underlying the reported clinical improvements.

PHARYNGEAL ELECTRICAL STIMULATION

Pharyngeal electrical stimulation (PES) differs from non-invasive brain stimulation techniques in that it is not applied directly to the central nervous system. Instead, a weak electrical current is applied to the sensory receptors of the pharyngeal mucosa via surface electrodes embedded in a catheter.[80] This technique deserves mention as it has been systematically evaluated in several seminal studies in both healthy and swallowing-impaired populations. The cumulative evidence so far suggests that this approach may provide a suitable means of modifying the excitability of corticobulbar projections relevant for swallowing. When applied using optimal stimulus parameters,[80] increased excitability of the pharyngeal cortical motor representation was accompanied by an improvement in dysphagic symptoms, including pharyngeal transit times and aspiration scores.[81] Similarly, a single application of PES in a group of patients presenting with chronic stroke resulted in an increase in corticobulbar excitability of the unaffected hemisphere and was associated with a decrease in aspiration scores.[82] The neuroplastic effects induced by PES appear to have a cortical origin[80] and may be modified by genetic influences.[81] Based on these preliminary findings, PES may be a promising alternative to non-invasive stimulation techniques that are directly applied to cortical neuronal tissues, especially in patients who meet exclusion criteria for these techniques.

NON-INVASIVE BRAIN STIMULATION IN THE CONTEXT OF EVIDENCE-BASED PRACTICE

The transition of any new intervention from the research laboratory into routine clinical practice will naturally need to occur within the framework of evidence-based practice. Sackett et al. define this as the synthesis of external research evidence, internal clinical expertise of the treating clinician and client preferences.[83] As outlined in this chapter, a growing body of external scientific evidence presently outlines the promising potential of peripheral or central stimulation techniques targeting swallowing-related neuronal networks to support swallowing rehabilitation efforts. Further large-scale clinical trials are required to establish optimal stimulation paradigms and to test these for their safety and efficacy. The judicious clinician will eventually be able to incorporate this knowledge into their own clinical reasoning and guide their clients towards making fully informed decisions. In recognition of our responsibilities regarding beneficence and non-maleficence in research and clinical practice, this process will occur gradually and within the framework stipulated by the Declaration of Helsinki (2013).

SWALLOWING REHABILITATION – A RAPIDLY CHANGING LANDSCAPE

As outlined in this chapter, swallowing rehabilitation practices are undergoing a significant and rapid expansion from focusing solely on modification of peripheral biomechanics towards understanding and harnessing the neurophysiological mechanisms that underlie human swallowing. As such, researchers and clinicians are challenged to address the required cultural, ethical and organizational issues that accompany the development of novel skill-training and brain-stimulation techniques. These challenges include questions regarding the provision of neuromodulatory interventions to patients, determination of professional competencies and scope of practice as well as practical implications for patient services.[58] Partnerships between stakeholders across the various professions involved in swallowing rehabilitation will facilitate the development of required institutional frameworks locally and globally. Unrestricted access to information via the internet has accelerated the transition from bench top to routine clinical application in many areas of health services. It is therefore likely that patients will increasingly become more vocal stakeholders in the clinical decision-making process than perhaps has previously been the case. It will be the responsibility of clinical service providers to guide their patients in this process by providing individually tailored, evidence-based advice.

KEY POINTS

- Swallowing rehabilitation practices have traditionally focused on enhancing oropharyngeal swallowing biomechanics primarily through muscle strengthening exercise.
- With increased recognition of the role of the cortex in modulating swallowing behaviour, contemporary approaches to rehabilitation are shifting attention from muscle strengthening to the capacity for control adaptation.
- Skill-based behavioural training approaches are emerging that maximize voluntary volitional control, with early research seeking to define this type of treatment and provide proof of concept outcomes.
- Neuromodulatory approaches that employ cortical and peripheral non-invasive neurostimulation techniques are being actively researched with preliminary evidence to suggest that certain non-invasive brain stimulation protocols can improve some aspects of dysphagia.
- The development of competency and regulatory frameworks will be required to facilitate the transition of novel behavioural and neuromodulatory approaches to clinical practice.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: dysphagia, aspiration, unsafe swallow, cricopharyngeal dysmotility, pharyngeal pouch and laryngeal incompetence.

INTRODUCTION

The larynx, trachea and bronchi form the conduit between the lungs and the external environment through which respiratory gases are transported and pulmonary secretions are expectorated. The larynx is also the primary organ of phonation, acts to protect the airway from aspiration during swallowing and provides important sensory feedback and movements that are critical to the control of ventilation.[1] Swallowing is a highly complex process, both voluntary and involuntary, requiring the precise coordination of many different muscle groups through the actions of sensory and motor nerves via the central nervous system.

Charles Darwin noted in *On the Origin of Species* that the human is the only animal whose upper aerodigestive tract fails to adequately serve its principal evolutionary functions of preventing aspiration and acting as the gateway to the lungs.[2] In all mammals, including the human infant, the pharyngeal airway is short and the epiglottis and the soft palate are anatomically related, allowing simultaneous swallowing and breathing. Starting at 4–6 months of age, the larynx descends in man, leading to loss of nasolaryngeal association. The neonate's larynx lies at the level of the 3rd cervical vertebra and the adult larynx lies at the level of the 6th cervical vertebra. This adult position allows humans to meet the requirements of complex speech through resonance and articulation.

Aspiration is contamination of the tracheobronchial tree with secretions, food material and other contaminants. Prevention of aspiration occurs primarily through reflex laryngeal closure, laryngeal elevation and cessation of breathing during swallowing, and any aspirated contents are expelled through coughing. A certain amount of aspiration is normal in humans, especially during sleep,[3] but is tolerated without complications in healthy subjects with normal tracheobronchial ciliary function and normal immunology.

The response to even small quantities of aspiration will depend on the pH of the aspirate, microorganisms present and the person's pulmonary and immunological status. This may lead to cough or in some cases life-threatening pulmonary complications. In cases where the cough reflex is reduced or absent, 'silent' aspiration may occur. Acute severe aspiration of a large bolus may lead to airway obstruction and may prove fatal, whereas chronic small

volume aspiration may risk pneumonia or respiratory failure through chronic pulmonary emphysematous disease or bronchiectasis.

Chronic or intractable aspiration is usually associated with a significant impairment of the normal swallow, especially if there is a dysfunction of the larynx or pharynx.

PRESBYPHAGIA

Although it is widely believed that swallowing function deteriorates with age, the evidence supporting this is inconclusive, especially if one excludes the affects of neurological disorders, diabetes mellitus and connective tissue diseases.[4] The changes in swallow function with age appear to be modest but there does appear to be a reduction in the swallowing function reserve and 'plasticity', lowering the threshold for dysphagia and aspiration, and impairing the success of swallowing therapies, manoeuvres and corrective surgery.

Swallowing is a complex process that requires finely coordinated neurological inputs and is therefore susceptible to a variety of structural and neuromuscular diseases.[5–7]

EVALUATION OF THE 'ASPIRATING PATIENT'

All patients with severe swallowing problems and aspiration should be assessed and managed in a multidisciplinary setting. This team should include an otolaryngologist with a special interest, swallowing therapist, gastroenterologist, neurologist and dietitian, and have access to appropriate radiology and respiratory medicine.

A thorough history from the patient, relative or referring physician will often reveal the cause of the aspiration.

Physical examination is essential and must include examination of the head, neck and upper aerodigestive tract with functional assessment of the cranial nerves.

Flexible nasal endoscopy in the clinic will help exclude tumours and masses as well as determine laryngeal function and sensation. The signs may be subtle, with even small quantities of pharyngeal residue or secretions indicative of a swallowing problem. At the other extreme there may be significant pooling of secretions, bathing an oedematous, asensate larynx and freely entering the airway.

Videofluroscopic (VF) assessment of swallowing should always be performed in conjunction with a swallowing therapist. The investigation provides valuable information about the nature of the swallowing disturbance and degree of aspiration. Ideally it is performed using limited amounts of barium but where there is clinical suspicion of aspiration then a water-based radiological contrast agent should initially be trialled.

Functional endoscopic evaluation of swallowing (FEES) uses dyed liquids, semi-solids and solids, which are sequentially swallowed with nasopharyngeal fibre-optic observation and video recording. Swallowing strategies can be trialled and recorded during the assessment. The technique will diagnose aspiration but has the added advantages that it avoids radiation and can be performed by the bedside. In addition, it can be viewed with the patient, and provides biofeedback to the patient regarding the benefits of swallowing strategies and manoeuvres.

Objective assessment tools for aspiration are available. The Penetration-Aspiration Scale[8] uses data from FEES and VF studies, and the New Zealand Index for Multidisciplinary Evaluation of Swallowing (NZIMES)[9] and the MBS Measurement Tool for Swallow Impairment (MBSImp)[10] rely on data from VF. The most widely accepted subjective score for dysphagia is the Eating Assessment Tool (EAT-10).[11]

PRINCIPLES OF MANAGEMENT

The aims are to protect the airway, avoid life-threatening respiratory complications and achieve adequate nutrition, while also considering the psychological and social aspects of food and feeding. As previously mentioned, these patients should be assessed and treated in a multidisciplinary team environment.

TABLE 56.1 Causes of an unsafe swallow

Neurological and neuromuscular disorders	Auto-immune disorders	Damage to larynx, pharynx or neck	Others
• Cerebrovascular accidents • Head injuries • Hypoxic brain injuries • Parkinson's disease • Amyotrophic lateral sclerosis • Multiple sclerosis • Motor neurone disease • Muscular dystrophy • Myasthenia gravis • Guillain-Barre syndrome • Myopathies • CNS tumours • Neurosurgery or skull-base surgery	• Systemic sclerosis (scleroderma) • Bullous mucosal conditions • Systemic lupus erythematosis • Sjögren's syndrome and salivary gland diseases	• External trauma (RTA or sports injuries) • Internal trauma (caustic ingestion) • Reflux diseases • Post-surgical (conventional and trans-oral laser) • Post-irradiation • Neoplasms • Strictures	• Intoxication or drugs • Eosinophilic oesophagitis • Pharyngeal pouch • Cricopharyngeal muscle discoordination/ spasm • Achalasia • Severe illness or nutritional deficiencies • Amyloidosis

Under the direction of the swallowing therapist, where possible, compensatory techniques, dietary modification and appropriate exercises should be trialled (discussed in Chapter 66, Speech/voice therapy for voice disorders). Medical therapy should be directed at dealing with the underlying cause of the dysphagia. Excessive secretions sometimes respond to the use of anticholinergic patches but these may be associated with unacceptable side effects. Alternatively, ultrasound guided botulinum injections to salivary glands[12] may be considered.

The oral phase of swallowing is quite complex and attempts at surgical restoration, usually following cancer surgery, at best create a mass of tissue to optimize any residual function with compensatory techniques. Surgery for swallowing is generally limited to the pharyngeal or oesophageal phases and even then it can only be directed at specific sites contributing to the dysphagia or aspiration. In many cases surgery is not possible because of the very poor health of the patient or poor prognosis, or because a surgically correctable cause is not identifiable.

Progressive deterioration of swallowing function, leading to aspiration, can be assessed at intervals in the multidisciplinary swallowing clinic and appropriate investigations, therapies or procedures can be directed for the best possible quality of life for the patient. Patients may present acutely with severe aspiration, usually following an acute neurological event. A bedside assessment is usually adequate to identify those in whom oral intake should be discontinued and an alternative route of nutrition provided. Initially this will be via a small nasogastric feeding tube but where recovery is unlikely, or is likely to take many days or weeks, then a gastrostomy feeding tube should be considered. Antibiotics and pulmonary physiotherapy should be commenced where appropriate.

Nasogastric and gastrostomy feeding tubes will not eliminate aspiration of secretions and further consideration needs to be given to airway protection. A tracheostomy tube with a low-pressure cuff allows airway toilet in patients with copious secretions; however, current cuff design does not eliminate the passage of secretions into the lower airway.[13] The tracheostomy tube also reduces laryngeal elevation by 'anchoring' the trachea, and the inflated cuff compresses the oesophagus,[14] resulting in partial obstruction (**Figure 56.1**). In addition the tracheostomy reduces the effectiveness of the cough, and bypassing the normal flow of air through the larynx may reduce laryngeal sensitivity. On intensive care units there is increasing use of tracheostomy tubes with a suction port above the cuff, reducing the risk of secretion aspiration.

A tracheostomy tube is therefore not the ideal solution to chronic aspiration and when used for this purpose will require close attention and frequent suctioning of the oropharynx and tracheostomy, especially in the debilitated patient.

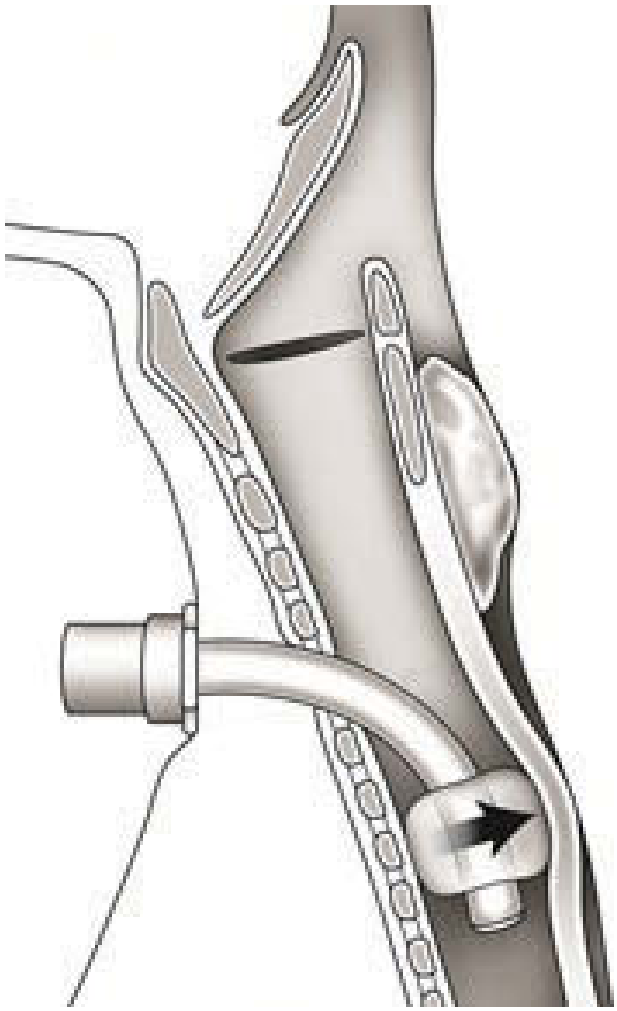

Figure 56.1 A tracheostomy tube can have an adverse effect on swallowing by reducing laryngeal elevation and also by oesophageal compression through direct transmission of cuff pressure.

SURGERY FOR CHRONIC ASPIRATION

Patients with palatal incompetence suffering nasal reflux or escape may benefit from prosthetic appliances to elevate the soft palate, or velopharyngeal flap techniques may be considered.[15]

In cases of dysphagia and aspiration due to parapharyngeal or retropharyngeal masses, then surgical removal of these is likely to be helpful.

It is well recognized that the trans-oral laser approach to removing even small tumours on the posterior pharyngeal wall may result in severe dysphagia and aspiration,[16] even in the younger patient. This is thought to be due to disruption or damage to the pharyngeal plexus. Careful thought should also be given to external surgical approaches to the pharynx and upper oesophagus in the older patient. These patients have minimal swallowing reserve and surgical scarring contributing to tethering of the larynx or pharynx, or damage to the pharyngeal plexus may adversely affect the safety of swallowing.

Sometimes osteophytes from the cervical spine will be seen to overhang the laryngeal inlet and act as a 'ski-slope' for food and secretions in to the airway (**Figure 56.2**). The trans-oral, trans-pharyngeal approach to these will certainly risk exacerbating the swallowing problem. An external approach to the anterior cervical spine, with

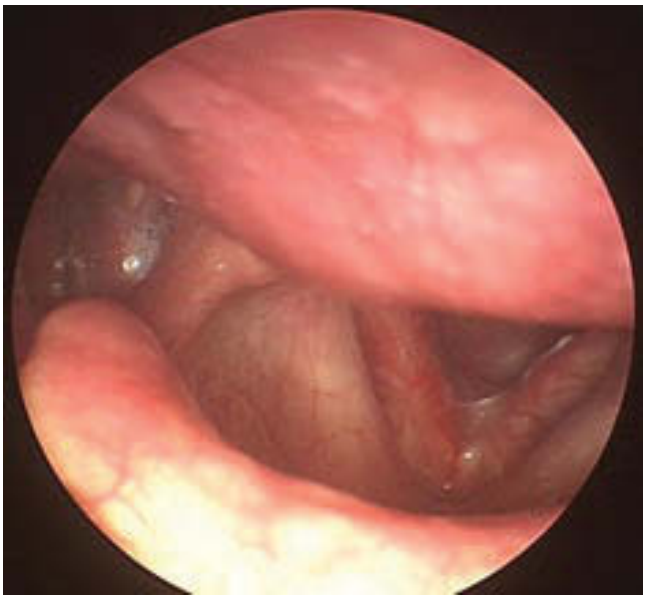

Figure 56.2 Osteophyte from cervical spine overhangs the laryngeal inlet and can be associated with secretions dripping into the airway.

Figure 56.3 Fibre endoscopic view of larynx in a patient who has aspiration (milk with green dye during FEES study).

Figure 56.4 View of cricopharyngeus through a laryngoscope. Botulinum toxin is injected in the three positions (arrows) to produce the effects of a 'temporary myotomy'.

lateral retraction of the larynx and pharynx, is a viable option but may affect swallowing, for the same reasons mentioned earlier in this chapter, and there is potential for injury to the recurrent laryngeal nerve. Sometimes a laryngeal suspension procedure will elevate the larynx away from such an osteophyte and not risk the swallow further.

SURGERY TO THE CRICOPHARYNGEAL SPHINCTER

If flexible nasendoscopy demonstrates pooling of secretions in the hypopharyx (**Figure 56.3**), then based on the medical history and videofluoroscopic imaging it is possible to determine whether this is due to weakness of the pharyngeal musculature, a hypertonic or discoordinated cricopharyngeal sphincter, or both.

In these circumstances it is logical to think about an upper oesophageal myotomy. One cannot always be confident of the results of an external approach myotomy and for this reason the authors prefer a trial of a 'medical myotomy' using botulinum toxin.[17] A total of 80–120 units of botulinum toxin A is administered into cricopharyngeus in three separate injections, dividing the total dose. A short general anaesthesia and direct visualization of this muscle, using a laryngoscope, allows one central and two postero-lateral injections to be placed accurately (**Figure 56.4**). If this treatment is successful it can either be repeated or be followed by an endoscopic CO2 laser myotomy (**Figure 56.5**).[18] Very rarely is an external approach myotomy required.

LARYNGEAL INCOMPETENCE

The airway has several levels of protection against aspiration. During a swallow the larynx moves up and forwards to lie under the tongue base, the epiglottis moves to lie above the laryngeal inlet and the true and false cords adduct. If there are residual secretions in the hypopharynx, aspiration can still take place even if the larynx is functioning normally. Even though the larynx elevates during a swallow, as it descends to its resting position retained secretions can enter the airway. Usually this will produce a cough, but this may not be the case in a neurologically impaired patient. In addition, when the larynx has been exposed to chronically retained secretions there is associated oedema of the laryngeal mucosa and diminished supraglottic sensation.

More commonly the cause of laryngeal incompetence is damage to a vagal nerve, high in the neck, which affects both motor and sensory function of the unilateral larynx as well as the associated pharyngeal musculature.

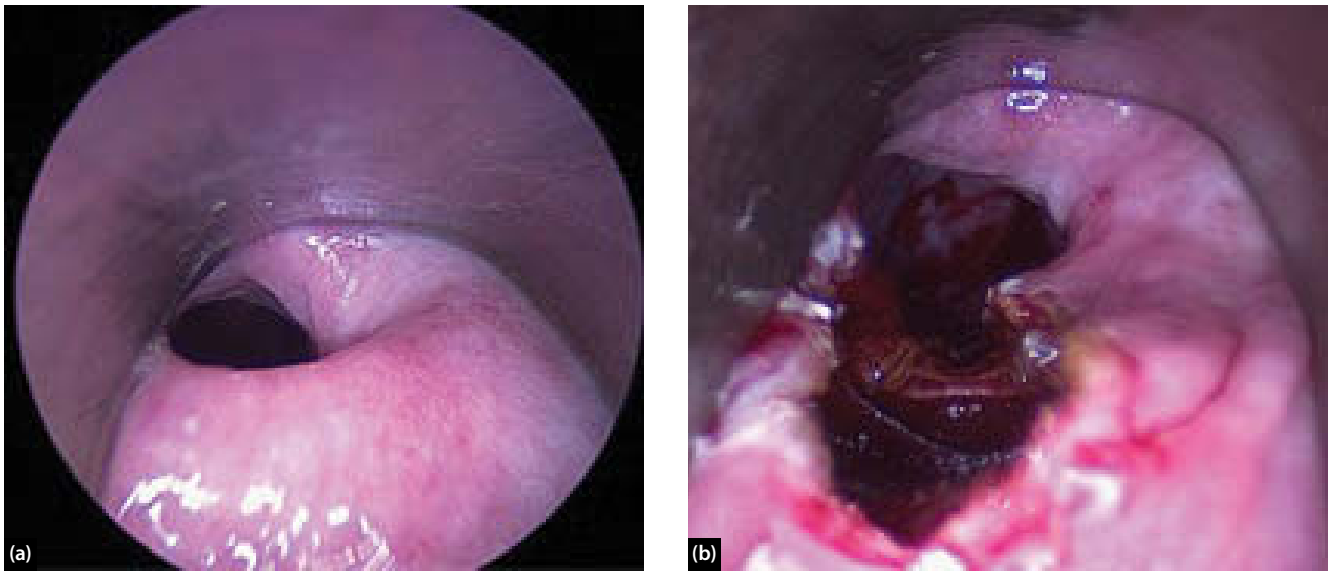

Figure 56.5 Result of endoscopic CO2 laser cricopharyngeal myotomy (right).

Cerebrovascular events, especially if involving the brainstem, and progressive muscle wasting conditions can also lead to impaired laryngeal and pharyngeal competence. A plethora of approaches has been described to deal with this particular problem; the sheer variety, and the absence of large trials, would suggest inconsistent results.

Bilateral vocal fold medialization techniques have been described to deal with this problem. These can consist of injections lateral to the thyroarytenoid muscle. Laryngeal injections can be carried out under local or general anesthesia and most are temporary (see Chapter 68, Movement disorders of the larynx). They are ideally suited for conditions where there is likely to be a recovery of laryngopharyngeal function within a few weeks, or as a test of medialization suitability prior to medialization thyroplasty procedures that are described as permanent. Thyroplasty implants include Gore-Tex ribbon, titanium, hydroxylapatite and silicon. Bilateral medialization thyroplasties were first described for vocal cord bowing[19] as seen with presbyphonia. In these circumstances the posterior edge of the implant needs to sit anterior to the vocal process of the arytenoid so that it does not interfere with normal abduction of the cords. However, bilateral medialization for aspiration requires adduction of the entire vocal cord.[20] The technique works in carefully selected cases of mild aspiration[21] as it does not prevent all aspiration and risks patients requiring a tracheostomy.

Unilateral vocal fold medialization or arytenoid adduction[22] techniques in combination with cricopharyngeal myotomy are described for cases of vagal nerve injury leading to aspiration. In some cases of high vagal injury there is associated hypopharyngeal dilatation leading to excessive pooling of secretions in the pyriform. Denker originally devised a technique for excising the redundant pharyngeal mucosa on the affected side, through an external approach, which others have modified with the use of plication sutures or a stapling device.[23] With these 'hypopharyngeal pharyngoplasty' procedures it is usually necessary to perform a cricopharyngeal myotomy and cord medialization at the same time.

GLOTTIC AND SUPRAGLOTTIC LARYNGEAL CLOSURE

The first glottic closure procedure, performed through a median laryngofissure, was described by Montgomery in 1975[24] and involved stripping the vocal cord mucosa on both sides and suturing the cords together to encourage fibrous union. As an alternative to damaging the vocal cords, a two-layered closure of the supraglottis (**Figure 56.6**) was devised via a pharyngotomy approach.[25] This was later modified by Remacle et al.[26]

The problems with these two approaches are that they run a high risk of breakdown and, as the larynx is closed, the patient is tracheostomy dependent and has no voice. Also these procedures are not easily reversible. In 1975 Biller et al.[27] described a two-layer, vertical supraglottic closure, with a small opening at the tip of the epiglottis (**Figure 56.7**). The procedure was designed to prevent aspiration in total glossectomy patients. Some retained the

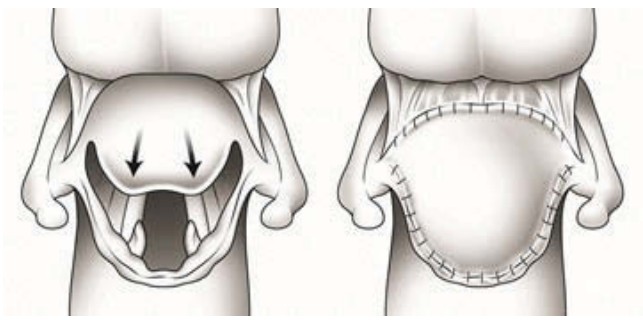

Figure 56.6 Horizontal closure of the supraglottic larynx via a lateral pharyngotomy approach.

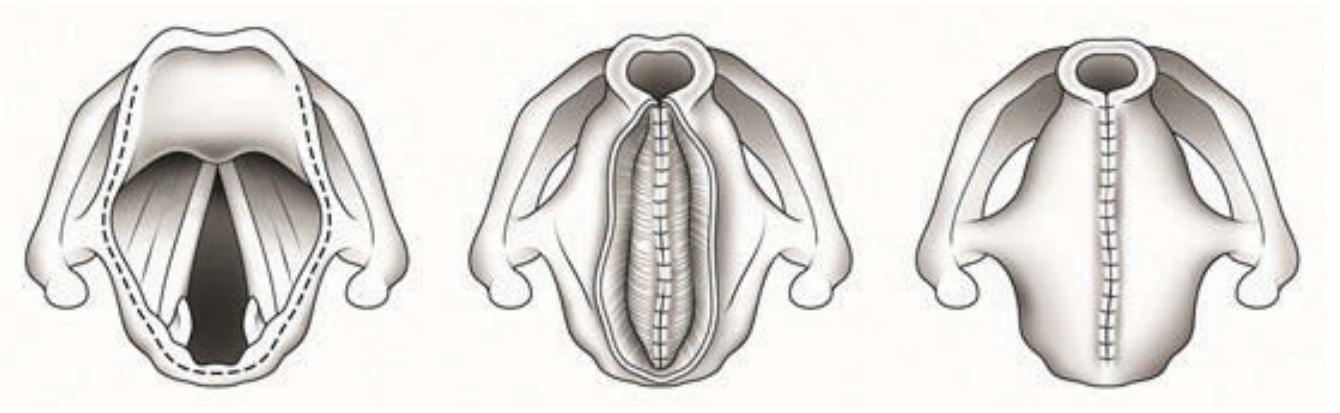

Figure 56.7 Biller supraglottic laryngoplasty for treating chronic aspiration in total glossectomy patients.

ability to speak and others could commence oral intake but retained a tracheostomy tube.[28]

LARYNGEAL PROSTHESES

A translaryngeal, closed stent is one means of preventing aspiration and can be placed endoscopically and held in place with trans-cervical sutures.[29] The theoretical advantage is that the stent can be removed if the patient recovers a safe swallow. Unfortunately these stents cause scarring at the level of the glottis, are uncomfortable and do not provide a reliable seal to secretions.[30] With advances in biointegratable materials and the work on implantable larynges[31] there is hope for prostheses that allow voicing, without aspiration, but the patient may still need a tracheostomy.

OESOPHAGEAL MOTILITY DISORDERS

Oesophageal motility disorders can lead to retained secretions in the hypopharynx and risk aspiration. They result from either primary diseases of the musculature or from an imbalance between excitatory and inhibitory innervations. Historically the diagnosis has been based on VF but high-resolution manometry with oesophageal pressure topography has become the current gold standard.

Abnormalities of oesophageal function are common in patients with gastro-oesophageal reflux disease (GORD).[32] Mild cases of dysmotility can be managed by suppressing gastric reflux through the use of proton pump inhibitors, prokinetic antibiotics (macrolides) or prokinetic drugs (domperidone). In severe cases, such as spasm or hypertensive peristalsis, medical treatment with nitrates and calcium channel blockers may prove effective. Endoscopic dilatations and Botox injections may help with more localized problems such as achalasia (lower oesophageal sphincter) or cricopharyngeal spasm (upper oesophageal sphincter). A permanent solution in these patients includes a myotomy.

Secondary motility disorders may be related to neurological or connective tissue diseases, as well as diabetes and rarer disorders such as amyloidosis, Sjögren's syndrome and eosinophilic oesophagitis.

PHARYNGEAL POUCH

A pharyngeal pouch (Zenker's diverticulum) is a posterior pulsion diverticulum occurring, in a natural weakness (Killian's dehiscence), between the fibres of thyropharyngeus and cricopharyngeus. They are associated with an oesophageal motility disorder in the vast majority of cases. The symptomatic patient complains of dysphagia, regurgitation of food, coughing, aspiration or repeated chest infections. Treatment is indicated when symptoms impact on quality of life or pose a risk to the patient's health.

Endoscopic techniques transect the diverticulo-oesophageal wall so that material does not collect in the pouch. This transection also divides cricopharyngeus (**Figure 56.8**) and some upper oesophageal muscle fibres, and quite neatly performs a synchronous myotomy (**Figure 56.9**). Division of this dividing wall has evolved from using electrocoagulation, the CO_2 laser and more recently endoscopic stapling devices.[33] The endoscopic approach is not always feasible if there is poor access

Figure 56.8 Pharyngeal pouch party wall.

Figure 56.9 Pharyngeal pouch party wall divided.

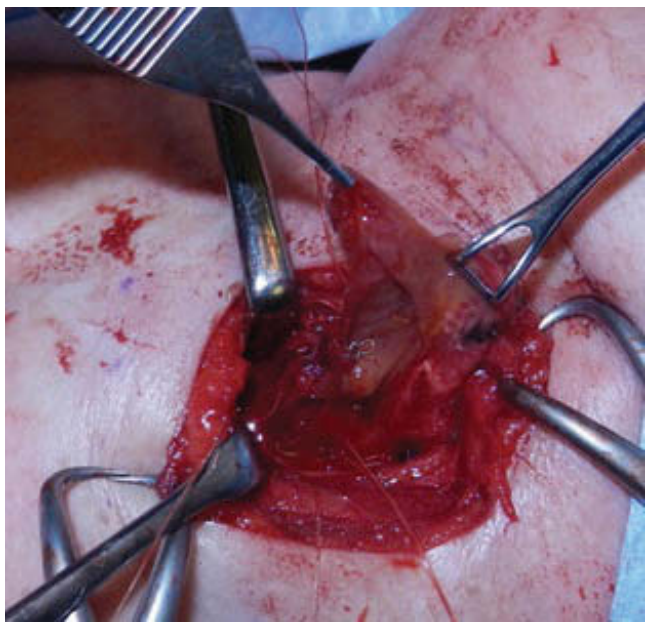

Figure 56.12 Mucosal edge of open pharynx and oesophagus with pouch excised.

and it is not always suitable for very small or very large pouches, and there is still a small incidence of post-operative leaks with the risk of mediastinitis.[34] In some cases it is necessary to perform an external approach diverticulectomy (**Figures 56.10–56.12**) combined with a cricopharyngeal myotomy. This does, however, mean a longer hospital stay with increased morbidity (see Chapter 52, Cricopharyngeal dysphagia).

RADIOTHERAPY-RELATED DYSPHAGIA AND ASPIRATION

Radiotherapy to the head and neck is responsible for both early and late changes to the irradiated site. The effects of radiotherapy can vary between individuals even if the dosing is identical. In general the degree of radiotherapy damage depends on: total dose; adjuvant chemotherapy; the extent of the radiotherapy fields at the primary site; and whether the neck has also been treated.

Early radiotherapy therapy changes include mucositis, erythema and pain but also oedematous thickening of soft tissues, weakness of muscles altered taste, altered sensation and reduced oral secretions. Late changes (beyond 6 months) include tissue fibrosis, damage to the blood supply, neuropathic changes, reduced contraction of muscles and joint mobility restriction. The irradiated pharynx will be poorer at clearing secretions and the larynx, if irradiated, may demonstrate poor closure and elevation. In patients receiving radiotherapy for hypopharyngeal or post-cricoid tumours, the scarring and stricture formation may continue for 10 to 20 years after exposure and aspiration may be a very late presentation.

Treatment of post-radiotherapy-related dysphagia and aspiration includes compensatory manoeuvres, dietary

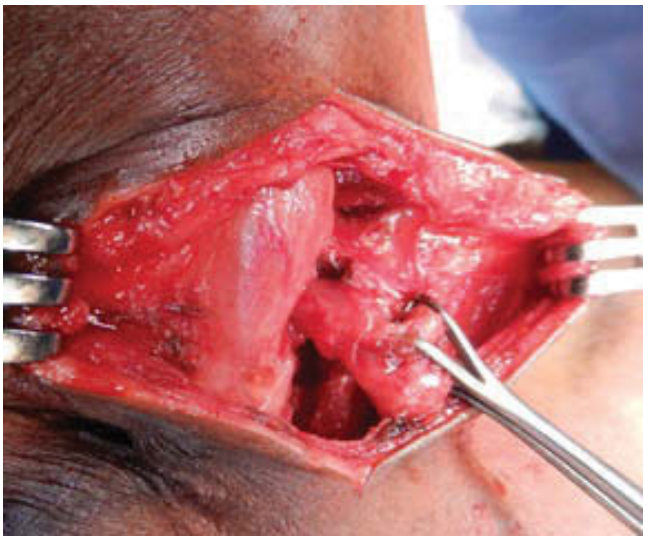

Figure 56.13 Transverse colon transposition in a patient with caustic injury to the pharynx, oesophagus and gastroduodenal areas. Hypopharynx visualized, scarred neck from previous surgery for caustic pharyngeal and oesophageal injury.

modifications and other forms of nutrition. Surgical options are often limited to serial dilatations or ultimately a laryngectomy or laryngopharyngectomy with free flap reconstruction. The authors have used lateral pharyngeal augmentation techniques, with rotational or free myocutaneous or bowel flaps, in cases of hypopharyngeal strictures following caustic ingestion (**Figures 56.13–56.16**), in whom results are more favourable, but the results in radiotherapy patients have been poor.

New radiotherapy techniques, such as intensity-modulated radiotherapy (IMRT), can minimize exposure and damage to structures related to swallowing and the salivary glands and are likely to reduce the incidence of these complications.

LARYNGOTRACHEAL SEPARATION

Laryngotracheal separation[35] is described as a simple procedure that allows protection of the airway, while preserving the swallow. The patient's lower airway opens as stoma in the neck and the trachea just below the subglottis is closed as a 'blind-ending' (**Figure 56.17**). As it is reversible it has the potential for restoring voice when the patient recovers. It is however, associated with a high incidence of complications (40%) that include wound breakdown and fistulae, and also airway stenosis at the subsequent tracheal anastomosis; some of the patients go on to require a long-term tracheostomy or laryngectomy.[36]

Tracheo-oesophageal diversion is a modification of the Lindeman procedure described above. The proximal tracheal segment is anastamosed in an end-to-side fashion to an opening in the anterior oesophagus thus eliminating the 'sump' of secretions that results with the former technique. The modification does add to the potential for complications at the primary procedure and when reversed. Both of these procedures make it difficult to be confident

Figure 56.14 Transverse colon mobilized in a heavily scarred abdomen.

Figure 56.15 Transverse colon mediastinal transposition.

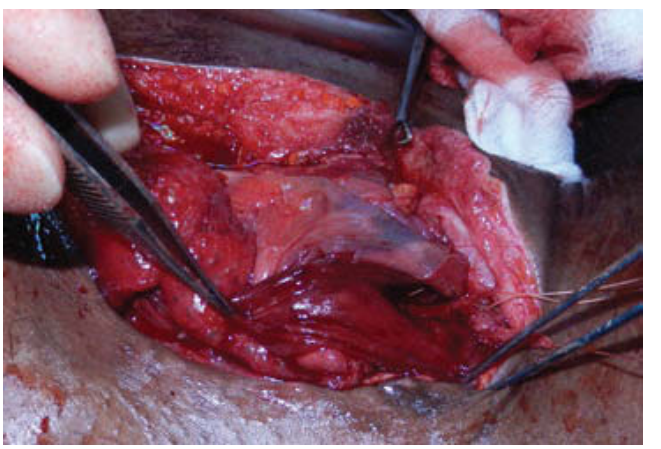

Figure 56.16 Pharyngo colonic anastomosis.

of adequate recovery of swallowing function to commit to a reversal, as evidenced by the number of patients requiring subsequent tracheostomies and laryngectomies.[36]

LARYNGEAL AND LARYNGOHYOID SEPARATION

In severe cases of aspiration where there is reduced laryngeal elevation, excessive pooling of hypopharyngeal secretions and reduced laryngeal sensation, or severely discoordinated swallowing, the aspiration poses a significant risk to life. If there is also limited likelihood of recovery of swallow function, yet life expectancy is still

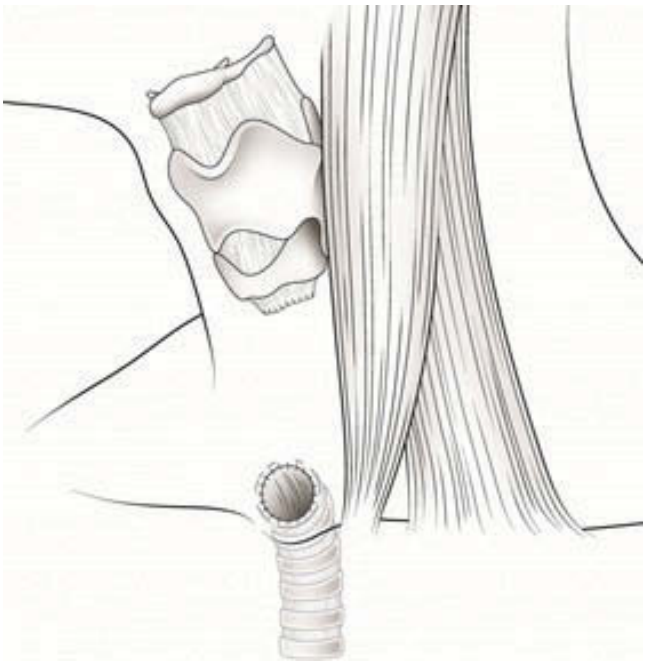

Figure 56.17 Laryngotracheal separation procedure. The airway is closed below the subglottis and the distal trachea is brought out to the skin surface as a stoma.

reasonable, then the safest option is to consider a narrow-field laryngectomy.

There are, however, some intermediate measures to consider before taking such a drastic step. Laryngeal suspension to the hyoid bone is well documented[37] but the results are not always reliable. Part of the problem is that the degree of suspension achieved is fairly limited and often less than 1 cm. The authors have developed an 'enhanced laryngeal suspension' procedure where the thyroid cartilage is removed starting a few millimetres above the level of the glottis, the base of the superior horn of this cartilage is also resected and a more significant thyrohyoid approximation is achieved using braided monofilament sutures. As the sutures in the thyroid cartilage are placed postero-laterally and those in the hyoid near the midline, anterior transposition of the thyroid cartilage is achieved. This technique should be performed synchronously with a cricopharyngeal myotomy and can be combined with a medialization thyroplasty (**Figure 56.18**).

Hans Mahieu[38] performs a standard laryngeal suspension but also suspends the thyrohyoid complex to the mandible (**Figure 56.19**) and includes an upper oesophageal sphincter myotomy. This elevates the larynx away from hypopharyngeal secretions but also pulls open the upper oesophageal inlet.

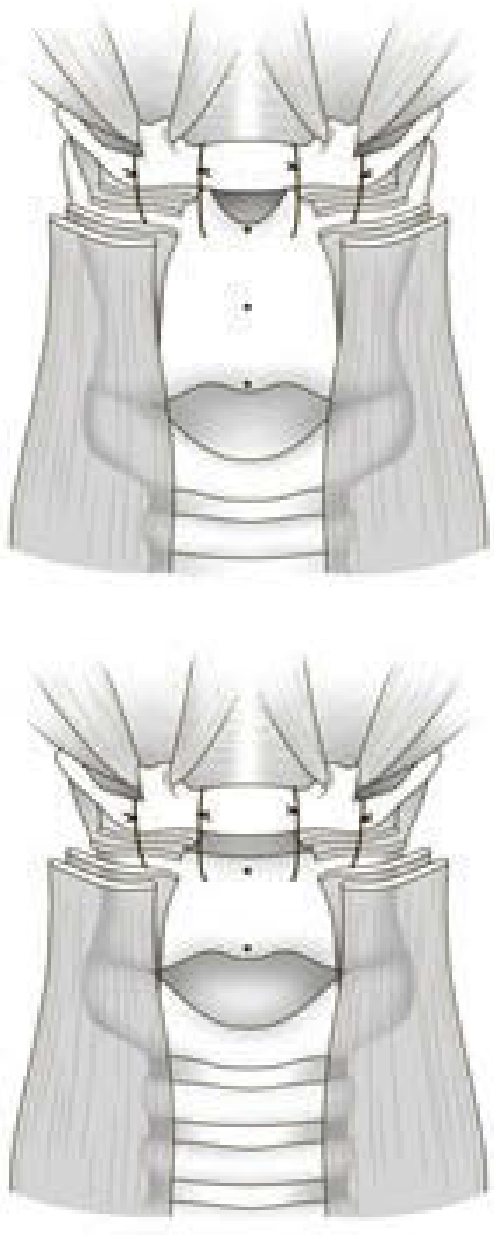

Figure 56.18 (a) a standard laryngeal suspension. (b) an enhanced laryngeal suspension. The thyroid cartilage is excised, from within its perichondrium, above a line representing the level of the glottis (midpoint dot on (a)). The base of the superior horn of the thyroid often needs to be divided to allow successful thyrohyoid approximation.

LARYNGECTOMY

A narrow-field laryngectomy removes the laryngeal skeleton but spares the hyoid, the strap muscles and hypopharyngeal mucosa allowing for a multiple layer closure with reduced incidence of a fistula. Preservation of pharyngeal mucosa also means that pharyngeal closure could be achieved using a linear stapling device[39] and feeding commenced within 5–7 days.

DISCUSSION

The ideal surgical procedure for chronic aspiration would be simple, associated with few complications, allow speech and swallowing, and be easily reversible without long-term sequelae. The majority of patients with a

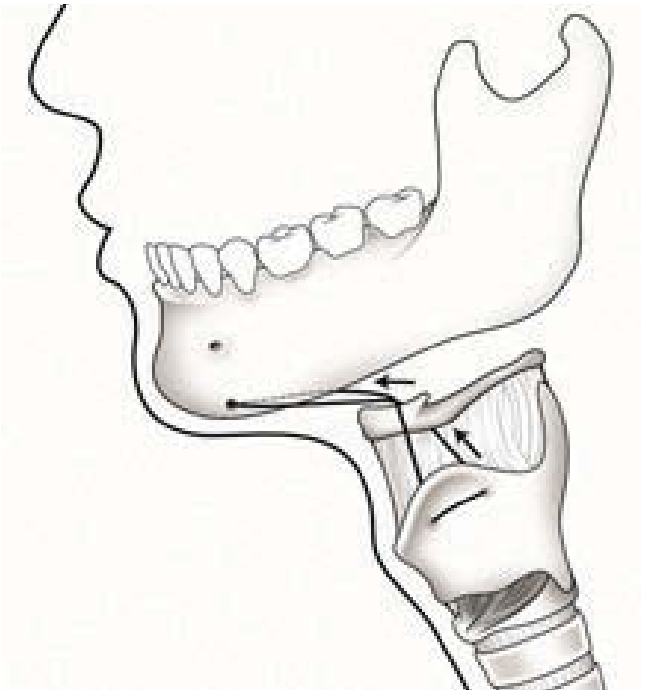

Figure 56.19 Thyrohyoid complex is suspended to mandible.

reversible neurological deficit tend to show recovery within a few months and it is the practice in most units to manage these patients with tracheostomies and feeding tubes even though this may be far from ideal. There are therefore very few indications for reversible procedures. Dysphagia with mild aspiration due to dysfunction of cricopharyngeus, weakness of the hemilarynx or reduced pharyngeal constrictor activity can usually be managed with a cricopharyngeal myotomy, vocal cord medialization with or without excision of the redundant pharyngeal mucosa. Laryngeal or laryngohyoid suspension may be considered in more severe cases.

The difficult decision is in those patients who are not going to recover a safe swallow or who are suffering with either a neurological condition that is progressive, or severe scarring and contracture related to radiotherapy treatment. Supportive procedures described above may be helpful for a period but there will come a time when a laryngectomy may become the procedure of choice. It provides a definitive separation of the respiratory and digestive tracts. Feeding tubes and tracheostomies are avoided and depending on residual dexterity and neurological function surgical voice restoration may be possible.

KEY POINTS

- Swallow disturbances may arise from deranged function in the oral cavity through to the oesophagus.
- Dysphagia patients should be assessed in the MDT clinic.
- Directed dysphagia history will identify the likeliest cause of dysphagia.
- Qualitative questionnaires can help chart management response.
- Swallow therapist instruments for swallow including FEES VFS are necessary before trialling intervention.
- Temporary procedures should be trialled before embarking on irreversible surgical correction of aspiration.
- The larynx is the prime organ for airway protection whilst the pharynx is actively involved in deglutition.

SEARCH STRATEGY

Data in this chapter are based on a PubMed search using the keywords: temporomandibular joint, temporomandibular disorder, TMJ pain, myofascial pain, rheumatoid arthritis, arthroscopy, arthrocentesis and joint replacement.

INTRODUCTION

Temporomandibular joint (TMJ) problems are a common cause of morbidity with around 30% of the population complaining of problems related to the joint at some stage during their life. Approximately 10% of the population has one or more TMJ symptom or sign at any one time. Differential diagnosis can be confusing and patients are often considered to have 'earache' and referred for ear, nose and throat (ENT) advice. This chapter will aim to provide guidance in the differential diagnosis and primary management of TMJ disorders, with advice when onward referral for subspecialist surgical advice is appropriate.

The most common form of TMJ disorder has various names, including TMJ pain dysfunction, myofascial pain dysfunction and TMJ dysfunction syndrome. Internationally the term temporomandibular disorder (TMD) has been largely introduced from the research and diagnostic criteria. This is a group of disorders of the joint and related masticatory muscles and is best defined as a spectrum from internal derangement (disc-related disorder) to masticatory myofascial pain (purely muscle disorder). The majority of this chapter will deal with this spectrum but will include the other less common disorders affecting the joint.

EPIDEMIOLOGY OF TMJ DISEASE

TMJ disorders present in all age groups, but in the under-40s there is little degenerative disease, unless there is a history of significant trauma or joint surgery. In the over-40s there is increasing evidence of remodelling of the joint (wear and tear or osteoarthrosis) and ultimately degenerative disease (osteoarthritis when associated with pain and inflammation), although this may not be the cause of the patient's symptoms. Symptoms however, present more commonly in the under-40s.

In youths (14–30 years), acute restriction of opening is generally due to a reduction in lubrication within the joint – called anchored disc phenomenon[1] – and this can be dealt with effectively by arthrocentesis (joint washout under pressure; see below). Additionally, acute muscle spasm secondary to clenching or grinding (particularly around the time of examinations or other times of stress) is common in this age group. This problem can also affect older age groups at times of stress as the balance of wear

and tear to repair is tilted towards the former by raised adrenaline levels causing increased muscle spasm, with induction of myofascial type symptoms and consequent compression of the joint.

Women seem to be affected more commonly than men with various ratios from 2:1 to 10:1 being reported.[2] The rationale behind this may be a variance in oestrogen joint receptors although the correlation of this is not fully clear, with raised free radicals also being found in joint aspirates of affected individuals.

Predisposing factors include previous trauma to the joint (macro-trauma) including previous open joint surgery, a history of a clicking joint (present in up to 30% of the population) and a history of clenching in particular, but also grinding (nocturnal bruxism), which causes recurrent microtrauma. There is no conclusive evidence for the role of occlusal/dental factors in induction of disease; indeed, the American Association of Orthodontists devoted significant research into this area in the late 1980s to show that orthodontic management did not induce or reduce the incidence of TMJ disorder or clicking during or after orthodontic treatment. Subsequent Cochrane studies[3] have shown no benefit for occlusal modification in the management of TMJ disorders, as much of the literature on TMD are case series, not randomized studies.

HISTORY OF TMJ DISEASE

The primary symptoms to be elicited from the history (**Box 57.1**) are discussed below.

Pain

Pain from TMD may be from the joint itself (TMJ pain) or in the related muscles of mastication (myofascial pain). The history and examination should distinguish these two prior to definitive management, although initial care is the same for both. Often both are interlinked, giving a spectrum of disease from joint pain at one end to muscle pain at the other. Pain should be recorded using a reproducible pain score, such as a 10 cm analogue scale such that outcomes can be assessed.

Pain localized in front of the tragus of the ear, which can be pointed to with the finger, is likely to be TMJ pain. It is often made worse by function (eating and yawning), and may radiate to surrounding structures. Biting on a tongue spatula on the side of the pain induces the pain in the joint, helping to confirm the diagnosis.

BOX 57.1 Symptoms to be determined from clinical history

1. Pain
2. Joint noises
3. Locking
4. Restriction of opening
5. Disturbance of the bite
6. Alteration in facial appearance
7. Other joint disorders, particularly rheumatological and hypermobility

Myofascial pain is often less well defined with complaints of 'numbness' or aching on the side of the face, which is poorly localized but often in the region of the ramus of the mandible or lateral cheek below the zygomatic process or into the temple. This tends to be worse in the mornings, due to clenching or grinding the teeth at night (a habit that can sometimes be confirmed by the patient's partner), or after particularly 'stressful' situations (e.g. a long drive through heavy traffic or around exam times). Occasionally temporalis pain may be described as headache.

Joint noises

Clicking or cracking of the joint are common. Clicking is related to anteromedial displacement of the disc (ADD) of the TMJ repositioning itself over the joint and predisposes to joint disease (see under 'Internal derangement' below). Click alone does not warrant any treatment other than reassurance that it will reduce with time and does not indicate or lead to 'arthritis of the joint'. Cracking or crepitus again does not warrant treatment but suggests 'scarring' or degeneration within or around the joint. Without associated symptoms the patient can be reassured, although occasionally it can be a presentation of arthritic conditions.

Locking

Locking is the inability to either fully open or fully close the joint. Inability to fully open the joint (confusingly called closed lock) will often be overcome following massage, with a click or crunch restoring full opening. This was considered to be due to anteromedial disc displacement with reduction (ADDR), although it may be due to acute muscle spasm of the lateral pterygoid muscle, which attaches to the anterior portion of the disc, or any of the other muscles of mastication (secondary to myofascial spasm). It may also be due to alteration in the lubrication of the joint (anchored disc phenomenon). Inability to fully close over a period of time (open lock) is usually due to a joint effusion (synovial fluid) or blood (haemarthrosis). Both may be secondary to trauma although the former may also be secondary to the acute synovitis seen in rheumatoid diseases. The frequency of locking should be recorded.

Restriction of opening

Normal range of mouth opening for an adult is above 35 mm inter-incisal distance (with upper and lower dentures in if present). An opening greater than 55 mm suggests hypermobility.

Muscle spasm and disc displacement can both cause restriction, as can ankylosis of the joint, trauma or the spasm associated with cervicofacial infection. Opening less than 25 mm in a young adult without associated systemic illness suggests anchored disc phenomenon, due to loss of joint lubrication. This should be managed urgently

by a maxillofacial specialist with an interest in TMD who will consider early arthrocentesis which is usually curative. Significant delay may lead to a permanent restriction (**Figure 57.1**).

Disturbance of the bite

Collapse of the joint with reduction in height of the ramus will cause a premature contact on the side of the collapse. There may be associated centreline deviation of the chin or teeth towards the side of collapse. If both sides collapse the chin point will move backwards (class 2 deformity) with bilateral loss of ramus height and an anterior open bite (inability of the front teeth to bite together).

Alteration in facial appearance

Collapse of the joint may cause retrusion of the chin if bilateral, or rotation of the chin centreline towards the side of collapse. In addition there will be loss of definition of the angle of the mandible due to loss of ramus height (**Figure 57.2**). The opposite features occur where there is joint overgrowth with centreline deviation towards the opposite side and lengthening of the ramus with possible open bite on the affected side.

Other joint disorders

The TMJ can be affected by rheumatoid joint diseases or hypermobility.[4] Rheumatoid disease often presents with pain and ultimately can lead to joint collapse with a disturbance in the way the teeth bite together (malocclusion) or ankylosis. Ankylosing spondylitis may lead to joint ankylosis with pain and restriction of opening. Psoriatic arthropathy also may cause pain, restriction, ankylosis and occasionally joint collapse.

Hypermobility can lead to joint dislocation. This occurs when the condyle of the mandible is displaced anterior and superior to the articular eminence of the temporal bone. It tends to occur in two age groups – young adults with generally hypermobile joints and the elderly who have loose ligaments and overclosure of the jaw due to lack of teeth. The frequency of dislocations should be recorded. Often patients may complain of 'dislocation' when in fact they are describing a click or locking.

CLINICAL EXAMINATION

The aim of clinical examination is to determine the sites of tenderness and the degree of disorder present. The examination comprises the steps shown in **Box 57.2**.

Figure 57.2 (a) A young woman with juvenile arthritis of the TMJ, demonstrating undergrowth on right side. **(b)** The OPG of the same patient showing condylar under-development on the right side.

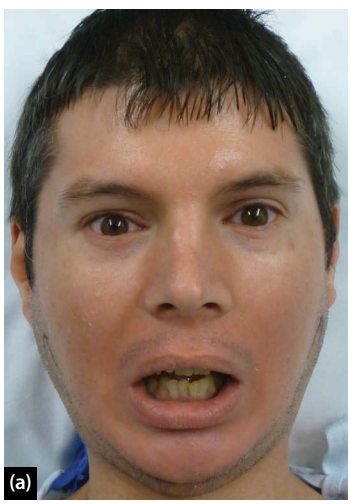

Figure 57.1 (a) Limited mouth opening in a young man with psoriatic arthropathy. **(b)** Fixed neck flexion in the same patient due to pseudo ankylosing spondylitis.

BOX 57.2 Clinical examination of the TMJ

- Palpation of the joint for tenderness and noises/crepitus laterally and posteriorly with the mouth both closed and open
- Palpation of the masseter muscles for tenderness and areas of muscle tightness
- Palpation of the temporalis muscles for tenderness and areas of muscle tightness
- Use of a tongue spatula to bite between the teeth on each side
- Measurement of inter-incisal mouth opening in millimetres
- Observation of the opening path of the mandible in relation to the maxillary centreline
- Interdigitation of the teeth (dental occlusion)

Palpation of the joint

The TMJ is palpated just in front of the tragus of the ear. Movement consists of rotation in the lower joint space and glide from the upper joint space over the articular eminence at the base of the zygomatic arch. Tenderness may be elicited over the lateral aspect of the joint while stationary or in motion. The posterior aspect of the joint can only really be felt in wide opening by palpating between the back of the joint and the tragal cartilage or with a finger in the external auditory canal. Tenderness over a joint indicates inflammation in the joint related structures of capsule, synovium and bone.

Noises may be palpated and heard such as a click or crepitus (crunching). Due to the close relation of the joint to the ear, the patient may complain of noises that either are intermittent or cannot be palpated or heard by the examiner. Assume the noise is present if the patient complains of it. Tinnitus is not generally a symptom of TMD.

Palpation of the masseter and temporalis

The masseter muscles lie over the vertical ramus of the mandible up to the base of the zygomatic arch. The temporalis lies above the zygomatic arch, extending behind and above the ear and onto the forehead below the hairline. Tenderness in a muscle during clenching or the palpation of tight bands of muscle indicates myofascial spasm and pain.

Headaches may be a symptom of TMJ disorder when there is associated muscle or joint tenderness, but alone are not indicative of TMJ problems. They may also be associated with stress-related disorders.

Use of a tongue spatula

It is relatively difficult and impractical to determine areas of tenderness in the other muscles of mastication and the author does not feel this is necessary in non-specialist practice. Placing a tongue spatula between the teeth and asking the patient to bite on it will elicit pain in the joint on the ipsilateral side or pain in the lateral pterygoid on the contralateral side, and provides a useful indirect palpation of the muscle.

Measurement of inter-incisal opening

The distance between the upper and lower incisors during maximal mouth opening gives a reliable and reproducible measure of loss of function and outcome. Around 97% of the population has an opening of greater than 35 mm and this provides a useful distance to aim for as a treatment outcome. Some patients with an opening greater than this will have subjective restriction and others with an opening less than this will be normal. Improvement in opening following treatment gives a good measure of outcome.

Observation of opening path

Mouth opening tends to deviate towards the side of pathology. The early phase of opening is a rotation of the condyle of the mandible against the disc in the lower joint space. From 20–25 mm, opening continues with glide between the disc-condyle complex and the glenoid fossa of the temporal bone in the upper joint space. This latter movement causes the joint to move away from the side of the gliding. As much of the joint pathology causing restriction is related to upper joint space problems, muscle spasm restricting disc movement or muscle or joint pain restricting movement, the loss of glide is the most common outcome and therefore the 'normal' joint glides causing the jaw centreline to deviate towards the diseased side. Looking for this particular clinical sign aids confirmation of the side and site of the problem.

Interdigitation of the teeth (dental occlusion)

The way the teeth bite together can be altered by joint collapse. If one joint collapses the fulcrum on that side moves superiorly, causing the posterior teeth to meet prematurely on that side and the centreline to deviate towards that side. If both sides collapse, the front teeth will not meet (anterior open bite) when the patient reports they previously did (**Figure 57.3**).

Conversely, if there is an effusion (inflammatory fluid in the joint) or haemarthrosis (blood in the joint) the joint space increases, lowering the fulcrum, preventing the posterior teeth on the side of the effusion from meeting. Minor variances in the occlusion are usually irrelevant.

INVESTIGATIONS

Plain radiographs form the mainstay of initial examination of the TMJ, although they have little diagnostic value as they only show a section of the joint surface and show nothing of the soft tissues associated with the joint. Other pathologies should be excluded (including dental pain, sinus problems, trigeminal neuralgia etc.) from the history and examination, and often an orthopantomogram (OPG) radiograph is taken to exclude possible

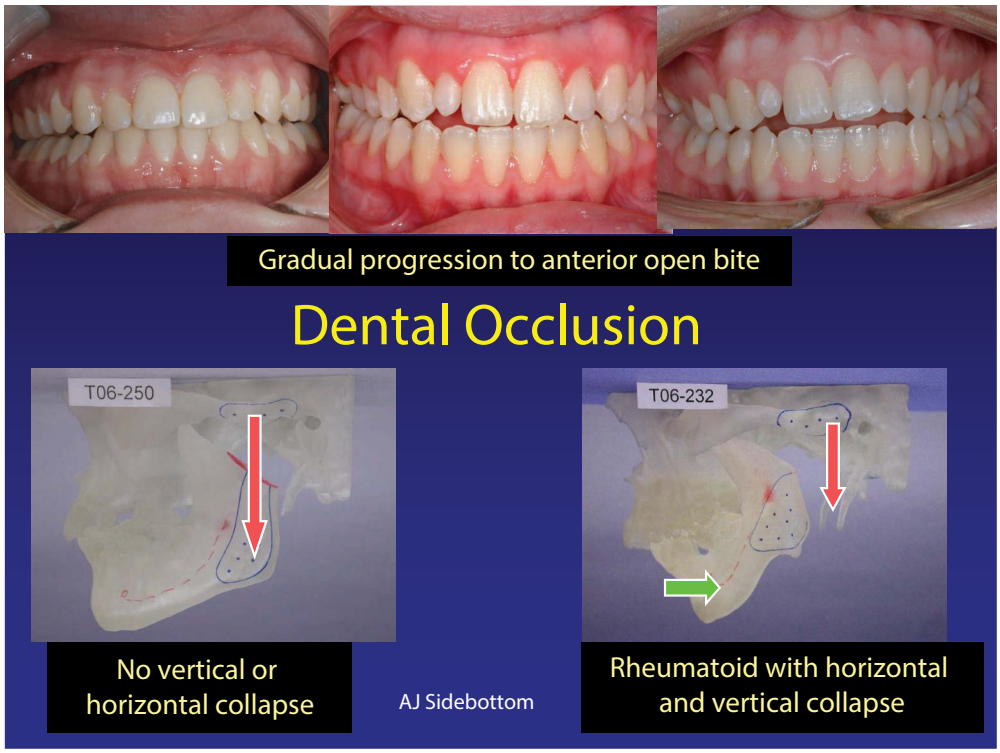

Figure 57.3 These pictures illustrate the development of anterior open bite and ramal collapse in a patient with bilateral temporomandibular joint collapse. The accompanying models of the facial skeleton demonstrate the joint collapse.

dental causes. Transpharyngeal and transcranial views may be requested, as may open and closed views, but they add little to a thorough clinical examination and an OPG showing both TMJs.

Further investigations, where indicated, include an isotope bone scan if hyper or hypoplasia of the condyle is suspected. CT scanning of the joint shows the bony structures well and three-dimensional reconstruction can aid in localizing bony pathology, particularly when joint resection and reconstruction are indicated (**Figure 57.4**). Less dosage but more restricted views can be obtained with cone beam CT (CBCT). The soft tissues are best imaged with MRI scanning, which will help to determine disc displacement, tears and disc movement.

Isotope bone scanning involves injecting the patient with ^{99m}Tc. This circulates the body and is taken up in bone that is actively turning over. Radiographs are taken 2 hours after injection. Uptake is increased at sites of active bone turnover and therefore will show as a 'hot spot' in a hyperplastic condyle. It will also show where there is acute infection (possibly dental). The isotope is largely expelled within 24 hours. Positron emission tomography (PET) is often used at the same time and shows similar results.

CT scans are best placed to show the bony anatomy of the joint and surrounding structures. They are essential in planning for joint replacement, but of little use in assessing the joint soft tissues. The scan itself can be used to generate a three-dimensional computer-aided design/computer-aided manufacture (CAD/CAM) model of the joint to aid planning and reconstruction.

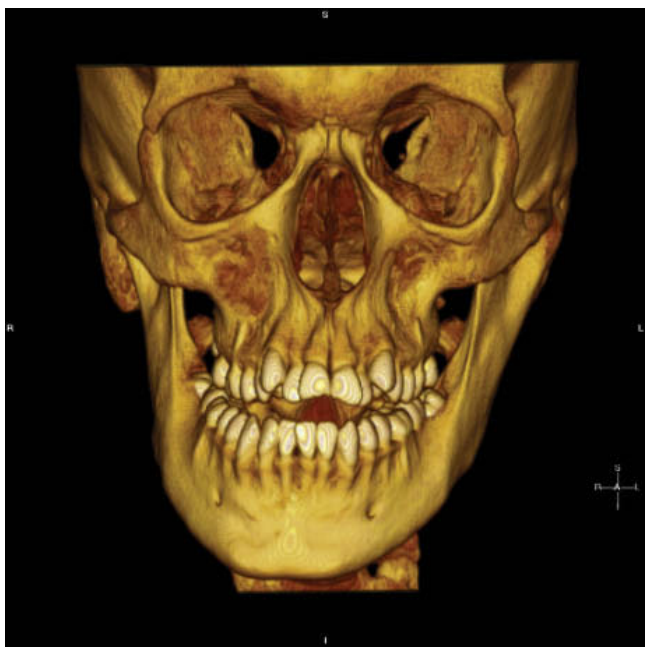

Figure 57.4 3D-CT scan showing left condylar hyperplasia with centreline deviation and lengthening of left ramus.

MRI scanning is increasingly accurate in determining the position and state of the soft tissues around the joint and the position of the disc. Unfortunately these are static scans in the most part and therefore do not look at function. Disc position can be displaced due to pain stopping the disc relocating, lack of intra-articular lubrication

or scarring within the joint holding the disc in position. This cannot be differentiated by an MRI scan and therefore the author tends not to use this modality of assessment as it seems to add little to clinical diagnosis at present. Likewise, the accuracy of the scan lies in the quality of the scan and the quality of the radiologist interpreting it. Even in the best hands, under- and over-diagnosis of disc related disease is made in 50% of cases. The wise surgeon will manage a patient according to the clinical signs and symptoms and not based solely on radiological investigations, which should be an aid to or confirmation of diagnosis.

Arthroscopy, which will be discussed in more detail later (see 'Surgical management of the TMJ' below), in good hands, provides not only a significant aid to diagnosis, but also helps to relieve over 70% of patients of their symptoms.

Open surgical exploration of the joint should only be considered as a last resort and there should be a specific pathology that the surgical treatment is aimed at relieving. It should not be considered as a diagnostic aid.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of TMJ disorders follows the standard surgical sieve. While there are numerous mnemonics for remembering this, the author finds the acronym TINNED VIIM works (**Box 57.3**).

While this surgical sieve is useful, the majority of patients presenting with TMJ symptoms have internal derangement or myofascial pain and these disorders will be dealt with first, followed by the standard surgical sieve.

INTERNAL DERANGEMENT

This condition affects up to one-third of the population at some stage during their lives. Most patients suffer nothing more than a 'clicking joint' and this is so common that some would say it is a normal variant. The clicking may be associated with pain, locking or restriction of movement. Clinical examination should determine if there is tenderness over the joints laterally and posteriorly, whether there is associated muscle tenderness and how much motion the joint can achieve by measuring the inter-incisal distance and lateral deviations. Where in the cycle the click occurs can be useful, but a determination of whether there is any glide (upper joint space movement) is more useful in determining whether there is physical restriction. Movements under 25 mm with no glide (loss of lateral deviation away from the affected side) suggest that the upper joint space is occluded, and the joint spaces are sticking together due to lack of lubrication (anchored disc phenomenon). This can be simply dealt with by early arthrocentesis if 6 weeks of conservative management fail to improve the movement.

There is often overlap of signs and symptoms of internal derangement with myofascial pain. Fortunately the initial management of both of these conditions is the same, namely rest, non-steroidal anti-inflammatory drugs (NSAIDs) and a bite splint[5] (the author uses a lower soft splint as it is cheap and easy to fit) for at least 6 weeks.

BOX 57.3 TINNED VIIM as a surgical sieve

- Congenital lesions
- Acquired lesions:

  - Inflammatory
  - Infective
  - Neoplasms:
    - primary
    - secondary
- Nutritional
- Endocrine
- Degenerative
- Vascular
- Idiopathic
- Iatrogenic
- Miscellaneous

INITIAL MANAGEMENT

The primary management of most TMJ disorders initially is reassurance that there is unlikely to be a significant underlying condition, it is unlikely to precede arthritis and the majority of patients can be managed with non-surgical treatment. A significant proportion of patients will have some psychological component to their disease process, whether this is a primary cause or a secondary effect, and the reassurance will go some way to improving their symptoms. Also the placebo effect should effect a 'cure' in around 40%. This explanation should be supported by some form of written leaflet to facilitate retention of knowledge.

Explanation of the disease process along the lines of a 'sprain' of the joint with consequent joint pain due to inflammation and resultant muscle spasm will help to empower the patient and reduce the risk of following internet mis-advice. Initial rest with avoidance of chewy foods (chewing gum and sticky toffees) and tough foods (steaks and crusty bread), and restriction of wide mouth opening (occasionally the pain may have been induced by a long dental visit) will improve symptoms, but this regime must be persisted with for several weeks. The addition of topical non-steroidal anti-inflammatory gels[6] applied to the area of the joint four times daily for 4 weeks will give additional benefit in terms of pain relief and reduction of joint inflammation. Paracetamol as a simple analgesic can additionally be used.

A lower soft full occlusal coverage splint to wear at night should be provided.[5] The patient's dentist should be able to make this. No splint has been shown to be better than any other and since a full coverage lower soft splint worn part-time is unlikely to cause untoward occlusal effects, this method is used by the author. Hard splints should cover all the teeth and make a stable occlusion. They are more costly and time consuming, but are recommended by some restorative experts. The splint helps to reduce the load on the muscles and joint overnight, particularly in those patients who have a clenching habit. It will also help to eliminate the habit. It may take a few nights for the patient to get used to the splint and it may take a few

weeks for symptoms to start to improve. There is no benefit shown by occlusal adjustment of the teeth, although some dentists may feel this is the case.[3] Cochrane analysis has shown that doing nothing is just as effective and is much less harmful.

Although physiotherapy may be beneficial in the short term there is no evidence of its long-term efficacy. Steroid injections to the joint should be avoided and it should be left to a maxillofacial surgeon to decide whether these are indicated, as repeated injections may cause joint collapse. While exercises have often been prescribed there seems to be no good evidence that they are beneficial in internal derangement. Often the exercises are poorly explained and carried out inadequately by the patient and it seems illogical to suggest that an injured joint should be exercised – imagine telling a patient with a sprained ankle they should run on it daily! Exercises may, however, be beneficial in mobilizing patients with acute muscle spasm secondary to myofascial pain or following surgery.

Following a 2-month trial of these treatments, if there has been no significant improvement, the above measures cannot be instituted or there is acute severe restriction in opening, then referral to a maxillofacial specialist, preferably with an interest in TMD, should be considered (**Box 57.4**).

Earlier intervention by means of therapeutic arthroscopy (examination and washout of the joint) or arthrocentesis is indicated in patients with restricted opening who fail to improve or in those with persistent locking. Around 80% will improve with this procedure.[7, 8] Additionally arthroscopy under general anaesthesia gives a good idea of how much of the restriction is due to muscle spasm and pain and also whether there is any intra-articular damage. Follow-up physiotherapy gives added benefit.

Where there has been no improvement following arthroscopy, and the joint was normal and mouth opening improved during anaesthesia, it is assumed that the majority of the problem is due to muscle spasm/pain and a muscle relaxant medication may be suggested. Commonly a low dose tricyclic such as amitriptylene or dothiepin is indicated with doses starting at 10 mg and potentially rising to 75 mg titrated to symptoms and side effects. These medications take around 3 weeks to become effective and doses should be increased on a monthly basis until full pain relief is achieved or side effects prevent a further increase in dose. The pain-relieving dose is maintained for 6 months and then the patient should be weaned off, according to recurrence of symptoms, over the next few weeks. Unfortunately, no long-term studies have shown benefit from this management regime. Alternative therapy currently under investigation is the injection of botulinum toxin into the areas of muscle spasm, which is effective in around 70% of patients in the author's series of more than 100 cases.[9]

Other modalities that have been used successfully in myofascial pain include cognitive behavioural therapy, in which the patient receives psychological counselling to prevent the cause of the muscle hyperactivity and manage the pain. Acupuncture may also be successful in dealing with the muscle spasm, but also the pain of internal derangement. It is however difficult to find a suitably trained specialist to manage the TMJ in particular. Transcutaneous electrical nerve stimulation (TENS) can also help in the management of the chronic pain associated with myofascial pain following failure of the other techniques.

Where arthroscopy has shown intra-articular problems these may be addressed with open joint surgery if symptoms do not improve. A variety of techniques have been used along orthopaedic principles, with, ultimately, joint replacement as the final option. The latter is not to be considered lightly and in the UK at present fewer than 100 total joint replacements are carried out each year by a small handful of recognised joint replacement surgeons. National guidelines suggest when these may be indicated.[10]

BOX 57.4 When to refer for maxillofacial advice

- Acute severe restriction of opening
- Failure of simple conservative measures in conjunction with dentist over 2 months
- Associated rheumatological disease
- Recurrent dislocation of the joint
- Disturbance of the dental occlusion

CONGENITAL

Congenital lesions of the joint are uncommon and often lead to facial asymmetry.

HEMIFACIAL MICROSOMIA

Some of the effects are due to failure of the condyle to develop, possibly secondary to loss of the blood supply in utero. This causes associated undergrowth of the ear, ear canal, joint and fossa to varying degrees. This is a complex craniofacial disorder and should be managed in a supra-regional craniofacial centre. The management involves craniofacial bone and soft tissue reconstruction in various stages throughout life. It may occur on both sides.

CONDYLAR HYPERPLASIA

This is due to either overgrowth of the condylar growth centre on one side before or during puberty, or continued growth after completion of puberty with cessation of growth on the contralateral side. The patient will present with progressive disturbance of the occlusion, usually with centreline deviation of the dental centreline and associated deviation of the chin point (hemimandibular hyperplasia) (see **Figure 57.2**). It may also present with bowing of the mandible downwards and associated maxillary dentoalveolar compensatory growth with the occlusion developing a downward cant towards the side of the abnormality (hemimandibular hypertrophy). There is not

usually associated pain, although in the adult onset version there may be limited translatory movement of the TMJ on the affected side.

Diagnosis is aided by seeing an elongated condylar neck on OPG (pubescent type) or an abnormal condyle (post-pubescent). Ongoing growth can be confirmed by an isotope bone scan using ^{99m}Tc or a PET scan. These will both show increased uptake on the affected active side. Management where there is increased uptake is to remove the growth plate by means of a condylar shave procedure where the cartilage growth centre is removed surgically.[11] If the disease is burnt out or has been treated by condylar shave, the resultant deformity and centreline correction is managed by orthognathic surgery (jaw realignment). These procedures require referral to a maxillofacial surgeon.

TRAUMATIC

Trauma to the TMJ is a common occurrence in fractures of the mandible. The majority of facial fractures in the UK are related to interpersonal violence. Condylar fractures are one of the more common mandibular fractures, occurring in around 30% of cases. They may also occur bilaterally or be associated with fractures elsewhere on the bony mandible. Occasionally the fracture may involve the temporal bone (with haemotympanum) or may cause perforation of the external auditory canal (with associated bleeding form the external canal).

In children fractures of the condyle tend to occur within the capsule and are difficult to treat operatively. Diagnosis in a child follows a direct blow over the joint or an indirect blow to the mandible elsewhere, particularly the chin. The child will complain of pain in the area, difficulty opening the mouth fully and sometimes inability to close the teeth together due either to bone displacement (contralateral open bite) or fluid within the joint (ipsilateral open bite) secondary to intra-articular soft tissue injury. There will be swelling and tenderness over the area of the fracture and the occlusion may be disrupted as above.

Initial management is often with mobilization and analgesia as this injury can affect the secondary growth plate in the condyle, causing undergrowth, overgrowth or fusion of the joint surfaces (ankylosis). Intermaxillary fixation (holding the teeth together with elastics or wires) for a 2–4-week period may be considered where the occlusion is deranged. Occasionally, internal fixation may be considered with resorbable plates.

Effusion or haemarthrosis should be managed with arthrocentesis to enable joint recovery.

The child should be monitored long term to observe for growth abnormalities such that these can be treated at a stage when compensatory growth has not occurred to such an extent to make future management more difficult.

In the adult the fracture pattern is often different. Extra-capsular fractures are more common. Symptoms and signs are similar to those in children with pain over the site of the injury and on function, swelling and possible malocclusion. If the occlusion is normal then the fracture is managed non-operatively with a soft diet and mobilization for 4–6 weeks. Derangement of the occlusion warrants management either with intermaxillary fixation of some variety or, in some cases, open reduction and internal fixation with miniplates may be required. There is considerable controversy as to the best way of managing these fractures and the reader is referred to the standard maxillofacial trauma texts if they are interested in considering this further. Growth disturbances and ankylosis are much less common in adults. Dislocation into the middle cranial fossa has been rarely described. These injuries should all be managed by a suitably trained oral and maxillofacial surgeon.

INFECTIVE TMJ DISORDERS

Infection of the TMJ is an uncommon occurrence in the developed world. It does, however, remain a major source of morbidity.

Infection may be due to direct infection of the joint, from local spread from the surrounding structures or due to deposition from a distant site, usually from a polyarticular infective processes.

Primary infection may be of the intra-capsular bone – osteomyelitis – or infection of the intra-articular soft tissues – arthritis. Both can be destructive of bone and soft tissues and lead to either joint collapse or ankylosis (fusion) of the joint. In childhood they will lead to secondary growth arrest with subsequent deformity. The usual organism is *Staphylococcus aureus* in immune competent individuals, with other staphylococci or unusual organisms where the host is immunocompromised.

The most common cause of infection is spread from neighbouring structures of the ear, brain and nasopharynx. All of the organisms causing mastoiditis, otitis media and meningitis can be implicated, but again *Staphylococcus* spp. are most likely to invade the joint. The effects of the infection long-term are similar to those from direct infection, but in children ankylosis often ensues.

Haematogenous spread rarely occurs, but is occasionally secondary to enteric organisms (*Salmonella* spp.) or systemic organisms causing a more generalized polyarthritis (syphilis, bacterial endocarditis, septicaemia). Effects are similar to the other two causes, but often the systemic infective process carries more morbidity and risk of mortality.

Diagnosis is from a history of pain and swelling localized to the area of the joint, with acute onset limitation of movement. The patient will have generalized signs of an infective process with pyrexia, rigors, sweating (particularly night sweats) and malaise. They may also have signs and symptoms of other joint involvement. Locally there will be the signs of acute inflammation with tenderness over the joint, swelling, redness and heat. There may be additional cervical lymphadenopathy and tenderness over the mastoid if there is middle ear involvement.

The diagnosis can be confirmed with aspiration of pus from the joint and this should be sent for urgent culture and sensitivities. The patient should be admitted

to hospital and broad spectrum intravenous antibiotics should be commenced with thorough arthrocentesis of at least 500 ml of isotonic solution or until the aspirate is clear. This should be repeated if necessary. The advice of a microbiologist should be sought for local sensitivities in guidance for antibiotic treatment. General systemic support would include antipyretic (paracetamol and NSAID) and adequate hydration, with management of the causative disease process. Systemic involvement with septicaemia may require admission to intensive care.

Ultimate management may involve open surgical drainage. The long-term sequelae of the process may require further surgical input and early maxillofacial surgical advice is essential, in addition to long-term support. Reconstruction and rehabilitation may require open surgical procedures, osteotomies, rib grafts or joint replacement.

INFLAMMATORY DISEASE OF THE TMJ

Many of the inflammatory arthropathies can affect the TMJ.[12] Rheumatoid disease can occur in the child, adolescent and adult. It will usually present with the signs and symptoms of synovitis, namely pain, swelling, heat and restriction of movement, and therefore can be difficult to differentiate from infective causes. Progression can lead to joint collapse resulting in malocclusion with an anterior open bite and a retrusive chin (see **Figure 57.3**). Usually other joints, particularly the hands and feet, will have been involved for some time, as rheumatoid disease is a polyarticular arthropathy tending to affect the smaller joints. Diagnosis can be confirmed serologically with a positive rheumatoid factor present in 80%. Sero-negative arthropathy can occur with a similar clinical picture. In the head and neck there can be associated dry mouth, dry eyes (Sjögren's syndrome) and difficulty with oral hygiene due to involvement of the hands.

Management of the rheumatoid TMJ should initially follow the same principles as for most TMJ disorders. Rest, with a soft diet and avoidance of wide opening, NSAIDS (topical or systemic) regularly and a soft splint to rest the muscles, which may be overactive, and to offload the joint. Early consideration of arthroscopy and arthrocentesis will help to eliminate the inflammatory mediators from within the joint. If synovitis is active then steroid injection should be considered, although repeated injections, which calm down the inflammatory process, may lead to increased cartilage loss and joint collapse. End-stage management of the collapsed joint is with total joint replacement. A rheumatologist should be involved as they may instigate disease-modifying medication.

Ankylosing spondylitis may initially present similarly in the TMJ. The patients are mostly male and tend to have generalized signs with fixed kyphosis (flexion of the spine, particularly the neck). Classically they are HLA-B27 positive, although this is not exclusive to ankylosing spondylitis. The process leads to ankylosis of the TMJ, and the restriction of mouth opening is made worse by the fixed flexion of the neck towards the chest wall (see **Figure 57.1**). Release of the ankylosis surgically with joint reconstruction is required, optimally with total joint replacement to give a large enough gap to prevent reankylosis and enable adequate function. Fat graft interposition is suggested to reduce the risk of reankylosis.

Psoriatic arthropathy may affect the TMJ, causing acute synovitis, joint collapse or ankylosis. The patients initially present with the skin condition of psoriasis (although up to 50% have minimal skin signs and these may need to be carefully sought out), with involvement often of the larger joints in a degenerative type of arthropathy. Some patients may be HLA-B27 positive and these tend to progress towards an ankylosis picture rather than the synovitis that often characterizes this disease process. Management of the synovitis is with rest, NSAIDs and bite splints. Arthrocentesis can help relieve symptoms, as can steroid injections. Ultimately joint replacement may be required due to joint collapse or ankylosis.

All of the rheumatoid diseases may be managed by a rheumatologist with disease-modifying medication, which may have significant side effects on the oral mucosa and may also interact with various other medications. Routine dental care is essential as the patient may have difficulty with oral care due to hand disability, or have a dry mouth. Bisphosphonates may be used, particularly with osteopenic rheumatoid conditions, and due diligence in general dental management with support to prevent disease to the oral structures is essential such that the occurance of bisphosphonate related osteonecrosis can be prevented. Leucocyte inhibition medication may cause mild immunosuppression and aggressive management of infection is essential in these patients. Stopping these medications prior to any form of surgery should be discussed with the rheumatologist as they can inhibit wound healing.

NEOPLASTIC DISEASE OF THE TMJ

Neoplasms may be primary or secondary, benign or malignant. Primary benign neoplasms of the TMJ are rare and include chondroma, synovial chondromatosis, osteochondroma and osteoma. Malignant neoplasms are even more uncommon and the condyle seems to be preserved when the mandible is invaded by squamous carcinoma. Chondrosarcoma, osteochondrosarcoma and osteosarcoma are extremely rare in the head and neck and even more so in the condyle. They are dealt with elsewhere in this book. The slightly anomalous pigmented villonodular synovitis behaves as a neoplasm with locally invasive tendency, but again is rare.

Benign neoplasms tend to slow growth (the commonest being osteochondroma) and therefore can present with pain, loss of movement and slowly progressive deformity with a lateral open bite on the side of the neoplasm. There is occasional centreline shift of the chin and dental centreline, but more commonly downward bowing of the lower border of the mandible occurs. Diagnosis is from clinical and radiological examination, supported, if necessary, by open joint surgery to biopsy or excise the lesion

and subsequent reconstruction and/or orthognathic correction of the resultant malocclusion and facial deformity.

Synovial chondromatosis is a rare condition that affects the joint, often secondary to degenerative disease. Production of large numbers of small chondromata from the synovium occurs, producing numerous millimetre-sized, rounded loose bodies in the joint. These affect joint function (with pain, locking and noises) and can induce pain. Management is with open washout as they are often too large to pass through an arthroscope. This should allow the joint to function although there is often degenerative change that warrants surgical treatment in its own right. It is felt to be due to overproduction of cartilage by the synovium and therefore synovectomy is advocated.

Metastasis may occur to the condyle as to any other region of the mandible. The common neoplasms metastasizing to bone include breast, kidney, thyroid, and colon with osteolytic lesions and the prostate with osteosclerotic lesions. Diagnosis and management of the primary site is essential, but the metastasis should be managed symptomatically with either resection and reconstruction, radiotherapy or pain management.

DEGENERATIVE DISEASE OF THE TMJ (OSTEOARTHROSIS)

This is the final common pathway for a number of TMJ conditions from trauma, infection, inflammation, neoplastic and iatrogenic causes. Primary degenerative disease can also occur but it is much less common than involvement of the knee and hip. Overuse causing bone compression is the often-quoted reason for any degenerative joint disorder. Internal derangement of the joint is a very common condition that does not usually lead to degenerative osteoarthrosis if the wear and tear component of this disease can be converted to repair by appropriate non-invasive interventions. It is much less common than degenerative disease of the major joints as the load is significantly less in the TMJ. It tends to occur when the wear and tear in the joint overtakes the repair. Pain, swelling and restriction of movement are the common symptoms. Clinical examination reveals a tender joint with palpable crepitus and restriction of movement, with intermittent swelling.

Radiographic findings are more noticeable on CT scan and include sclerosis, loss of joint space, osteophytes and erosions or cyst formation.

Initial management is with conservative measures followed by arthroscopy, open surgery and, ultimately, joint replacement as above.

IATROGENIC/IDIOPATHIC

The former use of open joint surgery for pain, restriction and joint noises has led to the increasing frequency of degeneration of the joint from multiple operations, particularly in the USA. Surgery for joint noise alone has now been accepted as inappropriate. Less commonly, however, patients following open surgery may have dysaesthetic pain due to damage to the surrounding nerves. This is a debilitating type of pain, which is difficult to manage. It may be of a shooting nature or dull background ache with acute exacerbations. Management under the direction of a pain team is indicated and is usually with low dose tricyclic antidepresants or antiepileptic medication (carbamazepine, gabapentin, etc.).

SURGICAL MANAGEMENT OF THE TMJ

Surgery of the joint can be divided into closed and open surgery. Closed surgery comprises arthrocentesis and arthroscopy.

Arthrocentesis is the washing out of (usually) the upper joint space with isotonic solution under pressure (recommended 150 mm Hg) using around 200 ml of solution to eliminate inflammatory mediators and free radicals and to re-lubricate the joint initially with the solution, but allowing the lubricant producing cells to recover. Usually two needles are used to carry out this procedure – inlet and outlet. Whilst this procedure can be performed under local anaesthesia potentially with sedation, the preference in the UK is for general anaesthesia (GA). The advantage of carrying out the procedure under GA is that the patient can be examined with the muscles relaxed, giving a good idea of the degree of restriction due to muscle spasm. It is a day case procedure and has been shown to be successful in improving 70–80% of cases of locking, restriction and pain.[1, 7, 8]

Arthroscopy is a similar procedure, although a small rigid fibre-optic endoscope is inserted into the joint rather than two needles. A needle is still used as the outlet. The scope size varies from internal diameter of 2.1 mm, although disposable endoscopes of 1.2 mm are now available. There is some debate regarding the advantage of arthroscopy over arthrocentesis, as the insertion of a larger scope should carry more morbidity. The rationale behind inserting a scope is to aid in diagnosis, not outcome. The outcomes are similar for arthroscopy and arthrocentesis, but arthrocentesis does not see into the joint and will miss diagnoses of disc damage, joint surface damage, scarring and synovitis, and the accuracy of this technique in experienced hands is very high.[13] There have been no comparisons of complications with arthrocentesis and arthroscopy and no long-term obvious detrimental effects of arthroscopy have been reported, other than an ~1% risk of temporary temporal branch weakness of the facial nerve.

Open joint surgery follows the principles of orthopaedics. The joint is approached via a pre-auricular incision, staying close to the cartilaginous auditory meatus to avoid damage to the temporal branch of the facial nerve. If there is damage to the disc this is removed and may or may not be replaced with temporalis muscle flap or auricular cartilage, although there has not been any benefit shown to providing this replacement. Damage to the joint surfaces can be improved using eminoplasty (modification of the articular eminence) or condylar shave (modification of the condylar head). The outcomes of this surgery following

failed arthroscopy are around 60% discharge with manageable symptoms.[14]

Severe degeneration of the joint with associated pain and restriction of opening, ankylosis or inflammatory joint disease with joint collapse warrant joint replacement. Whilst this was often with a costochondral graft (rib), recently alloplastic joint replacement has become the mainstay of treatment using a combination of cobalt-chrome and titanium or all titanium on high molecular weight polyethylene for replacement (similar to total knee replacement). Outcomes of 90% joint survival at 15 years[15] are reported with improvement of dietary scores and pain of 90% at one year[16] and significant improvements in mouth opening. The frequency of use of this procedure warrants, at present, the surgery only being carried out in limited numbers by a few high volume operators, although the indications seem to be increasing. For this reason NICE guidelines have suggested indications for this line of management.[17]

CONCLUSION

Temporomandibular disorders are a common cause of morbidity in general practice, although most can be managed with simple measures, such as reassurance that joint noises do not require any form of management and do not necessarily lead to degenerative joint disease. The final common pathway of a number of conditions is degenerative disease and surgery should be considered a last resort.

KEY POINTS

- TMJ problems are largely managed conservatively with little requirement for surgical input.
- Most TMJ problems do not progress to arthritis.
- Symptoms include pain, restriction of opening, locking and joint noises.
- Signs include tenderness/spasm in muscles of mastication, limitation in opening < 35 mm, deviated mouth opening, joint line tenderness, rarely malocclusion.
- Initial management is rest, topical anti-inflammatories, muscle massage and a bite splint.
- Early arthrocentesis is useful in acute severe restriction of opening.
- Arthroscopy is both diagnostic and therapeutic.
- Open surgery should only be considered where arthroscopy has demonstrated an abnormality which has not responded.
- Joint replacement is the final common pathway and should only be undertaken by a surgeon with experience and training in this technique.

SEARCH STRATEGY

Data in this chapter are based on a PubMed search using the keywords: larynx, airway, trachea, bronchi and pulmonary.

INTRODUCTION

The human larynx protects the lower respiratory tract, provides a controlled airway, allows phonation and allows the generation of a high intrathoracic pressure for coughing and lifting. The evolution of the larynx provides an insight into its functional priorities. In its most primitive form, it can be found as a muscular sphincter around the entrance to the respiratory tract in the Bichir lungfish (*Polypterus bichir*), controlling the entry of water and the expulsion of air from the lungs. A further evolutionary variant is seen in the Mexican salamander, which possesses lateral cartilages that aid in opening and maintaining patency of the respiratory tract. The ability of the larynx to facilitate speech is only found in humans and represents a more specialized function of the larynx; it is, therefore, a very late evolutionary event.

To fulfil its complex functions the larynx has to be mobile, coordinated and sensate. In rehabilitating the damaged larynx there is often a need to make a trade-off between optimum airway, voice and swallowing.

EMBRYOLOGY

Embryology of the larynx

At four weeks of embryonic development, an outgrowth of the primitive foregut forms the primordial respiratory system. The epithelium of the larynx, trachea and bronchi is of endodermal origin and the other soft tissues arise from the surrounding splanchnic mesoderm (fourth and sixth branchial arches).

The traditional theory of respiratory system embryology states that there is initially a wide communication with the foregut, which expands and becomes separated by two longitudinal oesophagotracheal ridges. These were thought to fuse to form a septum dividing the ventral trachea and lung buds from the dorsal oesophagus. More recent research supports assertions that the respiratory diverticulum develops from the ventral aspect of the foregut and elongates, drawing out a stalk and giving rise to the trachea (**Figure 58.1**). It is proposed that the septum is present from the initial appearance of the lung buds and that there is no migration of the separation point while the trachea descends.

When moving in a craniocaudal direction, the larynx, which is formed at the most cranial end of the respiratory tract, then leads to the trachea, bronchi and lungs. These tubes of endoderm, which project ventrally from the foregut, elongate into the surrounding mesenchyme from which the connective tissue, cartilage, non-striated muscle and vasculature of the bronchi and lungs develop.

Arytenoid swellings appear on both sides of the tracheobronchial diverticulum and, as they enlarge, the epithelial walls of the groove adhere to each other, and the aperture of the larynx is occluded until the third month, when the lumen is restored. The rudimentary laterally based arytenoid swellings elongate cranially, creating a cleft that is open cranially and bounded laterally by the aryepiglottic folds. More ventrally, at the front of this cleft, the hypobranchial eminence becomes the epiglottis.

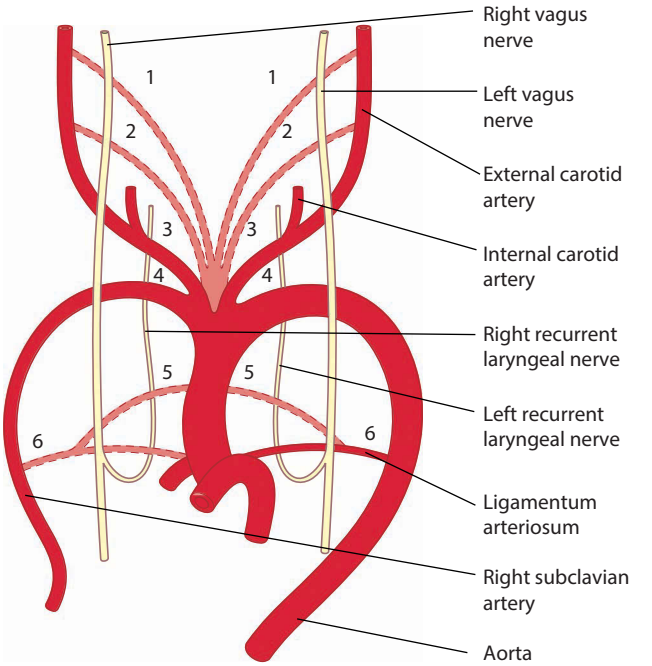

Figure 58.2 The relationship between development of the branchial arches and recurrent laryngeal nerves. The numbers indicate the number of the branchial arch.

The glottis forms just above the level of the primitive aperture. Surrounding this, the thyroid cartilage develops from the ventral ends of the cartilages formed in the mesoderm of the fourth pharyngeal arch and appears as two lateral plates, each of which possesses two chondrification centres. The cricoid cartilage and the cartilages of the trachea develop from the sixth arch during the sixth week of gestation. The trachea rapidly increases in length in a craniocaudal direction from the fifth week of gestation onwards.

The mesoderm of each pharyngeal arch differentiates into the cartilage, muscle and vascular structures of that arch. As part of its dorsoventral direction of development, each arch receives an afferent and efferent nerve supply for the skin, muscles and endodermal lining of that arch, which in the case of the fourth and sixth arches are the superior and recurrent laryngeal branches of the vagus nerve respectively. The primitive recurrent laryngeal nerve enters the sixth visceral arch on each side below the sixth aortic arch artery. On the left side, the arch artery retains its position as the ductus arteriosus so the nerve is found below the ligamentum arteriosum after birth. On the right side, the dorsal part of the sixth arch artery and the whole of the fifth arch artery disappear, leaving the nerve below the fourth arch artery, which becomes the subclavian artery (**Figure 58.2**). Occasionally, the proximal portion of the fourth arch artery also disappears leaving nothing in contact with the right recurrent laryngeal nerve, which, instead of being pulled down into its usual position, passes directly from the main vagal trunk to enter the larynx, demonstrated as the non-recurrent laryngeal nerve.

Embryology of the trachea and bronchial tree

The trachea and the two lateral bronchial buds form from the lung bud and at the fifth week each bronchial bud develops into a main bronchus. The right goes on to form three secondary bronchi, the left developing into two. They continue to grow caudally and laterally, expanding into the developing body cavity. During further development there are further divisions of the buds in a dichotomous fashion. By the end of the sixth month there are approximately 17 generations of subdivisions. An additional 6 divisions occur during postnatal life to form the final structure of the pulmonary tree.

ANATOMY OF THE LARYNX

General description

The larynx extends from the laryngeal inlet to the inferior border of the cricoid cartilage (**Figure 58.3**). In the absence of respiration at neutral lung volume, it lies in front of the third to sixth cervical vertebrae, being a little higher in women than in men.

The infantile larynx is proportionally smaller than that of the adult compared to body size and is more

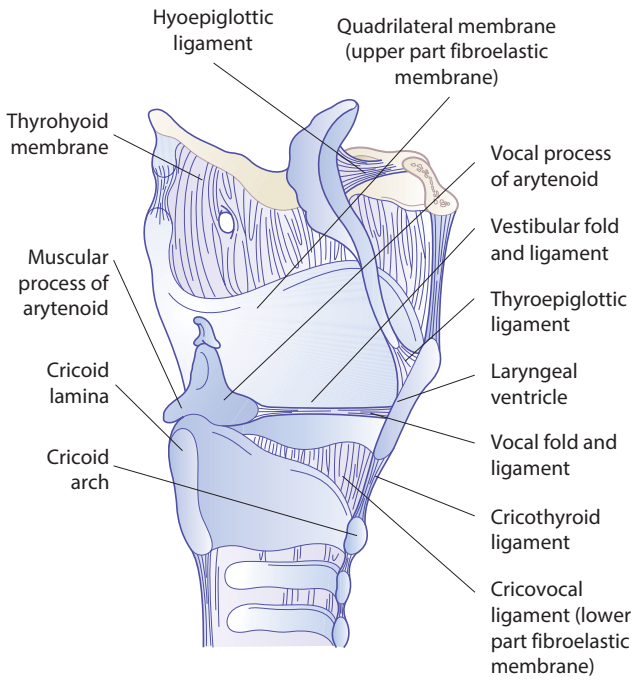

Figure 58.3 Sagittal section across the larynx looking laterally.

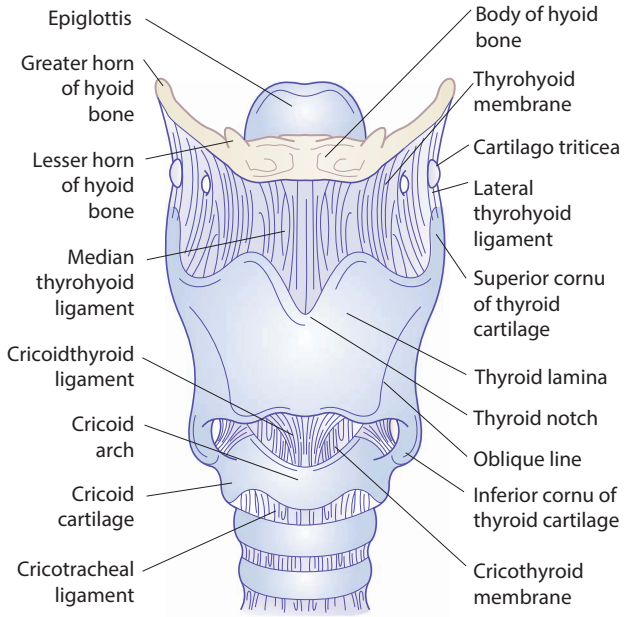

Figure 58.4 The framework of the larynx.

funnel shaped. Its narrowest part is at the junction of the subglottic larynx with the trachea and even a slight swelling in this area may result in marked airway obstruction. In contrast, the narrowest part of the adult larynx is the glottis. The laryngeal cartilages are much softer in the infant than the adult and collapse more easily on forced inspiration as a consequence of the Bernoulli effect. The larynx starts high up under the tongue in early life and with age assumes an increasingly lower position in the neck. As the larynx grows, there is little difference in its size between boys and girls until after puberty when the anterior–posterior (AP) diameter of the larynx almost doubles in men to reach a final AP dimension average of about 36 mm in men and 26 mm in women.

The larynx is divided anatomically into the supraglottis, glottis and subglottis by the false and true folds (see **Figure 58.3**). The term 'vocal cord' is not anatomically accurate; the term vocal fold is more appropriate. Vocal cord is an inaccurate term that has remained in common use and fails to emphasize the layered structure of the vocal fold. In addition, the term 'cord' does not give a sense of a structure that might vibrate in the vertical (and indeed multiplanar) fashion that the vocal folds have been shown to do.

In a craniocaudal direction, the supraglottis commences at the epiglottis and aryepiglottic folds as they sweep down to the arytenoids. Its lower border is a horizontal line drawn through the apex of the laryngeal ventricle. This line, therefore, also forms the upper border of the glottis. The glottis extends caudally from this line and includes the vocal cords as well as anterior commissure and posterior commissure. The line of demarcation between the glottis and the subglottis has been debated in the literature at some length but is now widely accepted to be a line drawn 1 cm below the free edge of the vocal folds. More definitively, the subglottis becomes the trachea at the lower border of the cricoid.

The framework of the larynx consists of the hyoid bone and a number of cartilages connected by ligaments and membranes, as well as intrinsic and extrinsic muscles. It is lined with a mucous membrane that is continuous above with the pharynx and below with that of the trachea. The spaces around the larynx are filled with adipose tissue and loose connective tissue, the 3D orientation of which are key to understanding the spread of tumours within the larynx.

The framework of the larynx

HYOID BONE

The hyoid is a U-shaped bone that is suspended by several suprahyoid muscles and ligaments from the bony structures of the skull base and mandible, and provides the superior attachment for many of the extrinsic muscles of the larynx, thereby suspending the larynx in the neck (**Figure 58.4**). The hyoid bone consists of a body anteriorly from which the greater cornua project backwards on each side. The lesser cornua are two small conical eminences that are attached to the upper aspect of the body of the hyoid laterally (and sometimes from the medialmost aspect of the greater cornua), either by a fibrous band or, sometimes, by way of a synovial joint.

THYROID CARTILAGE

The thyroid cartilage is composed of two laminae that are fused in the midline anteriorly giving rise to the laryngeal prominence (see **Figure 58.4**). The angle of fusion is about 90° in men and 120° in women. The posterior border of

each lamina is prolonged above and below to form the superior and inferior cornua, respectively. The superior cornu is long and narrow and curves upwards, backwards and medially, ending in a conical extremity to which the lateral thyroid ligament is attached. The inferior cornu is shorter and thicker and curves downwards and medially. On the medial surface of its lower end is a small oval facet joint for articulation with the cricoid cartilage.

On the external surface of each lamina, an oblique line curves downwards and forwards from the superior thyroid tubercle, situated just in front of the root of the superior horn, to the inferior thyroid tubercle on the lower border of the lamina. This line marks the attachment of the thyrohyoid, sternothyroid and inferior constrictor muscles. On the inner aspect of the thyroid cartilage, just below the thyroid notch in the midline, is attached the thyroepiglottic ligament and below this and on each side of the midline, are attached the vestibular and vocal ligaments and thyroarytenoid, thyroepiglottic and vocalis muscles. The fusion of the anterior ends of the two vocal ligaments produces the anterior commissure tendon. The remaining parts of the inner aspect of the thyroid lamina are smooth and are mainly covered by loosely attached mucous membrane. The superior border of each lamina gives attachment to the thyrohyoid ligament and the inferior border, on the medial portion of its inner aspect, the cricothyroid ligament.

CRICOID CARTILAGE

The cricoid cartilage is the only complete cartilaginous ring in the airway (**Figure 58.5**). It forms the inferior part of the anterior and lateral walls and most of the posterior wall of the larynx. It has a deep broad lamina posteriorly and a narrow arch anteriorly with a facet for articulation with the inferior cornu of the thyroid cartilage, near the junction of the arch and lamina. Rotation of the cricoid cartilage on the thyroid cartilage can take place about an axis passing transversely through both joints. The lamina has sloping shoulders on which the articular facets for the arytenoid cartilages are found. A vertical ridge in the midline of the lamina gives attachment to the longitudinal muscle of the oesophagus and produces a shallow concavity on each side for the origin of the posterior cricoarytenoid (PCA) muscle. The entire inner surface of the cricoid cartilage is lined with mucous membrane. The importance of the cricoid in laryngeal health and disease cannot be overemphasized. The luminal mucosa is at risk of necrosis and circumferential scarring, which results in debilitating subglottic stenosis. The cricoarytenoid joint – together with an associated functional PCA muscle – is regarded as a key functional unit of the larynx, facilitating vocal fold motility to ensure a patent airway when abducted and airway protection when adducted.

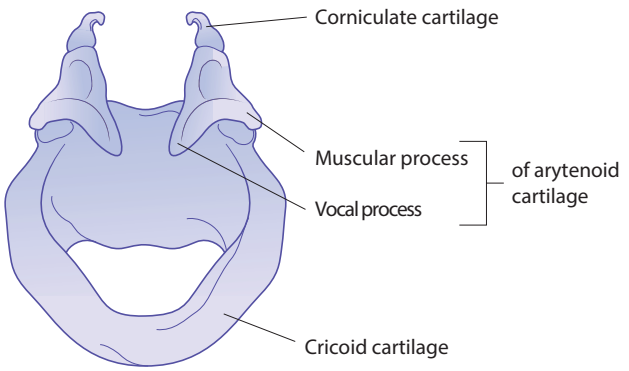

Figure 58.5 The cricoid and arytenoids.

THE ARYTENOID CARTILAGES

The arytenoid cartilages are irregularly shaped, broadly conforming to a three-sided pyramid with a forward projection, the vocal process, to which the dorsal end of the vocal folds are attached a lateral projection, the muscular process, to which the posterior cricoarytenoid and lateral cricothyroid muscles attach (see **Figure 58.5**). Between these two processes, the anterolateral surface is irregular and divided into two fossae by a crest running from the apex. The upper triangular fossa gives attachment to the vestibular ligament and the lower to the vocalis and lateral cricoarytenoid muscles. The apex is curved backwards and medially and is flattened for articulation with the corniculate cartilage, which sits atop it. The medial surfaces have no muscular attachments, are covered with mucous membrane and form the lateral boundary of the posterior glottis. The posterior surface of each cartilage is covered by the transverse arytenoid muscle, which inserts onto each cartilage across the midline.

The base is concave and presents a smooth surface for articulation with the sloping shoulders of the upper border of the cricoid lamina. This is a synovial joint with lax capsular ligaments allowing both rotatory movements and medial and lateral gliding movements. However, the posterior cricoarytenoid ligament is more rigid and prevents forward movement of the arytenoid cartilage on the cricoid.

CORNICULATE AND CUNEIFORM CARTILAGES

The corniculate cartilages (of Santorini) are two small conical nodules of elastic fibrocartilage, which articulate through a synovial joint with the apices of the arytenoid cartilages. They are situated in the posterior part of the aryepiglottic fold. The cuneiform cartilages (of Wisberg) are two small, elongated flakes of fibroelastic cartilage, one in each free margin of the aryepiglottic fold. The function of these cartilages is uncertain. They may act to provide structural rigidity to the aryepiglottic folds somewhat like curtain weights.

EPIGLOTTIS

The epiglottis is a thin, leaf-like sheet of elastic fibrocartilage that projects upwards behind the tongue and the body of the hyoid bone. It is attached inferiorly to the thyroid cartilage, just below the thyroid notch in the midline, by the thyroepiglottic ligament and also to the hyoid bone anteriorly by the hyoepiglottic ligament. The space between

these ligaments forms the pre-epiglottic space. From the sides of the epiglottis, the aryepiglottic folds sweep downwards and backwards to the apex of the arytenoids. The posterior (laryngeal) surface of the cartilage is indented by numerous small pits into which mucus glands project. The anterior (lingual) surface of the epiglottis is covered with mucous membrane superiorly and forms the posterior wall of the vallecula. The mucous membrane overlying the epiglottis is reflected onto the base of the tongue, forming the glossoepiglottic fold in the midline and laterally the lateral glossoepiglottic folds.

Ligaments and membranes of the larynx

EXTRINSIC LIGAMENTS

The extrinsic ligaments of the larynx connect the laryngeal cartilages to the hyoid above and trachea below (see **Figure 58.4**). Superiorly, the thyrohyoid membrane stretches between the upper border of the thyroid cartilage and the posterior surface of the body and greater cornua of the hyoid. The membrane is composed of fibroelastic tissue, reinforced by fibrous tissue in the midline as the median thyrohyoid ligament and posteriorly as the lateral thyrohyoid ligament. The latter connects the tip of the superior cornua of the thyroid cartilage to the posterior ends of the greater cornua of the hyoid. The ligaments often contain a small nodule of cartilage, the cartilago triticea. The membrane is pierced by the internal branch of the superior laryngeal nerve and by the superior laryngeal vessels. The cricotracheal ligament unites the lower border of the cricoid with the first tracheal ring.

INTRINSIC LIGAMENTS

The intrinsic ligaments of the larynx connect the laryngeal cartilages together, strengthen the capsule of the intercartilaginous joints and form a broad sheet of fibroelastic tissue, the fibroelastic membrane, which lies beneath the mucous membrane of the larynx forming an internal framework (see **Figures 58.3** and **58.6**).

The fibroelastic membrane is divided into an upper and lower part by the laryngeal ventricle. The upper quadrilateral membrane extends between the lateral border of the epiglottis and the arytenoid cartilages. The upper margin forms the framework of the aryepiglottic fold and the lower margin is thickened to form the vestibular ligament underlying the vestibular fold (false vocal fold). The lower part is thicker, containing many elastic fibres. It is commonly called the cricovocal ligament, cricothyroid ligament or conus elasticus. It is attached below to the upper border of the cricoid cartilage and above it is stretched between the inner surface of the midpoint of the laryngeal prominence of the thyroid cartilage anteriorly and the vocal process of the arytenoid behind. The free upper border of this membrane constitutes the vocal ligament the framework of the (true) vocal fold. Anteriorly, there is a thickening of the membrane, the cricothyroid ligament, which connects the cricoid and the thyroid cartilages in the midline.

Muscles of the larynx

The extrinsic muscles of the larynx attach the larynx to neighbouring structures and maintain the position of the larynx in the neck (**Table 58.1**). The infrahyoid muscles work in synergy with the elevators of the larynx, one set of muscles relaxing (infrahyoid) whilst the other contracts (suprahyoid) to facilitate laryngeal elevation. Under normal physiological conditions, descent of the larynx is due to elastic recoil of the trachea and lower respiratory tract and therefore, relaxation of the suprahyoid musculature is the only requirement.

The intrinsic muscles are all paired and function in a coordinated fashion to move the cartilages of the larynx thereby governing laryngeal function (**Table 58.2** and **Figures 58.7–58.11**). They control the overall position and shape of the vocal folds as well as the elasticity and viscosity of each layer. The majority of intrinsic muscles act to move the arytenoid at the cricoarytenoid joint. The joint has a complex range of movements but broadly speaking the arytenoid rotates inwards and downwards to close and upwards and outwards to open the glottis.

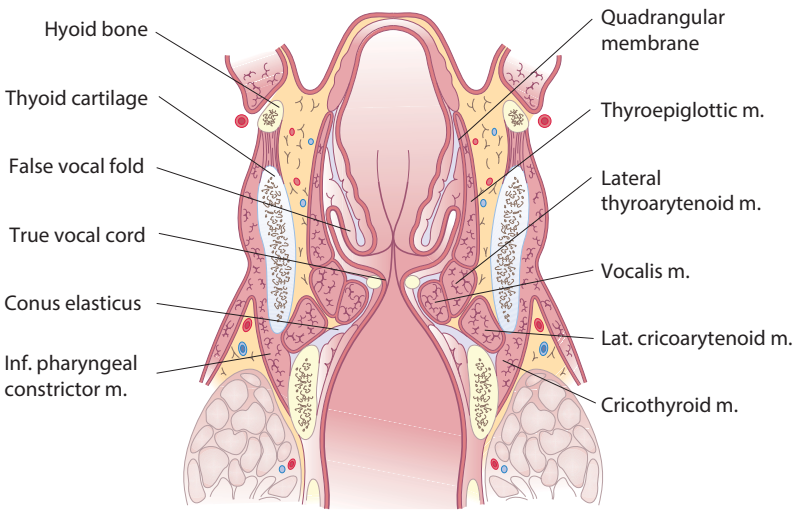

Figure 58.6 Coronal section through the larynx looking anteriorly.

TABLE 58.1 Extrinsic muscles of the larynx

Name	Origin	Insertion	Function	Innervation
Infrahyoid group				
Thyrohyoid	Oblique line of thyroid lamina	Inferior border of the greater cornu of the hyoid	Elevates the larynx on a fixed hyoid or depresses the hyoid on a fixed larynx	Hypoglossal (C1 root)
Sternothyroid	Posterior surface of manubrium and edge of the first costal cartilage	Oblique line of the thyroid lamina	Depresses the larynx	Ansa cervicalis (C2, 3 roots)
Sternohyoid	Clavicle and posterior surface of the manubrium	Lower edge of the body of the hyoid	Depresses the larynx by lowering the hyoid	Ansa cervicalis (C1, 2, 3 roots)
Suprahyoid group				
Mylohyoid	Mylohyoid line on inner aspect of the mandible	Midline raphe and body of the hyoid	Raises and pulls the hyoid anteriorly	Nerve to mylohyoid (inferior alveolar branch of V3)
Geniohyoid	Genial tubercle on mandible	Upper border of the body of the hyoid	Raises and pulls the hyoid forwards	Hypoglossal (C1 root)
Stylohyoid	Back of the styloid process (splits around the digastric tendon)	Base of greater cornu of the hyoid	Retractor and elevator of the hyoid for swallowing	Facial nerve
Digastric	Digastric notch on the medial surface of the mastoid process	Lower border of the mandible (fibrous sling holds the tendon to the lesser cornu of the hyoid)	Anterior belly pulls the hyoid anteriorly and up	Posterior belly – facial nerve
			Posterior belly pulls the hyoid posteriorly and up	Anterior belly – nerve to mylohyoid
Stylopharyngeus	Medial aspect of the styloid process	Posterior border of the lamina of the thyroid cartilage (side wall of the pharynx)	Elevates the larynx	Glossopharyngeal nerve
Palatopharyngeus	Palatine aponeurosis and posterior margin of hard palate	Posterior border of thyroid alar and cornua	Helps tilts the larynx forwards	Accessory nerve (pharyngeal plexus)
Salpingopharyngeus	Eustachian tube	Posterior border of the thyroid cartilage (side wall of the pharynx)	Elevates the larynx	Pharyngeal plexus

The posterior cricoarytenoid is the only abductor of the larynx – and is arguably, therefore, the most important muscle in the body. The thyroarytenoids cause some adduction but largely shorten and thicken whilst altering the tension of the vocal fold. The interarytenoid muscles draw the arytenoids together posteriorly whilst the lateral cricoarytenoid muscles internally rotate the arytenoid cartilages by pulling their muscular processes caudally and anteriorly resulting in vocal fold adduction.

The cricothyroid muscles are the only intrinsic muscle that do not insert into the arytenoid cartilages; they therefore exert their action by bringing the thyroid and cricoid cartilages closer together in a visor-like motion. In doing so both vocal folds are simultaneously stretched with a consequence increase in tension.

Some muscles are able to exert more than one action and therefore possess segmental compartmentalization. For example, the posterior cricoarytenoid has two components with different fibre types, nerve branches and insertions into the muscular process of the arytenoid, which allows for external and backward rotation of the arytenoid cartilage on the cricoarytenoid joint. (See **Table 58.1** for additional examples.)

The glottis

The glottis lies between two horizontal lines, one drawn through the apex of the laryngeal ventricle, the other drawn 1 cm below the medial free edge of the vocal fold when the larynx is at rest. The scaffolding of the false and true vocal folds is formed by the vestibular and vocal ligaments, respectively (see **Figures 58.3** and **58.6**). Laterally, intervening between the vestibular and vocal ligaments, a horizontal slit opens into an elongated recess, the laryngeal ventricle. From the anterior part of the ventricle, the saccule of the larynx ascends between the vestibular ligament and the inner surface of the thyroid cartilage as high in some people as the upper border of the thyroid cartilage. It occasionally protrudes through the thyrohyoid membrane. Fibrous tissue surrounds the saccule. Dilatation of the saccule results in the formation of a laryngocele. The ventricle and saccule can harbour occult cancers and need to be actively inspected during diagnostic endoscopy.

The vestibular folds are thick folds of mucous membrane scaffolded on a narrow band of fibrous tissue, the vestibular ligament, which is the lower border of the upper quadrilateral membrane. It is fixed in front at the angle of the

TABLE 58.2 Intrinsic muscles

Name	Origin	Insertion	Function	Effect
Open and close the glottis				
Posterior cricoarytenoid	Lower and medial surface of the back of the cricoid lamina	It fans out to be inserted into the back of the muscular process of the arytenoid	Opens the glottis. Upper horizontal fibres rotate the arytenoids and move the muscular processes towards each other separating the vocal processes and abducting the cords. Lateral vertical fibres draw the arytenoids down the sloping shoulders of the cricoid separating the arytenoids	Abducts and elevates the tip of the vocal process The vocal fold becomes elongated and thin. The free edge of the vocal fold is rounded and passively stiffened
Lateral cricoarytenoid	Superior border of lateral part of the arch of the cricoid	Muscular process of arytenoid	Adducts and lowers the tip of the vocal process by rotating the arytenoids medially	Vocal fold adducted, lowered, elongated and thinned. The edge of the vocal fold becomes sharp and is passively stiffened
Transverse arytenoids – unpaired	Posterior surface of the muscular process and outer edge of the arytenoid	Crosses over and attaches to the same point on the other arytenoid	Adducts the vocal fold and controls the position of the vocal fold	No significant effect on the mechanical properties of the vocal fold
Oblique arytenoids – paired	Posterior aspect of the muscular process (superficial to the transverse arytenoid)	Apex of the other arytenoid		
Control the tension of the vocal folds				
Thyroarytenoid (vocalis): A broad sheet of muscle which lies lateral to and above the free edge of the cricovocal ligament. The lower part of the muscle is thicker and forms a distinct bundle called the vocalis muscle.	Back of the thyroid prominence and cricothyroid ligament	Vocal process of arytenoid and anterolateral surface of the body of the arytenoid		Lowers, shortens and thickens the vocal folds causing the edge of the fold to be rounded. The body of the fold is actively stiffened but the transition layers are passively slackened. Many fibres are prolonged into the aryepiglottic fold some continuing to the margin of the epiglottis as the thyroepiglottic muscle which tends to widen the inlet of the larynx pulling the aryepiglottic folds slightly apart
Cricothyroid: This is the only intrinsic muscle that lies outside the cartilaginous framework of the larynx	Lateral surface of the anterior arch of the cricoid. Fibres fan out and pass backwards in two groups	Lower oblique fibres pass backwards and laterally to the anterior border of the inferior cornu of the thyroid cartilage. Anterior straight fibres ascend to the posterior part of the lower border of the thyroid lamina		Rotates the cricoid cartilage about the horizontal axis passing through the cricothyroid joint. It lengthens the vocal folds by increasing the distance between the angle of the thyroid cartilage and arytenoids. On contraction, the vocal folds are brought into a line between the anterior commissure and the posterior cricoarytenoid ligament, the level of the vocal folds is lowered and the entire fold elongated and thinned. The edge of the vocal fold becomes sharp and all the layers are stiffened
Alter the shape of laryngeal inlet				
Aryepiglotticus: A continuation of the oblique arytenoid	Posterior aspect of the muscular process of the arytenoid	Fibres pass around the apex of the opposite arytenoid and insert into the aryepiglottic fold		Weak sphincter of the laryngeal inlet
Thyroepiglotticus: A continuation of the thyroarytenoid	Back of the thyroid prominence and cricothyroid ligament	Fibres pass upwards into the aryepiglottic fold		Widens the inlet of the larynx pulling the aryepiglottic folds slightly apart

All the intrinsic muscles of the larynx are supplied by the recurrent laryngeal nerve except the cricothyroid, which is supplied by the external branch of the superior laryngeal nerve. The unpaired transverse arytenoid and paired oblique arytenoid make up the interarytenoid muscle.

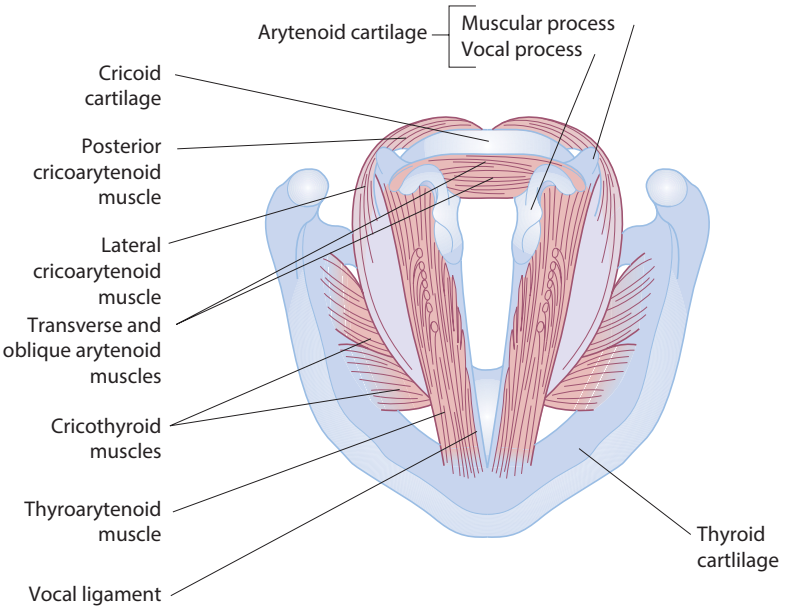

Figure 58.7 Dissected view of the larynx from above

thyroid cartilage just below the attachment of the epiglottic cartilages and behind the anterolateral surface of the arytenoid cartilage just above the vocal process (see **Figure 58.7**).

The vocal folds extend from the middle of the angle of the thyroid cartilage to the vocal process of the arytenoid cartilages and scaffolding them is the upper border of the conus elasticus. Each fold is a layered structure consisting of a superficial layer of nonkeratinizing, stratified squamous epithelium, beneath which is the lamina propria. This has three distinct layers. The superficial layer (Reinke's space) contains a fibrous substance with similar characteristics to gelatin. The intermediate layer contains elastic fibres and the deep layer collagen fibres. The intermediate and deep layers make up the vocal ligament. The vocalis muscle, which forms the main body of the vocal fold, lies lateral and deep. The loose areolar tissue of Reinke's spaces allows lax movement of the overlying mucosa, giving rise to a mucosal waveform during phonation.

The layered structure of the vocal fold is not uniform in its entire length. At the anterior end of the vocal fold there is a mass of collagen fibres (anterior commissure tendon or Broyle's ligament), which are connected to the inner perichondrium of the thyroid cartilage and to the deep layer of the lamina propria posteriorly. Adjacent to this mass of collagen fibres just posteriorly, there is another mass of elastic fibres continuous with the intermediate layer of the lamina propria called the anterior macula flava. A similar structure is seen at the posterior end of the membranous part of the vocal fold. These structures appear to serve as cushions to protect the ends of the vocal folds from mechanical damage caused by vocal fold vibration.

The anterior three-fifths of the vocal fold (from the anterior commissure to the tip of the vocal process) is the membranous part. The remaining two-fifths posteriorly extend from the tip of vocal process to the face of the arytenoid cartilage, and are called the cartilaginous part of the vocal fold. The height of the vocal folds diminishes towards the anterior commissure mainly because the inferior edge of the vocal fold slopes upwards. At the anterior commissure the lower edges of the vocal folds form the apex of a triangle via Broyle's ligament to the epiglottis, so tumour involving the anterior commissure readily involves the subglottis. The vocal folds are therefore almost wedge shaped, with the 'blunted' apex of the wedge anteriorly.

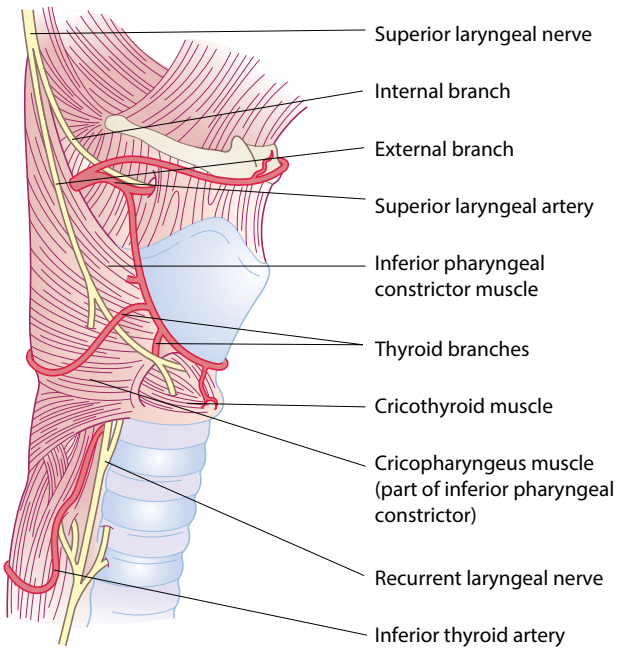

Figure 58.8 Lateral view of the larynx (complete).

Mucous membranes of the larynx

The mucous membrane lining of the larynx is closely attached over the posterior surface of the epiglottis, the corniculate and cuneiform cartilages and over the vocal ligament. Elsewhere, it is loosely attached and prone to oedema. Most of the larynx is lined by pseudostratified ciliated columnar 'respiratory'-type epithelium. The upper half of the posterior surface of the epiglottis, the upper

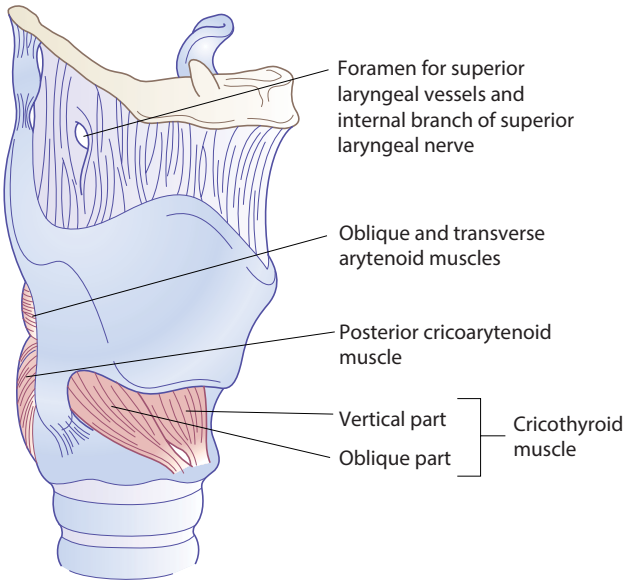

Figure 58.9 Lateral view of the larynx with extrinsic muscle removed.

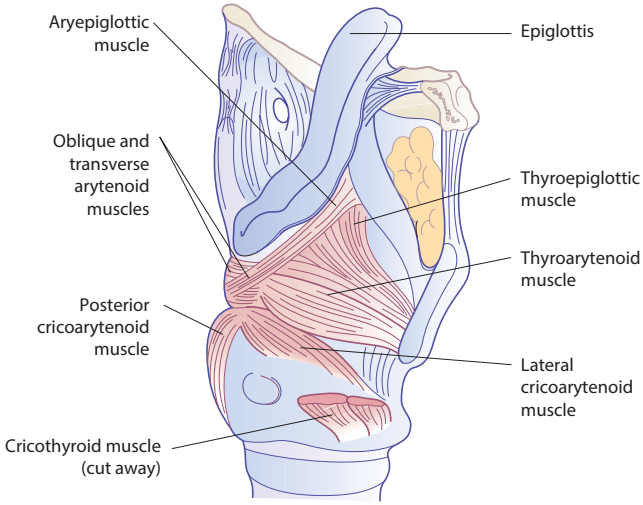

Figure 58.10 Lateral view of the larynx with the ipsilateral thyroid cartilage and cricothyroid muscle removed.

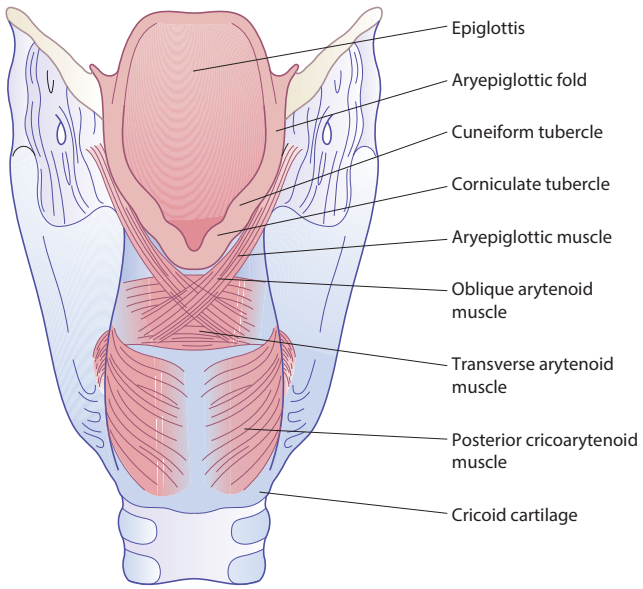

Figure 58.11 Posterior view of the larynx.

part of the aryepiglottic fold, the posterior glottis and the vocal folds are covered with non-keratinizing stratified squamous epithelium.

Mucous glands are freely distributed throughout the mucous membranes and are particularly numerous on the posterior surface of the epiglottis where they form indentations into the cartilage and in the margins of the lower part of the aryepiglottic folds and in the saccules. The vocal folds do not possess any glands and the mucous membrane is lubricated by mucus from the glands within the saccules. The squamous epithelium of the vocal folds is therefore prone to desiccation if these glands cease to function, for example after radiation.

Spaces within the larynx

Spaces in the larynx contain fat, lymphatics and vessels. They represent potential pathways of tumour spread that may have a significant bearing on treatment and prognosis.

PRE-EPIGLOTTIC SPACE

The pre-epiglottic space is a wedge-shaped space with the point of the wedge inferiorly (see **Figure 58.3**). It is bounded anteriorly by the thyrohyoid ligament and hyoid bone and posteriorly by the epiglottis. Superiorly, the hyoepiglottic ligament connects the epiglottis to the hyoid bone. Tumour may spread into this area through small perforations in the epiglottis or directly through the hyoepiglottic ligament. The pre-epiglottic space is continuous laterally with the paraglottic space as no anatomical boundaries exist.

PARAGLOTTIC SPACE

The paraglottic space is bounded laterally by the thyroid cartilage, medially by the conus elasticus and quadrangular membrane and posteriorly by the piriform fossa mucosa. It contains the laryngeal ventricles and saccules (see **Figures 58.7** and **58.12**). Tumours may spread extensively in this submucosal space in the absence of significant mucosal changes

Nerve supply of the larynx

The motor and sensory nerves of the larynx are derived from the vagus by way of its superior and recurrent laryngeal nerves (see **Figure 58.8**). The superior laryngeal nerve arises from the inferior ganglion of the vagus and receives a branch from the superior cervical sympathetic ganglion. It descends lateral to the pharynx behind the internal carotid artery and at the level of the greater horn of the hyoid divides into a small external branch and a larger internal branch. The external branch provides motor supply to the cricothyroid muscle, while the internal branch pierces the thyrohyoid membrane above the entrance of the superior laryngeal artery and divides into two main sensory and secretomotor branches. The upper branch

supplies the mucous membrane of the lower part of the pharynx, epiglottis, vallecula vestibule of the larynx and the lower branch descends in the medial wall of the piriform fossa beneath the mucous membrane and supplies the aryepiglottic fold and the mucous membrane of the larynx down to the level of the vocal folds. In its course beneath the mucous membrane of the medial wall of the piriform fossa, the superior laryngeal nerve is accessible for injection of local anaesthesia, providing excellent anaesthesia for most of the piriform fossa. The internal branch of the superior laryngeal nerve also carries afferent fibres from neuromuscular spindles and other stretch receptors in the larynx. The superior laryngeal nerve ends by piercing the inferior constrictor of the pharynx and unites with an ascending branch of the recurrent laryngeal nerve. This branch is called Galen's anastomosis and is purely sensory.

The right recurrent laryngeal nerve leaves the vagus as it crosses superficial to the right subclavian artery and loops under the artery, ascending in the tracheoesophageal groove to reach the larynx. On the left, the nerve originates from the vagus as it crosses the aortic arch. It then passes under the arch and the ligamentum arteriosum to reach the tracheoesophageal groove. In the neck, both nerves follow the same course and pass upwards accompanied by the laryngeal branch of the inferior thyroid artery. They pass deep to the lower border of the inferior constrictor muscle and enter the larynx behind the cricothyroid joint. The recurrent laryngeal nerve then divides into motor and sensory branches. The motor branch has fibres derived from the cranial root of the accessory nerve, which supply all the intrinsic muscles of the larynx except the cricothyroid. The sensory branch supplies the laryngeal mucosa below the level of the vocal folds and also carries afferent fibres from stretch receptors in the larynx.

There is some evidence to suggest there are variable anastomoses between the internal and recurrent laryngeal nerves. The existence of a 'laryngeal plexus' or multiple anastomoses may explain the variable clinical presentations of laryngeal nerve injuries and recovery from laryngeal injury.

The relationship between the recurrent laryngeal nerve and the inferior thyroid artery is variable. The nerve may cross in front of or behind the artery, or may pass between the terminal branches of the artery. On the right there is an equal chance of the nerve being in any of three locations in relation to the artery, although on the left it is more likely to lie posterior to the artery.

Laryngeal vasculature

ARTERIAL

The arterial supply of the larynx is derived from laryngeal branches of the superior and inferior thyroid arteries and the cricothyroid branch of the superior thyroid artery (see **Figure 58.8**). The superior laryngeal artery arises from the superior thyroid artery and passes deep to the thyrohyoid muscle. Together with the internal branch of the superior laryngeal nerve, it pierces the thyrohyoid membrane to supply the larynx. The superior laryngeal artery can be injured in endoscopic laryngeal laser surgery as it enters the paraglottic space at the anterior end of the aryepiglottic fold. Therefore, meticulous care to ensure haemostasis must be taken during supraglottic endoscopic surgical resections. The inferior laryngeal artery arises from the inferior thyroid artery at the level of the lower border of the thyroid gland and ascends on the trachea with the recurrent laryngeal nerve. It enters the larynx beneath the lower border of the inferior constrictor to supply the larynx. The cricothyroid artery is a branch of the superior thyroid artery and passes across the upper part of the cricothyroid ligament to supply the larynx. This ligament is penetrated by the branches (up to five) of the cricothyroid artery, which can be injured during cricothyroidotomy or endoscopic resection of anterior commissure cancers.

The arteries of the larynx form a communicating plexus in the paraglottic space, which can be the source of brisk bleeding during endolaryngeal surgery.

VENOUS

The veins leaving the larynx accompany the arteries. The superior laryngeal veins enter the internal jugular vein by way of the superior thyroid or facial vein. The inferior laryngeal veins drain into the inferior thyroid veins, which connect with the brachiocephalic vein. Some veins drain into the middle thyroid vein and then into the internal jugular vein.

LYMPHATIC DRAINAGE

The lymphatic drainage of the larynx is separated, by the vocal folds, into upper and lower drainage systems. The larynx above the vocal folds is drained by vessels that accompany the superior laryngeal vein and pierce the thyrohyoid membrane emptying into the upper deep cervical lymph nodes. The larynx below the vocal folds drains to the lower deep cervical chain, often through prelaryngeal (Delphian) and pretracheal nodes. The vocal folds themselves are firmly bound down to the underlying vocal ligament and there are no lymphatics present in this plane. Early cancers of the vocal folds do not therefore readily spread to the lymph nodes.

ANATOMY OF THE TRACHEA AND BRONCHIAL TREE

General description

THE TRACHEA

The trachea is a pathway for ventilation and clearance of bronchial secretions. It begins at the lower border of the cricoid cartilage and ends at the carina (**Figure 58.13**). The average length of the adult male trachea is 11.8 cm (range 10–13 cm). It has an ovoid shape, with average external diameters 2.3 cm (anteroposterior) by 1.8 cm (transverse) in the male and 2.0 cm by 1.4 cm in the female. The diameter of the paediatric trachea is 3 mm at birth.

The trachea slopes backwards from an anterior position in the neck to a posterior position in the mediastinum, at an angle that varies with age and spinal position. The trachea is mobile, moving upwards in swallowing and down and forwards on inspiration. The relatively fixed position of the left main bronchus under the arch of the aorta means that with any degree of kyphosis, the position moves more towards the horizontal and can limit the amount of trachea that is brought into the neck by extension of the neck.

The cross section of the trachea is D-shaped with incomplete C-shaped cartilaginous rings. The free posterior ends of cartilage embed into the smooth muscle trachealis, which has longitudinal and transverse fibres. There are approximately 2 rings per centimetre of trachea with each ring averaging 4 mm in length. This corresponds to 18–22 rings in the tracheal wall, which is approximately 3 mm thick. The size of the tracheal lumen may be altered by age and by disease.

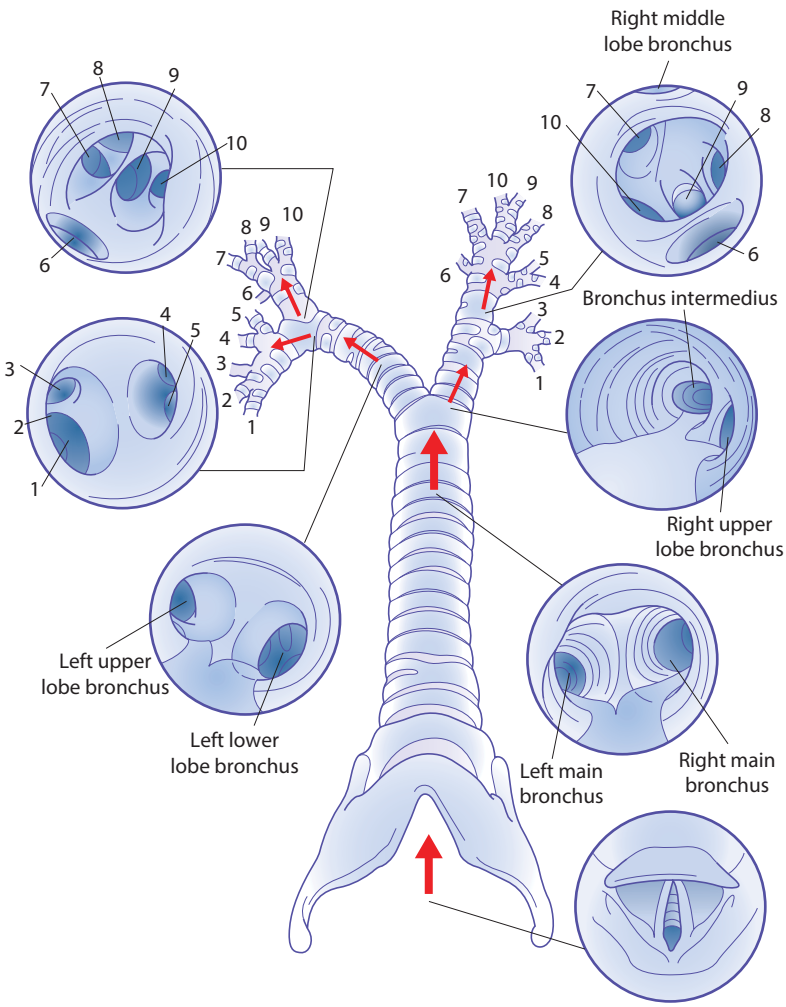

Figure 58.13 The tracheobronchial tree and views seen on endoscopy. Right lung, upper lobe bronchus: 1, apical; 2, posterior; 3, anterior, middle lobe bronchus; 4, lateral; 5, medial, lower lobe bronchus; 6, apical; 7, medial basal (cardiac); 8, anterior basal; 9, lateral basal; 10, posterior basal. Left lung, upper lobe bronchus.

THE CARTILAGES

The C-shaped cartilage rings line the trachea and bronchi where they both stiffen the wall and provide a degree of flexibility. Two or more cartilages may unite, either partially or completely, or bifurcate. Their elasticity may decrease with age as they become increasingly calcified.

The first cartilage is broader and may be joined to the cricoid cartilage or it may be separated with clearly defined cricotracheal ligament. The last ring above the carina is thick and broad and forms a bridge between the right and left main bronchi with a downwards curving triangular process continuing from the inferior border, which forms the posterior of the carina.

THE FIBROUS MEMBRANE AND TRACHEALIS

Each cartilage is enclosed in and nourished by perichondrium, which is continuous with an enveloping fibrous membrane. The membrane consists of a dense sheet of irregular connective tissue encircling the rings of cartilage, trachealis and the deficient posterior borders of the extrapulmonary bronchi. Composed of collagen and elastin fibres in crossing orientations, they permit expansion and aid elastic recoil of the airways. Constriction of the tracheal lumen is facilitated by trachealis, the transverse fibres inserting into the perichondrium at the free margins of the cartilage rings. The longitudinal trachealis fibres and the outer fibrous layer blend in with the fascia over the oesophagus and loose areolar fibres of the mediastinum.

THE MUCUS MEMBRANE

The lining of the upper airways is pseudo-stratified, ciliated, columnar epithelium with numerous goblet cells, resting on a broad basement membrane. The cilia beat the mucus blanket upwards towards the larynx and eventually the pharynx, where it is swallowed. The lamina propria is rich in longitudinal elastin fibres and overlies a submucosa of loose connective tissue containing the neurovascular structures, tubular glands and lymphoid patches.

The epithelium becomes thinner with increasing branching of the segmental bronchi. There are fewer goblet cells and a thinner basement membrane. Eventually the epithelium becomes a single layer. The smaller airways have less cartilage and are relatively more muscle until the circular muscle fibres are almost circumferential within the cartilage, rather than the fibromuscular tissue found higher up in airway. Contraction of these muscles, which form an interlacing network of fibres, both shortens and constricts the segmental bronchi.

CARINA AND BRONCHI

The trachea bifurcates and narrows slightly at the carina with the origin of the left and right main bronchi (**Figure 58.13**) at the level of T5 (posteriorly) and the manubrium (anteriorly). The right main bronchus makes an angle of 25–30 degrees with the carina, less than the 45-degree angle made by the left main bronchus. Therefore aspirated foreign bodies are more likely to continue into the right rather than left main bronchus.

RIGHT MAIN BRONCHUS AND BRANCHES

With an adult length of approximately 5 cm and a diameter of 17 mm (+/– 4 mm) in men and 15mm (+/– 4 mm) in women, the right main bronchus lies above the right pulmonary artery and below the azygos vein. The bronchus continues as the bronchus intermedius after take-off of the right upper lobe bronchus at a distance of 12–20 mm from the carina, and further down this terminates in the middle and lower lobe bronchi (see **Figure 58.13**).

The right upper lobe bronchus is approximately 1 cm long and divides into an apical, posterior and anterior segmental bronchi, which supply the right upper lobe. A variation of this anatomy exists where the apical segmental bronchus originates from the trachea at the level of the carina.

The right middle lobe bronchus arises approximately 2.5 cm down the bronchus intermedius, and terminates in lateral and medial segmental bronchi. The segmental bronchi of the right lower lobe consist of superior, anterior basal, posterior basal, medial basal and lateral basal divisions.

LEFT MAIN BRONCHUS AND BRANCHES

At 5.5 cm in length, the left main bronchus is longer, but 2–3 mm narrower than the right. It crosses anterior to the oesophagus, thoracic duct and descending aorta, travelling inferior to the aortic arch. The left pulmonary artery lies first anterior then superior to the left main bronchus, which terminates in the left hilum at the level of T6 as the upper and lower lobe bronchi.

The left upper lobe bronchus divides into apico-posterior (which further subdivides into apical and posterior) and anterior segmental bronchi (see **Figure 58.13**). The upper lobe bronchus terminates in the lingular bronchus, which gives superior and inferior segmental bronchi.

Similar to the right side, the left lower lobe bronchus gives five segmental bronchi-apical (superior), lateral basal and posterior basal and the final two medial basal (cardiac), anterior basal, which share a common stem.

Neurovascular supply of the tracheobronchial tree

NERVE SUPPLY

The recurrent laryngeal nerves provide motor supply to the smooth musculature and also carry sensation from the mucosa. Sympathetic supply derives mainly from the middle cervical ganglion and interconnects with the recurrent laryngeal nerves. The lungs are supplied by the anterior and posterior pulmonary plexuses situated at the hilum of each lung.

Parasympathetic supply of the trachea and bronchi is from the vagus with efferent stimulation provoking

bronchoconstriction, glandular secretion and vasodilatation. Vagal afferents are involved in the cough reflex.

BLOOD SUPPLY

The blood supply enters the lateral walls of the trachea in a distributed segmental fashion. The cervical trachea receives its blood supply from the inferior thyroid artery. Most often the upper half of the trachea is supplied by three tracheoesophageal branches of the inferior thyroid artery. The branches may pass anterior or posterior to the recurrent laryngeal nerves. The 2nd and 3rd branches also supply the oesophagus.

The segmental arteries to the trachea branch superiorly and inferiorly over the width of several tracheal rings, forming a series of longitudinal anastomoses along the lateral walls of the trachea. The arterial branches also give anterior and posterior branches near to the tracheal wall. The anterior branches further anastomose near the midline. The posterior branches supply the membranous wall, which also receives supply from the oesophageal arteries. The veins drain to the inferior thyroid plexus.

The bronchial tree and carina receives its arterial supply via the bronchial arteries, of which there are usually three. Two of these are on the left and are direct branches from the aorta. On the right the bronchial artery comes from the third right posterior intercostal artery. The bronchial veins drain into a superficial system, draining into the azygos vein on the right and the accessory hemiazygos on the left. The deep drainage, which also drains the lung parenchyma, drains into the pulmonary veins.

LYMPHATIC DRAINAGE

The lymphatics in the trachea and bronchi arise in a submucosal plexus and connect with a plexus in the outer fibrous membrane, where pulmonary associated lymph nodes are located. The pulmonary nodes drain into the bronchopulmonary nodes found at the points of subdivision of the airway. The subcarinal nodes are important as they drain from both lungs and drain into the ipsilateral para-tracheal nodes. Lymphatics from the trachea drain into the pretracheal and eventually into the para-tracheal groups of nodes (level VI), which also drain the superior tracheobronchial nodes.

The para-tracheal nodes drain into the vessels from the internal thoracic and brachiocephalic lymph nodes to form the bronchomediastinal trunks, which drain into the right lymphatic duct and the left sided thoracic duct.

Surgical anatomy

TRACHEA

The trachea is covered from deep to superficial by skin, superficial and deep cervical fascia, sternohyoid and sternothyroid muscles and, for a variable distance, the thyroid isthmus (**Figure 58.14**). The isthmus usually lies over the second to fourth tracheal cartilages but can vary in size and thickness with age and disease.

In the lower neck the trachea is anteriolaterally related to the inferior thyroid artery (when present) and anteriorly to the inferior thyroid veins and the thymus gland, which can be large and fleshy in infants. In the mediastinum the left brachiocephalic vein and artery, the arch of the aorta, the left common carotid artery, the deep part of the cardiac plexus and pre-tracheal lymph nodes are located anterior to the trachea (**Figure 58.15**). In infants the brachiocephalic artery crosses the trachea at a higher level, just as it descends behind the suprasternal notch. The brachiocephalic vein, due to a relatively higher position in the neck in infants, is at risk with surgical access to the trachea, as it may lie above the suprasternal notch.

Lateral relations of the trachea are the lobes of thyroid gland, carotid sheath and contents and para-tracheal nodes. Postero-laterally the recurrent laryngeal nerves run in the tracheo-oseophageal groove and the oesophagus is located posteriorly.

HILUM OF THE LUNG

The hilum of the lung is enclosed in a sheath of pleura and is the entry and exit for pulmonary structures.

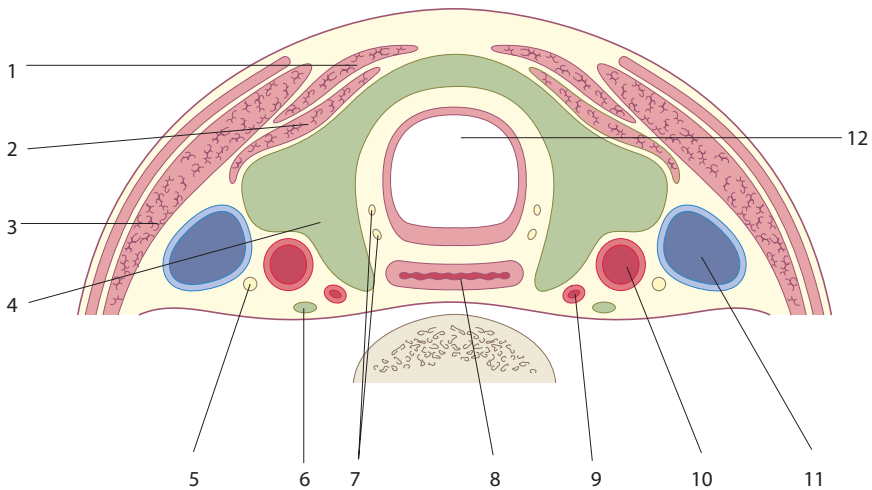

Figure 58.14 Axial section at C7 showing the relationship of the upper trachea to surrounding structures. 1, Sternohyoid muscle; 2, sternothyroid muscle; 3, sternocleidomastoid muscle; 4, thyroid gland; 5, left vagus nerve; 6, cervical sympathetic ganglion; 7, left recurrent laryngeal nerve; 8, oesophagus; 9, inferior thyroid artery; 10, common carotid artery; 11, internal jugular vein; 12, trachea.

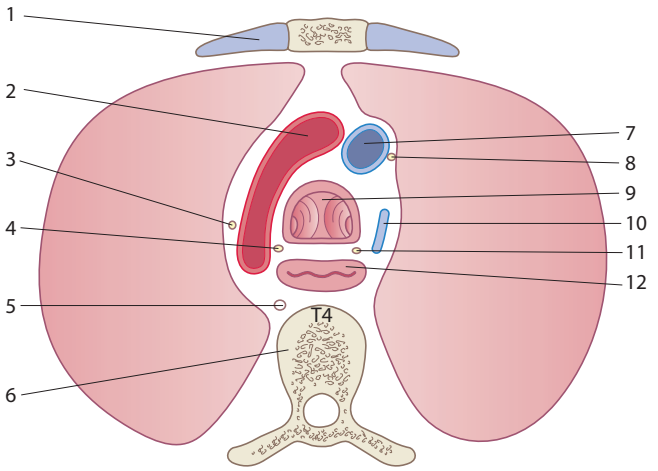

Figure 58.15 Axial section at T4 showing the relationship of the thoracic trachea to surrounding structures. 1, Second costal cartilage; 2, aortic arch; 3, left vagus nerve; 4, left recurrent laryngeal nerve; 5, thoracic duct; 6, fourth thoracic vertebra; 2, superior vena cava; 8, right phrenic nerve; 9, tracheal bifurcation; 10, azygos vein; 11, right vagus nerve; 12, oesophagus.

From anterior to posterior the structures are anterior plexus, pulmonary vessels (artery superior, two veins inferior), bronchi and bronchial vessels, and posterior plexus (**Figure 58.16**). The right side differs from the left as there is an additional upper lobe bronchus lying superiorly. There are lymph nodes and nerves within each hilum.

Anterior to the hilum is the phrenic nerve on the left and the superior vena cava on the right. The descending aorta and left vagus nerve crosses posteriorly to the left hilum, with the right vagus nerve posterior to the right hilum. Superior relations include the aortic arch on the left and azygos vein on the right. Inferiorly a sleeve of pleura hangs down as the pulmonary ligaments and allows movement of the hilar structures.

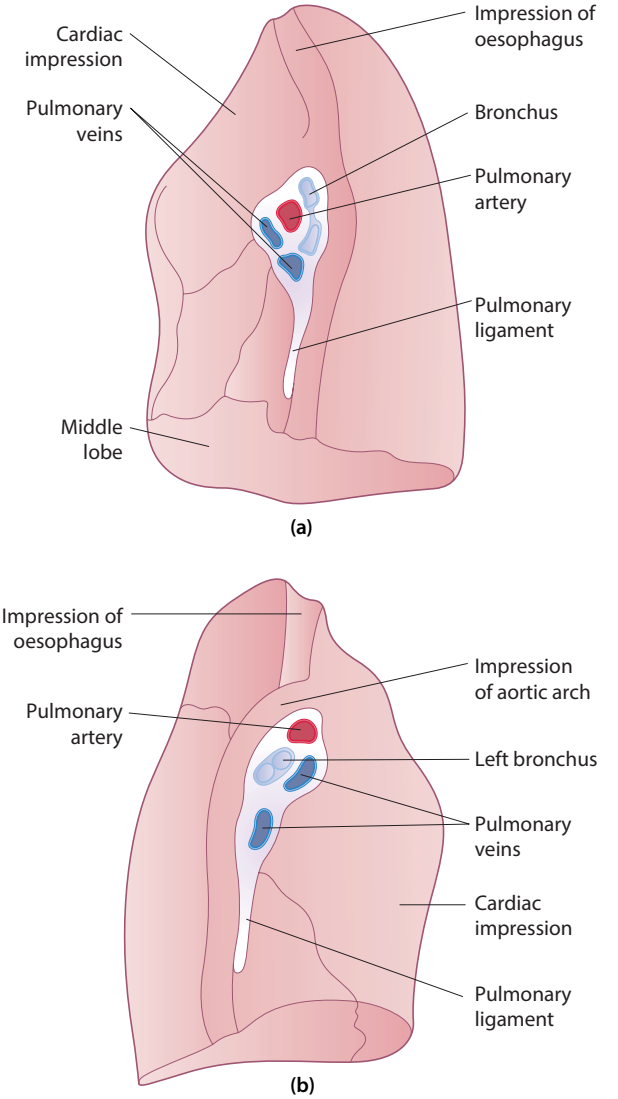

Figure 58.16 Structures in the hilum of the lung: (a) right hilum; **(b)** left hilum.

KEY POINTS

- Minimal swelling in the subglottic larynx can cause severe airway obstruction in infants.
- The pre-epiglottic and paraglottic spaces are connected and allow the unrestricted spread of tumours within the larynx.
- The posterior cricoarytenoid muscle is the only abductor of the vocal cords.
- All the intrinsic muscles of the larynx, except the cricothyroid, are supplied by the recurrent laryngeal nerve.
- The right main bronchus is wider, shorter and more vertical than the left, making it more susceptible to aspiration.

SEARCH STRATEGY

The information in this chapter can be explored more extensively by undertaking a Medline search using the following keywords: voice, larynx, laryngeal physiology, vocal registers, laryngeal innervation, laryngeal mechanoreceptors, neuroanatomy of phonation, biomechanics of phonation, vocal registers, vocal fold vibration.

INTRODUCTION

This chapter is concerned with the functions of the larynx, with particular emphasis on its role as the source of the voice. The motor and sensory laryngeal nerve supply is described and the neuroanatomy of phonation is described in greater detail. A concise section on the role of the larynx in swallowing, coughing and effort closure is followed by a more extensive description of the biomechanics of phonation. It should be noted that it is essential to be familiar with the considerable potential range of laryngeal adjustments that can occur in normal phonation, in order to avoid drawing inappropriate conclusions about phonatory physiology in a clinical setting.

The larynx has a number of functions, the most important of which is to prevent foreign material from entering the airway (aspiration). This is achieved by a combination of heightened sensitivity, a strong sphincteric action during swallowing and a means of effective expulsion (via coughing). The larynx also acts as a valve that can control air pressure and airflow, and as a vibrator for generating sound; both functions are of fundamental importance during breathing, weight bearing and phonation. This chapter is concerned with the neurology and biomechanics of laryngeal functions and lays the foundations for Chapter 60, Voice and speech production.

THE NEUROANATOMY OF PHONATION

Phonation can be defined as a laryngeal motor behaviour used for speech production, which involves a highly specialized coordination of laryngeal and respiratory neuromuscular control.[1] It is dependent upon the integrated functioning of many elements of the central and peripheral nervous systems (CNS and PNS). Although the motor and sensory tracts serving the larynx are relatively well understood, the way in which phonation is initiated and controlled continues to be the subject of neurological research. In addition to the cortical loci associated with voluntary phonation, there is evidence of subcortical representation which is responsible for reflex laryngeal function and involuntary phonation.[2] There is some evidence that the periaqueductal grey matter (PAG), a region of the mid-brain, is a crucial site for mammalian voice production.[3] Not only is it involved in the production of emotional or involuntary sounds but it also appears to generate specific respiratory and laryngeal motor patterns fundamental to human speech and singing. Davis et al. concluded that the patterned muscle activity corresponding to the major categories of voiced and voiceless sound production are represented in the PAG.[3] The role of the PAG might also include integration of cortical and subcortical aspects of language with basic respiratory and

laryngeal motor patterns by which speech is produced.[4–6] The linguistic demands of intonation, phonemic differentiations and emotional nuances in quality would appear to be regulated by such an independent sub-cortical reflex neural system.

The motor activity for vocalization appears to be integrated through a projection from the PAG to a column of neurones known as the nucleus retroambigualis (NRA).[7] The NRA appears to play a significant role in generating respiratory pressure and laryngeal adduction that occurs in both vocalization and vegetative manoeuvres, such as coughing.

Larson[4] suggested that the cortical mechanisms involved in vocalization and speech may have a role in modulating the subcortical systems that are involved in involuntary, or vegetative, phonation such as crying. It is possible that these are the mechanisms for coordinating timing, pitch and intensity fluctuations with the segmental and supra-segmental aspects of speech and voice. There is also evidence arising from clinical cases that the frontal lobes and other cerebral structures are important in the integrated neurological systems required for phonation. Functional magnetic resonance imaging (fMRI) has shown that there is common volitional control of the two upper airway functions of phonation and exhalation.[1] It has also been shown that multiple forebrain systems converge on motor neurones innervating the thyroarytenoid muscle.[8]

The neural pathways for voluntary vocalization arise in the pre-central gyrus of the motor cortex in both cerebral hemispheres and fibres descend as part of the corticobulbar tract, which is part of the pyramidal system or 'direct activation' tract. On reaching the medulla some fibres of the corticobulbar tracts take a direct pathway, remaining on the same side of the body throughout their route. These fibres synapse with the ipsilateral vagus nucleus and subsequently with lower motor neurones without interruption. Other fibres decussate (cross over) and change sides at the bulbar level to synapse with the contralateral vagal nucleus. The vagal nuclei, in the nucleus ambiguus within the reticular formation of the medulla, lie in a group of cells also containing the ninth and eleventh cranial nerve elements. They are influenced by both the pyramidal and extrapyramidal systems.

The indirect neurones of the pyramidal tract have multiple offshoots and synapses with the basal ganglia and reticular formation in the brain stem. They appear to contribute to temporospatial orientation while the direct system is related to discrete movement. The upper motor neurones do not govern isolated muscles, but groups of muscles. The frontobulbar portions of the pyramidal tracts connect with cranial nerves IX–XII, thus controlling articulation, phonation and respiration. The extrapyramidal system refers to tracts other than the pyramidal tracts and includes the basal ganglia in the cerebral hemispheres, the substantia nigra and subthalamic nucleus in the upper brainstem, the cerebellum and the thalamus, among other structures. The basal ganglia consist of the corpus striatum and its associated nuclei, the caudate and lenticular nuclei. The latter is divided into the putamen and the globus pallidus. The cerebellum has an integrating and controlling role over movements that arise in other parts of the motor system. It regulates the force, speed, range, timing and direction of movements throughout the body so that excesses are inhibited. The extrapyramidal system influences the pyramidal tract, the function of which is to regulate the muscle tone required for posture and for changing position. It is also involved in the automatic component of skilled voluntary movement. The specific function of each of these elements of the extrapyramidal system with respect to phonation is unknown but phonation may be influenced adversely by neurological conditions involving these structures.[9]

The extrinsic and intrinsic muscles of the larynx are under voluntary cortical control. They are responsible for the pre-phonatory tuning that precedes phonation and is followed by the phasic, tonic and volitional contractions and also maintenance of length, tension, bulk and position of the vocal folds.[10] The phonatory modulations that take place in speech, however, happen with a precision and speed that suggests a finely coordinated system of reflex controls over the laryngeal muscles themselves, and over the abdominal and intercostal muscles that maintain subglottic air pressure at appropriate levels.[11]

It seems that such fine tuning cannot be cortically regulated.[12] Stimulation of all categories of laryngeal mechanoreceptors initiates activity in the larynx, which presumably ensures that the vocal folds are stabilized and return to their pre-set pattern following displacement by the expiratory air-stream. This process, by monitoring the tonicity and position of the vocal folds, enables necessary adjustments to be made instantaneously and accurately. Although it would seem inevitable that there must ultimately be integration of this feedback system with other control systems during phonation, Wyke[12] and Kirchner[11] stated that this process is independent of auditory feedback.

LARYNGEAL INNERVATION

The vagus nerve (CN X) provides all the innervation to the intrinsic laryngeal muscles and the sensory structures of the larynx. It also supplies the pharynx, palate, trachea, bronchi, lungs, heart, external ear and parts of the gastrointestinal tract. Some of the fibres of the vagus originate in the medulla in the nucleus ambiguus while others originate at a higher level. Cells from the rostral pole of the nucleus ambiguus contain motor neurons for the glossopharyngeal nerve (CN IX), the middle part for the vagus nerve and those from the caudal pole for the accessory nerve (CN XI). The nerve fibres originating in the cranial nerve nuclei form the lower motor neurone pathway. The right and left vagus nerves, which they form, provide ipsilateral innervation to the larynx. The neural 'commands' that travel down to the cranial nerve nuclei are largely responsible for what is ultimately transmitted to the laryngeal muscles via the lower motor neurone pathways. These 'commands' are fashioned by complex interaction of, and constant remodelling by, many cortical, basal ganglia and brainstem influences.

Cranial nerves IX, X and XI are so intimately connected in the medulla that all the muscles supplied by them are frequently involved either equally or progressively in medullary lesions. For this reason, Walshe[13] grouped them together in pathological conditions affecting the nucleus ambiguus in what is termed the 'glossopharyngeal-accessorius complex'. Nuclear lesions of the vagus can be associated, therefore, with paralysis of the palate, tongue and larynx.

The vagus forms a flat cord from its many united filaments and leaves the skull through the jugular foramen, passing vertically down the neck within the carotid sheath. It branches to form the superior laryngeal nerve (SLN), the recurrent laryngeal nerve (RLN) and the pharyngeal nerve:

- The SLN branches off from the vagus at the ganglion nodosum (inferior ganglion), below the level of the jugular foramen, and subdivides into the internal and external SLNs. The internal branch of the SLN consists of both sensory and parasympathetic secreto-motor fibres, which supply glands within the tissue above the level of the vocal folds. This branch of the SLN in turn divides into three branches: (i) the superior branch runs to the lingual surface of the epiglottis and sends small fibres through the epiglottic foramina to the laryngeal surface; (ii) the middle branch runs through the aryepiglottic fold into the ventricular fold; and (iii) the inferior branch runs to the pyriform sinus (or pyriform fossa) and to the postcricoid region, forming various anastomoses with the RLN.[14] The density of nerve endings providing sensory innervation appears to be greatest at the laryngeal inlet as part of the protective mechanism for the respiratory system. The laryngeal surface of the epiglottis has the greatest sensory innervation, while the vocal folds have a lower density of sensory fibres.[15] The anterior vocal folds also have a lower density of sensory receptors than the posterior half. The external branch of the SLN provides the motor supply to the cricothyroid muscle.[14]
- The left and right RLNs provide the motor supply to all the intrinsic laryngeal muscles (see also Chapter 58, Anatomy of the larynx and tracheobronchial tree). The RLNs contain both adductor and abductor fibres.[15] They differ significantly with regard to their origin and pathway. The right RLN arises from the main trunk of the vagus in front of the subclavian artery and the left RLN arises from the vagus at the arch of the aorta round which it winds before ascending to the larynx. Because of its extensive course, the left recurrent nerve is more liable to injury than the right, and is especially vulnerable to pressure from aortic aneurysm and intrathoracic masses. It is also injured during thyroidectomy and thoracic surgery. Therefore, left vocal fold paralysis is far more common than right vocal fold paralysis. The RLNs on both sides ascend the groove between the trachea and oesophagus for a variable distance, before dividing into anterior and posterior branches and entering the larynx behind the cricothyroid articulation.

There is recent evidence that ventricular fold adduction appears to be a result of ventricularis muscle contraction that is mediated by the RLN.[16]

The RLN provides the sensory supply to the glottis and subglottis (see **Figures 59.1** and **59.2**).

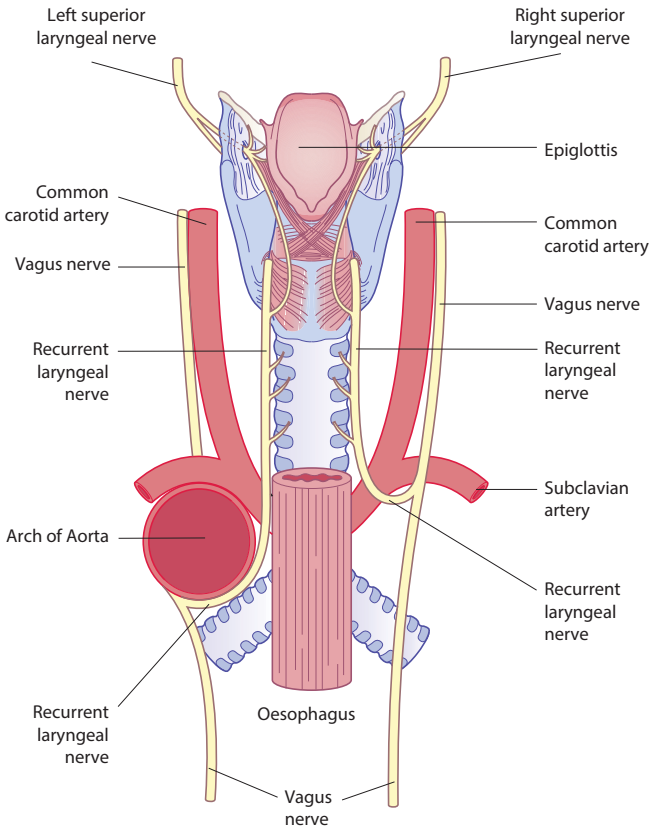

Figure 59.2 Posterior view of the larynx showing the distribution of the left and right laryngeal nerves. Redrawn with permission from Lesley Mathieson.

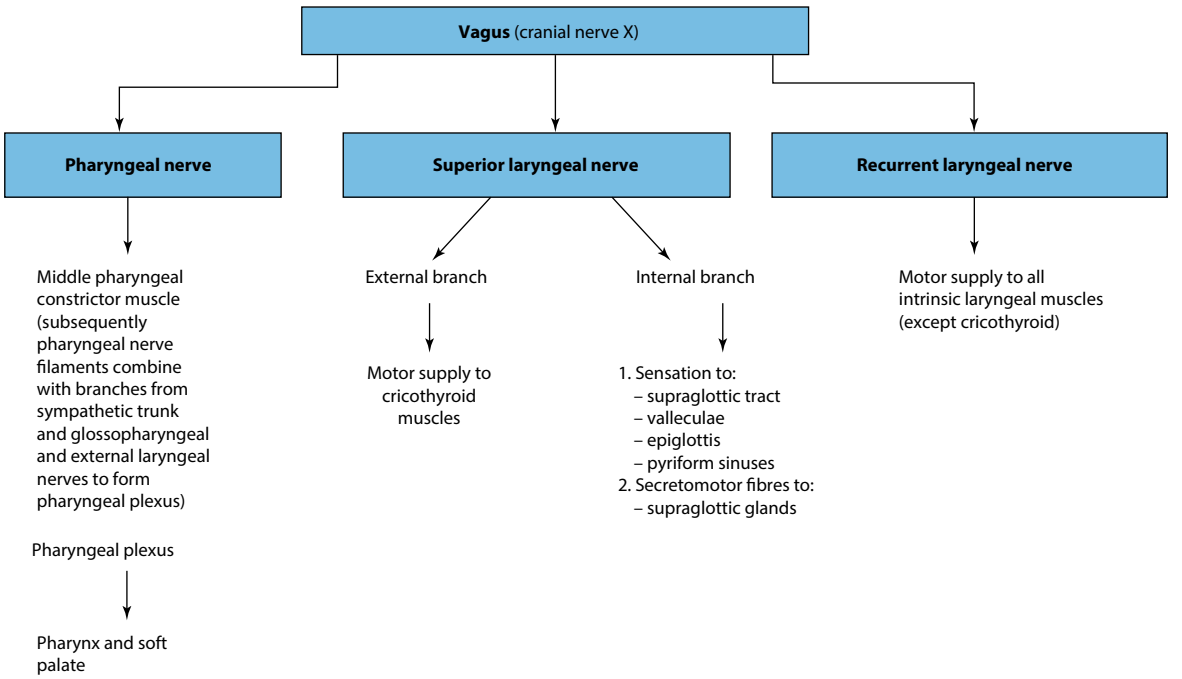

Figure 59.3 Diagrammatic representation of the laryngeal nerve supply. Redrawn with permission from Mathieson.

- The pharyngeal nerve descends between the internal and external carotid arteries to supply the middle pharyngeal constrictor muscle. Its fibres subsequently join with the glossopharyngeal and external laryngeal nerves, together with branches from the sympathetic trunk, to form the pharyngeal plexus. The pharynx and all the muscles of the soft palate, except the tensor palati, are supplied by fibres from the pharyngeal plexus.

Cranial nerves V (trigeminal), Vll (facial), Xll (hypoglossal) and cervical spinal nerves C1–C3 provide the motor supply for the extrinsic laryngeal muscles (see **Figure 59.3**).

Laryngeal mechanoreceptors

Free fibrils and terminal filaments enclosed in capsules constitute the receptor end organs (the mechanoreceptors) embedded in the laryngeal tissues at sites sensitive to muscle stretch and airflow pressures. Some are involved in protecting the airway while others contribute to the control of phonation.[17, 18] Reflex closure of the larynx is triggered by tactile receptors in the glottic and supraglottic mucosa, which evoke reflex contraction of the laryngeal muscles. Similar receptors in the subglottic mucosa elicit laryngeal closure and cough.[11]

Wyke[19, 20] postulated that mechanoreceptors are found in three sites:

1. **The mucosal lining of the larynx (mucosal mechanoreceptors).** The corpuscular nerve endings in the surface covering of the vocal folds are particularly numerous and sensitive to the stimuli of muscle stretch, air pressure level, liquid and touch.[5] They discharge impulses into the afferent fibres of the vagus.
2. **The capsules of the articulatory joints (articular mechanoreceptors).** The existence and function of this group remain controversial.
3. **The extrinsic and laryngeal muscles (myotatic mechanoreceptors).** The tone of the laryngeal muscles depends on the myotatic reflex, which is a function of the muscle spindles. The laryngeal muscles contain a large number of muscle spindles.[21]

FUNCTIONS OF THE LARYNX

Swallowing (deglutition)

During swallowing the primary function of the larynx is to prevent food and liquid entering the airway. This is achieved by means of the sphincteric action of the aryepiglottic folds, the true vocal folds and the ventricular folds, which occurs simultaneously with elevation of the larynx. Laryngeal elevation is also important in controlling pressures and the function of the cricopharyngeal sphincter, in order that the bolus can pass into the oesophagus.[22] The process of swallowing can be divided into the oral stage and the pharyngeal stage. The oral stage is under voluntary control and consists of the oral preparatory stage and the oral transport stage.[23] The food bolus is manipulated by the tongue and broken down before being propelled towards the oropharynx. The pharyngeal stage of swallowing is a reflex activity that is initiated as the bolus reaches the back of the tongue. During this process, the glottis is closed by adduction of the arytenoids and contraction of the lateral cricoarytenoid muscles, false vocal folds and true vocal folds. Vocal fold adduction during swallowing is thought to average approximately 2.3 seconds.[23] The airway is also protected by the epiglottis, which covers the laryngeal entrance and directs the bolus into the valleculae and the

pyriform sinuses. When the bolus arrives at the upper border of the cricopharyngeus muscle, the sphincter relaxes to allow the bolus to enter the oesphageus. An essential feature of normal deglutition is the rapid laryngeal elevation that occurs during the pharyngeal phase of the swallow. This manoeuvre results in the hyoid bone being displaced anteriorly, which further helps to protect the airway from aspiration and also serves to pull open the upper oesophageal sphincter. There is also a drop in pressure and transient negative pressure in the cricopharyngeal sphincter as the bolus passes from the pharynx into the oesophagus. If laryngeal elevation is impaired, then peri-swallow aspiration is more likely, cricopharyngeal opening is limited, the pressure drop during deglutition is slower and the fleeting negative pressure does not occur. A more detailed treatment of swallowing physiology is presented in Chapter 48, Physiology of swallowing.

Coughing

Coughing is the process by which material is expelled from the airway. The laryngeal adductor response is a protective reflex that prevents aspiration. It is preceded by rapid inspiration, followed by forceful closure of both the vocal folds and ventricular folds. Air pressure is then built up below the adducted folds as the diaphragm ascends spasmodically until the folds separate explosively and mucus or foreign material is expelled. This laryngeal motor response to sensory stimuli is not suppressed during volitional laryngeal tasks.[24]

Effort closure

Laryngeal structure has evolved in order to contain intrathoracic pressure, so as to provide a stable fulcrum for the upper limbs. Expiratory effort against a closed glottis is known as the Valsalva manoeuvre.[25] During any form of exertion involving use of the arms, the vocal folds are firmly adducted preventing expulsion of air and collapse of the chest walls, thus providing a fixed origin for the arm and shoulder muscles. This fact is clinically important in that those who have undergone laryngectomy or who have vocal fold paralysis may have difficulty with weight-bearing activities because of their inability to close the glottis effectively. Clinical experience also suggests that trauma to the vocal fold mucosa can occur or be aggravated by forceful, prolonged vocal fold adduction during some types of physical training, such as lifting weights.

Effort closure of the larynx also occurs during childbirth and defaecation as the abdominal contents are compressed by the abdominal muscles in order to achieve expulsion.

The biomechanics of phonation

The vocal folds are composed of laryngeal connective tissues with complex matrix composition and organization that provides the viscoelastic mechanical properties required for producing voice.[26] When the larynx is at rest and respiration is quiet, the vocal folds abduct on inspiration and slightly adduct on expiration. They move up and down slightly in sympathy with the outflow and inflow of respiratory air, while the larynx descends on inspiration and ascends on expiration.[27] The folds are drawn wide apart to a position of full abduction in forceful inspiration. Subglottic and supraglottic influences must be taken into account when analyzing vocal fold dynamics.[28]

INITIATION OF VOICE

Immediately before phonation, the vocal folds rapidly abduct to allow the intake of air. Wyke[20] termed this the 'pre-phonatory inspiratory phase'. Subsequently, the vocal folds are adducted by the contraction of the lateral cricoarytenoid muscles. The vocal note is generated by pulmonary air as it is exhaled between the adducted vocal folds. The vocal folds working together constitute a vibrator, which is activated by the excitor, the exhaled air. The production of the vocal note at this point is the result of the repeated vibratory movement of the vocal folds, known as vocal fold oscillation. The mobility and deformability of the vocal folds determines the ease with which vocal fold vibration can be initiated.[29] Subglottic air pressure increases below the adducted vocal folds until it reaches a level that overcomes their resistance and blows them apart, thus setting in motion the vibratory cycles which result in phonation. The vocal folds, in common with all vibrators, have a degree of inertia, which has to be overcome in order for phonation to occur. The amount of air pressure required to begin voicing is known as the 'phonation threshold pressure'.[30] The size and tension of the vocal folds in combination with the viscoelastic properties of the vocal fold cover will affect the phonation threshold pressure.[29]

THE VIBRATORY CYCLE

Each vibratory cycle of the vocal folds consists of three phases: adduction, aerodynamic separation and recoil (**Figure 59.4**). As the increased subglottic air pressure overcomes the resistance of the adducted vocal folds at the onset of phonation, the vocal folds peel apart from their inferior border. When they finally separate at their superior margin, a puff of air is released. The resulting negative pressure in the glottis caused by the Bernoulli effect results in the vocal folds closing rapidly as they are sucked together, the inferior vocal fold margins closing first. The Bernouilli effect is a drop in pressure dependent on particle velocity. In relation to the vocal tract, Maran[31] described it as follows: 'When air passes from one large space to another (e.g. from lung to pharynx), through a constriction (the glottis), the velocity will be greatest and the pressure least at the site of the constriction.' As a result of the drop in pressure at the glottis, the vocal fold mucosa is drawn into the space between the vocal folds.

Contact between the vocal folds increases until the subglottic air pressure is high enough to blow the vocal folds apart again, and the cycle recommences. Each cycle of adduction, separation and recoil is the manifestation of a mucosal wave travelling from the inferior to the superior surface of each vocal fold. The process by which this undulating wave of movement of the mucous membrane

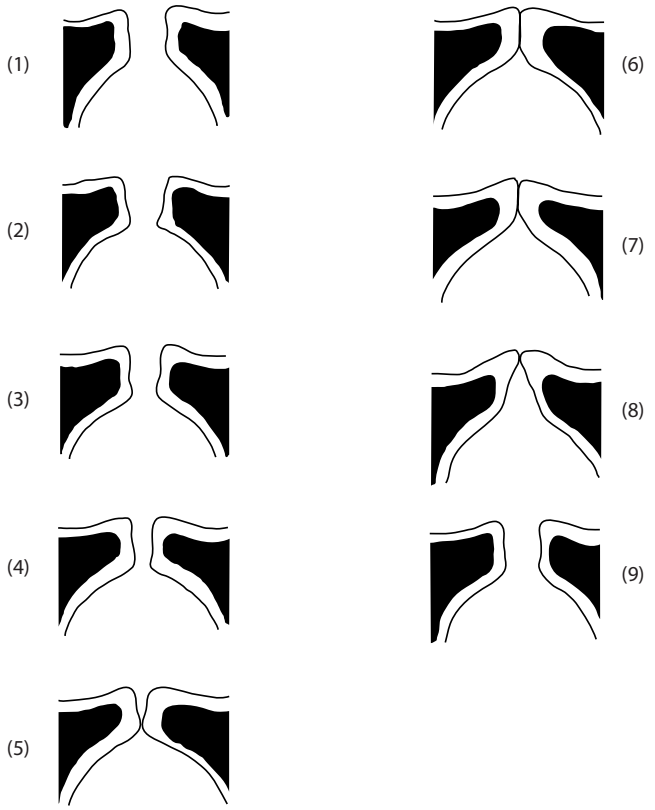

Figure 59.4 Vocal fold vibratory cycle. Redrawn with permission from Mathieson.

occurs is dependent on what is known as the cover/body theory. That is, the vocalis muscle provides the firm body of the vocal fold over which the mucous membrane cover of the vocal fold is blown by the expiratory air stream. These undulations of the vocal folds' thin cover, and any abnormalities of the mucosal wave, can only be observed using laryngostroboscopy or high-speed photography.[32]

The periods of vocal fold contact and lack of contact in one vibratory cycle can be divided broadly into closed and open phases, respectively, with associated closing and opening phases.[33] The closing phase of the vocal folds is more rapid than the opening phase. The phases of the vibratory cycle can be classified, therefore, into four stages as shown in **Box 59.1**.

The vocal folds have to be structurally and functionally symmetrical, at the same level, and close rapidly in order that a clear vocal note can be initiated and maintained.[34] Insufficient approximation of the vocal folds (glottal insufficiency) results in air wastage and production of a breathy voice quality. When the vocal folds fail to approximate completely along their membranous portion, with a slightly increased aperture in the cartilaginous section, turbulent air escapes and is audible in the voice.

BOX 59.1 The periods of vocal fold contact and lack of contact in one vibratory cycle

Closing phase: The vocal folds begin to close rapidly from their lower margin

Closed phase: The medial edges of the vocal folds are in full contact

Opening phase: The vocal folds begin to separate from their lower margin and gradually peel apart. The superior margin remains in contact until the end of this phase.

Open phase: The vocal folds are separated. (The longest part of a normal vibratory cycle.)

Reproduced with permission from Mathieson.

In production of notes of middle pitch, the interarytenoid muscles adduct the cartilaginous portion of both vocal folds and hold them together while the anterior portion of each fold is gently adducted but free to vibrate in the expiratory airflow. Although full vocal fold adduction during phonation has traditionally been regarded as the norm, clinical observation and various studies have refuted this view by showing that normal phonation can occur when there is incomplete glottal closure.[35, 36] This pattern of vocal fold adduction is more common in women than in men. In all speakers, incomplete glottal closure can be considered normal in high frequency modal voice and in falsetto (see **Figure 59.5**), when hourglass or spindle glottal configurations can occur in normal subjects.[37] It also appears that different types of glottal configurations are associated with different age groups. Incomplete closure of the posterior part of the vocal folds (posterior glottal chink) is a common finding in young and middle aged women, but elderly women are more likely to exhibit anterior chinks.[35, 38] High-speed digital imaging has revealed that glottal configuration and phase closure for children with normal voices are distinctly different from those of adults. It has been suggested that posterior glottal gap and a predominantly open phase of the glottal cycle should be considered as normal glottal configuration in children during modal pitch and loudness.[39] It is essential, therefore, that clinicians dealing with vocal pathology recognise that incomplete vocal fold closure may be a normal glottal configuration during phonation in certain subjects and at certain frequencies. Similarly, asymmetries within the larynx should be viewed with caution as they are not necessarily indicative of pathology. For example, a lack of strong differences in the prevalence of arytenoid asymmetries in the adducted position have been found in speakers with and without voice disorders.[40]

Age-related changes to the vocal tract can give rise to vocal instabilities in non-pathological voices. Changes in pitch and breath rate in older individuals indicate a fundamental change in the body's maintenance of the speech mechanism.[41] Reductions in pulmonary elastic recoil and respiratory muscle strength can affect the way in which older adults generate subglottal air pressure required for speech production. They have been shown, for example, to have very different lung volume adjustments for loud speech, compared to young adults.[42]

VOCAL REGISTERS: CHARACTERISTICS OF VOCAL FOLD ADDUCTION AND VIBRATION

Significant variations in vocal fold vibratory characteristics and adduction can also be observed according to

the vocal register that is being used. The subject of vocal registers is confusing and controversial. This is partly because the definition of what constitutes a register has been unclear but also because a number of terms are used to describe each register. Traditionally, registers have been regarded as the perceptually distinct regions of vocal quality over certain ranges of pitch and loudness[32] but listener identification of the change from one register to another is not reliable.[43] The terms used vary according to whether they are being employed by singers or speech scientists, but even then their use is not uniform. Singers tend to classify the registers as head, middle and chest but these terms are regarded as unsatisfactory by voice scientists, many of whom refer to three main vocal registers: falsetto, modal and vocal fry. These classifications, however, do not relate directly to each other. Baken and Orlikoff[44] noted that the problems of definition and terminology had been clarified by Hollien's suggestion[45] that registers should be defined in terms of laryngeal behaviour, rather than in acoustic terms, as registers are governed by the degree of contraction of the vocalis muscle. As a result, the terms loft, modal and pulse registers can be used with less confusion; they describe the vibratory pattern of the vocal folds and the acoustic parameters being produced (see **Table 59.1**):[46]

- **Loft register (or falsetto)** covers the highest frequencies of the voice. The vocal folds are lengthened, extremely tense and thinned so that there is minimal vibration. The knife-thin free edges are almost adducted and subglottic air pressure is high. During the production of these high frequencies, the larynx is raised by the suprahyoid muscles and the pharynx is shortened.[47]
- **Modal register** encompasses the range of frequencies usually employed in speech and singing. The membranous portions of the vocal folds are adducted and make complete closure in the closed phase of each vibratory cycle. In cross-section, the vocal folds are triangular in shape. In low notes the intrinsic muscles relax, the folds increase in bulk and their opposing surfaces deepen from 3 mm to 5 mm. They vibrate slowly along their whole length, the lower surfaces of their 'lips' making contact and separating as the upper surfaces approximate in a rolling motion or figure of eight. In lowest notes the infrahyoid muscles pull the larynx down.[48]
- **Pulse register (or glottal fry or vocal fry or creaky voice)** occurs during the lowest vocal frequencies and is a feature of normal speech.[49] This terminology reflects the pulsatile nature of the laryngeal sound generated. There is a long closed phased in each vibratory cycle.

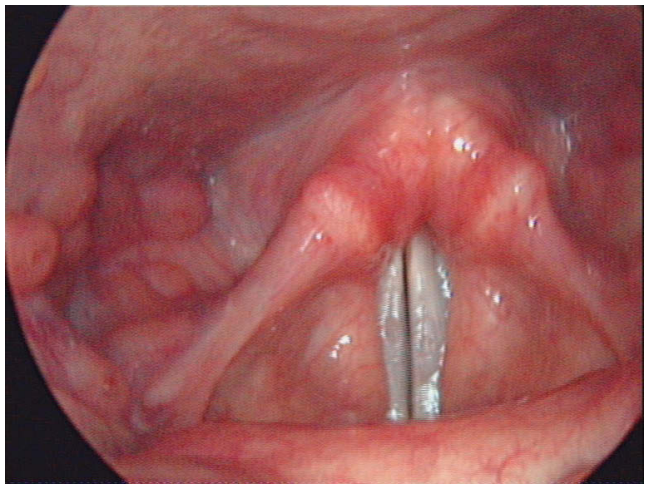

Figure 59.5 Normal falsetto phonation.

The terminology and underlying modes of vocal fold behaviour during the production of each register are outlined in **Table 59.1.**

Appreciation of the normal patterns of vocal fold movement and the way in which laryngeal adjustments affect the sound of the voice is essential to evaluating laryngeal findings in cases of disordered voice. Considerable variations of structure and function can be found even in the normal larynx and there are probably even more permutations of laryngeal behaviour. A comprehensive range of vocal tasks throughout the patient's pitch range during laryngoscopic examination is essential, therefore, if inappropriate conclusions regarding laryngeal pathology are to be avoided.

TABLE 59.1 Vocal registers

	Register may include	Equivalent terms	Vocal folds	F0 range (Hz)
Loft register	Highest vocal frequencies	Falsetto	Thin, tense, lengthened. Minimal vibration	275–1100
Modal register	Range of fundamental frequencies most commonly used in speaking and singing	Chest, head, middle, heavy voice	Complete adduction	100–300
Pulse register	Lowest range of vocal frequencies: laryngeal output is perceived as pulsatile	Vocal fry, glottal fry, creaky voice	Long closed phase	20–60

The terminology related to vocal registers is not consistent. Various overlapping terms are used that have different theoretical bases.

FUTURE RESEARCH

- Detailed innervation of the laryngeal structure.
- The processes of regulation of the linguistic demands of intonation and emotional nuances in vocal quality.
- The cerebral systems controlling phonation.
- Studies of normal variations of the vocal tract during phonation.

KEY POINTS

- The prime function of the larynx is to protect the airway. It also acts as a valve controlling airflow and air pressure and as a vibrator for generating sound (voice).
- The vagus nerve (CN X) provides all the innervation to the intrinsic laryngeal muscles and to the sensory structures of the larynx.
- Phonation involves highly specialized coordination of laryngeal and respiratory neuromuscular control.
- The quality of the glottal source sound is dependent on the structure and function, particularly the efficiency of approximation, of the vocal folds.
- An understanding of normal and age-related differences of glottal configurations is essential in order to avoid pathologizing normal laryngeal structure and function.

SEARCH STRATEGY

Data in this chapter can be explored more extensively by undertaking a Medline search using the following keywords: speech, voice, articulation, larynx, phonatory biomechanics, vocal fold vibration, vocal registers, intonation, phonetics and paralinguistic features.

INTRODUCTION

This chapter outlines how humans produce speech and voice. The characteristics of the glottal source (vocal fold vibration) are described. How the sound is modified within the oral tract is then addressed in detail. This is followed by a brief explanation of the fundamental principles of speech and articulation. Finally, the importance of the paralinguistic features of voice and speech are described.

The vibration of the vocal folds ('phonation') constitutes the raw glottal sound source. However, the voice we hear is far more complex than the acoustic signal generated by the vibrating larynx. This fundamental vibratory sound is modified and resonated by the rest of the vocal tract to produce a recognizable human voice quality. Hence, analysis of voice quality (perceptual or instrumental) must recognize the role of the whole vocal tract in the production of the sound that finally radiates from the mouth. Furthermore, the articulatory structures of the vocal tract (lips, tongue and soft palate) shape the sound source in an infinite number of combinations to make speech. This co-ordination of phonatory and articulatory behaviours represents arguably the most advanced sensorimotor system to be found in the human body.[1] Speech and voice require precise co-ordination of reflexive and learned behaviours resulting in intricate muscle movements executed with accuracy and speed. The flexibility of the vocal tract and the anatomical variations between people allows for an enormous range of normal voice and speech qualities and an inevitable overlap between 'normal' and 'abnormal' parameters. This has implications for how we assess and measure components of speech and voice for diagnostic and outcome evaluation purposes.[2] The main features of human voice and speech production are described in more detail below.

The specific characteristics of an individual's speech and voice are the product of the organic and phonetic features of the speaker.[3] Organic factors are derived from the nature of the speaker's individual anatomical apparatus; the dimensions and geometry of the nasal and oral structures, pharynx, larynx and respiratory system. Phonetic features refer to the speaker's habitual muscular adjustments of the speaking apparatus in terms of long term muscle 'settings' (for example, larynx position or tongue body position). The specific anatomical configuration of the vocal tract is unique to each individual and produces a voice and speech quality that distinguishes one speaker from another. These phonetic muscular habitual settings are learned (often unconscious) behaviours that fulfil the speaker's social, geographical, cultural and personal needs.

CHARACTERISTICS OF THE SOUND SOURCE/GLOTTAL SIGNAL

Voice quality

The quality of the vocal sound source is wholly dependent upon the vibratory characteristics of the laryngeal structures.[4] More specifically, it is dependent upon the

nature of vocal fold adduction during phonation and the regularity of the mucosal waves of the lamina propria (see Chapter 59, Physiology of the larynx). However, regular ('periodic') vocal fold behaviour also requires a stable airflow to generate vibration of the laryngeal structures.

- Incomplete adduction of the vocal folds during phonation will commonly result in audible air leakage and a 'breathy' voice quality. Whisper occurs when there is insufficient vocal fold adduction to achieve vibration but sufficient adduction to produce audible turbulent air. It is also associated with an increase in infra-glottic airflow.
- An irregular mucosal waveform vibration will result in an aperiodic sound that will be perceived as 'hoarse'. There are many possible causes of irregular laryngeal vibration, including inflammation, focal lesions and muscle imbalance.
- A pressed or strained voice quality occurs when the vocal folds are strongly adducted (often with supraglottic muscular involvement) and there is raised subglottal air pressure.
- It is quite possible for several aspects of suboptimal vibration to co-occur and hence produce a complex voice quality of more than one aberrant feature.

In a hypothetically perfectly functioning larynx, adduction of the vocal folds would be complete during the closed phase of phonation and abduction would be smooth and quick (in order to start the closing phase of the next vibratory cycle). Furthermore, each vibration of the mucosal waveform would be identical to the previous one and the sound signal produced would be perfectly periodic (a sine wave). The sound thus produced would contain only a fundamental frequency and its harmonics. However, all human voices are a combination of periodic and aperiodic sound. Aperiodic sound or 'noise' is a sound that is not a harmonic of the glottal signal. The main sources of 'noise' in the larynx are air escape and irregular vibration.[2] The more severe the noise component of the sound (in relation to the periodic component), the more 'hoarse' the voice will sound.[2, 5] It is possible to measure the degree of 'hoarseness' in a voice by calculating the ratio of periodic sound compared to aperiodic sound. This is usually termed a 'harmonics-to-noise ratio' (HNR).[5] It is important to note that the acoustic HNR measurement provides some indication of the degree of hoarseness but no information as to the source of the noise component.[4] HNR measurement has become a popular measure of dysphonic severity and of change in voice quality during treatment.[2]

Voice frequency

The frequency of the glottal signal is a result of the number of vibratory cycles per second (measured in hertz). The rate of vibration of the vocal folds is a function of the vocal fold length, elasticity, tension and mass, and their subsequent resistance to subglottal air pressure.[4] The maintenance of a steady vocal frequency requires control of all of these interacting physiological features. Frequency increases with a lengthening of the vocal folds and the subsequent thinning and stiffening of the vocalis muscles.[6] The perceptual correlate of frequency is pitch although the relationship between the two is a complex one. The frequency, intensity and spectral properties of a sound interact in very complex ways to lead to a given pitch perception.[5] Considerable normative data of habitual speaking pitch or mean speaking fundamental frequency (MSFo) exists.[5] However, there is a huge range of what is considered 'normal' depending on the age, sex, emotional state, communicative intent, mood and personality of the speaker. Similarly there are data on vocal pitch range both in terms of maximum range and habitual speaking range.[5] It is generally accepted that there are three pitch registers: loft (or falsetto) register; modal (or middle) register; and pulse (or chest) register (see Chapter 59, Physiology of the larynx). These registers basically distinguish between different vibratory patterns of the vocal folds determined by the degree of contraction of the vocalis muscles.[7] Short-term (cycle-to-cycle) variance in the frequency of vocal fold vibration is called 'jitter' or pitch perturbation. In a speaker who is trying to maintain a stable pitch, a measurement of jitter may indicate instability in the phonatory mechanism and may be a further useful index of dysphonia.[2, 5]

Voice amplitude

Vocal loudness is the perceptual correlate of amplitude – the size of the oscillation of the vocal folds. The amplitude of these vibrations is largely determined by the force of the transglottal airflow. Increasing both the airflow through the larynx and vocal fold resistance (and subsequent subglottal pressure) will result in an increase in vocal loudness. Like vocal frequency there are data on normal vocal intensity (habitual and range) in a variety of settings.[5] Short-term variance in the intensity of the vocal signal is called 'shimmer' or amplitude perturbation. An inability to maintain stable amplitude when intended may indicate important characteristics of the dysphonic speaker.[2, 5]

MODIFYING THE GLOTTAL SIGNAL

The sound source produced by the vibrating vocal folds is modified by the rest of the vocal tract to produce the voice quality that radiates from the speaker's mouth to the listener's ear. In a normal voice, the glottal signal is essentially periodic and composed of a fundamental frequency and its harmonics. This complex acoustic signal is then filtered by the supralaryngeal tract with some anatomical structures resonating different harmonics of the source signal more than others. Changes in the shape of the whole vocal tract (and the dimensions of the oral, nasal, pharyngeal and laryngeal cavities relative to each other) can be achieved in numerous ways. For example, protruding the lips, retracting the tongue base, lowering the larynx or lowering the soft palate will all dramatically alter the sound of the resultant voice even when performed in isolation. The fact that the voice is more than its vibratory

source is a fundamental principle of auditory evaluation of voice quality.[2, 8] It is important to note that some voice quality rating scales concentrate on laryngeal vibratory features only (i.e. the grade, roughness, breathiness, asthenia, strain (GRBAS) scale) whilst others take into account distinguishing perceptual features of the whole vocal tract (i.e. the Vocal Profile Analysis Scheme).[8] The modification of the sound source by the supraglottic vocal tract also represents the main problem in the instrumental measurement of voice quality. For this reason most methods of acoustic analysis prefer to analyze 'steady-state' prolonged vowels where the speaker is attempting to maintain steady pitch and intensity and where the variance in supralaryngeal tract configurations is kept to a minimum.[2, 5]

VOCAL RESONANCE

As explained above, the supralaryngeal tract acts as a resonating chamber for the complex acoustic signal generated by the vibrating vocal folds. The specific geometry and dimensions of an individual speaker's vocal tract will determine the 'timbre' or resonating properties of the voice. Skilled speakers and singers learn to manipulate these oral, nasal and pharyngeal structures to maximize their resonant properties. This is not easy to do since vocal resonance changes continually as we speak (i.e. changing vocal pitch or intensity, articulating different consonants or vowels). Oral resonance is affected by the degree of jaw movement, mouth opening, tongue body raising and pharyngeal constriction. Nasal resonance is affected by excessive or limited action of the velopharyngeal sphincter during speech, or by some degree of nasal obstruction. For a majority of normal speech the velopharyngeal sphincter is closed; the diaphragm of the velum reflects most of the sound into the oral cavity. However, some speech sounds require significant resonation into the nasal cavity (i.e. m, n and ng sounds). The final result is a voice with an appropriate oral/nasal balance. Appropriate oral/nasal resonance is not only necessary for normal sounding speech and voice but is also important to facilitate good voice projection (by enhancing the fundamental frequency and its harmonics).[9]

Velopharyngeal incompetence or significant lowering of the soft palate will result in a hypernasal speech quality. In more extreme cases, audible nasal air escape can be heard during speech. There is evidence to suggest that listeners tend to associate negative personal attributes to individuals with hypernasal speech.[10] Structural abnormalities such as a cleft palate or submucosal cleft often result in marked hypernasality. Conversely, an inability to produce appropriate nasal resonance (especially for sounds m, n and ng) will result in hyponasal speech quality. This is, of course, most likely to occur in space-occupying conditions of the nasopharynx. Removal of the space-occupying lesion or tissue may result in hypernasality although this is likely to be temporary in most cases. A significant but poorly investigated possible complication of the uvulopalatopharyngoplasty (UPP) surgical procedure is the resultant hypernasal speech.[11]

FUNDAMENTALS OF SPEECH/ ARTICULATION

Orchestrated movements of the organs of articulation change the vocal sound into recognizable speech. This process is often called the 'source-filter' model of voice production.[12] These articulatory movements can be classified as vowels or consonants (although the actual distinction between the two is theoretically complex). In simple terms, vowels are sounds in which there is no obstruction to the flow of air as it passes from the larynx to the lips. Consonants require a more definite obstruction by one or more of the articulators in the oral tract. This distinction becomes less useful for sounds such as 'w' or 'y', which we call consonants but are in reality articulated like vowels. For this reason these sounds are commonly called 'semi-vowels'.[13, 14]

All vowel sounds are continuants (i.e. they have length of varying periods of time). For practical purposes it is sufficient to differentiate between short vowels (i.e. p**i**t) and long vowels (i.e. p**ar**t). In a diphthong, two vowel sounds are combined (i.e. f**ire**). Vowel articulations are made by varying the resonating shape of the oral and pharyngeal cavities.

Changing the shape of the vocal tract subsequently changes its resonating behaviour; different shapes responding to different components of the harmonic structure of the glottal sound source. The resonance peaks of the vocal tract are called formants. These formant structures vary for each vowel and are easily identifiable on a sound spectrograph.[5] It is possible to distinguish between vowels by changing (i) the height of the tongue raising in the mouth, (ii) the part of the tongue which is raised (front, centre, back) and (iii) the position of the lips (spread or rounded). For example, the vowel /i:/ as in '**see**' is made with the front of the tongue raised and with lips spread. In contrast, the vowel /u:/ as in '**sue**' is made with back tongue raising and rounded lips. Diphthongs (i.e. '**beer**', '**air**') start with one oral tract articulatory shaping and glide to another.

Speech consonants are defined by their much clearer articulation (and often obstruction of the airflow) within the oral tract. Distinction between consonants can be made using three main elements: the place of articulation (i.e. lips, alveolar); the manner of articulation (i.e. plosive, fricative); and the state of the larynx (voiced or voiceless). All of these elements require further explanation.

The place of articulation

Consonants are clearly articulated at different places within the oral tract. Bi-labial consonants refer to articulation between the upper and lower lips (p, b, m, w). Labio-dental consonants require top teeth and lower lip articulation (f, v). Dental articulation refers to tongue tip and top teeth occlusion (th). Alveolar consonants are made by the tongue tip touching the ridge behind the teeth (t, d, n, s, z, r, ch, dj). Articulation of the middle tongue with the hard palate produces 'y'. Velar consonants require back of tongue and soft palate articulation (k, g, ng). See **Table 60.1** for a complete list of standard English consonants.

TABLE 60.1 Standard English consonants

	Bi-labial	Labio-dental	Dental	Alveolar	Palatal	Velar	Glottal
Plosive	p **b**			t **d**		k **g**	
Fricative		f **v**	Th[i] **th**[ii]	s **z** sh **jz**[iii]			
Affricate				ch **dj**[iv]			
Nasal	**M**			**n**		**ng**[v]	
Approximant	**W**			**l r**	**Y**		**H**

Bold signifies voiced; [i] as in 'th ink'; [ii] as in 'th at'; [iii] as in 'mea s ure'; [iv] as in 'j aw'; [v] as in 'si ng'.

The manner of articulation

The manner of consonant articulation refers to how the airflow is obstructed in the oral tract. Traditionally these are split into five categories: plosives, fricatives, affricates, nasals and approximants.

English has six plosive consonants: /p, b, t, d, k, g/. These plosives have different places of articulation (see previous section and **Table 60.1**). In all cases one articulator is moved against another in order to completely interrupt the airflow through the vocal tract. The air is temporarily compressed behind the point of articulation and then released with an audible noise called 'plosion'.

In contrast, fricatives are continuant consonants (they can continue for a relatively long time). The main characteristic of fricatives is the air turbulent sound that is made by air 'hissing' through the close (but not complete) approximation of two articulators. Like plosives, fricatives have different places of articulation (see **Table 60.1**). Examples of English fricatives include f, z, and s.

Affricates are a combination of plosion and fricative articulation. A common example is the affricate consonant heard at the beginning and end of the word 'church'. It begins with the plosive t and then the tongue moves to the position for the fricative sh. The plosive is followed immediately by the fricative noise but is heard as one consonant sound. There are only two affricate sounds in English (ch and dj, as in the beginning and ending sounds in 'church' and 'judge'), and both are articulated with the tongue tip and alveolar.

The basic characteristic of the nasal consonants (m, n, ng) is that air escapes through the nose. The air is prevented from passing through the mouth by obstructive lip or tongue articulation and the soft palate is lowered to allow nasal air escape. The soft palate is raised for all other standard consonants and vowels. Inadequate velopharyngeal competence will result in inappropriate 'nasalization' of non-nasal consonants and vowels. Permanent obstruction in the nasopharynx and lower nasal passages will result in 'denasalization' of nasal consonants.

Approximant consonants occur when the articulators are not sufficiently close to produce 'complete' consonants such as plosives, fricatives or nasals. Again, place of articulation can vary (see **Table 60.1**). These consonants are articulated similarly to vowels and are therefore often called semi-vowels. English examples of approximants include w and y. The lateral approximant 'l' varies slightly since the passage of air escapes along the sides of the tongue.

The state of the larynx

Finally, consonants can be either 'voiced' or 'voiceless'. A number of consonants can be 'paired', where the only difference between them is whether their articulation is accompanied by voicing or not (i.e. p and b, t and d, k and g, s and z). The place and manner for both members of each pair is the same. The only difference is that the first in each pair is 'voiceless' – there is no vibration of the vocal folds for the split second that these consonants are being articulated. The voiceless consonant 'h' does not have a voiced twin in standard English. This means that in connected speech, vocalization is not continuous. Phonation is switched on and off (for milliseconds of time) to signal voiceless consonants. This extremely subtle phonatory timing is crucial for intelligible speech and is a characteristic problem of some dysphonic voices. In **Table 60.1** the voiced consonants are signalled by **bold** type.

PHONEMES, ALLOPHONES, PHONOLOGY AND LANGUAGE VARIANCE

Phonetics is the study of speech sounds and how the rules of language organize and change sounds in different contexts.[13, 14] The consonant and vowel articulation described in the previous section is theoretically accurate but, in reality, can be modified and varied on an almost infinite level. Any speech sound (or phoneme) may be articulated slightly differently according to the other sounds around it. These variations of the same phoneme are called 'allophones'. For example, the sound 't' in the words 'tea' and 'tree' are, in fact, articulated with a slightly different tongue position. This is one reason why simulated (computerized) speech does not sound natural. In more extreme cases, speech sounds may change altogether depending on their phonetic environment or even be omitted altogether. For example, consider how 'handbag' is regularly pronounced 'ha**m**bag' and 'nightmare' is pronounced 'nigh'mare'.

Phonology is the sound patterns of a particular language. The way children develop the phonology of the language is well understood[15] and the differentiation between development phonological deviance as opposed to phonological delay is an important clinical consideration.[15] Clearly, different languages have different phonological sets and therefore will include some consonants and vowels that may not feature in English speaking at all.

PARALINGUISTIC FEATURES OF VOICE AND SPEECH

Speech and voice are more than just the products of muscular movements. For example, they represent an immensely powerful (and efficient) means of conveying mood, personality and intent. Our speech and voice also provides messages about our education, social status, emotional state and personality. All of these things are interpreted from the way the speaker uses features such as speech rhythm, speech rate, vocal intonation, vocal tone or quality and voice loudness. 'Everything is said in a certain way, in a certain tone of voice and at certain loudness.'[4] However, it is rare for a speaker to be using these features consciously (unless the speaker is an actor). The unconscious use of these paralinguistic features may be more revealing than the speaker anticipated and more enlightening than the language content of what is being spoken. It is partly for these reasons that voice or speech impairment may result in severe levels of personal handicap, disability and distress.[16, 17]

Speech rhythm is learned as an integral part of early childhood speech, voice, language and communication development. Early babbling is a 'working vocal guidance system … in which the ear monitors vocal tract activity and informs speech-motor control systems about targets and adjustments needed for mimicry of ambient speech'.[18] Speech rhythm is language- and even accent-specific. Speech rhythm (and stress) is one of the most difficult linguistic features for foreign speakers to master and will distinguish them from truly bilingual speakers who were exposed to several speech rhythm patterns from birth.[19] To complicate the matter further, regional accents often demand different speech rhythms again. For example, it may be possible to identify locals from Newcastle simply by how they stress the syllables in the word 'Newcastle'. Locals will stress the second syllable (New**castle**) whereas most other speakers will naturally stress the first syllable (**New**castle). Finally, loss of rhythm and incorrect stress may render speech almost unintelligible even when articulation and voice production are normal.[4]

Speech rate is often interpreted as an indicator of anxiety (if it is too fast) or low intellect (if it is too slow).[20] Our speech rate is also likely to reflect our state of arousal (excited, drowsy, stressed etc.) and is clearly linked to other physiological systems such as pulse and respiratory rate.

Vocal intonation refers to the use of varying vocal pitch to indicate various grammatical, psychosocial and semantic features. We use intonation to indicate communicative intent (e.g. to characterize a question or to indicate certainty in a statement) and to manipulate conversation (e.g. to encourage a response). Patterns of intonation are often used unconsciously by the speaker and are, of course, open to misinterpretation by the listener. Similarly, the pitch range used by a speaker may reflect emotional status. A wide frequency range indicates arousal in contrast to a narrow ('flatter') range, which may be interpreted as sadness or impassiveness.[21] Habitually low pitch may indicate depression and high pitch may suggest anxiety.[22] A clear understanding of the components of phonatory behaviour (e.g. laryngeal muscle tone, pulmonary airflow, subglottal pressure, supralaryngeal tension) provides a physiological explanation for these paralinguistic features of voice.

The emotional content of a verbal message is also likely to be reflected in changes in vocal tone or quality.[23, 24] These result from changes in laryngeal and supralaryngeal tension, which in turn affect vocal features. For example, a breathy vocal quality may indicate anxiety[25] or vulnerability[26] and may be interpreted as revealing lower social class, especially when associated with harshness.[27] Conversely, vocal creak (low pitched, irregular vocal fold vibrations) may indicate a relaxed state and has been shown, at least in one study, to correlate with higher social status.[27] Vocal loudness appears to be different between the sexes even when the context and linguistic content are similar: men talk more loudly than women.[27] Not surprisingly, we commonly associate vocal loudness with confidence and extrovert personality but inappropriate loudness may indicate insensitivity and poor pragmatic skills.[28] Clearly, the interpretation of a speaker's vocal quality and volume are, like all other paralinguistic features, subjective and may subsequently result in misunderstandings.

Almost all paralinguistic aspects of speech and voice are intuitively known but not consciously learned (or manipulated). They contribute as much to our individual speech and voice characteristics as our specific anatomical configurations and habitual vocal settings. These paralinguistic features of speech and voice remain a crucial aspect of speech and voice production and help to explain why many people with a speech and voice disorder report severe personal, social and economic consequences.

FUTURE RESEARCH

- Cultural differences in speech and voice and the importance of these differences on non-organic voice pathology.
- The impact on voice and speech disorders on tonal languages.
- Closer mapping of acoustic and physiological measurement to the auditory features of speech and voice.
- Development of a reliable and practical auditory perceptual rating scale for supraglottic features of voice quality.
- The application of the analysis of paralinguistic features of speech and voice in psychiatric and psychological differential diagnosis.

KEY POINTS

- The voice is the product of vibrating vocal folds and sound resonance throughout the vocal tract.
- The specific characteristics of an individual's speech and voice are the product of the organic and phonetic features of the speaker.
- The quality of the glottal sound is wholly dependent upon the vibratory characteristics of the laryngeal structures.
- Orchestrated movements of the organs of articulation modify the vocal sound into recognizable speech.
- Paralinguistic features of voice and speech include speech rhythm, stress, accent and vocal intonation.

SEARCH STRATEGY

Data in this chapter are based on Medline, PubMed, hand searches and the Cochrane review database using the keywords: larynx, clinical examination, adult, paediatric, laryngoscopy, endoscopes, optical imaging and difficult airway.

INTRODUCTION

The purpose of the chapter is to review the techniques available for accurate and safe examination and assessment of the upper respiratory tract. The otolaryngologist must have a systematic method to process symptoms and signs in order to achieve the correct diagnosis.

ASSESSMENT IN THE CLINIC

Evaluation of the patient begins as soon as he/she enters the clinic room. Preliminary assessment of their respiratory status can be made during history taking. The patient with respiratory distress may be unable to speak a few words before needing to rest, whereas a healthy individual will converse without difficulty. Voice quality can also be subjectively monitored at this time. Persistent or progressive dysphonia may suggest an organic lesion in the larynx compared to intermittent dysphonia that may suggest a functional disorder.

It is not routine practice in the otolaryngology clinic to undress a patient in order to examine the respiratory system, but this should be done if the clinical history suggests chest disease, such as suspected metastasis or severe chronic obstructive airway disease (COAD) limiting fitness for surgery, that might influence the decision-making for the ENT condition.

Clinical signs and symptoms of upper respiratory impairment include:

- dyspnoea
- tachyponea
- stridor
- dysphonia
- cyanosis
- use of accessory muscles of respiration.

The examiner should be aware of general systemic signs of disease that are relevant to the respiratory tract, such as nicotine staining to the hands, clubbing, anaemia, jaundice and spider naevi.

Nasal airway

The upper airway begins with the nasal cavity and therefore the nasal airway should always be assessed. Although it is covered in Chapter 88, Outpatient assessment, a summary is provided here. Nasal airflow and patency should be subjectively assessed through each of the nares using the palmar surface of the thumb or a shiny Lack tongue depressor. Anterior rhinoscopy should be supplemented with endoscopic examination of the nose in order to inspect the posterior nasal cavity.

Laryngoscopy

Indirect laryngoscopy examination with a mirror, a technique with an illustrious history,[1] is still used as a method of visualizing the larynx. This examination method has several limitations including perceptual errors,[2] difficulties in the user reliably recording the side of lesion, the learning curve in acquiring and maintaining the skillset,[3] and a significant failure rate which, prior to the era

of readily available flexible endoscopy, often mandated direct endoscopy under general anaesthesia.

Significant advantages include widespread availability in all ENT departments, low cost to buy and maintain and a learning curve that is not insurmountable. Regular practice on all suitable patients in the early years (an anatomical model to facilitate this process has been described)[3] and continued later use can often maintain the skillset for this technique. A few studies exist on minor laryngeal procedures that can be carried out with indirect techniques successfully,[4–6] including obtaining photographic images as the sole operator. It is a procedure free of complications except for gagging and failure to visualize the lesion,[7, 8] which occurs more frequently than with flexible or direct laryngoscopy. Failure of indirect laryngoscopy suggests that microlaryngoscopy may be difficult.[9] Magnifying laryngeal and nasopharyngeal mirrors have been described.[10]

Endoscopic assessment, either with a rigid or flexible laryngoscope, has supplanted mirrors due to better optical resolution and higher sensitivity.[11, 12] Endoscopes in the ENT clinic should now be considered the standard of care.

The rigid Hopkins rod system uses 70- or 90-degree angled lenses and allows an excellent view of the larynx through a transoral approach. This is the favoured technique for laryngologists in the 'voice clinic' as the wider rigid rod lens produces a much higher optical resolution for more detailed assessment of phonation.[13] Laryngoscopy can be supplemented with stroboscopy, laryngography or digital acoustic voice analysis (see Chapter 62, Evaluation of the voice).

TECHNIQUE FOR FLEXIBLE LARYNGOSCOPY

The endoscope is passed through the anterior nares, along the floor of the nose under the inferior turbinate. Passage between the middle and inferior turbinate or through the opposite nostril may be necessary if the airway is narrowed. Once the endoscope is in the postnasal space, the patient is asked to inspire through the nose, and this opens the postnasal sphincter allowing passage of the endoscope into the oropharynx (**Figure 61.1**).

A stepwise assessment of the larynx is made: the vallecula is inspected (by tongue protrusion), the supraglottic larynx, followed by the glottic larynx. Attention should be taken to record accurately the correct side of any lesion identified as errors are common.[14] Newer extended applications of this technique include flexible endoscopic evaluation of swallowing, with or without sensory testing,[15] videoendoscopy of the hypopharynx and cervical oesophagus,[16, 17] including biopsy and foreign body removal through a biopsy channel, paediatric adenoid assessment[18] and neonatal upper airway assessment.[19]

Topical anaesthesia

Topical nasal administration of local anaesthetic is often used prior to flexible laryngoscopy in the clinic

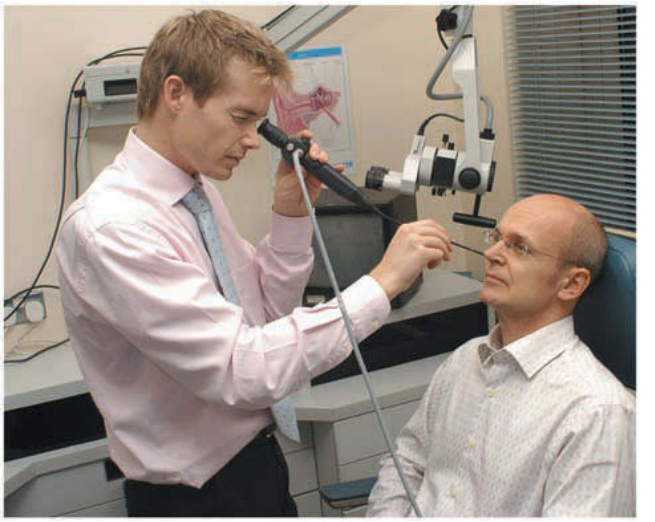

Figure 61.1 Flexible laryngoscopy in the clinic.

in order to decongest the nose and facilitate examination.[20] Cocaine was traditionally used in the past either as aerosol (10%) or as paste (4%). However, concerns regarding cardiotoxicity and drug misuse, as well as contamination from the delivery system for cocaine, have resulted in newer derivatives such as cophenylcaine or amethocaine being used.[21] Some authors have questioned the necessity of using any anaesthetic for this procedure.[22, 23] Eight randomized studies[21–28] have been published, of which four are double-blind randomized trials,[23, 24, 26, 28] but all have some methodological flaws. Unfortunately, two of the double-blind studies[24, 26] draw inappropriate conclusions from their data. A more recent systematic review of the few randomized control trials on this subject found no reduction in pain scores with the use of vasoconstrictive, topical anaesthetic or lubricating agents.[29] Further well-designed, sufficiently powered, double-blind studies incorporating all options are warranted. Overall, current evidence suggests that the benefits of local anaesthesia cannot be large in these circumstances.

Consent and complications

Informed consent prior to any surgical procedure is a fundamental aspect of clinical practice, to prevent patient-doctor complaints and medical malpractice claims. It has been suggested that all interventions, including laryngoscopy, require a consent form to be completed. Thus far, it is not routine clinical practice to obtain written consent before performing flexible laryngoscopy in the clinic. Currently, there is no literature on this subject.

No robust literature on complications of flexible nasoendoscopy exists, but these include discomfort of variable degree and occasional epistaxis during difficult insertion, excessive gagging in the absence of local anaesthesia, coughing, transient laryngospasm, gluteraldehyde allergy and infection due to laryngoscope contamination. Paediatric, including neonatal, flexible awake nasoendoscopy are now accepted procedures,

but, particularly in the latter group, the procedure may be associated with episodes of significant oxygen desaturation, laryngospasm, bronchospasm and coughing.[30] Some patients may experience psychogenic pain and other symptoms which may last for prolonged periods. The increased prevalence of MRSA, hepatitis B and C and HIV has resulted in more rigorous infection control systems to be implemented for all invasive procedures.

Decontamination principles

Sterilization practices used to vary considerably throughout the UK.[31] Most large hospitals have opted for a central decontamination unit to handle the sterilization of endoscopes in order to maintain optimum anti-infective standards, while some units use a chemical soak system, but the type of disinfectant, method of delivery and duration of soak used vary widely. A few hospitals use disposable sheath systems and some still only wipe endoscopes with alcohol wipes between patients. Protocols for high-risk patients demonstrated a parallel lack of uniformity. A similar divergence in practice has been recorded in South Africa[32] and other parts of the world.[33]

UK national guidelines for the cleaning of nasoendoscopes have now been produced.[34, 35, 36] The main points to come out of these guidelines are summarized below.[34, 37] The risk of transmitting infection between scope and patient has not been quantified for nasoendoscopes, but for gastroscopes it is 1 in 1.8 million. The risk of variant Creutzfeldt–Jacob disease transmission is probably extremely low provided scrupulous attention is paid to the detail of decontamination. The risk of transferring infection from the user to the scope is minimized by removal of all jewellery, including wristwatches, proper hand decontamination and the wearing of disposable gloves. Should an outbreak of infection occur, a logbook should be available which records patient details, time and date of use, name of user and person responsible for sterilization, and the method of sterilization. Details of the instrument used, including serial numbers, should be recorded in the patient's notes. Appropriate training programmes for all involved staff and an up-to-date list of authorized personnel and what each individual authorization covers should be available in each department. Policies need to cover these issues when the scopes are used in a variety of settings outside ENT departments. Even if a disposable sheath is the preferred mode of ensuring clean nasoendoscopy, daily high-level disinfection of the endoscopes is required.

Used endoscopes from locations distant to the site of decontamination should be transported to the place of decontamination in a labelled disposable bag in its case if possible. Decontamination involves both cleaning and high-level disinfection. Methods chosen need to be approved by manufacturers to uphold service contracts and warranties. Inspections of scopes should be visual and by formal leak testing.

Cleaning may be manual or mechanical but must remove all visible debris. It is no longer recommended to use gluteraldehyde for chemical high-level disinfection owing to its toxicity[38–40] and ability to fix proteins onto the endoscope surfaces, making their subsequent removal more difficult.[35] Suitable options for chemical disinfection include electrolyzed saline (Sterilox®); chlorine dioxide (Tristel®); peracetic acid (Steris®, Nucidex®, Perasafe®, Gigasept®). Peracetic acid is irritant to skin and the respiratory system.[34] Tristel is used by many ENT clinics in the UK.[34, 41]

There is no ideal disinfectant, with the choice of agent dependent on its microbicidal activity, toxicity profile and approval for use by the various endoscope manufacturers. Disposable sheaths are a safe and effective alternative to chemical decontamination and have been introduced in order to reduce the necessity of formal sterilization between examinations. These have been shown to be effective in acting as a barrier to infection, even by viral particles.[42] Sheaths currently available have an improved design that requires no special equipment for application and removal, which, if improperly used in the past, caused damage to the endoscope covering at the tips, making it costly or impossible to repair.[43] There is a risk of endoscopic contamination if the sheath is breached. No significant difference has been noted between sheathed and unsheathed endoscopes from the user and patient perspective, as well as in image quality.[44] This may well provide a much more cost-effective, user-friendly and safe solution to some forms of chemical disinfection.

Local or central automatic endoscope washer-disinfectors (AEWDs) are also gaining widespread use as they free up clinic support staff from the manual tasks involved in decontaminating endoscopes, as well as providing a standardized endoscope sterilization protocol which is very useful from a clinical governance perspective. The high set-up costs involved in acquiring AEWDs as well as the logistical challenge from the slow turnaround of endoscopes, especially if the central facility is at a distant site from the ENT clinic, are some of the disadvantages in opting for an AEWD system. Out-of-hours cleaning and disinfection of nasoendoscopes by junior medical staff is still a real problem, mainly due to lack of knowledge and access to the appropriate facilities, usually based in outpatient departments.[45]

Most ENT departments are implementing a flag system to record details of each laryngoscopy episode. Flexible endoscopes are expensive and relatively fragile instruments. They require careful handling, maintenance and cleaning; a designated health practitioner should be responsible for their care. Storage of endoscopes is best achieved with the scopes hung vertically in storage cupboards, or in custom-made storage/transport trays. This prevents repeated twisting and bending of the scope, which will result in breaking of the optical fibres, thus reducing the lifetime of the scope.

Considerations of consent, accurate documentation of findings and sterilization are important as they all have time and resource implications in the clinic.

KEY POINTS

- Indirect laryngoscopy is a technique with definite limitations, but its low cost, widespread availability and lack of associated complications should mean that it survives as part of the otolaryngologic skillset.
- Flexible endoscopy has rightly replaced the above as the first-choice tool for examination of the upper aerodigestive tract owing to its extended applications.
- The evidence for topical anaesthetic use, choice of agent and the extent of benefit is not clear-cut.
- There is no significant literature on consent issues.
- There is still debate as to the most cost-effective means of decontaminating flexible laryngoscopes. It is acceptable, however, to decontaminate endoscopes manually without a biopsy channel using chemical wipes such as chlorine dioxide, avoiding the high costs and logistical issues from the use of a central sterile services unit.[34,35]
- Gluteraldehyde is no longer recommended for use in the UK due to the high risk of sensitivity. Disposable sheaths are another alternative to minimize cross-contamination.
- Regardless of the decontamination protocol used, an adequate endoscope traceability system needs to be in place for clinical governance and risk-management purposes.

OPERATIVE LARYNGOSCOPY

Anaesthetic considerations for laryngoscopy in the operating theatre

Accurate assessment of the larynx under general anaesthetic requires a systematic approach involving cooperative work on the shared airway between the otolaryngologist and the anaesthetist. It is therefore important to develop a good working relationship with one's anaesthetic colleague and have a system that you are both happy to work with. When applied to appropriate patients, laryngoscopy, can be performed safely as a day-case procedure.[46]

There are several methods of performing laryngoscopy under general anaesthesia and there is a balance between maintaining a secure airway and obtaining a clear, unobstructed view of the larynx. A systematic review of each technique will be discussed, and the clinician must decide upon a technique that they find most satisfactory.

MICROLARYNGOSCOPY TUBE

The microlaryngoscopy tube is a small-diameter cuffed endotracheal tube (ET), which is placed in the posterior glottis. The diameter ranges from 16 to 22 French gauge. This type of tube has been shown to be safe for operative laryngeal microsurgery.[47] If transoral laser microsurgery is planned, specifically designed non-combustible non-reflective laser tubes are used. These have indicator dyes incorporated into the cuff to identify whether the cuff is damaged, in order to reduce the risk of an airway fire hazard.[48–50]

TOTAL INTRAVENOUS TUBELESS ANAESTHESIA

This technique involves anaesthesia maintained by continuous intravenous infusion of propofol with topical lignocaine and the patient breathing spontaneously. It has been described for both diagnostic and therapeutic laryngoscopy, including laser microsurgery. It is not recommended for high-risk patients (ASA III or IV) or patients with an obstructed airway. Total intravenous tubeless anaesthesia should only be undertaken by those who have expertise in this technique.[51–53]

HIGH-FREQUENCY JET VENTILATION

High-pressure jet (Venturi) ventilation of anaesthetic gases without an ET tube can be administered via the supraglottis, glottis or subglottis, or via the transtracheal/ cricothyroidotomy route. This technique has been widely used for endolaryngeal surgery, including laser surgery;[54] advantages include the absence of combustible material in the airway, thus providing a clear view of the larynx and deep anaesthesia to allow for microsurgery.[53] Large multicentre studies of 643 patients based in France and 872 patients in the USA have shown low complication rates using this technique. Problems such as pneumothorax were encountered in 1%, hypoventilation in 2% and surgical emphysema in 8% of cases.[55,56] The Venturi technique has also been described in paediatric practice.[57] Relative contraindications to using this technique would be the unstable or obstructed airway, difficult access to the larynx (micrognathia/overhanging teeth) or respiratory failure (with emphysematous bullae).[57,58]

RIGID LARYNGOSCOPY

The patient is prepared and anaesthetized as standard for the operating theatre. The position is supine, with head extension and neck flexed in order to open the laryngeal inlet. Eye cover, dental protection and antiseptic draping are applied.

The widest laryngoscope to maximize vision is passed perorally in the midline and the tongue is negotiated in order to visualize the epiglottis. Care must be taken to prevent dental trauma and trauma to the lips. The endoscope is used to elevate the epiglottis in order to visualize the larynx. Different telescopes can be utilized to inspect the subsites of the endolarynx (**Figure 61.2**), such as the anterior commissure scope, which is designed to

Figure 61.2 A selection of rigid endoscopes for laryngoscopy.

maximize the view of the anterior glottis. Suspension of the laryngoscope frees both hands to operate.

Rigid laryngoscopy offers improved visualization of the larynx through better illumination, higher magnification and wider and deeper fields of vision. By incorporating the microscope and combination of 0, 30 and 70 degree angled endoscopes, a full view of the endolarynx can be obtained (**Figure 61.3**). The angled endoscopes allow better perspectives of the ventricle, free edge and under surface of the vocal cord. It is important to define and record accurately the findings of the laryngoscopy. The site, extent, dimensions, shape, colour and surface characteristics of the lesion should be defined. Vocal cord mobility and airway patency should be recorded. The use of printed operative diagrams should be encouraged (**Figure 61.4**).

Photo documentation is becoming an important part of otolaryngology practice. It improves case review between clinicians and is increasingly forming part of routine practice in the current medicolegal climate. High-resolution digital imaging is now available to facilitate still, video and hard-copy documentation.

NEW TECHNIQUES IN LARYNGEAL ENDOSCOPY

Optical imaging techniques have evolved over the past two decades from our greater understanding of fluorophores, the fluorescent properties of intracellular and extracellular components, as well as advancing laser, optical filters, endoscope and computer software technology. As always, the challenge with new technology is defining how it can be incorporated into daily clinical practice, given the variation in requirements during assessment of the upper respiratory tract and the group of patients or clinical scenario: for example, general population versus those at high risk of neoplasia, determining precancerous versus malignant lesions, assessing tumour margins intraoperatively, or post-treatment surveillance following primary surgical treatment versus chemoradiation therapy. The gold standard against which these new technologies are compared is histopathological analysis and, while the sensitivity, specificity and accuracy of the techniques described below are still under investigation, none yet matches the gold standard.

Figure 61.3 Theatre set-up for rigid laryngoscopy under general anesthesia. Note the telescope and the two-handed technique to assess, document and obtain biopsy.

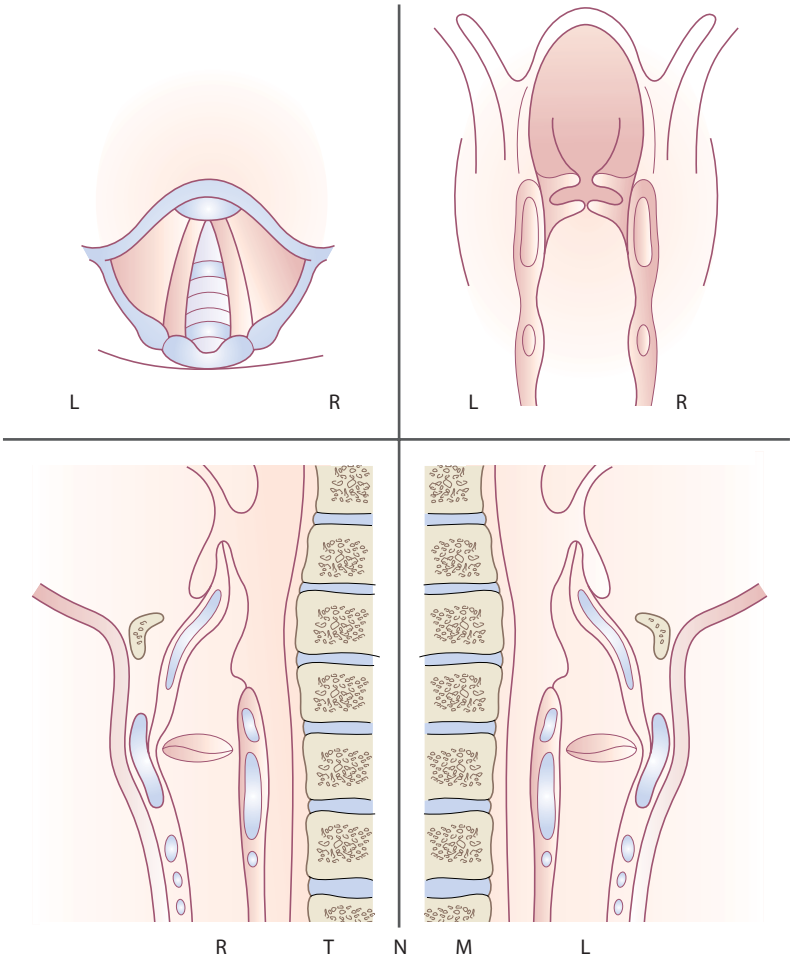

Figure 61.4 Printed operative diagrams used to record findings.

Contact endoscopy and microlaryngoscopy

This new technique allows for microscopic assessment of the epithelial cells of the larynx *in vivo* and *in situ*. The process involves staining the epithelium with methylene blue or Lugol's iodine. A modified Hopkins rod laryngoscope is applied against the mucosa of the larynx. At ×60 and ×150 magnification cytological characteristics of the cells, nuclei and cytoplasm can be appreciated in the first three layers of epithelial cells, in addition to the subepithelial microvascular network.[59] Premalignant conditions, such as dysplasia, could therefore potentially be detected earlier. It is designed not as a substitute for histology but as a research tool to allow better understanding of the cytological changes that occur in the laryngeal epithelium in the transition from normal to disease. Preliminary studies have shown good correlation between its findings and formal histology,[60,61] with sensitivity and specificity of 90% and 94% respectively, and an 88% agreement with histopathological findings after appropriate training.[62] The use of contact endoscopy in the larynx is confined to clinical research but does show promise for a wider application in the future.

The main advantage is that it is a non-invasive procedure, and avoids complications related to unnecessary tissue biopsy, especially in irradiated patients. The technique, however, is limited by the superficial depth of penetration, the inability to distinguish confidently between intraepithelial neoplasia and invasive carcinoma, the experience required to minimize trauma to delicate tissues with the endoscopes, and the impaired visualization of malignant cells in the presence of scarring, chronic inflammation or keratosis.

Autofluorescence

Various extracellular and intracellular structures such as collagen, elastin, mitochondria and porphyrins naturally emit light following absorption of light at a specific wavelength. This physical phenomenon is a property of fluorophores. Knowledge of the specific wavelength at which specific fluorophores are excited allows investigators to take advantage of particular intracellular or extracellular constituents that may be altered in the disease state and consequently stimulated using monochromatic light in the blue or ultraviolet range of the electromagnetic spectrum (wavelengths between 375 nm and 460 nm), in the form of a laser. Normal mucosa fluoresces green, while neoplastic mucosa has reduced autofluorescence and emits a red-violet colour (**Figure 61.5**).[63,64] Changes in autofluorescence can be detected by sophisticated endoscopes or observed as spectral changes using optical filters and specialized detectors.

When combined with microlaryngoscopy, autofluorescence may be better at identifying invasive carcinoma, with a reported sensitivity of 87–97% and specificity of 78–87%.[65–69] The limitations of autofluorescence are the difficulty in assessing the basal mucosal layer due to a restricted depth of penetration, and the low specificity, with false positives arising from granulation tissue, scarring and chronic inflammation. Further studies are required to determine the benefits of microlaryngoscopy and autofluorescence in increasing detection of discrete upper airway lesions, and in reducing the rate of positive margins following surgery, but there is a paucity of work using this tool, indicating that it may be on the wane.

Narrow-band imaging

White-light laryngoscopy is limited by the inability to detect very small epithelial changes and is also unable to differentiate between benign and malignant lesions *in vivo*. Narrow-band imaging (NBI) is a novel endoscopic technique which aims to overcome some of the limitations of white-light endoscopy by using filtered light to visualize mucosal and submucosal neoangiogenic microvascular patterns that have been characterized previously.[70, 71] Certain neoangiogenic features such as intraepithelial papillary capillary loops are associated with precancerous and malignant mucosal lesions (**Figures 61.6** and **61.7**).

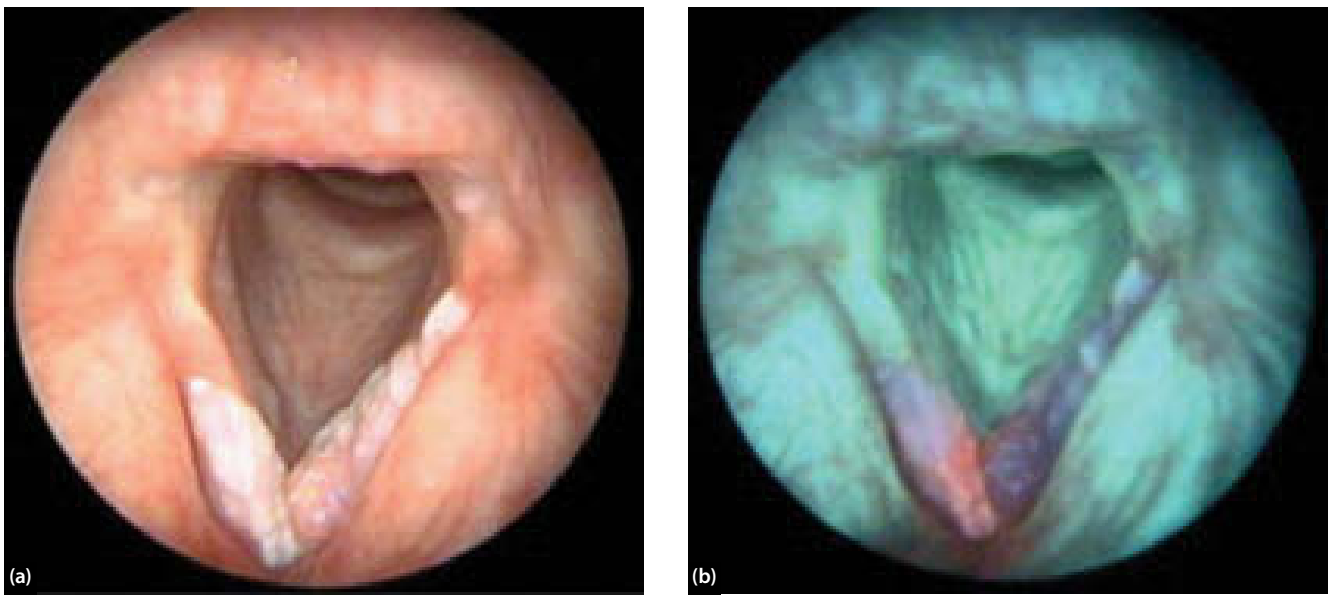

Figure 61.5 **(a)** White-light image shows an abnormal lesion on the right cord, suggestive of a neoplastic process. **(b)** Autofluorescence endoscopy shows loss of autofluorescence, giving an orange/red colour, typical for invasive malignancy. With Permission fom Springer Nature, from Arens C, Dreyr H, Glanz et al. Indirect audofluorescence laryngoscopy in the diagnosis of laryngeal cancer and its precursor lesions. *Euro Arch Otorhinolaryngol* 2004.

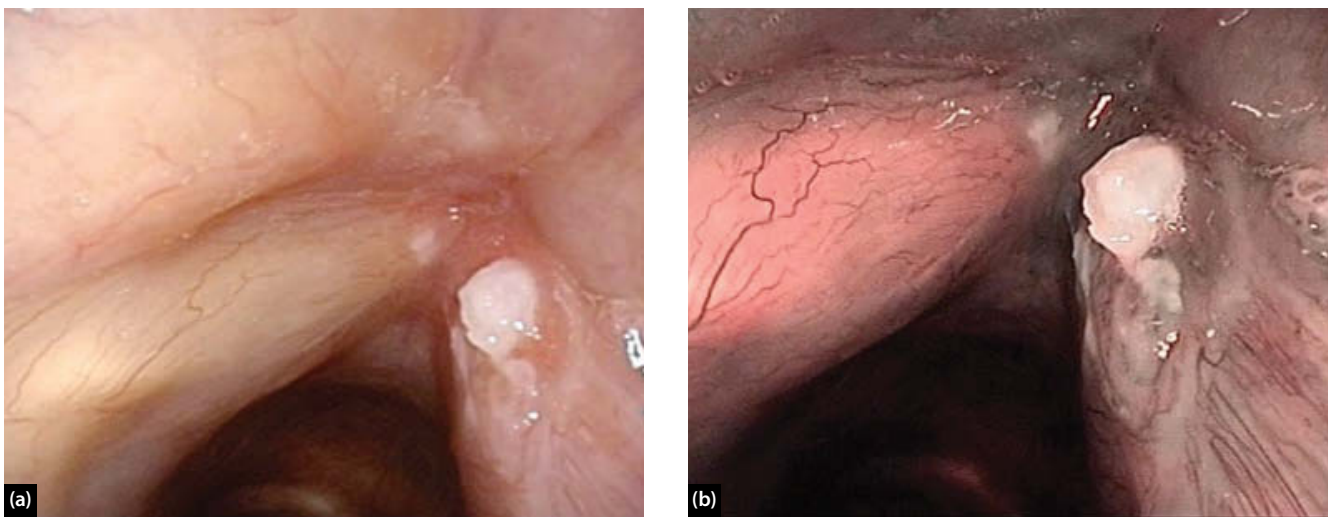

Figure 61.6 **(a)** White-light image shows an area of leukoplakia on the right glottis. **(b)** Narrow-band image shows a carcinoma *in situ*, with better definition of margins (inferior extension and satellite lesion extending in the ventricle). (Image courtesy of Professor Cesare Piazza, University of Brescia.)

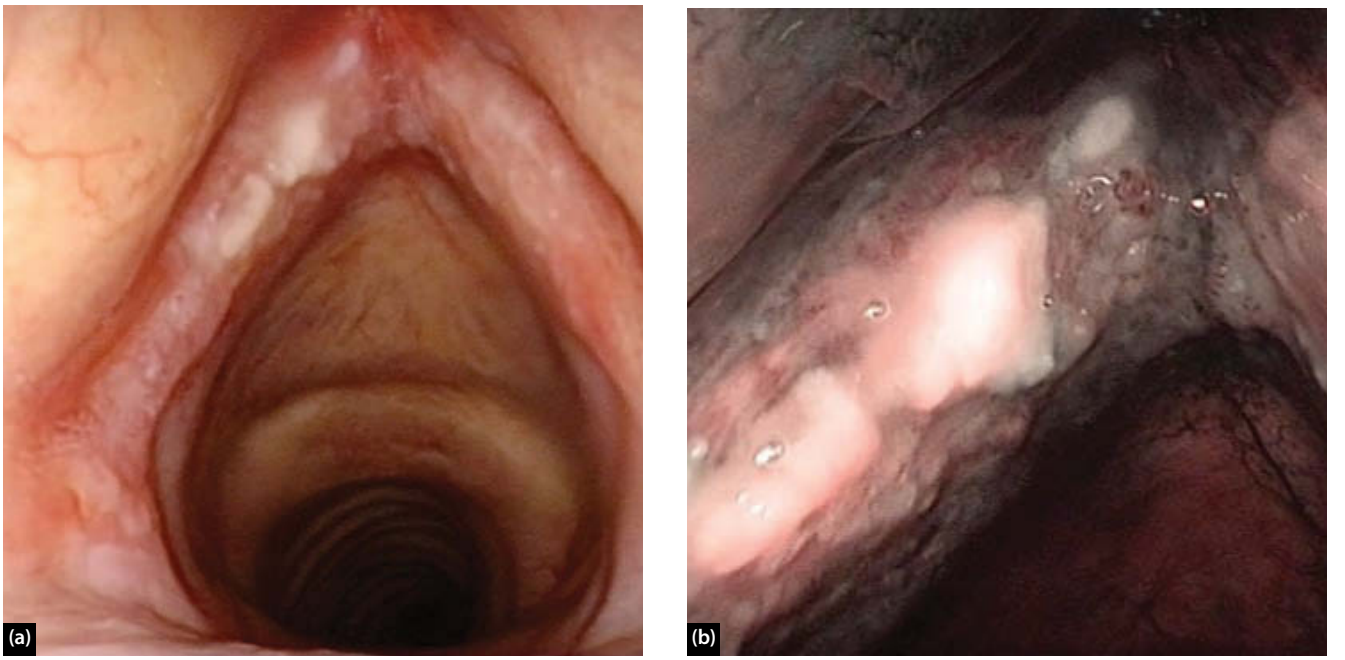

Figure 61.7 **(a)** White-light image shows an abnormal glottic lesion. **(b)** Narrow-band image shows findings typical of squamous cell cancer and also reveals extension to the contralateral cord. (Image courtesy of Professor Cesare Piazza, University of Brescia.)

NBI technology is based on knowledge that the depth of light penetration is a factor of its wavelength, and through the use of special filters, blue and green light are selected from white light, corresponding to the peak of absorption of haemoglobin. Narrow-band blue light (415 nm) highlights superficial capillary networks, while narrow-band green light (540 nm) displays subepithelial vessels and, in combination, the two wavelengths produce a very high-contrast image of the tissue surface, which is particularly evident when using a high-definition television (HDTV) camera.

NBI has been able to achieve sensitivity and specificity of 89% and 93% respectively in the diagnosis of primary laryngeal lesions,[70] and higher values have been achieved in the context of assessing lesions following radiation and chemoradiation therapy,[72] therefore reducing the requirement for a tissue biopsy in these cases.

NBI mode is a standard feature on some videoendoscopes, thus making the technique readily available. However, it is limited by the learning curve required to understand aberrant microvascular architecture and, as with other optical imaging techniques, the superficial depth of penetration precludes assessment of the deep extent of neoplasia.

Optical coherence tomography

Optical coherence tomography (OCT) is an analogue of ultrasound, using light instead of sound to produce a high (micrometre) resolution cross-sectional image, similar to a vertical histological section (**Figure 61.8**).[73] A beam of light is directed onto tissue and back-reflected from components with different optical properties. Because the velocity of propagated light is several magnitudes greater than sound, and the resultant echo time delay cannot be measured using conventional electronics, a specialized technique known as interferometry is required to measure echo time delay and the intensity of back-reflected light. Interferometry uses light that has travelled a known reference path length and time delay.[73]

A number of investigators have used endoscopic versions of OCT to analyze both healthy and diseased laryngeal mucosa. In combination with microlaryngoscopy, OCT has been shown to significantly increase the sensitivity of determining benign versus malignant lesions and the grade of precancerous lesions when compared to microlaryngoscopy alone.[74] Further studies are needed, however, to determine whether the optical biopsy derived from OCT can indeed replace an excisional tissue biopsy.

Fluorescence lifetime imaging

Fluorescence lifetime imaging (FLIM) is another non-contact optical method which has several advantages over contact endoscopy, providing complementary ultrastructural and spectral detail. FLIM is based on the principle that the fluorescence lifetime of a fluorophore depends on its molecular environment but not on its concentration. Molecular effects in a sample can therefore be investigated independently of the variable and usually unknown concentration of the fluorophore (**Figure 61.9**).

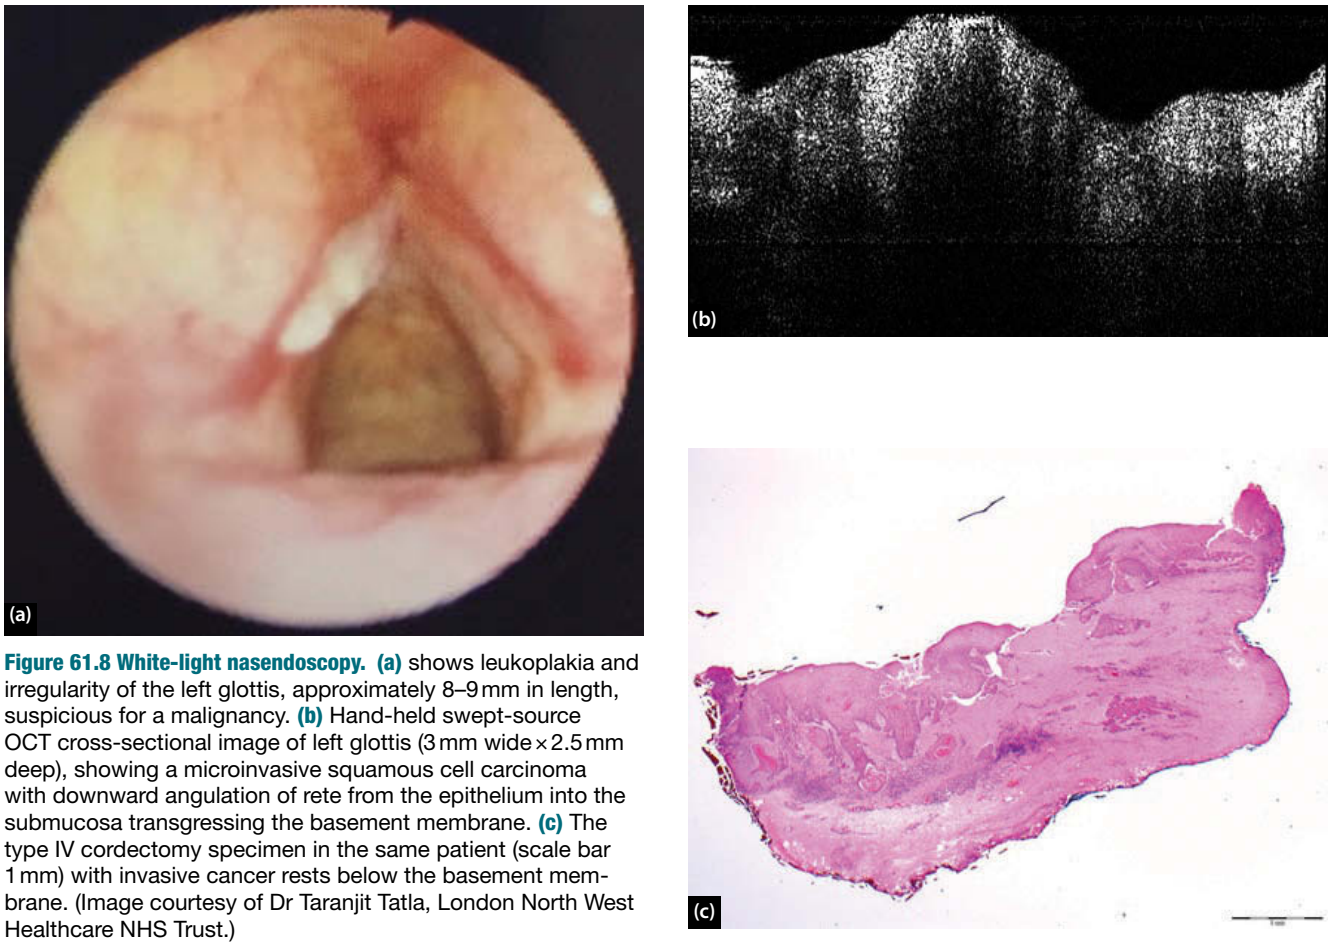

Figure 61.8 White-light nasendoscopy. (a) shows leukoplakia and irregularity of the left glottis, approximately 8–9 mm in length, suspicious for a malignancy. **(b)** Hand-held swept-source OCT cross-sectional image of left glottis (3 mm wide × 2.5 mm deep), showing a microinvasive squamous cell carcinoma with downward angulation of rete from the epithelium into the submucosa transgressing the basement membrane. **(c)** The type IV cordectomy specimen in the same patient (scale bar 1 mm) with invasive cancer rests below the basement membrane. Laryngeal ultrasonography

Ultrasound scanning is a well-established method of imaging in the head and neck. A new application of this technique in the larynx involves applying the ultrasound probe against the external surface of the larynx during microlaryngoscopy. This holds potential in providing information regarding invasion of deeper compartments of the larynx, such as paraglottic and pre-epiglottic spaces.[75] The usefulness of this technique in laryngology is still being evaluated.[76, 77]

Assessment and management of the obstructed or difficult airway

Those patients who present for endoscopic assessment with upper airway obstruction pose a complex problem for the otolaryngologist and anaesthetist. This short section will discuss the assessment of these patients and provide a management algorithm. A further discussion on detailed management of the obstructed airway can be seen in Chapter 72, Upper airway obstruction and tracheostomy.

PRE-OPERATIVE ASSESSMENT

Pre-operative assessment must be carried out in order that both surgeon and anaesthetist are prewarned of potential problems. Mild to moderate chronic airway obstruction may exist undetected, as these patients may have compensated over time compared to individuals who present with acute severe airway dysfunction. The presence or absence of stridor at rest or on exertion, lying flat, or when bending down, decreased exercise tolerance and nocturnal dyspnoea when lying supine are all indicative of a problem. An assessment of the patient's respiratory reserve is essential. Those patients with respiratory failure will tend to desaturate rapidly if there is prolonged or difficult intubation. A difficult airway can be anticipated in medical conditions such as rheumatoid arthritis, obstructive sleep apnoea, acromegaly and mucopolysaccharidosis, and in craniofacial syndromes, particularly Treacher Collins and Pierre Robin syndromes. Specific features include short neck, receding jaw, maximal mouth opening less than three fingerbreadths, inability of the lower jaw to protrude beyond the upper jaw (jaw slide) and a short thyromental distance less than three fingerbreadths indicating high larynx. The Mallampati score, which classifies visibility of oropharyngeal structures, is used to predict the ease of endotracheal intubation. The anaesthetist usually carefully assesses these specific features, but some appreciation of the potential problems by the surgeon is important. Prediction of potential airway difficulty is a complex business but can be rewarding when severe or obvious problems are identified. When there are no obvious problems, evaluation is imperfect and safe airway management depends on the adoption of a strategy that is able to respond to unexpected difficulty with intubation or oxygenation.

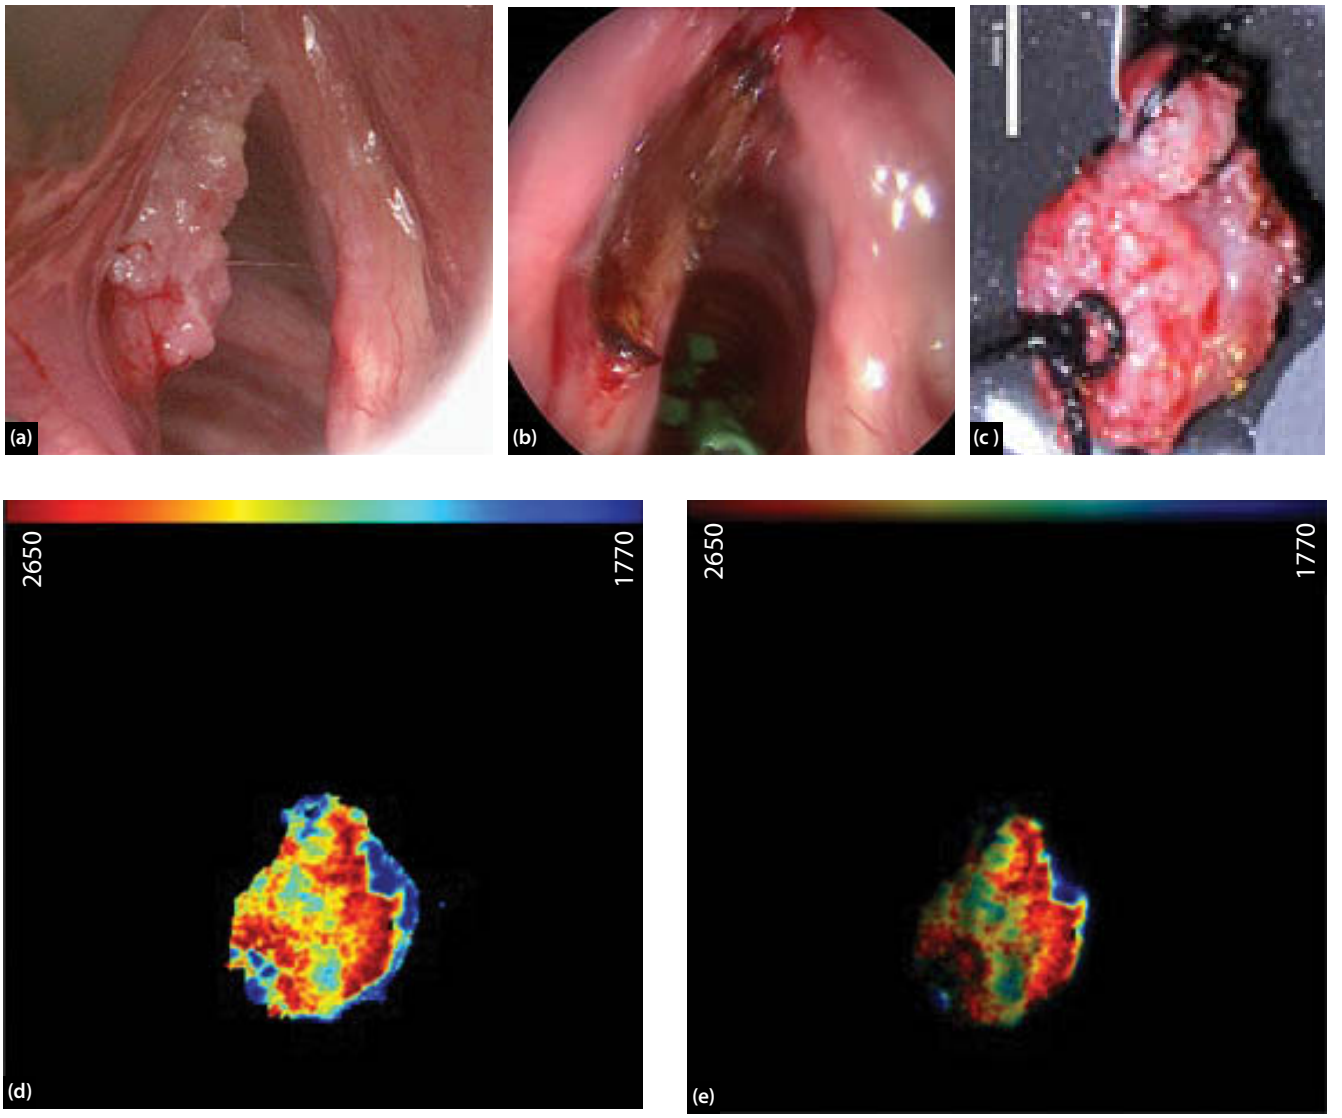

Figure 61.9 **(a)** White-light 00 rigid Hopkins rod endoscope view (high-definition TV) of glottis lesion with irregular surface outline, staged T1a. Previous biopsy has confirmed this to be a moderately differentiated squamous cell cancer in the left glottis in a background of carcinoma *in situ*. **(b)** CO_2 transoral microsurgical laser excision of left glottis lesion (type IV cordectomy). **(c)** Anteroposterior, medial-lateral orientation of resected glottis specimen with suture markers for pathology sectioning and reporting. **(d)** The fluorescence lifetime image map and **(e)** the specimen intensity-merged fluorescence lifetime image map. Reduced fluorescence lifetime (green) appears to correlate with the pathologist-reported extent of carcinoma *in situ* (cis extending to the lateral margin of the specimen). There appear to be islands of reduced lifetime amid islands of longer lifetime (yellow/orange/red) which would not be atypical for mucosal carcinoma *in situ* changes. Histopathology reported a 1 mm cancer, lying 1 mm from the lateral margin, 3 mm from the medial margin and 1.5 mm clear of the resected deep margin. (Image courtesy of Dr Taranjit Tatla, London North West Healthcare NHS Trust.)

Specific investigations other than careful flexible nasoendoscopy are rarely safe in acute airways obstruction but plain radiographs, CT/MRI and flow loops may well be indicated in chronic stable obstruction, particularly in suspected subglottic lesions. All patients undergoing panendoscopy for stridor should be counselled and consented regarding the possibility of a tracheostomy being performed.

OPERATIVE MANAGEMENT

Securing a safe airway is the primary aim of the procedure, followed by an accurate assessment of the cause, level and degree of airway obstruction and a biopsy if necessary. It should be remembered that tumours of the supraglottic larynx and tongue base are a particular problem. A moderate chronic airway obstruction may develop into complete obstruction with respiratory arrest when the patient lies supine with muscle relaxant administered. Tumours may be haemorrhagic and friable and this may make the intubation difficult.

The difficult intubation equipment should be ready for these patients, which includes a selection of rigid laryngoscopes and bronchoscopes, intubating bougies/guidewires, ETs and fibre-optic intubation equipment. The team should decide upon the following options for airway management:

- awake fibre-optic intubation
- induction anaesthesia and endotracheal intubation with/without guide wires or bougies, or by the surgeon using rigid endoscopes

- induction anaesthesia and jet ventilation (endolaryngeal or percutaneous)
- local anaesthetic tracheostomy.

The chosen airway strategy must have a plan A and plan B, for intubation, ventilation and extubation (see Chapter 72, Upper airway obstruction and tracheostomy).

The patient is asked to breathe 100% O_2. Looking at the bag will indicate the degree of airflow. Anaesthesia may be induced in the operating theatre; alternatively, the surgeon should be in the anaesthetic room with the rigid laryngoscope ready and tracheostomy set available for a surgical airway to be secured if necessary.

Failed intubation

If the anaesthetist is unable to identify the glottis and intubate, the patient should be maintained with the facemask and reoxygenated. The ENT surgeon should then attempt endotracheal intubation. The rigid bronchoscope is often quoted as a useful method of finding the glottis in difficult airway patients. The authors' preference is to use the anterior commissure endoscope to visualize the glottis. A rigid bougie can be passed through the scope into the trachea and a small ET tube passed over it.

In certain difficult cases with the airway obstructed by tumour, a retrograde intubation approach can be adopted. The rigid laryngoscope scope can be passed into the hypopharynx and then slowly withdrawn, with the tip angled anteriorly to see the glottis.[78, 79]

Tracheostomy under local anaesthetic is not an easy procedure in a patient with an acute airway obstruction. Consent for emergency tracheostomy should always be taken when planning any surgical procedure that may have an associated significant risk of airway obstruction. The patient is positioned in the supine position with sufficient neck extension to allow palpation of the trachea. In the conscious patient, constant reassurance is mandatory as the patient may be struggling and unable to lie still for a long period of time. Pressure on the larynx during dissection may worsen the patient's sense of obstruction. Local anaesthesia (20 mL of 1% lignocaine) should be injected if time or patient condition permits and is strongly advocated.

The operation is more difficult in small children and adults with adipose necks because of the difficulty in tracheal palpation. A vertical midline incision is made from the inferior aspect of the thyroid cartilage to the suprasternal notch and continued through the infrahyoid muscles and thyroid isthmus irrespective of bleeding, although an experienced assistant providing suction and retraction is most helpful.

After carefully palpating for the cricoid cartilage in order to avoid cutting it, a vertical incision is made in the trachea from the second to fourth ring, the knife rotated through 90 degrees and an appropriate tube rapidly inserted. Thereafter, haemostasis is obtained, and all blood suctioned out of the airway. Once the situation is under control, it may be appropriate to refashion the tracheostoma to prevent later complications. After securing the airway, general anaesthesia is induced and endoscopy proceeds. A detailed discussion of the compromised airways can be found in Chapter 72, Upper airway obstruction and tracheostomy.

BEST CLINICAL PRACTICE

- ✓ Examination of the upper aerodigestive tract should include:
  - ✓ flexible nasolaryngoscopy
  - ✓ microlaryngoscopy
  - ✓ Hopkins rods and telescopes
  - ✓ photo documentation.
- ✓ Careful clinical history taking and traditional examination techniques still yield useful results, particularly when technology fails.
- ✓ Flexible endoscopy is a widely used simple technique whose role is being extended to cover swallowing assessment, cervical oesophagoscopy, biopsy and foreign body removal, as well as paediatric and neonatal assessment.
- ✓ Current evidence suggests that local anaesthesia prior to flexible nasolaryngoscopy confers no significant advantages, but cost issues around cophenylcaine use are significant.
- ✓ Infection control issues around flexible endoscopy still require clarification but the newer sheaths may provide an alternative to chemical disinfection systems and their attendant risks.

KEY POINTS

- Close cooperation with anaesthetic colleagues in deciding how the airway will be shared is essential.
- The correct patient position for rigid laryngoscopy is supine, with the head extended and neck flexed to open the laryngeal inlet.
- Modern rigid and microlaryngeal endoscopy equipment has greatly improved visualization and tissue handling, but the principles of use remain essentially unchanged.
- A wide choice of rigid laryngoscopes is available. Usually the widest scope to maximize vision should be chosen with suspension allowing both hands free for the surgeon. Accurate recording on preprinted diagrams and/or photo documentation is ideal and the latter will increasingly become the norm. Visualization of difficult areas can be improved with the use of specialist rigid scopes and/or angled Hopkins rods.
- New techniques to assess the upper respiratory tract include contact endoscopy, autofluorescence, narrow-band imaging, optical coherence tomography and laryngeal ultrasound.
- The management of the obstructed airway will always remain among otolaryngology's greatest challenges but has been hugely facilitated by the much wider availability of awake fibre-optic intubation skills in most anaesthetic departments.

GENERAL CONSIDERATIONS IN VOICE EVALUATION

Definitions

Speech is the expression of or the ability to express thoughts and feelings by articulate sounds.[1] The term **voice** is often used to refer to speech as a whole. However, when used in the context of voice evaluation, it is generally restricted to the acoustic output resulting from the interaction of vocal fold vibration with the vocal tract in vowel production.[2, 3] **Phonation** is a term used to describe the physical and physiological processes of vocal fold vibration in the production of speech sounds.[3] Impaired voice production due to abnormal vocal fold vibration is known as **dysphonia,** while no voice or whispery voice associated with no vocal fold vibration is termed **aphonia.**[4] **Hoarseness** is a non-specific, general term used to describe any change in voice quality.[5]

Normal speech and voice production

Normal voice production requires three essential elements:

- a pressure gradient across the vocal folds created by the flow of expired air from the lungs against the partly close vocal folds
- vocal folds of appropriate structure, mass and elasticity that approximate with appropriate tension to allow them to vibrate at a range of frequencies
- a resonating chamber, the vocal tract, whose size and shape can be changed to modulate the acoustic properties of sound generated by the vocal folds.

Speech consists of both these 'voiced' sounds, where the vocal folds vibrate, and 'unvoiced' sounds, where the is no vibration. Examples of 'voiced' sounds include English vowels (e.g. /a/, /e/, /i/, /o/, /u/) and some consonants (e.g. /b/, /d/, /g/, /v/, /n/, /l/, /w/, /j/). Consonants are produced by the sudden release of air from other parts of the vocal tract (e.g. lips for /b/) or aperiodic turbulent airflow (noise) through constrictions of the vocal tract (e.g. between the lips and teeth for /v/). Pure 'unvoiced' consonant sounds include /p/, /t/, /k/, /f/, /th/, /s/, /h/ where there is no associated vocal fold vibration. Together they provide the framework on which spoken language is constructed.[6] For more information see Chapter 60, Voice and speech production.

In voice evaluation the main focus of interest has been on the acoustic output resulting from the interaction between vocal fold vibration and modulating effect on the sound by the vocal tract in the production of vowels. To understand the relevance of some of these measures it is important to summarize the essential features of the acoustic properties of voice. Vocal fold vibration, acting as the sound source, produces a laryngeal tone which is a complex sound wave that, if heard without the vocal tract, has a buzzing quality. The sound wave can be characterized acoustically in terms of fundamental frequency (Hertz or Hz), frequency spectrum amplitude and intensity (dB).[3] The rate of vibration of the vocal folds (cycles per second) determines the fundamental frequency (F_0). Normal vocal fold vibration, however, does not simply produce a pure tone (sine wave) like, for example, a tuning fork. It consists of a spectrum of frequencies which are multiples of this fundamental frequency. They are called harmonics or overtones and are of varying amounts of energy or sound intensity.[3] Sound intensity decreases by approximately

12 dB for every doubling of the fundamental frequency (harmonic).[3] This relationship between the harmonics and sound intensity can be displayed in the form of a spectrum (see 'Normal voice' below). For breathy voices the energy decreases more rapidly at higher frequencies but is maintained in more strident voices which project more.

In addition, the vocal tract acts as a filter, selectively reducing the energy in specific bands of frequencies from the sound source (vocal folds) while allowing others to pass with maximum levels.[3] It acts in a similar fashion to pressing the keys on the bore of an oboe to alter the resonant properties of the instrument. The bands of frequencies that retain their energy levels reflect the resonant properties of the vocal tract and are known as formants. Altering the shape and dimensions of the vocal tract by changing the height of the larynx, position of the tongue, soft palate and lips changes the resonant properties of the vocal tract and formants. Correct production of formants is essential to allow distinction between different speech sounds.

For good and 'normal' voice production three conditions are required:

- quasi-periodic vibration of the vocal folds
- a well-defined harmonic structure of the voice signal radiating from the mouth
- a voice signal that is loud enough or has enough sound intensity (energy) to overcome the threshold of hearing of the listener.

Altering the height of the larynx, positioning of the tongue, soft palate and lips changes the dimensions of the supraglottis, pharynx and oral cavity. This in turn causes certain bands of harmonics to be preferentially reduced (damped) or enhanced. The effects on the perceived sound is to alter the formant structure or its quality (e.g. 'brassy', 'nasal').[7] For example, each vowel can have the same fundamental frequency but may be distinguished by the relative prominence of bands of harmonics (formants) and have an additional quality such as 'brassy' or 'breathy' by the relative prominence or absence of the energy at specific frequencies.[3, 6] Overall, there must also be enough energy (sound intensity) in the voice projected from the lips in order to excite adequate vibration in the listener's hearing mechanism. Increased loudness requires increased subglottal air pressure and abrupt and appropriate duration of closure of the vocal folds during the vibratory cycle to allow efficient conversion of aerodynamic energy into acoustic energy and vocal tract shaping particularly at higher frequencies.[3]

Pathological voice production

Abnormalities in the vocal folds, dimensions or structure of the vocal tract and inadequate control or amount of subglottic pressure can all contribute to a pathological voice. Abnormalities in the mass, elasticity and tensioning of the vocal folds can have two main effects: on the frequency rate and on the regularity of vibration. Alterations in frequency may lead to the voice being perceived as being too high or too low in pitch for the speaker's age and gender. It may also lead to restrictions in the dynamic frequency range of the voice during speaking or singing. Additional supraglottic structures such as the false folds, aryepiglottic folds and mucosa over the arytenoids can also be induced to vibrate either at the same time or in lieu of the vocal folds, providing an additional or alternative sound source. Irregular vibration of the vocal folds, caused by the abnormalities described above, will affect voice quality by producing a less clear fundamental frequency and harmonic structure. This irregularity is perceived as hoarseness and roughness.

Another important influence on the harmonic structure is the addition of noise to the voice 'signal'. For a listener, this may be environmental noise (e.g. trying to hear someone when there is loud background noise) or contained within the speaker's voice itself. For example, if there is a gap between the vocal folds during phonation, air will escape causing turbulent air flow which is perceived as noise (sound energy across all frequencies), reducing the relative amount of energy in the harmonic components and increasing the energy in the subharmonic components.[3] This is perceived as both hoarseness and breathiness or a voice lacking in power (asthenia). Alterations in the relative size, shape and length of the vocal tract, for example from a mass, increased pharyngeal muscle tension or reflective properties of the vocal tract, can all influence the energy levels and harmonic structure of the radiated sound causing the voice to sound strained or effortful.

Normal voice

Every human voice is unique because of anatomical, physiological, psychological, cultural, sociolinguistic and behavioural factors. In addition, a wide range of information about the speaker's gender, age, personality, emotional status and physical health is conveyed by their voice quality, pitch range and the systematic use of pitch patterning (intonation). Defining what is a normal voice is therefore difficult as there is a spectrum of what is considered normal. This can vary between different cultures and there is a continuum between 'normal' and 'dysphonic' sounding voices.[4] A generally accepted and pragmatic definition of a normal voice is one described as having the following characteristics:

- It is audible, clear or stable in a wide range of acoustic settings
- It is appropriate for the gender and age of the speaker
- It is capable of fulfilling its linguistic and paralinguistic functions
- It does not fatigue easily
- It is not associated with discomfort and pain on phonation.

Pathological voice

Pathological voice can be defined pragmatically as one that does not fulfil the criteria above. Variations in voice quality can provide valuable cues about our current emotions, physical health and psychological well-being. Patients generally

seek a consultation about their voice complaint because it causes one or more of the following problems:[8]

- **impairment**, i.e. an alteration in the structure or function of the vocal apparatus (structural abnormality, inflammation, neuromuscular abnormality or muscle tension imbalance) causing symptoms such as hoarseness, a weak voice, pitch change, throat discomfort
- **limitation in activity**, such as a reduction in vocal range in singing or the voice tiring or becoming hoarse with prolonged use in a noisy environment or if raised
- **participation restriction**, e.g. not being able to work or sing in a choir as a result of the voice problem.

The consequences of voice problems can therefore be one or more of the following: physical, functional, psychosocial, occupational and financial.

Potential use of voice evaluation

There are four main potential uses for voice evaluation:

- to provide a measure of severity of the disorder and degree of variance from established normal values
- as an outcome measure to help assess responsiveness to treatment
- to help during voice therapy to set therapy goals, in education about voice production and help patient achieve a target production[10]
- to help characterize the voice and voice problem, thereby providing supportive evidence for a differential diagnosis and pointers for treatment.

Overview of methods of objective evaluation of voice used in clinical practice

There are many hundreds of methods of assessment of the voice and voice production that have been developed over the years but the relevance of many of them to patients' complaints is often not clear. Visual assessment of the larynx (including, on occasions, diagnostic microlaryngoscopy) remains mandatory for confirmation of diagnosis in all cases and this is discussed further in Chapter 61, Assessment and examination of the larynx.

The most commonly used methods of evaluation in the UK are patient self-reported questionnaires and perceptual evaluation of the voice. It is argued that both are inexpensive, with the former giving a (subjective) measure of the impact of the 'pathological voice' on the patient's quality of life and the latter a semi-objective assessment of voice quality. They can be used to measure severity of the condition and as a therapeutic outcome measure.

To help with target production during therapy and characterize the voice or voice problem, and provide specific objective outcome measures, other more instrumental techniques are required. These include measures that relate directly to the voice signal (acoustic measures) or indirectly to the function of the vocal system, such as electrolaryngography (also called electroglottography), aerodynamic measures, voice accumulator measurements and combined measures (**Table 62.1**). No single measure can satisfactorily fulfil all functions and a multidimensional approach is ideally required. This, however, is a balance between the time, effort and expense it takes to perform versus its value in the management of the patient.

Previous high hopes that acoustic and other measures would provide a non-invasive means of diagnosing voice conditions have not been realized to date due to poor specificity and sensitivity. Attempts have been made to set standards for measurement and assessment.[10–12] These have largely been developed from expert consensus opinion and as a whole are not widely used in routine clinical practice in the UK.

SPECIFIC MEASURES

Quality-of-life measures

The need for treatment is largely determined by the patient's degree of disability, i.e. their perceived impairment, limitation in activity and participation restriction.[8, 13, 14] Various disease-specific patient questionnaires have been developed (**Table 62.2**) which allow self-reported grading of the effect of the voice problem on quality of life.[15–21] They have also been used as an outcome measure and indicator of response to treatment.[15, 22–24] Of these, the VoiSS questionnaire[18] has undergone the most rigorous development but the most widely used is Voice Handicap Index (VHI-30 and VHI-10).

The VHI-30 consists of 30 items which assess the impact of the voice disorder on physical, functional and emotional aspects of the patient's quality of life.[16] The patients rate their perception of their voice problem from 0 (= never) to 4 (= always), giving a possible total score of 120. More recently, the VHI-10 has been introduced.[20] This uses a subset of the VHI-30 items and has shown to have good correlation to the VHI-30 with the advantage that it is quicker and easier to complete.[20] In general, there is good correlation between all the different measures.[24–26]

Mean normative values of total score for the VHI-30 are 6.86 (standard deviation = 9.88) and for the VHI-10 are 2.83 (standard deviation = 3.93).[27] The highest values for the VHI total score are seen in patients with vocal cord palsies, severe structural abnormalities of the larynx and muscle tension dysphonia of origin.[22] For the VHI-30, the threshold value between vocal health and voice dysfunction is considered to be 12 points.[28] A 14-point difference in the total VHI-30 score is considered significant response to treatment, with values rarely returning to normative levels.[22, 24, 29, 30]

Perceptual evaluation of voice

Perceptual evaluation of the voice refers to the process of assessing the characteristics of the voice and grading the severity of specific abnormal features such as hoarseness,

TABLE 62.1 Methods of objective evaluation of voice

Evaluation	Description	Examples
Laryngeal visual assessment	Inspection of the structure and dynamic function of the larynx and rest of the vocal tract together with the vibratory patterns of the vocal folds during phonation	Endoscopic laryngoscopy including stroboscopy, videokymography and high-speed digital imaging (see Chapter 61, Assessment and examination of the larynx)
Quality-of-life measures	Using self-administered, validated disease specific or generic questionnaires to assess the patient's perception of the impact of the voice condition on their quality of life in terms of physical complaints and restriction in participation in daily activities	VPQ, VHI-30, VHI-10, VoiSS, VAAP, V-RQOL
Perceptual evaluation of the voice	Using rating scales to grade the presence and severity of defined qualities of the voice that we can hear such as hoarseness, roughness, breathiness	GRBAS, CAPE-V, VPA
Acoustic analysis	Extracting and objectively evaluating various factors related to the acoustic waveform or spectrum recorded using a microphone placed near the mouth	Fundamental frequency measurements, sound intensity, perturbation measures, spectral measurements
Electrolaryngography / electroglottography	Determined by measuring the changes in electrical conductance between two electrodes placed on the skin over the thyroid cartilage during vocal fold vibration	Fundamental frequency measurements, degree of vocal fold contact, perturbation measures
Aerodynamic measures	Measures of the forces that initiate and maintain vocal fold vibration	Air volume, airflow and subglottal pressure
Voice accumulator	These are means of sampling the voice or aspects of vocal function either over a prolonged period of time or before, during and after a specified vocal stress test	Phonation time, frequency and sound intensity measurements
Combined measures	These attempt to provide a multidimensional measure of voice function	Dysphonia Severity Index, Cepstral Spectral Index of Dysphonia

TABLE 62.2 Patient self-report questionnaires

Patient self-report questionnaire	Abbreviation	Reference
Patient Questionnaire of Vocal Performance	VPQ	Carding and Horsley[15]
Voice Handicap Index	VHI-30	Jacobson et al[16]
Voice-related Quality of Life	V-RQOL	Hogikyan and Sethuraman[17]
Voice Symptom Scale	VoiSS	Deary et al[18]
Voice Activity and Participation	VAAP	Ma and Yiu[19]
Voice Handicap Index-10	VHI-10	Rosen et al[20]

roughness and breathiness.[4, 31] Numerous schemes have been developed (**Table 62.3**) which require the expert listener to rate the voice characteristics using either categorical or visual analogue scales.

The GRBAS (**G**rade, **R**oughness, **B**reathiness, **A**sthenia and **S**train) scheme (**Table 62.4**) is probably the most widely used, partly due to its relative simplicity. Each dimension is rated on a four-point scale where 0 = no perceived abnormality, 1 = mild, 2 = moderate and 3 = severe abnormality. The overall Grade of hoarseness is the most reliable voice quality parameter with Strain and Asthenia (weakness) being relatively poor.[37, 38]

The CAPE-V is a newer measure which replaces the four-point scale with a 100 mm line Visual Analogue Scale. It also encompasses other factors such as pitch and loudness.[36] The Voice Profile Analysis (VPA) scheme is based on a phonetically grounded description of voice quality and is recognized as being a valid and detailed descriptor of voice quality.[7] Many consider it to be too complex for routine clinical use and not a valid tool for assessing outcome.[40]

Acoustic analysis

Acoustic analysis provides quantitative measures based on the voice signal (waveform and spectrum) recorded using a microphone placed near the mouth. The microphone acts as a transducer, converting the acoustic signal into an electrical signal. The amplified electrical signal is most commonly recorded directly to hard disk as uncompressed .wav files. A variety of free and commercial software programmes are available for display, measurement and statistical analysis of the acoustic waveform and spectrum.

TABLE 62.3 Summary of the most common schemes described for perceptual evaluation

Scheme	Abbreviation	Reference(s)
Grade (of hoarseness), Rough, Breathy, Asthenic, Strained	GRBAS	Hirano[32]
Grade (of hoarseness), Rough, Breathy, Asthenic, Strained, Instability	GRBASI	Dejonckere et al[33]
Rauhigkeit (Roughness), Behauchtheit (Breathiness), Heiserkeitsgrad (Hoarseness) method	RBH	Nawka and Anders[34] Nawka et al[35]
Consensus Auditory Perceptual Evaluation of Voice	CAPE-V	ASHA[36]
Vocal Profile Analysis	VPA	Laver[7]

TABLE 62.4 The psychoacoustic and physiological findings associated with each of the five dimensions of the GRBAS scheme[32, 39]

Factor	Psychoacoustic/physiological correlates
Grade (G)	Overall rating of severity of abnormality ('hoarseness') of voice
Roughness (R)	Perceived irregularity in voice Irregular perturbation of pitch and amplitude, noise in low-frequency region and the presence of spectral subharmonics
Breathiness (B)	Audible breath or air escape on the voice Noise below the mid frequencies, incomplete closure of vocal folds resulting in high expiratory flow rate
Asthenia (A)	Weakness or lack of energy in the voice Less harmonic content in the high-frequency region, irregularity of pitch and amplitude, a fading amplitude contour
Strain (S)	Perception of excessive vocal effort Reflects higher pitch, noise in the higher frequencies, increased amplitude of the higher harmonics and increased pitch and amplitude perturbation

VOICE MATERIAL

There are three main types of voice material used in acoustic analysis: sustained vowels, fluent speech and consonant–vowel sequences:[41]

1. **Sustained vowels** have traditionally been used as voice test material in clinical practice for the following reasons:
   - They are the simplest separable components of speech.
   - Although the vowel systems of the world's languages cover a very large range of sound types, three oral vowels are almost universally present so can be used for comparison across studies:[6]
     - a close ('high') front articulation /i/ (as in English b*ee*t)
     - a back ('high') /u/ (as in English b*oo*t)
     - an articulatory open vowel /ɑ/ (as in English f*a*r).
   - Loudness, pitch, intonation and timbre can, to a degree, be separated and controlled for far more readily than for other elements of speech.
   - They predominantly reflect vocal fold vibratory activity.
   - If analysis of phonatory onset and offset are excluded, the stable mid-portion of the utterance is thought to represent the intrinsic quality of a voice which is independent of language.[42, 43]
   - The measurement is quick and easy to perform and has been used in many of the reported clinical studies of pathological voice production.[41]

   Measurements are usually made on a 1000 ms midsection of the sustained vowel, usually /i/ or /ɑ/, produced at a comfortable pitch and loudness.[41] Effort levels and day-to-day variability may influence the results and must be taken into consideration when comparing inter- and intrasubject results.[44]
2. **Fluent speech**, however, has several advantages:
   - It is more directly relevant to the patient's day-to-day experience.
   - It is more related to ordinary voice production, and also to a listener's impression of the speaker's phonatory ability, than sustained vowels.
   - It potentially produces more clinically relevant measures of voice production than sustained vowels.
   - It takes into account the acoustic cues associated with vowel onset and offset, pitch, loudness and intonation control that take place during speech production.

   Two types of speech material are typically used: **read text** and **spontaneous speech**. Read text has the advantage that the same sets of speech sounds are elicited for each recording, allowing cross-clinical comparisons to be made. The disadvantage is that some patients are not able to read aloud or read in a way that is not representative of their fluent spontaneous speech. The most frequently used texts used are *The North wind and the Sun*, 'The rainbow passage', and *Arthur the rat*.[41, 45] Each is phonetically balanced and the choice is largely down to personal preference. Read text and spontaneous speech give

similar but not identical results.[41] Approximately 40 s of a speech sample is needed for perceptual evaluation in order to begin to obtain a useful representation of the main voice characteristics. For electrolaryngography (ELG) measures (see below) and to see the effects of vocal fatigue in more severe cases, 120 s is better.

3. **Consonant–vowel sequences** are also used in two particular situations:
   - For the investigation of rapid voice 'switching' in diadochokinetic sound sequences, the rate (mean number of utterances per second) of repetition of utterances such as alternate voiceless consonants with a vowel, e.g. /pʌ/, /tʌ/, /kʌ/ ('pu-tu-ku') or /pʌ/, /tɜ/, /kɜ/ ('pu-terr-kerr'), can be measured and an assessment made of the accuracy of articulation and rate variability during the task.[41]
   - In the determination of laryngeal airway resistance or indirect subglottic measurement,[46] the sound sequence is a succession of only /pʌ/or /pi-pi-pi/ – the bilabial closure providing a time interval during which intraoral pressure equals that at the glottis.

One caveat when performing any assessment is that it is performed at that point in time and may not reflect the variation in voice quality that is frequently reported by patients. Newer software such as OperaVOX™, which can be set up as an app on a mobile phone or tablet, can allow simple measurements and recordings of the voice to be made by the patient at home at any time of the day.[47] Alternatively, voice accumulators may be used (see below).

MICROPHONES

Accurate measurements of acoustic parameters across the range of vocal frequencies and intensities require a good-quality condenser or electret, omnidirectional, pressure-sensitive microphone.[48] The sound pressure wave radiating from the mouth is converted by the microphone into an electrical signal such that the induced voltage change is proportional to the pressure level. Ideally, it should have a minimum sensitivity of –60 dB and reasonably flat frequency response (i.e. equally sensitive to all audio frequencies) across the range of human hearing (20–20 000 Hz).[12, 41] The microphone-to-mouth distance should be kept constant and the recording system should be calibrated to ensure standardization of recordings.[48, 49] A microphone can be mounted on a headset when it is usually positioned 8 cm from the corner of the mouth. It is usually offset by 45 degrees to avoid overstimulation from the breath stream particularly from plosive sounds.[49] Alternatively, it can be set at a fixed distance (30 cm) from the mouth using either a boom or a lanyard round the neck.[47] Recordings should be done in a quiet room free from extraneous noise.

ACOUSTIC PARAMETERS

Acoustic measures of the voice quantify the physical characteristics of the sound pressure waveform radiating from the lips. There are several parameters that are used in objective measurements based on the fundamental frequency, frequency perturbation (jitter), spectral analysis or sound intensity or combinations thereof. The validity and clinical utility of acoustic parameters as a measure of overall voice quality have been questioned.[50] Many measures have been described[12, 41, 51] but only some of the more common ones in clinical use will be discussed here.

Fundamental frequency

Fundamental frequency is a measure of the rate of vibration of the vocal folds. It is the inverse of the time taken to complete a single vibratory cycle and is measured in cycles per second or Hertz (Hz). It can be measured from short segments (1–2 s) of a sustained vowel made at a 'comfortable pitch and loudness' or from speech (speaking fundamental frequency (SFF)). It can be measured from either the acoustic (F_0) or the ELG (F_x) signal (see below). The reliability of the automatic F_0 calculation from the acoustic signal, however, worsens with increasing severity of the dysphonia.[12] In males the SFF drops from young adulthood into middle age and rises again in old age. In women the SFF remains fairly constant from 20–50 years and then drops.[41]

$$\text{Fundamental frequency } (F_0) = \frac{1}{\text{time to complete one vibratory cycle}}$$

Sound intensity and sound pressure level (SPL)

The amplitude of the signal relates to its sound pressure or strength. As a listener we perceive this as loudness. In practice, sound intensity is measured in terms of the logarithmic ratio of the absolute sound pressure to a reference sound pressure level (SPL) expressed in decibels. This means that doubling the sound pressure raises the SPL by 6 dB. For a more in-depth discussion see Baken and Orlikoff[41] and Speaks.[52]

Speech intensity levels for sustained vowels are quite different from connected speech due to the physiological and linguistic pauses in the latter causing marked fluctuations in pressure. Comparison of results published in the literature are extremely difficult due to the lack of standardization of the measuring techniques.[41] The mean SPL for a read text passage of connected speech produced at a comfortable phonation level by healthy subjects is approximately 70 dB measured at 30 cm from the mouth. However, the intersubject variability is approximately 20 dB for men and slightly less for women and the intrasubject variability for repeated measurements is approximately 3 dB.[53]

Jitter and shimmer

It is normally possible for an individual to produce a vowel sound for several seconds with little variation (perturbation) in the frequency (jitter) or intensity (shimmer). Pathological voice samples have been shown to have higher

levels of jitter and shimmer than normal[41, 51] although, for jitter, these have not been universal findings and the validity and reliability of these measures has been questioned, particularly in severely dysphonic voices.[54–56] Although widely used as 'objective' measures of voice, there is poor correlation between perceived vocal quality and acoustic measures of jitter and shimmer.[57, 58] This is mainly due to the perceptual difficulties of isolating jitter and shimmer as separate dimensions and from the spectral noise in the voice. In addition, there are many different ways of calculating jitter and shimmer, which adds to the confusion. For a detailed discussion on these perturbation measurements see Baken and Orlikoff.[41]

Voice range profile (phonetogram)

A voice range profile (VRP) or phonetogram is a visual display of the dynamic range of the voice in terms of frequency and vocal intensity[59] and has been used in both adults and children.[60, 61] It is usually produced by recording the patient's ability to produce sustained vowels (usually 10 continuous, periodic cycles of an /a/ vowel[62] across their frequency range at the quietest and loudest note they can produce.[60] Experience in performing the procedure to a given protocol is extremely important.[63–65] The features of interest are the overall shape, loudness and frequency ranges and phonatory area.[59, 64] It is of particular value in determining and documenting areas of difficulty in the singing voice[66] and for demonstrating improvement in the dynamic range of the voice following treatment of voice disorders.[67] It is not widely used in the UK as it is time-consuming to perform but it is commonly performed in many European phoniatric departments.

Spectrogram and long-term average spectrum

The acoustic output of the vocal tract resulting from the interaction of the vocal fold vibration with the vocal tract can be displayed graphically in a 3D way in what is known as a spectrogram. Time from beginning of the vowel utterance to the end is displayed on the *x* axis. A logarithmic display of the frequency distribution is seen on the *y* axis while the amplitude or amount of energy in the spectrum for a given frequency or frequency band is represented by increasingly dark shades of grey.

There are two forms of spectrogram: narrow-band and broadband (or wide-band) spectrograms. The narrow-band spectrogram (**Figures 62.1a** and **62.2a**) displays the concentrations of energy in each harmonic across the frequency range. The number of harmonics displayed is largely determined by the loudness of the voice and the abruptness of vocal fold closure (see below). The broadband spectrogram, on the other hand, gives more information about the how the 'groupings of the harmonics' (formants) are arranged (**Figure 62.3a,b**).[41, 68] The most dense and central parts of these broadband spectrograms (i.e. those with the greatest energy or amplitude) are taken to represent the resonant frequencies of the vocal tract.

Linear predictive coding (LPC) and fast Fourier transform (FFT) are automated and mathematical ways of picking out and displaying these formant peaks (**Figure 62.4**).[41] Although it is probably more reliable overall to pick out the formant frequencies by hand, these automated techniques provide a useful quick alternative. They are not always reliable, particularly if the signal changes abruptly, the F_0 is too high (above 350 Hz) and if there are significant anti-resonances, i.e. when there is significant nasalization of the speech sound.[41]

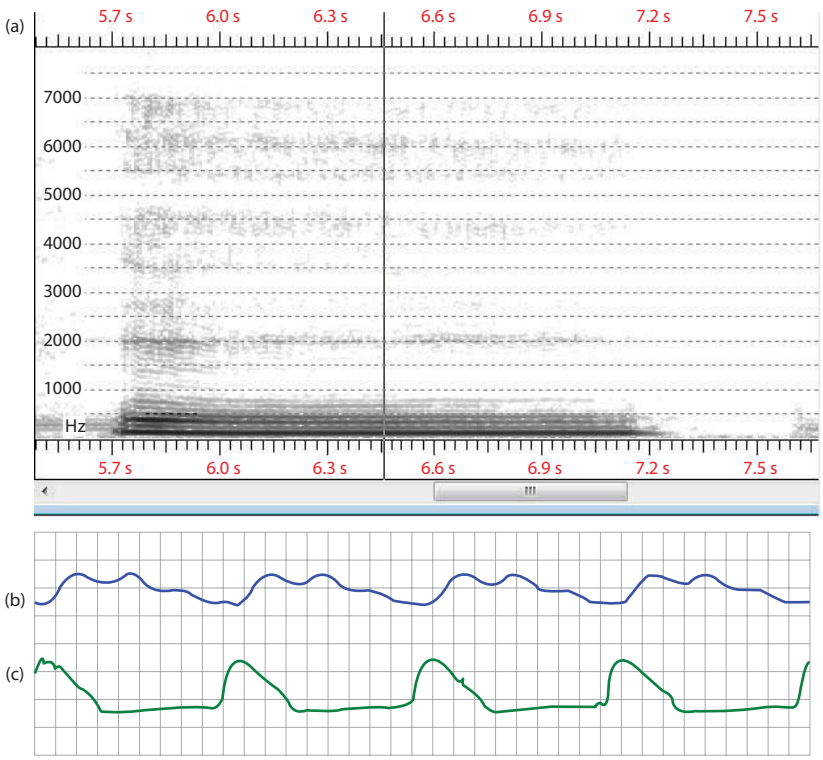

Figure 62.1 Sustained /i/ vowel produced at 109 Hz by 53-year-old male patient with left recurrent laryngeal nerve palsy pre-thyroplasty. (a) Narrow-band spectrogram showing poorly defined harmonic structure and ill-defined high-frequency band (5500–7000 Hz) due to breathiness of voice; **(b)** speech (acoustic waveform) and **(c)** ELG waveform at the point in utterance indicated by the vertical line on the spectrogram. Note the short contact quotient on the ELG waveform (mean Qx: 28.25%) associated with poor vocal fold contact.

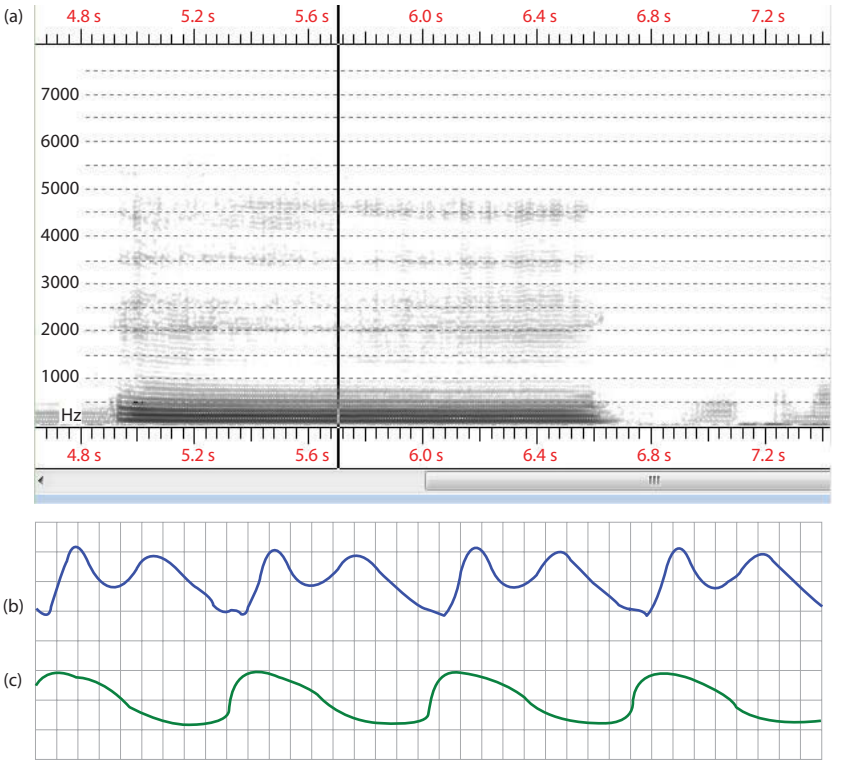

Figure 62.2 Sustained /i/ vowel produced at 106 Hz by same patient as in Figure 62.1 post-thyroplasty. (a) Narrow-band spectrogram showing better-defined harmonic structure particularly and beginning and end of utterance and loss of high-frequency noise component (5500–7000 Hz); **(b)** speech (acoustic waveform) and **(c)** ELG waveform at the point in the utterance indicated by the vertical line on the spectrogram. Note the improved contact quotient on the ELG waveform (mean Qx: 48.16%) associated with better vocal fold contact from the medialization procedure.

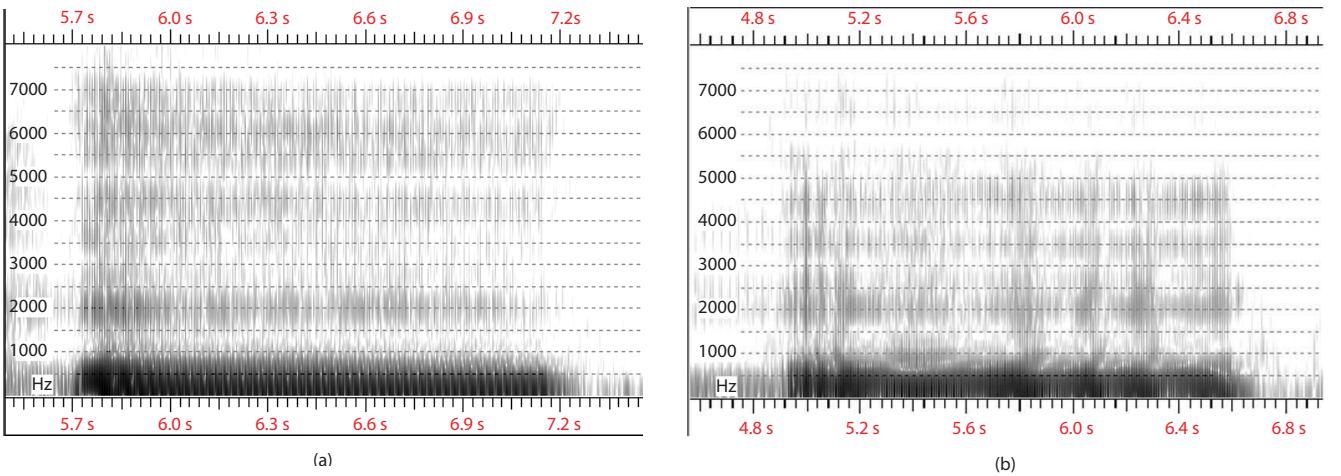

Figure 62.3 Broadband equivalents from Figures 62.1a and 62.2a for sustained vowel /i/. Neither shows really strong banding (except for first formant) but pre-thyroplasty shows more noise in signal in general, particularly at higher frequencies.

A different way of displaying these data is to look at the average amount of energy at each frequency for a given time period. The averaged relative amplitude of the sound level in dB is displayed on the *y* axis against the frequency range on the *x* axis. The display is known as a long-term average spectrum (LTAS) (**Figure 62.5**). Some workers consider LTAS a potentially good index of voice quality.[41, 69] Depending on the nature of the sound, for a given F_0 the strength or amplitude (amount of energy) of the harmonics changes as the frequency increases and the rate of change is known as the spectral slope (usually measured in dB/octave). Vocal fold closure occurs much faster than vocal fold opening and it is this abrupt closure that largely determines (i) the amount of energy in the acoustic spectrum, (ii) the overall number of harmonics produced and (iii) the energy in the high frequencies. This abrupt closure results in a voice which is perceived as 'bright' and which projects well. It is associated with a slowly reducing spectral slope. Conversely, incomplete or slow vocal fold closure results in less energy in the 'acoustic spectrum' and fewer higher harmonics. This means less energy is radiating from the lips and will result in a steeper spectral slope. The voice may be perceived as breathy and will not project well, which, in more extreme cases, can make the sound pattern unrecognizable or inaudible.[41]

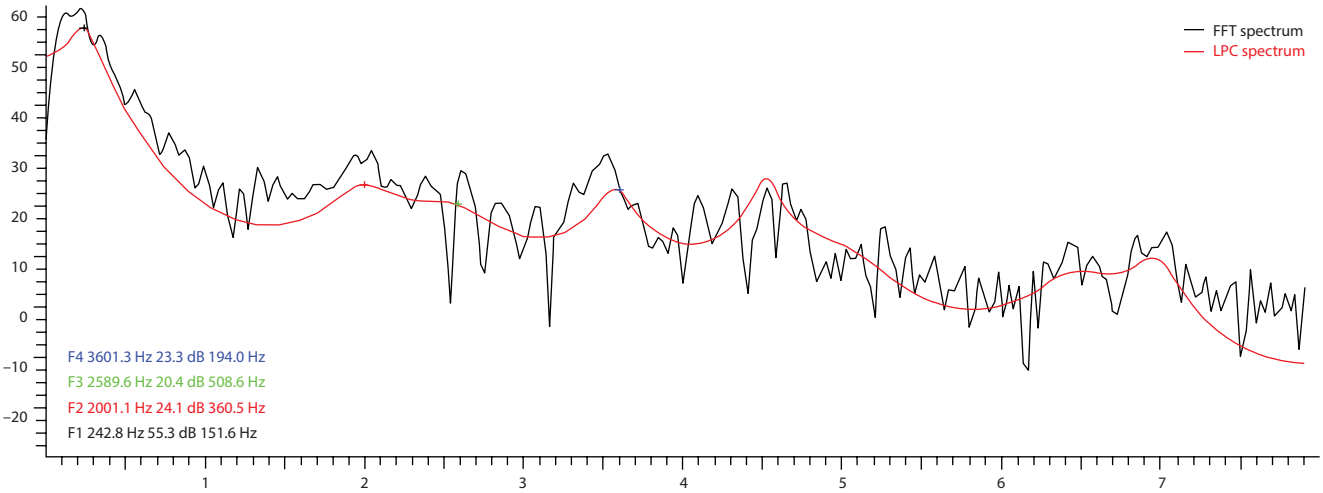

Figure 62.4 Formant frequency identification for post-thyroplasty patient on sustained British English /i/ vowel using linear predictive coding (LPC) and fast Fourier transform (FFT). Values F1–F4 represent the respective formant frequencies (Hz), amplitude (dB) and bandwidth (Hz).

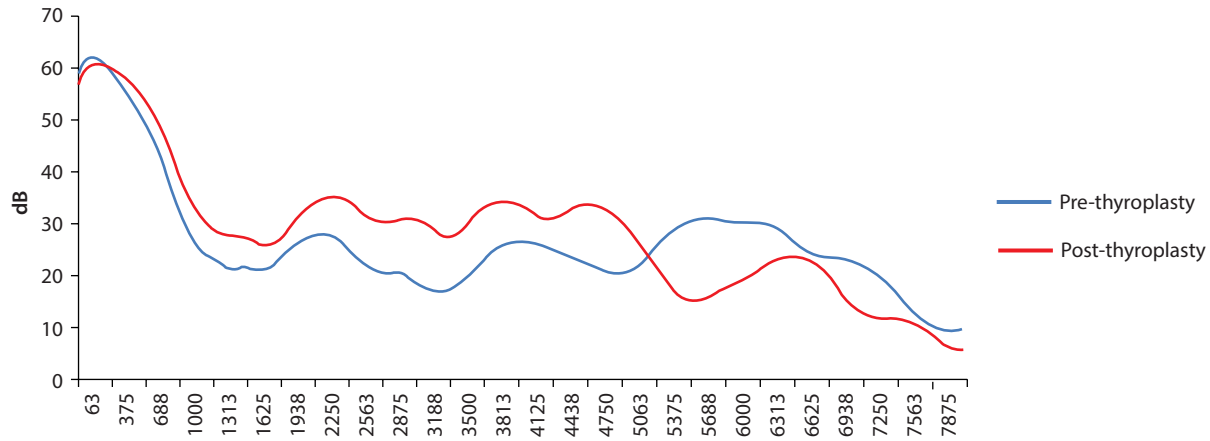

Figure 62.5 Broadband long-term average spectra (LTAS) for a patient with recurrent laryngeal nerve palsy on sustained vowel /i/. This is a graphical display of the spectral information in Figure 62.3 showing improvement in formant frequency energy and a reduction in noise element in the 5500–7500 Hz range before thyroplasty (blue) and following surgery (red).

Measurements of spectral noise energy versus harmonic energy

Speech and voice have two components: a well-defined periodic signal that has a clear harmonic spectrum and an additional source of random 'spectral noise'.[70, 71] Spectral noise is inherent in normal as well as pathological voice and increases with the openness of the vowel. For example, it is greater for vowels such as /œ/ (as in b*a*d) and least for /u/ and /i/ (as in b*oo*t and b*ee*t respectively).[72] Increasing vocal effort and lower pitches are associated with an increase in spectral noise and there is a reasonable correlation (0.74–0.92) between spectral noise and the perceived roughness of a vowel.[73] The noise element can be generated from irregular (aperiodic) vibration of the vocal folds or some other structure within the vocal tract (e.g. the false cords) and/or turbulent airflow (e.g. air leakage through an incompletely closed glottis).

The commonest measures used in clinical practice are the harmonics-to-noise ratio, normalized noise energy and the signal-to-noise ratio (see below). Unfortunately, these measures do not distinguish between pathological changes as a result of turbulent noise and irregular glottal excitation.[74, 75]

Harmonics-to-noise ratio The harmonics-to-noise ratio (HNR) (measured in dB) is the mean intensity of an average waveform (noise-free) divided by the mean intensity of the isolated noise component for the series of waveforms in the utterance.[41, 76] The greater the noise, the lower the HNR (**Table 62.5**). Some authors report higher normative and post-treatment values.[41]

$$\text{Conceptual HNR dB} = 10^{*}{}_{\log 10}\frac{\text{energy contained in the harmonics alone}}{\text{energy in the noise alone}}$$

The correlation between the HNR and perceptual evaluation has varied considerably between studies. Yumoto et al[76] found a correlation between hoarseness and HNR of 0.849 but Wolfe et al[77] noted a –0.32 correlation with a seven-point

TABLE 62.5 Some examples of HNR values for /α/ (as in *far*) vowel in normal, dysphonic and treated patients. There was no statistical difference between men and women[76]

	Mean (dB)	SD	Range (dB)
Normal (*n* = 42)	11.9	2.32	7.0–17.0
Pre-op dysphonics (*n* = 18)	1.6		–15.2–9.6
Post-op (*n* = 23)	11.3	3.13	5.9–17.6

severity of dysphonia score. It has been found to be an excellent predictor of breathiness[78] but tends to overestimate the noise energy in the presence of jitter and shimmer.[75, 79]

Normalized noise energy Normalized noise energy (NNE)[80] assesses the relative level of vocal noise to that of harmonics but bases the analysis on a relatively small number of vocal periods (as opposed to individual cycles as in the HNR). This has the advantage that it avoids the effects of drift in fundamental frequency or intensity during the utterance, which can be a problem in the calculation of the noise component of the HNR. Like other acoustic measures, the degree of effort used in producing the voice sample, day-to-day variability[44] and algorithms for calculating the noise energy in the signal can all influence results[41] so care must be taken when comparing studies. The higher the negative value, the better the voice. NNE has been shown to correlate with perceived breathiness in dysphonic children.[81] A few studies have been published where it has been used as an outcome measure and to distinguish pathological from normal voices.[82–85]

Signal-to-noise ratio The signal-to-noise ratio (SNR) is an alternative approach that avoids the need for harmonic analysis yet effectively achieves the same end result.[86] The underlying concept is that, since noise is random, its average is zero and the average amplitude will be an essentially noise-free estimate. Subtraction from the raw signal then leaves the noise alone. A ratio higher than 1:1 (greater than 0 dB) indicates more signal than noise. The process depends, however, on the assumption that the voice signal is truly periodic.

$$\text{S/N dB} = 20^{*}_{\log 10} \frac{\text{average amplitude of mean vocal fold cycle}}{\text{average of difference between mean and raw cycles}}$$

In practice it is difficult perceptually to distinguish between the sensations associated with the following:

- frequency irregularity from cycle to cycle of vocal fold vibration
- amplitude irregularity from cycle to cycle
- the presence of random noise in the voice.

Electrolaryngography

The electrolaryngograph (ELG) consists of two electrodes placed on the skin on either side of the thyroid cartilage. A high-frequency current (3 megahertz) is applied between the two electrodes and held at a constant voltage. Vocal fold vibration changes the electrical conductance between the electrodes. The resulting waveform can be analyzed automatically to obtain measures of the rate of vocal fold vibration (fundamental frequency, Fx) and frequency perturbations (e.g. jitter). Experimental data have also shown the waveform can be used to measure indirectly variations in the contact area between the mucosa of the two vocal folds during a vibratory cycle (**Figure 62.6**, and see **Figures 62.1c** and **62.2c**).[90] As the ELG signal is a simpler waveform which is unaffected by resonances of the vocal tract, it provides one of the most accurate methods of determining the fundamental frequency, even in severely dysphonic voices. However, it is not always possible to detect a waveform, particularly when the soft tissues of the neck are thick.

SPEAKING FUNDAMENTAL FREQUENCY AND F_0 RANGE

Mean speaking fundamental frequency (SFF) can be measured from a 2-minute sample of speech and can be plotted as a frequency histogram (**Figure 62.7**) to give a graphical representation of the dynamic frequency range of the voice. In the Speech Studio (Laryngograph Ltd) programme, for example, frequency measurements are displayed on a logarithmic scale which is divided into 120¼ tone 'bins' between 27.5 Hz and 440 Hz. These frequency 'bins' correspond well to perceived pitch and tend to bias the higher frequencies. In addition, a second frequency histogram (DFx2) can be overlaid on the graph. This counts the 'pitch-pairs' (i.e. when two consecutive periods differ by no more than 10%) and represents the minimum number of consecutive vibratory cycles that can potentially be perceived as periodic. Poor voice quality is in

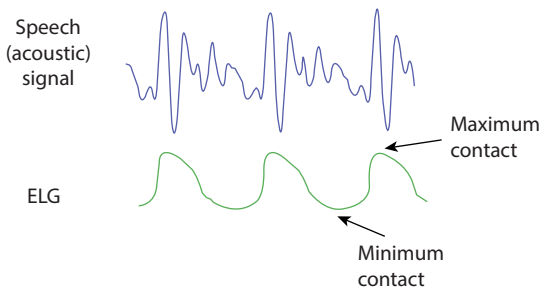

Figure 62.6 **(a)** Laryngograph® electrodes placed over thyroid cartilage. **(b)** Speech (acoustic) waveform acquired using a tie clip or head-mounted microphone. **(c)** The ELG waveform reflects the variation in conductance between the electrodes during phonation. In modal voice the vocal folds close more rapidly than on opening, giving a sharper rise in the waveform.

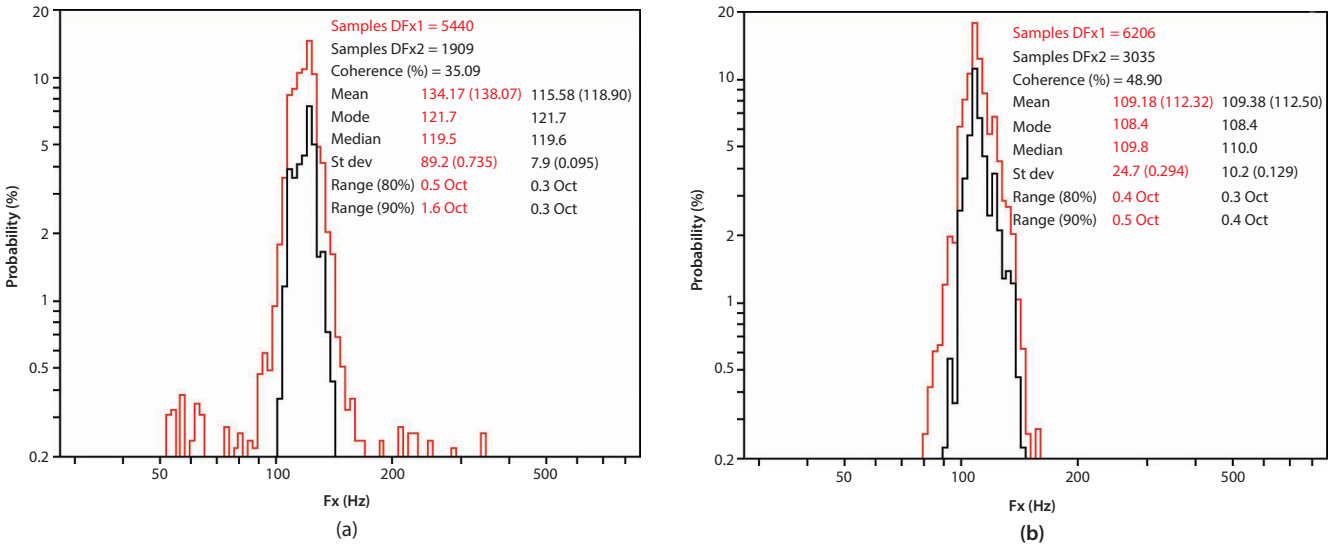

Figure 62.7 DFx1 and DFx2 frequency histograms (a) pre-thyroplasty and **(b)** post-thyroplasty. DFx1 demonstrates the relative number of times the vocal folds vibrated at a certain frequency (or more precisely frequency bin, see text) during the reading of a passage of text. The DFx2 demonstrates 'pitch-carrying pairs' indicating smooth vibratory frequency change associated with good quality voicing. In general, the closer the DFx1 and DFx2 distributions are graphically, the better the quality voice. This can be quantified in terms of percentage coherence value.

TABLE 62.6 Example of normative data based on a total of 43 female and 14 male Portuguese subjects with no self-reported voice problems (including smokers)[89]

	Men		Women	
Mean	**Reading**	**Conversation**	**Reading**	**Conversation**
Mean SFF (Hz)	109.6	109.2	190.3	186.6
Dynamic frequency range DFx1 90% (octaves)	0.75±0.18	1.18±0.49	0.86±0.22	1.12±0.48
Irregularity score (CFx)%	12.5±7.3	23.5+/–15.6	7.6±5.2	12.3±7.4
Mean contact quotient (Qx)%	45.9	46.3	44.1	43.8
Standard deviation of contact quotient (Qx)%	5.9	7.5	6.1	7.3

general associated with poor correspondence between the DFx1 and DFx2 histograms (**Figure 62.7b**) and reflected in a reduced coherence percentage value. Various parameters can be measured, such as the mean, mode and median SFF and the 80% and 90% ranges. Rather than absolute values, the range in octaves is perhaps more meaningful. Examples of normative values for vocally healthy individuals are given in **Table 62.6**.

$$\text{Coherence \%} = \frac{\text{Number of samples DFx2}}{\text{Number of samples DFx1}}$$

A lower than average mean SFF is found in conditions that increase the mass per unit length of the vocal fold mucosa such as Reinke's oedema[91, 92] and hypothyroidism.[93, 94] A higher than average SFF is seen in puberphonia,[95, 96] scarring of the vocal folds, laryngeal cancer[97] and in some cases of recurrent laryngeal nerve palsy.[98]

A restricted frequency range is found in both organic conditions of the vocal folds, neurological conditions such as Parkinson's disease[99, 100] and psychological conditions including depression and, to a lesser extent, schizophrenia.[101, 102] Some patients also find empirically that by restricting their frequency range they can maintain a reasonably stable vocal fold vibratory pattern and voice quality. An extended range with good correspondence between DFx1 and DFx2 indicates an exaggerated use of the dynamic range of the voice. In contrast, a large range with poor correspondence suggests poor control over vocal fold vibration and is associated with perceptually severe dysphonia.

PERCENTAGE IRREGULARITY SCORE (CFx)

Plotting frequencies of successive vocal fold vibrations against each other during running speech (approximately 120 s) should result in a well-defined single diagonal distribution for normal voice. In pathological voice, such as a recurrent laryngeal nerve palsy, the ability to control cycle-to-cycle variation in frequency is impaired, resulting in deviation from the diagonal line (**Figure 62.8**). This deviation can be quantified by measuring the number

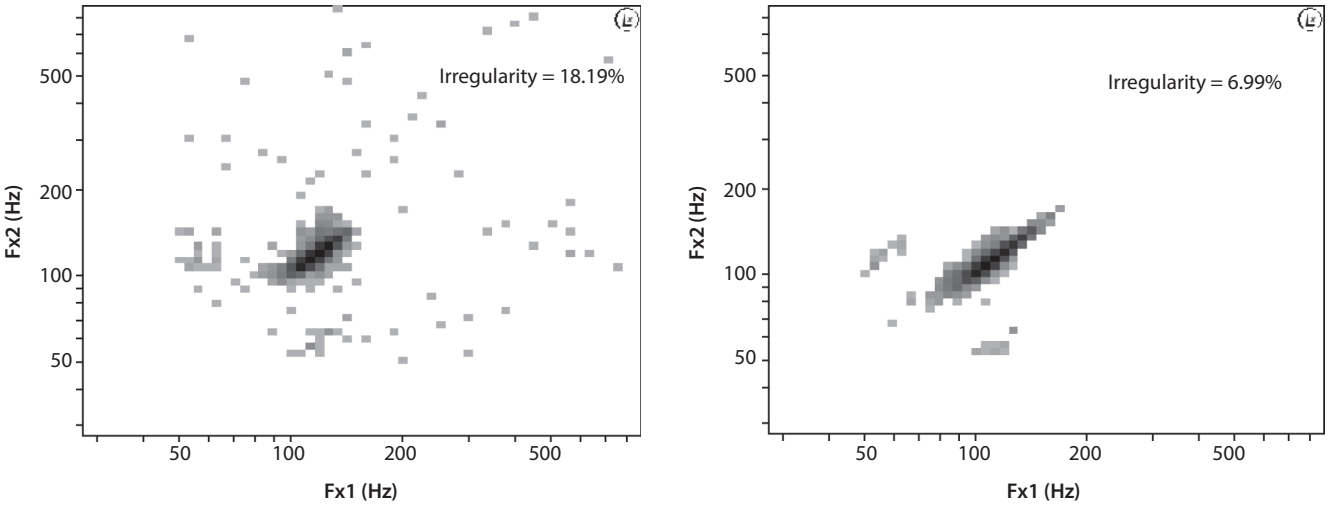

Figure 62.8 CFx1 distributions (a) pre- thyroplasty and (b) post- thyroplasty. This demonstrates the cycle-by-cycle change in frequency of vibration of the vocal folds. The better the voice the straighter and less scatter from the diagonal. This can be quantified in terms of a percentage irregularity score.

of data points straying ±3% away from the diagonal and expressing this as a percentage of the total number of data points registered. It can be seen that the CFx percentage irregularity score values for normal individuals in **Table 62.6** (which include smokers) are greater for males and for conversational voice. For the pre- and post-operative examples in **Figure 62.8** the irregularity scores are 18.9% and 6.99% respectively.

CONTACT QUOTIENT MEASUREMENT (CQx)

As well as frequency measurements it is also possible to derive information about the degree of contact between the vocal folds during the vibratory cycle from the ELG waveform. This can be expressed as a percentage of time to complete one vibratory cycle.

$$\text{Percentage contact quotient Qx} = \frac{\text{Lx closure width 70\% down from positive peak}}{\text{time to complete one vibratory cycle}}$$

There appears to be a positive correlation between contact quotient and vocal intensity for sustained vowels.[103, 104] The contact quotient increases with the level of vocal training[105, 106] but also in pathological conditions when the mass of the vocal folds is increased, such as Reinke's oedema and certain types of muscle tension dysphonia where the voice is pressed. Reduced contact quotients are usually found in cases of vocal fold palsy and paresis (**Figure 62.9**) and in some cases of presbylaryngis and muscle tension dysphonia associated with weak, breathy or asthenic voices. The standard deviation of the contact quotient is generally increased in dysphonic patients,[89] reflecting the increased difficulty in controlling the degree of contact in speech tasks.

Aerodynamic measures

Clinically there are three main factors that can be measured which are of interest in voice production: air volume, air flow and subglottic pressure.[107]

AIR VOLUME

Tidal volume (5–6 L) is a usable part of total lung capacity (6–7 L). In quiet respiration we use only 10–15% of the tidal volume but the full amount can be used for respiration or voice in demanding physical activities, such as exercise or singing. Actual lung volumes are in themselves not particularly informative in speech science but the changes in air volume during speech (airflow) are of much more potential interest.[41] Body plethysmography remains the gold standard for obtaining measurements of changes in air volume during speech or singing but is only used in research settings. Alternative approaches, again only really used in research, are to use magnetometers and inductance plethysmographs placed over the chest and abdominal walls, although the accuracy of these techniques has been questioned.[41, 108] As flow is essentially the change in volume over time, there are two alternative methods of deriving flow and volume measurements from a single transducer:

- by mathematically integrating the oral airflow signal from a pneumotachograph[107]
- by differentiation of the output of a volumatic device such as a spirometer.[41]

In clinical practice where this is undertaken, the pneumotachograph is more commonly used. The main drawback, however, is the interference with speech and change in vocal resonance due to the face mask.[107]

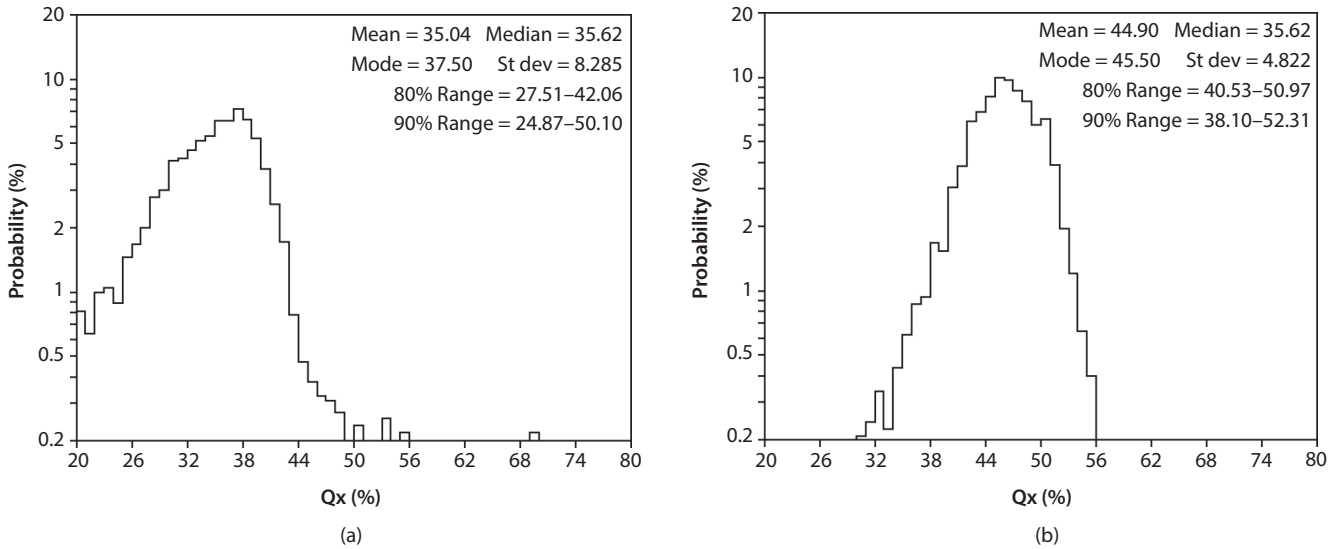

Figure 62.9 DQx1 data (a) pre-thyroplasty and (b) post-thyroplasty. The change in percentage contact with each cycle of vibration is displayed as a probability histogram. The improvement in contact quotient following surgery is seen with a return to normal mean and modal values.

AIR FLOW

Airflow associated with phonation is usually specified in terms of volume velocity (litres per second). It can be used to measure:

- flow during sustained phonation to provide an indicator of functional efficiency of the laryngeal system
- flow associated with consonants to evaluate oral articulatory events
- nasal airflow to assess the velopharyngeal function.[41]

Only the important measures associated with the first use will be discussed here:

Mean airflow rate, Vocal Velocity Index and glottal flow waveform

- The **mean airflow rate** (**MFR**) is the volume of air displaced during phonation on a sustained open vowel such as /œ/ (as in b*a*d) divided by the time taken to produce the phonation.[32] It is usually measured using a facemask or mouthpiece to channel air through an airflow transducer such as a pneumotachograph.[41]
- The **Vocal Velocity Index** (**VVI**) is a variant designed to provide a degree of flow comparison normalization between different-sized speakers.[41, 109] It is calculated by dividing the MFR by the speaker's vital capacity. Normal values for a range of British speakers have been reported.[41, 109] Laryngeal disorders are often associated with excessive air escape and consequently increased MFR and VVI.[41] Conversely, where glottal contact is excessive in conditions such as spasmodic dysphonia, these values are reduced.[41, 109] Both the MFR and VVI have been used as objective outcome measures following treatment.[41]
- The **glottal flow waveform** or **flow glottogram** is a representation of the airflow during each glottal cycle. It is derived from the oral airflow signal through a special pneumotachograph placed in a circumferentially vented facemask using a technique known as **inverse filtering**.[41, 107] From this, values such as peak flow (L/sec), AC flow (L/sec), minimum flow (L/sec) and maximum flow declination rate (L/sec/sec) can be derived. It is used mainly as a research tool.

Maximum phonation time, phonation quotient and s/z ratio

- **Maximum phonation time** (**MPT**) is measured by asking the subject to inhale as deeply as possible and then sustain a steady /ɑ/ vowel (as in f*a*r) for as long as possible.[32, 41] The longest of three repeated measurements is selected. Values under 10 s are regarded as pathological.[32] It is a simple tool used widely in clinical practice as an indicator of the severity of the dysphonia and as an outcome measure, but its reliability has been questioned.[41] It does not allow distinction between poor glottal closure from reduced pulmonary function and vocal cord abnormalities such as a recurrent laryngeal nerve palsy.[41]
- The **phonation quotient** is defined as the vital capacity divided by the MPT.[41] It provides some correction for the size of the speaker's movable air supply on maximal vowel duration in a similar way to the VVI. Although it correlates with the MFR, it is less sensitive and is of questionable clinical value.[41]
- The **s/z ratio** is a variation of the MPT whereby the maximum sustained time for a speaker to make both an /s/ and /z/ sound are recorded.[41, 110] A normal speaker can usually maintain the sound for approximately the same amount of time for both the voiceless /s/ and voiced /z/ consonant, giving a ratio of approximately 1 : 1. Abnormalities which interfere with vocal fold vibration or which affect glottic closure would be expected to reduce the /z/ value but not have any significant effect on the /s/ time, thus increasing the ratio.

Although this simple test is used quite widely in clinical practice, some of the original precepts have been challenged as it depends on eliciting a maximum performance in a speaker. Subsequent studies have shown that there is a wide range in normal values and its sensitivity and utility are therefore questionable.[41]

MEASURES OF SUBGLOTTIC PRESSURE

The vocal folds will only vibrate when the air pressure in the subglottis overcomes the tissue resistance of the vocal folds. The **phonation threshold pressure** is the minimum subglottal pressure required to induce oscillation.[111, 112] Low-frequency phonation threshold pressure has been measured at 0.3–0.4 KPa and generally increases with the frequency of vibration, increased tissue viscosity (stiffness) and increased glottic/false cord constriction.[111, 113–115]

Normal values of **subglottic pressure** during habitual phonation are in the range of 0.5–1.0 KPa[32] and there is a positive correlation with intensity.[41] Subglottic pressure is potentially an important clinical value to measure as failure to generate an adequate, stable level can result in abnormal speech intensity levels or sudden shifts in the fundamental frequency.[116] An inadequate subglottic pressure can result from chest disease (lung parenchyma or thoracic wall), laryngeal disease or neuromuscular conditions that affect the laryngeal resistance (e.g. vocal fold palsy).[41] Excessive subglottal pressures are seen in hyperfunctional voice conditions when the voice is pressed and in adductor spasmodic dysphonia.[117, 118]

Unfortunately, subglottic pressure during phonation is not easy to measure. The most accurate direct method is to place a pressure-sensing device in the subglottis. This can be achieved by performing a percutaneous cricothyroid or tracheal puncture with a large-bore hypodermic needle and attaching it to a pressure transducer.[118] Alternatively, a very small-pressure transducer can be inserted via the nose and positioned directly in the subglottis.[32, 41] Both these direct methods are invasive and used only in research studies. An alternative, more practical clinical method is to estimate the subglottic pressure by measuring oral pressure during the production of a sound sequence such as /pi-pi-pi-pi-pi/ at a constant rate, pitch and loudness.[119] During the production of /p/, vocal folds are abducted and the peak intraoral pressure is essentially equal to that throughout the airway including the subglottis. An estimate of the average subglottal pressure during vowel production can be obtained by measuring pressure at the midpoint of a line connecting two successive pressure peaks.[107, 120] Care must, however, be taken in the interpretation and extrapolation of the results from this very specific speech task into connected speech.[115, 120]

Voice accumulators

'Voice accumulators' are wearable voice-monitoring systems which can provide reliable and objective measures of voice use during daily activities away from a clinic environment. They can potentially provide a better understanding of the role of daily voice use in the causation of voice disorders. Most contemporary devices are based on contact microphones or accelerometers placed at the base of the neck. Recording vocal fold activity rather than the voice allows a degree of privacy to the wearer and efficiency in post-acquisition processing.[121] This relatively new technology can provide data on the proportion of the time spent using the voice (phonation time), fundamental frequency, sound intensity measurements and potentially estimates of airflow.[122] They are used mainly as research tools at present.

Combined measurements

There is an intrinsic attraction in combining multiparameter measures of voice function to help discriminate between normal and pathological voices. Several schemes have been developed[123, 124] and, of these, the Dysphonia Severity Index (DSI) is probably the most widely used, especially in Europe.

DYSPHONIA SEVERITY INDEX

The DSI is a single quantitative measure that has been derived by multivariate analysis from 387 dysphonic subjects.[123] It is calculated by summing four weighted aerodynamic and acoustic factors as follows:

+ Maximum phonation time (seconds) × 0.13

+ highest frequency (F0) achievable (Hz) × 0.0053

− lowest intensity (dB) × 0.26

− jitter (%) × 1.18

+ 12.6 (correction factor)

= DSI score

In the original study a perceptually normal voice gives a maximum value of +5 while lesser values (to a maximum of −5) represent worsening degrees of dysphonia.[123] A more recent study suggests that +8 to −8 may be more practical.[125] A reduction of the DSI score by 2.5 is accepted as a clinically significant therapeutic outcome although this value has been challenged.[126, 127] The inverse DSI score has also been shown to correlate well with the VHI total score.[123] However, the component measures of the DSI may be prone to variability that may affect the stability of the DSI itself.[126, 127] There is some test–retest variability in normal subjects.[126, 127]

FUTURE DEVELOPMENTS IN VOICE MEASUREMENT

It is likely that laryngostroboscopy will remain the most useful clinical tool in the evaluation of voice disorders for the foreseeable future as the image quality continues to improve. Although currently expensive, the CCD

chip nasoendoscopes (videoscopes) overcome the main problem of poor image quality currently obtainable with many video fibre-optic systems. Patient self-rated questionnaires will remain an important determinant of patient's perception of the impact of the voice disorder (and therapeutic intervention) on their quality of life. Given the complexity of voice, the huge range of normality and 'normal' inter- and intrasubject variability, it is unlikely that any single acoustic, aerodynamic or other measure will be sensitive and specific enough to characterize a given type of voice disorder. It is hoped that advances will continue to be made in the use of analysis of connected speech and multiple combined measures which may lead to a better profile of the vocal capabilities of the individual. Understanding and measuring the variability in patients' voices with use and in different environments with voice accumulators may also allow better targeted treatment. The constraints of patient tolerance, clinical time and cost will also play an important part in determining which tests are acceptable in clinical practice. The patient's perception of their impairment, limitation in activity and participation restriction should remain the prime motivator for deciding on the need for treatment once serious laryngeal disease has been excluded.

KEY POINTS

- Speech, voice and phonation are terms with specific definitions.
- Abnormal vocal fold vibration results in dysphonia whilst an absence of vocal fold vibration results in aphonia.
- Normal voice production requires a pressure gradient across the vocal folds, appropriate vocal fold structure mass and elasticity and a resonating chamber of variable size and shape (the vocal tract).
- Health-related questionnaires (specific and generic), Perceptual Evaluation, Acoustic Analysis and Electrolaryngography are all used to measure voice quality.

SEARCH STRATEGY

Data in this chapter may be updated by Medline, Embase and the Cochrane Library searches using the keywords: voice disorders, vocal cords, structural, lesions, polyps, nodules, varices, haemorrhage, sulcus, cyst, inflammatory, reflux, muscle tension, dysphonia and Reinke's oedema. Unfortunately, there have been very few good quality, randomized, controlled studies in this area and most of the evidence is level 2–4.

INTRODUCTION

The larynx is a complex organ in the upper aerodigestive tract with multiple functions. Because of its location, any disease condition affecting the larynx may present with symptoms including hoarseness, breathing or swallowing difficulty and aspiration pneumonia; multiple symptoms are often seen. This chapter discusses a comprehensive approach to evaluation of the patient presenting with an altered voice.

ASSESSMENT AND EVALUATION

The assessment and evaluation of patient with voice disorder should ideally be done in a multidisciplinary clinic by a laryngologist and a speech therapist. A voice coach may be part of this team depending on the case mix in the clinic and if the clientele includes a large number of professional singers. This recommendation is not prescriptive but an example of best clinical practice.[1]

History

Assessment of a patient with laryngeal disorders should start with a detailed history. Often one may be able to establish the diagnosis from the history alone. The patient should be allowed to present his/her story in his/her own words without interruption at first. Some voice disorders are diagnosed entirely by listening to the patient's voice (spasmodic dysphonia, functional dysphonia) and after excluding other conditions by physical examination of the larynx.[2] There are different terminologies that the laryngologist may use in describing voice symptoms. These must be explained to the patient in simple terms. Examples of terminology used to describe voice symptoms are:

Dysphonia: Any impairment of the voice or difficulty speaking.
Dysarthria: Difficulty in articulating words, caused by impairment of the muscles used in speech.
Dysarthrophonia: Dysphonia in conjunction with dysarthria, for example after a cerebrovascular accident, head injury or part of a degenerative neurological condition, such as motor neurone disease.
Dysphasia: Impairment of the comprehension of spoken or written language (sensory dysphasia) or impairment of the expression by speech or writing (expressive dysphasia), especially when associated with brain injury.
Hoarseness: A perceived rough, harsh or breathy quality to the voice.
Odynophonia: Pain when talking.

Generally speaking, the term dysphonia is interchangeable with hoarseness but most patients understand the term husky voice better. Very often, the voice symptom is not just a single entity but a description of how the voice is perceived by the patient, or their impression of how other people perceive their voice. It is therefore useful to use self-administered questionnaires and perceptual rating of voice questionnaire to assess the voice. These tools will not only help the laryngologist understand the severity of

the voice problem but also help in measuring outcomes after treatment. Commonly used measures are:

- GRBAS – Grade, Roughness, Breathiness, Astenia and Strain[3] (**Box 63.1**)
- VoiSS – Voice Symptom Scale[4] (**Box 63.2**)
- VHI-10 – Voice Handicap Index[5] (**Box 63.3**)
- RSI – Reflux Symptom index[6] (**Box 63.4**).

A normal voice is difficult to define (see Chapter 62, Evaluation of the voice). Although we normally think of a disordered voice as one that is hoarse, this is not always the case. It may only cause problems when certain demands are placed upon it. A disordered voice can be defined as one that has one or more of the following characteristics:

- It is not audible, clear or stable in a wide range of acoustic settings.
- It is not appropriate for the gender and age of the speaker.
- It is not capable of fulfilling its linguistic and paralinguistic functions.
- It fatigues easily.
- It is associated with discomfort and pain on phonation.

Voice disorders are often multifactorial in aetiology and, to complicate matters, patients may develop compensatory vocal behaviours to be able to communicate effectively. This may mask the true underlying or primary disorder, such as muscle tension imbalance secondary to

BOX 63.1 GRBAS[3]

GRBAS is an acronym for five dimensions of voice quality referred to as 'Grade', 'Roughness', 'Breathiness', 'Asthenia' and 'Strain'. Speech and language therapists score their patients by giving a numerical value, i.e. an integer in the range 0–3, to each of these five dimensions of GRBAS.

BOX 63.2 VoiSS: Voice Symptom Scale[4]

VoiSS is suitable for general adult dysphonia populations.
Each item is scored 0–4 on the frequency response:
0 = never, 1 = occasionally, 2 = some of the time, 3 = most of the time, 4 = always

The **total VoiSS score (max = 120)** indicates the level of general voice pathology.

The **subscales** are completed by summation of items as follows:

Impairment: 1, 2, 4, 5, 6, 8, 9, 14, 16, 17, 20, 23, 24, 25, 27 (max = 60)

Emotional: 10, 13, 15, 18, 21, 28, 29, 30 (max = 32)

Physical: 3, 7, 11, 12, 19, 22, 26 (max = 28)

BOX 63.3 VHI-10 – Voice Handicap Index[5]

These are statements that many people have used to describe their voices and the effects of their voices on their lives. Ask the patient to circle the response that indicates how frequently they have the same experience:
0 = never, 1 = almost never, 2 = sometimes, 3 = almost always, 4 = always

1.	My voice makes it difficult for people to hear me.	0 1 2 3 4
2.	I run out of air when I talk.	0 1 2 3 4
3.	People have difficulty understanding me in a noisy room.	0 1 2 3 4
4.	The sound of my voice varies throughout the day.	0 1 2 3 4
5.	My family has difficulty hearing me when I call them.	0 1 2 3 4
6.	I use the phone less often than I would like to.	0 1 2 3 4
7.	I'm tense when talking to others because of my voice.	0 1 2 3 4
8.	I tend to avoid groups of people because of my voice.	0 1 2 3 4
9.	People seem irritated with my voice.	0 1 2 3 4
10.	People ask, 'What's wrong with your voice?'	0 1 2 3 4
	Total score	

BOX 63.4 Reflux Symptom Index[6]

Ask the patient to rate the following items on a scale of 0–5. The composite of these scores should be 10 or below. If it is more than 10, you should consider an evaluation to check for 'silent gastro-oesophageal reflux disease' or laryngopharyngeal reflux.
Within the past month, how did the following affect you?
0 = No problem → 5 = Severe problem

1.	Hoarseness or a problem with your voice	0 1 2 3 4 5
2.	Clearing your throat	0 1 2 3 4 5
3.	Excess throat mucous or postnasal drip	0 1 2 3 4 5
4.	Difficulty swallowing food, liquids or pills	0 1 2 3 4 5
5.	Coughing after you ate or after lying down	0 1 2 3 4 5
6.	Breathing difficulties or choking episodes	0 1 2 3 4 5
7.	Troublesome or annoying cough	0 1 2 3 4 5
8.	Sensations of something sticking in your throat	0 1 2 3 4 5
9.	Heartburn/chest pain/indigestion/stomach acid coming up	0 1 2 3 4 5

extraoesophageal (laryngopharyngeal) reflux. There are four main causes of voice disorders:

- inflammatory
- structural or neoplastic
- neuromuscular
- muscle tension imbalance.

Often, patients will have more than one condition contributing to their voice disorder. For example, a patient with vocal fold nodules may well have a degree of muscle tension imbalance and extraoesophageal reflux.

In assessing singers and other professional voice users, an understanding of their occupational and voice requirements is essential.[7–10]

In summary, it is important to determine:

- the nature and chronology of the voice problem
- exacerbating and relieving factors
- lifestyle, dietary and hydration issues[11]
- contributing medical conditions or the effects of their treatment
- the patient's voice use and requirements
- the impact on their quality of life, social and psychological well-being
- their expectations for outcome of the consultation and treatment.

Patients' complaints are most frequently related to:

- changes in voice quality (hoarseness, roughness and breathiness)
- a pitch that is increased or decreased which is not appropriate for their age and sex
- an inability to control their voice as required (pitch breaks, voice cutting out)
- an inability to raise the voice or make the voice heard in a noisy environment (reduced loudness)
- an increased effort and/or reduced stamina of the voice or one that tires with use
- difficulties or restrictions in the use of their voice at different times of the day or related to specific daily, social or work-related tasks
- a reduced ability to communicate effectively
- difficulty in singing
- throat-related symptoms (soreness, discomfort, aching, dryness, mucus), particularly related to voice use
- the consequent emotional, psychological effects caused by the above.

Many of the patient self-report questionnaires that have been developed to measure the impact of the voice problem on the quality of life are concerned with these areas of voice complaint.

Good examples of checklists for taking a detailed history in patients with voice disorders can be found in Mathieson[12] and Colton and Casper.[13]

General examination

The examination of a patient with a voice disorder should start with a general examination of the patient, as with any ENT disorder. Special attention should be given to the ears, nose and throat; for instance, the voice problem might be related to a blocked nose or sinus problems and can affect resonance and quality of the voice, as may be the case in professional voice users, or hearing loss causing the patient to strain their voice as they have to speak loudly to hear themselves.[14] The neck should be inspected for any scar that may indicate previous surgery or trauma, or neck masses, which will need a different sequence of investigations. A full neurological assessment might be necessary to assess the cranial nerve function or any signs of central neurological disease. The larynx is best examined with a videolaryngostroboscope, but this equipment may not be available at every centre.

VIDEOLARYNGOSTROBOSCOPY

Visual inspection of the larynx is mandatory for diagnosis or exclusion of laryngeal disease. This is usually performed in the clinic, but occasionally a diagnostic microlaryngoscopy needs to be performed when this cannot be tolerated in the outpatient setting or when the diagnosis is still uncertain (e.g. in some cases of chronic laryngitis).

The simplest method of examining the larynx and vocal folds is with a mirror.[7] Although excellent views can be obtained by an experienced examiner, the images are relatively small, of brief duration and frequently the anterior glottic region is not well visualized. In addition, the mucosal wave cannot be seen due to the relative speed of vibration of the vocal folds (usually over 100 cycles per second) compared with the ability of the retina to process individual images (five images per second).[8] Superior views of the larynx can generally be obtained using flexible fibre-optic and videoscopic transnasal endoscopes or rigid telescopes inserted through the mouth. Either approach has its own advantages and drawbacks. The transnasal flexible videolaryngostroboscope is associated with less gag reflex compared to the transoral rigid videostroboscopy. However, the rigid telescope may give a slightly better picture quality, although the distal tip high definition flexible videolaryngostroboscope provides images almost as good as those obtained on rigid videostroboscopy.[15] Occasionally both modalities may be helpful.[16] The examination should be recorded for further review if necessary.

Using a stroboscope gives additional information about the vibratory pattern of the vocal fold mucosa[17] and improves the accuracy of diagnosis.[18] It has led to changes in diagnosis in approximately 30% of cases when compared to examination with continuous light alone. Several rating forms for assessing the laryngostroboscopic images have been described, but none has been shown to have good inter- or intrarater reliability.[19] Although they are not used regularly in clinical practice, they are useful in ensuring that a systematic evaluation of the images is performed. The important features are listed in **Table 63.1**.

TABLE 63.1 Key features in the interpretation of laryngostroboscopic images

Laryngostroboscopic evaluation		
Glottal closure pattern	Anterior or posterior gap	
	Hourglass or spindle-shaped	
	Irregular or regular	
	Closed phase	absent/reduced/normal/prolonged
Mucosal wave (right/left) in response to changes in pitch and loudness	Symmetry	of amplitude
		of phase
	Periodicity (regularity)	regular/variable/irregular
	Degree of change	absent/decreased/increased
Description of lesion	Colour	
	Shape	
	Multiple/single	
	Surface	
Vocal fold opening/closing pattern (right/left)	Range full/reduced	
	Normal/lag	
	Presence of spasm/tremor	
Supraglottic appearance	False cords medial constriction: right/left/both	
	Anteroposterior constriction (arytenoid–epiglottic approximation)	
	Prominence/lesion(s)	
Symmetry of arytenoids (vocal processes and apices/corniculate cartilages)	Sagittal/coronal/axial planes	

Further assessment

If the diagnosis is not clear from the initial assessment, the patient may undergo one of the following options.

- further in-depth assessment by a voice therapist:
  - to ascertain more background information including exploration of contributing psychological issues
  - to undertake a probe or trial therapy to deconstrict the larynx and assess response to a treatment regime
- a trial of vocal hygiene/lifestyle advice or medical treatment
- laryngeal electromyography
- objective voice measurements (see Chapter 62, Evaluation of the voice).
- 24-hour pH monitoring ± impedance testing or oesophagoscopy
- diagnostic microlaryngoscopy
- referral to another voice disorders team or professional for a second opinion, such as a clinical psychologist, specialist singing teacher (familiar with voice problems in singers), neurologist, respiratory physician, gastroenterologist or upper gastrointestinal surgeon.

TREATMENT OVERVIEW

Ideally, the patient should be assessed in a multiprofessional voice clinic by a laryngologist and voice therapist and a joint treatment plan should be formulated. Not all patients presenting with a voice disorder want treatment and some may be happy being given a diagnosis, an explanation of their voice problem and reassurance that there is no serious underling condition present. If treatment is required, it will usually consist of one or more of the following options, depending on the patient's symptoms, vocal requirements and clinical findings:

- vocal hygiene, lifestyle and dietary advice
- voice (speech) therapy
- specialist therapy, e.g. singing therapy, osteopathy
- medical treatment
- phonosurgery.

Vocal hygiene, lifestyle and dietary advice

It is likely that most patients with a voice disorder will benefit from advice on vocal hygiene, lifestyle and diet. Depending on the relevance to the patient, this may consist of a discussion or video presentation in either individual or group sessions. Additional material is usually given in patient information leaflets. The areas covered may include:

- an explanation of how the voice works
- the links between lifestyle, phonatory and non-phonatory vocal activities and stress on voice disorders

- the potentially traumatic effects to the vocal folds of 'vocally abusive behaviours', such as talking or singing too loudly, talking too fast, shouting, throat clearing and harsh coughing
- communicating effectively without raising or straining the voice, e.g. using a whistle in the school playground or using amplification devices where practical and conserving the voice where possible or in extreme situations discussing the possibility of changing jobs
- the importance of adequate hydration for vocal fold function, i.e. by drinking water and use of steam inhalations, and avoiding excessive amounts of drinks containing caffeine, i.e. coffee, tea and colas
- smoking cessation, reducing alcohol and social drug consumption (particularly spirits, cannabis and cocaine) and avoiding exposure to fumes, dust and dry air
- diet and reflux reduction, e.g. avoiding eating late at night, large or fatty meals.
- For more details on these subjects, see Chapter 65, The professional voice, and Chapter 66, Speech/voice therapy for voice disorders.

Voice therapy

Voice therapy is the mainstay of treatment for muscle tension dysphonia (MTD) and may be delivered as an individual course of therapy, usually for no longer than eight sessions, or in groups. Examples of the latter include groups for voice care, professional voice users and for presbylaryngis.

The aims of voice therapy sessions are:

- to help the patient find a better voice quality which is stable, reliable and less effortful to produce
- to make better use of vocal resonance and tonal quality
- to increase the flexibility of the voice by improving the pitch range and loudness without undue effort
- to increase the stamina of the voice.

Various techniques are used, including one or more of the following:

- vocal exercises with the aim of targeting and strengthening specific muscle groups and improving glottal closure and efficiency
- increasing awareness of and reducing excessive tension in the muscles around the larynx, neck and shoulders
- advice on posture and improving breathing during speech
- laryngeal massage
- general relaxation exercises and stress management
- psychological counselling
- remedial singing lessons.

Some techniques may need additional specialist input from clinical psychologists, singing teachers and osteopaths, for example. Ideally, these individuals should be part of the extended voice disorders team (see Chapter 65, The professional voice, and Chapter 66, Speech/voice therapy for voice disorders, for more details).

Medical treatment

Medical treatment mainly includes treatment for acid reflux and upper respiratory tract infections and allergies. It may also include recommendations to change medication for other medical conditions, such as asthma inhalers, diuretics and other antihypertensive medication. The National Center for Voice and Speech has an excellent website which lists medications that can potentially cause an effect on the voice (http://www.ncvs.org/rx.html).[20] Botulinum toxin injections into the laryngeal muscles may be used in cases of spasmodic dysphonia and arytenoid granuloma.

Phonosurgery, including medialization procedures

Phonosurgery refers to any surgery designed primarily for the maintenance, restoration or enhancement of the voice.[21] It encompasses the following:

- phonomicrolaryngosopy
- injection laryngoplasty
- laryngeal framework surgery
- recurrent laryngeal nerve reinnervation
- laryngeal pacing.

More information can be obtained from Chapter 67, Phonosurgery, Chapter 54, Neurological disease of the pharynx, and Chapter 71, Contemporary management of laryngotracheal trauma.

PHONOMICROLARYNGOSCOPY SURGERY

A phonomicrolaryngoscopy is the examination of the larynx usually under general anaesthesia to further establish a diagnosis, but more importantly to surgically treat a pathology with the aim of improving voice. This is done with a suitable sized rigid laryngoscope. A good view is obtained by use of a microscope but inspection of the larynx with a 0- and 30-degree telescope is recommended. The larynx should be palpated too using crocodile laryngeal forceps. A sulcus or small cyst might be revealed which otherwise would not have without close inspection and palpation. The range of interventions includes biopsy and removal of lesions, vocal cord injection and laser surgery.

INJECTION LARYNGOPLASTY

This procedure aims to medialize an adductor vocal cord palsy where the cord is in a lateral position. There are different approaches and materials that can be used. The selection of injectable materials depends on the availability and the surgeon's experience. Most of the injectable materials are temporary and will only last an average of 6 months.[22] Injection laryngoplasty is discussed in greater detail in Chapter 78, Paralysis of the larynx, and Chapter 79, Outpatient laryngeal procedures.

LARYNGEAL FRAMEWORK SURGERY

Laryngeal framework surgery was first described by Isshiki in 1974.[23] It is defined as a procedure on the laryngeal cartilage to change the position or tension on the vocal cords in order to achieve the desired voice outcome. There are four different techniques, all with different purposes. These procedures should ideally be performed under local anaesthesia as originally described by Isshiki. This allows intra-operative auditory feedback to the surgeon and the patient and helps to assess the impact of the altered position of the vocal cords on the voice. Not every patient can tolerate a procedure under a local anaesthesia, however, and some patients may need general anaesthesia, but they will have the disadvantage of not knowing what their voice is going to sound like when they wake up! Further details on laryngeal framework surgery can be found in Chapter 78, Paralysis of the larynx.

RECURRENT LARYNGEAL NERVE REINNERVATION

The paralyzed vocal cord can be reinnervated to restore its function. The two techniques used are non-selective reinnervation and selective reinnervation.

Non-selective reinnervation

Non-selective reinnervation is indicated in hoarseness due to unilateral adductor vocal cord paralysis. It is performed under general anaesthesia via an ipsilateral neck incision at the level of the cricoid cartilage. The ansa cervicalis and the recurrent laryngeal nerve are identified and anastomosed using a 9/0 nylon suture.[24]

Selective reinnervation

Selective reinnervation is indicated in stridor due to bilateral abductor vocal cord paralysis.[25] It is performed under general anaesthesia via an extended anterior neck skin incision at the level of the cricoid cartilage. This is a more complex procedure that involves identification of several nerves for anastomosis. The C3 root of the phrenic nerve is identified on one side and anastomosed with a cable graft harvested from the great auricalar nerve in a Y-shape which is then inserted into both posterior cricoarytenoid muscles. The next step involves identification of the descending branch of the ansa hypoglossi and the recurrent laryngeal nerve on both sides of the neck and anastomoses carried out between these nerves bilaterally.

LARYNGEAL PACING

This technique is still being evaluated in clinical trials.[26] It involves inserting an electrode into each posterior cricoarytenoid muscle which then causes automatic abduction and adduction movement of the vocal cords. The electrode is connected to an external pacing device that is surgically fixed under the skin on the chest wall, in a similar way to a cardiac pacemaker.

SPECIFIC VOICE DISORDERS

The most common voice disorders seen in secondary practice in a voice clinic are:

- MTD
- laryngitis/MTD secondary to poor vocal hygiene, dietary and lifestyle issues
- extraoesophageal reflux (laryngopharyngeal reflux)
- vocal fold nodules
- vocal fold polyps
- vocal fold cysts
- vocal fold palsy and paresis
- arytenoid granulomas.

Less frequently seen conditions include:

- sulci and mucosal bridges
- spasmodic dysphonia
- papillomatosis
- microvascular lesions
- laryngeal trauma, including post-surgical causes
- other neuromuscular causes
- hyperkeratosis, dysplasia and carcinoma
- endocrine causes
- amyloid
- other laryngeal tumours.

Inflammatory disorders

OVERVIEW

Inflammation of the larynx can be broadly classified into infective and non-infective causes. Sometimes the aetiological factors are easily identified in the history (e.g. hoarseness associated with an upper respiratory tract infection). In many other cases the cause may be less clear (e.g. in cases of extraoesophageal reflux), may be multifactorial, may require empirical treatment or a biopsy and microbiological culture (e.g. in the case of tuberculosis) or may resolve spontaneously without a cause being identified. Patients often complain of:

- hoarseness
- huskiness
- reduced pitch
- loss of part of the range of the voice
- pitch instability
- an increased effort to speak
- vocal fatigue and pain or discomfort on speaking
- throat symptoms, such as globus sensation and irritation, dryness, throat clearing or chronic cough.

Laryngitis is simply a descriptive term indicating a variable degree of erythema, oedema, epithelial change which may include ulceration, leukoplakia and stiffness of the mucosa of the vocal fold. There is often an increased amount of thick mucus present, which may be white, grey, yellow or green in colour. There may be associated inflammation of the rest of the subglottic, supraglottic and interarytenoid

regions of the larynx and the pharynx. In severe cases, there may be associated shortness of breath and stridor. The voice is usually hoarse (rough, strained, breathy or whispery), which may be due to impaired vocal fold vibration due to stiffness from the inflammatory process and/or secondary to muscle tension imbalance. This can result in the vocal folds being held splinted apart and therefore extra effort being required to induce vocal fold vibration causing perilaryngeal pain or discomfort.

Accurate diagnosis may require a diagnostic microlaryngoscopy with biopsy. Treatment consists of reduced voice use and abuse, voice rest, vocal hygiene, lifestyle and dietary advice, and appropriate medical or surgical treatment.

SPECIFIC INFLAMMATORY CONDITIONS

Arytenoid granuloma

Arytenoid granulomas are benign inflammatory lesions that arise from the medial surface of the arytenoid cartilages, and in particular the vocal processes. Other terms for them include:

- contact ulcer or granuloma
- vocal process granuloma
- intubation granuloma
- contact pachydermia
- peptic granuloma.

These consist of a proliferation of granulation tissue with epithelial hyperplasia. They result from injury to the thin mucoperichondrium over the vocal processes from mechanical trauma, either following intubation or from repeated high-velocity impact of the vocal processes against each other from throat clearing, coughing or talking in a habitually low-pitched, creaky, hyperfunctional manner.[27] Men tend to develop granulomas secondary to hyperfunction, while women develop them more commonly as a result of intubation. In addition, extraoesophageal reflux is recognized as an important aetiological factor either contributing to the symptoms leading to the mechanical trauma or preventing healing of the damaged mucosa.[28]

Patients present with a change in the voice and/or vocal fatigue, a constant tickling sensation, discomfort or pain localized to the posterosuperior aspect of the larynx which is worse on phonation, coughing and throat clearing and can radiate to the ear. In addition, there may be symptoms associated with extraoesophageal reflux, including choking episodes and, in severe cases, stridor. These symptoms may come on insidiously, after intubation, an infection or a period of stress. They may be unilateral or bilateral and range from a nodular, diffuse thickening over the vocal process to large pedunculated, exophytic masses obscuring the posterior glottis (**Figure 63.1**).

The main treatment principles include reducing the effects of laryngeal irritants, i.e. stopping smoking, improving vocal hygiene, treating any respiratory tract infections, allergies and extraoesophageal reflux. Voice therapy, in terms of raising awareness of and reducing hyperfunctional and vocally abusive behaviour and psychological counselling where necessary, is also of use.[29] Surgery does not usually cure arytenoid granulomas when used in isolation as there is a high rate of recurrence. It is useful in confirming the diagnosis histologically, excluding a carcinoma and in debulking large lesions.[30] Laser vaporization after biopsy reduces the amount of bleeding but it is important to avoid thermal damage to the underlying cartilage.[28] There is no good evidence in support of the use of antibiotics or steroids in general. Botulinum toxin injections into the thyroarytenoid muscle can be useful as an adjunct treatment in resistant cases as this helps reduce the impact of vocal processes against each other, allowing the epithelium to heal.[31, 32]

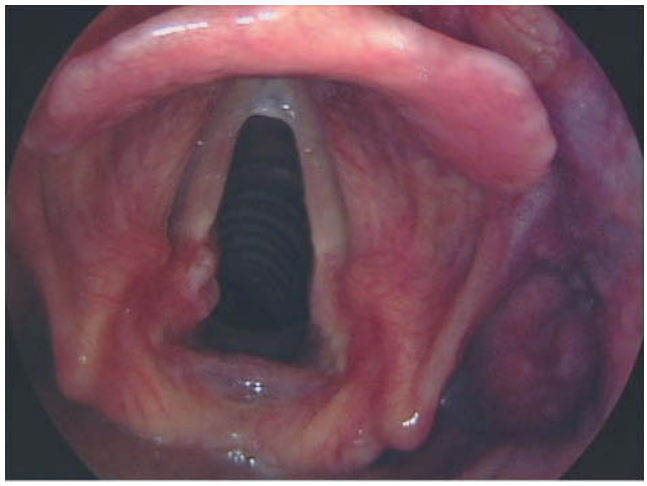

Figure 63.1 Arytenoid granuloma.

Structural or neoplastic lesions

OVERVIEW

Structural abnormalities can result from neoplasms which may be benign or malignant, or trauma to the laryngeal skeleton or soft tissues. Tumours of the larynx and laryngeal skeletal trauma are dealt with elsewhere in the text (see Chapter 14, Tumours of the larynx, and Chapter 71, Contemporary management of laryngotracheal trauma). This chapter will be confined to discussing the more common benign lesions resulting in referral to secondary care clinics and which involve the superficial layers of the vocal folds.

When a patient is observed to have a nodular swelling (i.e. a localized swelling on the membranous portion of one or both the vocal folds), it is important to consider the differential diagnosis in **Table 63.2**. Accurate diagnosis can be challenging and depends on a detailed history, the use of stroboscopy and, to some extent, objective measures.[33] Even then, a working diagnosis should be made and a decision needs to be made as to whether to try an empirical trial of therapy or proceed to a diagnostic microlaryngoscopy. A conservative approach is to reserve a 'microlaryngoscopy and proceed' for 'failed therapy' cases after appropriate informed consent.

TABLE 63.2 Differential diagnosis of a nodular lesion

Grey, white or translucent lesions	Haemorrhagic lesions	Yellowish lesions
True vocal nodules 'Physiological nodules' Prenodular swellings Pseudocyst Polyp Mucus retention cyst ± contact lesion Epidermoid cyst ± contact lesion Localized oedema of the vocal fold: • Reinke's oedema • Lower lip of a sulcus • Associated with a vascular abnormality, e.g. ectasia	Haemorrhagic polyp Ectasia Papilloma Carcinoma Arytenoid granuloma	Rheumatoid nodule Epidermoid cyst`

SPECIFIC STRUCTURAL OR NODULAR LESIONS

Vocal fold polyps

A true vocal polyp is a benign swelling of greater than 3 mm that arises from the free edge of the vocal fold (**Figure 63.2**).[34] It is usually solitary, but can occasionally affect both vocal cords. It is claimed that polyps are the most common structural abnormality that cause hoarseness and they affect men more than women. They are most frequently seen in smokers and between the ages of 30 and 50 years.

In many cases the exact cause of polyp formation is not known, but most authors agree that phonotrauma is an important aetiological factor. Some are heralded by a sudden onset of hoarseness or loss of voice after yelling or shouting, particularly if the vocal folds are inflamed from acute infective laryngitis or extraoesophageal reflux. A large proportion of patients with vocal cord polyps are also smokers. Cigarette smoking can cause injury to the vocal cord leading to hyaline degeneration in polyps.[35] There appears to be disruption to the vascular basement membrane, capillary proliferation, thrombosis, minute haemorrhage and fibrin exudation.[36] Although some polyps have a haemorrhagic appearance, others are more gelatinous and grey. Whether these gelatinous polyps have a different pathogenesis is not known.[34, 37]

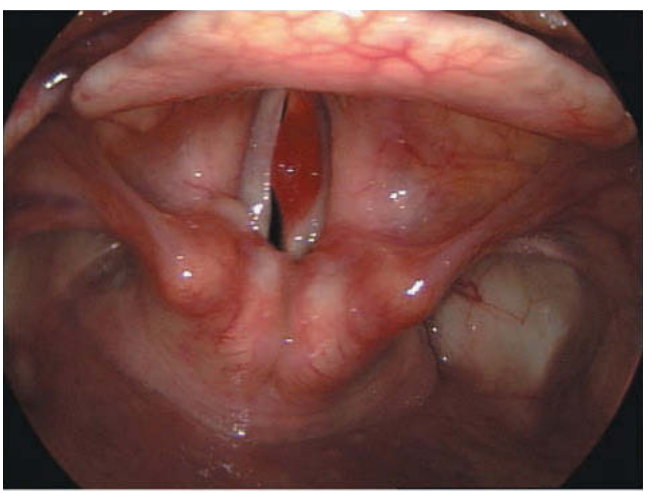

Figure 63.2 Vocal fold polyp.

Occasionally, a sulcus, mucosal bridge or intracordal cyst is found immediately opposite on the other vocal fold.[38, 39] It is hypothesized that in these cases the resulting disordered vibration and stiffness of the vocal fold make it more likely to damage the other vocal cord causing localized trauma and polyp formation.

Alteration in voice quality and voice complaints will depend on the effect of the mass of the polyp (and any other associated lesion) on vocal fold vibration, its effect on vocal fold closure and the secondary compensatory changes, i.e. increased muscle tension. The patient may complain that the voice is hoarse, has lowered in pitch and cuts out in speech, that they have lost part of the range of the voice and that it is a strain to speak.[40] Very rarely, large polyps can cause difficulty in breathing and episodes of choking.

Polyps can shrink spontaneously or even be coughed up. Voice therapy may provide the patient with coping strategies, preventative advice and help ease symptoms, but is unlikely to result in resolution of the polyp.[41] Any concomitant inflammatory conditions should be treated. Most polyps need removal under a general anaesthetic and a variety of techniques to achieve this have been described. This might be by using laser or cold steel suspension microlaryngoscopic technique (see Chapter 67, Phonosurgery).[42, 43] The aim is to restore the smooth edge of the vocal cord to allow them to close fully and vibrate normally.

Vocal fold nodules

Vocal fold nodules are small bilateral swellings (less than 3 mm in diameter) that develop on the free edge of the vocal fold at approximately the midmembranous portion (**Figure 63.3**). In some cases, particularly in singers, they may be smaller, more pointed and white in colour, reflecting a more superficial response to trauma. They may be associated with microwebs at the anterior commissure in up to 23% of cases. They are of variable size and are characterized histologically by thickening of the epithelium with a variable degree of underlying inflammation.

The exact incidence and prevalence of nodules in the general population is not known, but in various population studies nodules have been shown to be the cause of

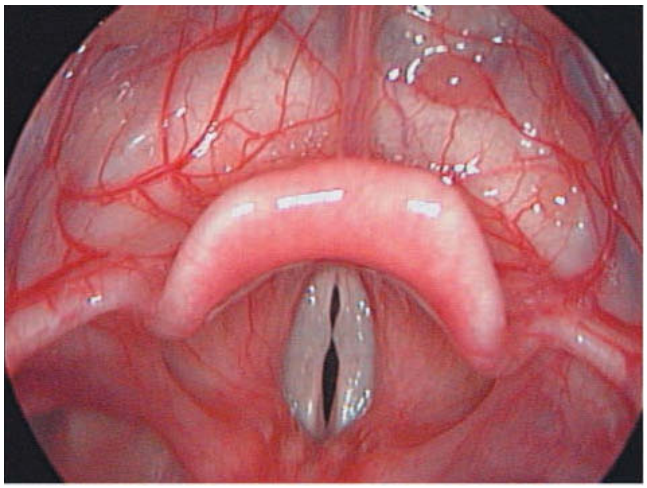

Figure 63.3 Vocal fold nodules.

persistent hoarseness in just under 25% of children and in 6% of adults with voice problems.[44] Higher percentages are found in teachers and singers with voice problems. In children, they are more common in boys than in girls, while in adults they are very much more commonly found in women, particularly under the age of 30.

The aetiology of vocal nodules is not known, but traditionally they are thought to be due to 'voice abuse' rather than overuse. Voice abuse is characterized by forced voice production due to strain in the neck and shoulder region producing a harsh quality to the voice.[45] It may be precipitated by talking for prolonged periods in a loud voice (often above background noise), repeated shouting and/or singing above one's natural range and occasionally repeated coughing and throat clearing. The vocal folds are thought to impact on each other in such a way that the repeated trauma of the midmembranous portions leads to localized swelling and epithelial thickening. Shearing forces may be important and a whiplash hypothesis has also been proposed.[46] Psychological factors, nasal, throat and chest infections, allergies and extraoesophageal reflux are increasingly being recognized as playing an important part in the aetiology of vocal nodules.[46–49] Nodules disappear spontaneously in boys with the relatively large growth of the larynx in puberty.[44] In girls, they may persist into early adulthood.

The voice quality is often husky and breathy, worsening with voice use and often associated with perilaryngeal discomfort or throat soreness on phonation. The voice may become a little deeper in pitch and associated with voice breaks, particularly at the higher end of the range of the voice. The vocal folds are usually hourglass in appearance with often only the nodules making contact at the midmembranous zone.

There is no good evidence on which to base the treatment of vocal fold nodules. Nodules may develop after the individual has been projecting and using their voice more than usual and often settle spontaneously once the demand on the voice returns to 'normal'. If nodules are not causing significant voice problems, they should be left alone. Aggravating factors, such as inadequate vocal fold lubrication, allergies, infections and extraoesophageal reflux, should be treated to reduce their irritant effects. In the UK, the mainstay of treatment for persistent vocal nodules is voice therapy with the aim of modification of lifestyle and vocal behaviour, providing information and guidance on voice care, producing the voice more effectively with less strain and coping strategies. Not infrequently the voice and voice function improves, but the nodules persist. Some argue that complete and rapid return of voice function is only possible if the nodules are excised. Others would reserve surgery for those who fail voice therapy and remain symptomatic. Most would agree that a significant number of nodules recur if surgery is performed without voice therapy either pre- or post-operatively.[50] If surgery is performed, the aim must be precise excision of the nodule alone with no exposure or damage to the underlying ligament.[43, 51]

Pseudocysts

The exact definition of a pseudocyst varies between authors. Some define it as a lesion that differs from cysts and polyps in that it has no cyst wall and is filled with serous fluid, having an appearance similar to that of a blister. Others have defined it as localized Reinke's oedema, which may indicate the presence of underlying paresis.[52] The exact aetiology is not known, but is probably phonotrauma. The initial management of a pseudocyst is by behavioural therapy. Surgical excision might be necessary in cases that did not resolved with speech therapy.[53]

Reinke's oedema

Reinke's oedema is a term used to describe the vocal folds when they become chronically and irreversibly swollen (**Figure 63.4**). Other terms for the condition include:

- polypoid vocal cord, polypoid degeneration or polypoid hypertrophy; cordal polyposis or polypoid corditis
- chronic oedema of vocal folds
- pseudomyxoma or pseudomyxomatous laryngitis
- smoker's larynx.

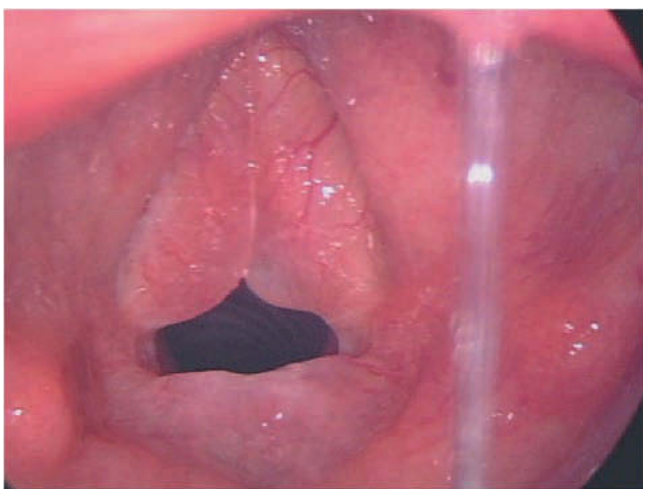

Figure 63.4 Grade 4 Reinke's oedema.

It occurs almost exclusively in moderate to heavy smokers, although the exact role of smoking in inducing these changes is not known.[54] Some studies have also suggested that voice strain and extraoesophageal reflux may also play a part in its development, although the importance of these other factors is not clear. Hypothyroidism may be found as a concomitant feature in some cases, but it is not thought to be an aetiological factor. The epithelium shows non-specific changes and the basement membrane layer is usually thickened. In Reinke's space, there are lakes of oedema, extravasated erythrocytes and thickening of the walls of the subepithelial vessels.

The true prevalence of Reinke's oedema is unknown. It is probably one of the most common conditions to affect the vocal folds in smokers and it is very likely that many people with this condition do not seek medical attention. A meta-analysis of 1538 cases showed that men and women are affected more or less equally, although the pitch-lowering effects on the voice are more conspicuous in women. Patients most commonly seek a medical opinion between the ages of 40 and 60 years of age.

Patients with even quite severe Reinke's oedema may have no complaints about their voice or problems with voice use. The most common symptoms are:

- deepening of the pitch of the voice with women often being mistaken for a man, particularly on the telephone
- gruffness of the voice
- effortful speaking
- an inability to raise the pitch of the voice
- choking episodes
- other symptoms associated with extraoesophageal reflux.

The diffuse lesions of the membranous part of the vocal fold are bilateral in 62–85% of cases, although they may be asymmetrical. Typically the vocal folds are grey or yellowish in colour with prominent superficial vessels. Alternatively, the oedematous folds may appear diffusely red when coexistent extraoesophageal reflux should be suspected. Leukoplakia is uncommon but may be due to hyperplasia, dysplasia or very rarely carcinoma in situ. In severe cases the vocal folds look like bags of fluid that flop up and down through the glottis with respiration. The severity of the swelling is best judged on deep inspiration and is frequently underestimated if an assessment is made solely on phonation as the oedematous tissue bunches up on the superior surface and into the ventricle. A severity grading system has been proposed and validated by Tan et al. (**Table 63.3**).[55] There may be a variable degree of associated increased muscle tension present.

The decision to treat a patient with Reinke's oedema depends on their symptoms, the severity of the oedema and the presence of leukoplakia. In most cases, conservative measures, such as reassurance, an explanation of their condition and vocal hygiene advice, including smoking cessation, should be tried initially. Hypothyroidism, upper airway infections and allergies and extraoesophageal reflux should be treated to reduce the throat symptoms associated with these conditions. The role of voice therapy is controversial but may be indicated if vocal hygiene issues and excessive MTD are prominent in a well-motivated patient. It certainly has a role in restoring voice function after surgical treatment.

TABLE 63.3 Grading of Reinke's oedema

Grade	Appearance
1	Marginal edge oedema
2	Obvious sessile swelling, thrown over vocalis muscle during phonation
3	Large bag-like swelling, filled with fluid
4	Partially obstructing lesion, medial borders in contact along most of length

Surgical treatment should be considered when:

- leukoplakia is present and a histological diagnosis is required
- gross Reinke's oedema is present causing choking episodes or airway compromise
- pitch elevation of the voice is the main requirement of treatment.

Other symptoms may not necessarily be helped by surgery and there is the potential for making patients worse by causing scarring or an irregular edge to the vocal fold. Patients must be aware that after surgery:

- friends and relatives may not recognize them by their voice
- the singing voice may be permanently altered
- speaking may be more effortful for up to 1 year (or occasionally permanently), particularly if excessive mucosa is removed due to stiffness from scarring and anterior web formation
- the voice seldom returns to 'normal', but is generally of better quality
- the Reinke's oedema is likely to return within 2 years if the patient continues to smoke.[56]

The principles of surgery for Reinke's oedema include:

- reducing the bulk of the mucosa (mass per unit length) of the vocal fold
- obtaining a straight mucosal edge, i.e. avoiding leaving small deposits of the myxoematous material behind
- avoiding damage to and exposure of the underlying ligament, thereby reducing the chances of scarring and web formation.

'Reduction glottoplasties' can be performed with phonosurgical instruments or one of the new generation of microspot lasers. KTP laser treatment of Reinke's oedema may be performed in the outpatient department under local anaesthesic via a channelled endoscope.[57] Care should be taken not to remove excised epithelium and not to overheat the vocal cord ligament as this may result in a permanent scar and hoarseness.[58] The myxoematous

material from the superficial lamina propria layer is aspirated, removed with forceps or vaporized and the epithelial edges apposed following excision of redundant mucosa as necessary. Good results from unilateral treatment have been reported with patients often electing not to have further surgery on the second side. Post-operative voice therapy may be required.

Endocrine causes

Hyperthyroidism has been associated with increased anxiety, hoarseness and tremor affecting the voice. The vocal folds have been reported as looking 'hypervascularized and hyperkinetic'. Hypothyroidism is associated with:

- hoarseness
- deepening of the pitch of the voice
- voice fatigue and weakness
- dryness of the throat
- slow and hesitant speech.

Small prevalence studies have not shown an increase in prevalence of biochemical hypothyroidism in patients with Reinke's oedema, but one uncontrolled study suggested that subclinical hypothyroidism may be more prevalent. Although the vocal folds are often described as being oedematous in hypothyroidism, there is little histological evidence to support myxoedematous infiltration of the vocal folds or muscles.

Abnormalities of endocrine function, in particular related to the thyroid and sex hormones, can have varied effects on the voice and voice function. Most have not been studied in great detail and are beyond the scope of this chapter. Of note are the effects of androgens and androgenic drugs, such as Danazol, which cause irreversible enlargement of the female larynx with the consequent effects of deepening of pitch. The fundamental frequency of the voice is lowered and the high tones lost at the menopause.[59]

Autoimmune diseases of the larynx

Laryngeal manifestions of autoimmune diseases are not uncommon and have been described previously. Examples are cricoarytenoid fixation, mucous inflammation, subglottic stenosis, vasculitis, laryngeal edema, vocal fold paralysis, infection, or vocal fold lesions such as vocal fold rheumatoid nodules and bamboo nodes.[60–63]

Bamboo nodes

Bamboo nodes are round pale yellowish lesions found in the mid third of the membranous vocal cord (**Figure 63.5**). It is because of their appearance that they are called bamboo nodes. These patients usually present with hoarseness. A blood test to exclude autoimmune diseases is mandatory if the patient is not already diagnosed with an autoimmune disease. Examples of autoimmune conditions associated with bamboo nodes are rheumatoid arthritis, systemic lupus erythromatous (SLE), Sjögren's syndrome, Hashimoto thyroiditis and systemic sclerosis. The blood test may reveal elevations in the sedimentation rate, rheumatoid factor, Sjögren's antibodies and antinuclear antibody titres, as well as hypergammaglobulinemia.

Figure 63.5 Bamboo nodes.

The diagnosis of a bamboo node is made from history and clinical examination. A videolaryngostroboscopy is essential to examine the vocal cords and the mucosal wave. This will give an indication of the effect of the node on the vocal cord vibration.

Conservative management is by speech therapy. A systemic steroid may be helpful but patients may not tolerate long-term treatment due to the side effects.

Steroid injection may be necessary in cases that have failed to respond to conservative management alone. This should not be given more than three times a year so as not to develop atrophy of the vocal cord.

Resistant cases may need phonosurgical excision of the nodes. Care should be taken not to damage the vocal ligament, which can lead to a permanent scar and hoarse voice. For this reason, this type of surgery should be done under a high microscopic magnification during a suspension microlaryngosocopy.[64, 65]

Cysts, sulci, mucosal bridges and vergeture

Cysts are found less frequently than polyps and nodules, and sulci and mucosal bridges even less so. There are two primary types of cyst: a mucus retention cyst and an epidermoid cyst. Both cause the voice to be constantly hoarse, which may worsen with use, with varying degrees of roughness and breathiness depending on the interference with vocal fold vibration and closure. Part of the vocal singing range may be affected, with pitch breaks or cutting out altogether.

A mucus retention cyst (**Figure 63.6**) is thought to arise from a blocked minor salivary gland, possibly secondary to phonotrauma or inflammation. It is lined by cuboidal or low columnar epithelium and can be associated with oedema and fibrosis in Reinke's space. It is usually unilateral and is found on the free edge of the vocal fold or

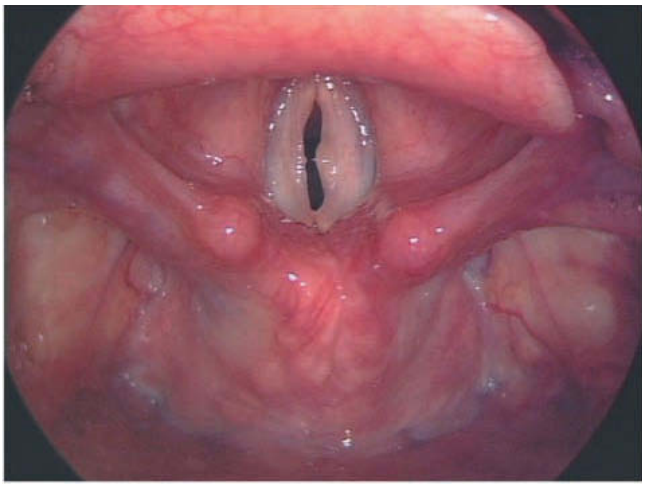

Figure 63.6 Mucus retention cyst.

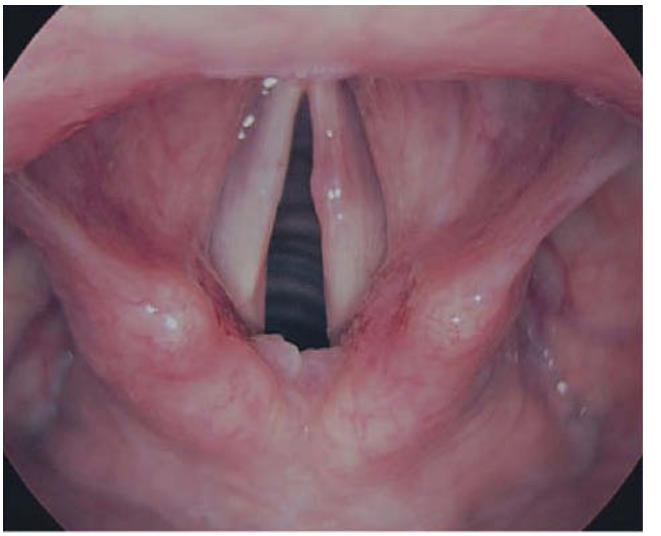

Figure 63.7 Epidermoid cyst.

can arise in the ventricular fold (false cord) (**Figure 63.6**). In the vocal fold they should be suspected in cases of asymmetrical nodular swellings (cyst plus contact nodule) and can be difficult to distinguish from polyps on laryngoscopy. Stroboscopy can help in the differential diagnosis, but frequently a definitive diagnosis can only be made on microlaryngoscopy and by performing a cordotomy.

Ventricular cysts need to be differentiated from other tumours (see Chapter 14, Tumours of the larynx). They can affect the voice by prolapsing on to the vocal fold interfering with vibration and causing secondary hyperfunction.

Epidermoid cysts (**Figure 63.7**) are lined by squamous epithelium and are filled with keratin and cholesterol debris. There is often an inflammatory exudate in the surrounding Reinke's space. It is unclear how these cysts develop, but various theories have been proposed including a metaplasia in a long-standing mucus retention cyst, microinclusion of epithelium from surface trauma or some defect in epithelialization during development (congenital or dysembryoplastic theory). They are thought to arise as a result of voice abuse and misuse. Large cysts cause a yellowish/white bulge within the vocal fold, but smaller, deeper cysts may only be suspected by the presence of localized absence or reduction in the mucosal wave on stroboscopy or abnormal blood vessels over the cyst or the appearance of unilateral or bilateral chronic laryngitis. The diagnosis may only be confirmed at microlaryngoscopy and cordotomy in these cases.

The term 'sulcus' has been used to describe different entities in the literature. Two entities can be distinguished: sulcus vocalis and mucosal bridge.

- A **sulcus vocalis** is best used to describe a localized invagination of the mucosa of varying depth[66] (**Figure 63.8**). These may be described as 'open cysts', which may describe their aetiology. The justification for this is that they are commonly found in association with epidermoid cysts and it would seem logical that trauma to the neck of a cyst would lead to it widening and discharging its contents.

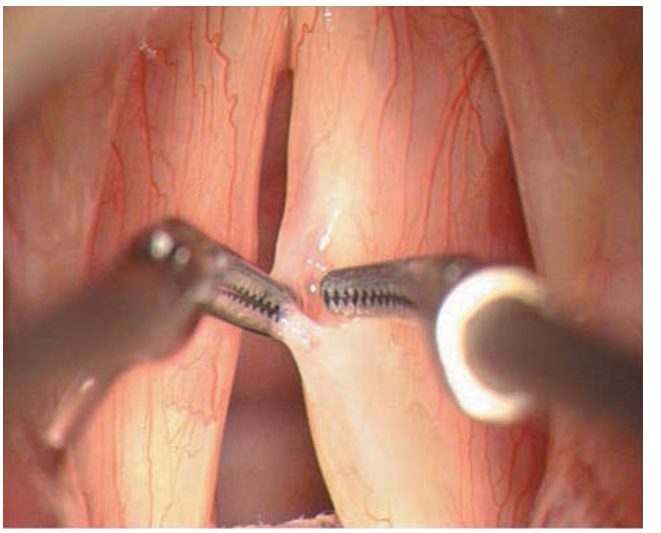

Figure 63.8 Sulcus vocalis. (With thanks to Romain Perouse.)

- Sulcus vocalis has been classified into three types:
  - **Type 1: Physiologic sulcus.** This is a superficial longitudinal depression of the epithelium not beyond the superficial lamina propria. The vocal ligament is not involved. Videolaryngostroboscopy may only show mild mucosal wave abnormally and the voice is not affected significantly. Treatment for this should be conservative with speech therapy and sometimes antireflux medication.
  - **Type 2a: Sulcus vergeture** (**Figure 63.9**). This is more extensive invagination extending into the vocal ligament with some loss of superficial lamina propria. Reinke's space exists superolaterally and inferomedially to the vergeture. They are thought to result from a congenital failure of development of Reinke's space as they are commonly apparent at puberty and can be familial. There is moderate mucosal abnormality on videolaryngostrobostoscopy and may have moderate dysphonia.

Figure 63.9 Sulcus vergeture.

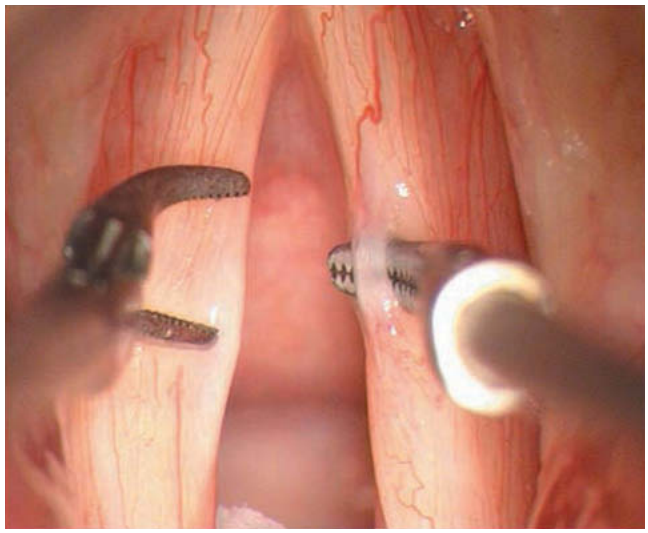

Figure 63.10 Mucosal bridge. (With thanks to Romain Perouse.)

- **Type 2b: Classic sulcus vocalis or a pouch type.** This is characterized by a focal pit that extends beyond the vocal ligament into the thyroarytenoid muscle. The is marked loss of superficial lamina propria. Video laryngostroboscopy shows significant mucosal wave abnormality with loss of vibratory pattern and patient may present with severe dysphonia.

- A **mucosal bridge** (**Figure 63.10**) may also be found in the presence of sulci and epidermoid cysts. This rare finding is thought to arise by the rupture through of the deep aspects of two sulci or cysts to form a tubed pedicle of mucosa.

Patients with sulcus vocalis and mucosal bridges present with variable degrees of dysphonia and roughness and breathiness, depending on the number of lesions, position and depth of the sulcus, the effect on glottal closure and degree of associated inflammation and MTD. Patients with sulcus vergeture often have a high-pitched monotone, weak (aesthenic), breathy and strained voice which is an effort to produce.

Patients with vocal fold cysts should be given a trial of voice therapy, particularly when symptoms are relatively mild. Many will require surgery but this must be done precisely, preserving the overlying mucosa as much as possible. It is important to avoid leaving part of the wall behind, which will result in a recurrence or cause localized scarring and poor voice results. This is more so for mucus retention cysts as dissection of the thin wall is more difficult. Post-operative voice therapy helps patients to restore vocal function and improvement may continue for up to 9 months. There may occasionally be problems with glottal closure following excision of large cysts and fat or collagen medialization may be of benefit. Ventricular fold cysts should be removed to confirm the diagnosis. There is the potential that they can cause airway obstruction if large or they become infected. Complete sharp dissection of the cyst with microlaryngoscopy instruments or with the laser is the treatment of choice.

The treatment of both types of sulci is difficult and the results variable. If surgical treatment is required for sulcus vocalis, careful dissection of the pocket off the ligament is required. The difficulty is in defining the plane between the base of the sulcus and the ligament and avoiding excessive resection of the mucosa and damage to the ligament.[67] Sulcus vergeture may be best treated by bilateral medialization procedures rather than attempted resection of the vergeture, which is technically extremely difficult.[68]

The ongoing challenge in the management of sulcus is that no single treatment modality is superior to others and no sufficient evidence for matching a given treatment to a given patient is yet available.[69]

Laryngeal hyperkeratosis

Laryngeal keratosis is an inflammatory disease of the epithelium of the vocal cords due to chronic hyperplasia and hyperkeratosis of the laryngeal mucosa with the resultant hyperkeratosis of the vocal cord epithelium. The aetiology is non-specific but it may have association with smoking, alcohol and reflux. The predominant symptom is hoarseness.[70]

The appearance is of white plaques, which can be confluent or patchy (**Figure 63.11**). Often the terminology is interchangeable with leukoplakia. *Leukoplakia* is a Greek word for a white plaque that cannot be simply scraped off. A histological diagnosis is mandatory to exclude neoplasia or dysplastic lesion. Laryngeal hyperkeratosis may appear easy to excise but laryngologists know that this condition is notorious for recurrence.

The management is by suspension microlaryngoscopy and surgical excision for histology. This condition may be precancerous, hence a biopsy is required. However, the treatment should be a conservative surgical approach to improve or maintain voice. Cold steel and laser therapy have been used but there is anecdotal evidence that an angiolytic laser such as the KTP laser offers longer-term cure.

Figure 63.11 Laryngeal hyperkeratosis

Ackermann's tumour (verrucous carcinoma)

Ackermann's tumour is a slow-growing variant of squamous cell carcinoma that does not metastasize. It can cause a diagnostic and treatment challenge for both the histopathologist and the otolaryngologist. Macroscopically it may be hard to distinguish from hyperkeratosis. It has a typical exophytic appearance (**Figure 63.12**).

Although radical treatment such as laryngectomy is not necessary, a complete endoscopic excision is recommended to prevent recurrence. This tumour is less radiosensitive than others but extensive tumours may be treated with radiotherapy instead of radical surgery.

Figure 63.12 Ackermann's tumour (verrucous carcinoma).

Microvascular lesions

Microvascular lesions (varices or capillary ectasias) are collections of abnormally large and weakened vessels that are most commonly found (83%) on the superior or medial aspect of the midmembranous portion of the vocal folds (**Figure 63.13**). They are most frequently seen in professional vocalists (including singers) and are thought to arise secondary to repetitive trauma, hormonal variations or repeated inflammation. They may occasionally be incidental findings but can result in vocal fold haemorrhage, scarring and polyp formation. The lesions can interfere with the vibratory pattern of the vocal folds, causing a lack of clarity of the voice, vocal fatigue or sudden dysphonia associated with haemorrhage.

Voice and singing therapy, treatment of associated inflammation and occasional precise vaporization or point diathermy of the feeding vessel(s) may be required. Recurrences may still occur after treatment.[71]

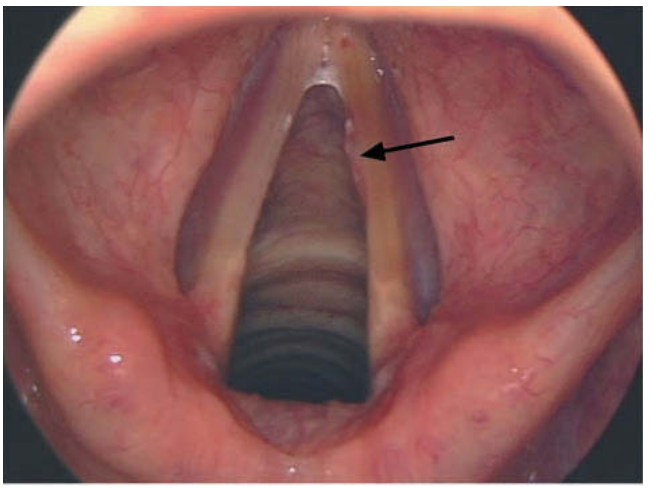

Figure 63.13 Microvascular lesions (arrow).

Neuromuscular causes

Neuromuscular causes are considered in detail in Chapter 54, Neurological disease of the pharynx. Apart from a vocal fold palsy, they are relatively uncommon. The prevalence of vocal fold paresis in dysphonic patients is unknown, but appears to be higher than previously thought if monopolar needle electrodes are used to detect the condition.[72] A palsy or paresis should be considered in any case where the complaint is of effortful phonation, throat discomfort or vocal fatigue with use or where the voice 'cracks'. Perceptually, the voice may sound breathy, unstable or higher in pitch. An obvious laryngeal paresis will show asymmetry of movement on abduction and adduction, i.e. it 'lags behind' the normal side. This asymmetry may only be apparent on prolonged observation using a fibre-optic endoscope and asking the patient to phonate and then sniff repeatedly. More subtle signs are an asymmetry of phase and amplitude of the mucosal wave and apparent bowing on the affected side on stroboscopy.

An effect on the voice may be the first sign of a more general neuromuscular disorder, such as Parkinson's disease, motor neurone disease, multiple sclerosis and myasthenia gravis. Neuromuscular disorders should always be considered in patients where the vocal folds look normal but the pattern does not fit with an MTD or fails to respond to treatment or the dysphonia worsens.

Spasmodic dysphonia is an uncommon and frequently overlooked condition. Traditionally it is classified as adductor, abductor, mixed and tremor and respiratory forms, although further subtypes have been described.[72–74] The adductor form is characterized by a strained/strangled quality to the voice, which cuts out at the onset of phonation, while the rare abductor type (approximately 15%) is characterized by breathy breaks following consonant sounds.[72, 75] Some patients present with a whispery (compensated voice) that is easier for them to use in conversation. Others have a mixed form that becomes more obvious during treatment, as the untreated form often worsens or is complicated by tremor. The spasmodic laryngeal activity can be seen by careful observation with a fibre-optic endoscope during speech.

The mainstay of symptomatic treatment remains botulinum toxin injection into specific intralaryngeal muscles, although the results are not always predictable and poorer for those with the abductor form and those with tremor.[72, 76–79] Improvements in outcome in the future may come with better targeting of the involved muscles. Other surgical treatments for adductor spasmodic dysphonia are now available. These are Isshiki thyroplasty type 2 using a titanium bridge implant to separate the anterior commissure by a few millimeters.[80, 81] Selective laryngeal adductor denervation–reinnervation surgery (SLAD–R),[82, 83] CO_2 laser thyroarytenoid myoneurectomy.[84, 85]

Muscle tension dysphonia or 'functional dysphonia'

OVERVIEW

Muscle tension imbalance causing MTD is one of the biggest causes or contributors to voice disorders. Although it is often a 'diagnosis of exclusion', i.e. the 'the vocal folds look and move normally', it is often present with inflammatory, structural and neurological conditions as laryngeal muscles try to overcome a deficiency in the voice-producing mechanism, such as poor respiratory function, impairment of normal vocal fold vibration or nasal blockage affecting resonance.[86] In addition, MTD can lead to trauma and structural changes in the vocal fold mucosa, for example in some cases of nodules. It is for the laryngologist and voice therapist to agree a treatment plan with the patient in these more complex cases.

MTD is therefore a group of conditions characterized by an imbalance of the synergist and antagonist muscles affecting the vocal fold position and tensioning relative to one another and also the position of the larynx relative to the rest of the vocal tract (**Figure 63.14**). Usually one or more sets of muscles is hyperfunctional, giving recognizable patterns of clinical presentation and laryngeal appearance.[87, 88] It is now thought that previously described hypofunctional states either are 'end stages' of hyperfunctional laryngeal activity or represent an underlying paresis.[89] The hypotheses are:

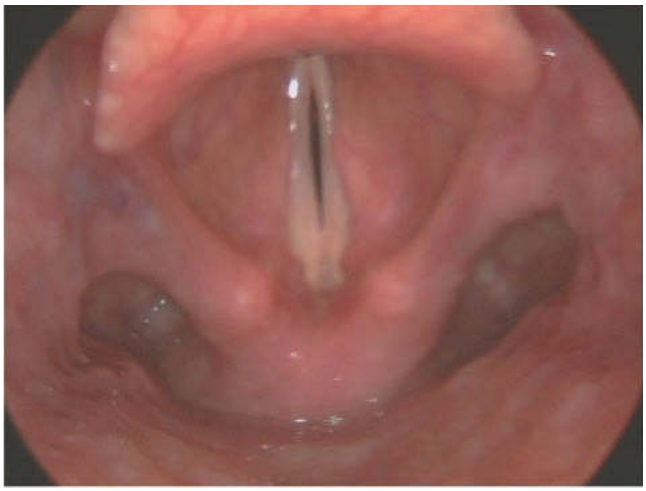

Figure 63.14 Muscle tension dysphonia. This is just one of the many patterns of muscle tension seen.

- that chronic imbalance of muscle pull, for example, of the cricothyroid muscle can lead to irreversible joint damage and ligament stretching giving a flaccid bowed appearance to the vocal folds
- that a viral neuropathic paresis has developed causing hypotrophy of the thyroarytenoid muscle and consequent poor glottal contact and secondary compensatory hyperfunction.[90] The evidence to support this comes from electromyographic studies.[72]

True hypofunctional cases do exist in neurological conditions such as myasthenia gravis, Parkinson's disease and motor neurone disease, but they are relatively uncommon.

There are multiple primary aetiologies of MTD[7, 29, 88] including:

- stress, anxiety and depression
- conversion disorders
- postural and breathing problems
- poor vocal hygiene
- talking in poor acoustic environments or above background noise for prolonged periods at work or socially
- exposure to excessive environmental dust, smoke or fumes.

The degree of dysphonia is variable, ranging from an intermittent problem related to a particular voice task (e.g. teaching) to severe and constant hoarseness. Other symptoms include:

- pitch of the voice may be too high or too low and reduced in range
- a sensation of tightness, constriction or lump in the throat
- effortful voice production
- discomfort on speaking or singing
- vocal fatigue.

The variability in the voice quality may be apparent during the consultation or with probe voice therapy. The laryngeal patterns on laryngoscopy have been classified into six main groups,[91] although some of these features may also be seen in the normal population.[92] Palpable increased tension and often tenderness in the suprahyoid, thyrohyoid and cricothyroid muscles may also be found, although these findings are not always consistent.[91, 93, 94]

Treatment, if required, consists of identifying precipitating causes and treating as appropriate, such as:

- vocal hygiene, dietary and lifestyle advice[29]
- voice therapy targeted at specific muscle groups[95]
- laryngeal manipulation[96]
- behavioural therapy[97]
- medical treatment, e.g. of extraoesophageal reflux.

SPECIFIC MUSCLE TENSION DYSPHONIAS

Puberphonia 'adolescent transitional voice disorder' or 'mutational falsetto'

Normally at puberty the voice drops by an octave in boys, but only three to four semitones in girls. In boys, the transition takes 18 months to 3 years and is usually completed by the age of 14. This voice change in puberty is accompanied by pitch instability and register breaks. The voice appears to be too high in pitch for the individual's age and sex and is often described as 'never broken'. The voice is often momentarily deeper on non-phonatory tasks, such as laughing or coughing and this is a key indicator of the condition. Even if it is recognized that the individual has 'two voices', i.e. higher and lower pitched, the latter is not perceived, as their voice is abnormal so consequently not used. The voice can tire and be effortful to produce on shouting or when projected. Occasionally, some patients experience pain and discomfort in the supralaryngeal region due to the elevated position of the larynx. There is often some associated psychological distress as the boys are frequently ridiculed and taunted because of their abnormal voice and inferred effeminacy.

As part of the normal pubertal changes, the total length of a boy's vocal cords increases by as much as 60%, reaching 17–23 mm in the bass voice with a relative increase in the ratio of the membranous and cartilaginous parts of the vocal cord. The thyroid cartilage virtually doubles in size and the dimensions of all other aspects of the laryngeal anatomy increase proportionally. The epiglottis changes from an omega shape to a more flattened shape. It also increases in size and elevates. The mucosal lining of the vocal cord becomes stronger and thicker. The cricothyroid muscle increases in bulk and strength to enable the thyroid cartilage to tilt forward for head or falsetto voice.

In puberphonia, the larynx tends to be held high in the neck, thereby shortening the vocal tract.[97] The cricoid cartilage is usually tilted backwards and the vocal folds remain too lax and limited in their ability to adjust to demands in change in tension and vibrational frequency. The vocal folds are stretched and thin with minimal mucosal waves. The cricothyroid remains excessively contracted. Acoustic analysis shows a speaking fundamental within the normal female range, intensity and harmonics-to-noise ratios within normal limits and a reduced contact quotient on electrolaryngography.

It is important to exclude organic conditions, such as endocrinological abnormalities, vergeture and scarring. Although most who present are keen to improve their voice, those who attend at the behest of family and friends and who are not concerned by their voice generally have a poor prognosis regarding resolution.

The treatment of choice is voice therapy,[97–99] although occasionally botulinum toxin injections into the cricothyroid muscles have been shown to be effective in resistant cases. Relaxation thyroplasty type 3 may be indicated in cases that failed speech therapy.[100]

Presbylaryngis

The ageing voice has certain characteristics.[101, 102] In males, the mean fundamental frequency tends to rise after the age of 50 and the voice is often perceived as high-pitched, thin and reedy in old age. In women, the mean fundamental frequency tends to decrease with age. Voice change may be related to the general fitness, voice use and previous training of the individual. The changes are related to ossification of the laryngeal skeleton, arthritic changes in the cricothyroid and cricoarytenoid joints, reduced muscle volume with a preferential loss of type I (slow contracting) muscle fibres, an increase in density of collagen deposition and decreased hyaluronic acid in the lamina propria, associated with a reduction in fibroblasts and atrophic changes in the epithelial layer. The net effect is stiffened, bowed, atrophic-looking vocal folds.[103] Other factors that will affect voice quality are laryngeal position, vocal tract atrophic changes and loss of lung capacity. Patients may just require an explanation of their voice problem and be happy with the exclusion of malignancy. If treatment is indicated, vocal care and voice therapy with the aim of building up the laryngeal musculature and improving vocal control are most usually offered.[104–106] Injection medialization procedures using fat, hydroxylapatite[107] or bilateral (modified) thyroplasties have been used with good effect, although the results with fat are less predictable.

BEST CLINICAL PRACTICE

- ✓ Best clinical practice is achieved by accurate clinical diagnosis with high-quality imaging techniques and having a patient-focused approach, taking into consideration their vocal requirements and concerns.
- ✓ A multiprofessional team approach allows cost-efficient, multidimensional assessment and targeted planning and delivery of treatment.

FUTURE RESEARCH

- There is a real need for multicentre studies to determine the best treatment options for almost all aspects of voice disorders.
- Fundamental questions need to be answered as to the role of inflammation, in particular extraoesophageal reflux and paresis in the aetiology of voice disorders.
- The management of sulcus vocalis and vocal cord scars remains a dilemma. Often the diagnosis is difficult in the outpatient setting and numerous cases are either misdiagnosed or missed completely as result. There is a need for a collaborative study on what is the best approach to diagnosis and management of this rare but not uncommon condition.

KEY POINTS

When assessing a patient, it is important to consider the following questions.

- Which one or more of the following four conditions is present?
  - inflammatory causes
  - structural or neoplastic causes
  - neuromuscular causes
  - muscle tension imbalance (dysphonia).
- Is there any suspicion of a malignant or premalignant condition?
- Which is/are the predominant condition(s) causing the symptoms related to the voice complaints? For example, the treatment of extraoesophageal reflux may be more effective in relieving the patient's symptoms in Reinke's oedema than surgical debulking.
- Which is or was the primary condition and which are secondary or compensatory? The symptoms and signs of a secondary MTD may mask the presence of an underlying paresis, for example.
- Will treating the 'easily treatable factors' improve the patient symptoms enough to either reverse structural laryngeal changes or improve the laryngeal biomechanics sufficiently for adequate functional voice production, i.e. the voice may not be perfect, but they can live with it?
- Could the potential complications of an intervention, particularly surgical treatment, create more problems than they help?

SEARCH STRATEGY

The information in this chapter can be explored more extensively by undertaking a Medline using the following keywords: functional dysphonia, non-organic dysphonia, muscle tension dysphonia, psychogenic dysphonia, vocal misuse and vocal strain.

INTRODUCTION

A functional voice disorder applies to an alteration of voice quality where there is no structural or neurological laryngeal pathology or where the dysphonia is disproportionate to the pathology detected. Nomenclature is problematic in this area and there are many synonymous and similar diagnostic labels in use, including (most commonly) 'functional dysphonia' and 'non-organic dysphonia'. These terms are generic and indicate characteristics of a syndrome rather than a specific diagnosis. Several key authors have defined several subcategories which more accurately reflect the underlying pathogenesis[1–4] and these will be discussed below. Functional disorders of the voice represent by far the commonest presentation to voice clinicians, accounting for at least 50 000 new cases per year in the UK.[5, 6] The impact of this condition is considerable: it is known to affect communication in all contexts, and is related to impaired personal and work relationships, low self-esteem and reduced quality of life.[6–8] In addition, people with functional dysphonia also suffer from increased levels of anxiety, depression and poor general health.[6, 9, 10]

It is also important to note that there is an overlap between 'organic' and 'functional' voice disorders and that they do not represent dichotomous disorders.[11] A number of benign vocal pathologies (e.g. vocal nodules, oedema of the lamina propria, contact granulations) are attributable to vocal hyperfunction, voice misuse and poor voice technique.[12, 13] Similarly, aberrant phonatory physiology viewed on endoscopic examination (e.g. bowing of the vocal folds, supraglottic constriction) may also be a consequence of vocal hyperfunction and poor technique.[12, 13]

THEORETICAL PERSPECTIVES

Most contemporary authors have accepted that functional disorders of the voice might usefully be divided into two different subcategories: 'muscle tension' dysphonia and 'psychogenic' dysphonia.

- **Muscle tension dysphonia (MTD)** is primarily the result of vocal misuse or poor vocal technique.[1, 2] In these cases, psychological factors are considered negligible or secondary. Furthermore, Morrison and Rammage[4] describe different types of MTD (based on endoscopic appearance) but with the understanding that they all arise from laryngeal muscle tension during phonation. They further suggest that psychological factors are important only insofar as they influence autonomic arousal.
- **Psychogenic dysphonia** is marked by loss of vocal control associated with 'disturbed psychological processes' (such as stressful life events at onset, anxiety or depression and actual conversion).[2] Some authors[1] consider psychogenic dysphonia as an example of classical (Freudian) conversion. Butcher et al[1] detail three types of psychogenic conversion dysphonia:
  - **type 1:** classical hysterical conversion dysphonia
  - **type 2:** cognitive behavioural conversion

- **type 3:** 'habituated conversion', in which the suppressed conflicts of a cognitive behavioural conversion have been largely resolved, but the vocal symptoms and musculoskeletal tension persist as a matter of habit.

It is a common clinical experience to see a mixed picture where some elements of both muscle tension and psychogenic dysphonia combine to make a function voice disorder which is complex to treat.[4] It is also recognized that the relative contribution of these factors may change for a patient over time.

PATHOGENESIS OF FUNCTIONAL DYSPHONIA

There are several ways to consider the pathogenesis of functional voice disorders.

One approach is to consider the 'voice capability' curve model. It is possible to conceive that the voice capabilities of the whole population would provide a Gaussian (normal) distribution (**Figure 64.1**).

Most speakers would fall into the blue area where their voice capabilities are average but perfectly adequate for their personal, occupational and social needs. A smaller number of the population are likely to have exceptional vocal capabilities (red area). These individuals are likely to have the following attributes:

- maximally flexible and responsive laryngeal structures – this will result in quasi-periodic vocal fold vibration with good amplitude and will produce an extensive dynamic range of both frequency and amplitude[14]
- patent oral, nasal, pharyngeal and laryngeal cavities and an ability to manipulate their relative dimensions to resonate the different harmonics of the sound source signal[34, 40, 43] – this will result in a voice which is appropriate 'timbre' and will facilitate good voice projection[15]
- excellent control of pulmonary function to 'excite' vocal fold vibration at the minimal phonation threshold and to maintain consistent transglottal airflow through different vocal tasks[16]

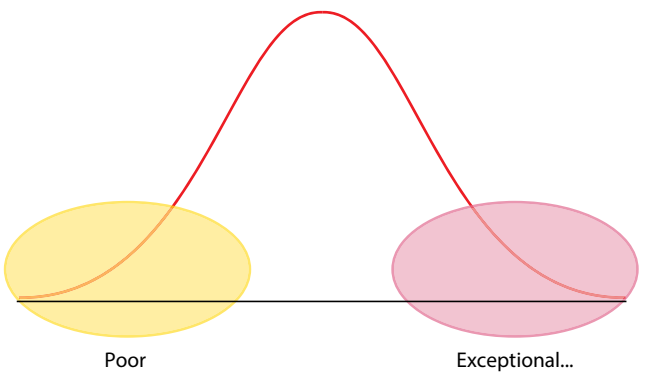

Figure 64.1 Voice capability.

- superior vocal technique (coordination of the first three attributes above) enabling smooth transition between different modalities of voicing and different vocal tasks without undue deterioration or fatigue[17]
- excellent paralinguistic features (speech rhythm, speed and vocal intonation) (see Chapter 60, Voice and speech production)
- superior auditory skills to constantly monitor vocal output, to maximize vocal effect and to detect any adverse voice quality changes.

Conversely, some speakers will have poor vocal capability and, hypothetically, these patients are more vulnerable to developing a functional or muscle tension disorder of the voice. These speakers are likely to have the following attributes:

- inflexible laryngeal structures with restricted vibratory amplitude and a limited dynamic range for both frequency and amplitude
- limited natural vocal resonance
- poor coordination of airflow for voice production
- limited awareness of vocal technique or ability to adapt vocalization depending on the task
- poor paralinguistic features
- limited auditory skills and auditory awareness of their own vocal characteristics.

It follows that people with limited vocal skills and capability are more likely to develop voice problems. This may be especially true if they experience a period of ill health, adverse life events or large vocal demands, for example. These additional factors are explored more fully below.

The more common approach to understanding the pathogenesis of functional voice disorders is to describe a constellation of predisposing, precipitating and perpetuating risk factors.[13, 18, 19] A recent review[19] stated that these multiple etiological factors can be categorized into three subgroups: vocal misuse and abuse, psychological and/or personality factors,[10, 20] and compensatory vocal habits for underlying laryngopharyngeal infection or disease. Similarly, other authors[13, 18] have identified four central tenants of MTD: gastro-oesophageal reflux, high personal stress levels, excessive voice use, and excessive vocal loudness demands. Clearly, not all of these factors need to be present in every case, and the relative contribution of each factor will vary between patients. Therefore, while the exact nomenclature may vary, it is common to conceive MTD schematically, as shown in **Figure 64.2**. It is important to note that previous authors have not discussed auditory skills in their explanatory models of functional dysphonia.

Deary[21] provides valuable further insight into these predisposing, precipitating and perpetuating factors and compares them to similar findings in other clinical areas of medically unexplained symptoms. He concludes that functional dysphonia appears to bear 'a striking resemblance to other medically unexplained conditions in terms of what

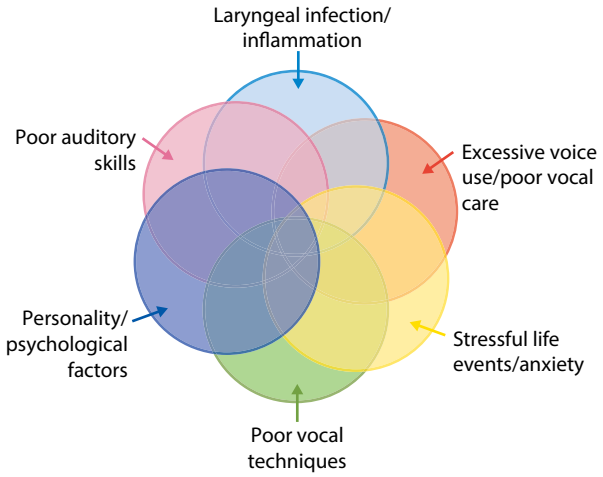

Figure 64.2 Predisposing, precipitating and perpetuating factors in functional dysphonia.

starts, triggers and maintains it'. Furthermore, he suggests a patient profile which is likely to increase the susceptibility for functional dysphonia.[21] This profile includes:

- a vocally demanding occupation[22]
- an abusive childhood[7]
- a 'distress-prone' and/or neurotic personality[23]
- a 'perfectionist' personality[24]
- a series of life events prior to onset[25]
- a history of fatigue.[24]

The literature would suggest that high vocal demand remains the most significant 'risk' factor for functional dysphonia. There are many studies that indicate the high prevalence of professional voice users among voice clinic attendees.[18, 26] While some authors remain entranced by the Freudian notion that the lack of voice has symbolic significance,[1–3] it is more likely that the voice is simply the vulnerable point (due to excessive demand) that breaks first in a person who is generally stressed and unwell.[21]

In conclusion, functional dysphonia is a diagnosis by exclusion (of pathology). However, it is a generic term that requires further investigation and analysis. A full understanding of the nature of an individual's functional voice disorder can only be determined by a detailed and comprehensive case history and interview. Appreciating the relative balance of the predisposing, precipitating and perpetuating factors for any one individual is paramount to successful treatment.

TREATMENT

There is strong evidence that voice therapy by a specialist speech and language therapist is a highly effective treatment for functional dysphonia. The objectives of voice therapy for this condition are twofold: to return the patient's voice to normal (or best possible voice within their anatomical and physiological capabilities) and to satisfy the patient's occupational, social and emotional vocal needs.[12, 27, 28] Voice therapy generally consists of a combination of indirect and direct therapy approaches. Direct therapy involves specific, targeted exercises to control and coordinate the various aspects of the vocal system.[28–34] Indirect voice therapy concentrates on helping the patient manage the contributory and maintaining aspects of the voice disorder and includes patient education, voice care advice, stress management and general relaxation.[28–34] **Table 64.1** lists typical direct and indirect voice therapy techniques for functional dysphonia.

A Cochrane review in 2009,[5] which reviewed articles up to 2007, stated that there was good evidence of the benefits of voice therapy for patients with functional dysphonia (six studies met their inclusion criteria; (total n = 163, controls = 141). Only randomly controlled studies that included patient-reported outcome measures (PROMs) were selected for detailed review. Three studies support a combination of direct and indirect voice therapy, and there is some evidence that indirect therapy alone is effective for particular patients.[5] A further review published in 2011[46] describes additional strong evidence for voice therapy intervention for functional dysphonia as well as an acknowledgment of the need to measure outcome from a multidimensional perspective. A number of recent treatment effectiveness studies have published details of voice therapy content.[47–52]

While traditional voice therapy has been shown to significantly improve the voice, there is limited evidence to date of any effect of this approach on the more general well-being of patients.[6] This has led many commentators in the field of functional dysphonia[1, 12, 27, 38, 41] to call for broader issues to be addressed in the treatment of these patients. Given the level of distress that some patients experience, professional psychological interventions may be necessary to augment existing treatment.[21] Roy suggests that, if the key predisposing, precipitating or perpetuating features of the functional dysphonia are not addressed, then relapse is a likely consequence.[41] Several recent studies[44, 45] report promising findings from CBT-enhanced voice therapy effectiveness studies. Treating the distress, along with the voice, could lead to more general and lasting improvement in patients. However, large longitudinal studies are required to examine these complex issues.

TABLE 64.1 Direct and Indirect voice therapy techniques

Direct	Indirect
Yawn–sigh method[31]	Vocal rest[32, 39]
Chewing technique[32, 42]	Patient education[32, 39]
Vocal function exercises[33]	Reassurance and counselling[42]
Airflow therapy[34]	Vocal hygiene programme[32, 38]
Resonance therapy[35]	Auditory training[31]
Deconstriction therapy[36, 37]	Elimination of voice abuse[31, 42]
Easy vocal onset techniques[36, 37]	Vocal diary[31]
Pitch variation and control[34, 39]	Avoidance of laryngeal irritants[39]
Confidential voice therapy[38, 42]	Hierarchy analysis[32]
Accent voice therapy[40]	Voice conservation[32, 39]
Voice skills therapy[17]	General relaxation[39]
Laryngeal manipulation[41, 42]	
CBT-enhanced voice therapy[44, 45]	

KEY POINTS

Functional dysphonia represents the most common presentation of functional disorders to voice clinicians

- There are several subcategories of Functional dysphonia including muscle tension dysphonia and psychogenic dysphonia.
- Functional dysphonia is not dichotomous from organic dysphonia (some untreated functional voice disorder may result in benign organic pathology)
- One way to understand the pathogenesis of functional voice disorder is to consider the voice capability curve model.
- There are a number of predisposing, precipitating and perpetuating factors in functional voice disorders.

INTRODUCTION

What is the professional voice? A broad range of professions are reliant on their voices to conduct their work including teachers, telephonists, telesales workers, lawyers and many others. This chapter concentrates specifically on individuals who rely on their voices, speaking and singing, for performance at either a professional or an amateur level. For a clinician, it can be flattering to be asked to see a famous performer in the voice clinic but it is important to remember that the same standard of professional service is demanded for all patients, whether they are a primary school teacher or a top professional singer in a West End musical.

PARTICULAR PRESSURES AND DEMANDS ON PERFORMERS

Singers, actors and other performers work in an extremely competitive world. An inexperienced performer may feel considerable pressure to take on a role that is outside his or her range, or that places vocal demands beyond where they are comfortable. The hours of rehearsal are often extensive and it is not unusual for there to be up to eight performances in a week, but performers are reluctant to complain about such working conditions. Indeed, performers often continue to use their voices for long periods after they have developed vocal problems, which can compound their vocal pathology as a consequence. The reluctance to consult a laryngologist is exacerbated by a stigma about vocal ill health, in which the performer worries that they will not be given further work if it is perceived that they are 'fragile'.

The members of the voice clinic should be sensitive to all of these demands and the emotional stress that goes alongside them.

HISTORY

Vocal performers are often exquisitely sensitive about subtle changes in their voices and will be able to pinpoint very precisely the nature of their problem. The consultation should start with an open question allowing the patient to explain their difficulties.

The **style of singing** undertaken can have a profound effect on the ability of a performer to sustain their vocal instrument: singing in the musical theatre style, for example, has a tendency to be very vocally demanding, with a high 'closed quotient' (the vocal folds being closed for a large proportion of the vibratory cycle). The same can be said of many styles of rock and pop singing. In the popular music genre, there is the additional problem of the Lombard effect, i.e. the tendency to increase vocal

intensity in response to increased background noise. In the absence of any auditory feedback, singers tend to oversing and generate ever more strained patterns of laryngeal muscle usage.[1]

A change in **repertoire** can have a great impact: it is not unusual, for example, for singing students to be required to change their repertoire from one college term to the next. A change of repertoire requires a change in the set-up of the laryngeal musculature and can lead to vocal problems.

The extent of **vocal training** is an important factor. It is surprising how many young performers have relatively little training and are thrown into rehearsal and performance schedules without adequate preparation. This is particularly true for amateur and semi-professional performers.

Some performing roles require **specific vocal demands**. This might include foreign accents, shouting or other vocal effects. If these gestures are unfamiliar to the performer, or if they are to be sustained for a whole performance, they can lead to unhelpful muscle tension patterns and even vocal fold phonotrauma.

MAINTAINING VOCAL HEALTH

Most performers are aware of the importance of warming up their voices. Warm-up regimes vary from performer to performer, but the aim is to prepare the voice for the performance to follow. For many, this will involve humming exercises, sirening (a glissando sliding of the voice from low to high) and singing scales and arpeggios. These warm-ups should not (at least initially) be performed at full vocal intensity. The aim, as with an athlete warming up before a race, is to encourage blood flow to the muscles, and to encourage flexibility in the muscles and other structures of the vocal tract. The application of good 'vocal hygiene' is of paramount importance.

PSYCHOLOGICAL ISSUES AND PERFORMANCE ANXIETY

Psychological issues are often a major factor in the vocal problems of professional performers. Major life events such as relationship difficulties, bereavement and changes in circumstances can have a profound impact on the patient's psychological well-being, and their vocal problems may be a subtle manifestation of this sort of strain. Delicate and tactful questioning is required to elucidate these factors, without suggesting that the problems are 'all in the mind' of the patient.

Performance anxiety can become a major barrier for singers and actors. For some, the heightened autonomic arousal can act positively but, for others, it can be very destructive. Some performers will require specific counselling and psychotherapeutic interventions to overcome such barriers. Beta-blockers have been used by musicians and athletes to prevent tremor but they have no beneficial effects on the voice and their use should be avoided in vocal performers.[2]

LIFESTYLE ISSUES

Much of the performer's working lifestyle revolves around late nights, meals late in the evening, and much travelling. All of these can lead to fatigue and, particularly the late meals, can exacerbate any problems with laryngopharyngeal reflux.

Frequent flights will have their own effects: the ambient noise in aircraft means that it is often necessary to raise the voice to be heard; performers frequently report that air conditioning has a 'drying' effect on the larynx, so adequate hydration when flying is important; and the closed environment of the cabin allows for easy spread of viral upper respiratory tract infections.[3]

In addition to their performing and travelling activities, social lifestyle factors can exacerbate a performer's problems. Young performers in particular think little of socializing several nights each week. Noisy restaurants and clubs place considerable demands on the voice that can significantly hinder the performer's ability to perform to the best of their abilities.

THE VOICE CLINIC

A professional voice user would expect – indeed, would often demand – to be seen in a clinic with a full range of equipment for diagnosis, which should include a stroboscope. A detailed discussion of assessment of the larynx can be found in Chapter 61, Assessment and examination of the larynx.

It is important that the patient has confidence in the voice clinic they are attending. It is not unusual for laryngologists themselves to have experience of performing, and this allows for a conversation in which the patient feels that the clinician has an insight into the demands placed on them. The use of musical terminology relating to vocal registers and styles will put the patient at their ease and will help the clinician to understand the patient's current problems.

It is common for voice clinics to employ a singing teacher in addition to a laryngologist and a speech therapist. Some clinics also use a psychotherapist and/or a physical therapist.

Voice evaluation

It is often the case that the normal conversational spoken voice in a vocal professional will be unaffected. As discussed above, the vocal professional will more frequently present with subtle problems relating to a certain aspect of their performing voice. It may therefore be useful to ask the patient to demonstrate the particular vocal difficulties they are experiencing by performing part of a song or speech that they find particularly problematic. Detailed evaluation in terms of objective acoustic analysis

(e.g. jitter, shimmer, noise-to-harmonic ratio) is less frequently required.

Physical examination

Palpation of the neck will reveal any neck masses or lymphadenopathy. It will also highlight any muscular tension or tenderness.

Stroboscopic examination of the vocal folds is mandatory: it is only with the benefit of high-quality videostroboscopic equipment that one will gain sufficient detail of the mucosal surfaces of the vocal folds to be able to exclude subtle pathology. Fibre-optic and mirror examination of the larynx are no longer acceptable modes of examination in vocal professionals.

Stroboscopic examination can be performed either with a rigid endoscope (70 degree or 90 degree) or with a chip-tip (distal-chip) flexible endoscope. The details of stroboscopy are discussed in Chapter 61, Assessment and examination of the larynx, but it is worth bearing in mind the biomechanics of examination in each situation. Rigid endoscopy requires the patient's neck to be slightly extended, and for the tongue to be protruded. The endoscope can then be advanced over the tongue and the vocal folds can be examined. Needless to say, this is a very 'unphysiological' position in which to be phonating. In general, it is only possible to elicit an 'ee' vowel in this position. By contrast, with the chip-tip endoscope passed through the nose, the performer can sing and speak almost as normal. A wide variety of vocal gestures can be performed, including those specific gestures that are causing the performance problems. This is particularly helpful when muscle tension is believed to be a feature. On the other hand, the images achieved with the distal-chip flexible endoscopes are not quite as good as the rigid views. Different vocal problems may call for different examination techniques, or sometimes both.

Feedback

A crucial part of the consultation with a vocal professional is the explanation of the findings. It is imperative to take time to explain the laryngeal images, so the patient can understand (and engage with) the plan of management.

SURGERY ON THE VOCAL TRACT

Surgery on the vocal folds themselves is described in Chapter 67, Phonosurgery. One aspect that must not be overlooked is that surgery on any part of the vocal tract can have a large impact on the voice. Changing the resonance chamber of the pharynx (by, for example, performing a tonsillectomy) can result in a change in the patient's voice. This is true also of nasal surgery or adenoidectomy.

Performers requiring surgery of other sorts should outline their profession to the anaesthetist: if possible, surgery should be performed using a laryngeal mask airway so as to avoid any trauma to the vocal folds.

ACUTE ILLNESS

Performers live in dread of developing an upper respiratory tract infection at any time, but particularly during a run of performances. It is important to differentiate between an upper respiratory infection with or without laryngeal involvement. An upper respiratory infection can be managed conservatively with adequate hydration and steam inhalations. If there is laryngeal involvement, particularly hyperaemia of the vocal folds, then ideally the performance should be cancelled. In certain circumstances where the performance is a career make-or-break situation, steroids may have a role to play but the risk is that they could lead to a vocal fold haemorrhage. Aspirin is also associated with vocal fold haemorrhage via its action on the platelets and should be avoided at all times by the professional voice user.[4]

Cancelling a performance can have serious consequences, both financial and professional, and it is recommended that full records of the consultation and examination, including stroboscopic images, be documented for reference.

MANAGEMENT

It is self-evident that the management of the patient will be governed by the pathology (or lack of it) found in the examination. However, other factors will come into play, and a selection of scenarios may help to illustrate and expand on this.

Performing arts student

A 22-year-old student at a performing arts academy is having problems with her voice. She is a music theatre singer, and typically becomes hoarse after a few performances. When she rests her voice for a few days, her voice returns, but she runs into similar difficulties when she starts another run of shows. She usually has to sing in one show each day for a week at a time. Examination shows soft vocal fold nodules in the usual locations.

- In this situation, one must explain that vocal fold nodules will often resolve with speech and language therapy and with the assistance of a good singing teacher.

Consider the same student again. She is now 25 years old and is having similar difficulties to those she experienced 3 years previously. She has seen two laryngologists in recent years, and has had extensive speech therapy and voice coaching. Despite this, she is having the same problems of vocal fatigue and inability to complete a run of shows. In fact, she now becomes fatigued after just five performances.

- This is now a difficult situation. She appears to have instituted all the necessary changes, and is still not able to perform to the required standard. Of particular concern is that she is not, at the moment, being required to

perform as frequently as a full-time performing professional: if she were in a professional cast, she would be expected to perform up to twice per day for 5 or more days per week. The clinician should have a frank discussion with her about this, and consider either surgical excision of her nodules or a change in her performing regime/style.

Professional opera singer

A 27-year-old professional opera singer asks for an urgent consultation: he has a performance tonight, but was having difficulties during last night's performance, and his voice has not 'felt right' today. The performance tonight is the last one for several weeks. There is no problem with his speaking voice and there are no other features in the history of concern. Examination shows mildly oedematous vocal folds but no focal pathology, and no evidence of hyperaemia.

- Given that tonight's performance is his last for some time, and that there is no evidence of vocal fold haemorrhage or hypervascularity, it would probably be reasonable to consider a single dose of a corticosteroid to help to reduce some of the laryngeal inflammation. It would be important to review the patient in the days after the performance to ensure that the inflammation has settled.

Rock singer

A 26-year-old rock singer is in the middle of a tour of the UK. After last night's concert, he was markedly hoarse and he has requested an urgent laryngeal evaluation. He has a further 15 shows to perform in the next 3 weeks, and his management team accompany him to his consultation. They are extremely keen to avoid cancelling any shows. Stroboscopic examination shows haemorrhage of the left vocal fold, with blood tracking under the whole length of the mucosal surface.

- You are duty-bound to advise absolute voice rest and that the remaining shows are cancelled. Vocal fold haemorrhage of this type can be catastrophic for a performer, and it is imperative that the voice is rested to attempt to avoid the formation of scar tissue.

KEY POINTS

- Vocal performers should be considered as 'athletes', with very specific professional demands.
- A detailed history is required, focusing on the specific vocal difficulties and whether there is any variability in the symptoms.
- A multidisciplinary approach in a voice clinic is essential, using the expertise of a laryngologist, a speech therapist and a singing teacher/voice coach.
- In addition to a discussion about the difficulties with the performing voice, the history should cover other aspects such as social voice usage and nights out.
- Stroboscopy (either rigid or via a chip-tip endoscope) is mandatory in the vocal professional. Video archiving is imperative.

Data in this chapter are based on searches of the Medline, CINAHL, PubMed and Cochrane Library databases using the keywords: dysphonia, voice disorder, voice therapy.

INTRODUCTION

'Voice therapy' is used to describe speech and language therapy for voice disorders. This intervention is provided by clinicians who are called speech and language therapists (SLTs) in the UK, speech and language pathologists in Australia and the USA, and logopedists across much of Europe.

Voice therapy, as provided by SLTs, is the therapeutic treatment of a voice disorder diagnosed by an ear, nose and throat (ENT) specialist doctor. This chapter discusses the principles of management of voice disorders, and provides an overview of voice therapy interventions and their evidence base.

Voice therapy captures a wide variety of activities and interventions, and the evidence base of therapeutic interventions continues to develop. While both adults and children present with voice problems and voice therapy is the treatment of choice for a number of voice disorders, focus in the literature has been on the voice therapy treatment of adults with functional dysphonia. Even within this diagnostic group, clinical practice is varied. Depending on the organization of services, voice therapy may be provided by a community-based SLT or voice specialist SLT within a multidisciplinary team. The SLT may choose to use a specific, well-described programme of intervention carried out over a set number of sessions, or prefer an eclectic approach based on individual needs.

SLTs delivering voice therapy will need postgraduate training, as specific voice therapy interventions, such as certificated programmes described below, are not included in undergraduate degree courses. SLTs will also need knowledge and skills of anatomy and physiology, vocal pathologies, instrumental and perceptual voice measures, advanced communication skills and competence and experience in a range of appropriate treatments. Some voice therapy interventions need intensive voice training (e.g. Voicecraft)[1] while others, such as vocal function exercises,[2] can be self-taught from a provided package. Some interventions are pathology-specific (e.g. Lee Silverman Voice Therapy for Parkinson's disease (LSVT®),[3] while others, such as Estill Voice Training,[4] are used to improve function in both the disordered and the healthy voice.

Voice therapy embraces principles from biomechanics of voice production and motor-learning principles,[5–7] as well as psychological interventions to facilitate voice change in people with voice disorders.[8–10] In the management of voice disorders, the SLT is guided by clinical guidelines, as summarized in **Boxes 66.1** and **66.2**.[11] The American Speech and Hearing Association's clinical practice guideline for management of hoarseness for clinicians managing dysphonia is also recommended.[12]

BOX 66.1 Summary of the Royal College of Speech and Language Therapists clinical guidelines for the assessment of clinical voice disorders[11]

ASSESSMENT

Each individual is to be examined by an ear, nose and throat (ENT) surgeon prior to or simultaneously with SLT intervention, ideally in a joint ENT/SLT clinic.

SLT voice assessment to include:

- perceptual assessment of vocal and respiratory behaviour
- good quality voice recording, to allow instrumental analysis of vocal parameters such as aerodynamics, pitch, intensity, resonance, vibratory cycle and vocal quality
- perceptions of the individual about their voice disorder, its symptoms and impact on their life
- palpation of the extrinsic laryngeal musculature
- consideration of differential diagnosis of the voice disorder.

BOX 66.2 Summary of the Royal College of Speech and Language Therapists clinical guidelines for the management of clinical voice disorders[11]

MANAGEMENT

Intervention to include explanation and discussion of:

- normal anatomy and physiology for voice production
- causal and maintaining factors to the voice disorder
- voice care and conservation that will include hydration, environmental factors, voice use and lifestyle.

As part of the goal for more effective and efficient voice production, direct voice therapy approaches may aim to:

- alter vocal fold adduction
- reduce supraglottic activity
- adjust articulatory tension
- modify pitch
- alter resonance
- alter respiratory patterns.

Additional indirect approaches, e.g. relaxation strategies and psychological counselling, will be used where psychological or social factors are contributing to the development or maintenance of a voice problem. Their application may involve other members of the multidisciplinary team such as a psychologist.

UNDERSTANDING THE NATURE OF THE PROBLEM

Successful voice therapy must be based on a clear understanding of the problem.[13, 14] Since a voice disorder's aetiology is multifactorial, assessment needs to be systematic, use objective and subjective measures, and consider the impact of certain variables on individual patients.[15] Assessment data and diagnosis provided by the ENT are a starting point for therapeutic involvement. By considering the multifactorial aspects of the voice disorder, SLTs gain an understanding of the individual's voice in the full context of their life. SLT assessment requirements are summarized in **Box 66.1**, and salient aspects are discussed below.

Phonatory physiology

Detailed laryngoscopic examination gives SLTs information about phonatory physiology. Laryngoscopic findings can link directly to a therapeutic goal; for example, a finding of 'poor glottic closure and lateral false fold constriction' would guide intervention to restore vocal efficiency by reducing laryngeal constriction and improving vocal fold approximation. SLTs with appropriate training and supervision undertake laryngoscopy to gain detailed information about vocal fold function prior to therapy and during intervention to provide feedback to the patient.[16, 17]

Perceptual assessment

SLTs describe the presenting features of the voice disorder by listening to and rating the patient's voice quality in conversational speech and a standard reading passage, such as 'The rainbow passage' or *Arthur the rat*. There are different systems with differing terminology to describe the voice. Some require specific training, such as Laver's Vocal Profile Analysis Scheme.[18] SLTs use the GRBAS scale[19] to rate overall severity or **G**rade of voice change, **R**oughness, **B**reathiness, **A**sthenia and **S**train, where 0 = normal/typical; 1 = mild change; 2 = moderate abnormality; 3 = severe abnormality. The CAPE-V[20] is a more recent adaptation of the GRBAS scale, where SLTs also rate pitch and loudness on a visual analogue scale. Perceptual assessment is used continuously in voice therapy as a way of monitoring progress.

Instrumental measures

SLTs analyze voice samples from maintained vowels and connected speech with acoustic analysis packages, Laryngograph®, or with software such as PRAAT (the Dutch word for 'talk').[21] Instrumental voice measures are used in assessment before and after intervention, and these can also be helpful in providing visual feedback during treatment. Voice applications that display pitch and loudness can be downloaded on mobile devices and can support patients of all ages to practise voice work between sessions.[22, 23]

Asking the patient

SLTs investigate the voice complaint by thorough consideration of the patient's perspective. By filling in a questionnaire such as the Vocal Handicap Index,[24] Voice Symptom Scale[25] or Vocal Performance Scale,[26] patients rate voice symptoms and their impact. SLTs use these scores as part of outcome measurement, and to identify specific items to discuss more fully with the patient. During a detailed case history,[27, 28] patients outline what they have noticed about their voice, including hoarseness, limited dynamic range, poor projection, discomfort, fatigue and voice loss. Specific occupational and social vocal demands are identified, as well as strategies patients may already be using successfully to improve or maintain voice. It is important to note the language used by patients to describe their

voice problem. This reflects their understanding of what is happening to their voice, their expectation of therapy and their readiness to change. A successful case history will provide the clinician with relevant patient-specific information, build rapport and establish the SLT as a credible, skilled and trustworthy professional.[28]

THERAPY GOALS

Ideally, SLTs working with voice are part of a multidisciplinary team and take part in a joint voice clinic[29] or an SLT-led voice clinic. Within the team, the SLT's focus is always functional rather than structural.[14] As the relative importance of specific aetiological factors for a given individual are identified, patient-specific goals and an individualized intervention plan are developed. Broadly speaking, the aims of voice therapy are:

- to restore voice to normal (e.g. in functional voice disorders, muscle tension dysphonias, psychogenic voice disorders)
- to maximize voice function given permanent limitations (e.g. in vocal fold palsy, scarring, papilloma, post-radiotherapy voice)
- to reduce handicap and distress associated with the voice disorder (e.g. amplification, counselling)
- to establish strategies and vocal habits promoting vocal health so voice improvement is maintained.

These aims divide up into treatment goals linked to specific outcome measures and smaller, patient-centred goals (**Table 66.1**).[14] SLTs can personalize these goals further if required.

Joint goal setting is crucial to the success of voice therapy. This ensures therapeutic goals are specific and directly relevant to the individual with the voice disorder, clarifies expectations of both the patient and the SLT, and establishes the patient as an active partner in therapy, with the SLT as facilitator. When voice work is more personally meaningful to patients and they experience improved vocal control, motivation and compliance improve, and voice change is likely to be quicker and maintained better.[5, 30]

GENERAL THERAPY DESIGN AND DELIVERY

Clinical guidelines relating to intervention of clinical voice disorders are summarized in **Box 66.2**. There are a number of considerations for therapy delivery and design.

Individual or group

Voice therapy is usually delivered one-to-one, so that sessions can be tailored to the presenting condition, preferred intervention approach and vocal skills relevant to the individual. There are, however, aspects of voice intervention, such as delivery of voice care advice, that can be standardized and delivered in groups. One advantage unique to group voice therapy is that participants motivate and derive support from each other.[31]

Therapy content

Research suggests that effective voice therapy consists of a combination of direct and indirect approaches, rather than direct or indirect intervention alone.[26, 32, 33] Direct voice therapy consists of specific, targeted exercises to control and coordinate various aspects of the vocal system.[34] Direct therapy tends to work on phonation through facilitative techniques, a set programme of treatment, or a combination of approaches. Indirect intervention does not work directly on vocal skills, but on environmental factors, lifestyle issues, and general contributory and maintaining factors to the voice disorder.[34] Typical examples include discussing voice care advice, making patients

TABLE 66.1 Example of patient-centred goal setting related to outcome measure, for patient 'A', a supply teacher and rugby coach with hyperfunctional dysphonia and globus pharyngeus

Therapy goal	Suggested outcome measure
Eliminate mild bilateral vocal fold inflammation	Laryngoscopy
Establish voice within vocal norms on perceptual and instrumental measures	Clinician voice quality rating (GRBAS* or CAPE-V**) Laryngograph® or acoustic assessment
Eliminate vocal tract discomfort and tiredness	Patient rating Questionnaire
Eliminate habitual throat clearing	Chart and patient rating
Achieve effortless phonation	Patient report Clinician rating
Develop vocal projection skills to match demands of teaching/coaching	dB measure Patient report of performance and/or questionnaire
Experience reduced stress associated with dysphonia	Patient report Questionnaire

* GRBAS: Grade, Roughness, Breathiness, Aesthenia and Strain.[19]
** CAPE-V: Consensus of Auditory Perceptual Evaluation – Voice.[20]

aware of unhelpful habits, such as throat clearing, and explaining how the voice works. The proportion of voice therapy spent in direct/indirect intervention varies. Two methodologically different studies found that direct intervention constituted one-third[35] or more than two-thirds[36] of therapy time.

Hierarchical structure

Regardless of the approach chosen, voice therapy consists of incremental steps or skills that patients develop sequentially.[37, 38] Awareness of the amount of muscle tension or habitual level of loudness comes before producing voice with less tension or loudness, for example. In terms of the stimuli used for training and practice, SLTs control the level of difficulty so the desired voice quality can be successfully attained by the patient in different tasks. This may start in voicing without tension or roughness of vocal note on a single vowel sound, progress to rote speech (counting, days of the week), to reading aloud, and conversational speech. Carry-over or generalization strategies are integral to therapy,[38] so the desired vocal behaviour is present in clinic, at home and finally in the most vocally challenging settings for the patient.

Learning principles

SLTs are mindful of how vocal tasks are demonstrated, learned and practised. Certain intervention programmes, such as Estill Voice Training[4] and Lessac-Madsen Resonant Voice Therapy (LMRVT),[39] combine exercise principles with motor-learning theory and feedback to develop and maintain new vocal behaviour. The SLT's role is to guide the patient's awareness, perception and experience of better and healthy phonation during a session. It is thought that this specific attention and experience, in combination with distributed, random practice in different environments produces better learning.[5, 7]

Length of therapy

Although the literature reports considerable variability in length of therapy,[40, 41] it is suggested that patients attend no fewer than four to eight sessions to allow the voice change to take effect.[30, 38] Many programmes of intervention take at least eight sessions (e.g. LMRVT and LSVT).[39, 41]

Prognostic indicators

There are many variables affecting therapeutic progress. The following patient features are indicators of successful voice therapy:

- agreement of active role
- a willingness to change
- realistic expectations
- compliance and commitment
- elimination of other medical problems that may limit progress or stop the patient attending.

SLT factors likely to result in successful therapy are:

- high level of knowledge and skills of voice and voice techniques
- advanced communication skills
- ability to demonstrate listening skills, empathy, compassion, counselling
- ability to motivate.[42, 43]

Length of time from ENT referral to SLT appointment and length of therapy programme affect patient dropout.[44]

VOICE THERAPY APPROACHES

Indirect intervention

There is a wide range of activities in voice therapy where the SLT supports the patient in managing the contributory and maintaining aspects of the voice disorder. This includes explanation, stress management and general relaxation.[14, 34] The following activities are included in indirect voice therapy:

- vocal rest programme
- patient education, explanation of the problem
- vocal hygiene programme
- elimination of habitual coughing, throat clearing
- reassurance
- counselling
- general relaxation.

Direct intervention: Facilitative techniques

A number of facilitative techniques used by SLTs, many of them well described by Boone,[45] have been used historically by voice clinicians to stimulate and improve phonation.[34] These include:

- yawn–sigh
- chewing
- pitch variation and control
- reduction of vocal loudness
- elimination of hard glottal attack
- specific laryngeal relaxation
- voice 'placing'
- pushing exercises for glottal incompetence
- confidential voice.

Facilitating techniques are part of symptomatic voice therapy, and are used to establish best voice for the patient and subsequently practised to stabilize improved voice production.[43] There is no unifying evidence base or underlying theoretical framework as they are a wide range of techniques. Though evidence of efficacy in treatment is largely based on case studies, a skilled SLT may find these techniques a useful adjunct to other approaches.

Direct intervention: Voice therapy programmes

ACCENT METHOD

The aim of this method, developed by Svend Smith, is to resolve the voice disorder by improving coordination between breathing, voicing, articulation, body movement and language for individuals.[46] It trains normal patterns of voice production, rather than consciously correcting faulty vocal behaviour. In gradually more complex exercises, the patient copies the SLT's vocal model, thus developing kinaesthetic awareness of the desired control and coordination.[46] Emphasis in training is on producing easy voice with abdominal engagement in breath flow. Rhythmic consonant sound patterns called 'accents' are first used in slow, low-pitched exercises, then in faster, higher- and variably pitched tasks, and graduating in speech tasks. This method is shown to be effective with vocal fold lesions, vocal fold atrophy and muscle tension dysphonias.[47]

ESTILL VOICE TRAINING AND ALISON BAGNALL'S VOICECRAFT

Singer, voice researcher and teacher Jo Estill developed the Estill Voice Training (EVT) system, which enables individuals to gain isolated control over individual structures within the voice production system.[4] The structures include: head and neck, velum, lips, tongue, jaw, larynx, aryepiglottic sphincter, false vocal cords, true vocal cords, thyroid and cricoid cartilage, and torso. By controlling these structures in various combinations, different voice qualities are produced: for example, speech quality, twang and belting. SLTs guide the patient to develop kinaesthetic awareness of their vocal habits and of the muscular effort involved. By increasing this awareness and gaining specific motor control over relevant structures, the patient can identify and adopt more healthy and useful vocal behaviour. Singing teachers and voice coaches for professional voice users such as actors also use EVT to maximize voice control and function. Like EVT, Alison Bagnall's Voicecraft[1] focuses on teaching differential control of multiple parameters of the larynx and vocal tract.[48] Voicecraft is applied to and predominantly taught in the context of disordered voice. Clinical voice work of many SLTs in the UK is informed by Estill and Voicecraft training.[29, 30] There is a clear scientific basis and rationale for the work, as Jo Estill's extensive research data on aspects of EVT attests,[4] though there are as yet no published studies of systematic use of these interventions with a disordered voice population.

LARYNGEAL MANUAL THERAPY

SLTs use circumlaryngeal manual therapy, digital laryngeal manipulation, voice massage or laryngeal manual therapy (LMT) to manipulate the perilaryngeal area to redress muscle tension.[49–51] Methods of manual therapies vary but essentially focus on reducing excessive tension in the extrinsic laryngeal musculature. Initial palpation helps the SLT to note laryngeal posture (e.g. held high or forced lowered), muscle tone and pain or tenderness of muscle tissue. Areas the SLT may work on include sternocleidomastoid muscles, supra-laryngeal muscles, hyoid position and surrounding musculature, lateral laryngeal movement and rotation.[52] Evidence suggests manual therapies are an effective treatment for muscle tension dysphonia and can resolve even severe hyperfunctional dysphonia.[49–52]

LEE SILVERMAN VOICE THERAPY (LSVT®)

Lee Silverman Voice Therapy (LSVT®) has been developed to treat hypofunctional dysphonia associated with Parkinson's disease.[3] The aim is to alter phonatory effort and 'recalibrate' the patient's perception of effort and loudness levels in speech. SLTs encourage patients to 'think loud', and provide feedback with a decibel meter during repetitions of loud sustained vowels and other speech tasks. The programme is structured and intensive: patients attend individual sessions four times a week for a month, and practise at home in between sessions. LSVT is increasingly used with other hypofunctional dysphonias. It is contraindicated for use with patients with normal neurological function or hyperfunctional dysphonia and, if used inappropriately, may be harmful to both client and SLT.[38] The programme has been used with good results for Parkinson's patients with long-term effects, improving clarity of speech and overall speech intelligibility.[53]

LESSAC–MADSEN RESONANCE VOICE THERAPY (LMRVT)

Based on the work of Arthur Lessac and Mark Madsen, Katherine Verdolini-Abbott has developed a structured intervention programme to reduce aberrant vocal behaviour by establishing easy and clear or resonant voice.[39] SLTs encourage the patient to notice vibratory sensations towards the front of their face on certain voiced sounds (e.g. /m/). Patients practise forward placing of the voice in combination with a sense of ease of voice production in various speech tasks. Individual therapy sessions of 30–45 minutes take place once or twice a week over a 4–6 week period. Research suggests LMRVT is a useful approach in treating functional voice disorders and associated pathology such as nodules, and in improving vocal fold healing in acute inflammation.[54, 55]

SEMI-OCCLUDED VOCAL TRACT THERAPY (SOVT)

Flow phonation, 'lax vox' and SOVT are treatment approaches aiming to reduce muscle tension and hyperfunctional voice by altering air pressure levels in phonation.[56, 57] Exercises with straws, narrow tubes or lip-rounded vowels can improve vocal stability as phonation threshold pressures in the vocal tract are altered.[5] SOVT can train a patient with a hyperfunctional or 'pressed' voice to produce phonation with less effort and adopt more efficient and less effortful phonation. Principles of SOVT are present in other

voice interventions, such as the accent method, resonance therapy, and twang in Estill/Voicecraft.[56] These interventions are based on scientific and physiologic principles,[5, 56] and have long been present in voice therapy practice. The evidence base for lax vox and SOVT as intervention programmes with disordered voice populations is limited.

STEMPLE VOCAL FUNCTION EXERCISES (VFE)

Stemple vocal function exercises (VFEs) are based on a physiological approach[43] and centre on the principle of exercise to achieve optimal coordination of breath support, phonation and resonance, in combination with stamina and strength. SLTs encourage patients to produce 'quiet' (not projected) voice with a forward placement, sensed by the patient as a 'buzzing' of the lips. The programme is highly structured and requires patients to do specific exercises four times a day over 8–10 weeks.[2, 43] Exercises include a vocal warm-up, maximal pitch glides (low-to-high and high-to-low) and maximal vowel prolongations at different pitches. The standardized nature of the programme lends itself well to research, and the evidence base for this intervention is considerable.[43]

ECLECTIC VOICE THERAPY

In the UK, the Royal College of SLTs recommends that SLTs have an eclectic approach in voice therapy. Drawing on many of the above techniques and approaches, the skilled SLT targets the specific factors relevant to the individual with the voice problem, with an intervention approach that is uniquely suited to them. This approach is potentially the most holistic and client-centred. Unlike in a structured programme, in eclectic voice therapy no SLT would provide exactly the same intervention twice, even to an ostensibly 'identical' case of muscle tension dysphonia or vocal fold palsy. Eclectic voice therapy is based on sound clinical rationale and a thorough understanding of intervention strategies and underlying principles. Establishing an evidence base for eclectic voice therapy is methodologically challenging though not impossible, as shown by Mackenzie et al's randomized controlled trial in functional dysphonia.[32]

CONCLUSION

SLTs working with patients with voice disorders facilitate behavioural change in a principled way. Voice therapy encompasses a variety of patient-centred activities, resulting in demonstrable vocal improvement as shown by a range of outcome measures.

Review of the level of evidence in voice literature suggests there are small numbers of level 1 and 2 articles as compared with medical and otolaryngology literature.[58]

FUTURE RESEARCH

- The majority of voice research in the UK is produced by practising clinicians, resulting in clinically applied research.[17] The level of research in the field of voice is predominantly grade B, level 2 and 3, consisting mainly of effectiveness and some larger-scale efficacy studies. The evidence base for voice therapy continues to develop, with a need for future studies to be larger, methodologically sound, replicable and generalizable.[33, 40, 59]
- Suggested areas for future research include:
  - content of voice therapy in relation to pathologies
  - comparison studies of direct interventions with same and different pathologies.

KEY POINTS

- Voice therapy aims to:
  - restore voice
  - maximize vocal potential
  - assist in communication adjustments where voice improvement is likely to be limited by laryngeal structure.
- Voice therapy is based on:
  - systematic, multifactorial assessment of the voice
  - individualized goals for patients linked to assessment findings
  - joint planning with patient
  - a hierarchical treatment plan.
- Multifactorial assessment of current vocal behaviour includes:
  - phonatory physiology
  - perceptual voice rating (using GRBAS or CAPE-V rating scale)
  - patient-reported symptoms and their impact (questionnaires such as VHI, VoiSS and VPQ)
  - acoustic profile using instrumental measures of voice such as PRAAT and Laryngograph®.
- Intervention consists of a combination of direct and indirect treatment approaches.
- Types of direct voice therapy include:
  - accent method
  - Estill Voice Training and Voicecraft
  - laryngeal manual therapy
  - Lee Silverman Voice Therapy
  - resonance therapy
  - vocal function exercises.
- Voice therapy is often eclectic, where a skilled and experienced voice specialist may draw from a range of interventions based on sound clinical rationale to suit the individual's vocal needs.
- The evidence base for voice therapy is mainly at grade B with some level 1 evidence. Future studies need to be larger, methodologically sound, replicable and generalizable.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: voice, larynx, vocal fold and focusing on phonosurgery and results.

INTRODUCTION

Voice disorders are typically only appreciated by those afflicted with these conditions. While there have been great advances throughout the years within the diagnosis and treatment of voice disorders, we are still quite limited in the overall range of intervention available to the practitioners concentrating in this critical area. The last 50 years has seen an increased awareness and emphasis on vocal results and the expansion of phonosurgery, which is defined as 'any surgery designed primarily for the improvement or restoration of the voice'. Nowadays, 'surgery' refers to office-based procedures, interventions under light anaesthesia (conscious sedation), or surgery with general anaesthesia.

Prior to any surgical intervention, complete assessment of patients with a voice disorder should minimally include a complete history (typically as informative as the physical examination) and thorough physical examination. Critical aspects of the physical examination include lateral neck palpation, thyroid examination, observation of laryngeal elevation, tongue and palate mobility, respiratory status, and nasal examination. Once these areas are sufficiently evaluated, the larynx may then be imaged via office-based indirect laryngoscopy. Indirect laryngoscopes (either flexible or rigid) are preferably combined with video recording, which is of crucial importance for immediate review of physical findings as well as comparative evaluation following interventions. Stroboscopy has been a standard of vocal fold cover evaluation, though this technology is inherently weakened by its requirement of normal vibratory patterns, which is discussed in further depth in Chapter 61, Assessment and examination of the larynx and Chapter 62, Evaluation of the voice. High-speed videolaryngoscopy is a useful adjunct in the diagnosis of voice disorders. Additional examination modalities include laryngeal electromyography and voice measurements (both quantitative and qualitative). The formation of multidisciplinary voice clinics allows an academic and scientific approach to voice disorders and greater emphasis on an evidence-based approach to laryngology.

Like any surgical intervention, phonosurgery should be considered the very last treatment option once all conservative measures have either failed to improve the voice or they are deemed inadequate based on our understanding of certain pathologic conditions. Too quickly taken to the operating theatre, patients may end up in worse situations both vocally and medically following unnecessary surgical interventions. A helpful philosophy is to approach potential patients as if attempting to convince those patients away from surgery; and in this manner only the most necessary pathologies will be exposed to the risks of surgery.

As glottic cancer is discussed in Chapter 14, Tumours of the larynx, our discussion of phonosurgery will be limited to benign disease. The topics that will be discussed include microlaryngeal surgery, injection laryngoplasty and laryngeal framework surgery (including nerve grafting).

MICROLARYNGOSCOPY

History

Claudius Galen is credited with recognizing the larynx as the organ responsible for voice production in the second century of the common era. Avicenna (Abu Ali al-Husain ibn Abdullah ibn Sina), recognized as one of the fathers of modern medicine, in the 10th century described in detail the muscular control of the laryngeal cartilages, including an in-depth discussion regarding the role of the corniculate and cuneiform cartilages. In the 1700s the science was advanced with Giovanni Morgagni's connection between vocal fold pathology and dysphonia. Although Manuel Garcia[1] is often credited with the first description of mirror indirect laryngoscopy, Bozzini[2] was actually the first to report on mirror visualization of the larynx and indeed described the first indirect laryngoscope for surgery on the vocal folds. Indirect laryngoscopic surgery was the norm at the beginning of the 19th century and may have played a role in the well-documented tale of Morell McKenzie and the transoral management of laryngeal cancer in Crown Prince Frederick. At that time, there was fear that transoral laryngeal biopsies could induce cancer of the larynx and as a result laryngeal diseases, such as tuberculosis and syphilis, were often treated by an open procedure with or without a tracheostomy. These were associated with a high morbidity and even mortality and there is postulation that Virchov purposely misdiagnosed Prince Frederick's carcinoma because he was aware of Van Bergman's (the prince's surgeon) abysmal survival statistics following total laryngectomy.[3] Horace Green described the first direct laryngeal surgical case, which was the removal of a laryngeal polyp in an 11-year-old girl.[4] Due to the fact that in a child the larynx is in a high position, Green was able to use a bent tongue spatula and sunlight to obtain direct vision and remove the polyp. Oskar Kleinsasser described the adaptation of the microscope to direct laryngoscopy allowing for fine manipulation of the vocal folds. Since then, numerous developments and modifications have taken place but all demonstrate the fundamental phonosurgical principles as detailed in this chapter.

Anatomy

A knowledge of the anatomy of the larynx, specifically the microarchitecture of the vocal folds is essential (**Figure 67.1**). The layered structure of the vocal fold and the different mechanical and physical properties of each layer allow for the unique capacity for continuous vibration (or entrained oscillations). While the true mechanics of vocal fold vibration is still beyond our full understanding and requires active investigation, it is critical that this unique microarchitecture is preserved as its loss (i.e. vocal fold scar) results in the dramatic loss of voice quality. Vocal fold epithelium is the first identified layer of the vocal fold. The mucosa is comprised of stratified squamous epithelium, which transitions to pseudocolumnar cells superiorly into the laryngeal ventricle and inferiorly when the glottis transitions to the subglottis and trachea. The epithelium thickness is approximately 50 microns. The limited depth of the epithelium prevents physical manipulation of this layer alone. Surgical interventions designed to excise, or lift, the epithelium therefore requires some level of manipulation of the lamina propria. The specific layering of the human lamina propria is unique amongst mammalian species. The lamina propria is divided into

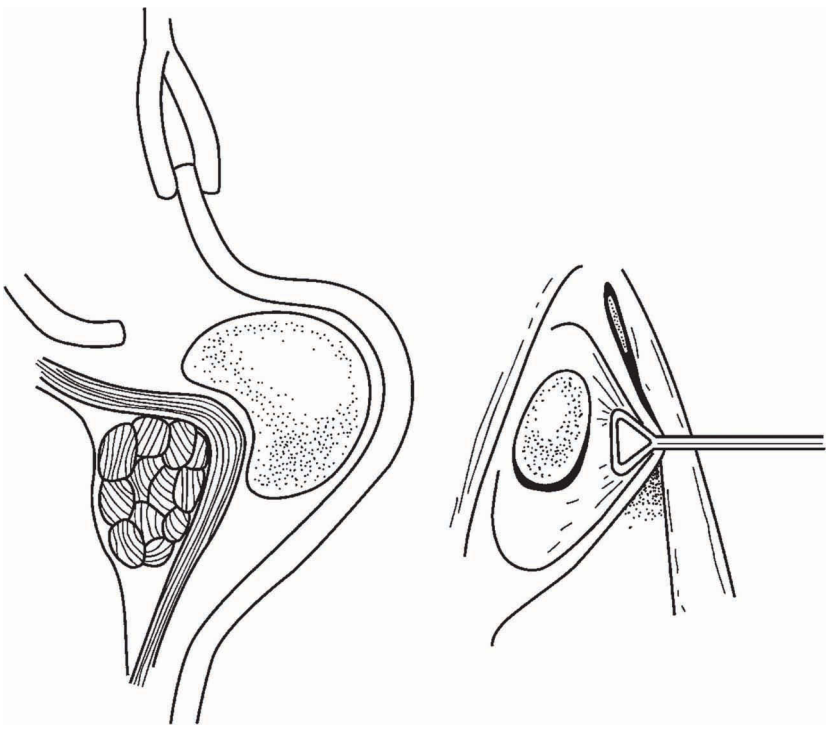

Figure 67.1 Intracordal cyst approached via cordotomy and mucosal flap.

three components: superficial, intermediate and deep. The main component of the lamina propria is collagen fibres. The composition of collagen fibre type and the fibre density distinguishes the three layers of the human vocal fold, which transitions from less-to-more dense structure extending from the superficial to deep. Depth of the superficial lamina is 0.14 mm in women and 0.30 mm in men. The vocal ligament is typically defined as the combined structure of the intermediate and deep layers of the lamina propria, which is readily identified histologically as well as microsurgically.

Exposure

A flexed cervical-thoracic junction and extended atlanto-occipital joint, described by Chevalier Jackson, is now returning as the accepted position for microlaryngoscopic surgical access (**Figure 67.2**). Individual anatomic variations may require departure from this recommended patient position, including flexion at both cervical points, which can be easily modified prior to commencing vocal fold manipulation. Anatomic variations are also optimally managed through the use of different sized (length and diameter) and style (e.g. anterior lip, distending) rigid laryngoscopes. It is critical for the laryngologic surgeon to have several laryngoscopes available for each surgery. Difficult cases can be improved through external laryngeal counter pressure, which can be done either with an assistant's fingers or gauze padding and elastic tape.

Instrumentation

Proper instrumentation, in addition to the laryngoscopes discussed, is required. Microlaryngeal instruments need to be fine, sharp and well maintained to allow precise manipulation of the vocal fold to limit scarring risk. The authors utilize atraumatic soft tissue microlaryngeal forceps (i.e. Bouchayer forceps) in a vast majority of surgeries. Manipulation and trauma to areas beyond what is absolutely necessary will undoubtedly increase scarring and thereby negatively impact post-treatment voice quality. Limiting the area of surgery not only applies along the periphery, or along the surface, but the deep extent of surgery should also be limited to what is absolutely necessary.

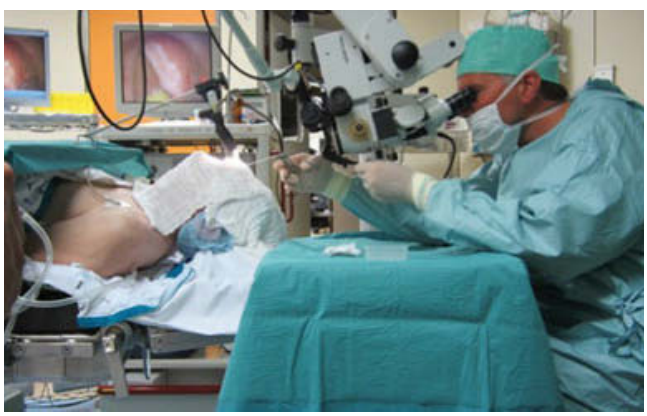

Figure 67.2 Microlaryngoscopy set-up. The patient is positioned with the recommended cervical flexion and extension. Laryngoscope is suspended by fulcrum suspension bar.

Benign disease is usually located in the mucosal layer or in the superficial part of the lamina propria. Surgery should, therefore, be superficial, staying out of the vocal ligament, with limited mucosal excision only. There is no role for stripping of the mucosa of the vocal fold for benign disease, and vocal fold preservation should be the paramount concern of phonosurgery for benign disease.

Lasers and technologic instrumentation

The laser is not merely a precise surgical knife and the surgeon must have an understanding of the effects of wavelength spot size, wattage and mode (pulsed or continuous), their soft tissue interaction and the important hazards linked to their use. Currently, the three most widely utilized laser types include CO_2, potassium titanyl phosphate (KTP) and diode. The specifics of each laser type can be found in Chapter 50, Laser principles in otolaryngology, head and neck surgery, but it is critical that the laryngologic surgeon understands all aspects of the wavelength, spot size and power settings of the utilized laser before attempting even the smallest of procedures. Benninger[5] described a prospective study on patients using the CO_2 laser and microsurgery and came to the conclusion that in a trained laryngologist's hands, both are excellent tools in the management of phonosurgical disorders. In many ways, laser and cold instruments should be considered as synergistic tools rather than in direct opposition. It is, therefore, a personal choice but the authors prefer to limit laser to vascular lesions or those that bleed on removal, such as papillomatosis or granulomas, or to the removal of cartilage and when excising large areas of tissue. Although the laser plume in the management of papillomas has been considered a potential risk of infection, this risk is only theoretical and no case report for this type of infection exists.

Some surgeons now advocate the use of power instrumentation, such as the laryngeal microdebrider. The microdebrider has been used for various laryngeal lesions including papillomas and there is an early report using subjective methods that patients have less post-operative pain and a quicker return to a usable speaking voice.[6] Others have used the debrider for polyps and Reinke's oedema, and also for removing tumours at both glottic and subglottic levels. Once again, one must be aware of the microanatomy of the vocal folds and the principles of phonosurgery and whether accurate depth of resection can be made with this tool. A suction collection pot must also be used to confirm histological diagnosis but margins and orientation of the specimen are lost with this technique.

Anaesthesia

General anaesthesia is the norm for microlaryngeal surgery although there have been some articles describing indirect phonosurgery under a local anaesthetic with stroboscopic control[7] or direct laryngoscopy with nerve blocks and topical anaesthesia. These techniques have

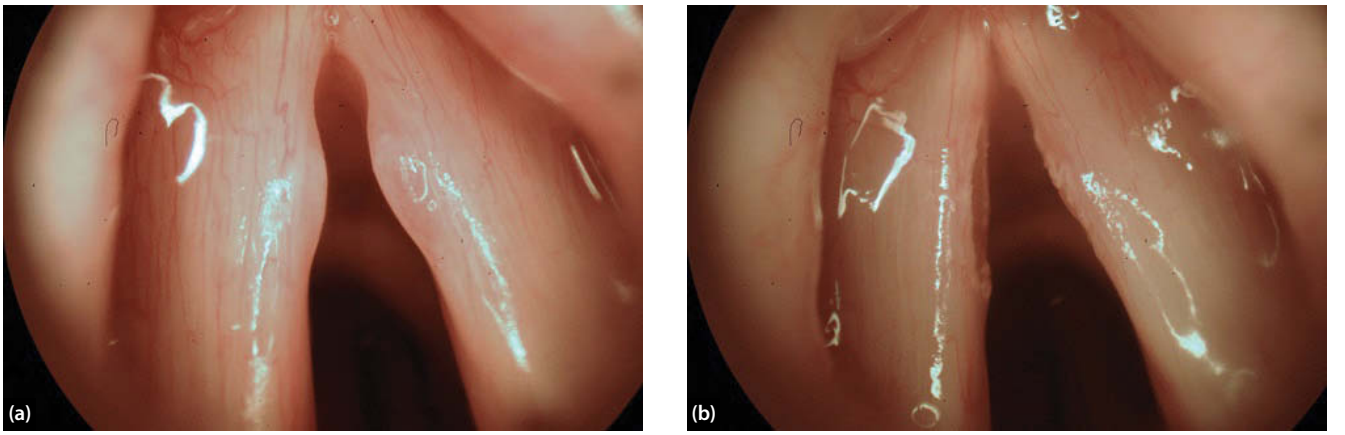

Figure 67.3 Vocal fold nodules. The patient demonstrates bilateral and symmetric phonatory lesions along the anterior one-third of the membranous vocal volds **(a)**. After voice therapy, the nodules persisted and the lesions were resected with CO_2 laser phonosurgery **(b)**.

not been widely accepted. General anaesthesia may be induced and maintained through three main techniques: intubation, apnoea or jet ventilation. Standard oral-tracheal intubation is to be performed only by the most experienced anaesthesiologists as unwanted vocal fold manipulation may impart more phono-damage than then planned phonosurgical procedure. General anaesthesia is typically recommended so muscular relaxants (paralytic agents) can be administered to maintain motionless vocal folds during surgery. Endotracheal tube choice should be made in consultation with the treating anaesthetist, though the endotracheal tube with the smallest outer diameter that can offer safe respirations should be utilized. The authors rarely utilize endotracheal tubes larger than size 5.0 during phonosurgery. Additionally, when available, micro-laryngoscopy tubes (MLT) should be requested to improve the overall length of the tube with smaller diameters. If laser is used during surgery, a laser-safe endotracheal tube should be placed, again with the smallest possible outer diameter, and the tracheal balloons filled with normal saline. Apneic technique calls for intermittent ventilation either by mask ventilation or intermittent endotracheal intubation to oxygenate and ventilate the patient, and the patient is left without active respiration during the phonosurgery. This technique is useful when the lesion is in the posterior glottis, where endotracheal tube would otherwise be visually obstructing and jet ventilation is otherwise not indicated or not available. Jet ventilation offers the best exposure of the larynx and can be performed for prolonged periods. Jet ventilation should *not* be used in cases where bleeding is expected as there is no barrier for aspiration of the blood.

Post-operative voice rest

Although there are no control studies looking at the role of voice rest in recurrence and healing, it is now a generally accepted rule that 48 hours of absolute voice rest following a phonosurgical procedure is essential. The authors recommend a minimum of 7–10 days of strict vocal rest followed by resumption of voicing under the guidance of voice pathologists.

Pathology

NODULES

These are bilateral lesions of functional aetiology and the vast majority resolve completely following compliant voice therapy. They are found at the midpoint of the vocal folds (membranous vocal cord) and are confined to the superficial squamous epithelium. Histopathological studies show thickening of the basement membrane together with areas of haemorrhage, fibrin deposits and hyalinization. Their aetiology is associated with phonatory strain and a stroboscope can be useful in distinguishing this pathologic entity from others that are more readily treated with phonosurgery. In the very rare situation where true vocal fold nodules do not respond with compliant treatment, surgery may be offered to remove these lesions. It must be restated that patients who are non-compliant with their voice therapy should not have surgery offered as their poor vocal behaviours will undoubtedly cause poor healing and scarring, which is a situation more challenging to treat than nodules. During surgery, the centre of the nodule is held with atraumatic forceps and pulled medially towards the opposite cord. The mucosa is cut at its base, by cold instruments or laser, producing a straight vibratory edge and preventing secondary notching. The opposite nodule can then be removed in a similar fashion, taking care not to damage the mucosa of the anterior commissure. There is no contraindication to removing both nodules at the same time using this precision technique.

POLYPS

These are usually unilateral, localized areas of oedematous tissue although some may be angiomatous and may also contain areas of haemorrhage. Though a trial of voice therapy is indicated, these lesions are more likely to require phonosurgery than nodules. The site of the lesion is again superficial to the vocal ligament and careful examination may show a contact response on the contralateral vocal fold, which should rarely be addressed. Gentle, steady traction is applied by grasping forceps towards the opposite cord and the base of the polyp is sectioned.

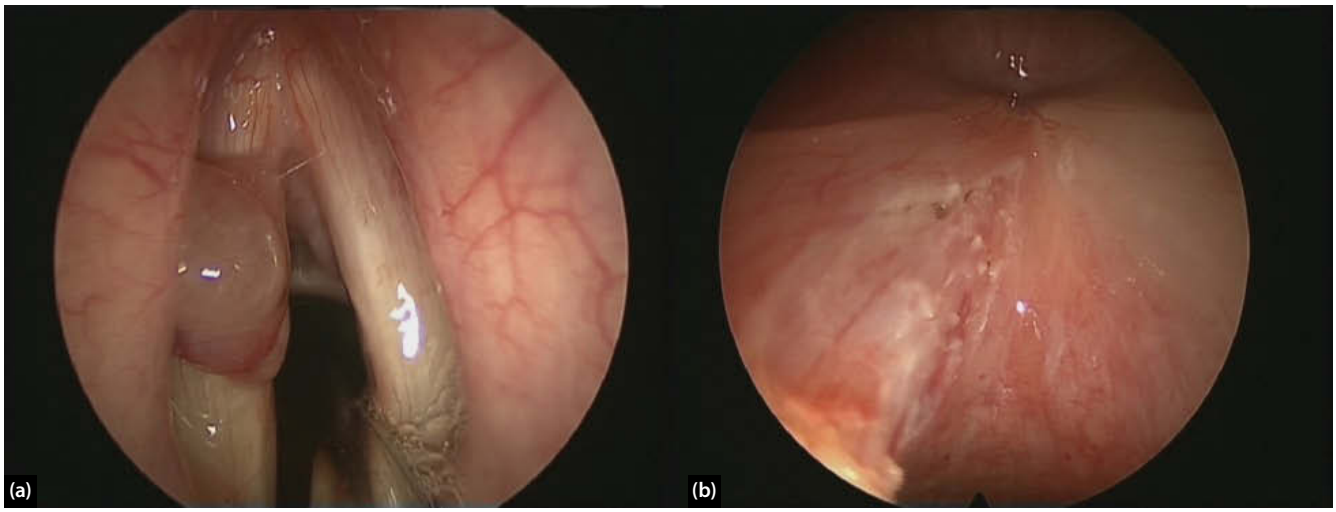

Figure 67.4 Vocal fold polyp. The patient demonstrated left vocal fold polyp at the mid-membranous portion of the vocal fold. CO_2 laser excision preserving the cover layer will allow for excellent healing. (70° endoscopic view.)

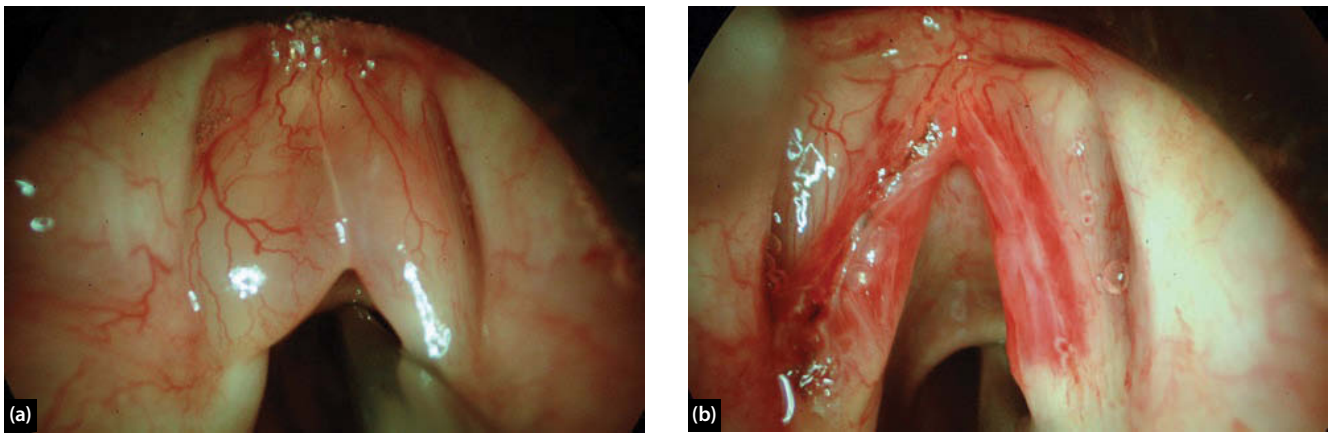

Figure 67.5 Reinke's oedema. The patient demonstrates severe oedema of the vocal fold cover along the anterior-posterior length of the membranous portion of the vocal folds **(a)**. Phonosurgery utilizing CO_2 laser excision of the oedematous tissue preserving the cover layer will allow for excellent healing **(b)**.

Preservation of mucosa is essential, too little resulting in reformation of the polyp, too much resection giving a notched, scarred cord with tethering of the layers of the vocal fold, as seen in **Figure 67.4**.

REINKE'S OEDEMA

This is a bilateral diffuse condition where there is a collection of polypoidal tissue in the superficial layer of the lamina propria, as seen in **Figure 67.5a**. This condition is almost universally associated with cigarette smoking. Patients who continue to smoke should be considered poor surgical candidates as this condition has a high likelihood of recurrence with continued smoke irritation. The pathophysiology is suggested to stem from the poor lymphatic drainage of the vocal folds resulting from the unique embryological origins of the supra and subglottic areas. This poor lymphatic drainage, however, is also advantageous by giving a good prognosis for small glottic tumours. Incision is made on the lateral aspect of the superior surface of the vocal fold with micro-scalpel or laser. The median vibrating edge of the vocal fold is, therefore, preserved. Mucosa is then elevated with a blunt dissector and myxomatous contents either aspirated (suctioned) or removed with cupped forceps. Care must be taken to avoid damaging the vocal ligament or traumatizing the overlying mucosa with excessive suction. Following removal of the contents, the mucosal flap is replaced and any excess epithelium trimmed with microscissors, as seen in **Figure 67.5b**. The mucosal flap can be laid on the surface and left to heal by surface tension, suturing or tissue glue (autologous or commercial) used to hold this in place. Providing care is taken in the region of the anterior commissure, there is no contraindication to operating on both folds at the same time.

INTRACORDAL CYSTS

These primarily surgical lesions may be either secondary to mucosal retention or epidermoid cysts, and stroboscopy has greatly increased the ease of diagnosis, though it remains an ultimately a very challenging diagnosis at times.

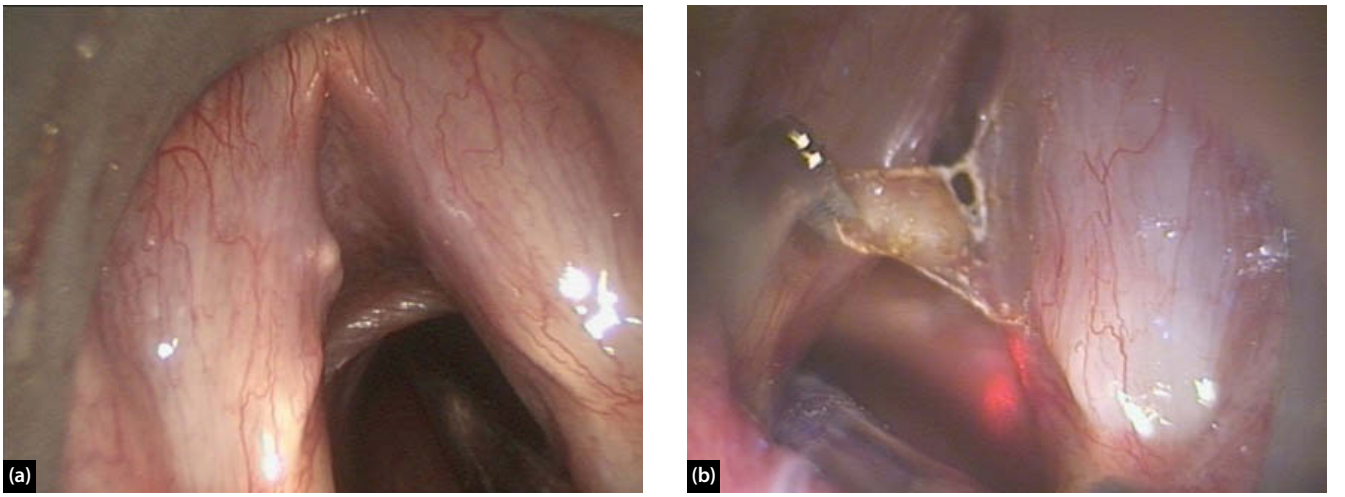

Figure 67.6 Intracordal cyst. The patient demonstrates a right mucous retention cyst at the mid-membranous point of the vocal fold **(a)**. Also seen is intra-operative view of a cyst being dissected from the vocal fold cover by CO_2 laser **(b)**.

The mucous retention cyst is found in the cover of the vocal fold and can be removed either with cold instruments or with the laser, but again remaining superficial to the ligament. An epidermoid submucosal cyst can be approached via a lateral microflap where an incision is made on the superior surface of the vocal fold away from its medial edge. The flap is then elevated from lateral to medial, the lesion excised and the flap replaced. There are good quantitative results in phonosurgery following this approach although some debate exists as to whether there is damage to the basement membrane when elevating the flap. Blood vessels have been identified in the flap and would suggest that the plane of dissection should be deep to the basement membrane, therefore objections of greater damage to the basement membrane may not be founded. As a result of this work, however, Sataloff et al.[8] devised a mini microflap, which involves elevating a small section of epithelium directly over the lesion via a medially based incision as seen in **Figure 67.6**. They also report good results both subjectively and quantitatively using this method.

VOCAL FOLD VARICES

These are often considered a potential source of haemorrhage but in most cases, if lying in a longitudinal orientation, they can be left and treated conservatively unless recurrent haemorrhage occurs. The presence of vessels lying at 90 degrees or at a different orientation may indicate underlying disease, possibly neoplastic, and require further investigation. Recurrent haemorrhage from these vessels can be dealt with either by lasering the blood vessel or needle cautery to ablate the vessels. Angiolytic lasers such as KTP or pulse-dye lasers can be of particular utility with these lesions.

ANTERIOR WEBS

If these are small and thin, they can be divided either with a laser or with cold steel. A microweb is frequently associated with vocal cord nodules[9] and can be removed at the same time. Thick webs have a 50% chance of recurring following laser excision and may require insertion of a keel, either endoscopically or via an open procedure, to prevent recurrence. A local mucosal flap covering the exposed tissue on one side has also been reported.[10]

GRANULOMAS

These are located on the vocal process of the arytenoid cartilage and are usually unilateral, sessile, bilobed lesions. Aetiologic factors include endotracheal intubation, trauma, pharyngolaryngeal reflux, hyperfunctional voice disorders and combinations of these factors. The characteristic posterior position in the glottis is diagnostic and tissue diagnosis is rarely indicated. Granulomas frequently recur following surgery alone. The primary treatment for unilateral granuloma is therefore bilateral vocal fold injection of botulinum toxin (Botox) to the adductor muscle groups, similar to the treatment of adductor spasmodic dysphonia. However, the dose is about 10-fold higher when treating granulomas. Patients must be counselled regarding the 3-month period of decreased vocal loudness, though this pharmacologic-induced voice rest is critical for complete resolution of even moderate to severely hypertrophic granulomas. Botox injections must be coupled with conservative measures including aggressive laryngopharyngeal reflux treatment and voice therapy. Some granulomas present at such an advanced stage, where airway obstruction is a concern. Such lesions can be excised through phonosurgery, though the vascularity of these lesions typically requires the use of laser energy instead of cold instruments. However, Botox injections should still be administered at the time of resection to reduce the risk of recurrence.

PAPILLOMA

These neoplastic lesions are due to the human papilloma virus (subtypes 6 and 11) and frequently recur. They are

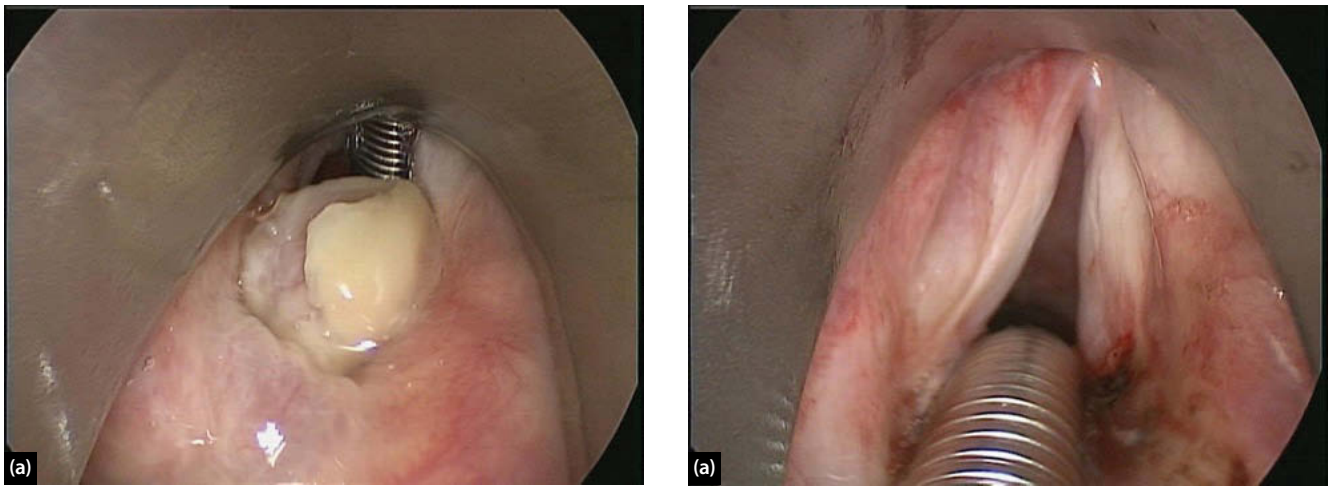

Figure 67.7 Granuloma. The patient demonstrates a large right vocal fold granuloma arising from the posterior glottis and obstructing the glottal space **(a)**. Following excision by CO_2 laser, the glottis is then clear of obstruction **(b)**. Importantly, the adductor muscle groups were treated with Botox injections bilaterally.

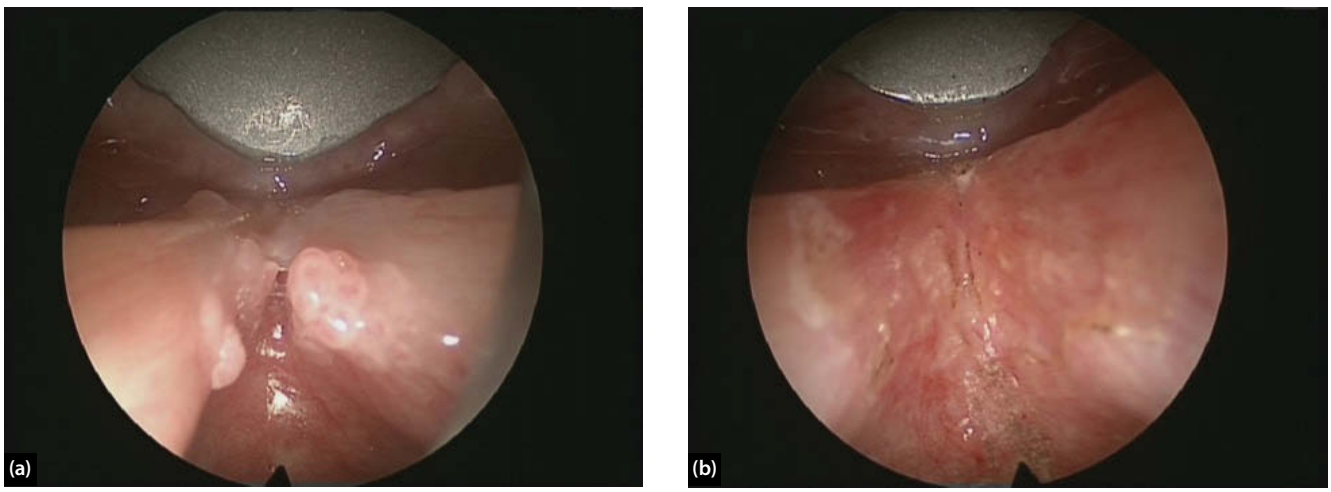

Figure 67.8 Papilloma. The patient demonstrates sessile papillomatosis of the membranous vocal folds bilaterally involving the anterior commissure **(a)**. Following ablation by CO_2 laser, vocal fold cover is preserved **(b)** (70° endoscopy).

often found at areas of transition in the upper aerodigestive tract where there is increased air turbulence, drying and cooling of mucosa, and at the change of ciliary to squamous epithelium.[11] CO_2 laser excision is the treatment of choice in the authors' hands, with minimal trauma to surrounding tissue (that may contain dormant virus). An endoscope with a smoke evacuation channel is useful. Single papillomas are grasped gently as they may be friable and the laser is used to excise the base. Surgical techniques for multiple papilloma include using injection of saline (+/– epinephrine) submucosally (hydrodissection) and excising the mucosa *en bloc*. This gives a lower recurrence rate than surface ablation. It is also (by addressing the principles of phonosurgery and remaining superficial to the ligament) less likely to give scarring by better definition of tissue planes, as seen in **Figure 67.8**. Many case reports in the past have reported success of different treatments by the frequency of repeated lasering but there are now many established scoring systems taking into account the distribution and appearance of papillomas in recognized areas of the larynx. This allows a more scientific and quantitative approach to future treatments. There is encouraging work looking at an immunodeficiency of T-cell lymphocytes in patients with papillomas and the use of adjuvant treatments, such as retinoids, alpha interferon, ribavirin, cyclooxygenase 2 inhibitors, and cidofovir. Photodynamic therapy is also in its experimental stage.[12]

VOCAL SULCUS

This is a groove along the mucosa and can be classified into three types: the first is a physiological or pseudosulcus often associated with reflux; the second is a sulcus vergeture, which goes down to the superficial layer of the lamina propria; and the third is a sulcus vocalis going down to the deeper layers of the ligament. There is a theory that a sulcus is related to ruptured congenital cysts and may well be more common in the Indian subcontinent. They frequently present with persistent dysphonia following puberty. Numerous phonosurgical approaches

have been suggested from excising the sulcus to injecting collagen or fat to boost the underlying layers. Pontes[13] advocates a technique involving parallel mucosal incisions of varying lengths running in a cephalad to cordal direction to break up the linear scar of the vocal fold. A lengthy post-operative recovery time may be required, sometimes up to a year. Despite the above, no treatment has been demonstrated to be reliably effective for this frustrating cause of dysphonia.

BEST CLINICAL PRACTICE

- ✓ Nodules:
  - ✓ Nodules are managed by speech and language therapy with compliant voice therapy and laryngopharyngeal reflux therapy.
  - ✓ Rarely, surgical removal is indicated and involves grasping the centre of a nodule, pulling it medially and then using microscissors to cut mucosa close to the base, thus preserving normal mucosa and keeping a straight vibratory edge.
- ✓ Polyps:
  - ✓ During phonosurgery, excess mucosa is resected by laser or cold instruments resulting in smooth medial surface.
- ✓ Reinke's oedema:
  - ✓ Only following smoking cessation may surgery be offered.
  - ✓ Surgical intervention involves:
    - making a cordotomy incision on the superior aspect of the vocal fold (preserving the median vibrating edge)
    - elevation of the mucosa and aspiration or removal of the myxoedematous contents
    - replacing the mucosal flaps and trimming excess epithelium
    - laying flap onto surface and leaving it to heal by surface tension.
  - ✓ There is no contraindication to operating on the contralateral fold at the same operative setting.
- ✓ Papillomatosis:
  - ✓ Papillomas are recurrent and excised as needed.
  - ✓ Options for excision include CO_2 laser, angiolytic laser, or a microdebrider.
  - ✓ Further studies are required to address best frequency of treatment.
  - ✓ Adjuvant treatments include retinoids, alpha interferon, ribavarin, cyclooxygenase 2 inhibitors and cidovir, but additional trials are required to establish these treatments as standard of care.

KEY POINTS

- Use of surgical lasers requires understanding of the effect of spot size, wattage, mode, soft tissue interactions and hazards.
- Choosing CO_2 laser or cold dissection are a matter of clinical need and experience.
- Powered instruments, such as the microdebrider, can eliminate the risk of laser plume in infected cases, for example, when dealing with papillomatosis.

VOCAL FOLD INJECTION

Brunings[14] was the first to describe injection of the vocal folds in 1911 when he injected paraffin via a direct laryngoscopic approach under local anaesthesia. It is Arnold[15] in 1962, however, who popularized this technique and the introduction of Teflon. Since then, numerous materials have been introduced and some of these are listed in this section.

Materials

TEFLON

Teflon is discussed here for its historical importance only. There is no clinical indication in which its use justifies the risk of soft tissue reaction.

Teflon is a polymer of tetrafluoroethylene and is sold as a paste consisting of 50% glycerine. The glycerine component is absorbed in the first few weeks and its volume is partially replaced initially by an acute inflammatory reaction and later by a localized chronic inflammatory response, which encapsulates the remaining Teflon. This is, in effect, a localized granuloma but the difference in the initial volume injected and the final space-occupying lesion is unpredictable, which may cause a good immediate result to deteriorate with time. If Teflon is incorrectly placed superficially and erosion of the overlying mucosa occurs, this can lead to a granuloma on the surface of the vocal fold, and a 36% incidence of granuloma production has been reported. Teflon particle sizes in the paste are sold as 50–100 microns, too large for immediate lymphatic spread since macrophage lymphatic cut-off is 40 microns. Studies on a commercial preparation of Teflon, however, have found particles of 4–40 microns, which must lead to the question of distal spread. A study on Teflon injection into the peri-urethral areas has shown spread to both regional and distal organs via venous channels, but although local spread to lymph nodes and the thyroid gland has been demonstrated with laryngeal injection, no distal spread has yet been documented.

Removal of Teflon granulomas with a CO_2 laser gives high thermal damage and the vocal fold is scarred to such an extent that poor voice is almost guaranteed. As a result, excising the Teflon via an external approach and using a local muscle flap has been described with good results.[16]

FAT

This autogenous material has numerous advantages: it is easily harvested, readily available and does not give a foreign body reaction. There is no unified technique for its harvesting, with some authors recommending liposuction (which can lead to up to 30% cell destruction and an increased hypersensitivity reaction) whilst others harvest through a larger incision followed by irrigation with saline and soaking in insulin. However, universally, fat injection requires the morbidity of the harvesting site. It is reported that 30–50% of this fat will be absorbed within the first month and long-term studies also suggest a decrease in

volume with time.[17] As a result of its absorption, many suggest overcorrection at the time of injection. The material is of high density and requires insertion deep into the vocal fold. Encouraging quantitative voice results have been reported post-injection.

GLYCERINE

This can be used as a temporary material as it is absorbed within the first 2–6 weeks. It is completely reversible and frequently combined with laryngeal electromyography (EMG) in cases of a temporary paralysis. The EMG can be used prognostically to look at reinnervation of the vocal fold and the glycerine, by augmenting the paralyzed fold, allows glottic closure. Once again, its site should be deep within the muscle of the vocal fold.

COLLAGEN

This protein is a natural constituent of the lamina propria of the vocal fold. Widely used in dermal augmentation, it has been popularized by Ford et al. for use in the larynx where it becomes incorporated and even assimilated by new host tissue.[18] A cross-linkage ensures better stability and reduces the rate of hypersensitivity, which is <1%. Skin testing pre-operatively is recommended before the collagen is injected superficially into the vocal ligament. It is a challenging procedure with blanching of the vocal fold mucosa if too superficial. Although excellent results are reported by Ford, others have found this technique difficult and noted irregularity in its mode of absorption and replacement.

SILICONE

Bioplastique is a silicone gel consisting of vulcanized polydimethylsialoxane particles ranging from 150 to 600 microns suspended in hydrogel. After an initial acute inflammatory reaction, the material develops a fibrous capsule[19] and, although not used in the United States, it has been used sparingly in Europe. Location of the material should be deep within the body of the vocal fold but so far there are few long-term results on the quality of voice or any complications with migration.

CALCIUM HYDROXYAPATITE

Radiesse voice implant is a solution of calcium hydroxyapatite carried in an aqueous gel allowing for injection through small gauge needles (25G or 27G). It has found widespread usage since the commercial supply of bovine collagen has been limited. The most critical aspect of this material is a deep injection as superficial implantation will lead to long-term hoarseness.

Selection of operative methods

These may be subdivided as follows:

- general anaesthesia: (direct laryngoscopy)
- local anaesthesia: (indirect laryngoscopy):
  - transcutaneous route through the cricothyroid membranes
  - transcutaneous route through the thyroid cartilage
  - transcutaneous route through the thyrohyoid membrane
  - transoral route.

GENERAL ANAESTHESIA

Drawbacks include visualization problems due to the anaesthetic tube or some other means of ventilation, the abnormal anatomical position of the neck, difficulty in gaining access to the larynx in patients with cervical spine problems or other anatomical factors preventing direct laryngoscopy and, most significantly, lack of patient feedback via phonation during injection. This last factor plays an essential role in deciding the amount of material to inject at the time of surgery in patients undergoing procedures under local anaesthesia. Advocates of injections under general anaesthesia argue that physical manipulation of the injection material following injection can lead to a more uniform and wider area of medialization.

LOCAL ANAESTHESIA

Injection laryngoplasty is also routinely performed under local anaesthesia with the guidance of real-time visualization, typically through nasolaryngeal flexible laryngoscopy. The laryngologist typically practices a single injection site most frequently, but should be comfortable utilizing any of the described techniques as variation in patient comfort and anatomic composition will require alterations of the method. Transcutaneous techniques maintain the benefit of being procedures that can be carried out in the office with minimal time commitment for both the provider and patients.

There are three well-described transcutaneous methods. First, a transcutaneous piercing of the thyroid cartilage is typically the most straightforward approach to injection laryngoplasty. Penetration should be through the inferior half of the thyroid cartilage but difficulty can occur when the cartilage is ossified or the needle bore is blocked with cartilage. Penetrating the cricothyroid membrane is becoming a more familiar technique now that botulinum toxin injections into the thyroarytenoid muscle for adductor spasmodic dysphonia are increasing. The injection needle can either pass directly into the cord without entering the laryngeal lumen or pass initially into the lumen and then penetrate the fold whilst being visualized via a nasendoscope (**Figure 67.9**).[20] The transcricothyroid membrane approach is similar in its approach and if ossified thyroid cartilage ala is identified then the needle point is angled inferiorly to tuck under the inferior edge of the thyroid cartilage and an audible click is usually heard once the membrane is penetrated. The needle should then immediately be angled superior-laterally to find a position deep within the adductor muscle group. The transthyrohyoid method requires topical anaesthesia of the glottis (typically topical 4% lidocaine) before injection. Following adequate anaesthesia the needle is placed at the thyroid notch and

angled immediately inferiorly. Under direct visualization, the needle tip is seen exiting the petiole mucosa at midline to enter the supraglottic lumen. Following this, the needle tip can be guided under visualization laterally into the deep adductor muscle group where laryngoplasty can be performed. Finally, with the use of a rigid curved cannula (Abraham cannula), a needle may be guided transorally following adequate mucosa topical anaesthesia to achieve direct injection into the superior surface of the lateral vocal fold.

KEY POINTS

- Injectible materials include autologous fat, glycerine, collagen, silicon, and calcium hydroxyappatite.
- All provide immediate results, though optimal voicing may take 3 days for the injectate to even out.
- The provider must have comfort with multiple injection methods as individual patient needs and anatomy will require variability in planned approaches.

LARYNGEAL FRAMEWORK SURGERY

Payr,[21] in 1915, is credited with the first description of laryngeal framework surgery. This has been refined over many years by other surgeons but Isshiki[22] was the first to describe using an alloplastic material (Silastic) and also to stress the benefits of carrying out the procedure under a local anaesthetic using the patient's voice for feedback. His name, and the classification of laryngeal framework surgery into four types of thyroplasty, remain as shown in **Figure 67.10**.[22]

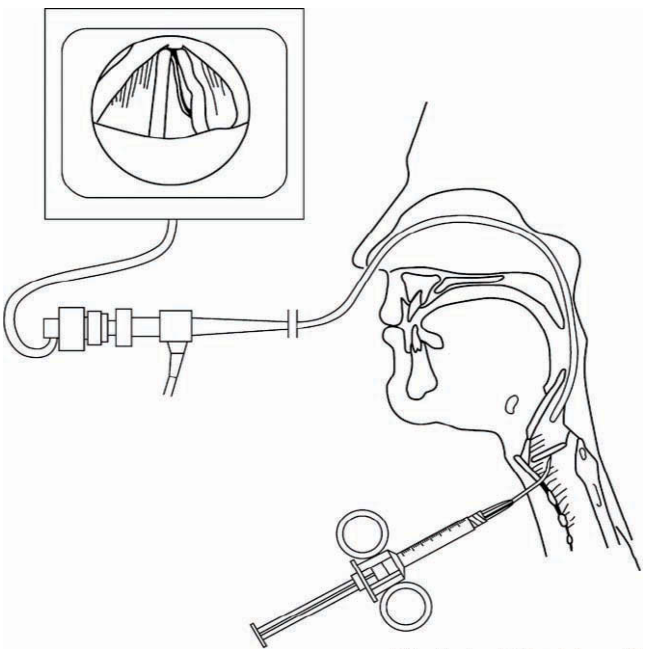

Figure 67.9 Transcutaneous technique with nasolaryngeal flexible laryngoscopy.

Laryngeal framework surgery allows the size of the glottic aperture, plane of closure of the vocal folds and vocal fold length to be modified. Laryngeal framework surgery also maintains the laryngeal dynamics without invasion of the vocal folds and alteration of their mass or stiffness.

Selection of patients

Type I, or medialization thyroplasty, can be performed for patients with a unilateral vocal cord paralysis. Waiting 12 months in idiopathic cases is recommended for possible spontaneous recovery of vocal fold motion. Injection laryngoplasty should be provided within this initial time period to allow for adequate voicing and cough. Medialization thyroplasty can also performed bilaterally in cases of bilateral bowed vocal cords, as can be caused by ageing, and may be useful to correct soft tissue defects in the vocal fold as a result of previous surgery, although the final voice expectations for these diagnoses should be quite guarded.

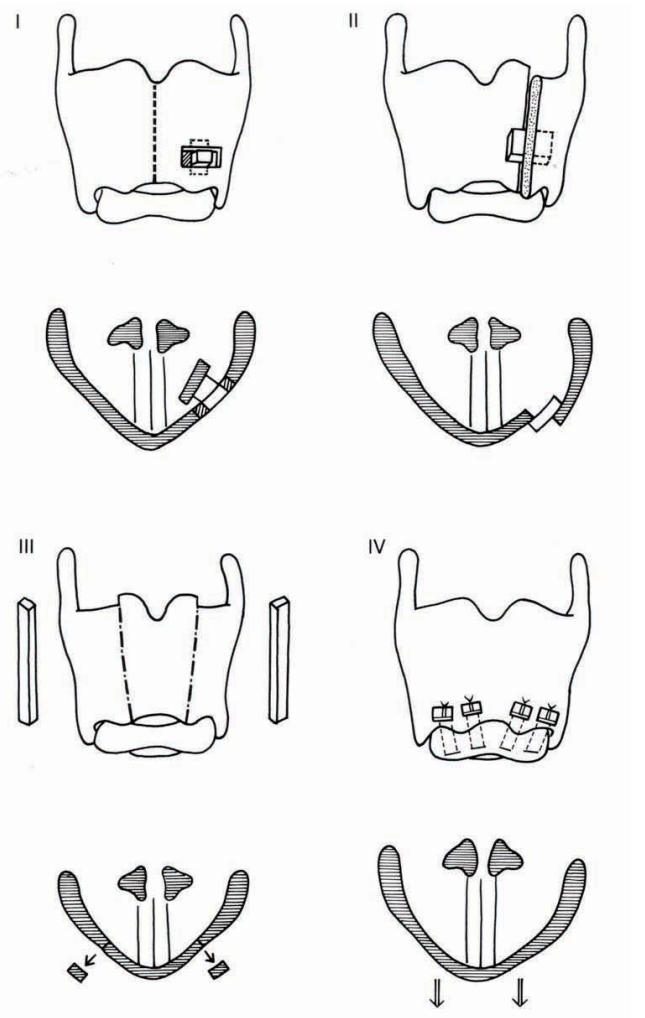

Figure 67.10 Types I, II, III and IV laryngeal framework thyroplasties, as described by Isshiki.

Techniques

Thyroplasty type 1 essentially involves medialization of the vocal cord by its inward displacement with an implant placed through a window in the thyroid cartilage (**Figure 67.11**). The comprehensive operating technique is well established[20] but some of the finer details are described here. In the original description the cartilage window was preserved but many now remove this island of cartilage, believing it can be displaced or absorbed, leading to later complications. There are specific instrument kits available for medialization laryngoplasty, which are not essential but can help to reduce the time of the procedure and ideally 30–40 minutes for a routine thyroplasty is adequate. Interestingly, one should preserve the outer perichondrium when using Gortex as this will need to be sewn back to close the defect (window) in the thyroid cartilage. It is still not certain whether a posterior glottic chink can be closed with a medialization thyroplasty alone and research on the anatomy of the cricoarytenoid joint suggests that when the paralyzed cord is on a different vertical plane to the normal one, then a medialization laryngoplasty is insufficient for full closure.

Isshiki[23] described an arytenoid adduction procedure for patients where there is a large posterior gap and the paralysed cord is at a different vertical level. Good results have been reported, both initially for a competent larynx and long term for voice production.[24] A modification of this technique is the arytenoid fixation and cricothyroid subluxation as described by Zeitels.[25] With an extended incision, the arytenoid cartilage is exposed, its attached muscles divided and the arytenoid cartilage is fixed in a midline position. Tension of the paralyzed cord is obtained by a suture between the inferior horn of the thyroid cartilage and the cricoid cartilage anteriorly (**Figure 67.12**). This is usually combined with a medialization thyroplasty and allows correct positioning of the arytenoid cartilage and gives tension and bulk to the paralyzed vocal cord. Although technically challenging, it is the author's personal choice for patients with a large posterior glottic chink.

Common problems with thyroplasty include inserting a prosthesis that is too small or inserting a prosthesis in the incorrect place. Revision thyroplasties have shown that many insert the prosthesis too high as they do not define the lower border of the thyroid cartilage (**Figure 67.11**). The vocal cords are found deep to the inferior half of the thyroid cartilage and inserting the prosthesis too high will displace the false cord and not allow glottic closure.

BEST CLINICAL PRACTICE

- ✓ Specific instrument kits are not essential; they may help to reduce operating time, but risk a one-size-fits-all surgery.
- ✓ Implants are made of silastic, hydroxyapatite or Gortex.
- ✓ Implant design varies to accommodate modifications in insertion technique and maximize some effects.
- ✓ Thyroplasty alone is unlikely to be able to close the posterior glottic chink.
- ✓ Poor results are usually due to the superior location of the thryoid window.

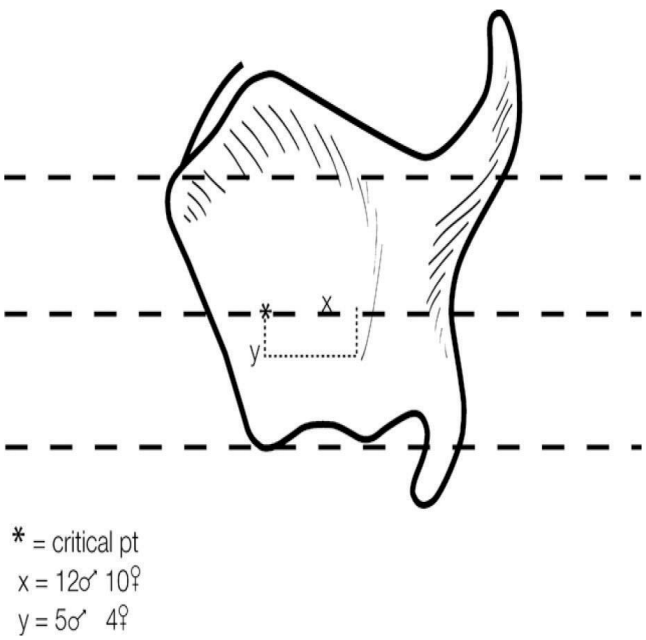

Figure 67.11 Dimensions (in mm) and location of window in thyroid cartilage.

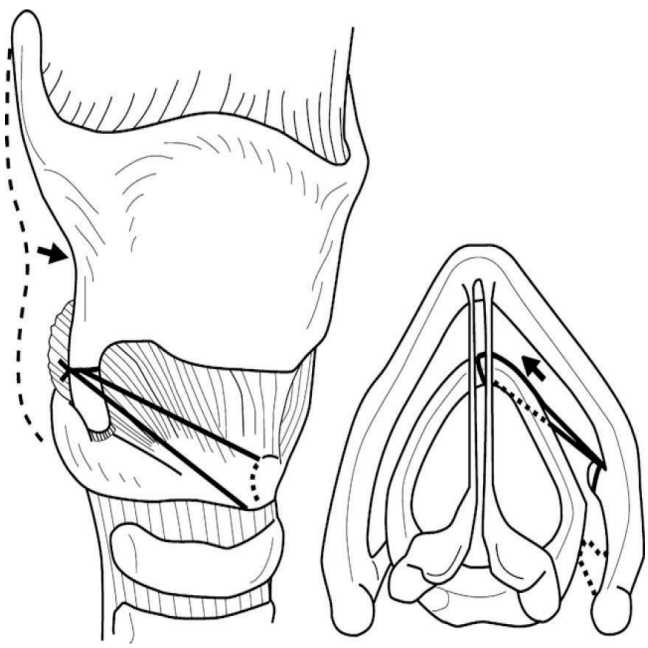

Figure 67.12 Suture gives tension to the paralyzed vocal cord with the arytenoid cartilage fixed medially.

REINNERVATION PROCEDURES

Recurrent laryngeal nerve anastomosis was initially described in 1909 by Horsley[26] and further work suggested that this was a successful technique but with no objective evidence to support the conclusions. Recently, Crumley[27] has popularized the technique of ansa cervicalis to recurrent laryngeal nerve anastomosis.

Neuromuscular physiology

The recurrent laryngeal nerve is a mixed nerve containing afferent, sympathetic, parasympathetic and 500–1000 motor axons in an adductor to abductor ratio of 5 : 1. The ansa cervicalis, however, contains efferent fibres from the first three cervical nerves to innervate the strap muscles. Whereas the intrinsic laryngeal muscles are controlled to contract at specific times, the strap muscles have not been shown to have any phasic action in the primate. Reinnervated muscle takes on the characteristics of its supplying nerve, and the selection of the donor nerve should take into account the muscle fibre composition of the muscle to be reinnervated.

Muscle fibres can be divided into specific types based on the histochemical and contractile properties. There are three basic groups:

1. **Type 1:** slow contractile period and aerobic metabolism
2. **Type 2B:** fast contractile period and anaerobic metabolism
3. **Type 2A:** intermediate contractile period and both aerobic and anaerobic metabolism.

Muscles that produce low tension over a sustained time period will have a high concentration of type 1 muscle fibres. A high concentration of type 2 fibres will be seen in muscles that contract rapidly generating high tension over a short time. The intrinsic muscles of the larynx differ in their constitution of muscle fibres but the thyroarytenoid muscle (part of which is the vocalis muscle of the vocal fold) has a fast contraction time (14 milliseconds) and < 36% type 1 muscle fibres. The strap muscles, however, have a higher percentage of type 1 muscle fibres (66%) and a contraction time of 50 microseconds. The distribution of neuromuscular endplates in each of the intrinsic laryngeal muscles and the strap muscles are also different, with a diffuse pattern in the thyroarytenoid but a typical skeletal muscle distribution in the strap muscles where they form a narrow band at the midpoint. This gross difference in the histochemical and contractile properties of these muscle groups and their nerve supply makes them poor recipients and donors for nerve transfer. It is proposed that the unfavourable synkinesis that occurs in

TABLE 67.1 Comparison of procedures currently used for the rehabilitation of a patient with unilateral vocal fold paralysis

Procedure	Time taken (minutes)	Results	Anaesthetic	Demand on technical skill	Complications
Fat injection	10–30	Immediate but 30–50% and in 1/12 good voice results	Local/general	Moderate	Under-injection
Glycerine injection	10–30	Immediate	Local/general	Moderate	Over-injection
					Airway compromise
					Under-injection
					Over-injection
Fat injection	10–30	Immediate but 30–50% and in 1/12 good voice results	Local/general	Moderate	Airway compromise
Collagen injection	10–30	Immediate	Local/general	High	Under-injection
					Over-injection
Glycerine injection	10–30	Immediate	Local/general	Moderate	Airway compromise
Silicone injection	10–30	Immediate	Local/general	High	Under-injection
					Over-injection
Collagen injection	10–30	Immediate	Local/general	High	Airway compromise
Laryngeal framework surgery	35–75	Immediate	Local/general	Moderate	Wound infection
					Haematoma
Silicone injection	10–30	Immediate	Local/general	High	Airway compromise
					Mucosal perforation
					Dislodgement and/or extrusion
Reinnervation	60–120	2–3 months (+ Gelfoam/Glycerine injection)	General	Most	Wound infection
					Haematoma
					Loss of abnormal synkinetic tone (Flaccid fold)

a damaged recurrent laryngeal nerve with mixed partial axonal regrowth is replaced by a more favourable synkinesis from the ansa cervicalis.

Muscle nerve pedicle reinnervation has also been described using a block of omohyoid with its branch from the ansa cervicalis, although some surgeons are now combining neural anastomosis with laryngeal framework surgery as it appears that neural anastomosis alone does not give a good result in a lateralized cord. In the author's opinion, there is currently no convincing clinical or scientific evidence that the reinnervation techniques give better or equal results to either injection, medialization or laryngeal framework surgery in the management of a unilateral vocal cord paralysis. **Table 67.1** shows the advantages and disadvantages of the most common procedures currently used for the rehabilitation of a patient with a unilateral vocal cord paralysis.

FUTURE RESEARCH

Phonosurgery would benefit from:

- ➤ improved methods of measuring voice (i.e. objective, subjective, patient based) for meaningful comparison
- ➤ reliable surgical interventions for vocal fold scar
- ➤ Clinical trial for the establishment of safe adjuvant treatment for successful management of respiratory papillomatosis.

KEY POINTS

- The underlying etiology of the vocal abnormality must be established before any treatment can be offered.
- Complete assessment with videostroboscopy and voice measurements pre- and post-surgery are desirable.
- Knowledge of the anatomy and microstructure of the vocal cords and location of lesion is essential.
- Selection of laryngoscopes, micro-instruments and operative lasers are required before phonosurgery can be performed.
- Vocal fold nodules should rarely, if ever, require phonosurgery.
- Materials such as calcium hydroxyappetitie have replaced Teflon for vocal fold injection laryngoplasty.
- Laryngeal framework surgery can be performed under local anaesthesia for intra-operative auditory feedback.

ACKNOWLEDGEMENTS

The authors would like to thank Meredydd Harries, FRCS MSc in the authorship of the previous versions of this chapter.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: dysphonia, spasmodic dysphonia, Parkinson's disease and vocal tremor.

INTRODUCTION

The larynx is subject to highly complex neurological control to fulfil its roles in phonation, deglutition and respiration. Dysfunction of the movement of the larynx may reflect a wider neurological condition or may be an isolated disorder of the vocal tract.

In broad terms, disorders of movement of the larynx can be thought of as either hypofunctional or hyperfunctional. Further conditions may be related to poor coordination or stability of the voice.

HYPOFUNCTIONAL CONDITIONS

Parkinson's disease

Parkinsonism is a term referring to a group of conditions including idiopathic Parkinson's disease (PD), Parkinson's plus syndromes and secondary Parkinson's.

Idiopathic PD accounts for around 80% of cases of Parkinsonism; it is a nigrostriatal disorder characterized by a deficiency of dopamine. Generalized rigidity is seen, along with bradykinesia (slowness of movement). These two aspects are collectively described as hypokinesia. Tremor (typically a 'pill-rolling' tremor) is a very common feature. PD is a relatively common neurological disorder, with a prevalence of 1 per 1000 of the population, rising to around 1 per 100 in the over-60 age group.[1]

Although PD is usually thought of as a condition of older age, it can also affect younger patients.

The voice in patients with PD is typically described as 'monotone' and reduced in volume. These features are a consequence of reduced activation of the thyroarytenoid muscle.[2] Examination of the larynx will characteristically show bowing of the vocal folds, resulting in a quiet and breathy vocal quality. This weakness of voice is accompanied by dysarthria (poor articulation).

MANAGEMENT OF PD

Systemic treatment with dopaminergic agents (levodopa, l-dopa) can achieve significant improvements in the peripheral symptoms; however, these improvements are not always reflected in changes in the voice.[3] In recent years, the application of the Lee Silverman Voice Treatment (LSVT) has resulted in dramatic improvements for many patients. The LSVT mode of management requires a specific programme of intensive sessions of daily therapy over a one-month period.[4]

PARKINSON'S PLUS SYNDROMES

Progressive supranuclear palsy

Progressive supranuclear palsy (PSP) is a neurological condition that results from accumulations of tau protein in the basal ganglia, brainstem and cerebral cortex. Initial symptoms include loss of balance and bradykinesia.

Ocular symptoms such as poor control of eye movements are seen. The speech and laryngeal manifestations in patients with PSP include dysarthria and monotone voice. Treatment is essentially palliative, with l-dopa sometimes providing some control of symptoms.

Multiple-system atrophy

Multiple system atrophy (MSA) is a degenerative disease in which there is cell loss in specific areas of the brain. Autonomic failure is a common feature, and in these cases, the condition is referred to as Shy-Drager syndrome. The laryngeal manifestations may include bilateral vocal fold paresis or paralysis. The voice may exhibit hypo- or hyper-functional features, being either breathy and weak or loud and strained.

Motor neurone disease

Motor neurone disease (MND) refers to a group of disorders that includes amyotrophic lateral sclerosis (ALS), progressive bulbar palsy (PBP), progressive muscular atrophy (PMA), and primary lateral sclerosis (PLS). Of these, ALS is the most common. MND is characterized by progressive degeneration of the motor cells of the brain and spinal cord. Both lower motor neurone (LMN) and upper motor neurone (UMN) dysfunction occurs, usually with LMN signs predominating. The progression of the disease is usually rapid and life expectancy is typically 2 to 5 years from diagnosis.

The usual presentation (in 80% of cases) is in the limbs, with limb weakness, fasciculations and brisk reflexes. However, 20% of cases will present with bulbar signs and symptoms; these include dysarthria (as a result of limitation of tongue movement), tongue fasciculation, dysphagia and nasal regurgitation. Voice changes can comprise a 'wet' sounding voice as a result of pooling of secretions in the larynx, along with a harsh and/or breathy voice quality, and often vocal tremor. Hypernasality can result from poor velopharyngeal function.

Swallowing is generally affected as well as voice, with aspiration pneumonia a possibility. Not infrequently, adjunctive management of swallow (with a gastrostomy) as well as of airway (with tracheostomy) are required.[5]

Myasthenia gravis

Myasthenia gravis (MG) is an autoimmune disorder in which antibodies to the postsynaptic acetylcholine muscle receptors prevent neuromuscular transmission. This results in progressive muscle weakness and fatigability. Small muscles are usually the first to be affected, most frequently those around the eye. That said, up to 20% of patients initially present with voice changes – most often vocal fatigue; this is frequently with a negative acetylcholine receptor antibody titre.[6] Other laryngological changes include stridor and voice weakness. More broadly, the voice may sound hypernasal and the patient may be dysarthric. A misdiagnosis of superior laryngeal nerve palsy and/or bilateral vocal fold paresis may delay the formal diagnosis of MG.

Because fatigability is a key finding in MG, laryngeal examination should include asking the patient to perform repeated vocal tasks.[7] Treatment of MG centres on the administration of anticholinesterase drugs (pyridostigmine); in some cases steroids are required and occasionally thymectomy is undertaken.

Vocal fold paralysis

Paralysis of one or both vocal folds may result from one of a wide number of neurological conditions – many of these are described above. A detailed description of vocal fold paralysis is outlined in Chapter 78, Paralysis of the larynx.

HYPERFUNCTIONAL CONDITIONS

Pseudobulbar palsy

A UMN lesion in the corticobulbar pathway may cause difficulty chewing, manipulating a food bolus in the oral cavity, swallowing, and dysarthria. The most frequent cause is cerebrovascular accident, but other causes may include demyelination (multiple sclerosis), PSP, ALS, PD, MSA and malignancy. The voice may exhibit a strained and strangled quality, and running speech shows dysfluency.

Huntington's disease

Huntington's disease is inherited in an autosomal dominant pattern. It is a neurodegenerative disease in which patients exhibit involuntary muscle movements (chorea), as well as cognitive and psychiatric problems.

Poor coordination of muscle movements is also seen in the larynx, and results in a wide variety of vocal changes: poor control of pitch and volume may occur, along with a strained voice quality or complete voice breaks.[8, 9]

Spasmodic dysphonia

Of the conditions described above, few are amenable to specific treatment that can improve the vocal quality, and in most cases, only supportive treatment can be offered. In contrast, the symptoms of spasmodic dysphonia (SD) are readily controlled with injections of botulinum toxin, combined with voice therapy to eliminate hyperfunction.[34]

SD is a voice disorder arising from a focal dystonia involving certain laryngeal muscles[10–12] but reflecting central motor processing issues/abnormalities.[13] It is only present during certain specific speech vocal tasks, and can be overridden by vegetative phenomena such as laughing or by chanting or singing. There is a background of normal speech overlain by vocal spasms that are not under voluntary control. This leads to a typical strained and strangled speech pattern[14, 15] that was recognized by MacKenzie more than a century ago.[16]

SPASMODIC DYSPHONIA: AETIOLOGY AND INCIDENCE

Early theories suggested that SD was a psychoneurosis.[17, 18] It was then determined to be of neurological origin and to represent a focal dystonia.[9, 19] Recent functional MRI (fMRI) studies have failed to identify any specific structural defect. In most instances the aetiology of SD is unknown/idiopathic although not uncommonly the patient will relate onset to a specific event such as a 'flu-like syndrome or an emotionally traumatic event.

At the time of writing this chapter, at least 13 genes or chromosomal locations have been associated to dystonias and several to voice disturbances on case-report basis. Recently, the DYT6 dystonia (a primary, early-onset torsion dystonia) has been found to be caused by mutations in the THAP1 gene (thanatos-associated protein domain containing apoptosis-associated protein 1).[20–22] Further studies have identified THAP1 mutations in certain dystonias (both generalized and focal), and this has included cases with early involvement of the larynx.[23] Involvement is limited, however, and in 160 patients with SD screened, only 1% had THAP1 mutations.[23]

In general, approximately 8% of patients have a family history of dystonia,[20, 24] but this is less commonly the case with SD. Blitzer[25] highlights that most cases of SD are sporadic, although Schweinfurth et al. in their case series noted a 20% association with other forms of focal dystonias.[14, 26]

Estimates of incidence vary, with one being given at 1 per 100 000.[27] It is unclear if SD is a relatively rare disorder or whether failure of recognition of the condition results in a low pick-up rate. There are approximately 30 000 to 50 000 people in North America affected. Because of the difficulty securing the diagnosis, there is usually a long interval between onset of symptoms and diagnosis; in our experience, this is approximately 2–3 years (Costello and Rubin, personal observations). SD is more prevalent in females than in males and the average age of onset is 40 years.

Ludlow summarizes that the current view points to focal dystonia is due to a combination of genetic predisposition interacting with acquired factors later in life, for example head injury, drug exposure or peripheral injury.[15]

SOCIAL IMPLICATIONS

SD has significant social implications and impacts on the patient's quality of life. Due to the phonation breaks and strangled quality of the voice (and the fact that symptoms are worse when stressed or when speaking over the phone), individuals affected may become socially isolated. There is no question that it affects communication and causes major social disruption in the lives of sufferers. Izdebski et al. have noted that SD affects job performance in 77–93% of affected individuals and that 26–37% need to change job or be reclassified within the work setting.[28–31]

CLINICAL FEATURES

SD is a task-specific dystonia: the spasm only occurs on phonation. On endoscopy at rest, the larynx appears normal, but on phonation, spasm of the laryngeal musculature is seen and heard. It is also typically worsened by use of the telephone or in times of heightened anxiety, for example when meeting people for the first time. Many patients report that alcohol intake ameliorates symptoms of SD.

The airway is not compromised in SD – adduction occurs only on phonation and never during respiration.

SPASMODIC DYSPHONIA: TYPES

SD tends to be differentiated by symptoms into **adductor**, **abductor** and **mixed** types.

Adductor SD

Adductor SD is by far the commonest type, affecting approximately 90% of patients with SD.[32] The characteristic adductor spasm results in a strangled and staccato voice. This can easily be mistaken for muscle tension dysphonia, and is frequently treated as such for some time before SD is diagnosed.

It is characterized by phonation breaks associated with vowels, in particular words ending with a vowel and being followed on by a word starting with a vowel (for example 'we – eat') and words with two vowels in tandem (for example, eighty-year – eels). The vowels /i/ ('ee') and /a/ ('ah') are particularly problematic. Interestingly, patients may often produce a relatively normal phonation on a continuous vowel sound.

Hyperfunctional voice and psychogenic voice disorder may be confused with SD. Hyperfunctional voices tend to have voice hallmarks of prolonged, constant strained voice but with no phonation breaks. Spastic UMN conditions may also be misdiagnosed as SD.

Abductor SD

Abductor SD is far less common. In our practice we have identified it as the predominant presentation in under 10% of individuals presenting with voice dystonias. Individuals with abductor SD have particular difficulty with voice onset after voiceless consonants at the beginnings of words or phrases (words starting with /w/, /b/, /s/, /t/, /p/, /f/, etc.), often leading to problems with vocal fold closure for the following sound. Typical examples given include phrases such as 'who has hidden Harry's hat?'. Attempts to pronounce such sounds lead to voiceless voice breaks.

Disorders that may be confused with abductor SD include psychogenic voice disorders such as whisper dysphonia and neurologic disorders, in particular forms of Parkinsonism.

DIAGNOSIS

The diagnosis of SD is made on clinical grounds, and usually solely by the listening skills of an experienced clinician. Both in adductor and abductor SD, it is often the case that patients have seen numerous clinicians before a diagnosis of SD is reached. To the untrained ear, the voice may sound so unusual that patients are sent for speech

therapy, psychotherapy and alternative therapies to treat what is thought to be a psychogenic phenomenon.

Electromyography (EMG) will demonstrate bursts of involuntary spasms of electrical activity overlaid on normal interference pattern.[33] In adductor SD, increased thyroarytenoid activity is observed during these bursts.[33] That said, EMG does not really improve the diagnosis made with the ear, but instead serves to confirm it, except in particularly difficult diagnostic circumstances (Rubin, personal observation).

Assessment of SD requires evaluation by a multidisciplinary team. Core members include the speech-language therapist, otolaryngologist, neurologist and neurophysiologist. It is most helpful to have a good relationship with psychologist and psychiatrist as well. A careful case history, emphasizing the psychosocial aspects, is fundamental to diagnosis as well as successful management.

Nasendoscopic inspection and recording with playback to the patient is the gold standard. It is interesting to note that the insertion of the nasendoscope may temporarily diminish the spasm. This unexpected finding gives weight to the hypothesis that SD may be primarily a disorder of sensory input: the altered afferent input from the pharynx and larynx during endoscopy appears in some way to modulate the efferent motor signals, and can reduce the amount of spasm. Assessment by the speech-language therapist with a trial of voice therapy generally occurs, and all patients are referred for baseline neurological evaluation.

Speech-language therapists have a crucial contribution to differential diagnosis. Their role includes perceptual and instrumental assessment that are critical to measurement of baseline status and outcome, patient counselling in all cases and voice therapy in some cases; therapeutic techniques, when combined with botulinum toxin injections, can improve outcomes.[34]

The voice assessment includes repetition of sentences loaded with voiced segments and vowels, as this will provoke (worsen) symptoms (i.e. more strain, voice breaks). In adductor SD, sentences loaded with voiceless segments will decrease symptoms (i.e. improved performance, less strain and fewer voice breaks) whilst voiced consonants will make the voice worse (**Box 68.1**).

Other task-specific tests to detect adductor SD include:

1. Sentences with all voiced consonants to provoke more symptoms: 'Early one morning a man and a woman were ambling along a one-mile lane running near rainy island avenue.'[35]
2. Sentences with mostly voiceless consonants to provoke fewer symptoms (i.e. better voice with this phonetic context): 'He saw half a shape mystically cross fifty or sixty steps in front of his sister Kathy's house.'

BOX 68.1 Voiced (voice 'on') versus voiceless (voice 'off')

Voiced consonants	Voiceless consonants
Stops /b/, /d/, /g/	Stops /p/, /t/, /k/
Fricatives /v/, /z/,/ zh/	Fricatives /f/, /s/, /sh/, /h/
Affricates /dz/	Affricates /ch/
Glides & liquids /w/, / r/, /l/, /j/	

BOX 68.2 Laryngoscopy protocol

Quiet respiration
Prolonged /i/; /a/
Repetitive /i/ /i/ /i/
/si/ /si/ /si/
/mi/ /mi/ /mi
/isi/ /isi/ /isi/
We eat eel every day
She speaks pleasingly
We mow the lawn all year
Peter will keep at the peak
The puppy bit the tape
Harry has a hat; his hat is on his head
When he comes home we'll feed him
Taxi, Taxi, Taxi
Tell me about your voice problem or how did you get here today
Alternating high and low pitch phonations

In the clinic, two vocal tasks are particularly helpful: adductor SD is commonly more detected when the patient counts upwards from the number 80 ('80–81–82–83…'). For abductor SD, counting from 50 ('50–51–52–53…') will exacerbate the spasm. These tasks may be used prior to and then during nasendoscopy (**Box 68.2**).

Tremor

Vocal tremor can occur on its own or with SD. It is said to be present in approximately one-third of individuals with SD.[36] In tremor, regularly spaced voice breaks are noted particularly on prolonged vowel /a/ or /I/. The modulation is at between 3 and 5 Hz. Tremor affects women most commonly, especially in middle age. Often, tremor is more evident in the chest voice, rather than the head voice.

Familial forms of tremor may lead to vocal manifestations in the absence of laryngeal dystonia. Essential tremor, the most common form of movement disorder, has a prevalence of approximately 4% of individuals aged 40 and older, increasing with age. Whilst it affects all age groups, its incidence increases with age. No genes have been identified yet but inheritance patterns are said to be most consistent with autosomal dominance. Hands and feet are most commonly affected, but the voice is affected in 4–20% of cases. On PET scanning, in certain instances the olivo-cerebellar tracts have been noted to be abnormal, with increased cerebellar activity even at rest.

TREATMENT OF SPASMODIC DYSPHONIA

As no definitive cause for SD has been established, the treatment centres on controlling symptoms.

Speech therapy

There is little role for speech therapy in the management of SD. In some cases, therapy may help to ameliorate some of the compensatory tension patterns that develop as a consequence of the dystonia, but therapy alone is never curative. This is borne out by recent research[37] demonstrating no additional improvement in voice outcomes with the inclusion of therapy as well as botulinum toxin injection.[34]

One form of voice therapy, 'inhalational speaking', has been espoused by Shulman to allow individuals with severe SD to phonate.[38] We have anecdotally noted several of our patients to attempt phonation in this manner (Rubin, personal observation 2011).

However, the role of the speech therapist in the diagnosis of SD is essential, as therapeutic techniques can often help to differentiate between SD and muscle tension dysphonia. They also have a critical role in monitoring voice quality and managing side effects.

Medical therapy

In cases of isolated SD, there is no role for systemic medical therapy. However, in cases of SD associated with other dystonias (facial dystonia, for example), low-dose benzodiazepines may be useful.

Botulinum toxin

The mainstay of treatment of SD is repeated botulinum toxin injections.[39–42] In clinical practice in the UK, most clinicians use botulinum toxin type A.

Botulinum toxin is a neurotoxin produced by the gram-positive anaerobic bacterium *Clostridium botulinum*. There are seven types that are structurally similar but antigenically and serologically distinct. The established drug names have changed over time to reinforce the differences and prevent medication errors. The current products include:

- OnabotulinumtoxinA (Botox, Botox Cosmetic). Botox is approved for cervical dystonia, severe axillary hyperhydrosis, strabismus and blepharospasm. Botox Cosmetic is approved for moderate-severe glabellar lines.
- AbobotulinumtoxinA (Dysport), approved for cervical dystonia, moderate-severe glabellar lines.
- IncobutulinumtoxinA (Xeomin) approved for cervical dystonia and blepharospasm.
- RimabotulinumtoxinB (Myobloc) approved for cervical dystonia.

The molecule is synthesized as a single chain (150 kD) and then cleaved to form the dichain molecule with a disulfide bridge.[43, 44] Botulinum toxin acts by binding presynaptically to high-affinity recognition sites on cholinergic nerve terminals, causing a neuromuscular blocking effect by decreasing release of acetylcholine. Slow recovery occurs by proximal sprouting of axons and muscle reinnervation by the formation of a new neurotransmitter junction, with ultimate regeneration of the original neuromuscular junction.[45]

ADDUCTOR SD – BOTULINUM TOXIN INJECTIONS

For patients with adductor SD, the injections of the thyroarytenoid muscle with botulinum toxin may be performed permucosally (under local or general anaesthetic) or, more commonly, transcutaneously.

The transcutaneous injection technique approaches the thyroarytenoid muscle through the cricothyroid membrane. After sterilizing the skin, the needle is advanced in the midline through the cricothyroid membrane. Care must be taken not to enter the airway: this will cause the patient to cough. Having entered the skin and passed through the cricothyroid membrane, the needle is angled 15 degrees cranially and 30 degrees laterally and then advanced into the body of the thyroarytenoid muscle. No local anaesthetic is required as the injection needle is of a very small calibre (generally 26G) (see **Figures 68.1**, **68.2** and **68.3**).

Many clinicians use electromyographic (EMG) monitoring to ensure that the tip of the injection needle is appropriately placed in the thyroarytenoid muscle. The EMG needle electrode is a fine-bore needle with an insulated shaft and an exposed electrode tip at the point. The circuit is completed with a wire that is connected to an EMG. The use of EMG can confirm that the needle tip is in *a* muscle, but will not help the clinician to know *which* muscle. When the needle tip is thought to be in the muscle, the patient is asked to phonate (/i/) – this causes a characteristic burst of activity on the EMG monitor, and the botulinum toxin can be rapidly delivered into the muscle.

In general, patients will receive a low dose of botulinum toxin (between 3 and 10 units of dysport (equal approximately to between 1 and 3 units of botox)) into one or both thyroarytenoid muscles. In practice, a newly diagnosed patient will usually receive a small dose of botulinum toxin into one or other vocal fold. The dose is then titrated upwards (or downwards) according to the patient's response. The frequency of dosing is variable: in some patients, injections are only required every

TABLE 68.1 Commonly used preparations of Botulinum toxin A and their relative properties

Name of preparation	Botox	Dysport	Xeomin
Manufacturer	Allergan	Ipsen	Merz
Dose equivalence	1 unit is equivalent to	3 units are equivalent to	0.75 units
Storage	Refrigerated	Refrigerated	Room temperature

Figure 68.1 Setup for laryngeal injection of Botulinum toxin, with EMG machine.

Figure 68.2 Note that the skin is entered at the cricothyroid membrane.

Figure 68.3 The patient's neck is extended by placing a pillow under the shoulders.

6 months; in others, they can be required every 6 weeks. In the 7 days after an injection, the patient can expect their voice to be a little weak and breathy. During this time, they may also experience problems with aspiration of liquids. Following this, the voice will reach a steady state, and should reach its maximal benefit 2–3 weeks after the injection.

On the whole, a higher dose will have a longer duration of effect. On the other hand, a higher dose will also give rise to more side effects (such as breathy voice and aspiration of liquids). Every patient requires a subtly different timing and dosing of injections and will have personal preferences; for example, a retired patient who lives a long distance from the clinic may be happy to have a higher dose (and accept the initial side effects) if (s)he only has to attend every 6 months. Conversely, a working professional may be willing to attend the clinic every 6 weeks for a low dose in order not to have a period of vocal weakness.

In a questionnaire survey of American laryngologists injecting botulinum into the larynx, most reported that they used EMG to guide needle placement; more perform bilateral injections than unilateral; almost all are guided by their patients' wishes and complications from previous injections as to their subsequent injection and dosage; and most inject 3–4 times per year.[46]

We performed a subjective patient-reported questionnaire looking at relative success rate and complications (length of breathiness, swallowing issues, cough) in a group of our patients with adductor SD. We found 94% 'success' rate from the previous injection, mean dose (Dysport) in our unilateral injections of 3.6 iU, mean dose bilateral of 6.6 iU. In this group, we did not find significant differences in terms of length of breathiness, cough or dysphagia between low dose unilateral or bilateral injection.[47]

ABDUCTOR SD – BOTULINUM TOXIN INJECTIONS

Accessing the posterior cricoarytenoid (PCA) muscle for injection of botulinum toxin is more difficult; its location at the posterior aspect of the larynx makes injection more technically challenging. It may be approached transcutaneously by manually rotating the larynx into a position where the posterior cricoid ring can be accessed. This is a deep injection in the neck, and often requires local anaesthetic. If the PCA is injected transcutaneously, EMG guidance is essential; the muscle can be difficult to locate, and EMG confirmation (by asking the patient to abduct the vocal folds with a forced sniff) is required to confirm needle placement.

Some clinicians prefer to perform PCA injections under general anaesthetic. This is performed by lifting the larynx forwards with a laryngoscope and injecting behind the cricoid ring into the PCA muscle. Care must be taken to direct the injection laterally; erroneous injection of both PCA muscles might result in complete failure of the patient to be able to abduct *both* vocal folds, and consequent airway compromise.

Botulinum toxin injections for abductor SD appear to be less effective than for adductor SD. A larger dose is usually required to achieve adequate results.

SURGERY

Recurrent laryngeal nerve section/crush

In 1976, Dedo first described a technique of unilateral recurrent laryngeal nerve (RLN) sectioning for adductor SD.[48–50] Initial results were promising, but further follow-up[51] demonstrated that longer-term results were not maintained.

Recurrent laryngeal nerve selective denervation and reinnervation

There are two significant problems with nerve section/crush: first, the muscle may be prone to atrophy; and second, there is a likelihood of reinnervation by the cut end of the RLN. Berke et al. have postulated that selectively denervating the thyroarytenoid and lateral cricoarytenoid muscles, followed by providing tone to the muscles with an ansa cervicalis anastomosis, might preserve muscle tone.[52, 53] The results appear impressive, with 82% of patients reporting that they would recommend the surgery to others.[54]

Thyroarytenoid myotomy

A method of causing thyroarytenoid inactivity has been proposed by coagulating the muscle with a laser. In a small series, this has proven to be a promising treatment option.[55, 56]

Type 2 thyroplasty

Isshiki has proposed a type 2 thyroplasty as treatment for adductor SD.[57, 58] In this procedure, the anterior larynx is approached through a neck incision. The thyroid cartilage is divided in the midline (as for a laryngotomy), taking care not to enter the airway. A shim (of titanium in Isshiki's description) is inserted to produce a separation of the anterior vocal folds at the anterior commissure. This is performed under local anaesthetic, allowing the patient to talk, so that the correct size of shim can be ascertained intra-operatively. In this relatively large series (41 patients), the results are very promising.

KEY POINTS

- Systemic neurological conditions can have profound effects on the voice, airway and swallowing.
- Multidisciplinary working is critical, including neurologists, laryngologists, speech therapists (with specific skills in treating neurologically disordered patients) and radiologists.
- Many neurological conditions are best treated with voice therapy and supportive care.
- Spasmodic dysphonia is a rare focal dystonia of the larynx; it is frequently misdiagnosed but is readily amenable to treatment with injections of botulinum toxin.

SEARCH STRATEGY

Data in this chapter is based on a Pubmed and Ovid (Medline) search of the English language literature. The MeSH key words used were laryngitis, epiglottitis, croup, laryngotracheobronchitis, pertussis and other search terms used were supraglottitis, laryngeal infections, upper airway infections. The clinical recommendations are predominantly group C.

INTRODUCTION

Acute infections of the larynx are not unusual and are most commonly associated with an upper respiratory tract infection that is usually of viral origin. Therefore, these conditions are mostly managed in the primary care setting. However, there are specific types of infections of the larynx that require specialized care and it is therefore essential for the practising otorhinolaryngologist to be familiar with these conditions.

Furthermore, although the majority of acute laryngeal infections are self-limiting and resolve with supportive care, in a small number of cases an acute infection can progress rapidly into a life-threatening condition requiring urgent expert care in a hospital setting. This will often require input from an experienced team of clinicians, which may include an emergency medicine physician, otorhinolaryngologist, anaesthetist, paediatrician and microbiologist.

In this chapter, we provide an overview of the types of acute laryngeal infections and management strategies for dealing with these conditions.

CLINICAL FEATURES

The term laryngitis refers to inflammation of the tissues of the larynx. In acute forms the onset is usually abrupt. The general symptoms and signs of acute laryngeal infection are listed in **Table 69.1**.

Stridor is a serious symptom as it is associated with significant airway narrowing. It is more commonly seen in children and such cases should be managed jointly with a paediatrician in a hospital setting. Narrowing at the supraglottis or glottis is typically associated with inspiratory stridor. Narrowing below the level of the glottis may also present with inspiratory stridor but typically will be biphasic in nature.

Examination of children with stridor should be done by an experienced clinician with care taken not to cause any additional distress to the child. In adults, a flexible laryngoscopy is required for direct visualization of the larynx in most cases. This allows an assessment of

TABLE 69.1 Signs and symptoms of acute laryngeal infection

Symtoms	Signs
Dysphonia	Tender laryngeal framework
Dyspnoea	Stridor
Sore throat	Cervical lymphadenopathy
Odynophagia	Pharyngitis
Referred otalgia	Pooling of saliva

the vocal cords themselves, the supraglottis and an overall clinical assessment of the patency of the laryngeal airway.

ACUTE LARYNGITIS

Acute laryngitis is a common inflammatory clinical condition of the glottis and supraglottis. It is most commonly due to a virus associated with an upper respiratory tract infection. It may also occur secondary to infections of the upper and lower respiratory tract such as tonsillitis or chest infections.

The majority of cases of acute laryngitis are self-limiting and resolve within a couple of weeks. Patients typically present with a hoarse voice associated with symptoms of a common cold. In some cases, there may be a superadded bacterial infection that may lead to a more severe type of laryngitis. Fungal infections of the larynx are dealt with in 'Mycotic laryngitis' below.

Treatment initially includes vocal hygiene measures including voice rest, analgesics/anti-inflammatory medications, avoidance of irritants (e.g. smoking and alcohol) and maintaining good hydration of the larynx. Steam inhalation has been used although most of the reports are in children with croup and there is no good evidence of benefit.[1]

The role of antibiotics in cases of acute laryngitis should be reserved for cases where there is clinical suspicion of bacterial infection. Typically, these patients may have persistent and more severe laryngitis or other associated infections of the upper or lower respiratory tract. In general, antibiotics have little role in the treatment of the majority of cases of acute laryngitis,[2, 3] although there is some evidence that erythromycin may reduce voice disturbance in the first week and therefore may be considered in patients who are professional voice users.[4] The choice of antibiotic depends on any associated infections but penicillin has been reported as being ineffective[5] and macrolides (e.g. erythromycin or clarithromycin) have been shown to be effective, which may be a reflection of infection with *Moraxella catarrhalis*.[6]

There have been recent case reports of methicillin-resistant *Staphylococcus aureus* laryngitis[7, 8] and this should be considered in cases not responding to first-line antibiotics. Diagnosis will be made by microlaryngoscopy and cultures, which should be considered in cases that are not responding to first-line treatment.

Patients with stridor generally should be admitted to hospital and intravenous antibiotics, nebulized adrenaline and steroids considered. It is important to liaise with an experienced anaesthetist and the patient should be observed in an appropriate clinical setting such as a high dependency unit. If there is airway compromise that is deemed severe enough then early intubation and ventilation should be considered until the airway inflammation has improved. Tracheostomy is rarely indicated.

Patients with persistent hoarseness lasting for more than a few weeks should be reviewed in a specialized voice clinic along with a speech therapist. The pathogenesis of laryngeal inflammation can be multifactorial and factors in addition to the viral or bacterial infection, such as smoking, allergy, rhinosinusitis, voice abuse and laryngopharyngeal reflux, should also be managed appropriately.[9] If doubt as to the diagnosis persists then formal microlaryngoscopy should be considered.

EPIGLOTTITIS (SUPRAGLOTTITIS)

Epiglottitis is an acute infection of the supraglottis characterized by inflammation of the supraglottic structures. It is usually due to a bacterial infection and should be considered to be an emergency condition due to the potential rapid and fatal airway obstruction. The incidence of epiglottitis is 1–2/100 000.[10, 11]

Historically the most common causative organism was *Haemophilus influenza* type b (Hib), which accounted for almost 90% of cases.[8] The incidence of epiglottitis (particularly in children) has decreased significantly as a result of the *Haemophilus influenza* type b vaccination, which was introduced in the UK in 1985 to prevent childhood meningitis.[12, 13] However, this has led to the emergence of other causative organisms (e.g. *beta haemolytic Streptococcus*, *Streptococcus pneumoniae*, *Streptococcus milleri*, *Staphylococcus aureus*, *Escherichia coli*, *Klebsiella pneumoniae*, *Neisseria* spp.) and there has been an increase in the incidence of adult epiglottitis that is not related to *Haemophilus influenzae* infection.[11, 14, 15] Fewer than 20% of cases of adult epiglottitis are due to *Haemophilus influenzae*.[15] *Candida albicans* is an important cause to consider in immunocompromised patients.[14, 16]

Historically the condition was more common in children than in adults and it is important to recognize that the condition presents a somewhat different clinical picture between the two age groups. In a retrospective dataset study from the United States, Shah et al. found that the typical patient admitted with epiglottitis is a 40-year-old male and that the majority of mortalities from epiglottitis were in the adult population.[17]

The clinical features vary somewhat between children and adults. In adults, the main complaint is of a painful throat with associated odynophagia.[10, 11, 14] Dyspnoea, fever and drooling may also be seen but are not always present.[10, 12, 18] As the calibre of the airway is larger in adults than children, features of upper airway obstruction may not always be present. A significant proportion of adults presenting with epiglottitis will have comorbid conditions such as diabetes, hypertension, cardiac and respiratory conditions, complications of which have an associated mortality in patients with epiglottitis.[10, 11, 17]

Diagnosis is made on examination of the larynx by trans-nasal fibre-optic laryngoscopy, which may reveal an erythematous and congested epiglottis with inflammation of the surrounding supraglottic structures.[14, 18–21] Radiological investigations are usually unnecessary, although if an associated abscess is suspected then a CT scan may be useful.[22]

Treatment of epiglottitis

Patients should be admitted for observation in an appropriate setting such as an ENT department, high dependency or intensive care unit, depending on the status of the patient. It is important to manage these patients as a team, with involvement of anaesthetists and paediatricians appropriately. Despite advances in airway management, epiglottitis is still associated with mortality from associated complications and airway problems and early appropriate management is essential to minimize an adverse outcome.[23]

A tailored, selective approach based on careful evaluation of these patients is important and varies from conservative treatment with close observation to interventional treatment by an artificial airway for patients with respiratory distress or significant stridor. Close observation is mandatory as in a small number of patients progress from no respiratory distress to a significantly compromised airway may occur in just a few hours.[18] Advice on antibiotic treatment should be sought from microbiologists but in the first instance intravenous 3rd generation cephalosporins are recommended in conjunction with metronidazole if anaerobic bacteria are considered also to be causative.[11, 14, 15, 24]

Systemic corticosteroids and nebulized adrenaline may be used in patients with significant airway compromise. Most of the literature on use of these substances is based on a paediatric population presenting with croup. Although there is no clear evidence that it is an effective treatment,[12, 18] their use may be considered in patients with a compromised airway. A short course of steroids may help to decrease the airway inflammation, possibly decreasing the need for intubation.[16, 25] However, careful consideration should be given to this rather than using corticosteroids as a matter of routine, as the evidence on the role of corticosteroids is lacking.

Most patients will respond to medical treatment, showing an improvement within 24–48 hours, and this can be monitored by examination with trans-nasal fibre-optic laryngoscopy as well as monitoring clinical and biochemical parameters.[10] There is an association between patients reporting dyspnoea and the need for airway intervention.[10] Therefore, it is always important to consider the potential complication in epiglottitis of airway obstruction and if the airway is deemed to be at risk, then there should be a low threshold for intubation of the patient at a relatively early stage. This should be done in an operating theatre setting with an experienced anaesthetist due to the risk of occlusion of the airway with instrumentation of an inflamed larynx.[26] Tracheostomy should be required only rarely in very urgent cases where the patient has presented at a late stage and intubation is not possible; in a database study of epiglottitis in the United States, tracheostomy was performed in 3% of cases of adult epiglottitis.[17]

Epiglottic abscess formation is a recognized complication of epiglottitis, which has been reported to occur in 4–27% of cases; they occur mostly on the lingual surface of the epiglottis.[14, 18, 24, 27] Treatment usually requires surgical drainage and is associated with an increased risk of airway obstruction.[18, 28] Such cases must be managed in conjunction with an experienced anaesthetist due to potential complications of rupture of the abscess and airway obstruction.[29]

LARYNGOTRACHEOBRONCHITIS

Viral laryngotracheobronchitis (LTB) is the most common cause of stridor in children (also known as 'croup') and usually has a self-limiting course[30] in the majority of cases. However, in children progression to an impending airway can be more rapid when compared with adults due to the relatively narrow airway.[31] The symptoms of respiratory distress and biphasic stridor occur as a result of airway narrowing below the level of the glottis. It is not known why the subglottis is specifically affected in this condition.

Adult LTB is an uncommon condition that was first reported in 1990.[32] It is a community-acquired condition and tends to be more severe in adults than in children. Patients typically present with a sore throat, malaise, stridor and dyspnoea. Endoscopic examination will reveal subglottic oedema; the supraglottis is typically unaffected and appears normal.

Adult patients with LTB require admission and observation in an appropriate setting. Treatment with oxygen, steroids and nebulized adrenaline should be administered. Although it is thought that the majority of cases are as a result of a viral infection, broad spectrum intravenous antibiotics should be administered to treat any superadded bacterial infection.

If there is significant airway compromise not responding promptly to treatment then intubation by an experienced anaesthetist in an operating theatre setting should be considered.

PERTUSSIS

Whooping cough, or pertussis, is an acute illness caused by a gram-negative pleomorphic bacillus Bordetella, usually *Bordetella pertussis*. Endotoxins and exotoxins produced by the bacteria induce an inflammatory response, stop cilia functioning and cause epithelial cell necrosis. It is a notifiable communicable disease transmitted by coughing and sneezing that affects all age groups. Pertussis is most severe in children, particularly infants. Adults and adolescents may go undiagnosed and act as a reservoir of infection as they have a milder disease and a less severe cough.

Pertussis is the most prevalent vaccine-preventable disease. The WHO-expanded program of immunization has seen the number of children worldwide fully vaccinated rise from 5% in 1974 to 83% in 2008, avoiding 680 000 deaths per year. Still, 16 million cases were reported with 195 000 deaths, 95% in developing countries where immunization coverage is poor.[33] A paradoxical rise in the incidence of whooping cough in heavily vaccinated communities including the UK is as yet not fully understood.[34] Following 14 infant deaths in the UK in 2012, all pregnant mothers are now offered vaccination in the last trimester of pregnancy to maximize maternal

levels of immunoglobulin and facilitate passive protection of the newborn when most vulnerable in the first 3 months of life.[35]

Clinical features

Whooping cough presents with symptoms of a runny nose, dry cough and mild pyrexia, similar to a common cold. The cough occurs in prolonged paroxysms after one to two weeks and is followed by gasping and the characteristic whoop in children. Milder symptoms occur in adults and adolescences, classically presenting as a protracted cough rather than the characteristic 'whooping cough' of children.

Investigations

The diagnosis should be confirmed by serum serology and nasopharyngeal aspirate culture and assay, to determine causative organism, by polymerase chain reaction (PCR).

Management

Pertussis is usually not diagnosed until the cough has developed. A 7–14-day course of erythromycin is recommended, but this does not change the character of the cough or clinical course of the disease.[36] Erythromycin is thought to prevent patients from being infectious and is recommended as prophylaxis in affected households, but the effect has been described as modest compared with good quality vaccination.[37]

The cough should be treated symptomatically with cough suppressants; however, a systematic review of the use of steroids, β2-adrenergic agonists, pertussis-specific immunoglobulin, antihistamines or leukotriene receptor antagonists showed no clear evidence base for their use.[38] Alternative antibiotic choices options are clarithromycin, azithromycin and trimethoprin-sulfamethoxazole. Fluoroquinolones are also likely to be effective in adults but there are no supporting data of effectiveness.

BEST CLINICAL PRACTICE

- ✓ Pertussis should be considered in patients of any age presenting with a prolonged acute spasmodic cough of 3 or more weeks duration.
- ✓ Once recognized, treatment with a 7–14-day course of erythromycin should be commenced.

DIPHTHERIA

Diphtheria is caused by toxigenic strains of *Corynebacterium diphtheriae*, an anaerobic gram positive pleomorphic bacillus. Less commonly, when associated with consumption of raw dairy products, *C. ulcerans* species may be responsible. Toxigenic strains are lysogenic for one of a family of bacteriophages that carry the structural gene for the diphtheria toxin. Diphtheria, a preventable disease, was endemic in the UK until coordinated mass immunization was introduced in 1942. Classically transmission is by inhalation of droplets from the upper respiratory tract of an infected individual. It affects non-immunized children and susceptible adults, particularly the elderly. The usual site of infection is the tonsil and fauces, but it can also occur in the nasal cavities or spread to the larynx.

The last indigenous UK death from diphtheria was in 1982. The ease of world travel facilitates transmission and the vast majority of the 65 positive isolates recorded in England and Wales since 1986 were imported, predominantly from the Indian sub-continent, South East Asia and Africa. A 14-year-old boy who contracted diphtheria in Pakistan died in 1994.[39] High levels of herd immunity are essential to ensure and maintain disease control. Political instability amongst other factors lead to loss of blanket immunization and a diphtheria epidemic in Russia and the newly independent states of Eastern Europe. At its peak in 1995, more than 50 000 cases were recorded.[40]

Clinical features

Diphtheria causes a severe sore throat, malaise, pyrexia and nasal discharge if the nose is affected. Examination of the throat reveals a grey pseudomembrane, which may spread to affect the larynx. The cervical lymph nodes are enlarged and tender. An infected patient may become a carrier or clinically unwell depending on the host response, virulence and toxigenicity of the infective organism. If oropharyngeal diphtheria is suspected, a swab from the throat and or oropharynx should be obtained and screened for diphtheria. This should be considered in patients presenting with membranous or pseudomembranous pharyngitis/tonsillitis and/or following overseas travel or contact with a traveller to high-risk countries in the previous 10 days. Recent consumption of raw dairy products or recent contact with farm or domestic animals may suggest *C. Ulcerans* infection. Since *Corynebacterium diphtheriae* is not easily identified, throat swabs from all patients with sore throats should be separately screened. In the UK, positive isolates should be sent immediately to the reference laboratory for detection of the potent exotoxin 28.

Management

Treatment is with benzyl penicillin and antitoxin.[41] Acute airway obstruction should be managed accordingly, ideally with intubation. Close contacts and relatives should be immunized.

Complications

The diffusible exotoxin has a predilection for cardiac and renal tissue and causes myocarditis, arrhythmias and possible death. Neurological complications due to the exotoxin may develop a few weeks after the acute infection; the most frequent is soft palate paralysis but paralysis may also affect the diaphragm and the external ocular muscles. Other long-term sequelae include scarring of the

oropharynx and nasopharynx due to fibrosis and adhesion formation.

BEST CLINICAL PRACTICE

- ✓ A throat/nasopharyngeal swab should be obtained and screened for diphtheria in patients presenting with membranous or pseudomembranous pharyngitis/tonsillitis, particularly if there is a history of travel to a high-risk country in the previous 10 days, recent consumption of raw dairy products or contact with farm or domestic animals.[42]
- ✓ If diphtheria is suspected or diagnosed, benzyl penicillin and antitoxin should be administered.
- ✓ The airway should be monitored and, if obstructed, intubation should be considered.

INFECTIOUS MONONUCLEOSIS

Infectious mononucleosis (IM) or 'glandular fever' is a common disease caused by infection with the Epstein–Barr virus (EBV), a herpes virus. Sub-clinical infection is common although symptoms are often mild and self-limiting requiring minimal intervention. EBV has a special affinity for B lymphocytes, infecting the epithelium of the oropharynx and genital tract. It is transmitted via bodily secretions, most commonly saliva when kissing. Infectious mononucleosis is commonly seen in adolescents and young adults, with an incidence of up to 50 per 1000 persons.

Clinical features

Infectious mononucleosis has an incubation period of between 4 and 7 weeks.[43] Patients present with the classical features of sore throat, tonsil enlargement, cervical lymphadenopathy, periorbital oedema, especially of the lower lids (*Hoagland sign*) and fever. Palatal petechiae are more common in younger patients whereas hepatomegaly and jaundice are relatively more common in the older population. Splenomegaly is a late sign of infection and resolves within 3–4 weeks but fatigue and myalgia can persist for a number of months following resolution of the initial infection.

Investigation

Patients should have a full blood count (FBC), liver and renal function tests. Infectious mononucleosis is suspected if there is either a leucocytosis of >50% of the total white cell count (WCC) and 10% atypical leucocytes, or 20% atypical leucocytes.

The Monospot test and Paul-Bunnell test are types of heterophile antibody test. The Paul-Bunnell test is based on sheep red blood cell (RBC) agglutination, whereas the more sensitive and specific monospot test is based on latex agglutination using horse RBCs.[44]

Positivity to Monospot increases over the first 6 weeks of IM infection as the EBV heterophile antibody titres reach their peak; repeat testing 7 days later may be required. In the face of repeatedly negative Monospot tests, cytomegalovirus (CMV), human immunodeficiency virus (HIV), toxoplasmosis and rubella testing should be considered.

Management

As there is no specific treatment for infectious mononucleosis, supportive measures such as fluids, analgesia and rest are advised. Superimposed streptococcal throat infection may occur and antibiotic treatment required. Aminopenicillins such as amoxicillin or ampicillin should not be used due to the incidence of maculopapular rash. Acyclovir has not been proven to affect the outcome and is not advised in the management of uncomplicated infectious mononucleosis.[45] Corticosteroids improve pain scores and time to symptomatic resolution for pharyngeal infections, especially when given in combination with antibiotics.[46]

Complications

Airway obstruction due to cervical lymphadenopathy and tonsillar hypertrophy is a rare but potentially fatal complication of infectious mononucleosis.[47]

Other complications include anaemia, thrombocytopenia, encephalitis, transverse myelitis, Gullian–Barre syndrome, pericarditis and myocarditis.

Hepatomegaly resulting in jaundice and splenomegaly are late findings. Patients are counselled to avoid sport or vigorous activity due to potential splenic ruptures, the majority of which occur following minor trauma.[48] The rate of rupture is less than 1 in 500. Whilst recovery is usually quoted at 4–6 weeks, a small population of patients suffer prolonged fatigue, with 13% at 6 months and 4% at 2 years meeting the criteria of chronic fatigue syndrome.[49]

BEST CLINICAL PRACTICE

- ✓ Diagnosis of IM is by heterophile antibody test. The Monospot test is the most sensitive and specific test.
- ✓ Treatment is supportive.
- ✓ Steroids may aid in the management of the partially obstructed airway but intubation or tracheostomy are required when the airway is considered unsafe.
- ✓ Corticosteroid in combination with antibiotic treatment reduce pain scores and time to symptom resolution of pharyngeal symptoms.
- ✓ Amoxycillin should be avoided due to the risk of a macular rash in EBV infections.
- ✓ Patients should be counselled with regard to physical activity.

MYCOTIC LARYNGITIS

Fungal infections of the larynx are usually secondary to fungal inhalation in immunosuppressed patient with laryngeal mucosal disruption.[50]

Clinical features

Mycotic laryngeal infections are rare in patients with normal immune function; when they do occur they present as subacute or chronic infections. In contrast, immunocompromised patients, particularly those with haematological malignancy, are prone to acute infection from these opportunistic pathogens.[51] Mycotic laryngitis, with the exception of superficial candida infection, is usually associated with ulceration. Infections from candida and aspergillus are widespread but coccidioidomycosis, blastomycosis and histoplasmosis are endemic to specific geographical regions.

The larynx is probably affected by candida more often than realized and should be seriously considered in patients with refractory symptoms; up to 15% of patients with chronic laryngitis are diagnosed with mycotic lesions when examined.[52] In immune-competent patients, the most common predisposing factors are recent treatment with antibiotics, use of inhaled steroids,[53, 54] diabetes, chemotherapy, radiation therapy, smoking, acid reflux and inhalational or thermal trauma. Often, more than one predisposing factor is present. The characteristic finding in the larynx is a white pseudomembrane or adherent white plaque that can be mistaken for leukoplakia. It can also appear as diffuse erythema, with oedema and ulceration in severe infection. Whilst invasive candidal infections are rare, it is thought that colonization has an indirect effect on defence mechanisms and aids development of bacterial infections locally.[55]

Invasive aspergillosis is an opportunistic infection that occurs mainly in immunocompromised patients with haematological malignancies. Primary laryngeal aspergillosis is very rare, but recognition is important as steroids could have an adverse effect in affected patients with airway distress.

Investigation

Pulmonary fungal disease should be excluded and all patients with mycotic laryngitis should have a chest radiograph. Fungal trachea-bronchitis is generally limited to HIV-positive patients or the severely immunocompromised. Such cases present with stridor, fever and a productive cough.

Direct laryngoscopy and biopsy may be necessary to confirm a diagnosis of fungal laryngitis. It is of note that the more chronic fungal infections, such as blastomycosis, can present as a laryngeal mass requiring laryngeal biopsy for a definitive tissue diagnosis.[56] Special fungal stains, such as methenamine silver and periodic acid-Schiff, are required to identify the fungal hyphae. However, histology will not differentiate between the specific fungal species for which cultures are necessary.

Management

Systemic antifungal therapy is necessary for immunocompromised patients. Antifungal agents suppress fungal growth, making recurrent infection likely unless the underlying predisposing factors are addressed and corrected. Recurrence will also occur if the agent is used for too short a period or in an inadequate dose. Suitable agents include fluconazole, ketaconazole, itraconazole and amphotericin B. Each agent has its own characteristics: fluconazole for 3–4 weeks is the preferred agent for candida infection; itraconazole is particularly effective for aspergillus infections at a dose of 100–400 mg daily, monitored by regular blood levels; ketaconazole is the agent of choice for histoplasmosis and blastomycosis. Amphotericin B needs to be administered intravenously and also has significant adverse effects on the kidney, heart and liver.

BEST CLINICAL PRACTICE

- If acute mycotic laryngitis is suspected, immunodeficiency should be considered and investigated.
- Patients with a diagnosis of fungal laryngitis should have a chest radiograph.
- A direct laryngoscopy and biopsy is recommended in severe presentations and non-responders to initial therapy. Samples should be sent for histology and specific fungal cultures.
- A suitable course of a specific antifungal medication should be administered and predisposing factors should be addressed and corrected.

LARYNGOPYOCOELE

A laryngocoele is an abnormal dilation of the lateral most region of the laryngeal ventricle. The sac is lined with pseudostratified columnar ciliated epithelium, maintaining a connection to the ventricle. Laryngocoeles are described as internal, external or mixed. Internal laryngocoeles do not extend laterally through the thyro-hyoid membrane, external laryngocoeles exist lateral to the thyro-hyoid membrane, whereas mixed have both internal and external components. Laryngocoeles are more common in men and increase in incidence with age, though are still rare, with an incidence of 1 per 2.5 million per year.[56] The aetiology is unknown, with factors that increase intra-glottic pressure (e.g. glass blowing, trumpet playing, weight lifting) suggested as having a role in development. The laryngocoele normally contains air or mucus connecting with the airway. A laryngopyocoele forms when the neck of the sac become blocked and the laryngocoele becomes infected and contains mucopus.[57]

Clinical features

External laryngocoeles present commonly as a lump in the neck. It may possibly inflate on performing a Valsalva manoeuvre or may be emptied with external pressure (Bryce's sign).

Internal laryngocoeles may present with hoarseness, dysphagia or globus. Flexible nasendoscopy classically shows an enlarged and smooth swelling of the false cord, often making visualization of the cords challenging. Due to the association of laryngeal squamous cell carcinoma (SCC) within the ventricle and laryngocoele, it is advisable to carefully examine the area endoscopically.[58–60]

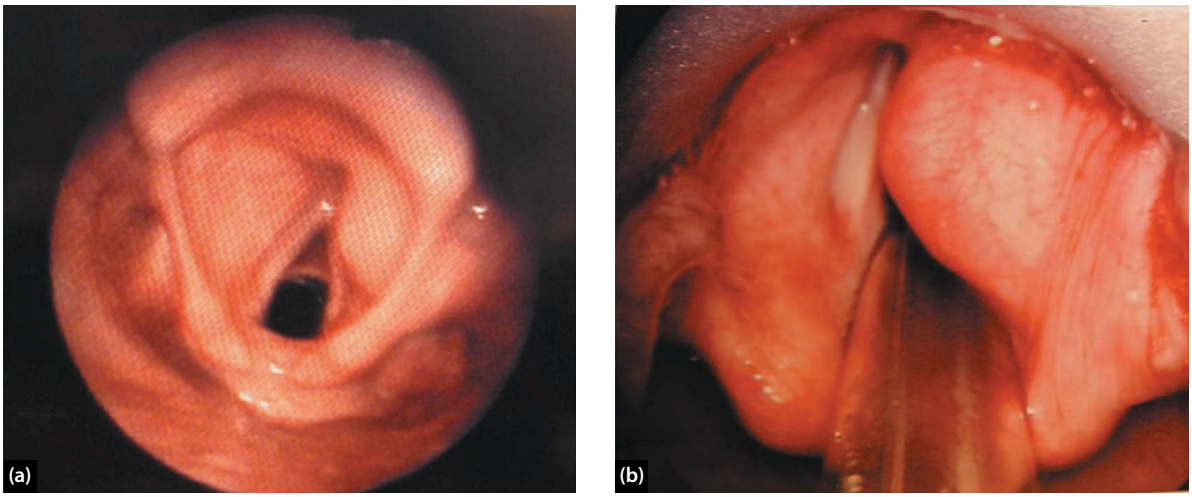

Figure 69.1 (a) Appearance of a right-sided laryngocoele as seen with a flexible laryngoscope. **(b)** Endoscopic appearance of right-sided laryngocoele at the time of surgery.

Laryngopyocoeles can present with pyrexia, dysphagia and potential airway compromise.[61]

Investigation

Cross-sectional imaging with CT allows delineation of cystic and laryngeal architecture. An MRI scan allows allows better characterization of soft tissue abnormalities.[62, 63]

Management

A patient with an evolving laryngopyocoeles may present as an acute airway emergency, stridulous and in respiratory distress. Definitive airway control via means of a tracheostomy or intubation may be required. For this reason surgical excision of laryngocoeles is advised prior to the evolution into a laryngopyocoele and the potential airway compromise. Patients presenting with a laryngopyocoele should be treated with intravenous antibiotics and dexamethasone, with needle aspiration of the external component if feasible. Following resolution of the infection a delayed excision of the laryngocoele is advised. Management can be either via the classical lateral external approach or endoscopically. Endoscopic excision using CO_2 laser has been shown to be effective in the management of the internal and external component.[64]

BEST CLINICAL PRACTICE

- Emergent airway management in cases of airway instability.
- Treatment with high-dose intravenous antibiotoics and dexamethasone.
- Tracheostomy placement if no improvement with conservative management.
- Early elective surgical excision.

KEY POINTS

- Consider early surgical management of laryngoceles to prevent a potential laryngopyocoele.
- Excision can be endoscopic or external approach.
- Laryngopyocoeles can cause airway obstruction

SEARCH STRATEGY

This search was carried out in conjunction with The Clinical Effectiveness Librarian, Glasgow Royal Infirmary, Greater Glasgow & Clyde NHS Trust and University of Glasgow using Medline, M base, and Pubmed to search with the following keywords: chronic laryngitis, aetiology, diagnosis and treatment.

INTRODUCTION

Chronic laryngitis is chronic inflammation of the laryngeal structures, most commonly affecting the laryngeal mucosa and to a certain extent the submucosa. The chronic inflammatory process can be due either to infectious or non-infectious causes, with a broad spectrum of aetiologies which may act singly or in combination. The chronic changes in the larynx can result in many laryngopharyngeal symptoms but the principal effect of the condition is a persistent and fluctuating change in voice and subsequent impact on the quality of life of the patient. The high prevalence of the main aetiological factors associated with chronic laryngitis, namely smoking and voice abuse, and the debated influence of reflux disease, whether it be laryngo-pharyngeal reflux or gastro-oesophageal reflux, results in the management of this condition being challenging in relation to both diagnosis and efficacy of treatment.

In 1976, Stell and McLoughlin commenced the debate around the aetiology of chronic laryngitis and concluded from their case controlled series that occupational effects had only minimal influence: smoking was no greater than in the control group, but that infection of the upper and lower respiratory tract was of significance.[1] Intuitively it would seem likely that the type of occupation, and associated environment might have a significant influence on the quality of the air, or the fumes inhaled, or how the voice might be used, for example, in the presence of background noise.

This has been supported by reports in various case series of the relationship between occupations and chronic laryngitis; with excess noise at work,[2] asbestos workers,[3, 4] cement workers,[5] solvents and shoe workers,[6] hairdressing,[7] and glass blowers.[8]

The association between the remainder of the respiratory tract and the larynx and possible concurrent aetiologies have been highlighted in reports relating to allergy.[9, 10] The underlying hypothesis is that allergens which cause adverse effects in the upper airways, such as the nose, nasopharynx and pharynx, are likely to have a similar effect on the larynx and hypopharynx. Whilst this may be the case, the more likely cause is through the use of inhaled drugs in lower respiratory tract disorders such as asthma and the overall management of

both nasal and paranasal sinus disorders. The effect of respiratory inhalers, not only with regard to their content but also their propellant, on the laryngeal structures is well documented and it remains a continuing challenge on how to balance the need for optimal treatment of the peripheral airways and improvement of the patients' ability to breathe, and subsequent quality of life, against the adverse effect of the inhaled drugs being present in the larynx and proximal trachea.

Significant debate exists about the aetiology and subsequent management of chronic laryngitis in the setting of gastro-oesophageal reflux (GORD) and laryngopharyngeal reflux (LPR). It would appear from the literature that clinicians consider a relationship to exist between these disorders,[11] but how this is diagnosed and ultimately managed effectively remains a significant challenge to all of those dealing with disorders in each of these subsites. A detailed treatment of GORD and LPR can be found in Chapter 77, Reflux disease.

Chronic laryngitis can be caused by a wide variety of infective organisms. Perhaps the most graphic example is seen with candidal infection affecting all areas of the upper aero-digestive tract, seen in patients with underlying immunocompromise, diabetes mellitus, after chemoradiotherapy or following prolonged antibiotic administration.

This spectrum of disease in the larynx will be considered in two main sections: the clinical diagnosis of general diffuse laryngitis with no identifiable cause and specific forms of chronic laryngitis due to rare but recognized aetiologies.

CLINICAL PRESENTATION

History

The key symptom associated with chronic laryngitis is alteration in voice quality in the form of hoarseness (dysphonia). In trying to differentiate this from other forms of dysphonia, the voice in chronic laryngitis generally tends to be rough or coarse, and may have an overall reduction in the pitch. It tends to develop gradually with an insidious onset and may be present for several months or years. The hoarseness is persistent with the voice being seldom, if ever, normal but it is rare for there to be aphonia.

There may be associated symptoms with the chronic laryngitis such as difficulty in swallowing (dysphagia), a sensation of something being in the pharynx, painful or strained speaking , throat ache or discomfort, throat clearing, persistent non-productive cough, halitosis, unusual taste or bitter taste, otalgia, water brash or indigestion.

It is important to establish the concerns of the patient with regard to any underlying issues such as their worry of the risk of malignancy through to whether they want complete resolution of their voice and upper aero-digestive problems. It may be that the patient has been a long-standing smoker and simply wants to be reassured that there is no malignancy or alternatively that they are a professional voice user, such as a teacher, whose voice problems are a result of the chronic laryngitis, preventing them from fulfilling their professional obligations. It is essential to establish the effect a patient's dysphonia on various spheres of activity, as it is well recognized this dysphonia has an overall impact on their quality of life.[12–15] To a certain extent this will influence, and possibly determine, the aims of the subsequent assessment and treatment strategy.

Having established the principal characteristics of the dysphonia, and associated symptoms, there are other key elements of the history which are important to elucidate with regard to potential aetiological factors. Clearly, these aetiological factors can act singly or in combination:

- Smoking: A key factor in chronic laryngitis. The type, frequency and duration of smoking should be noted.
- Reflux: Laryngopharyngeal symptom matrix may indicate possible reflux type. Past history of upper GI dysfunction such as *H Pylori* infection, upper GI investigations including gastroscopy, pH monitoring or manometry and possible upper GI surgery should all be noted.
- Patient's occupation: The working environment should be identified as it might highlight the environmental quality of air or presence of fumes and the noise level in which the patient has to communicate.
- Social activities: The type and environment of social activities should be noted as this may aggravate chronic laryngitis.
- Allergies: Both proximal and distal aero-digestive tract and their treatment.
- Co-existent disease which may be associated with chronic laryngitis such previous radiation therapy for head and neck malignancy, immuno-suppressed states, diabetes, and diseases associated with specific types of chronic laryngitis such as tuberculosis, sarcoid or granulomatosis with polyangiitis (previously called Wegener's granulomatosis).

Irrespective of the causation, the unrelenting effect on the voice, the co-existent laryngopharyngeal symptoms and the subsequent impairment on the ability of an individual to communicate and carry out their daily functions, either on a professional basis or socially, has a significant impact on their quality of life. Given both the chronicity and the relationship to long-established habits, there is a considerable challenge to try to improve the symptoms associated with this condition.

ASSESSMENT

Outpatient setting

Assessment of a patient with dysphonia starts during the consultation. During this time both consciously and subconsciously the clinician is assessing the quality of the patient's voice in relation to their history. Specifically, with regard to chronic laryngitis the severity of the dysphonia harshness and breathy components, strained intonation of the voice, associated tension and anxiety are all assessed.

Comprehensive assessment of the ear nose and throat is necessary. Examination of the ears and hearing should be carried out as it is important to establish that the hearing is within normal limits and rehabilitated appropriately. With regard to the nose it is necessary to establish if there are any significant nasal abnormalities which might result in persistent obstruction or mouth breathing, and whether or not there is any evidence of allergic rhinitis. Per-oral pharyngeal examination is carried out to ensure there is no significant oral or oropharyngeal pathology which might be associated with smoking, as well as identifying significant caries or candidiasis.

The key investigation in the management of this type of patient is examination of the larynx in the resting and neutral state. This is best achieved by fibreoptic nasendoscopy examination. To facilitate this, the nose can be prepared with topical decongestant and local anaesthetic agent such as Cophenylcaine. This anaesthetizes and vasoconstricts the nasal mucosa so allowing easier passage of the nasendoscope. The disadvantage of such a preparation is that patients frequently find it unpleasant, both in the application of the nasal spray due to its effervescent component and also the taste associated with it.

If a more detailed examination of the structures of the larynx is needed then per-oral rigid laryngoscopy is carried out, having applied some form of topical anaesthesia to the oropharynx. This is generally coupled to a camera system and may be used with or without stroboscopy. This combination of examination techniques allows more detailed examination of the structure and movement of the vocal cords and possible asymmetry as this may indicate any potential underlying malignancy or other pathology such as cystic lesions of the vocal cord.

The principal aim of these outpatient assessments is to determine whether microlaryngoscopy under general anaesthesia is required. This is generally determined on the level of suspicion following the outpatient examination with regard to the presence or otherwise of localized or discrete abnormal areas in shape and/or colour. If there is any concern about the presence of malignancy, this should precipitate the need for microlaryngoscopy.

Frequently, however, there are only vague, non-specific diffuse oedematous alterations in colour and structure, the combination of which may result in a provisional clinical diagnosis of chronic and inflammatory laryngitis.

The abnormalities may affect all subsections of the larynx, e.g. all of the true cords or be restricted to specific areas. Clinical experience suggests that there is considerable inter- and intra-observer variability when assessing the larynx in the outpatient setting. Pontes et al. reported in a case series of 85 patients with multiple benign laryngeal pathology that there was frequent inter-observer variation in relation to diagnosis of each of the pathologies involved.[16]

Given the wide range of non-specific appearances within the larynx, several workers have suggested descriptive criteria on which to base the recording of the assessment of the chronic laryngitis. This is a necessity when trying to evaluate treatment strategies, the most notable of which is the treatment of gastro-oesophageal and laryngo-pharyngeal reflux. An example of this is by Feehs and Koufman[17] who described the spectrum of findings without a numerical grading system. The grading system was hierarchical as follows:-

1. Red arytenoids and piled up into the arytenoid mucosa.
2. Diffuse oedema, including Reinke's space, mucosal thickening but possibly minimal erythema.
3. Diffuse oedema with granular friable mucosa.
4. Discreet granulomas, with or without, oedema and erythema.

Intuitively, it would seem reasonable to conclude that reasonable inter- and intra-observer repeatability can be achieved if there is a discrete lesion such as a granuloma and more specific pathology such as Reinke's oedema. However, with regard to chronic laryngitis, it is unrealistic to expect any repeatability that would be clinically meaningful.

In an attempt to try to achieve this, photographic recording of either the flexible or rigid endoscopic findings is advocated. Despite doing this, there is a still subjective assessment of these images which is open to a similar difference and variation in interpretation as in a 'live' examination.

At this stage, operative assessment may not be deemed appropriate in that the treatment may be principally non-surgical or medical, such as in chronic non-specific laryngitis, or because the patient does not wish any alteration to their voice, such as in Reinke's oedema or in vocal cord nodules. It may therefore be more appropriate to refer patients to speech and language therapy for consideration of a course of voice therapy.

OPERATIVE ASSESSMENT

The need for endoscopic assessment under general anaesthesia is established in the outpatient setting. A significant proportion of patients with apparent inflammatory changes within the larynx will require further assessment by carrying out microlaryngoscopy under general anaesthesia for the following principal indications:

- Any area of the larynx which might be considered suspicious with regard to dysplastic changes or overt malignancy.
- Co-existent pathologies such as vocal cord polyp, which need surgical management.
- Inability to examine the larynx comprehensively due to the patient not being able to comply due the larynx being obscured, for example by the presence of crusting of secretions.
- Failure to respond to medical treatment.

To facilitate the best operative view when carrying out the procedure, it is necessary to have appropriate maintenance of ventilation. A technique that allows completely unobstructed view while allowing visualization, whilst at

the same time facilitating the use of the CO_2 laser, is that of supraglottic jet ventilation. The disadvantage of this is that the effectiveness of this ventilation using capnography cannot be assessed readily, which may be relevant in patients with chronic obstructive airways disease. A more stable and secure way of ventilating the patient is to use a microlaryngeal tube, size 5 or 5.5, which has the added advantage of protecting the airway in the event of gastro-oesophageal or laryngo-pharyngeal reflux. The disadvantage is that it partially obscures the view of the vocal cord and has to be converted to a specific laser endotracheal tube of a similar size should the CO_2 laser be used.

The compromise is to ventilate using a subglottic form of jet ventilation such as the Hunsacker Mon-jet ventilation system. This small tube sits in the posterior commissure and allows a greater view of the larynx but at the same time ventilates in a more controlled fashion than the supraglottic jet ventilation. It has the added theoretical advantage that the end tidal CO_2 levels can be determined.

The patient's larynx is assessed using 0, 30 and 70 degree rod lens endoscopes so that the type and extent of any lesion or lesions can be determined. If the lesion is discrete then excision biopsy, if at all possible, should be carried out. This is generally done using cold instrumentation to resect the lesion carefully from the underlying structures with minimal trauma, resulting in a histopathological diagnosis with no change, or only minimal change, in the voice.

If there are diffuse changes throughout the larynx a representative biopsy should be taken and this can be carried out using a cupped biopsy forceps such as a 4 mm type. However, this is a significant size and it may be more appropriate to take the biopsy using cold instrumentation and excise a specimen assuming an appropriate amount of submucosal tissue is incorporated into the specimen. Consideration should be given to the position and amount of tissue to be removed. If there is a diffuse, but uniform appearance, then a representative specimen should be taken from an area unlikely to affect the voice. Such an area would be the superior, super lateral aspect of the vocal cord or from the supraglottis.

HISTOLOGICAL FEATURES OF CHRONIC LARYNGITIS

Microscopy reveals benign mucosa usually covered by squamous epithelium of variable thickness with a tendency to keratinization. The active changes are present in the epithelium but no convincing epithelial dysplasia is identified. The lamina propria may be oedematous and contains a chronic inflammatory infiltrate of variable intensity including lymphocytes and macrophages. A light scattering of acute inflammatory cells is also often present. Patchy permeation of the surface epithelium by the inflammatory cells commonly occurs. There is variable degree of fibrosis of the lamina propria and prominent small vascular channels may be seen.

There is a need for robust classification which reflects the histological characteristics of chronic laryngitis. The principle is that in a certain proportion of patients who have chronic laryngitis there may be characteristics of their disease state which are liable to undergo potential malignant change. There is therefore a need to identify the cohort of patients in whom treatment may have to be more aggressive with closer monitoring. The most widely used system is the WHO grading for dysplasia into mild, moderate and severe. However, this system is prone to low interrater agreement. An alternative is the Ljubljana classification system that has been in use for several years. Gale et al. reported in a retrospective case series the Ljubljana classification of laryngeal lesions in relationship to subsequent malignant transformation. The hyperplastic laryngeal lesions (n = 4574) were graded into simple, abnormal, atypical hyperplasia (risky epithelium) and carcinoma *in situ*. Malignant transformation in the atypical hyperplasia was 11.6% whereas in the benign group, simple and abnormal, it was 0.3%. From this analysis, the authors concluded that this classification system was of value with regard to identifying potential malignant transformation.[19] This has recently undergone further clinical validation and a change in nomenclature (current terminology is low-grade squamous intraepithelial neoplasia (SIL), high grade SIL, carcinoma-*in-situ*), with a detailed description of the morphologic criteria for these groups. The management of dysplasia is discussed elsewhere in the book, with consensus recommendations on treatment and follow up.

NON-SPECIFIC LARYNGITIS

Non-specific laryngitis is a common condition presenting with persistent and unrelenting dysphonia which can vary in quality, severity and duration. Depending on the aetiology, it may result in only a mild effect on the quality of the voice or render the patient's voice harsh leading up to aphonia. Associated with this change in voice, patients may have symptoms such as pain or discomfort in their throat, description of an awareness in their throat with globus pharyngeus type symptoms, halitosis or otalgia, or the report of symptoms of excess catarrh with persistent throat clearing. The most frequently implicated aetiological factors are smoking, voice abuse, and reflux disease, namely gastro-oesophageal reflux and laryngo-pharyngeal reflux.

To further challenge the clinician's comprehensive management of this disease is the wide range of clinical features which may be associated with the clinical diagnosis of non-specific laryngitis. These features can range from localized specific appearances within the larynx through to complete and diffuse changes in the larynx rendering the larynx almost unrecognizable from its normal appearance. Furthermore, this multiplicity of aspects of the disease process renders the assessment of the disease, and efficacy of any of the treatment strategies, extremely difficult. It may therefore be that the management of this ill-defined wide-ranging condition may have to be pragmatic by targeting management, by identifying potential

aetiological factors, confirming the diagnosis, initiating treatment and finally investigating or further modifying treatment should this pragmatic approach not improve the patient's symptoms.

IDENTIFYING THE POTENTIAL AETIOLOGY

Given the key aetiological factors, it is likely that they will vary in influence from country to country and within countries. Despite this epidemiological variation, it is likely that the most common aetiological factor in non-specific laryngitis is that of smoking which in turn may be the most challenging aspect of the disease to manage.

Intuitively, it could be expected that chronic contamination, or infection of the larynx, might be the key in generating a chronic laryngitic picture. Some authors have found that septic foci are present,[20] whilst others have not been able to demonstrate bacteria in chronic inflammatory laryngeal samples,[21] while other groups have demonstrated the presence of bacterial biofilm.[22] Furthermore, in relation to specific bacteria, *H pylori* has been identified in those patients with chronic laryngitis and laryngeal cancer[23, 24] and so the question arises to whether eradication strategies should be implemented in this group.[25] The specific role of bacteria continues to be debated and it would seem a rational approach to treat any overt bacterial infection, whether it involves the larynx directly or indirectly as a secondary effect caused by lower respiratory tract infection with the subsequent indirect traumatic effect on the larynx caused by coughing and expectoration.

A common potential aetiological factor is voice misuse or abuse. If an individual has to use their voice for a significant period of time in an environment which might be irritating, or where they may have to raise the volume of their voice over a significant period, then it is likely that they may develop secondary inflammatory changes in the larynx in response to the voice usage. If, following this period, there is not sufficient time for compensatory rest then the acute laryngeal changes may become chronic, particularly if the process of voice misuse is repeated on a regular basis.

The third key potential aetiological factor implicated in chronic non-specific laryngitis is reflux disease. When considering this potential aetiological factor, there is reliance on the other symptoms which may be present due to reflux, both gastro-oesophageal and laryngopharyngeal. Although there are other types of reflux, these are the two which are primarily implicated in most discussions around the evidence relating to chronic laryngitis and reflux. The recognized symptoms associated with reflux disease and chronic laryngitis are those of globus type symptoms of awareness in the throat, persistent throat clearing, alteration in the voice, altered taste in the mouth, and possibly symptoms of heartburn or indigestion.

The relationship between potential reflux and the symptoms associated with chronic laryngitis are based on two main hypotheses, firstly that of the direct contact and contamination of the upper airways by gastric acid or refluxate, in some cases pepsin, and secondly by the vaso vagal reflex triggered by acidification of the distal oesophagus. The association between ENT symptoms, not just those of chronic laryngitis, and reflux are well recognized and published widely.[26]

DIAGNOSIS

The majority of patients diagnosed with non-specific laryngitis are based on examination in the outpatient setting by identifying a group of signs present in the larynx on examination using the fibreoptic nasendoscope or the video-stroboscope having established an appropriate history. The key features of non-specific laryngitis are a diffuse inflammatory picture with widespread irregular mucosa, varying degrees of oedema, erythema, exudate, but inevitably with distortion of the normal anatomical features in a diffusely irregular and swollen manner. Given that a high proportion of these patients will have smoking as an aetiological factor, a key clinical decision is whether or not there may be any cancerous or precancerous elements in the larynx. If it is not possible to state unequivocally that the laryngeal appearances, although diffuse, are in keeping with a completely benign picture then the larynx will need to be examined in more detail by microlaryngoscopy, and representative histology of the laryngeal surfaces obtained. In severe cases, there may be gross abnormalities of the larynx with the surface mucosa being obscured by the presence of a substantial amount of exudate this covering possibly being dried and crusted, so obscuring the clinical picture. It is frequently necessary in this group of patients to irrigate the larynx with saline during microlaryngoscopy to ensure that detailed assessment and subsequent appropriate biopsy can be carried out without initially traumatizing the inflamed larynx by direct instrumentation by laryngeal suction.

In many patients, the diagnosis will be made on the symptom complex and the clinical examination. To try to aid in the differentiation between the various aetiological factors, methods of assessing potential contribution of reflux have been suggested. The most frequently one advocated is the Reflux Symptom Index (RSI) the validity and reliability of which were initially described by Belafasky et al, who described evaluation of this self-administered nine-item outcome instrument for LPR in relation to the Voice Handicap Index (VHI).[27] Although this relates specifically to the assessment of the RSI as a patient report tool in comparison to VHI, it did demonstrate that patient reported voice disorders had a significant improvement following empirical PPI treatment in those suffering from chronic laryngitis. The use of the RSI in conjunction with other patient reported voice outcome measures, namely the VoiSS, has been reported by Beech et al. again with good correlation.[28] In this group, acid suppression therapy was shown to be of some benefit in chronic laryngitis patients without troublesome reflux symptoms the RSI and the VoiSS scores both being improved with Proton Pump Inhibitor prescription and voice therapy carried out by Speech and Language Therapy.

To aid in the diagnosis of the possible influence of reflux in the larynx it has been suggested that the Reflux Finding Score (RFS) may be used and previous reports have shown

that although this is a sensitive method picking up pH proven reflux patients specificity may be quite low, with a sensitivity of 87.8% specificity of 37.5% respectively.[29]

The principal aim of having any of these scoring systems is to try to establish a process which would have a low inter- and intra-observer variability with a high level of repeatability so that treatment strategies can be evaluated comprehensively.

TREATMENT

If each of the investigations carried out identify that the laryngitis is indeed non-specific then the treatment that is used will address each of the main aetiological factors of smoking, voice use, and reflux.

Robust, evidence based smoking cessation strategies are currently available, ranging from counselling and behavioural therapy through to pharmaco-therapy including nicotine replacement, Varenicline and Bupropion sustained release.[30] Although this commitment and drive is present in cancer groups, in realistic terms it may be more difficult to persuade someone with chronic laryngitis to stop as at this stage there would be no life threatening condition present.

Voice misuse or abuse, must be addressed and is the main stay of treatment of chronic laryngitis is addressed in detail in Chapter 66, Speech /voice therapy for voice disorders.

The therapy designed by the speech and language therapists is comprehensive not only in relation to the laryngeal structure and function but also addresses aspects of lifestyle and voice use by discussing vocal hygiene and addressing dysfunctional components of voice production. This subtle combination of history taking, diagnosis, treatment planning and execution and 'ad hoc' psychotherapy has been recognized in the past to be of clinical value. There had, however, been little evidence in support of its use except for some level 3 evidence from short case series for voice therapy being used in specific conditions such as vocal cord nodules or Reinke's oedema.[31] In 2001, MacKenzie et al. reported a randomized controlled trial of the use of voice therapy in a heterogenous group of voice patients who had conditions which one would normally expect to see benefit from voice therapy namely vocal cord nodules, functional dysphonia and chronic laryngitis. The principal outcome from the study, patient self-report, was significantly better in the group who received voice therapy when compared with the control group of observation only.[14] The voice therapy used was based on the reported consensus of treatment by UK Speech and Language Therapists in a group of laryngological disorders, one of them being chronic laryngitis.[32] The study results indicate that referral to the Speech and language therapy team for voice therapy is highly appropriate and of benefit to those suffering with chronic laryngitis.

The most contentious area in the treatment of chronic laryngitis is that of precipitating or concurrent reflux disease. There is a wide range of evidence trying to address the issues surrounding the treatment of reflux disease. The extra oesophageal manifestations of those patients suffering from laryngo-pharyngeal reflux or gastro-oesophageal reflux disease are covered in detail in Chapter 77, Reflux disease. Delahunty described inflammation of the posterior third of the vocal cords associated with GORD on barium swallow and subsequent successful symptomatic treatment with antacid. This possible association between GORD and chronic laryngitis was initially known as acid laryngitis.[33]

In an observational series in 1982, Ward et al. described a group of 86 patients with chronic non-specific laryngitis which they hypothesized was due to local irritation by chronic coughing and throat clearing which in turn was secondary to a hiatus hernia and gastro-oesophageal reflux.[34] This hypothesis was tested further, and much more 'invasively', in a surgical series by Deveney et al. In a cohort of 13 patients with chronic non-specific laryngitis and confirmed GORD the performance of a Nissen fundoplication resolved the laryngeal problems in 11 (73%). This small study group was very carefully selected in that each patient had ceased smoking for at least six months. The conclusion was that surgical correction of the GORD in a select group of patients will resolve the laryngeal problems.'[35] However, it could clearly have been the cessation of the smoking which had the greater influence.

There are two principal theories to explain the pathophysiology. Firstly, the refluxate from the stomach and oesophagus crossing the upper oesophageal sphincter can cause an inflammatory effect on the laryngo-pharynx. Secondly, chronic repetitive throat clearing and coughing which is caused by a vagally mediated response from the oesophagus can indirectly cause laryngitis.[36] If either, or both of these theories, is correct then there should be an increased prevalence of laryngeal disorders in patients suffering from oesophagitis.

El-Serag and Sonnenberg demonstrated in a large case controlled series of patients with erosive oesophagitis (n = 101, 366) the higher statistically significant odds of laryngitis (odds ratio shows 2.1; 95% CI 1.53 to 2.63). This would strongly support this hypothesis.[37]

This study supports the empirical treatment of extra oesophageal manifestations of reflux disease, of which chronic laryngitis is only one. This empirical practice has been widespread in patients with laryngopharyngeal symptoms, with or without, gastro-oesophageal reflux symptoms. A frequently quoted study was carried out by El Serag et al. in 2001 to test the validity of this treatment strategy. A randomized controlled trial of PPI versus placebo was performed in a group of patients (n = 22) with chronic laryngitis. Following confirmation of the disease status by upper GI endoscopy 24 hour oesophageal, and pH monitoring, laryngoscopy, and symptom questionnaires, the patients were randomized to receive either Lansoprazole 30 mg bd or matching placebo for three months. The primary outcome of complete resolution of laryngeal symptoms was seen in 6 of the Lansoprazole group compared with 1 (10%) of the placebo group ($p < 0.05$).[38] The authors concluded that empirical treatment with Lansoprazole is efficacious when relieving symptoms of laryngitis compared to placebo but with a cautionary note that the study was carried out in patients with a high chance of having

GORD and that it would have to be repeated in the general population if it was to be universally applied to all patients presenting with laryngeal symptoms.

Essentially, the treatment strategies can be split into those who believe that it is appropriate, and indeed advisable, to treat potential reflux disease empirically[39–46] and those who do not.[47–49] The indications and thresholds for this treatment can vary enormously with the indications being fairly minimal and the treatments used being wide ranging. The commonest treatment advocated is the prescription of a PPI where the main protagonists would suggest a strategy where it should be tried for several weeks and if does not succeed then perhaps change in this treatment with change of PPI dosage or supplementation or augmentation by other treatment such as antacids and alginates.[50] Those who do not support this strategy would suggest that widespread non-specific or non-targeted treatment of such populations result in inappropriate treatment with the sequelae in individuals such as rebound and excess gastric secretion and altering the bacterial flora profile of a population.

Whilst it might be considered medically appropriate to carry out tests to determine the presence or otherwise of reflux, and indeed the type of reflux, a pragmatic approach to this very common disease management is frequently indicated. On balance, there is a majority of clinicians who have the view that at least a trial of anti-reflux medication in the form of a PPI, with or without an alginate, and in these patients in whom there is not an appropriate response when one is expected or anticipated then it would be necessary to proceed to more detailed and more specific investigations. This is supported by a meta-analysis by Quadeer et al, who concluded that 'PPI therapy may offer a modest, but non-significant, clinical benefit over placebo in suspected GERD related chronic laryngitis' and recommended that validated diagnostic guidelines be used to facilitate the recognition of the patients most likely to respond to PPI treatment.'[51]

This relatively unsatisfactory state of affairs regarding treatment does appear to be the current practice. We advocate that that clinicians carry out treatment strategies on assessment of patients on an individual basis rather than having a blanket strategy of simply giving each patient anti-reflux medication.

CHRONIC LARYNGITIS AND MALIGNANCY

The relationship between gastro-oesophageal reflux and laryngopharyngeal reflux disease in chronic laryngitis, laryngeal dysplasia, has been widely debated for many years.[52, 53] The difficulty, however, is trying to identify studies without the confounding effects of other possible aetiological factors such as tobacco and alcohol. From a practical perspective, however, a high number of patients with chronic laryngitis will be smokers and as such will be exposed to the carcinogenic effects of smoking. It is clear therefore that a proportion of these patients who will have been diagnosed initially as having chronic laryngitis will progress to invasive squamous cell carcinoma. It is likely, however, that this diagnosis may have co-existed with early dysplastic changes with the latter subsequently transforming into frankly invasive malignancy. This therefore would be co-existent pathologies rather than malignant transformation from chronic laryngitis itself. Irrespective of the origins the level of clinical suspicion and treatment need to be the same.

KEY POINTS

- Aetiologies generally multi factorial.
- Main aetiological factors are smoking, voice abuse, LPR and GORD, and environmental factors.
- Empirical treatment with PPI can be considered.
- Supplementation with alginates can be considered.
- Voice therapy is advised.
- Stopping smoking and lifestyle modifications would appear appropriate.

REINKE'S OEDEMA

This is a distinct form of chronic inflammation of the larynx and so theoretically falls into the category of chronic laryngitis. Pathologically, there is a chronic state of oedema in the membranous portion of both vocal cords from the anterior commissure to the vocal process, hence other terms used are polypoidal degeneration or hypertrophy.

The disease has a predilection for females in middle age, with co-aetiological factors of smoking and voice abuse, and invariably presents with dysphonia with an overall reduction in pitch of the voice and rarely with obstructive symptoms. Laryngoscopic examination shows that the vocal cords appear uniformly, diffusely swollen with a bulbous appearance with normal mobility.

Combined modality treatment is needed to optimize the resolution of the condition. The pathological changes within the vocal cords need surgical treatment. The inflammatory process results in an accumulation of fluid within Reinke's space, the potential space between the vocal ligament and the overlying mucosa. The aim of surgical treatment of this condition is to remove the fluid and reduce the excess mucosa with minimal damage to the underlying laryngeal architecture. This technique was described initially by Hirano.[54] An incision is made in the laryngeal mucosa overlying the superior aspect of the true vocal cord in its long axis. Reinke's space is entered, the submucosal fluid contents aspirated and the excess mucosa trimmed. The technique can be carried out either by using cold techniques or the CO_2 laser. The theoretical disadvantage of the CO_2 laser is the injurious thermal effect on the surrounding tissues. Although this may be the case in other laryngeal disorders, it could be argued that the fluid in Reinke's space is sufficient to absorb the heat. A further potential disadvantage is that the specimen may be either severely carbonized or non-existent. Dissection of the excessive mucosa can be relatively easily carried out with minimal trauma. Although both techniques have been practiced widely there is little evidence in support of one rather than the other. In a case series of 36 patients

Lumpkin et al. compared 'stripping', CO_2 laser and the Hirano technique and concluded that the Hirano technique was preferable.[55] Although there have been advocates of the use of microdebriders in this situation there is little substantive comparative evidence in its favour. Overall, to satisfy the original aim of the surgery the use of microlaryngeal cold instrumentation is advocated.

If the patient is a smoker, as is frequently the case, smoking cessation strategies should be adopted. Hojslet et al. described a case series of 29 patients in whom a stopping smoking strategy was supported strongly. This consisted of nicotine chewing gum being freely available and group counselling supervised by a psychologist. Eight of them (28%) refrained from smoking and although the discomfort was reduced none of the voices returned to normal. While the diffuse laryngitic appearances resolved, the laryngeal oedema persisted.[56]

To rehabilitate the consequences of voice abuse and poor vocal hygiene a course of voice therapy should be undertaken.

If left untreated, the concern is that there may be malignant transformation. There has been little reporting of such a phenomenon, and from clinical experience it would seem more likely that the converse is the case, i.e. that the presence of bilateral symmetrical Reinke's oedema would suggest that it is very unlikely that there is malignancy present. The exception to this observation would be in the case of unilateral 'Reinke's' oedema where clearly such a finding could be oedema associated with a deeply centred malignancy such as a squamous cell carcinoma in the laryngeal ventricle.

KEY POINT

- Treatment should be cold surgery of the laryngeal lesion, smoking cessation and voice therapy.

VOCAL CORD POLYPS

Inflammatory changes restricted to a small area of the vocal cords, for example, after some form of vocal trauma such as shouting, can transform into vocal cord polyps.

Occurring more often in young to middle aged male smokers, these patients present with a history of persistent dysphonia. Nasolaryngoscopy will show discrete lesions arising from the true vocal cords, usually in the anterior two thirds. Surgical excision of the polyp(s) by microlaryngoscopy under general anaesthesia using cold instrumentation techniques is usually curative. There is a plane of cleavage at the base of the polyp between the polyp and the vocal ligament. Following topical application of adrenaline (1 in 1000) to the vocal cord polyp, the polyp can be held in micro-forceps, retracted medially and dissected from the mucosa overlying the vocal ligament with preservation of its integrity. This latter aspect is imperative if the normal function of the vocal cord is to be restored. Once the lesion has been excised a period of voice rest for at least 48 hours is generally advocated. The evidence in support of both the type and duration of altered/reduced voice use is low level and scanty. Intuitively, however, it would seem highly appropriate to arrange a course of voice therapy to correct any habits of voice misuse in the patient as it was voice misuse which was the cause of the polyp initially.

KEY POINT

- Vocal cord polyps treated by surgical excision and voice therapy

AMYLOIDOSIS

Amyloidosis can affect the larynx as part of a primary or secondary process of systemic amyloidosis. The deposits of amyloid, proteinaceous aggregates, have a high fluid content and can occur as a diffuse submucosal process or as small subepithelial masses. The patients present with dysphonia because of the presence of the deposits in the various subsites of the larynx and their effect on the vocal cord mobility. Ultimately there may also be an effect on the airway. The mainstay of treatment is microlaryngeal surgery to remove the deposits with minimizing the laryngeal damage and this can be by either cold techniques or by CO_2 laser. The use of CO_2 laser tends to be effective because of its ability to vaporize the high fluid content within the deposits. Diagnosis is confirmed histologically because of the affinity of the amyloid for Congo Red.

TUBERCULOSIS

Invariably, tuberculosis (TB) occurs with the pulmonary version of the disease, with the patient complaining of dysphonia, pain on speaking and swallowing, and otalgia. There is a diffusely reddened and oedematous larynx affecting predominantly the posterior one third of the glottis. There may be ulceration and the appearances can be confused with squamous cell carcinoma. Thus, it is imperative to obtain histological confirmation before embarking on radical treatment. Diagnosis is made by biopsy of the laryngeal tissues. Histological examination demonstrates granulomas with caseating necrotic centres, Langhans-type giant cells and mycobacterium organisms. Treatment is to secure an airway followed by antituberculous drugs. If timely there should be resolution of the laryngeal and pulmonary disease and if not there will be the effects of chronic inflammation with stenosis and vocal cord fixation.[57, 58]

SYPHILIS

The larynx is rarely involved in this rare condition. Although each of the stages may occur the secondary and tertiary stages of the disease are more common. Hoarseness and dysphagia are common but pain is rare. There are diffuse erythematous papules (secondary stage) and nodular infiltrates coalescing into painless ulcers (tertiary stage), with the epiglottis and ary-epiglottic folds being principally involved. Appearances are similar to those of TB and carcinoma, with the diagnosis achieved by positive syphilis serology. Treatment is with high dose penicillin.

LEPROSY

Like TB laryngeal involvement in leprosy (also known as Hansen's disease) occurs only when there is concurrent systemic disease. Invariably there will be cutaneous lesions which may have been present for several years with the nasal cavity frequently being affected. In the larynx the supraglottic is often involved, in particular the epiglottis, showing an oedematous, nodular supraglottis with ulceration. The dysphonia is of a muffled voice quality. The diagnosis is achieved by biopsy of this area with isolation of *Mycobacterium leprae* from the tissues. Treatment is with diaminodiphenylsulfone, rifampicin and clofazimine and may have to be long term. Healing can result in fibrosis which if severe may necessitate tracheostomy.

SARCOIDOSIS

Sarcoidosis is a slowly progressive disease with the larynx involved in fewer than 5% of cases. The laryngeal appearances very similar to those of TB and fungal infection with the supraglottic structures being primarily involved. The larynx is rarely involved without clinical or radiographic evidence of pulmonary involvement. Diagnosis is achieved by demonstration of microorganism-negative, non-necrotizing granulomas in a biopsy specimen with concurrent clinical evidence of multisystem involvement. Treatment is ensuring a safe airway, either by laser excision or tracheostomy, and systemic corticosteroids. Outpatient based steroid injection has been reported as being a viable alternative to both systemic steroids and operative intervention and may obviate the need for prolonged intubation or tracheostomy.[59]

GRANULOMATOSIS WITH POLYANGIITIS

Formerly called Wegener's granulomatosis, granulomatosos with polyangiitis (GPA) is a systemic disease affecting the upper and lower respiratory tract and kidneys with necrotizing granuloma and vasculitis. In up to 25% of patients the larynx is affected with the appearances of an acute inflammatory reaction initially. Eventually granulomatous ulcers develop, affecting primarily the subglottis in the long term. The anticytoplasmic autoantibody (C-ANCA) is specific with biopsy findings showing necrotizing granuloma and vasculitis. Treatment is with corticosteroids or cyclophosphamide. The airway will need appropriate expert management and is discussed in Chapter 76, Laryngeal stenosis in adults.

CANDIDIASIS

Laryngeal candidiasis is due to the opportunistic infection by the oropharyngeal *Candida albicans* in the larynx. It can be associated with immunocompromised patients, for example, due to cytotoxic chemotherapy or AIDS or more commonly in those patients who have received broad spectrum antibiotics, corticosteroids, or prolonged inhaled corticosteroid use, or have received radical radiotherapy. In the latter case the laryngeal findings are a diffuse erythema of the mucosa with an irregular friable white exudate which is superficial. In the immunocompromised patient, the inflammatory reaction is much deeper and possibly with ulceration. In the superficial case, there is a degree of dysphonia, but little else, treatment is with nystatin or fluconazole and is generally successful. In the deeply infected, and potentially ulcerated, there is pain on speaking and swallowing in addition to the dysphonia. More intensive treatment is required and in this case amphotericin B may be required.[60]

HISTOPLASMOSIS

This is a systemic mycotic disease caused by *Histoplasma capsulatum*. There are nodular granulomas which can affect the anterior larynx and epiglottis and may ulcerate. The clinical picture is very similar to TB and squamous cell carcinoma. The presentation is dysphonia with varying degrees of pain and dysphagia. Diagnosis is by culture of the organisms on Sabouraud's agar from the laryngeal ulcers and the complement fixation test. As laryngeal involvement effectively only occurs in patients with the disseminated form of the disease, a useful guide to the diagnosis is the presence of multiple small calcifications on chest CT scanning. Treatment is by Amphotericin B and securing a safe airway.[60]

BLASTOMYCOSIS

Fungal disease caused by *Blastomyces dermatiditis* which affects multiple organs. Those at increased risk are individuals in North America with prolonged exposure in wooded areas. Although skin is the next most commonly affected site after the lungs when the larynx is involved there are granular erythematous changes which may progress to ulceration and microabscesses, primarily affecting the vocal cords. The principal complaint is dysphonia and as with other chronic inflammatory disease there may be confusion with squamous cell carcinoma. Diagnosis is by identification of the fungus from the microabscesses. Treatment is by itraconazole or ketoconazole and amphotericin B in advanced cases.[60]

ACTINOMYCOSIS

Systemic chronic suppurative disease can be caused by the anaerobic bacteria *Actinomycoses bovis* or *Actinomycoses israeli*. The larynx becomes involved following involvement of the soft tissues of the cervical or submandibular regions, possibly with abscess or sinus tract formation, with progression into the paralaryngeal region. The larynx is diffusely erythematous, swollen and wooden. Diagnosis is by identification of classical 'sulphur granules' in the biopsy material and culture of the microorganisms. Treatment is with penicillin or tetracycline.[60, 61]

RHINOSCLEROMA

This is primarily a chronic infection of the nasal cavity caused by *Klebsiella rhinoscleromatis* but may involve the larynx. It has three stages,: first, catarrhal, with marked purulent rhinorrhoea, second, granulomatous, with small painless granulomas, and finally, sclerotic, with sclerosis of the larynx. This sequence has only been postulated and can take a varying amount of time to occur. The glottis and subglottis are the main areas which are involved. Diagnosis is by histological identification of Mikulicz's cells, foamy vacuolated histiocytes, and Russell bodies, birefingent red inclusions, and bacteriologically by culture of the organisms. Treatment is by aminoglcoside, cephalosporins or tetracycline.[62]

KEY POINTS

- Chronic infective processes in the larynx are uncommon.
- The laryngeal appearances in each process can be very similar.
- The laryngeal appearances can be confused with those of squamous cell carcinoma.

RADIATION INDUCED CHRONIC LARYNGITIS

One of the commonest causes of chronic laryngitis in a Head and Neck practice is radical radiotherapy for a head and neck malignancy. During a course of radical radiotherapy, there is an incrementally increasing acute inflammatory reaction which develops into chronic laryngitis. Although to a certain extent the reaction is dose dependent there is considerable variation in individual responses to the treatment. Modern radiation delivery techniques can reduce the radiation dose to the larynx. The treatment of the resulting chronic laryngitis is based on similar principles to that of non-specific laryngitis. There is a high prevalence of smokers in this group of patients. To both increase the efficacy of the radical radiotherapy and decrease the severity of the chronic laryngitis smoking cessation strategies should be employed. Voice therapy would intuitively seem to be appropriate, however, there is little evidence in favour of it. There has been significant debate regarding the role of GERD in the development of laryngeal cancer and whilst this has not been resolved acid suppression would seem appropriate in this group of patients.

CHRONIC LARYNGITIS IN AN IMMUNOCOMPROMISED HOST

Colonization and infection of the larynx with *Candida albicans* may occur in patients who become immunocompromised secondary to AIDS, treatment such as chemotherapy or long-term corticosteroids. The larynx has white patches on a friable erythematous mucosa and diagnosis is made by culture of the laryngeal plaques and secretions. Treatment is by nystatin, amphotericin B or fluconazole.

BEST CLINICAL PRACTICE

- ✓ Chronic laryngitis frequently has a multifactorial aetiology.
- ✓ The main aetiological factors are smoking, voice abuse and reflux disease.
- ✓ Following clinical diagnosis, treat with voice therapy, smoking cessation therapy and consider anti-reflux treatment.
- ✓ Surgery should be used for excision of discrete lesions and tissue sampling only.
- ✓ Any intervention for chronic laryngitis must be assessed by some form of outcome, preferably patient-centred.
- ✓ Chronic infectious processes in the larynx are rare and frequently mimic squamous cell carcinoma.

Data may be updated by a PubMed search using the keywords: larynx, trachea, trauma, regeneration and transplantation.

INTRODUCTION

The laryngotracheal region plays a pivotal role in providing the important functions of airway protection, swallow and phonation. Injury to structures in this region is diverse and rare. The complex anatomy of the larynx and cervical trachea means that if traumatic injury occurs, severe morbidity and mortality can result, therefore early, thorough assessment and management of these injuries are vital for achieving optimal patient outcomes. The aims of treatment are to maintain a safe airway and appropriate upper aerodigestive tract function in terms of both a safe swallow and voice.[1]

ANATOMY

The laryngotracheal complex consists of an intricate cartilaginous framework, which supports a variety of muscular and ligamentous soft tissue structures.[2] This complex can deflect significant traumatic force before being injured. The larynx is a midline neck structure protected anteriorly by the mandible and strap muscles, inferiorly by the sternum, posteriorly by the cervical spine and laterally by the sternocleidomastoid muscles. The rarity of laryngeal injuries is attributed to this anatomical configuration, which provides a degree of protection to the soft laryngeal structures.[3] However, substantial dysfunction can result when injury does occur. The larynx is divided into three subsites, namely, supraglottis, glottis and subglottis, which is continuous with the trachea inferiorly. The subglottic region, being the only complete cartilaginous ring structure, is the most sensitive and therefore most vulnerable even during trivial trauma.

EPIDEMIOLOGY AND AETIOLOGY OF LARYNGOTRACHEAL INJURY

Laryngotracheal injury is diverse, rare and potentially life-threatening. The reported incidence of injury in the literature varies from 1 in 5000 to 1 in 137 000 emergency department presentations.[1, 4–5] More than 2000 cases of mortality are attributed annually to neck trauma in the UK.[8] Females are more susceptible to laryngeal injury as they tend to have longer and more slender necks compared to their male counterparts. Despite this anatomical predisposition, close to 80% of traumatic laryngotracheal injuries occur in males, particularly in the second and third decades of life, owing to greater participation in violent sports and other physical activities.[5]

Injury to the laryngotracheal complex may involve damage to the bony, cartilaginous, neurovascular and soft tissue structures of the neck. The resultant damage is related to the mechanism of injury. However, central to all laryngotracheal injury is the potential for a compromised airway.

The mechanism of injury to the larynx may be external or internal, through inhalational or iatrogenic injuries. External traumatic injuries are classified as either blunt or penetrating. The former is most commonly a result of motor vehicle accidents, as well as other causes such as hanging, strangulation and contact sports,[9, 10] while the latter occurs primarily from gunshot wounds, followed by stab wounds.[10–12] With improved standards of road safety and increasing incidence of violent crimes in the community, the incidence of blunt laryngeal injuries has decreased, while that of penetrating injuries has increased.[9] Studies have attributed only around 5% of aerodigestive injuries to blunt trauma,[10, 13] while up to 15% of these injuries are due to penetrating trauma.[12]

Blunt injuries

Blunt injuries can be further classified into crush, clothesline and strangulation type injuries. The former type of blunt injury is sustained especially in motor vehicle accidents where the victim is thrust forwards with a hyper-extended neck, particularly in the absence of a seatbelt, exposing the larynx to anterior crushing forces (**Figure 71.1**). Clothesline injuries occur when there is high velocity impact of the larynx with a stationary object. For instance, when a rider of an unprotected vehicle such as a motorcycle or snowmobile hits a stationary object, a large amount of energy is imparted over a small area. This can lead to instant exsanguination from cricotracheal separation or a crushed larynx (**Figure 71.2**).[14] In strangulation-type blunt injuries, such as hanging or strangulation by a soft object, initial injury may be minor, but can subsequently lead to laryngeal oedema and a compromised airway.[15]

Figure 71.2 'Clothesline' injury with tracheal separation.

Penetrating injuries

Penetrating laryngotracheal injuries can cause varying degrees of damage depending on the location and the nature of the weapon used. Injury to neurovascular and soft tissue structures can result in variable amounts of oedema, inflammation, haemorrhage, scarring and anatomical disruption. Low velocity gunshot wounds, such as those sustained with hand guns, tend to cause moderate damage to the injured tissue, while high velocity gunshot wounds, such as those sustained with rifles, can cause wide-field damage of laryngeal tissue that may extend beyond the limit of necrotic tissue.[16] Unlike gunshot wounds, stab wounds from knives have a predictable course of injury that generally does not cause damage beyond the entry and exit path of the knife.

Inhalational injuries

Inhalational injuries to the larynx and trachea occur following inhalation of toxic gases, exposure to fires or ingestion of toxic substances. This leads to oedema of the airway, which tends to be self-limiting. However, ingestion of caustic substances can lead to full thickness airway burns, leading to significant morbidity. Inhalational injury involves transfer of high levels of thermal energy. Reflex closure of the glottis occurs as a protective mechanism to limit thermal injury to the supraglottic region. Early securement of the airway is important as subsequent and delayed upper aerodigestive tract oedema can occur in the hours following injury.

Iatrogenic injuries

Iatrogenic injuries to the laryngotracheal complex can occur following any airway management procedure such as during routine oro- or nasotracheal intubation, cricothyroidotomy or during elective operations such as laryngeal surgery, laryngoscopy or routine tracheostomy. Urgent tracheostomy, required for the management of an acute airway problem, is particularly prone to injury involving the upper aerodigestive tract, including the laryngotracheal complex. Studies have identified factors contributing to post-intubation injury, such as high cuff pressure, prolonged duration of intubation, use of large diameter endotracheal tubes as well as patient co-morbidities, such as diabetes and chronic obstructive pulmonary disease.[17–19] Following prolonged intubation, the associated inflammation can lead to sequelae of granulation and scarring with subglottic stenosis, vocal fold dysfunction or airway compromise.[20, 21]

PATHOPHYSIOLOGY OF LARYNGEAL TRAUMA

Tissues involved in laryngeal injury include mucosa, nerves (superior and recurrent laryngeal nerves), soft tissue (muscle – intrinsic and extrinsic muscles, ligaments, superficial lamina propria), cartilages (arytenoid, thyroid, and cricoid) and trachea (including trachealis muscle). In the acute situation, the main concern is the integrity of the airway, but in chronic laryngeal injury there are ensuing complications, which are variable and unpredictable. Healing by secondary intention can result in scarring, subluxation, and ankylosis of the arytenoids and cricoarytenoid joints. Fibrosis of the laryngeal muscles disrupts the mucosal wave, with the appearance of non-vibrating segments. There can be anterior and posterior glottic webbing, and supra- and sub-glottic scarring. Neural injury can lead to muscle palsy, and cartilage fractures may heal by secondary intention, resulting in unstable fractures, mal-union or non-union. Such chronic effects, unlike the acute situation, are slowly progressive and therefore not discernable at the outset (**Figure 71.3**).

Mature scar tissue in the background of oedema, haematoma and collapsed tissue (soft tissue or cartilage) can have variable impact. For example, in the posterior glottis, where granulations mature over time, the posterior vocal folds can be drawn together, leading to progressive shortness of breath and airway obstruction. Other sequelae include glottic incompetence, dysphonia, aspiration and dysphagia, but the chronicity of the changes allows time for glottic compensation. This is in contrast to the acute setting, where there is no time for the larynx to adapt.

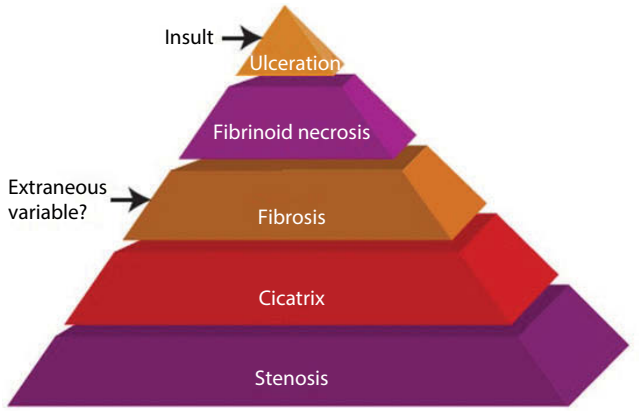

Figure 71.3 Pathophysiology in the development of a laryngeal stenosis.

BOX 71.1 Laryngotracheal injury classification by Trone et al[23]

Group 1:	Minor endolaryngeal haematoma without detectable fracture
Group 2:	Oedema, haematoma, minor mucosal disruption without exposed cartilage, non-displaced fractures noted on CT scan
Group 3:	Massive oedema, mucosal tears, exposed cartilage, fold immobility
Group 4:	As group 3, but with more than two fracture lines or massive trauma to laryngeal mucosa
Group 5:	Complete laryngotracheal separation (added by Fuhrman et al.[23])

CLASSIFICATION OF LARYNGEAL TRAUMA

A number of classification systems for traumatic laryngeal injury have been described. One such system by Fuhrman et al. classifies laryngotracheal injuries into five groups (**Box 71.1**).[22] This classification system is a modification of the previously proposed one by Trone et al, in which injury is divided into groups 1 to 4 only.[23] Group 1 comprises minor endolaryngeal haematoma without detectable fracture; group 2 injury involves oedema, haematoma, minor mucosal disruption, unexposed or undisplaced fractures; group 3 comprises injury where there is massive oedema, mucosal tears, exposed cartilage or vocal fold immobility; group 4 injury is as group 3 but with the addition of massive trauma to laryngeal mucosa or over two fracture lines; and group 5 injury is where there is complete laryngotracheal separation. These classification systems help to provide a unified approach to the assessment and management of laryngeal injuries.

Sequelae of major laryngeal trauma include stenoses at supraglottic, subglottic and/or posterior glottic levels. Classification of posterior glottic stenoses, described by Bogdasarian and Olson, is based on the structures involved (**Figure 71.4**).[24]

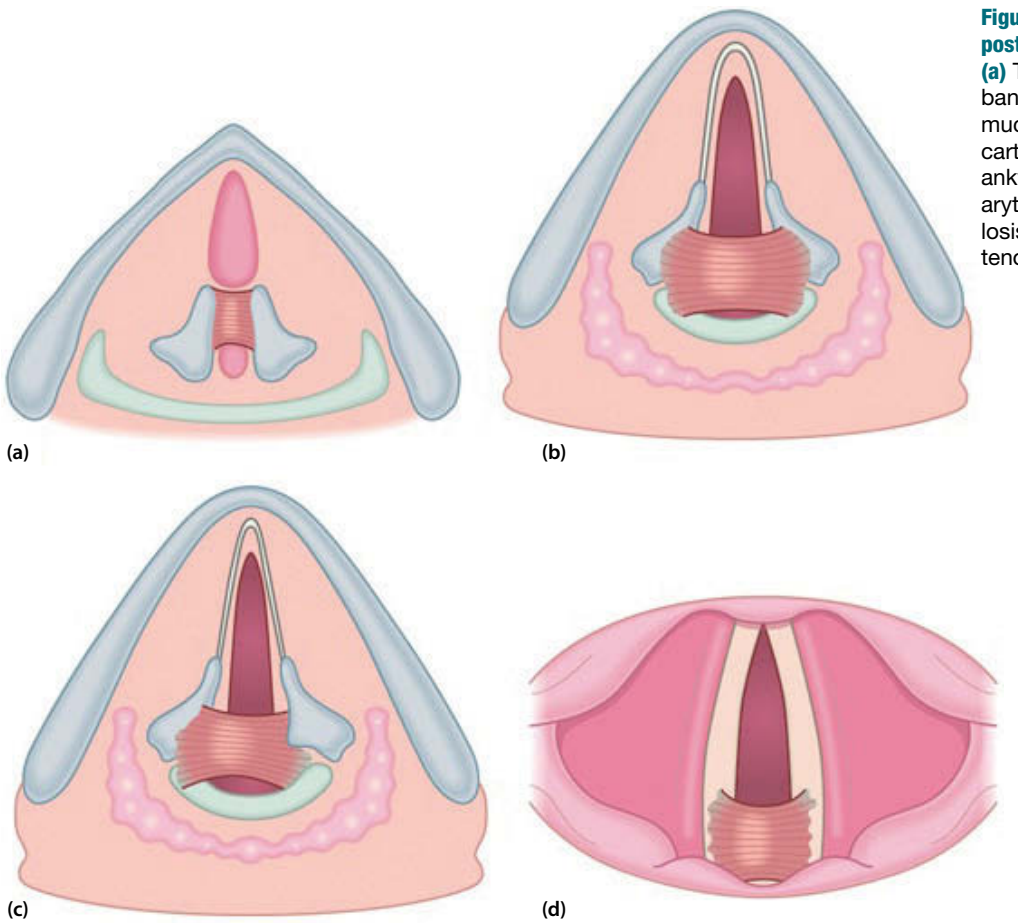

Figure 71.4 Classification of posterior glottic stenosis. **(a)** Type I, isolated interarytenoid band; **(b)** Type II, posterior glottic mucosal tunnel, but no arytenoid cartilage ankylosis; **(c)** Type III, ankylosis and immobility of one arytenoid joint; **(d)** Type IV, ankylosis and immobility of both arytenoid joints.

EVALUATION OF LARYNGOTRACHEAL TRAUMA

Timely assessment and management of laryngotracheal injury following the principles of advanced trauma and life support (ATLS) is essential.[25] It requires a multidisciplinary team approach including emergency physicians, trauma surgeons, otolaryngologists-head and neck surgeons, anaesthetists, radiologists, clinical nurse specialists and allied health professionals (**Figure 71.5**).

Signs and symptoms

Signs and symptoms associated with laryngeal injury vary with the mechanism and severity of injury. Laryngeal trauma may be part of multi-trauma involving other parts of the body and therefore must be assessed in a systematic manner. Urgent review of patients is vital as patients initially exhibiting only subtle symptoms and signs of upper aerodigestive tract dysfunction can progress to complete airway obstruction from worsening oedema.

The most common presenting symptoms include varying degrees of dysphonia and dyspnoea, followed by dysphagia, neck pain and haemoptysis. Patients with penetrating neck injuries can present with externally visible neck wounds, bleeding, expanding haematoma and/or bruising.[3, 6, 26] They may also be hypovolaemic, and in shock. Those with blunt injuries with no externally visible injury may have their injuries undetected for as long as 24–48 hours post-injury.[27, 28] The hallmark clinical signs of airway obstruction include stridor, increased respiratory rate, tachycardia, sweating and use of accessory muscles. The patient may be in shock, have ecchymosis in the skin of the neck, abrasions, open wounds, massive subcutaneous emphysema, expanding haematomas, tracheal deviation and cartilaginous and bony fractures.[28–30]

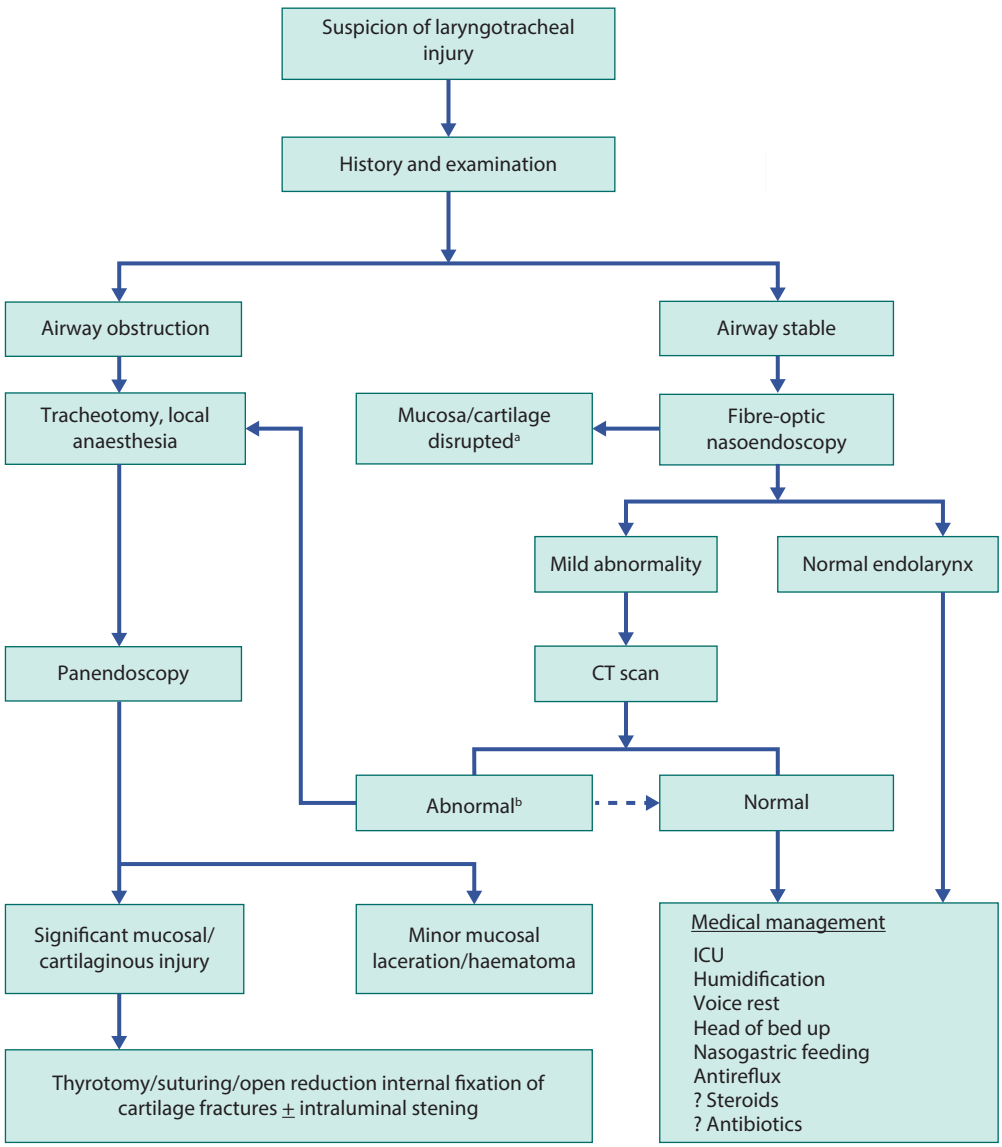

Figure 71.5 Management algorithm for patients presenting with laryngotracheal trauma.

AIRWAY MANAGEMENT

The primary goal in the initial evaluation and management of a patient with a suspected laryngotracheal injury, like any other presenting with a traumatic event, is to ensure the airway is adequately assessed and protected by the most senior and experienced medical staff available. Where there is any concern about impending airway obstruction, a safe airway must be established. Only after this has been achieved can the management of the trauma patient continue.

Once the patient is stabilized, a thorough history and examination including fibre-optic nasoendoscopy can be obtained to ascertain the mechanism, duration and extent of laryngeal injury and other concomitant injury. Fibre-optic nasoendoscopy can aid in assessing patency of the airway, vocal fold movement, presence of lacerations, haematomas and exposed cartilage.[31]

Options for acute management of the threatened airway include routine endotracheal intubation, fibre-optic awake intubation and tracheostomy under local anaesthetic. In emergent situations, cricothyroidotomy may be required, using a vertical incision to avoid the anterior jugular veins, allowing greater exposure of the airway.[28, 32] Blind endotracheal intubation must be avoided as it can lead to complete laryngotracheal separation in a partially transected airway held together by peri-tracheal soft tissue.[29] There is some controversy in the literature with regard to the best method to secure the airway. Several authors including Schaefer,[1] Fuhrman et al,[22] Hwang and Yeak[33] and Baron[34] recommend a tracheostomy under local anaesthetic as gold standard, while Gussack et al. recommend endotracheal intubation for airway management.[35] One argument for the former method is that a tracheostomy will enable examination of the site of laryngeal injury, as opposed to the latter technique, which may hinder further direct examination of the site of injury and may even cause iatrogenic aggravation of the existing injury.[6] Nevertheless, in experienced hands, there is adequate evidence in the literature to date supporting the safety of endotracheal intubation for airway management in laryngeal trauma.[6, 36]

When experienced personnel are unavailable, an emergency tracheostomy under local anaesthetic is recommended to secure the airway safely.[1, 37–39] This is ideally performed in a controlled environment as afforded by an operating theatre, where appropriate instrumentation, lighting and anaesthetic, surgical and nursing support are available. Tracheostomy under local anaesthetic is recommended to maintain spontaneous ventilation and patency of the upper aerodigestive tract until a definitive airway is established. However, in a struggling patient where this is not possible, an inhalational general anaesthetic with the highest possible inspired oxygen concentration may be administered. Muscle relaxants are contraindicated, as paralysis of spontaneous respiration and positive pressure ventilation can aggravate air leak and surgical emphysema, lead to loss of airway and result in respiratory arrest.[29] To avoid the area of laryngotracheal injury, the tracheostomy incision is ideally placed distal to the site of injury, slightly lower than usual. A horizontal incision midway between the cricoid cartilage and sternal notch is commonly used. Where a traumatic tracheotomy exists, Corneile et al. recommend the use of this wound to access the trachea as a means to provide greatest preservation of healthy trachea for repair and reconstruction.[28]

In paediatric laryngeal trauma, the preferred method of airway control consists of inhalational anaesthesia allowing for spontaneous ventilation, followed by securing the airway with rigid bronchoscopy and tracheostomy.[13, 40, 41] Cricothyroidotomy in this population is avoided as it may not provide adequate exposure, and can potentially compound the existing injury.[13, 40, 41]

Once the airway is established, further operative evaluation and exploration of the laryngotracheal injury can occur. Microlaryngoscopy, oesophagoscopy and bronchoscopy are essential aids to assess extent of injury, and photo-documentation can also be obtained simultaneously. There is some controversy with regard to timing of operative exploration once the airway has been established. Whilst some authors recommend delaying exploration until oedema at the site of injury has subsided,[42, 43] the consensus recommendation is exploration within 24 hours of injury.[1, 6, 44]

IMAGING

Following stabilization of the airway, computerized tomography (CT) with three-dimensional reconstruction and magnetic resonance imaging (MRI) are gold standard radiological modalities to assess the larynx and its framework. CT scans can provide useful information about the anatomy, and aid in management decisions.[12] The findings to look for in the setting of laryngotracheal trauma include cartilage fractures, haematoma, oedema, cricoarytenoid joint dislocation or subluxation, extra-tracheal subcutaneous air and airway stenosis. It is used in conjunction with, rather than as a replacement for, operative exploration.

Furthermore, CT and MRI can identify missed laryngeal injuries in symptomatic patients with chronic sequelae.[45] CT angiography is very important in cases of penetrating trauma, especially involving neck zones 1 and 3, where information on the location and trajectory of foreign bodies, such as bullets or shrapnel, and integrity of vascular structures must be obtained.[46]

MANAGEMENT OF LARYNGOTRACHEAL INJURIES

The management of laryngotracheal injuries may be non-surgical or surgical depending on the type and extent of injury and follows a thorough assessment of the patient.

Non-operative approach

Non-operative management options are determined by the type and extent of injury, and coexisting illnesses of the patient. Airway stability is integral to non-operative

management and assumes protection by the patient's own reflexes or by an endotracheal tube.

Atkins et al.[12] and Bisase et al.[47] recommend such an approach to management of patients with group 1 and 2 type traumatic laryngeal trauma. These injuries include minor mucosal lacerations without exposed cartilage or bone and minor hematomas. Bent et al,[4] Schaefer[1] and Close[15] also recommend such an approach in patients with undisplaced single fractures of the laryngeal cartilaginous framework. The non-operative management of these patients involves admission to an intensive care unit for airway monitoring for at least 24 hours and treatment with constant humidification, head elevation, nil by mouth and voice rest. Some patients may also require endotracheal intubation if there is concern about their ability to maintain their airway. Intubation also aids in performing a panendoscopy to rule out injury to other structures in the upper aerodigestive tract. If this examination is unremarkable, the patient can be safely managed using a closely monitored non-operative approach.

Blockade of gastric acid reflux is recommended to prevent further irritation of the injured laryngeal mucosa and laryngeal stenosis.[12, 48] The effectiveness of corticosteroids in reducing soft tissue oedema in laryngeal trauma remains unclear due to lack of supporting evidence. Further, if used, they must be given within a few hours of the injury. Similarly, the use of antibiotics in non-operative management of laryngeal trauma is also controversial. Some authors suggest that intravenous penicillin or cephalosporin can help reduce development of granulation tissue and potential infection following panendoscopy.[12, 49, 50]

Operative approach

Surgical intervention is required in patients in whom non-operative management options are unsuccessful in improving airway function, or those who continue to deteriorate despite these measures. Surgery is aimed at airway preservation, prevention of secondary sequelae of healing and restoration of function via repair of endolaryngeal and other concomitant injuries such as neurovascular damage, or thoracic injuries, and stabilization of fractures of the laryngeal framework. The type, timing and severity of injury and patient comorbidities, determine the surgical management, as detailed here.

ENDOSCOPIC

If the anaesthetist fails to intubate using an intubating laryngoscope, an anterior commissure scope can be passed by the otolaryngology head and neck surgeon to facilitate careful placement of a microlaryngoscopy tube. Once the airway is secured, examination of the laryngotracheal complex can be performed endoscopically using a variety of straight and angled telescopes. Haematomas of the vocal folds can be aspirated, and damaged folds re-approximated by suturing. Stents can be placed endoscopically in the acute situation to support the laryngeal framework and lumen, reduce the likelihood of adhesions, and maintain the structure of the anterior commissure for voice preservation, particularly if there is extensive mucosal disruption, or comminuted fracture(s). Rigid oesophagoscopy should also be performed acutely to exclude any injury to the integrity of the oesophagus.

Chronic sequelae of laryngeal trauma can be managed endoscopically. Cold steel or laser division of supraglottic webs, with or without an epiglottopexy, can be performed. Similarly, glottic adhesions can be divided and, if necessary, a cordotomy, cordectomy or arytenoidectomy undertaken. As in the acute situation, stents can be placed for the reasons described above.[51] Silastic keel placement, for 1–2 weeks, combined with vocal fold mucosal suturing can be used to treat post-traumatic laryngeal webs. Mucosal suturing of the vocal fold reduces raw surface exposure, and ultimately avoids long-term glottic stenting, laryngofissure, and requirement for tracheostomy.[52] Mitomycin-C can be injected to reduce fibrosis.[53–57] There is evidence in human and animal studies for the use of Mitomycin-C, which inhibits fibroblast proliferation by cross-linking DNA, and 5-fluorouracil/triamcinolone at the time of ablation of stenosis, or dilatation to inhibit restenosis,[53–57] although there is still some controversy regarding their effectiveness.

A bulking agent, such as hyaluronic acid, can be administered in an endoscopic injection thyroplasty procedure, to a vocal fold, injured from previous intubation or gastroscopy injury.[58] Endoscopic balloon or bougie dilatation, usually a temporizing option, can be performed with the adjunct of botulinum toxin injection to relax a stenosed cricopharyngeus.[59]

Endoscopic management of laryngotracheal stenosis is thought to be appropriate for patients whose injury does not involve the cartilage. Balloon dilatation can be used initially, but since the introduction of carbon dioxide (CO_2) lasers, a variety of endoscopic management techniques have evolved.[60] These include the neodynium-doped yttrium aluminium garnet (Nd:YAG) and microscope-mounted CO_2 laser.[61] Recently, CO_2 ablation via awake flexible bronchoscopy has been described.[62, 63]

OPEN

An open approach to traumatic laryngotracheal injury is recommended for patients with group 3 and 4 injuries, and a subset of those with group 2 injury who have minimally or non-displaced fractures. Emergent tracheostomy, surgical exploration and immediate repair is the standard of care in all patients in whom complete cricotracheal separation (group 5 injury) is suspected (**Figures 71.6a–71.6d**). In addition, the presence of concomitant neurovascular, thoracic or abdominal injuries, and individual patient factors, should tailor the surgical plan. There is some controversy regarding the timing of surgical intervention in those patients with group 3 and 4 injuries; some studies recommend surgery after soft tissue oedema has settled whilst others recommend surgical exploration early (within 24–48 hours) to avoid voice and airway dysfunction in the long term.[64] The consensus recommendation is exploration within 24 hours of injury.[6, 9, 44]

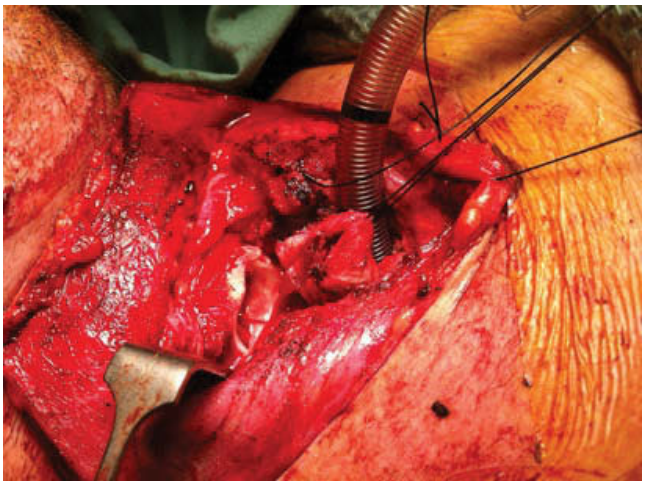

Figure 71.6a Patient presenting following a non-restraint motor vehicle accident with multi-system trauma including complete cricotracheal separation and multiple fractures of the cricoid cartilage.

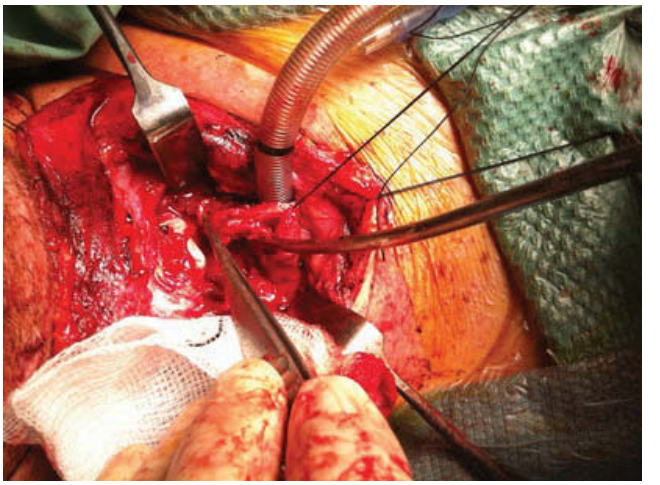

Figure 71.6b Forceps point to avulsed left recurrent laryngeal nerve.

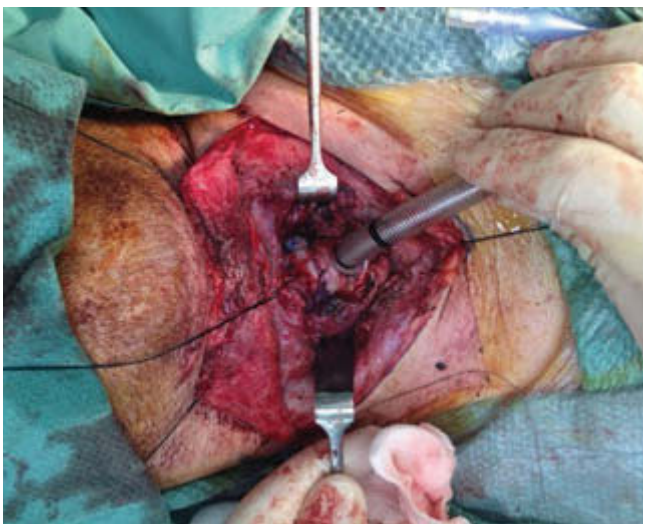

Figure 71.6c Repair was carried out in the operating theatre after tracheostomy was performed. The cricoid cartilage was repaired using non-absorbable sutures. Primary cricotracheal anastomosis was performed using vicryl.

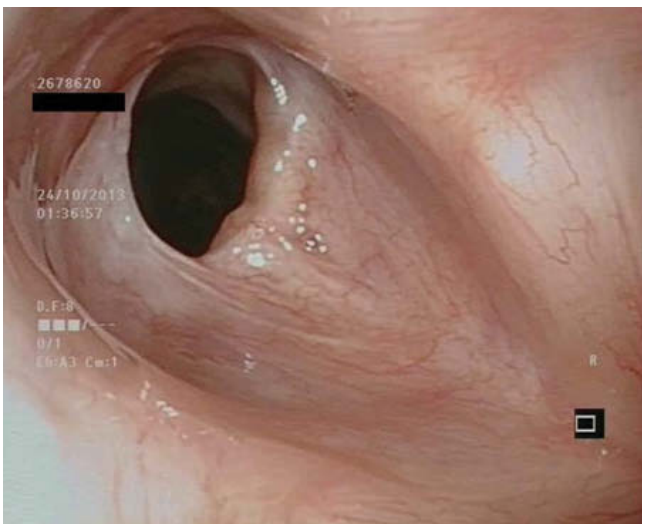

Figure 71.6d Appearance of larynx 1 year post-operatively, demonstrating a patent airway, despite the anterior glottic web and bilateral vocal fold palsies.

An open approach is reserved acutely for displaced or comminuted laryngeal fractures that are deemed unstable due to muscular forces, and therefore unsuitable for endoscopic repair.[65] Neural repair is rarely performed in the acute setting, unless iatrogenic, for instance in thyroidectomy. Suitable cable graft nerves include ansa cervicalis, great auricular nerve and sural nerve.

An open approach is used less commonly in the chronic situation, and usually addresses functional deficits relating to airway, voice and swallow. Cricotracheal resection may be performed for chronic subglottic stenosis, type I Ishiki open thyroplasty to medialize a paralyzed vocal fold, and cricopharyngeal myotomy for cricopharyngeal stenosis.

The open surgical technique of managing laryngotracheal stenosis is employed when cartilage integrity is not preserved or where repair is refractory to endoscopic techniques. A number of open approaches, including single and double stage reconstruction, cricotracheal resection (**Figure 71.7**), use of stents, and anterior and posterior grafting, have been described. The type of approach used is selected based on pre-operative evaluation of the stenotic region and patient comorbidities, and is discussed in detail in Chapter 76, Laryngeal stenosis in adults. Simple circumferential resection with primary anastomosis provides excellent outcome in suitably selected patients.[64, 65] Stenosis that is at a distance greater than 1.5 cm from the inferior aspect of the vocal folds is considered safe for resection with primary anastomosis.[66] Pearson et al. have suggested that up to half the trachea can be resected and managed with primary anastomosis.[67] Macchiarini et al. recommend resection of no more than 4 cm of stenosed trachea to avoid anastomotic tension and failure.[68] To achieve optimal outcome, patients must be optimized preoperatively in terms of treating their comorbidities, such

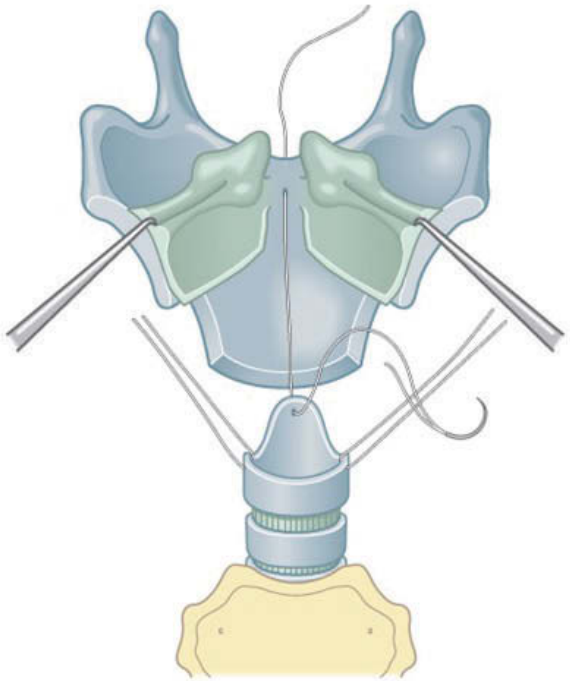
as those with immunosuppressive conditions (e.g. diabetes, vascular disease) or those taking immunosuppressive drugs. In addition, complete resection of the stenotic tissue and provision of adequate airway support post-operatively are essential for a successful outcome.

With regard to surgical approach, the patient is positioned supine with a shoulder roll to extend the cervical spine slightly. Typically, the upper aerodigestive tract is approached through a horizontal collar type incision at the level of the cricothyroid membrane, but the traumatic entry incision may provide an alternative means of entry.[40] Through this incision, superior and inferior subplastysmal flaps are raised, followed by division of the strap muscles and thyroid isthmus to maximize exposure of the laryngotracheal complex.[12, 40] Where more distal injuries are present, a partial sternotomy or right thoracotomy can be performed via this incision.[69] A laryngofissure (or midline thyrotomy) approach will expose the endolarynx, and avoids injury to the recurrent laryngeal nerve.[39, 70, 71] A laryngofissure enables debridement of contaminated tissue and removal of foreign material, repair of mucosal lacerations, and areas of denuded cartilage to be covered with mucosal flaps or skin grafts.[40, 71] Vocal folds can be repositioned and sutured in place, if necessary, using a dissolvable fine suture material.[12] This may also require an arytenopexy.[72]

All laryngeal fractures must be identified, reduced and stabilized. Repair of these fractures involves raising the perichondrial layer and suturing it with non-absorbable sutures. In addition to simple suturing, wiring the fractured cartilage segments and internal fixation with adaptation metal plates, when available, are the most contemporary methods used to stabilize laryngeal fractures.[73, 74] Alloy metal miniplates with self-tapping screws were traditionally used to bridge any fracture line, and enable the laryngeal framework to be restored as best as possible. An alternative to metal plates are malleable, non-metallic biodegradable plates, such as poly-L-lactic-acid-polyglycolic-acid,[75, 76] which slowly resorb over 1.5 to 3 years.

Avulsion injuries to the anterior commissure can also be repaired by careful suturing of the anterior aspect of the true vocal folds to the outer thyroid cartilage perichondrium.[9] Reconstruction options where there is loss of cartilage vary from the use of local muscle flaps, using either the strap muscles or parts of the sternocleidomastoid, to filling the defect, to the use of free grafts for more extensive cartilage loss, most commonly from the rib.[77] A covering tracheostomy, 2–3 tracheal rings below the site of repair, is placed for ventilation at the time of repair and to ensure a safe airway in the post-operative period.

The use of stents in laryngotracheal reconstruction is recommended where there is disruption of the anterior commissure anatomy, extensive mucosal trauma and comminuted fractures with significant damage to the laryngotracheal complex (**Figure 71.8**). Ideally these stents should be softer and more inert than hard intraluminal stents, and inserted for the shortest time possible, to avoid growth of granulation tissue.[78, 79] Schaefer recommends that they be secured in the larynx by double



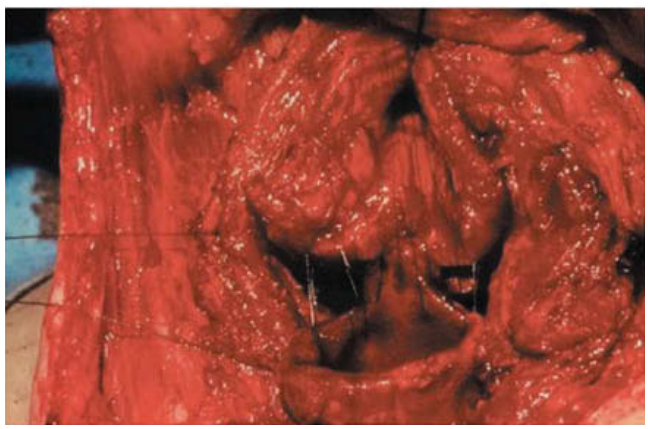


Figure 71.7 High cricotracheal separation with laryngofissure and repair using a membranous tracheal mucosa flap.

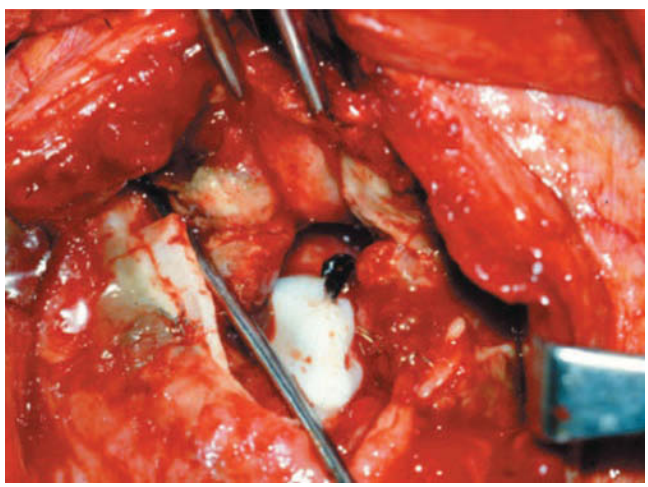

Figure 71.8 Thyroid and cricoid cartilage fracture with placement of Montgomery laryngeal stent.

sutures, and closed at the superior end, to avoid aspiration of fluids via the stent lumen.[9] In addition to a rolled silastic sheet and moulded Portex tracheostomy tube stent, a variety of newer laryngeal stents are available, which are softer and more inert. These include the Montgomery laryngeal stent, Montgomery T-tube, Aboulker stent, Eliachar laryngotracheal stent and the LT-Mold stent. However, regardless of the type of stent used, the decision to stent is made based on the need to stabilize the airway versus the potential for further laryngeal injury and infection from stenting.[80]

Repair of laryngeal nerve injury is still largely at an experimental stage. Recently, a rat model for the characterization of laryngeal function, routes of innervation, and sources of reinnervation following recurrent laryngeal nerve (RLN) resection has been developed.[81] In another rat model, the intact superior laryngeal nerve (SLN) has been used to investigate the reinnervation process of the posterior cricoarytenoid (PCA) muscle following RLN injury.[82] In this, PCA reinnervation was assessed by retrograde double-tracing techniques. The PCA was shown to receive dual innervation from both laryngeal nerves, even in the uninjured system. Following RLN injury, functionally significant collateral reinnervation originated from intact SLN fibres, mainly due to intra-muscular growth rather than by recruitment of more motor neurons.

FUTURE DIRECTIONS

Laryngeal tissue engineering

In the past decade, research into tissue engineering for laryngeal reconstruction has been growing, in particular for scarred vocal folds following trauma. This technique is still in its infancy, however, in terms of clinical application. Tissue engineering methods include the use of specific growth factors and mesenchymal stem cells (MSCs).[83]

Certain growth factors, such as basic fibroblast growth factor (bFGF), are already in use for vocal fold regeneration for cases of vocal fold atrophy. bFGF has been used to treat presbyphonia. Vocal fold atrophy was shown to improve at 1 week post-injection. Aerodynamic and acoustic parameters also demonstrated improvements, which were maintained up to 3 months.[84]

Transforming growth factor (TGF)-β3 reduces collagen synthesis and subsequent scar formation. This has been demonstrated experimentally in beagle dogs in which the lamina propria of the vocal folds was injected either with TGF-β3 or saline prior to the folds being injured by stripping of the lamina propria.[85] When larynxes were harvested at 6 months, histological analysis showed that TGF-β3 had suppressed granulation-tissue formation and scarring. Collagen distribution was well organized and less dense in TGF-β3-treated vocal folds compared to saline-treated vocal folds. TGF-β3-treated vocal folds demonstrated significantly better vibratory function.

Another growth factor, granulocyte-macrophage colony-stimulating factor (GM-CSF) assists in epithelial wound healing, and has recently been applied experimentally to promote tissue repair. In a study of vocal fold healing following injury to the vocal folds of New Zealand white rabbits, either GM-CSF or saline as a control was injected into their vocal folds.[86] The GM-CSF-treated vocal folds showed reduced collagen type I and fibronectin deposition in comparison to the saline-injected controls. Mucosal waves in the GM-CSF cohort exhibited significant improvement compared to the phosphate buffered saline cohort. In the *in vitro* arm of the study, human vocal fold fibroblasts (hVFFs) were cultured with GM-CSF. GM-CSF prevented TGF-β1-induced collagen synthesis by hVFFs, thereby reducing scar formation. The expressions of extracellular matrix-related enzymes and growth factors hyaluronan synthase-2, tropoelastin, matrix metalloproteinase-1, hepatocyte growth factor (HGF), and c-Met mRNA were significantly increased by GM-CSF. These findings suggest that GM-CSF offers therapeutic potential for the remodelling and regeneration of vocal folds following injury.

The application of growth factors could have a refractory effect if used inappropriately in terms of dosage, route and time of application. Therefore their application is in the process of being refined for safe and large-scale use in the near future.[83]

The use of MSCs has emerged as a potential therapy in the future for head and neck reconstruction. MSCs can differentiate along a specific cell lineage but also have the capacity for self-regeneration. However, this regenerative ability may be a double-edged sword due to the possibility of malignant transformation.[87, 88] MSCs are originally derived from adipose tissue but have also been derived from bone marrow and thymic progenitors.[89] These MSCs appear promising for reconstruction based on *in vivo* and *in vitro* studies in animals, due to their continuous circulation in the peripheral blood, ability to migrate to sites of injury to stimulate resident stem cell proliferation and secretion of growth factors,[90] and their differentiation into myofibroblasts and fibroblasts.[91]

An animal model study of green fluorescent protein-labelled MSCs in rats showed that MSCs were distributed throughout the vocal fold from day 1 following vocal fold injury, and that there was up-regulation of HGF compared with control-treated folds.[92] A suitable scaffold is necessary for MSC implantation. A subsequent *in vitro* study examined the role of Terudermis, an atelocollagen sponge derived from calf dermis with large pores that enable cellular entry.[93] It demonstrated adhesion of MSCs to Terudermis, with positivity for the cell adhesion molecules vimentin, desmin, fibronectin and fspl within the scaffold, showing the importance of Terudermis as a scaffold for MSCs in the treatment of scarred vocal folds. These results have been borne out by an *in vivo* study, which examined the effect of injecting MSCs that had been incubated in a scaffold of atelocollagen into beagle dog vocal folds.[87] Histological analysis

showed a greater degree of regeneration in those vocal folds that had been injected with the combined scaffold of MSCs and atelocollagen compared with atelocollagen alone.

Similar results for vocal fold healing have been obtained with an injectable hyaluronic acid/mildly cross-linked alginate (HA/ALG) hydrogel scaffold containing human adipose-derived MSCs (hAdMSCs).[94] Histological evaluation demonstrated that treatment with hAdMSCs in HA/ALG hydrogel produced more favourable changes to the extracellular matrix than hAdMSCs alone. In particular, the combination of hAdMSCs in HA/ALG hydrogel prevented excessive deposition of collagen type I and increased HGF activity in regenerating vocal folds. The combination treatment also resulted in functional improvements in viscoelastic properties.

These results highlight the potential therapeutic role of MSCs, held within a suitable collagen scaffold, in the regeneration of vocal folds that have been scarred by trauma, and show the importance of up-regulation of growth factors such as HGF and other cell adhesion molecules to produce a robust extracellular matrix for vocal fold regeneration.

Jungebluth et al. described successful transplantation of a bioengineered trachea using autologous bone marrow-derived MSCs, seeded on a bioartificial nanocomposite.[95] Due to the complexity of laryngeal anatomy and physiology, concerns about the neoplastic potential of MSCs, and their appropriate and safe harvesting and application, MSCs are, in some respects, more suited to bioengineered tracheal transplantation, where the tissue anatomy is more simplistic. Currently the role of MSCs and growth factors is limited to regeneration of vocal folds that have been scarred by trauma, rather than to injuries affecting the intricacies of the laryngeal framework.

Laryngotracheal transplantation

The concept of laryngotracheal transplantation has been present for decades; however, the difficult anatomy and microvascular structure of the region, as well as the necessity for prolonged inhibition of T-cell activation,[96] have posed some hurdles. The first attempt at human transplantation, whereby a partial laryngectomy was undertaken, was in 1969.[97] Following this, in 1998, a successful total laryngeal transplant was performed, which has survived at least 12 years later, despite issues of chronic rejection.[98, 99] A further 13 cases of laryngeal transplants have been reported from Colombia but their long-term reports are still awaited.[100] More recently, Farwell et al. have provided an account of a successful, modified transplant of a larynx with long segment of trachea.[101] They were able to revascularize successfully, and reinnervate parts of the transplant selectively, with patient recovery at 3 months showing no evidence of rejection.

Porcine laryngeal transplantation has been described, with patent airways and restoration of swallowing at 1 week, and no evidence of ischaemia-perfusion injury in major histocompatibility complex-matched pigs.[102, 103] More recently, staged laryngeal allotransplantation has been described in beagle dogs.[104]

It is evident that the idea of laryngeal transplantation is still in its infancy. It is only suitable for a subset of people who have endured severe trauma, requiring laryngectomy, and carries with it the challenges of a prolonged recovery and lifelong immunosuppression. With advances in transplant technology, this could become a more viable option in future. There are inevitable issues concerning patient selection, reinnervation, immunosuppression and cost-benefit to be overcome.[105]

CONCLUSION

Injuries to the laryngotracheal region are diverse, relatively rare and potentially life-threatening. The key to successful outcomes in terms of survival, airway, a safe swallow and voice is early recognition, assessment and state of the art management of these injuries. Advances in imaging techniques and fibre-optic endoscopy have aided improved evaluation of these patients. Furthermore, a multidisciplinary team approach is essential for managing laryngotracheal injuries and, depending on patient, injury and treatment-specific factors, may involve operative or non-operative techniques. The use of bioengineered laryngeal tissue and laryngeal transplantation may become viable options in the future, to provide improved functional outcome for patients.

KEY POINTS

- The aetiology of trauma to the larynx and trachea is wide-ranging, resulting in complex and potentially life-threatening injuries.
- A multidisciplinary approach in a centre with expertise in complex head and neck disease will enable airway protection and assessment of the extent of injury, to determine the best management and timing of any potential operative intervention.
- Chronic upper aerodigestive tract dysfunction is a likely sequela and requires prolonged rehabilitation.
- Laryngeal tissue engineering is an expanding field which has provided a foundation for transplantation in animal models and humans.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: upper airway obstruction, tracheostomy and focusing on diagnosis and management. The evidence in this chapter is mainly level 3/4 with some level 2 evidence. The clinical recommendations are predominantly B and C.

INTRODUCTION

The scenario of a patient presenting with upper airway obstruction is one of the most challenging that a doctor can be faced with. This chapter aims to review the options available for the management of upper airway obstruction. The primary goal is to secure a safe airway with minimal invasion appropriate to the clinical scenario.

The causes of upper airway obstruction are varied and some are immediately apparent whilst others are subtle. Penetrating and blunt trauma to the head and neck region with acute airway compromise are particularly difficult situations to manage, both in the pre-hospital setting and on arrival in hospital. Infections of the upper airway that may result in compromise include peritonsillar abscess, parapharyngeal space abscess, retropharyngeal abscess and epiglottitis. Hypertrophy and neoplasia of lymphoid tissue in the tonsils and tongue base typically evolves more slowly. Primary malignancy of the head and neck mucosal surfaces may also present with upper airway obstruction. Airway compromise associated with paralysis of the vocal cords and foreign body obstruction occurs far less commonly in adults.

There is potential for conflict between the considerations of the safe and secure airway and minimizing the intervention to be undertaken. This risk management problem is more apparent in the acute setting where comprehensive assessment of the ill patient is difficult and other coexisting medical problems may not be known.

SYMPTOMS AND SIGNS

In the absence of acute trauma to the upper airway, the symptoms described are often non-specific and include dyspnoea, cough and voice change. It should be noted that these symptoms might also indicate lower airway disease. Given the dual purpose of the upper aerodigestive tract, it is not surprising that these primary airway symptoms may coexist with dysphagia, pain on swallowing or referred otalgia. Noisy breathing implies turbulent airflow and airway compromise. Progression of this symptom heralds impending complete airway obstruction.

Stridor and stertor

Noisy breathing tends to have different characteristics depending on the level of upper airway obstruction. Stertor is defined as a heavy snoring sound that is low-pitched and indicates obstruction or collapse in the pharyngeal airway. Stridor is a high-pitched noise that can be mistaken for wheeze. Stridor arises from compromise of the airway at the level of the larynx and trachea and is generated by turbulent airflow. Stridor can be inspiratory, expiratory or biphasic (**Box 72.1**). Careful clinical assessment of timing of the stridor helps to localize the level of obstruction.

The extrathoracic airway has a tendency to collapse on inspiration and to expand on expiration. A reduction in the airway diameter at this level is therefore more

BOX 72.1 Stridor and level of airway obstruction

- **Inspiratory:** obstruction at and above the glottic larynx
- **Expiratory:** obstruction of the intrathoracic airway
- **Biphasic:** obstruction associated with subglottic and tracheal lesions

apparent on inspiration. This is the case with pharyngeal narrowing, or compromise of the supraglottis and glottis by a pedunculated lesion being sucked into the airway on inspiration and blown clear on expiration (producing a 'ball-valve' effect). The opposite applies to the intrathoracic airway where increased negative intrapleural pressure in inspiration leads to an increase in the airway diameter. During expiration, there is increased extrinsic pressure on the airway that exacerbates any narrowing. The subglottis and trachea is usually immune to the pressure fluctuations arising from the respiratory cycle due to cartilaginous support and therefore stridor at these levels is typically biphasic.

Increased work of breathing is also indicated by suprasternal, intercostal and subcostal recession as well as nasal flaring. This is accompanied by increased use of the accessory muscles of respiration.

Voice change

Changes in the vocal quality arise from impaired vocal fold vibration or altered vocal cord movement. Hoarseness results from many types of injuries and may signal oedema, mucosal disruption, cartilaginous injury and impaired vocal cord movement. Typically, the greater the degree of hoarseness, the greater the severity of laryngeal injury. Aphonia is often associated with severe injury. Voice change can also indicate the presence of a lesion altering the normal vocal fold structure producing impaired vibration.

Drooling and bleeding

Drooling is a symptom that indicates either pharyngeal or oesophageal obstruction or the avoidance of swallowing due to the presence of significant pain brought on by deglutition. This may arise from trauma or infection. Bleeding indicates mucosal trauma or exposure of a vascular structure by an invasive lesion. In the case of trauma, depending on the severity it may not be possible to identify the level of bleeding and it should be remembered that there may be more than one source.

Fractures and subcutaneous emphysema

Blunt trauma to the head and neck area may result in fractures of the maxilla, mandible, larynx or trachea. Significant pharyngeal trauma and fractures of the laryngeal skeleton or trachea may give rise to surgical emphysema. This may add to the extrinsic compression and independently worsen the upper airway obstruction.

MANAGEMENT

Assessment

The importance of the initial assessment and immediate management of the patient with upper airway obstruction cannot be underestimated. In resuscitation scenarios, the principle of an ABCDE approach is adopted. The airway (with appropriate consideration of the cervical spine in trauma) is always the first step in patient management, followed by consideration of breathing and circulation. This leads on to a neurological assessment and then a general evaluation. The general evaluation includes a determination of the extent and severity of the neck/chest injury.

The patient must be examined to exclude or address any immediately reversible causes of airway obstruction. Where any concern exists regarding the immediate safety of the airway, it should be secured by the least invasive technique that the attending clinician is capable of without delay. In trauma cases with possible cervical spine injury, appropriate imaging of the spine is required and in cases of uncertainty cervical spine protection must also be considered.

Whilst the assessment of the critically ill patient needs to be rapid it must also be systematic and thorough. Careful eliciting of the symptoms and signs will usually provide sufficient information on how to proceed. Where the airway is sufficiently stable but no cause for the airway compromise has been identified, the examination should include a transnasal fibre-optic endoscopy. This is generally well tolerated and provides vital information as to the site, degree and nature of the obstruction. It permits assessment of the state of the mucosa (presence of oedema, lacerations, blood) the appearance of the laryngeal structure (reduced view, position and mobility of the vocal cords) and the level or levels of airway compromise.

Treatment

The interventions available depend on the environment that the patient is in as well as the skill set and experience of the clinician (**Box 72.2**). It is important to remember that there can be rapid changes in the condition of the patient and that frequent revaluation is needed to respond appropriately to new symptoms and signs. Temporizing interventions should be utilized where possible initially; although tracheostomy is the definitive management

BOX 72.2 Principles of intervention in upper airway obstruction

- Secure the airway with the most straightforward and least invasive method.
- Adequate airway control must include securing the airway below the lowest level of obstruction.
- If known, coexisting medical conditions should be considered when deciding on the most appropriate intervention.
- Only address other medical problems once the airway has been adequately secured.

for upper airway obstruction, it may be difficult due to patient agitation (including effects of hypoxia) and movement (with use of accessory muscles of respiration).

The methods available for patient support in upper airway obstruction can be considered under the broad headings of non-invasive medical management and the use of alternative airways.

Medical management and non-invasive procedures

Whilst it should be borne in mind that 'the time to do a tracheostomy is when you first think of it', there are frequently times when minor trauma, infection or tumours cause airway obstruction that is moderate in severity and stable. Under such circumstances, it may be reasonable to institute a period of close observation allowing supportive and therapeutic measures to be commenced. This option is only suitable for clinicians who have experience in the management of patients with airway obstruction, and facilities exist for immediate intervention by intubation or tracheostomy in the event of patient deterioration. The most appropriate environment for such observation is in a high dependency setting, such as an intensive care unit. During this period, the airway should still be considered as potentially unstable and so all those involved in the management of such a patient must understand that any deterioration is an indication for immediate intervention to secure the airway.

INTERVENTIONS FOR OBSTRUCTION SECONDARY TO FOREIGN BODIES

In the case of upper airway obstruction due to a foreign body, including a food bolus, a stepwise approach is followed. Initially the patient is encouraged to cough. If this fails, then hard blows to the back with the heel of the hand is advocated before considering potentially more hazardous interventions including abdominal thrusts (the Heimlich manoeuvre). This manoeuvre involves the rescuer hugging the patient from behind and exerting pressure with the hands in the region of the xiphisternum to produce diaphragmatic movement. The lungs are compressed which may lead to dislodgement of the impacted foreign body. Complications of this technique include pneumomediastinum, pneumopericardium, surgical emphysema and gastric rupture. If the patient becomes unconscious, the emphasis switches to performing cardiopulmonary resuscitation. Inspection with a laryngoscope and removal under direct vision may be required. Where there is inability to remove the object a cricothyroidotomy is required.

OXYGEN AND HELIOX

The inspiratory oxygen concentration can be increased with the administration of high-flow oxygen via a facemask with a reservoir bag. In the emergency situation, the use of oxygen can be combined with simple airway methods including chin lift and jaw thrust. Use of humidification helps to break down secretions and makes them easier to clear. Heliox is a mixture of 80% helium with 20% oxygen. The properties of helium are a gas with low density and high viscosity resulting in less turbulence compared with air and pure oxygen. The patient experiences reduced resistance during breathing heliox and this is of proven benefit in the obstructed patient.[1]

STEROIDS

Steroids have a role to play in reducing the oedema produced by trauma, inflammation or infection.[2] There is no evidence to suggest a detrimental effect of steroids in the presence of infection when used as a short-term measure. Further indirect evidence on the benefit of steroids is provided by the use of corticosteroids to reduce the risk of post-extubation upper airway obstruction in adults and children.[3, 4]

ANTIBIOTICS

Antibiotics should be given in any case where acute infection is suspected and in cases where there is evidence or strong suspicion of a mucosal injury. Choice of antibiotic is usually guided by local institutional antimicrobial policy.

Alternative airways

The decision to proceed with the use of an alternative airway is based on an unstable patient and includes deteriorating obstructive symptoms and signs despite simple interventions. Patients in this situation are very challenging and appropriately trained and experienced individuals should carry out these interventions.

ORAL AIRWAY

In the event of a loss of consciousness or obstruction due to nasal injury, the airway may be improved with the use of an oral Guedel airway (**Figure 72.1**). A Guedel airway will not be tolerated if the gag reflex is present. This oral

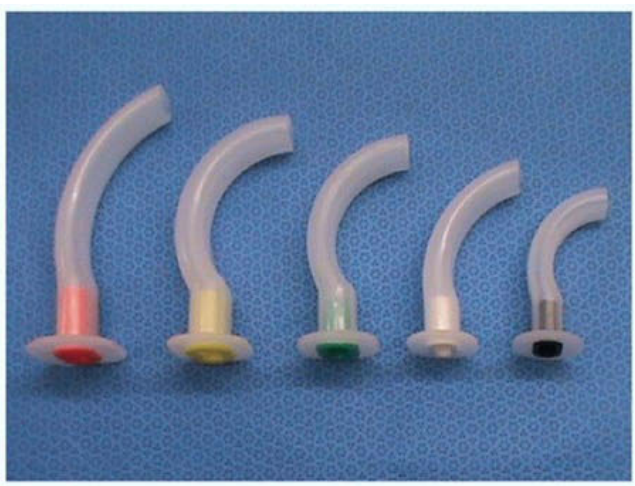

Figure 72.1 Selection of Guedel airways.

airway is easy to insert and bypasses obstruction in the oral cavity and nose but it is easily displaced. It can be used to assist ventilatory resuscitation with a facemask and ambubag. It also facilitates suctioning of the airway. The patient must still have a normal airway beyond the oral cavity and nasopharynx as well as a normal ventilatory drive for this intervention to be of value.

NASOPHARYNGEAL AIRWAY

A nasopharyngeal airway is a soft silicone plastic tube designed to be inserted via the nasal passageway to bypass obstruction at the level of the oropharynx, for example where the tongue base is pushed backwards in Ludwig's angina or angioedema and in cases of trauma with facial fractures (**Figure 72.2**). Insertion is straightforward and the tubes are well tolerated. The nasopharyngeal airway also facilitates suction. It should be noted that the tube can cause trauma to the nasal airway and resulting bleeding may give rise to further airway compromise. Use is contraindicated in patients with severe head or facial injuries where a skull base fracture allows the possibility of entering the intracranial compartment.

ENDOTRACHEAL INTUBATION

Endotracheal intubation is the intervention of choice where there has been a loss of respiratory drive necessitating assisted ventilation, or in cases of progressive upper airway obstruction. The person performing intubation should be supported by a trained assistant with access to a trolley containing a variety of laryngoscopes with a good light source, a range of endotracheal tubes, bougies and suction facilities.[5]

The usual route of intubation is via the mouth. This can be assisted by video-laryngoscopic devices.[6] The relative contraindications include cervical spine fractures, severe facial trauma and laryngeal trauma. In cases of cervical spine fracture, great care must be taken to avoid neck extension that may precipitate or worsen spinal cord injury. Facial trauma is usually associated with increased difficulty visualizing the larynx due to oedema, mucosal laceration and bleeding, trismus and bony instability. Great care is needed where there is laryngeal trauma, as the act of intubation may worsen the existing damage.

An alternative route to secure the difficult airway is by transnasal intubation. This is often performed using endoscopic guidance. The endotracheal tube is secured to a flexible nasal endoscope or bronchoscope (**Figure 72.3**). The tip of the endoscopic device is passed via the larynx into the trachea and the endotracheal tube is then passed over the fibre-optic endoscope into position. This is a skilled technique that requires experience, given the expected airway compromise with secretions, blood, and anatomical distortion resulting in poor views of the larynx.

TRANS-TRACHEAL CANNULATION

In the emergency setting, the trachea can be cannulated directly via the cricothyroid membrane using a large bore intravenous cannula. The airway can then be maintained temporarily by connecting the cannula to an ambubag using a syringe with a 7mm endotracheal tube adaptor inserted in the barrel (**Figure 72.4**).

Figure 72.3 Flexible nasal bronchoscope with endotracheal tube.

Figure 72.4 Large bore cannula with adaptation to connect to anaesthetic circuit.

Figure 72.2 Nasopharyngeal airway.

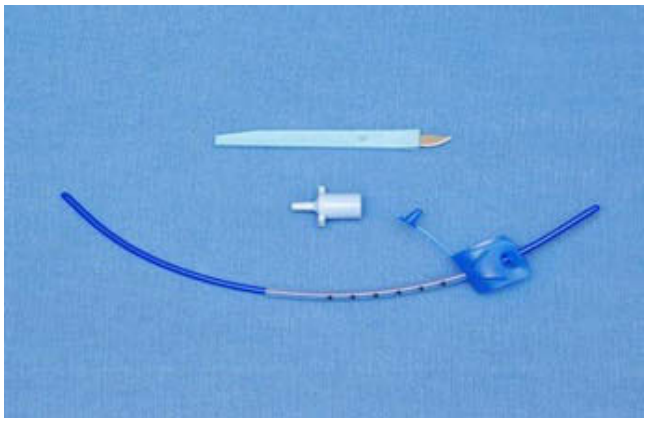

Figure 72.5 Cricothyroidotomy kit.

CRICOTHYROIDOTOMY/MINITRACHEOSTOMY

In an emergency, rapid control of the upper airway can be achieved by use of an airway inserted through the cricothyroid membrane. Once an incision has been made through the membrane a minitracheostomy tube or a wide bore cannula can be used to keep the tract open and provide an alternative airway (**Figure 72.5**). A sound knowledge of the anatomy and technique is required to minimize complications.[7]

The patient is positioned with the neck extended over a pillow. The cricothyroid membrane can be palpated and the area is infiltrated with local anaesthetic and epinephrine. The cricothyroid membrane can be incised either with a scalpel or a wide bore cannula attached to a syringe half filled with saline. In the former case, once the airway has been opened the blunt handle of the scalpel can be inserted and rotated to create space for a tube to pass into the trachea. In the latter case, the needle of the cannula is used to breach the membrane and as the needle and cannula are inserted the plunger of the syringe is withdrawn. Air bubbles into the syringe when the trachea has been entered. The cannula can then be introduced over the needle. The cannula can be connected via a universal connector to an ambubag and the patient can be ventilated for a short period of time. Using this system, CO_2 is not cleared and so conversion to a formal tracheostomy should be undertaken as soon as possible.

A minitracheostomy tube should not be left in situ for more than a short time as there will inevitably be some friction between it and the cricoid cartilage that will predispose the patient to subglottic stenosis.

TRACHEOSTOMY

Tracheostomy (**Box 72.3**) is one of the oldest surgical procedures.[8] There are references to the creation of a surgical airway in many ancient texts.[9] Until the end of the 19th century and the introduction of asepsis together with the development of safe anaesthetic techniques, the procedure was extremely hazardous. Tracheostomy was seen as a last resort in hopeless cases and was the cause of great anxiety for the patient and surgeon alike. Chevalier Jackson established the principles of the operation at the beginning of the twentieth century and these remain in place today.[10] The development of percutaneous tracheostomy has taken surgical airway management out of the exclusive province of the otolaryngologist. There is now a wide variety of clinicians involved in the challenges of tracheostomy care and decannulation strategies.

BOX 72.3 Definitions

Tracheotomy: a surgical opening in the trachea
Tracheostomy: the creation of a stoma at the skin surface that leads into the tracheal lumen

The commonest use of an elective temporary tracheostomy is for prolonged ventilatory support in a ventilated patient. A temporary tracheostomy may also be planned as part of a major surgical procedure in which there are concerns about post-operative swelling or bleeding, which may precipitate upper airway obstruction.

An emergency tracheostomy is a rare procedure, perhaps only indicated in cases of severe trauma or very late presentation. In all other cases, it could be argued that the performance of an emergency tracheostomy is indicative of an underestimation of the severity of the breathing problem. The majority of cases can be dealt with by carrying out an urgent procedure under local anaesthesia with the patient awake. In extremis, it should be possible to perform a cricothyroidotomy and maintain ventilation via a wide bore cannula until conversion to a formal tracheostomy can be undertaken.

A permanent or 'end' tracheostomy is an elective procedure carried out as part of a surgical procedure involving the removal of the larynx, such as a laryngectomy or pharyngolaryngectomy. A permanent tracheostomy is also created in laryngeal diversion procedures used to prevent aspiration. The continuity between the laryngopharynx and the trachea is permanently disrupted and the cut end of the trachea is sutured to the skin.

The effects of tracheostomy are shown in **Box 72.4**.

Indications for tracheostomy

Indications for tracheostomy are: upper airway obstruction; prolonged ventilation; removal of secretions; and part of another procedure.

UPPER AIRWAY OBSTRUCTION

This has been discussed above. Tracheostomy is considered as the ultimate form of airway control.

BOX 72.4 Effects of tracheostomy

- Laryngeal bypass – loss of cough and phonation
- Reduction in respiratory dead space
- Loss of nasal mucosa filtration and humidification
- Increased risk of infection
- Tube acts as foreign body leading to local inflammation
- Sump above tracheostome and below larynx where mucus collects.

PROLONGED VENTILATION

Tracheostomy is the safest means of assisting ventilation where prolonged positive pressure is needed. It is easier to secure a tracheostomy tube than either an orotracheal or nasotracheal tube and the reduced dead space assists weaning of respiratory support. It has been demonstrated that the introduction of percutaneous tracheostomy has led to a doubling in the number of tracheostomies being carried out.[11] It may be that the ease of access to tracheostomy has resulted in reduced duration of intubation.[11] However, with the introduction of low-pressure cuffs for endotracheal tubes, a longer period of intubation has become acceptable. There is evidence that early tracheostomy in trauma patients reduces length of ventilation and hospital stay[12] and it may be that the same applies for general ITU patients.

REMOVAL OF SECRETIONS

The accumulation of secretions in the lower respiratory tract is responsible for a reduction in gas diffusion within the alveoli. This results in respiratory failure. A tracheostomy reduces the dead space, so reducing the work of breathing, and also makes it easier to aspirate secretions with less patient discomfort.

PART OF ANOTHER PROCEDURE

A permanent tracheostomy is an unavoidable consequence of a major head and neck procedure (e.g a total laryngectomy). A temporary tracheostomy is usually needed for open resections involving the oropharynx or larynx. In these cases, the tracheostomy allows protection of the lower airway from aspiration of blood in the event of a haemorrhage, as well as guarding against upper airway obstruction from post-operative swelling. A percutaneous tracheostomy is probably not appropriate in these cases, as the pre-tracheal tissues fit tightly around the tube.[13] In the event of tube displacement, the tissues can collapse inwards, closing the airway with a potentially fatal outcome.[14]

Anatomy

As with any surgical procedure, when performing tracheostomy, it is essential to have a sound knowledge of the relevant applied anatomy of the upper trachea. Problems are likely to happen if the surgeon strays from the midline. The recurrent laryngeal nerve runs in the tracheoesophageal groove and the great vessels are lateral to this within the carotid sheath. It is rare in a straightforward tracheostomy to lose sense of where the midline is, but in obese patients and small children it is possible to lose the anatomical landmarks and stray laterally. The thyroid isthmus crosses in front of the trachea covering a variable number of the tracheal cartilaginous rings. It is a highly vascular structure and inadvertent damage during dissection or friction from the tube may result in post-operative haemorrhage. The innominate artery crosses the front of the trachea, from left to right, at a variable height. In cases of a high innominate artery it may be encountered during dissection or may suffer erosion from the tracheostomy tube with potentially fatal post-operative haemorrhage.[15]

Contraindications

There are no absolute contraindications to tracheostomy. However, in patients with a terminal prognosis, very careful consideration must be given to the psychological effect on the patient and the quality of life aspects. There is no right or wrong answer and each patient must be approached on an individual basis.

Pre-operative considerations

In the elective setting it is imperative that adequate consent is received from the patient or their relatives. As part of this process it is necessary to cover the risks and benefits of the procedure in some detail. This must be a frank and open discussion and the potential complications and sequelae of tracheostomy must be pointed out. This is particularly true of paediatric tracheostomy.

Operative procedures

PERCUTANEOUS TRACHEOSTOMY

First described more than 50 years ago,[16] this technique has grown in popularity and is now the commonest procedure for the provision of an alternative airway for ITU patients. The growth of the procedure followed the introduction over the last 15–20 years of commercial kits based on well defined techniques (**Figure 72.6**).[17–19] The most commonly employed kit in the UK depends on the dilatation technique originally described by Ciaglia.[20]

The patient should be positioned as for a formal surgical tracheostomy (see 'Open surgical tracheostomy' below). The trachea is punctured, using a needle and cannula, just below the first tracheal cartilage ring. A syringe half-filled with saline is attached to the cannula. Gentle aspiration allows correct positioning of the cannula,

Figure 72.6 Percutaneous tracheostomy set.

because air is aspirated through the saline as the needle passes into the trachea. The needle is withdrawn and a guide wire is inserted through the cannula. The cannula is withdrawn to allow for either a single dilator or a series of dilators with increasing diameter to be passed over the guide wire. The dilators create a passage that is wide enough for the insertion of a standard tracheostomy tube, which is secured in position within the trachea. It is advisable to view the internal lumen of the trachea during this procedure by using a flexible bronchoscope, as this may reduce complications.[19]

OPEN SURGICAL TRACHEOSTOMY

There are many variations in the technique of open surgical tracheostomy but they are all based on the same fundamentals. The technique described is that preferred by the authors. The procedure should, when possible, be carried out in an operating theatre, under sterile conditions. It is usual for the patient to have a general anaesthetic but where this is deemed hazardous the procedure can be carried out under local anaesthetic.

The patient should be positioned supine, with the neck extended by placing a sandbag under the shoulders. It is important that the patient is positioned square on the table with the shoulders at the same level as this will ensure that the midline structures of the neck are truly in the midline throughout the operation (**Figure 72.7a**). When operating under local anaesthesia it may be necessary to compromise on the degree of neck extension as over-extension may further restrict the airway.

A horizontal incision is sited halfway between the sternal notch and the lower border of the cricoid cartilage (**Figure 72.7b**). Once the skin has been incised, dissection continues through the subcutaneous tissues to the strap muscles, which are retracted laterally, following blunt dissection in the midline to separate them. Following this manoeuvre, the thyroid isthmus should be visible (**Figure 72.7c**). The isthmus should be clamped, divided and transfixed (**Figure 72.7d**). At this point the anterior tracheal wall is encountered. It is useful to identify the cricoid cartilage to plan the point of entry into the trachea. Ideally the tracheotomy should be made between the 2nd and 4th tracheal rings. Before entering the trachea, it is important to select an appropriately sized tracheostomy tube and check that the cuff and all connecting equipment works properly, so that ventilation can continue uninterrupted following the tracheostomy. There needs to be good communication between the surgeon and the anaesthetist.

Having informed the anaesthetist that the trachea is about to be opened, the tracheotomy can be performed. The guiding principle should be to cause as little disruption to the trachea as possible, maintain cartilage and prevent damage to the cricoid cartilage. These aims are best achieved by the use of a vertical slit between stay sutures. Once the trachea has been opened, the anaesthetist should withdraw the endotracheal tube under the direction of the surgeon, who can visualize the tube being withdrawn. When the tip of the endotracheal tube is immediately above the tracheotomy, withdrawal can stop and the tracheostomy tube should be inserted. The cuff should be inflated and the tube connected to the ventilator.

The incision should be closed loosely and the tracheostomy tube secured in position with tapes, sutures or both (**Figure 72.7e**).

Choice of tube

There is a wide variety of tracheostomy tubes available, made from different materials and with different features. The choice of tube depends on the indication for the tracheostomy, the post-operative needs of the patient and the anatomy of the patient.

CUFF

Cuffed tracheostomy tubes are used to provide a seal to allow positive pressure ventilation or to prevent aspiration. The pressure of air within the cuff must be high enough to provide an adequate seal but not so high as to damage the tracheal mucosa resulting in subglottic stenosis. The use of modern low-pressure cuffs has for the most part reduced this problem.

INNER TUBE

Some tubes are supplied with an inner tube that fits snugly inside the main tube. The tip of the inner tube projects a few millimetres beyond the distal end of the main tube. This means that secretions will collect in the inner tube that can be removed, cleaned and replaced without disruption to the patient or their airway.

FENESTRATION

The fenestration is sited at the point of maximum curvature in the tube and may be in the form of a single hole or a number of small holes. The fenestration allows air to pass from the tube through the larynx, so increasing the air available for phonation and increasing the volume of the voice.

FLEXIBILITY

In some cases, a rigid tracheostomy tube will not conform to the anatomy of the patient and will lie at an awkward angle or in a position that will result in tracheal trauma from the tip of the tube rubbing against the tracheal wall. In these circumstances, a softer and more flexible tube is preferred. If the use of a softer tube results in obstruction of the tube due to kinking, it may be necessary to use an armoured flexible tube.

ADJUSTABLE FLANGE

An adjustable flange allows the intra-tracheal length of the tube to be altered to take account of the depth of the stoma, which may be increased by alterations in anatomy, such as in patients with a large thyroid mass, or to bypass intra-tracheal obstruction.

Figure 72.7 **(a)** Patient positioned and marked for tracheostomy; **(b)** tracheostomy skin incision; **(c)** exposure of thyroid isthmus; **(d)** control of thyroid isthmus; **(e)** secured tracheostomy tube.

The tube placed at the time of the tracheostomy should be cuffed to allow ventilation of the patient and to prevent aspiration of blood or secretions resulting from the procedure. Ideally an inner tube should be available to allow easy clearing of secretions in the immediate post-operative period.

Post-operative considerations

It is important to remember that the patient requires multidisciplinary input. In addition to the requirements arising from the tracheostomy, which include communication, airway management and potential swallowing issues, there is also the need to address the pathological process that has generated the need for definitive airway control. A team-based approach is therefore essential for optimal patient outcome and minimizing complications with various studies and consensus.[21–24]

On return to the ward it is important that a nurse who is experienced in the care of tracheostomy patients and knowledgeable about the potential complications looks after the patient. Writing materials must be available for the patient to use for communication.

The original tracheostomy tube must be secured in position for at least 3 days to allow a good tract to form. The tube should be changed after 7 days and any sutures can then be removed. Tubes should be secured with tapes fastened by a secure knot on both sides of the neck, with the neck in a neutral position. If the neck is extended when the tapes are fastened, then the tapes will be too long and will not hold the tube in the appropriate position and it may be coughed out.

The cuff should be deflated once the risk of aspiration has passed. In most cases, there is no need for cuff inflation after the first 12 hours.

Following tracheostomy, the inspired air passes directly into the trachea without being warmed and humidified by the upper airway. As a result, the air is irritant to the trachea and there is an increase in the quantity and viscosity of the tracheal secretions. The patient may require frequent suctioning in the early post-operative period and the use of hot water bath humidifiers or nebulizers is essential to reduce the risk of tube obstruction due to crust formation. As the trachea becomes accustomed to the presence of the tube and the patient learns to clear the secretions by coughing through the tube, so the need for suctioning and humidification decreases.

Swallowing problems are common following tracheostomy. These are usually due to the sensation of pressure in the upper oesophagus because of an inflated cuff and because the movement of the larynx during swallowing is reduced secondary to the tethering effect of the tube.

If at any stage doubts occur regarding the position of the tube or obstruction of the lumen, a flexible nasal endoscope can usually be passed through the tube to inspect the lumen of the tube and the trachea.

Complications

Complications can be:

- Immediate (haemorrhage; air embolism; local damage)
- Intermediate (extubation; obstruction; subcutaneous emphysema; infection; fistulae)
- Late (tracheo-cutaneous fistula; tracheal stenosis).

IMMEDIATE

Haemorrhage is the commonest fatal complication of tracheostomy,[25] as well as the commonest complication. Bleeding is usually due to damage to the thyroid veins or the thyroid isthmus. If there is significant bleeding at the end of the procedure the wound should be explored and any bleeding vessel ligated. Packing the tracheostomy wound to tamponade the bleeding is widely practised but should be seen as little more than a temporary procedure prior to re-exploration of the wound.

Air embolism, while life threatening, is fortunately rare following tracheostomy. If the large veins of the neck are opened during the procedure air may be sucked into the venous system and pass into the right atrium.

Damage to structures in the vicinity of the operative field is often the result of altered anatomy or inattention to good surgical technique. Inexperienced surgeons may inadvertently stray from the midline and so cause damage to the contents of the carotid sheath, oesophagus or recurrent laryngeal nerve. In emphysematous patients, the apex of the lung may extend into the lower neck and can be damaged because of lateral dissection. An inadequate incision, poor retraction or poor haemostasis can result in less than ideal exposure and consequent damage to the tracheal walls or cricoid cartilage. Damage to the cricoid is particularly serious and if recognized at the time of surgery, the tracheostomy should be re-sited lower in the trachea and the damage repaired.

Immediate complications are best prevented by good haemostasis during surgery and meticulous attention to surgical technique.

INTERMEDIATE

Accidental extubation is easily avoided provided that the tube is adequately secured at the time of the procedure, by suturing the flanges of the tube to the skin. If the tube is displaced and comes to lie in the pre-tracheal space, the complication may not become immediately apparent. The patient continues to breathe as the soft tissues gradually prolapse around the tracheal opening, which slowly begins to seal. Dyspnoea slowly increases and by the time the displacement is apparent the tube may be impossible to replace as the tracheotomy has virtually closed. An experienced nurse will pick up on the early warning signs. Any difficulty breathing through the tube must be fully investigated. The use of a flexible scope passed through the lumen of the tube may identify displacement or obstruction of the tube due to crusting, granulation tissue or poor placement of the tube tip with respect to the tracheal wall.

If the tracheostomy tube or the trachea are obstructed and the skin incision has been closed tightly, then air may be forced out into the soft tissues of the neck during expiration resulting in subcutaneous emphysema. Surgical emphysema, under these circumstances, can track up to the lower eyelids and down into the upper chest. In severe cases the swelling may cause displacement of the tube.

Tracheo-oesophageal fistulae may be the result of intra-operative damage to the posterior wall of the trachea or persistent rubbing of the tip of the tube on the posterior wall in the early post-operative period. The fistula usually presents when the patient starts to show signs of aspiration despite the cuff being inflated. Tracheo-arterial fistulae present most commonly in previously irradiated patients, particularly if a low tracheostomy has been carried out. There is rarely any premonitory sign and the usual presentation is with sudden massive haemorrhage. The tracheostomy tube must be changed immediately for a cuffed tube; the cuff should be inflated to prevent further aspiration of blood and compression applied to any bleeding vessel via the tracheostome. The wound should be explored immediately as there is a very high mortality associated with this complication. The commonest artery affected is the innominate although there are reports of trachea-carotid fistulae.[26]

LATE

Epithelialization of the tract is a normal event in the evolution of a tracheostomy. The longer the tracheostomy has been present the more established the process is and the more likely the tract is to persist following decannulation. The incidence can be reduced if great attention is paid to ensuring an airtight seal is maintained once the stoma has been occluded. If there is evidence of granulation tissue

in the fistula, simple cautery with silver nitrate may assist spontaneous closure. A small number of cases will require formal surgical closure. This involves excision of the tract all the way down to the anterior tracheal wall and closure in several layers.

Tracheal stenosis is almost always the result of damage to the cricoid or first tracheal ring at the time of surgery or damage to the trachea from the rubbing of a poorly positioned tube, resulting in mucosal inflammation.

Decannulation

If the patient is able to breathe around the tube when it is occluded then there is no need to downsize the tube, which is usually the case if the initial cuffed tube has been replaced with an uncuffed fenestrated tube. Decannulation should take place in an ordered sequence. The tube should be blocked during the day and unblocked at night for the first 24 hours. If the patient tolerates this then the tube can be occluded for a full 24-hour period and if this is tolerated then the tube can then be removed. If the patient is unable to tolerate this occlusion of the tube then it may be necessary to downsize the tube to give more room around it. Patients who have been dependent on the tracheostomy for a long time may require a more prolonged decannulation process as it may take some time for them to overcome their anxiety about being unable to breathe without the tube in place. Variability in practice regarding the exact timing of tracheostomy still occurs.[27]

Once the tube has been removed an airtight dressing must be applied to occlude the stoma. In most cases, several gauze squares covered with an occlusive dressing will be sufficient. The dressing should be changed whenever an air leak appears to improve the chance of full closure of the fistula.

The national tracheostomy safety project

The National Tracheostomy Safety Project aims to produce a national tracheostomy safety resource and, through its membership of the Global Tracheostomy Collaborative, is working to improve the care of tracheostomy patients in all countries. Its website (www.tracheostomy.org.uk) provides a variety of open access educational resources and protocols for the management of patients.

TRACHEOSTOMY-SPARING INTERVENTIONS

Advanced cancers of the upper aerodigestive tract may present with significant upper airway obstruction. Many of these patients are managed with an awake tracheostomy under local anaesthetic or, following successful intubation, have a tracheostomy to secure their airway prior to anaesthetic reversal.

In certain situations of locally advanced upper aerodigestive tract carcinoma, other interventions may be used to re-establish a satisfactory airway and avoid the need for a surgical tracheostomy. Debulking of the tumour can be achieved, for example, with the use of a carbon dioxide laser (**Figures 72.8** and **72.9**), a microdebrider or biopsy forceps. Tumour debulking is a relatively low risk procedure, without the risks and morbidity associated with tracheostomy. It is especially suited for supraglottic tumours, but less effective for subglottic neoplasms. At the same time as achieving an improved airway, the debulking allows for samples to be harvested for histologic analysis. The operating surgeon can also gain a better appreciation of the clinical extent of the tumour. The avoidance of tracheostomy placement has several advantages: the potential for 'seeding' of the carcinoma to the stoma site is abrogated; incision planning is less complex if a laryngectomy is required for definitive treatment; and hospital stay is reduced.

These interventions are highly complex undertakings and significant combined expertise on the part of the anaesthetic and surgical teams is required to ensure a good outcome.[28] Good communication between the teams, including a thorough pre-operative briefing of all staff involved of what is expected as well as alternative

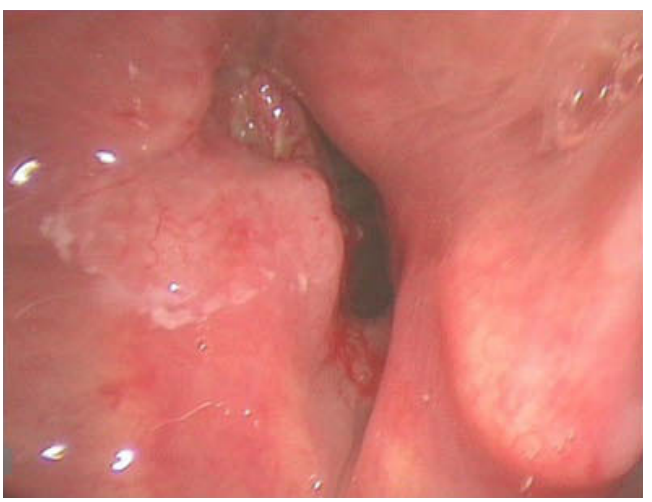

Figure 72.8 Left-sided laryngeal carcinoma involving supraglottic and glottic regions.

Figure 72.9 Airway following laser debulking.

strategies in the event of problems encountered, forms part of the expertise needed.

The presence of a tracheostomy tube can make radiation planning difficult and, where feasible, debulking can be repeated to achieve a stable airway.[28] There is evidence of a significant delay in starting definitive treatment for patients who undergo tracheostomy when compared with those undergoing debulking procedures.[29]

EMERGENCY AIRWAY MANAGEMENT DURING A 'CAN'T INTUBATE, CAN'T OXYGENATE' (CICO)

There has been a debate in recent years as to the safest way to secure the airway in the event of an emergency event in which it is not possible to intubate or oxygenate a patient (can't intubate, can't oxygenate, or CICO). The traditional approach by ENT surgeons has been to perform an emergency or 'crash' tracheostomy. However, over the last 10–20 years there has been a decrease in the number of routine open tracheostomies carried out as more percutaneous tracheostomies are performed in the intensive care setting. The National Confidential Enquiry into Patient Outcome and Death (NCEPOD) tracheostomy report, '*On the right trach?*' reviewed the care received by patients who underwent a tracheostomy.[30] This review reported that the majority of open tracheostomies are performed as part of another surgical procedure (major head and neck resection) or in patients who might be considered 'unfavourable' for a percutaneous procedure. The follow-on from this is that there are fewer opportunities for trainees to acquire skills to perform an open tracheostomy.

So, when called to an airway emergency, what is the most appropriate, safest and quickest technique to use to secure the airway? Ultimately the decision rests with the individual and must be based on their experience and ability as well as an assessment of the patient, the skills of other team members and the available equipment. However, a good argument can be made that the quickest and safest way to secure the airway is by the use of the 'Scalpel–Bougie' technique of cricothyroidotomy. This technique has been supported by the Difficult Airway Society in the UK for front of neck airway (FONA) in CICO events.[31] The technique is different from the standard 'needle' cricothyroidotomy, which has been shown to be ineffective in altering the outcome in CICO events.[32] A recent editorial with a multidisciplinary authorship has advocated that there should be an emphasis on Scalpel-Bougie cricothyroidotomy training for all medical professionals involved in the management of acute airway emergencies.[33]

KEY POINTS

- Assessment of the airway should be part of an overall systematic approach to managing the critically ill patient.
- The assessment should determine the level(s) of airway obstruction.
- Action should be decisive.
- The least invasive intervention that will bypass the level of the lowest obstruction should be used.
- Problems from comorbidities should be considered, particularly in cases of multiple trauma.
- Any intervention should be carried out by someone who is experienced in the use of that technique.
- The technique chosen to effect tracheostomy should minimize trauma whilst achieving the desired outcome of a secure airway.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: sleep disorders, classification of sleep disorders, sleep physiology, sleep deprivation, excessive daytime sleepiness, hypersomnia, insomnia, sleep-related breathing disorders, obstructive sleep apnoea, central sleep apnoea, sleep hypoventilation, obesity, hypoventilation, central disorders of hypersomnolence, narcolepsy, cataplexy, circadian rhythm sleep-wake disorders, parasomnias, sleep-walking, REM behaviour disorder, sleep-related movement disorders, restless legs syndrome, periodic limb movement and bruxism.

INTRODUCTION

Sleep is essential as a restorative process to maintain cognitive performance and work productivity as well as physical, psychological and emotional well-being. Although muscles may not need sleep, the brain needs sleep to function and control movements and thoughts.[1]

Normal sleep physiology

Sleep physiology may be assessed by polysomnography (PSG), which typically comprises sleep staging using electroencephalography (EEG) with multi-channel recording of video, snoring, nasal airflow, and thoracic and abdominal respiratory effort to produce an apnoea-hypopnoea index (AHI), as well as sensors to detect body position and leg movement. EEG and video are often omitted in assessment of subjects who are likely to have sleep-related breathing disorders, facilitating portable (ambulatory) or home monitoring as cardio-respiratory polygraphy (**Figure 73.1**).

During normal sleep, polysomnography (PSG) shows that subjects cycle through periods of light sleep (stages 1 and 2), deep sleep (N3 comprising former stages 3+4) in which the brain is resting and becomes refreshed, and rapid eye movement (REM) sleep in which the brain is active in consolidating thoughts, learning and memory (**Figure 73.2**).

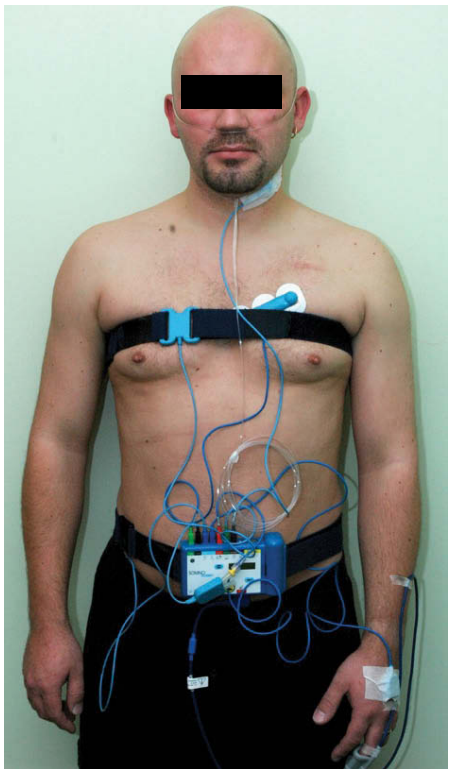

Figure 73.1 Cardio-respiratory polygraphy study (portable monitoring).

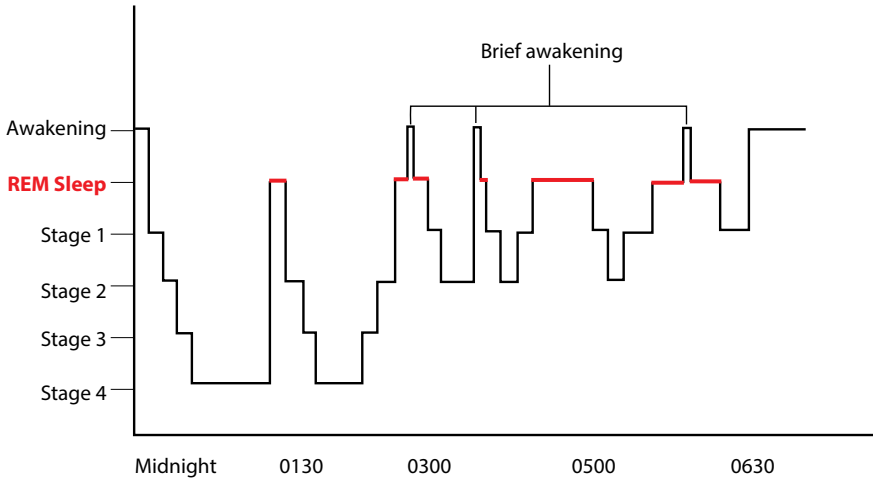

Figure 73.2 Sleep staging using polysomnography.

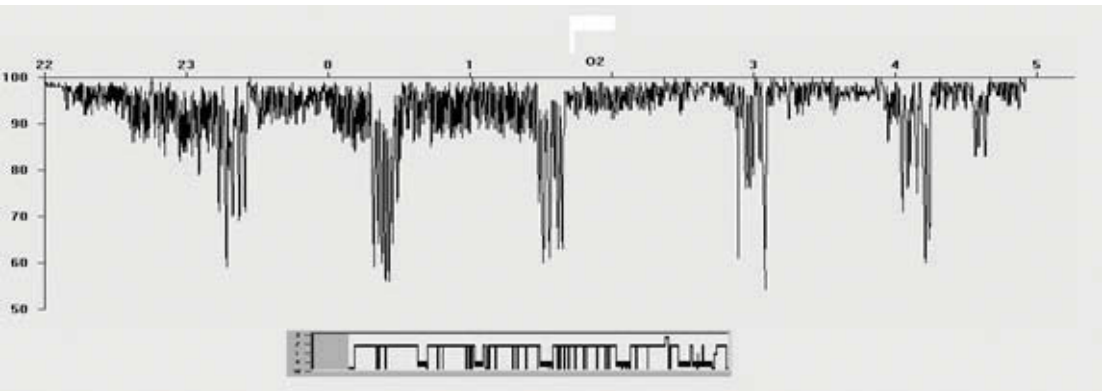

Figure 73.3 REM-related increase in frequency of nocturnal oxygen desaturation due to ventilatory failure in obstructive sleep apnoea.

As the night progresses, periods of deep sleep become shorter, while REM periods become longer. In REM sleep, pathognomonic rolling eye movements are noted, and there is generalized inhibition of skeletal muscles, including the intercostal, accessory and pharyngeal dilators, leaving largely the diaphragm to support ventilation. This is reflected in an increased respiratory rate and ventilatory failure is more likely, particularly in subjects with respiratory or neuromuscular disorders (**Figure 73.3**).

Sleep onset leads to hypoventilation with reduced metabolic rate. There is loss of voluntary and emotional control of breathing, loss of wakefulness drive and a decrease in reticular activating system (RAS) activity rate, leading to dependence on brainstem reflex activity. Reduced ventilation leads to a rise in partial pressure carbon dioxide ($PaCO_2$), and consequent fall in partial pressure oxygen (PaO_2). A small rise in $PaCO_2$ is necessary to exceed the apnoeic threshold and maintain ventilation. There is reduced medullary phasic electrical activity, and reduced chemo-sensitivity to partial pressures of arterial carbon dioxide ($PaCO_2$) and oxygen (PaO_2), together with increased airway resistance.[2, 3] The respiratory system is therefore less able to adapt to changes in sleep, including hypoxaemia.[4]

There is an endogenous circadian rhythm in pulmonary function, respiratory control and basal metabolism, which appears independent of daily changes in behaviour (including sleep) and environment.[5]

During the night there are diurnal falls in cortisol levels and body temperature, and increased cholinergic tone that may lead to increased airflow limitation in patients with chronic obstructive pulmonary disease (COPD).[6]

Sleep deprivation

Acute sleep deprivation leads to impaired cognitive, psychomotor and executive function, as well as increased cortisol, impaired glucose tolerance, androgen deficiency and increased appetite due to a reduced blood leptin/ghrelin ratio.[7–9]

Longer term sleep deprivation may lead to deranged metabolism with obesity, increased insulin resistance and risk of diabetes mellitus, hyperlipidaemia, cardiovascular disease, coronary events and increased all cause mortality.[10, 11]

Sleep deprivation has been shown to have an effect on pulmonary function with significant decline in minute ventilation and inspiratory muscle endurance after 24 hours. This is not clinically significant in healthy subjects, but can lead to a significant 5–6% fall in forced expiratory volume in one second (FEV_1) and forced vital capacity (FVC) in COPD.[12–14]

Sleep restriction and fragmentation may occur due to emotional stress, environmental factors such as shift

work, acute and chronic medical conditions including obesity, and a range of specific sleep disorders.[15–17]

Excessive daytime sleepiness

Excessive sleepiness is a subjective marker of many sleep disorders, although it can affect up to 12% of the normal population, and is more common in subjects with snoring, obesity, diabetes mellitus and renal failure.[18–20]

It is difficult to quantify consistently or objectively, but the Epworth Sleepiness scale (ESS) score is commonly used as a validated simple self-administered assessment tool (**Table 73.1**). A score of more than 10 is considered significant, but lower scores may not exclude sleepiness, possibly due to misinterpretation of the test.[21]

The multiple sleep latency test (MSLT) uses EEG to assess how quickly a subject falls asleep during 5 attempted naps over the course of a day. A shortened mean sleep latency of less than 8 minutes is considered consistent with pathological excessive sleepiness.[22] Sleep diaries (logs) may help to confirm adequate sleep opportunity.

The maintenance of wakefulness test (MWT) conversely assesses how long a subject can remain awake and may indicate reduced alertness if mean sleep latency is less than 20 minutes. Correlation between subjective and objective measurements may be poor.[23]

Psycho-motor vigilance can be measured using the Oxford Sleep Resistance (Osler) test, and in driving simulators.[24, 25]

CLASSIFICATION OF SLEEP DISORDERS

The International Classification of Sleep Disorders describes a range of respiratory and non-respiratory conditions that may be associated with insomnia or excessive daytime sleepiness while awake, or behavioural abnormalities in sleep (**Box 73.1**).

Insomnia

The criteria for insomnia include a report of subjective difficulty with sleep initiation or maintenance, including waking up earlier than desired, resistance to going to bed on appropriate schedule or difficulty sleeping without parent or caregiver intervention. This must be associated with adequate opportunity and circumstances to sleep, and also a requirement for a report of daytime consequences.[22] These include fatigue or malaise, impairment of attention, concentration or memory, impaired social, family, occupational or academic performance, mood disturbance or irritability, daytime sleepiness, behavioural problems (e.g. hyperactivity, impulsivity, aggression), reduced motivation, energy or initiative, proneness for errors or accidents, or concerns about, or dissatisfaction with, sleep.

Many people experience occasional insomnia (50%) with 6–10% describing chronic insomnia.[26] Insomnia is common in a range of medical and psychiatric disorders. Short-term insomnia is often associated with an identifiable cause or trigger, commonly particular daytime stressors.

BOX 73.1 International Classification of Sleep Disorders (ICSD-3)

- Insomnia
- Sleep-related breathing disorders
- Central disorders of hypersomnolence
- Circadian rhythm sleep-wake disorders
- Parasomnias
- Sleep related movement disorders
- Other sleep disorders

TABLE 73.1 Epworth Sleepiness Scale score

How likely are you to doze off or fall asleep in the following situations, in contrast to feeling just tired? This refers to your usual way of life in recent times. Even if you have not done some of these things recently try to work out how they would have affected you.
Use the following scale to choose the most appropriate number for each situation:
0 = no chance of dozing
1 = slight chance of dozing
2 = moderate chance of dozing
3 = high chance of dozing

Situation	Chance of dozing
Sitting and reading	
Watching TV	
Sitting inactive in a public place (e.g a theatre or a meeting)	
As a passenger in a car for an hour without a break	
Lying down to rest in the afternoon when circumstances permit	
Sitting and talking to someone	
Sitting quietly after a lunch without alcohol	
In a car, while stopped for a few minutes in traffic	
TOTAL	

A score of more than 10 indicates significant sleepiness.

Chronic insomnia disorder is defined by symptoms at least three times per week for a duration of 3 months, and is usually only made when the insomnia is especially prominent or unexpectedly prolonged, and under assessment or treatment. It combines a number of categories previously defined as psychophysiological insomnia, idiopathic insomnia, sleep-state misperception and inadequate sleep hygiene.[22]

The diagnosis of insomnia relies on a medical, sleep and psychiatric history and is aided by keeping a sleep log. Predisposing, potentiating and precipitating factors may be identified.

Management of insomnia involves dealing with identified underlying causes, and consideration of behavioural and drug therapies. Sleep hygiene advice includes restriction of caffeine and alcohol, especially during the evening. Cognitive behavioural therapy for insomnia (CBTI) also includes relaxation, stimulus control and sleep restriction techniques.[26, 27]

CBTI is preferred but can be combined with pharmacological treatments including benzodiazepines, non-benzodiazepines and low-dose antidepressants. Hypnotics should be used for a maximum of 2–3 per week to avoid dependence.[28, 29]

SLEEP-RELATED BREATHING DISORDERS

Sleep breathing disorders include a spectrum of problems with similar pathophysiology including obstructive sleep apnoea hypopnoea (OSA), and sleep-related hypoventilation, as well as the less common condition of central sleep apnoea (CSA) (**Box 73.2**). Children and adults with tonsillar hypertrophy, craniofacial syndromes and neuromuscular disorders have an increased risk for sleep breathing disorders.[30]

Although patients may be asymptomatic, ventilatory failure during sleep and consequent sleep fragmentation usually lead to presentation with one or more of a range of associated problems including snoring, subjective sleep disturbance, excessive daytime sleepiness, witnessed pauses in breathing, right heart failure (cor pulmonale) and cardio-metabolic comorbidities. Children may present with insomnia, enuresis, behavioural problems, hyperactivity, and reduced attention span, memory and learning ability. Growth may be impaired due to lack of deep sleep necessary to produce growth hormone.

BOX 73.2 Sleep breathing disorders

Obstructive sleep apnoea (OSA)
Central sleep apnoea (CSA)
- central sleep apnoea with Cheyne-Stokes breathing
- central sleep apnoea due to a medical disorder without Cheyne-Stokes breathing
- central sleep apnoea due to high-altitude periodic breathing
- central sleep apnoea due to a medication or substance
- primary central sleep apnoea
- treatment-emergent central sleep apnoea

Sleep related hypoventilation disorders
- obesity hypoventilation syndrome (OHS)
- sleep-related hypoventilation due to a medical disorder
- sleep-related hypoventilation due to a medical disorder

Sleep-related hypoxaemia disorder

Snoring is generated by the vibration of anatomical structures of the nasopharynx during sleep. Prevalence of habitual snoring ranges from 24% to 50% in men and from 14% to 30% in women and increases with age, obesity, alcohol ingestion and nasal obstruction. Isolated snoring, although asymptomatic, results in social disability and relationship disharmony. General population surveys have found a strong correlation between snoring and daytime sleepiness.[31–33] Snoring with sleepiness as features of obstructive sleep apnoea have been associated with hypertension, ischaemic heart disease, diabetes mellitus and cerebrovascular accident as well as increased morbidity and mortality from road traffic and work related accidents.

Obstructive sleep apnoea (OSA)

OSA is a common condition comprising intermittent complete collapse of the pharyngeal airway, followed by brief arousals or wakenings which then enable return of breathing (**Figure 73.4**). The term obstructive sleep apnoea-hypopnoea (OSAH) is used to include episodes of breathing with reduced amplitude (**Table 73.1**). The condition may be asymptomatic but often presents with witnessed snoring, pauses in breathing or choking during sleep, or with symptoms due to sleep fragmentation including excessive sleepiness, impaired alertness, loss of concentration or memory, comprising the OSAH syndrome (OSAHS).[34–36]

Upper airway resistance syndrome (UARS) is classified as a variant of OSA, characterized by increased airway resistance to breathing during sleep, without cessation of breathing. The primary symptoms are similar to those in OSAS although snoring may not be noted. Sleepiness and excessive fatigue develop due to arousals in sleep with changes in pulse transit time associated with respiratory flow limitation, and increased negative intra-thoracic pressure.[37]

The pathophysiology of OSA includes intermittent hypoxia and possibly sympathetic activation which drive insulin resistance and disordered lipid metabolism.as well as a systemic inflammatory cascade with free-radical production, inflammatory cytokine release and oxidative stress.[38, 39]

Interaction of haemodynamic and inflammatory changes promote vascular endothelial growth factor 3, endothelial dysfunction and vascular remodelling, which may combine to promote the development of atherosclerosis and cardiovascular disease, including heart failure and arrhythmias.[38–41] Organ, tissue or functional impairment is related to the severity of nocturnal hypoxia.[38, 42]

OSA may play a causative role in development of hypertension, insulin resistance and hyperlipidaemia in the cardio-metabolic syndrome, as well as in heart failure, pulmonary hypertension, coronary artery disease, arrhythmias and cerebro-vascular accidents.[36, 42–50]

Patients with heart failure may have less subjective daytime sleepiness despite significantly reduced sleep time such that the absence of subjective sleepiness is not a reliable means of ruling out OSA (**Table 73.2**).[51]

OSA is a risk factor for stroke independently of sex, body mass index (BMI), diabetes, and hypertension, at least in men.[52–54] Hypothyroidism, acromegaly and chronic renal failure may also be associated with OSA.[55–58]

TABLE 73.2 Physiological definitions in obstructive sleep apnoea

Obstructive sleep apnoea/hypopnoea (OSAH)	Obstructive sleep apnoea/hypopnoea syndrome (OSAHS)
Apnoea: • Absence of breathing for at least 10 seconds **Hypopnoea:** • 30% reduction in breathing amplitude with at least 3% oxygen desaturation; or • Respiratory-related arousal (RERA) via EEG or nasal flow limitation pattern **Apnoea-hypopnoea index (AHI)** is the hourly rate of apnoeas plus hypopnoeas: • AHI <5 – normal • AHI 5–15 – mild OSAH • AHI 16–30 – moderate OSAH • AHI >30 – severe OSAH	**Comprises:** >5 obstructed breaths/hour AND excessive daytime sleepiness not better explained by other factors OR 2 or more of the following: • choking or gasping in sleep • recurrent awakenings • unrefreshed sleep • daytime fatigue • impaired concentration

A number of studies have reported impaired glucose metabolism in OSA patients, independent of obesity, although possibly related to visceral obesity, and with prevalence 9 times more in subjects with OSA than controls matched for BMI.[59–71] Insulin resistance may develop due to the effect of intermittent hypoxia and increased sympathetic activity.[59, 62, 70] Cross-sectional studies show a strong association of diabetes mellitus with OSA, but in longitudinal studies, incidence of diabetes was not related to the initial severity of OSA.[70, 72] These cardiovascular and metabolic associations may, in addition to road traffic and work related accidents, contribute to the increased morbidity and mortality associated with OSA, and the reduction in mortality seen in uncontrolled treatment studies using continuous positive airway pressure (CPAP).

Central sleep apnoea (CSA)

CSA comprises recurrent episodes of apnoea during sleep despite a patent airway (**Figure 73.4**). CSA may be associated with periodic breathing in left ventricular cardiac failure with Cheyne-Stokes respiration (CSR) in which there is temporary loss of ventilatory effort or unstable ventilatory control (CSR-CSA). This may have an adverse effect on cardiac prognosis and mortality as it is associated with sympathetic activation, ventricular ectopy and atrial fibrillation. Central sleep apnoea, right ventricular dysfunction, and low diastolic BP are predictors of mortality in systolic heart failure.[47, 73] CSA may develop in subjects at high altitude and those with neurological disorders, autonomic dysfunction or narcotic opiate drug toxicity even at therapeutic dosage.[74–76] CSA may also occur with OSA in patients with nasal obstruction or after treatment with continuous positive airways pressure (CPAP) which reduces $paCO_2$.[79] Management involves treatment of the underlying condition, and continuous positive airway pressure and oxygen may be used.[77–79]

Sleep-related hypoventilation disorders

Obesity hypoventilation syndrome (OHS) is the combination of obesity (BMI 30 kg/m^2), with hypoxia during sleep, and hypercapnia during the day, due to hypoventilation. About one third of all people with morbid obesity (a BMI exceeding 40 kg/m^2) have elevated carbon dioxide levels in the blood.[80, 81] Typical clinical features include obesity, excessive daytime sleepiness, a plethoric complexion, cyanosis, and evidence of right heart failure including peripheral oedema. Surprisingly, patients may not complain of dyspnoea, despite obvious hypoxemia. Almost all subjects with OHS will also have OSAS as an overlap syndrome.[81] Alternative explanations for hypoventilation must be excluded including use of narcotics, severe obstructive or interstitial lung disease, kyphoscoliosis, severe hypothyroidism, neuromuscular disease and congenital central hypoventilation syndrome.[82]

Overlap syndromes

OSA commonly coincides with Chronic Obstructive Pulmonary Disease (COPD), and OHS, and those with COPD may have more severe nocturnal oxygen desaturation, and considerably greater risk of death.[83, 84] Features of cor pulmonale and pulmonary hypertension may be prominent. OSA may also coincide with narcolepsy, and may be a trigger for non-respiratory sleep disorders including sleep-walking and parasomnias.[83–87]

Assessment of sleep breathing disorders

A structured assessment and screening of patients with associated comorbidities will identify people with high probability for sleep breathing disorders. Reporting of apnoea by the bed partner has been more predictive of sleep apnoea than snoring alone.[88] Validated screening questionnaires for OSAS include the The Epworth Sleepiness scale score (**Table 73.1**) and the STOP-BANG questionnaire (**Box 73.3**) which has proved useful in preoperative anaesthetic risk assessment.[21, 89, 90]

Examination may reveal obesity (in 70% of patients with obstructive sleep apnoea), with BMI >30, often with increased neck circumference (often > 40 cm) and waist circumference (men > 94 cm; women > 80 cm).[91, 92] Some patients may have nasal airway obstruction (deviated nasal septum, rhinitis or polyps), or enlarged soft palate,

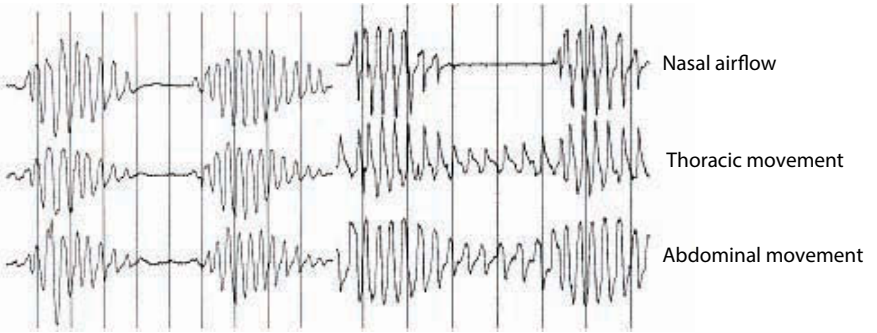

Figure 73.4 (a) Central apnoea with absence of airflow, thoracic and abdominal movement. **(b)** Obstructive apnoea with absence of airflow, but presence of thoracic and abdominal respiratory movement.

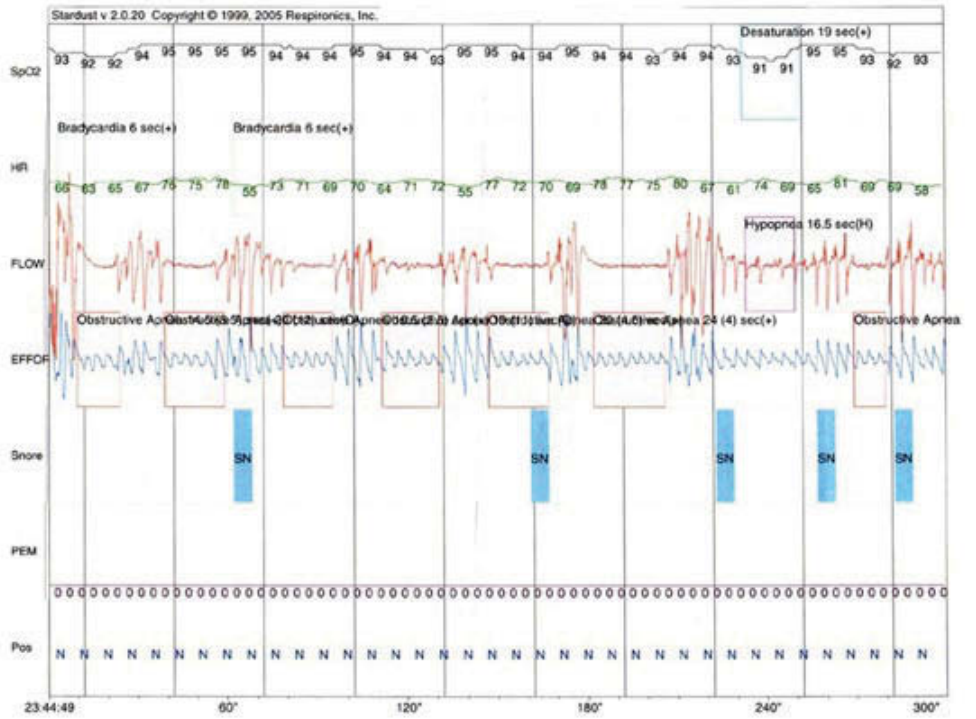

Figure 73.5. Cardio-respiratory polygraphy report. Episodic cessation of nasal airflow (FLOW) is associated with continued thoracic respiration (EFFORT) and is followed by transient fall in oxygen saturation (SpO_2). Heart rate (HR) slows following apnoeas and increases after return of respiration.

tonsils or uvula. Signs of cor pulmonale may occasionally be present including ankle swelling.

Physiological investigation of sleep-related breathing disorders

Cardio-respiratory polygraphy (multi-channel portable or ambulatory monitoring) allows diagnosis of sleep apnoea, classification, and assessment of severity in most patients with typical OSA in a home or inpatient setting.[93, 94] OSA is detected as absence of nasal airflow with persistence of chest and abdominal respiratory effort. using nasal airflow, chest and abdominal sensors, to measure respiration, producing an apnoea-hypopnoea index (AHI) (**Figure 73.5**). Oximetry in OSA typically shows a normal baseline oxygen saturation with intermittent dips and 4% oxygen desaturation index (ODI) of more than 10 per hour, together with heart rate variability (**Figure 73.6**). Overnight oximetry alone is relatively specific, but insensitive for OSA such that absence or relative paucity of oximetry dips does not exclude sleep apnoea.[95] Periods of low baseline oxygen saturation suggest other causes of respiratory failure including sleep hypoventilation syndromes and COPD which may be concurrent with OSA as overlap syndromes (**Figure 73.7**). Oxygen desaturation may occur due to other respiratory and cardiac disorders and expert interpretation is essential. In UARS apnoeas and hypopnoeas are absent or low in number, but a diagnosis may be made using a nasal cannula and pressure transducer to measure inspiratory airflow limitation, and detect a pattern known to be associated with respiratory related arousals (RERA) on EEG.[22]

Full PSG may be required in complex sleep disorders including cases of possible OSA which may overlap with comorbidities including cardiac failure, COPD, upper airway resistance, obesity hypoventilation syndrome or non-respiratory sleep disorders including periodic limb movement and narcolepsy.[96] Full PSG adds an electroencephalogram (EEG) for sleep staging and video recording and may help to differentiate OSA from nocturnal epilepsy, or demonstrate OSA as a trigger for sleepwalking or other sleep behavioural disorders (parasomnias). In UARS, multiple RERAs may be seen on EEG in association with nasal flow limitations, and if an oesophageal probe is used, progressive elevation of esophageal pressure fluctuations (Pes) terminating in arousals.[37]

Management of sleep breathing disorders

General measures for treatment of sleep breathing disorders include behavioural modification and lifestyle advice comprising weight control, elevation of the bed head, and avoidance of supine posture, alcohol, tobacco, sedatives and narcotics.[96, 97] Significant weight loss has been associated with a 'cure' rate of 10–20% in OSAHS.[98–101] Treatment of nasal congestion using nasal steroids may be helpful, especially if there is nasal obstruction or upper airway resistance due to rhinitis. Driving should be avoided if excessively sleepy and subjects with OSAS must inform the relevant driving licencing authority of the diagnosis. Driving may be allowed if symptoms are controlled on treatment, with confirmation by medical opinion.

A range of interventions may be employed in the treatment of sleep breathing disorders, including weight management, nasal continuous positive airway pressure (CPAP), oral appliance therapy and surgical intervention in OSAHS, as well as non-invasive bi-level ventilation in sleep hypoventilation syndromes, and these are dealt with in detail in other chapters.[96–112]

BOX 73.3 Stop-BANG questionnaire as a screening tool for OSA

S 'Do you snore loudly (louder than talking or heard through closed doors)?'
T 'Do you often feel tired, fatigued, or sleepy during daytime?'
O 'Has anyone observed you stop breathing during your sleep?'
P 'Do you have or are you being treated for high blood pressure?'
B Does the patient have a BMI of more than 35?
A Is the patient older than 50?
N Is the patient's neck circumference greater than 40 cm?
G Is the patient male?

Scoring: ≥3 high risk of OSA
<3 low risk of OSA

CENTRAL DISORDERS OF HYPERSOMNOLENCE

Narcolepsy and cataplexy

Narcolepsy is a condition in which subjects develop severe, often unavoidable chronic sleepiness, with fragmented sleep and frequent awakenings at night, often beginning in early adolescence or adult life. Its prevalence is 1 in 2500, but most are undiagnosed. Consequent problems include avoidance of social or emotional situations, exam failures, few work opportunities, marital difficulties, low self-esteem and depression.

Narcolepsy may be associated with other sleep disorders including restless legs syndrome (RLS) and periodic limb movement syndrome (PLMS), parasomnias, snoring, OSA and disorders of appetite and mood.[22] Sleepiness is usually severe, with ESS score often above 15. Subjects often develop hypnagogic (sleep onset) or hypnopompic (sleep offset) hallucinations and sleep onset/offset paralysis due to REM intrusion into wakefulness while falling asleep or

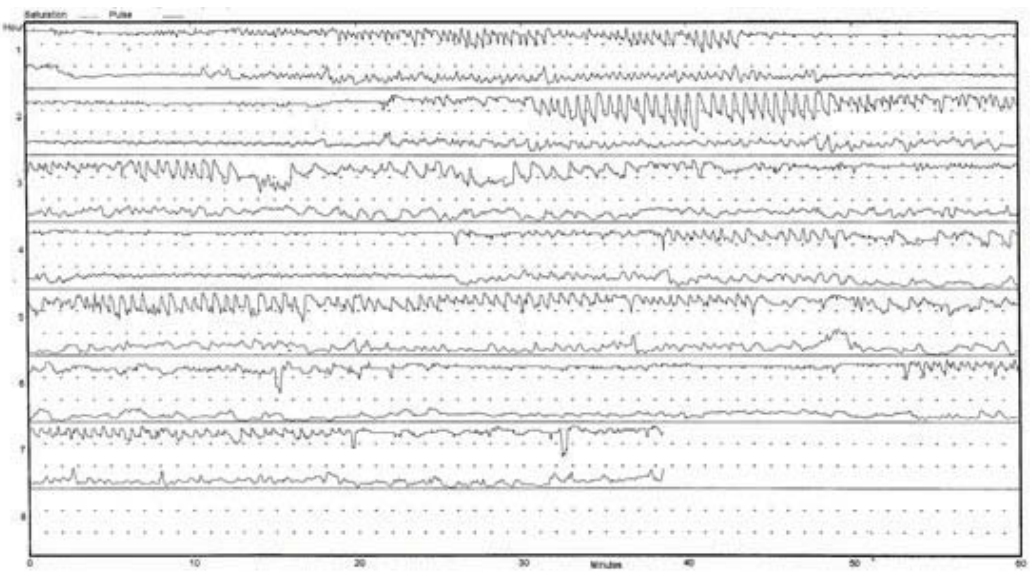

Figure 73.6 Overnight oximetry in OSA. Each horizontal band shows 1 hour of recording of oxygen saturation (above) and heart rate (below). There are frequent falls in oxygen saturation (>4%) with return to normal baseline, and associated heart rate variability.

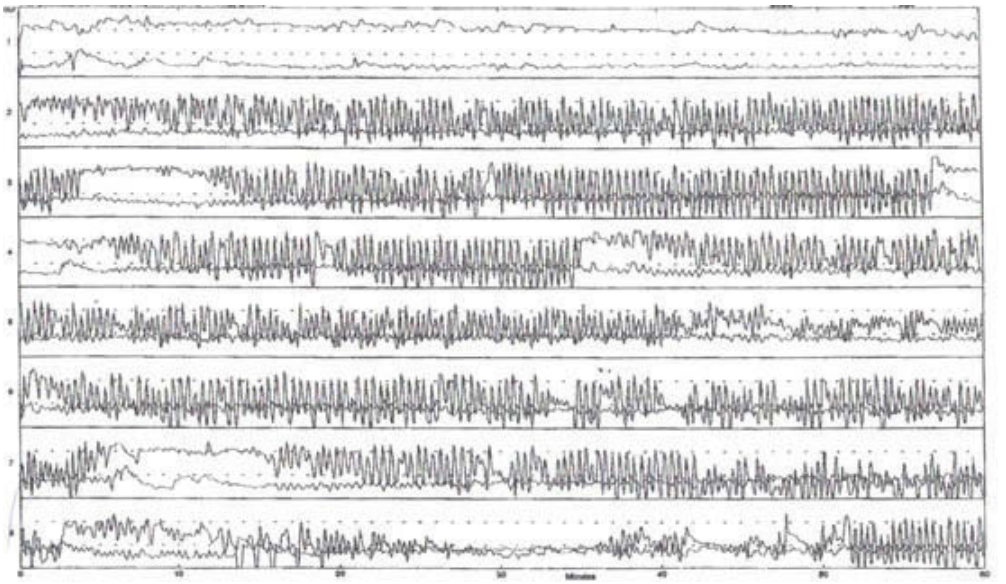

Figure 73.7 Overnight oximetry in obstructive sleep apnoea with obesity hypoventilation (overlap syndrome). Each horizontal band shows 1 hour of recording of oxygen saturation (above) and heart rate (below). There are frequent falls in oxygen saturation (>4%) but periods of low baseline oxygen saturation.

on waking. These are, however, non-specific features of sleep deprivation and they may occur in other conditions of significant sleep loss including shift work or sleep apnoea.

Cataplexy develops in 60% of subjects. During wakefulness, REM intrusions cause sudden episodes of bilateral muscle weakness leading to partial or complete collapse and often triggered by strong emotions such as laughter, anger or excitement. Episodes last 1–2 minutes and are not associated with impairment of consciousness at onset.[22, 113]

Narcolepsy is usually sporadic, and possibly auto-immune or related to brain injury, but genetic factors play an important role with a 40-fold risk in first-degree relatives. Most narcoleptics (50–90%) have HLA DR2 or DQB1*0602 antibody subtypes. The pathophysiology of classical narcolepsy involves a deficiency of the hypothalamic excitatory neuropeptide hypocretin (orexin). This is required to stabilize the hypothalamic sleep/wake switch between sleep promotion (ventro-lateral pre-optic nucleus) and wake promotion (tubero-mamillary nucleus). CSF examination reveals absence of hypocretin (orexin) in 90% of subjects.[114]

PSG may show a short REM latency 5–10 mins (in 50%). Frequent intrusions of REM cause fragmentation of deeper sleep, although total sleep time and time in REM are normal. A daytime MSLT may show sleep-onset REM (SOREM) episodes.[115]

A diagnosis of classical narcolepsy (Type 1) requires either cerebrospinal fluid hypocretin-1 deficiency (<110 pg/mL or less than one-third of the normative values with the same standardized assay) or a mean latency of <8 min with evidence of two SOREMPs on MSLT, (or one SOREMP on PSG and one or more on MSLT) and clear cataplexy. Narcolepsy Type 2 maintains the same MSLT requirements but cataplexy must be absent and cerebrospinal fluid hypocretin-1 levels, if measured, must not meet the narcolepsy Type 1 criterion.[22]

The differential diagnosis of narcolepsy includes OSA, depression, REM deprivation and drug toxicity, while the differential diagnosis of cataplexy includes epilepsy (especially gelastic and atonic), vertebro-basilar insufficiency, cardiac dysrhythmias, drop attacks, myasthenia gravis, periodic paralysis, faints, gelastic syncope and hysteria.

Management of narcolepsy includes planned napping, sleep hygiene and psychosocial support. Sleepiness may respond to stimulants including modafinil, dexamphetamine or methylphenidate. Cataplexy may respond to REM sleep-suppressing medications including tricyclic and SSRI antidepressants. Sodium oxybate or pitolisant may control cataplexy as well as sleep fragmentation and excessive daytime sleepiness.

Hypersomnia may also be idiopathic or due to medical or psychiatric disorders including Kleine-Levin Syndrome. Behaviourally induced insufficient sleep can be excluded by actigraphy or sleep logs to record wake and sleep using body movements over periods of days.

CIRCADIAN RHYTHM SLEEP-WAKE DISORDERS

Circadian rhythm problems include jetlag, shift work sleep disorder and advanced or delayed sleep phase syndromes. Delayed sleep phase is not uncommon in younger subjects who may be genetically predisposed to be 'night-owls', with difficulty in rising and excessive morning sleepiness. Symptoms may be incorrectly attributed to insomnia or depression, although these may be true comorbidities. Assessments are made using sleep diaries and actigraphy to record wake and sleep using body movements over periods of days. Treatment involves advancing sleep onset by use of evening melatonin and morning bright light therapy.[116]

PARASOMNIAS

The term parasomnia encompasses sleep-related behaviours, emotions, perceptions, dreaming and autonomic

nervous system events during entry into sleep, within sleep or during arousals from sleep.[22] Parasomnias may be occur in non-REM and REM sleep.

Non-REM parasomnias

Non-REM parasomnias include sleepwalking, sleep talking, confusional arousals, sleep terrors, sleep-related nocturnal eating disorder and catathrenia (groaning). Instinctual behaviours, including violence and sexual activity, may be released inappropriately.[117] Arousals in sleep leave the individual in a state of incomplete awakening, with inappropriate responsiveness. Higher cognitive functions and social inhibitions may be absent or impaired and primitive behaviours may appear unexpectedly with partial or complete amnesia.[22, 117]

Predisposition to non-REM parasomnias may be based on genetic susceptibility with a familial pattern. A priming factor may trigger an episode, for example sleep deprivation, situational stress, medications, fever, alcohol, sleep-disordered breathing (e.g. OSA), PLMS, noise and touch.[118]

Assessment requires a full medical and sleep history, neuropsychiatric and psychometric examination and EEG. PSG may reveal precipitating and modulating factors including OSA or PLMS.

Treatment comprises reassurance and explanation of the mechanisms and potentiating factors, and treatment of confirmed priming or trigger factors. Counselling and psychological intervention with cognitive behavioural therapy may have a role. Drug therapy is usually avoided in the absence of behaviour that causes violence to the subject or others. In that event, clonazepam or other sedatives are usually advised until the parasomnia resolves in the hope that a normal sleep pattern will return without prolonged drug therapy. Subjects with non-REM parasomnia (e.g. sleepwalking) may expect occasional relapse if under particular emotional stress, physically ill with fever or other physical stress, or under the influence of alcohol, drugs or other toxins.

REM-related parasomnias

REM-related parasomnias include REM sleep behaviour disorder (RBD), nightmares and recurrent isolated sleep paralysis. RBD involves vocalization or dream enactment during REM sleep, without the normal loss of muscle tone. The dream-enacting behaviours are usually non-directed and may include punching, kicking, leaping or jumping from bed while asleep. Subjects may recall the dream that corresponds to the physical activity, sometimes vividly or as nightmares. Abnormal sleep movements may lead to injuries include bruising, lacerations, fractures and subdural haematomas.[119] Subjects are often middle-aged or older at the time of presentation and RBD may be a precursor of degenerative brain disease or Parkinson's disease.

Acute RBD may follow withdrawal of alcohol or drugs including pentazocine, nitrazepam, tricyclic antidepressants or caffeine. Chronic RBD may follow toxicity from tricyclic or SSRI antidepressants, seligiline or anticolinergics. Chronic RBD may also be associated with neurodegenerative conditions, synucleinopathies (Parkinson's disease, multiple system atrophy and dementia with Lewy bodies) and other neurological disorders including multiple sclerosis, Guillaine-Barre syndrome, Shy-Drager syndrome, Arnold-Chiari malformation, Alzheimer's dementia, ischaemic strokes and narcolepsy.[120]

RBD may reflect dysfunction in the brainstem circuitry and the dorsolateral pontine tegmentum mechanisms responsible for the normal suppression of muscle tone and paralysis in REM sleep. PSG may show persistence of EMG tone in REM sleep, absence of seizure activity, and gross complex body movements that correspond to dream mentation.[121]

Management of REM-related parasomnias comprises removal of potential drug or other triggers. Drug therapies including clonazepam or other benzodiazepines, and melatonin may be helpful, avoiding the potential risks of opiate sedation.[122, 123]

Epilepsy may co-exist with, or mimic, sleep disorders. Sleep deprivation can increase the risk of seizure activity and seizures can affect the sleep-wake cycle. Nocturnal frontal lobe epilepsy may occur only during sleep, and can present with bizarre movements such that differentiation from parasomnia may be difficult, and expert assessment is required.[124]

SLEEP-RELATED MOVEMENT DISORDERS

Sleep-related movement disorders include restless legs syndrome (RLS), periodic limb movement disorder (PLMD) and sleep related bruxism (teeth grinding).

RLS is a clinical diagnosis, characterized by symptoms including unpleasant, creeping or crawling sensations deep within the lower legs, but sometimes in the upper limbs. It occurs only after rest, and is diurnal, becoming most severe in the late evening. There is an almost irresistible urge to move the legs, with relief on movement such as walking.[125]

The prevalence of RLS is 5–10% and it is slightly more common in women. It occurs at any age, but commonest onset is in those aged in the 5th and 6th decades. 60–80% of cases are familial with autosomal dominance and variable penetrance.

More than 80% of RLS patients have PLM in sleep (PLMS), although not all PLMS patients have RLS. PLMS comprises involuntary rhythmic muscular jerks, with extension of the great toe and dorsiflexion of ankles or other joints. PSG demonstrates a series of 4 of more consecutive movements lasting 0.5–20 seconds with an interval of 4–90 seconds. PLMS at a rate of more than 5 per hour, associated with arousals, can present as insomnia, excessive sleepiness or movements that wake the patient or bed-partner.[126, 127]

PLMD may be diagnosed when, in the absence of RLS, the frequency of PLMs is >15 per hour accompanied by clinical sleep disturbance or other functional impairment.

Predisposing factors for RLS/PLMS include some genetic variants, positive family history and female sex. Precipitating factors include iron deficiency, often related to pregnancy, menorrhagia, chronic renal failure or rheumatoid arthritis. RLS/PLMS may be precipitated or worsened by prolonged immobility, caffeine, nicotine,

and alcohol, and also by anti-depressants and dopamine antagonists including anti-psychotic and anti-emetics.

PSG can reveal periodic limb movement and associated arousals. Physiological changes include microarousals with fragmentation of normal sleep architecture, reduced time asleep, and frequent wakening.

The pathology in PLMS may involve defective dopaminergic neurotransmission and abnormal iron uptake and storage in the substantia nigra where it is a dopamine substrate.[128]

Management is by avoidance of caffeine, tobacco, and alcohol stimulants, as well as regular daily exercise, good sleep hygiene and avoidance of medicines that trigger symptoms. Prolonged iron therapy is indicated if serum ferritin is low or low normal (< 50 ng/ml) even if haemoglobin is normal. Treatment options include gabapentin, pregabalin, or dopaminergic agonists (rotigotine, ropinirole, pramipexole, L-dopa). Benzodiazepines, opiates and anticonvulsants can also be effective.

SUMMARY

Sleep disorders are common causes of morbidity and mortality, affecting the population beyond those with the condition. The presentation of sleep disorders is myriad due to complex pathophysiological mechanisms, such that important treatable conditions are often unrecognized. Greater awareness and screening of those at risk, including those with associated comorbidities, and those undergoing anaesthetic assessment and surgery, will lead to improved diagnosis and management outcomes.

KEY POINTS

- Excessive daytime sleepiness that is severe or unavoidable is suggestive of narcolepsy (sleep attacks), especially if associated with cataplexy.
- Excessive sleepiness may be due to multiple sleep disorders (e.g. narcolepsy and sleep apnoea, both often associated with excessive weight).
- Sleep Maintenance Insomnia associated with excessive daytime sleepiness suggests an underlying primary sleep disorder as a cause of arousals (e.g. sleep apnoea or periodic limb movement).
- Sleep initiation insomnia without excessive daytime sleepiness suggests adequate sleep but a possible psychological cause or misperception of actual sleep.
- RLS is a clinical diagnosis based on symptoms, whereas diagnosis of periodic limb movement requires PSG.
- Sleepwalking (non-REM parasomnia) is common, and often associated with a family or previous childhood history and complex stereotypical movement (e.g. talking).
- Parasomnias need careful differentiation from seizure disorders and degenerative brain disease, especially if movements are bizarre.
- Consider obstructive sleep apnoea in subjects with snoring, witnessed apnoeas, nocturnal choking or snorting, and excessive daytime sleepiness.
- Sleep maintenance insomnia with wakings and arousals associated with excessive daytime sleepiness suggests a possible underlying sleep disorder, e.g. sleep apnoea or periodic limb movement.
- Consider nocturnal hypoventilation in subjects with morning headache, otherwise unexplained ankle swelling (reflecting cor pulmonale and pulmonary hypertension).
- Screen for obstructive sleep apnoea prior to anaesthesia and surgery in subjects at high risk including those with retrognathia, craniofacial abnormalities, obesity, hypertension, diabetes mellitus Type 2, cardiovascular disease and cerebrovascular disease (e.g. stroke).

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: obstructive sleep apn(o)ea, excessive daytime sleepiness, continuous positive airway pressure, polysomnography and road traffic accidents.

INTRODUCTION

Obstructive sleep apnoea (OSA) can be regarded as a condition characterized by repetitive upper airway obstruction leading to sleep fragmentation, cardiovascular stimulation and oxygen desaturation during sleep. These together lead to symptoms such as snoring, unrefreshing sleep, excessive daytime sleepiness (EDS) and the increased risk of cardiovascular disease, hypertension, insulin resistance and road traffic accidents. Any individual with time may oscillate within a spectrum of sleep disordered breathing, from intermittent simple snoring, to chronic heavy snoring, to upper airway resistance syndrome (UARS), to mild OSA, to moderate OSA, to severe OSA or to obesity hypoventilation syndrome (OHS). OSA is characterized by complete breath-holds (apnoeas) and partial breath-holds (hypopnoeas) – scientific physiological descriptions are presented in Chapter 73, Physiology of sleep and sleep disorders. With the present obesity epidemic, ear, nose and throat (ENT), hypertension, obesity, diabetes and sleep specialists are witnessing a large increase in the prevalence of OSA in their practice. This chapter describes the medical management of OSA, especially associated comorbidities, diagnosis and continuous positive airway pressure (CPAP), all relevant to the work environment of ENT specialists. Mandibular devices are not discussed in this chapter and are described in Chapter 75, The surgical management of snoring.

EPIDEMIOLOGY, RISK FACTORS AND ASSOCIATED MEDICAL CONDITIONS

Earlier studies of the prevalence of OSA in society (Wisconsin Sleep Cohort Study) estimated that 4% of men and 2% of women had OSA with sleepiness,[1] also known as obstructive sleep apnoea hypopnoea syndrome (OSAHS). However, since then, the prevalence of obesity has been increasing in all age groups. In the UK, it is estimated that 26% of adults are obese (body mass index (BMI) $\geq 30\,kg/m^2$).[2] Further analysis of the epidemiology of OSA has suggested the prevalence of OSAHS is around 5% in a given population,[3] and it is likely this will increase with time. The exact incidence of OSA without EDS is unclear, as this population is less likely to seek medical input in the primary care setting. The prevalence differences between men and women are intriguing and the exact reason why OSA is more common and more severe in men is not fully understood. Men generally have a higher prevalence of OSA than women but the effects of menopause, pregnancy and the presence of polycystic ovarian syndrome have been shown to increase the risk of OSA in women.[4] Various mechanisms may exist, including body fat distribution, cranio-facial differences, and the role of female hormones, over and beyond simply BMI.[5] There is increasing evidence that ethnic differences do exist and people of oriental Chinese origin have a greater risk of

developing OSA at a lower level of obesity compared to European Caucasians. Cranio-facial differences may explain this phenomenon.[6] There is little information, however, on the prevalence of sleep disordered breathing in the South Asian population in the UK compared to the indigenous population in South Asia.

Obesity is recognized as an important risk factor for OSA. The prevalence of OSA rises with obesity[7] and it is estimated that up to 75% of those with a BMI above 40 kg/m^2 have OSA.[8] The exact relationship between obesity and OSA is not well understood, however, and is probably multifactorial. Factors including BMI, neck soft tissue mass, parapharyngeal and lingual adipose deposition, and body fat distribution all play a role. Any weight gain is not necessarily wholly adipose and an increase in soft tissue mass around the airway may be more crucial. Other factors such as pharyngeal muscle tone and the biophysical compliance relationship between airway patency and critical closing pressure remain unresolved.

OSA is associated with cardiovascular disease[9–11] and clinicians treating and dealing with patients with OSA are increasingly involved in modifying cardiovascular risk in their practice. OSA is associated with an increased risk of hypertension, as shown in population studies. There is growing evidence that treating OSA will decrease blood pressure, and even modest falls in blood pressure may translate into significant modification of cardiovascular risk. Associated comorbidities such as obesity, diabetes and smoking history may cloud any direct causal relationship between OSA and cardiovascular disease and further larger longitudinal studies assessing the impact of CPAP therapy on cardiovascular outcomes, particularly coronary artery disease, are warranted.[12]

The term metabolic syndrome has been increasingly used and described in relation to OSA.[13] Metabolic syndrome encompasses a cluster of features related to obesity, diabetes and hypertension. These include waist circumference, triglyceride and glucose levels, and hypertension. There is an increased incidence of metabolic syndrome in patients with OSA.[14] With increasing evidence that OSA is associated with insulin resistance and diabetes mellitus,[15–17] it is becoming more apparent that OSA may play an important role in metabolic syndrome and diabetes mellitus.

SYMPTOMS, CLINICAL EXAMINATION AND ASSESSMENT OF EXCESSIVE DAYTIME SLEEPINESS

Symptoms associated with OSA are shown in **Box 74.1**. Clinical assessment of OSA entails a detailed history, ideally with the partner present during the consultation. The partner may be able to describe the breath-holding, associated gasping, and movement arousals (associated with the apnoeas and hypopnoeas) and may possibly display a raised level of anxiety. Many couples may express marital strife and hence it is prudent for the clinician consider their issues with compassion. Even if the patient with possible OSA is banished to the next bedroom, the witnessed apnoeas are still reportable by the pauses in the audible snoring. Some patients may have had OSA for many years and therefore become accustomed to their EDS and hence may underestimate their symptoms. An appreciation of their sleep patterns is important, as one of the commonest causes of EDS is sleep deprivation rather than sleep fragmentation (i.e. OSA).

BOX 74.1 Symptoms of obstructive sleep apnoea (OSA)

- Snoring
- Fatigue
- Witnessed breath-holds
- Gasping and choking
- Excessive daytime sleepiness
- Fragmented sleep
- Unrefreshing sleep
- Reduced alertness
- Mood changes
- Nocturia

Some will relay how EDS may affect their working lives, especially those who work with heavy machinery or drive professionally. Taking a history of road traffic accidents (RTAs), therefore, is vital. Individuals with OSA are at a higher risk of RTAs, with associated costs.[18, 19] Although individuals may not have had an RTA as a result of falling asleep at the wheel, subtle clues such as drifting across lanes, clipping the kerb, or a history of being beeped at by other drivers whilst driving are useful indicators of driving whilst sleepy.

The presence of central obesity is a particularly relevant physical finding during an OSA consult. A BMI greater than 28 kg/m^2 should increase the suspicion for OSA. Neck circumference is a useful measure; above 43 cm may be predictive. Other examination features of importance include a detailed nasal and oropharyngeal assessment, including the Mallampati score,[20] and the presence or absence of retrognathia, cranio-facial abnormalities and tonsillar hypertrophy. Information about possible associated medical conditions such as hypertension, diabetes and dyslipidaemia should always be sought during the consultation.

Unfortunately, the assessment of history and clinical findings has been shown to lack sensitivity and specificity in diagnosing OSA. It is estimated that history and examination can only predict OSAHS in 50% of patients.[21] The measurement of EDS may be subjective and objective. The commonest subjective questionnaire used is the Epworth Sleepiness Scale (ESS; see **Table 74.1**), named after the Epworth hospital, Melbourne, Australia.[22] A score above 10 (out of 24) may indicate EDS; but the ESS lacks sensitivity and specificity. Therefore, in any individual, the ESS may not on its own be very useful, but act only as a guide. It is generally not recommended that clinical decision-making is based purely on the ESS. More recently, the STOP-Bang questionnaire (**Box 74.2**) has been developed as a pre-operative screening tool to identify patients with undiagnosed OSA,[23] and has been shown to identify moderate to severe cases of OSA in the surgical population.[24]

TABLE 74.1 Epworth Sleepiness Scale (ESS)
Assesses the likelihood of an individual dozing off at the following situations (score 0 = never, 1 = slight chance, 2 = moderate chance and 3 = high chance of dozing)

Situation	Chance of dozing
Sitting and reading	
Watching TV	
Sitting inactive in a public place (e.g a theatre or a meeting)	
As a passenger in a car for an hour without a break	
Lying down to rest in the afternoon when circumstances permit	
Sitting and talking to someone	
Sitting quietly after a lunch without alcohol	
In a car, while stopped for a few minutes in traffic	
TOTAL	

BOX 74.2 STOP-Bang questionnaire – answer Yes or No

- Snoring – Do you snore loudly (louder than talking or heard through closed doors)?
- Tired – Do you often feel tired, fatigued, or sleepy during daytime?
- Observed – Has anyone observed you stop breathing during your sleep?
- Blood pressure – Do you have or are you being treated for high blood pressure?
- BMI – BMI of more than 35 kg/m^2?
- Age – Age over 50?
- Neck circumference – neck circumference greater than 40 cm?
- Gender – Gender male?

High risk of OSA (AHI > 5/hr): answering yes to three or more items

Low risk of OSA (AHI < 5/hr): answering yes to less than three items

Objective measurements of EDS include the Multiple Sleep Latency Test (MSLT), which measures how quickly an individual can fall asleep, and the Maintenance of Wakefulness Test (MWT), which measures how long an individual can stay awake. However, such diagnostic tests can only be measured if full polysomnography facilities, including EEG, are available, as without EEG, accurate assessment of wake and sleep cannot be made.

THE DIAGNOSIS OF OBSTRUCTIVE SLEEP APNOEA

Methods designed to diagnose OSA may include domiciliary single channel (overnight oximetry), domiciliary multichannel (respiratory and oximetry signals) and in-hospital full polysomnography (PSG), which includes measurement of respiratory, oximetry and sleep architecture assessment using electroencephalography (EEG), electrooculography (EOG) and electromyography (EMG) parameters. The merits of each tool are discussed below.

Overnight oximetry

This method measures variations in oxygen saturation and pulse rate during sleep. It assumes that when an individual has an apnoea or hypopnoea, the oxygen saturation falls. Once the apnoea or hypopnoea is relieved, the oxygen desaturation recovers. The falls and rises are regarded as 'oxygen dips'. The pulse oximeter is applied over the end of a digit, which is attached to a wristwatch computer that the patient wears during the night. This is where the data are collected. For convenience, the device can be worn at home. More sophisticated software products provide pulse rate variability (e.g. the number of pulse rises of over six beats per minute averaged out per hour), which would reflect autonomic cardiovascular changes during arousals as a result of apnoeas and hypopnoeas. However, pulse rate variability can only be analyzed in the presence of sinus rhythm rather than in patients with atrial fibrillation.

In the UK, some sleep clinicians use oximetry alone as a screen for OSA. It is standard practice that a 'dip' of 4% oxygen saturation (e.g. from 94% to 90%) is regarded as more meaningful than a 2% or a 3% dip. An oxygen desaturation index (ODI) (i.e. the number of times the oxygen saturation falls by 4% averaged out per hour) of more than 15 per hour may be suggestive of OSA. The presence of other associated features that are measured that may lean towards a diagnosis of OSA in the presence of a 'positive' oximeter result include EDS (ESS > 10), obesity (BMI > 28 kg/m^2), and the presence of other comorbidities (e.g. hypertension, coronary artery disease, metabolic syndrome and diabetes mellitus). However, an ODI > 15 per hour can only be used if the resting saturation of oxygen is above 90% and there is an absence of obstructive airway disease. **Figures 74.1** and **74.2** show a classic case of repetitive oxygen desaturation during sleep, typical of OSA.

Although studies using overnight oximetry as a screening tool for OSA have shown good specificity and positive predictive value, this test is associated with poor sensitivity and negative predictive value.[25] In other words, overnight oximetry may miss patients with OSA who do not desaturate, but in the presence of a positive result, the oximetry can be a useful screen. However, an abnormal ODI may underestimate the true severity of OSA, as demonstrated in **Figures 74.3** and **74.4**. Generally it is accepted that young, less obese patients may not have oxygen desaturations in the presence of apnoeas and hypopnoeas and therefore will be missed by oximetry. Mechanisms why some patients desaturate and some do not is unclear but it may be related to lung volumes, functional residual capacity or central respiratory response to apnoeas (i.e. if an arousal response to airway obstruction is blunted then the individual is more likely to hypoventilate and desaturate). It is recommended that, if the ODI is less than 15 oxygen desaturations ('dips') per hour, but there is the presence of EDS, obesity or existing comorbidity, then a further

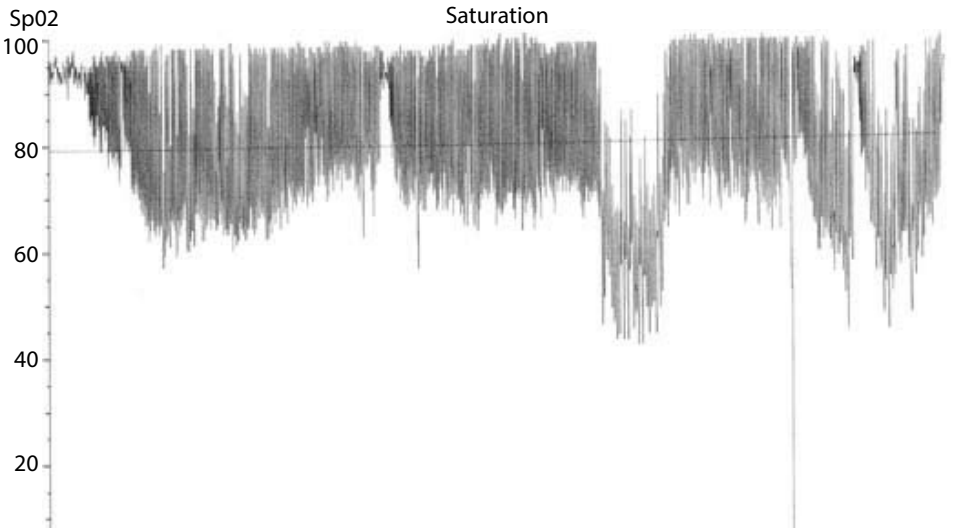

Figure 74.1 A patient with an oxygen desaturation index (ODI) of 55 4% oxygen dips per hour. The oximetry trace shows the whole night data. Minimum oxygen saturation is approximately 45%.

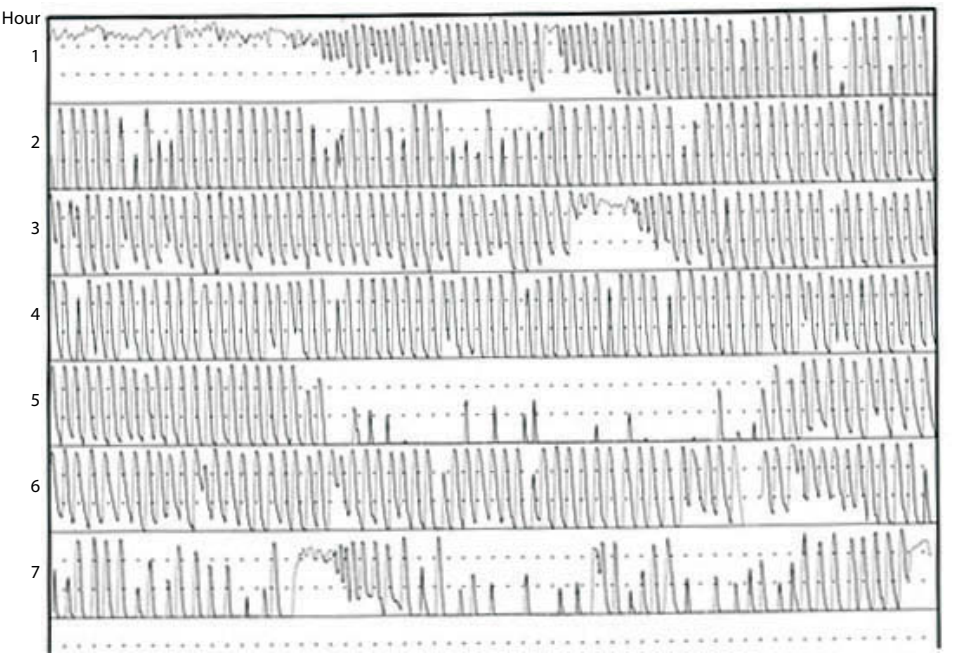

Figure 74.2 The same patient as in Figure 74.1, with a close up of the oximetry trace demonstrating oxygen dips. X axis is one hour. Y axis is 70–100% saturations. Note the marked repetitive desaturations of oxygen, typical of OSA. Occasional dips are below 70%.

referral for multichannel assessment of respiration is recommended. It is not advocated that a trial of CPAP be carried out in those where the diagnosis and severity of OSA s in question following a negative oximeter study.

Home multichannel testing

The advantages of home overnight respiratory monitoring over in-hospital studies are multiple. They include better patient comfort, cost savings and prevention of hospital admission, and allow quicker data analysis. Disadvantages include sensor failure at home and loss of signal (which may lead to repeat studies). Fewer channels will inevitably result in less available information. In particular, home monitoring without EEG will not determine when the patient is asleep during the night. Sleep disordered breathing occurs during sleep, and it may be possible that without an assessment of exact sleep time, home monitoring may underestimate the severity of OSA. Some home portable kits also include EEG probes to determine sleep architecture. However, in the UK, multichannel kits that measure nasal/oral flow via a pressure cannula, chest and abdominal movements via a pressure transducer housed in a velcro belt and pulse oximetry, but not EEG activity, are the most popular. A number of such products are available on the market. A classic example of repetitive apnoeas is shown in **Figure 74.5**. The chest and abdominal belt allows the assessor to determine if the apnoeas and hypopnoeas are related to respiratory effort (during the apnoea or hypopnoea, the chest and abdominal signals still display movement) and therefore obstructive in nature, as opposed to central sleep apnoea (CSA) where there is no chest or abdominal movement or effort during apnoeas. In contrast to OSA, the apnoeas seen in CSA originate from the respiratory drive centre of the brain and may occur in patients with cerebrovascular disease or

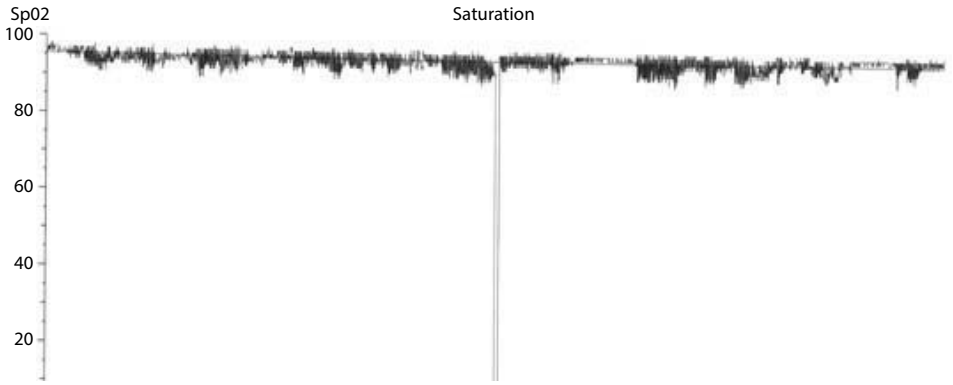

Figure 74.3 This patient has an ODI of 22 4% oxygen dips per hour, a body mass index (BMI) of 36 kg / m² and an ESS score of 6. The desaturation is not as marked as the example in Figure 74.1. The mid page reading signal to zero is an artefact.

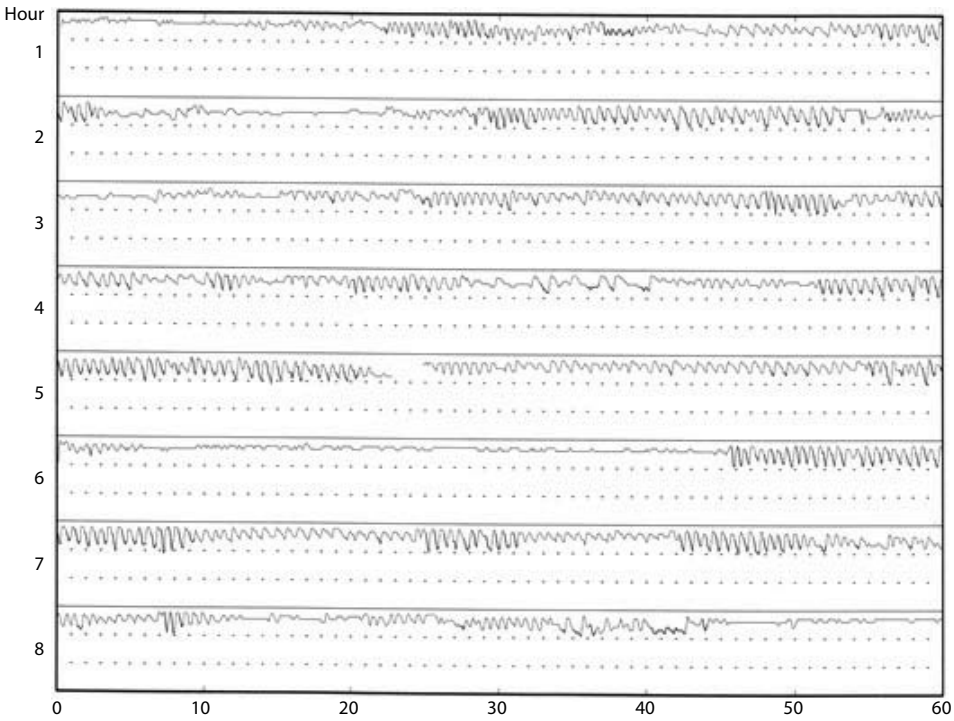

Figure 74.4 The same patient as in Figure 74.3, showing close up of oxygen dips from Figure 74.3. X axis is one hour and Y axis is 70–100% oxygen saturations. Repetitive but intermittent oxygen desaturations were seen, particularly 2% and 3% dips. The patient underwent a diagnostic polysomnography showing severe OSA, apnoea/hypopnoea index of 73 per hour. In this case the overnight oximetry on its own underestimated the true severity of OSA.

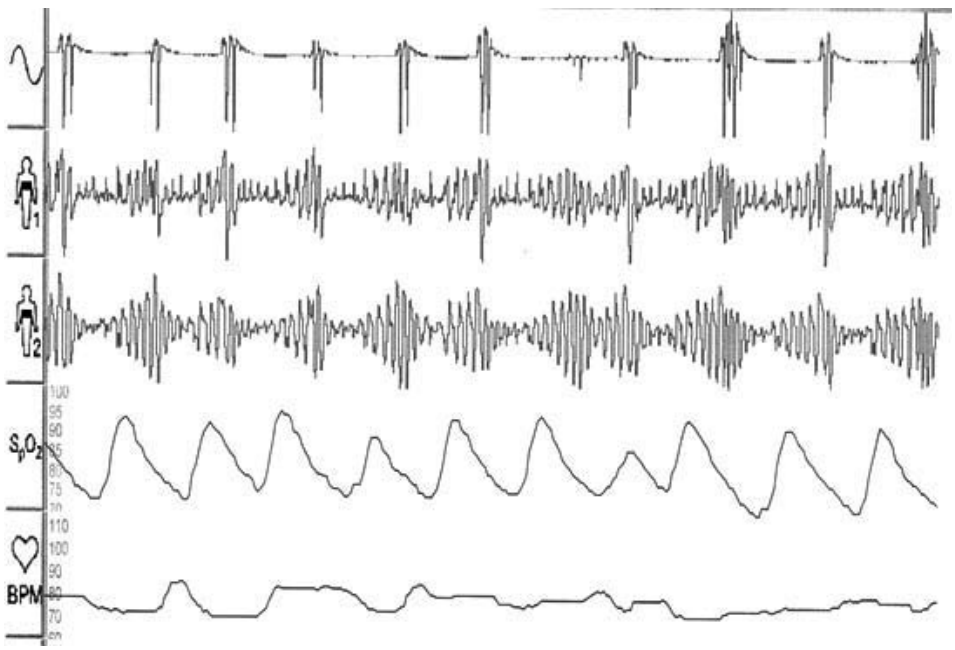

Figure 74.5 A classic example of OSA with repetitive apnoeas. X axis is 5 minutes. Top trace is oronasal cannulae flow trace, second trace is thoracic band, third trace is abdominal band, fourth trace is oxygenation and fifth trace is pulse rate. Note marked desaturations of oxygen with each apnoea, which recovers once apnoea is abolished and the pulse variability. Due to lag time effect, the nadir of oxygen saturation always follows the apnoea.

those who take regular opioids in high doses. One form of CSA known as Cheyne-Stokes respiration ('crescendo-decrescendo' chest and abdominal movements) is more common in patients with heart failure. Therefore oximetry alone would not pick up the origin of apnoeas (i.e. obstructive vs central), in such patients.

Patients are taught how to attach the necessary equipment, either at home or in the hospital physiology department. The patient then either goes home wearing the equipment or reattaches it themselves later in the evening. Following overnight data collection, the equipment is returned and the data are analyzed. Whilst in most models data analysis occurs automatically, it is recommended that the data are scored by a trained clinician or technician in an attempt to reduce software mismatching of apnoeas and hypopnoeas.

An apnoea is regarded as a completed cessation of airflow (more than 90% reduction in nasal airflow/pressure signal amplitude of the pre-event baseline) for at least 10 seconds, regardless of whether there is an associated oxygen desaturation or arousal. The definition of hypopnoea varies from centre to centre but it is typically regarded as a reduction in airflow/pressure signal amplitude by 30% of pre-event baseline or more with a 3% or more oxygen desaturation, or if the event is associated with an EEG arousal. These criteria are based on the updated American Academy of Sleep Medicine (AASM) guidelines 2012[26] (these guidelines superseded the 2007 AASM guidelines[27]). If the airflow signal is missing (e.g. mouth breathing or displaced oro-nasal cannulae), amplitude changes in the thoraco and abdominal wall movement signals can still be used to determine if apnoeas or hypopnoeas are taking place. As explained above, chest wall movement – and therefore by inference, respiratory effort – is measured indirectly as changes in pressure detected by a pressure transducer worn around the chest during sleep. The changes in pressure signal are proportional to airflow and any change in signal can be regarded as a change in airflow.

Overnight polysomnography

The disadvantages of in-hospital overnight PSG compared with domiciliary multichannel testing have been stated above. However, home testing is inadequate for a cohort of more complex OSA patients. For example, some patients may need further respiratory monitoring such as transcutaneous CO_2 testing, particularly if OHS is suspected. In other cases, such as patients with neuromuscular disorders, in-hospital assessment is warranted as assisted ventilation is required. Tertiary referral sleep centres will see a variety of sleep disorders where the EEG, EOG and EMG component of the PSG are essential (e.g. narcolepsy, parasomnias and periodic leg movement syndrome). Prior to assessment, equipment is arranged by a sleep technician. The patient stays overnight at the sleep centre and most have video monitoring during the night as well. In some centres, the technician observes the signals from a central computer room during the night. This allows for troubleshooting, such as disconnected leads, but also allows more complex assessments, such as trials with assisted ventilators or titration with CPAP machines. Whether the technician stays overnight is dependent on the staffing and funding in the particular centre. In cases where the PSG is unattended, if leads do become disconnected, with the subsequent loss of signal, a repeat PSG may be necessary.

Criteria for the diagnosis of OSA

The number of apnoeas and hypopnoeas averaged out per hour of sleep is regarded as the apnoea-hypopnoea index (AHI). Some centres use the term respiratory disturbance index (RDI), which incorporates the number of apnoeas, hypopnoeas and respiratory effort related arousals (RERA). The latter are diagnosed by EEG arousals associated with respiratory effort (from intra-oesophageal pressure measurement) in the absence of apnoeas and hypopnoeas. However, as intra-oesophageal pressures are seldom used, the term AHI is more reflective of clinical practice and is most commonly used. If home respiratory monitoring testing is carried out, an estimate of the number of hours slept by the individual is necessary. A common mistake is to calculate the total number of apnoeas and hypopnoeas and then divide this number by the total number of hours of respiratory recording and not sleep time.

The severity of OSA has been defined as:

- no evidence of OSA if AHI <5 apnoeas and hypopnoeas per hour
- mild OSA if AHI ≥ 5 and <15 apnoeas and hypopnoeas per hour
- moderate OSA if AHI ≥ 15 and <30 apnoeas and hypopnoeas per hour
- severe OSA if AHI ≥ 30 apnoeas and hypopnoeas per hour.

It is important to note that these criteria do not take into account the desaturation index or the length of apnoeas and hypopnoeas.

When to treat varies from centre to centre. Most centres would not treat mild OSA without EDS and/or existing comorbidities (i.e. hypertension, cardiovascular disease, coronary artery disease, diabetes mellitus) with CPAP. Lifestyle changes, such as weight loss strategies (particularly if the BMI is greater than $25\,kg/m^2$), and/or treatment of any troublesome rhinitis are recommended. However, if patients have mild OSA with EDS and/or comorbidities, or moderate to severe OSA with or without EDS and comorbidities, then a trial with CPAP therapy may be considered.

TREATMENT – CONTINUOUS POSITIVE AIRWAY PRESSURE

Continuous positive airway pressure (CPAP) is regarded as the mainstay of OSA treatment.[28] This technique was first described in 1981[29] and since then there have been immense technological advances driven by industry.

The mode of action can be regarded as a 'pneumatic splint' whereby the air pressure generated via a tube and mask, through the nasal and/or oral passageway, prevents collapse of the pharyngeal and palatal walls, and consequently, the airway.

The equipment

CPAP machines may provide a constant positive pressure ('fixed pressure') or may vary pressure depending on the presence of apnoeas. The latter system, delivered by autoCPAP machines, relies on an algorithm set in the machine mechanics, whereby a reduction of airflow (i.e. apnoea or hypopnoea) is detected by the machine and as a result the machine generates the appropriate retrograde flow (and therefore pressure) to overcome the apnoea or hypopnoea. For this to work successfully, a closed system between the machine and the patient has to exist.

Patient preference typically determines which mask is used but when a nasal mask is chosen, patients must ensure mouth leaks are minimized. To this end, chin straps are sometimes used to keep the mouth closed. Most masks are kept in place by Velcro straps. All masks must have an expiratory port to prevent re-inhalation of expired air. All patients are reminded to clean their masks and strappings regularly, to ensure longevity. The newer machines are smaller and lighter to allow easy portability. All new machines have an internal mechanism to allow switching between 220 and 110 volts, depending on where the user is around the world. The ease of using CPAP on planes can vary from airline to airline.[30] The use of an inverter mechanism will allow CPAP usage driven from a DC battery pack. For those who suffer from nasal congestion and/or a dry mouth, a humidifier is recommended.

Setting up CPAP

Centres differ in how a patient with OSA is set up on CPAP. All centres should have educational programmes to ensure patients gain a better understanding of their illness, in order to maximize long-term CPAP compliance. Some centres use group video workshops to achieve this. CPAP set-up should be carried out by a trained technician who understands the technology and appreciates where problems may arise.

Patients differ in the level of pressure necessary to eliminate the vast majority of their apnoeas and hypopnoeas. The method of determining this opening of airway pressure differs from centre to centre. Some use a mathematical equation. One example that has shown reasonable correlation with titration studies is: predicted pressure (cm H_2O) = (0.16 × BMI) + (0.13 × NC) + (0.04 × AHI) − 5.12, where NC is neck circumference (cm).[31]

Another method of titration of CPAP used in some centres is to admit a patient for overnight diagnostic PSG. The severity and diagnosis of OSA is confirmed by PSG during the first half of the night, then CPAP is commmenced for the second half of the night. This is referred to as a 'split night' regime. However, the process needs a supervising technologist and a big disadvantage is that the true severity of OSA may not be determined during the diagnostic first half of the night. However, an advantage is that both diagnostic and CPAP titration are performed on the same night, therefore saving an extra admission. The CPAP titration technique is carried out by a technologist from the central computer room, who has video access to the patient and electronic linkage to the CPAP machine. The starting pressure is usually around 4 cm H_2O and the pressure is quickly increased until all apnoeas and hypopnoeas are eliminated. It is the aim to reach the required pressure to eliminate the majority of apnoeas and hypopnoeas within an hour, and the rest of the night is spent fine-tuning and troubleshooting, for example, mask leaks or the need for supplemental oxygen in some cases.

Another technique that is increasingly being used is to send the patient home with an autoCPAP machine. Most autoCPAP machines will collect data on compliance, leaks and pressure profile. A trial of between 7 and 14 days may allow better adjustment to the concept of CPAP rather than an autoCPAP trial of one night. Generally autoCPAP machines are more expensive than the fixed pressure machines and as a result, in the UK, funding from clinical commissioning groups (CCGs) are predominantly for fixed pressure machines. Many centres set the fixed pressure as determined by the 90th or 95th centile pressure (i.e. the blowing pressure to eliminate 90% or 95% of apnoeas and hypopnoeas) as determined by the autoCPAP data download. CPAP therapy is recommended by the National Institute for Health and Care Excellence (NICE) as the treatment of choice for moderate to severe OSA.[32] The Scottish Intercollegiate Guidelines Network (SIGN) has produced useful recommendations on the management of OSAHS in adults.[33]

Side effects

Most side effects are related to the nasal/face mask interface. Claustrophobia can be problematic in some patients. Trying different face masks, from full face, to nasal, to an interface that sits on the nostril edge (nasal pillows) may be one solution. However, with patience, education and reassurance (an experienced technician is the key here), most patients are able to alleviate such claustrophobia issues. Nasal stuffiness is a common troublesome side effect, although interface technology has improved greatly recently to reduce this. However, despite this, nasal stuffiness and coryzal illnesses can lead to poor compliance in those patients with nasal masks. Heated humidification is recommended as one solution. Cold and dry air may provoke mucus production and vasodilation in the nasal mucosa and hence humidification may potentially address this. Although nasal corticosteroids and/or corrective surgery for mucosal thickening and polyps may be considered, most sleep centre practitioners believe that a full-face mask may be a simpler solution.

Other side effects, such as skin abrasions and leaks, are usually related to poorly fitting masks. Leaks can be a

nuisance, especially if they are directed towards the eyes. The patient has to be educated that a good fit rather than a tight fit is more likely to be successful in eliminating leaks without skin and eye trauma.

Air-swallowing and pulmonary barotrauma may also occur, although the latter is very rare. Air-swallowing and subsequent gastric distension is more likely if the pressure delivery exceeds physiological oesophageal sphincter pressure (e.g. above 15 cm H_2O). The obvious remedy is to reduce the pressure.

Compliance and troubleshooting

Compliance of CPAP usage is dependent on many factors. It has been reported that by 3 years, up to 12–25% of patients will have discontinued treatment.[34] Compliance has been defined arbitrarily in the literature as usage of CPAP for more than 4 hours for at least 5 nights per week. The biggest factor that will determine long-term compliance is the improvement of symptoms soon after commencing CPAP therapy and the severity of the OSA suffered by the individual.[34] What is unclear, when faced with an individual about to commence CPAP therapy, is whether 4 hours for 5 nights per week is enough to reduce the risk of RTAs or future cardiovascular comorbidity. It is anticipated that future clinical trial data will determine this but generally all patients are encouraged to use CPAP for at least 6 hours, 7 nights per week.

It follows that adequate education, follow-up by an experience technician and motivation of the patient all influence long-term adherence to CPAP. When CPAP failure does occur, troubleshooting interface issues, addressing side effects and assessing the presence of coexisting sleep disorders (e.g. shift-work related sleepiness, narcolepsy, psychological illness or drug-induced conditions) should be considered. This latter point is particularly important as it is not uncommon for an individual to have two coexisting sleep disorders.

There have been some suggestions that autoCPAP has advantages over fixed pressure CPAP, particularly with respect to comfort, possibly by reducing the average pressure applied throughout the night. However, although this may be the case, there is no evidence that this improves compliance or symptoms of EDS compared to fixed pressure CPAP.[35] A recent systematic review of fixed pressure CPAP vs autoCPAP showed that although there was an improved compliance by 11 minutes per night (0.18 hours; 95% CI, 0.05 to 0.31 minutes; $P = 0.006$), and that ESS score improved by 0.5 (95% CI, −0.81 to −0.15; $P = 0.005$) in the autoCPAP group, the clinical importance of these small margins of improvement remain unknown, despite being statistically significant.[36] Therefore, as the treatment effects are similar between APAP and fixed CPAP, the therapy of choice will be dependent on patient preference, the cost, and issues of non-compliance. Until there are definite cost-benefits shown for autoCPAP over the fixed pressure CPAP machine, there is no justification to mass provide autoCPAP machines on the NHS in the UK at present.

ALTERNATIVE STRATEGIES TO CPAP

Bilevel positive airway pressure (sometimes known as BiPAP) devices allow specific and separate pre-set inspiratory and expiratory pressures, for example inspiratory positive airway pressure (IPAP) between 10 cm H_2O and 20 cm H_2O, and expiratory positive airway pressure (EPAP) between 5 cm H_2O and 10 cm H_2O. These devices may improve compliance in some patients who are intolerant to CPAP but should only be used in selective cases. For those who have CSA, newer devices known as adaptive servo-ventilator (ASV) have been commonly tried. It is generally recommended that such treatment should be initiated by specialist sleep centres. Other novel treatments, such as nasal EPAP devices, are being introduced as alternative therapies[37] but randomized controlled trials comparing this form of device against CPAP are still awaited.[38]

FOLLOW-UP AND LEGAL ISSUES

At the time of diagnosis of OSA, in the UK, the individual is recommended to self-inform the Driver and Vehicle Licensing Authority (DVLA), Swansea, UK, of the diagnosis. However, the DVLA recognizes only the diagnosis of 'obstructive sleep apnoea syndrome', defined by the DVLA as OSA with sleepiness, but there is no indication of how the sleepiness is qualified or quantified and therefore diagnosis is at the discretion of the diagnosing clinician. The emphasis of responsibility to inform the DVLA in the UK is placed on the patient with 'OSA syndrome' and not the sleep clinician/ENT surgeon and so on. In reality, many patients do not inform the DVLA, as in many parts of the country the treatment for OSA (CPAP) may not be available immediately. All drivers should be reminded that by law (Road Traffic Act 1998), all drivers have a duty of care when driving. However, those patients deemed to be a genuine threat to the public by continuing to drive whilst sleepy may be considered for notification by the clinician, despite this potentially breaking rules of patient confidentiality.

Follow-up CPAP clinics are aimed to determine compliance, minimize intolerance, improve symptoms (as shown by reduced sleepiness) and continue to modify cardiovascular risk factors. Follow-up PSG with CPAP is not necessary unless other sleep disorders (e.g. periodic leg movement, insomnia) are suspected. Some centres utilize a repeat overnight oximetry with CPAP, but an abnormal tracing may not necessarily differentiate poor compliance from inadequate treatment pressure. A significant increase in weight with time may lead to the appearance of snoring with the mask on and an increase in the fixed CPAP pressure may be necessary. Leaks around the mask may be caused by the mask components wearing out, but if the mask is well looked after it should last for up to a year. CPAP machines that are provided on the NHS must be electrically serviced and checked by an engineer on an annual basis by law. The equipment technically belongs to the centre that provided the machine and therefore it is the

responsibility of the centre to ensure that it is electrically safe. During servicing, the engineer will routinely download usage data from the machine and this will provide useful compliance data. Patients with moderate to severe OSA who have suboptimal compliance are challenging to the clinician, and reasons for non-compliance should be addressed. If a patient refuses treatment with CPAP, then other solutions (e.g. weight loss, mandibular devices or even surgery) may be considered. The patient should be reminded of the issues of driving with OSA without treatment. Clinical psychology approaches, particularly cognitive behavioural therapy, may also be considered.

KEY POINTS

- Obstructive sleep apnoea is becoming more and more prevalent in society as more and more individuals become obese.
- A significant proportion of individuals with obstructive sleep apnoea are however not obese and therefore the clinician should look out for airway anatomical reasons for the apnoeas.
- Obstructive sleep apnoea is commonly associated with other comorbidities such as hypertension, cardiac disease, diabetes mellitus type II and cerebrovascular disease.
- Obstructive sleep apnoea is a common reason for impaired well-being particularly impaired mood, concentration, memory, and alertness.
- There is a higher risk of fatigue-related road traffic accidents in those who have severe obstructive sleep apnoea.
- The clinician looking after an individual with obstructive sleep apnoea should be aware of the medical (CPAP), dental (mandibular advancement splint) and surgical (Ear Nose and Throat) approaches of treatment.
- Services delivering diagnostic and therapeutic patient pathways are more commonly involving a multidisciplinary and holistic approach.

EPIDEMIOLOGY

Sleep-related breathing disorder (SRBD) encompasses a broad clinical spectrum of recurring partial or complete obstruction of the upper airway. This ranges from simple or primary snoring to severe obstructive sleep apnoea (OSA). Patients who have symptoms suggestive of OSA but do not have objective parameters in a sleep study confirming the condition can be classified as having upper airway resistance syndrome (UARS). These patients may have sleep fragmentation but do not have significant oxygen desaturation events or many obstructive events. A definition of apnoea, hypopnea and the apnoea-hypopnea index (AHI) is covered in Chapter 74, Obstructive sleep apnoea: medical management.

Snoring is a sound produced (usually during inspiration) by vibrations of the upper airway caused by a turbulent airflow that, in turn, is caused by varying degree of collapse of the upper airway lumen. Simple snoring is generally not associated with significant obstruction or arousals but can be linked with tiredness. It is thought that the reason for the tiredness may be that these simple snorers, in the absence of apneas, may still repeatedly wake up as there is a need to make a greater effort to overcome the airflow resistance; furthermore, they may be awakened by their partner who is being disturbed by the noise. The exact prevalence of snoring is not easy to quantify but in general it is thought that about 40% of adults snore and of these about 10% may have some degree of obstructive episodes. Men are thought to be more likely to snore than women.

OSA is thought to affect 2–4% of males and 1–2% of females, a level of prevalence comparable to Type I diabetes.[1] Basically, in OSA there is failure of dilator muscle tone of the upper airway lumen.

The morbidity and mortality related to OSA is well recognized as an independent risk factor for hypertension, cardiovascular, Type II diabetes and cerebrovascular diseases.[2] In addition, neurobehavioural morbidities of daytime sleepiness and impaired cognitive function may contribute to motor vehicle and job-related accidents.[3, 4] Overall, OSA significantly increases the risk of stroke or death from any cause; in a community-based sample, moderate to severe sleep apnoea is independently associated with a large increased risk of all-cause mortality.[5] The obesity epidemic means problems faced by health professionals in relation to OSA are only likely to increase in the immediate future.

In terms of aetiology and aggravating factors for both snoring and OSA, there is considerable similarity and overlap. In essence, the upper airway in these patients is of a relatively small size and/or narrowed. In many of these individuals it is not uncommon to encounter a multilevel obstruction. For example, an individual may have nasal congestion or obstruction secondary to deviated nasal septum or nasal polyps and may also have a crowded oropharynx as a result of hypertrophied tonsils or a lax soft palate and an elongated uvula. Nasal congestion may further contribute to the obstruction by causing mouth breathing that, in turn, accentuates palatal vibration or oscillation of pharyngeal tissue and worsening of

tongue retraction.[6] Excessive alcohol intake,[7] obesity,[8] smoking,[9] increasing age[8] and consumption of sedatives are thought to aggravate these conditions. Certain morphological features such as micrognathia or maxillary retrusion make some patients more prone to sleep-related breathing disorders.

CLINICAL PRESENTATION

It is prudent to fully evaluate a patient before imposing surgery upon them. The full evaluation would consist of a comprehensive medical history, clinical examination and assessment and special investigations to ascertain the severity and the site or sites of anatomical obstruction within the upper airway that may be responsible for the symptoms.

CLINICAL HISTORY

This is probably better obtained if the partner is present as well. Details of both nocturnal and daytime symptoms need to be addressed. As much information as possible about snoring and sleep should be gathered and could include many of the following:

- For the partner (i.e. questions that are not easy or possible for patient to answer):
  - How severe is the snoring (audible outside the room, downstairs, by next door neighbour)?
  - Does the patient snore with mouth open?
  - Is snoring positional?
  - Are there episodes of crescendo snoring, apnoea, choking or gasping?
  - Is the patient restless and are there any other limb movements?
  - Does the patient sleep walk or sleep talk?
- For the patient:
  - Do you feel that your sleep is refreshing?
  - Do you get morning headaches?
  - Do you feel tired during the daytime? (Complete Epworth Sleepiness score.)
  - Do you suffer from night sweats or palpitations?
  - Do you have vivid dreams or nightmares?
  - Do you feel that your nose is blocked?
  - Do you smoke and drink alcohol? How much?
  - Do you have any other medical problems such as high blood pressure, heart problems, diabetes, underactive thyroid gland or past history of stroke?
  - Do you feel that your cognitive functions such as concentration and memory are impaired?
  - Has your libido diminished?
  - Have you had any driving accidents?
  - What medications do you take?
  - Have you had any surgery previously? (Assess fitness or problems with general anaesthesia.)
  - Have you tried any conservative measures such as weight loss, reducing alcohol or intranasal steroid sprays?
  - Have you tried nasal strips or nasal valve dilators to improve nocturnal breathing?
  - Have you tried mandibular advancement devices to improve snoring?

CLINICAL EXAMINATION

This can quite easily be conducted in an outpatient setting, and addresses a general inspection and examination as well as specific upper airway evaluation.

Measurements of height and body weight are obtained to calculate the body mass index (BMI). The figure for BMI is derived by dividing the body mass in kilograms divided by the square of the height in metres. Values of BMI should take factors such as body frame and ethnic difference into account. In general, however, BMI values between 20–25 are considered as being normal, between 25–30 as being overweight and more than 30 as being obese.[10] Higher values would be categorized as being premorbid or morbid obesity. Neck collar size measurement is useful as it has been suggested that there is higher chance of OSA in patients with a collar size greater than 17 inches.[11] On general inspection one ought to be on the lookout for craniofacial or facial skeletal framework deformity such as seen in patients with acromegaly, maxillary retrusion or micrognathia.

Specific upper airway evaluation should commence with the examination of the nose and nasal cavity. External nasal deformity and abnormal nasal valve function can both contribute to difficulty in breathing and upper airway obstruction. Further examination of the internal nasal cavity can be conducted using a headlight and thudicum nasal speculum to identify abnormalities such as deviated nasal septum, septal perforation, enlarged turbinates or nasal polyps. This should be followed by simple examination of the oral cavity and oropharynx, starting with observation of the state of dentition as this may determine the suitability of the patient to use a mandibular advancement device. Other features to be noted should include limitation of mouth opening, laxity of soft palate, size of palatine tonsils, the length of uvula and the general crowdedness of the oropharynx. The Mallampati palate position[12] and Friedman tongue position[13] may also be used for further evaluation of the upper airway obstruction and may provide an indication as to the likelihood of success of certain surgical interventions.

More detailed examination of the nose and the pharynx should be carried out using a flexible, fibre-optic endoscope assessing the nasopharynx, oropharynx and the hypopharynx. The patient could simulate the snoring[14] whist the endoscope is in position and could also perform the Mullers[15] manoeuvre, which essentially is the reversed Valsava manoeuvre. Although these may provide an insight in to the site and severity of upper airway obstruction, one must bear in mind that this 'awake' assessment in the patient may not truly reflect the upper airway dynamics during sleep as the muscle tone would vary greatly. Furthermore, some patients do find these manoeuvres difficult to perform and there may be a great deal of subjectivity in its interpretation.

INVESTIGATIONS

Before embarking on any treatment, it is important to perform some investigations. For instance, blood tests to exclude anaemia and hypothyroidism should be carried out to exclude other causes of tiredness. A sleep study should be performed in individuals where history is suggestive of OSA, to determine the severity of the problem. Other investigations to assess upper airway obstruction include imaging, acoustic analysis, sleep nasendoscopy (SNE) and use of pressure transducers.[16]

Imaging

Although not routinely utilized, imaging can be useful under certain circumstances. For example, in patients being considered for radical surgery like maxillo-mandibular advancement, cephalometry provides vital information about upper airway dimensions.[17] Disadvantages of this kind of imaging include the fact that it can only be performed whilst the patient is awake, the exposure to radiation and the cost. It only provides two-dimensional information and may also not be widely available. More detailed and sophisticated data can be obtained by using computed tomography (CT) scanning or magnetic resonance imaging (MRI), allowing objective volumetric dimensions of the upper airway to be calculated.[18,19] These are both expensive, and CT scans also involve radiation. The MRI scans are very useful in evaluating the soft tissue aspect of the upper airway. Using these routinely during sleep would not be cost-effective or practical.

Acoustic analysis

In general, this form of evaluation is considered to be entirely safe as it is non-invasive, does not involve radiation, is relatively cheap and can be utilized during natural sleep over multiple nights. It can be conducted simultaneously with a hospital-based polysomnography or at home with an ambulatory sleep study. By using the sound frequency spectrum, acoustic analysis can potentially distinguish between primary snoring and OSA.[20] Attempts have been made to correlate snoring sound frequency with different anatomical levels of upper airway obstruction, and comparison of this technique has been made to SNE.[21] This was found to be difficult, particularly with multilevel involvement in most patients. The sensitivity and specificity of acoustic analysis has often been questioned and its role in selecting different treatment modalities is slightly limited.[22]

Sleep nasendoscopy

SNE, which is more popularly known as drug-induced sedation endoscopy (DISE) in the rest of Europe, was pioneered at the Royal National Throat, Nose and Ear Hospital in London.[23] Work from this institute, including an audit study of 2485 procedures, has demonstrated that SNE correlates well with AHI and mean oxygen desaturation values.[24] The beauty of this technique lies in the fact that it allows a three-dimensional visualization of the upper airway dynamics during sleep, albeit drug induced. It has to be appreciated that the muscle tone of the upper airway is different when the patient is fully awake compared to when they are asleep and therefore the assessment of the anatomy during sleep should prove to be useful. It has been demonstrated that SNE is useful in predicting treatment success in snorers using mandibular advancement devices.[25–27] Similarly, SNE has allowed site specific selection in surgical patients and improved surgical outcomes in patients undergoing laser palatoplasty with or without tonsillectomy, as well as with implanted upper airway stimulation therapy for OSA.[28–31]

This assessment should be carried out in an operating theatre setting with the help of an anaesthetist and adequate cardiovascular and respiratory monitoring. The sedative agents used are midazolam or propofol, or a combination of the two, where midazolam effectively induces sleep while propofol, with its rapid onset of action and recovery, is useful in the fine tuning of sleep.[24]

Advocates of SNE find it to be a useful evaluation technique but numerous controversies and debates have arisen. First and foremost, drug-induced sleep is different from natural physiological sleep as the drugs used may cause exaggerated muscle relaxation. However, one could argue that this impact of the sedation drug would be similar on the different segments of the pharynx; thus, it would theoretically allow us to compare the proportionate obstruction caused at each anatomical level in a similar manner that may exist in natural physiological sleep. Furthermore, criticisms were made by Marais,[32] who claimed that, when comparing snorers and non-snorers during SNE, snoring was not reproduced in some of the snorers and snoring could be produced in the non-snoring group, and thus concluded that SNE was not an appropriate technique. This was challenged by Berry et al,[33] who elegantly demonstrated in their study using target controlled infusion of propofol during SNE that all their snorers and non-snorers responded as expected, thus validating and advocating SNE. Questions and concerns raised about test-retest reliability and of inter-observer variation during SNE have been adequately addressed by various studies.[34–36] Another concern that has been expressed is about the depth or level of sedation at which the upper airway should be evaluated. If the patient is assessed too early, the muscle relaxation effect of the sedation drug may be over-emphasized; and if the patient is assessed whilst too deep then important obstructive episodes during lighter sleep may be missed. This has been clarified by studies that have utilized bispectral index monitoring during SNE.[37,38] This neurophysiological monitoring device continually analyzes a patient's electroencephalogram during sedation or general anaesthesia and gives an indication of depth of sedation.

A recent study using digital videostroboscopy during SNE[39] has shown that whilst assessing the upper airway during sedation, stroboscopic evaluation may help further understanding of the mechanisms of airway obstruction, particularly in those who have failed surgical treatment.

It is important to accurately document the findings of the upper airway evaluation during SNE. At present there are various classifications[40–42] and although there is some overlap and commonality amongst these, ideally we need a uniform grading system. To date the only technique that allows evaluation of the upper airway during sleep in conjunction with dynamic visualization is SNE and the use of this technique has further emphasized the differences between awake and asleep assessment.[43, 44]

Pressure transducers

Various devices that can measure pressure changes in the different segments of the upper airway have been described. This allows pressure recording in various anatomical sites of the upper airway during obstructive episodes. It is now common practice to use a multichannel pressure catheter[45, 46] to record pressures at different anatomical levels of the upper aerodigestive tract ranging from the nasopharynx to the oesophagus, where usually the reference transducer is positioned. These have been used to ascertain the level of obstruction before performing the appropriate surgical procedure. One of the more recent devices, known as Apnea-Graph AG200 (MRA, Medical UK), seems quite promising in that it is able to perform the dual function of providing severity of OSA as well as some idea of the site of anatomical obstruction simultaneously,[47, 48] during natural physiological sleep as well as during sedation endoscopy. It relies on measuring pressure and airflow simultaneously at different levels in the pharynx. It has the ability to store and analyze the cardio-respiratory data of a patient with simultaneous recording of two different sites in the upper airway using a micro-pressure and temperature transducer catheter. Problems that may potentially be encountered with this device include difficulty in tolerating the catheter for the whole night and the possibility of some movement of the various transducers during different phases of respiration and, therefore, the site of obstruction may not be very accurately detected. Furthermore, the transducers are in a fixed position on the catheter and do not consider the morphological variation in the distances between different anatomical landmarks in individual patients.

NON-SURGICAL TREATMENT OF SNORING AND OSA

Snoring patients with or without obstructive sleep apnoea (OSA) should be advised to try non-surgical measures before contemplating any surgical procedures. An advice leaflet on self-help suggestions could be prepared locally. Otherwise, patients are directed to a national association website to provide them with the advice and support that they need. In the UK, they are directed to the British Snoring & Sleep Apnoea Association website (http://www.britishsnoring.co.uk). These measures revolve around lifestyle changes or the use of devices to alleviate the snoring.

Lifestyle changes

- Dietary modification for weight loss is essential. Morbidly obese patients are advised to explore the option of bariatric surgery if they fail to reduce their weight with dietary measures. A recent study investigating the effect of weight loss surgery in 1728 patients showed significant improvement of all obstructive sleep apnoea symptoms compared to controls. The average reduction of BMI was 9.7 kg/m^2.[49]
- Avoiding alcohol before sleep helps by reducing the detrimental effect of alcohol on the muscle tone of the neck. A randomized control trial showed that the ingestion of alcohol was associated with a significant increase in the number of apnoeic events and oxygen desaturation.[50]
- Avoiding smoking.
- Positional therapy, avoiding the supine position using the tennis ball technique, helps a small group of patients as its associated discomfort reduces the patient's compliance.[51]
- Regular exercise improves the tone of the muscles of the neck and also helps the patient to lose weight.

Devices

MANDIBULAR ADVANCEMENT SPLINTS

Mandibular advancement splints (MAS) produce forward displacement of the mandible, thus bringing the tongue base anteriorly, increasing the dimensions of the upper airway. There are a number of devices available in the market. The maximal degree of mandibular protrusion should be assessed, and then the MAS should be designed to maintain the mandible between 50% and 75% of the maximal protrusion. For simple snorers, MAS was found to be better than placebo in the subjective improvement of snoring.[52] For sleep apnoea, a randomized controlled crossover study showed significant reduction of the apnoea hypopnoea index using the MAS when compared to a control palatal plate.[53] A recent systematic analysis showed that the improvement of the OSA with MAS was observed in an average of 52%.[54]

The reported side effects of MAS include excess salivation, xerostomia, temporomandibular joint (TMJ) pain and bite change. The overall compliance is around 50–75%.[52, 55]

CONTINUOUS POSITIVE AIRWAY PRESSURE (CPAP)

CPAP is the treatment of choice for OSA. It is also recommended for upper UARS, which is referred to as sleepy snorers. It acts as pneumatic stent to prevent upper airway collapse throughout the different phases of sleep breathing. The CPAP machines could be either fixed pressure or autotitrating, according to the flow generator delivering the pressure through air tubing to a nasal mask, nasal prongs or a face mask worn by the patient. The average pressure required is 5–10 cm H_2O. The night to night pressure required overnight was found to be variable,

therefore the autotitrating CPAP would be a better option for the patients.[56]

The average use of CPAP in compliant patients ranges from 2–6 hours per night. A recent study showed that the longer the use of CPAP per night, the better the improvement of daytime somnolence and the functional status of the patients.[57]

Side effects include nasal congestion, rhinosinusitis, nasal bridge and facial irritation, and nose bleeds. Poor compliance is usually related to the discomfort of the device or the noise of the machine.

SURGICAL TREATMENT FOR SNORING AND OSA

Surgery to correct or improve upper airway obstruction may involve minimally invasive soft tissue surgery with no gross change in the anatomical structure such as interstitial radiofrequency thermotherapy or, at the other extreme, may involve radical skeletal framework surgery such as maxilla-mandibular advancement.

Nasal surgery

Patients who present with significant nasal obstruction secondary to deviated septum, nasal polyps or nasal valve collapse in addition to the snoring, should be offered the appropriate nasal surgery. There is strong evidence in the literature that nasal surgery would improve the nasal airway but the impact on snoring would be minimal. A prospective study of 40 patients showed objective improvement of the nasal airway using rhinomanometry without any improvement of the snoring time, snoring intensity, nocturnal breathing or sleep architecture.[58] Another recent controlled study revealed no change in the polysomnographic parameters after nasal surgery, although the nasal airway was significantly improved.[59]

The rationale in performing nasal surgery in patients with snoring with or without OSA is to improve their nasal airways and to provide them with a better response and compliance with CPAP. Friedman et al. investigated the result of nasal surgery alone on OSA and showed no significant impact on the respiratory disturbance index (RDI) or lowest oxygen saturation levels, but CPAP levels required to correct OSA were reduced.[60]

Uvulopalatopharyngoplasty

The classic uvulopalatopharyngoplasty (UPPP) described by Fujita et al. in 1981[61] involves the excision of the uvula, the removal of 1–2 cm of the oral palatal mucosa in curvilinear fashion along the anterior pillars, followed by excision of the excess length of the soft palate. Then the nasopharyngeal mucosa is pulled anteriorly and laterally to widen the nasopharyngeal airway. Simmons et al.[62] described a modification that was adopted in the UK involving the excision of the tonsils, the uvula, half of the anterior and posterior pillars, and full thickness of the lower part of the soft palate. The soft palate was palpated and the incision was made posterior to the fold of the levator sling then followed by suturing of the anterior and posterior pillars in continuation with the inferior margin of the remaining soft palate. A number of modifications introducing different types of local flaps[63–69] were described to maximize the size of the oropharyngeal airway, in an attempt to improve the success rate and to reduce the incidence of post-operative complications. Using an outcome measure of a reduction of snoring level by 50%, the early post-operative success rate was 76%; however, the long-term success rate was only 45% with a low overall satisfaction.[70] In addition to this low success rate, a prospective multicentre study showed 1.5% incidence of serious non-fatal complications and a mortality rate of 0.2%.[71] Post-operative pain is a constant complaint after UPPP and patients should be warned about it.[72] Exacerbation of sleep apnoea and respiratory obstruction have been reported in the perioperative period as a result of the use of sedatives, muscle relaxants or post-operative pain management.[73] This early post-operative airway compromise might also be related to the resultant oedema of the tissues and it was noted to be directly proportional to the severity of sleep apnoea.[74] The most common late complication following UPPP is velopharyngeal insufficiency (28.5%),[75] which is related to scarring and excessive palatal resection.[76] Other complications include bleeding (0–6%), dry throat (10%), infection (0–10%), and swallowing problems (0–9%).[77, 78]

Potentially, UPPP might compromise the future use of nasal CPAP therapy because of the loss of the soft palate seal resulting in excessive mouth air leak. Mortimore et al. reported that patients after UPPP significantly tolerated less pressure and their compliance was poorer than sleep apnoea patients without UPPP.[79] The face mask CPAP has provided a solution to this issue but its compliance is worse than nasal CPAP.

Because of these associated complications, alternative approaches have been introduced.

Laser-assisted uvulopalatoplasty

Laser-assisted uvulopalatoplasty (LAUP) refers to a number of different techniques involving the use of the laser to the soft palate for the treatment of snoring. The first technique was described by Kamami in 1990, using a CO_2 laser to create vertical trenches in the soft palate (up to 2 cm) on either side of the uvula followed by partial vaporization of the uvula.[80] Numerous modifications of this technique were described using it, in single or multistage fashion, to stiffen the soft palate.[81–84] The second technique was introduced by Ellis in 1993, using an Nd-YAG laser to remove a 1.5 cm wide central longitudinal strip of mucosa from the whole length of the soft palate followed by excision of the uvula at its base.[85] Other modifications were described, extending the excised part of the mucosa, with or without using flaps of the palate, performed under local or general anaesthesia.[86–88] The aim of LAUP is to invite scarring to the soft palate, making it stiffer to minimize snoring due to palatal flutter.

The post-operative pain is worse than UPPP, with the peak reached on the 3rd post-operative day and it takes up to 15 days to resolve completely. The short-term success rate is 79%, dropping to 55% in the long term.[89–91] Other complications reported were haemorrhage (2.12%), local fungal infection (0.53%), temporary palatal incompetence (0.53%), temporary loss of taste (0.27%)[90] and globus type symptoms.[92] It has no significant impact on smell and taste.[93]

In a recent systematic review,[94] only two randomized controlled trials[95, 96] were found, with no significant difference between LAUP and controls in the treatment of snoring with or without mild sleep-related disorders. It was reported that some simple snorers developed mild OSA following LAUP. This might be related to increased palatal fibrosis, contraction of the velopharyngeal space and reduction of the space between the posterior pillars.[97]

Radiofrequency tissue volume reduction/thermal ablation (CAUP)

This technique employs the use of low frequency radio waves, delivered into the submucosal tissue with the tip of a wand, to create a channel of charged ions that heats the tissues, causing denaturation of the proteins and cell lysis at low temperatures (60–90°C). This destroys specific areas of tissue with minimal collateral damage to tissues, inviting scarring to the muscle layer, reducing its volume and making it stiffer.[72, 98, 99] Three radiofrequency devices are available: the Somnus unit;[99] the Celon device;[100] and the coblator unit.[101]

The main advantages of this technique are that it can be carried out under local anaesthesia and used at multiple levels. For the soft palate, using the somnus device, three channels are made in each side of the soft palate in addition to two lesions in the paramedian position with the entry point just distal to the junction between the hard and soft palate. However, with the Celon device, which uses bipolar technology, more than three applications to the soft palate can be made. A special technique called coblation assisted upper airway procedure (CAUP) was described by Tvinnereim et al.[46] This consisted of making a lateral palatal incision on each side, ablating three upward channels on each side of the midline (fan-shaped) into the soft palate, performing a partial uvulectomy with two upward channels in the uvula and finally channelling of the anterior and posterior pillars and the tonsils if they are present. Multilevel therapy of the palate, base of the tongue and tonsils was described, with a 33% improvement in OSA patients.[101] The long-term success rate of radiofrequency treatment to the palate was found to be 37%.[102] A recent review reported better visualization of the tongue base for the application of the probe by applying simultaneous pressure over the mylohyoid and the thyroid cartilage.[103] It also emphasized the point that general anaesthesia may be the preferred option if multilevel application of radiofrequency is needed to treat the soft palate and the tongue base simultaneously.

In general, radiofrequency treatment is associated with less pain than UPPP or LAUP. Complications reported after radiofrequency tissue ablation of the soft palate included haemorrhage, infections and velopharyngeal fistula in single cases.[72, 103, 104] For radiofrequency ablation of the base of the tongue, studies showed incidence of infections or tongue abscesses in 0–8% of patients, with few cases of temporary tongue base neuralgias.[105, 106] Single cases of mouth floor oedema and severe tongue swelling, and a case of pseudo-aneurysm of the lingual artery and heavy bleeding 14 days after surgery have also been reported.[105, 106]

Transoral robotic surgery for tongue base

A recent development in the surgical management of OSA is the use of da Vinci robot, allowing transoral robotic surgery (TORS). This is being utilized for patients with severe OSA who have failed CPAP treatment and persistent hypopharyngeal obstruction following experiences in tongue base malignancy.[107]

A minimally invasive telerobotic system allows excellent 3D visualization, immaculate precision and absence of tremor. This improved access allows oropharangeal enlargement anteriorly through tongue base reduction and treatment of inward inspiratory collapse of a floppy epiglottis, aryetenoids and aryepiglottic folds. Vicini et al.[108] present their preliminary outcome data at 3 years, demonstrating a polysomnogram success rate (post-op apnoea hypopnea index < 15) of approximately 80%. No emergency post-operative interventions were required and good functional results in pain, swallowing and quality of life were displayed.

The surgery was, however supplemented with multiple other procedures in the case series, including septoplasty, UPPP, supraglottoplasty, turbinate reduction and ethmoidectomy. Similarly, another case series[109] presents favourable outcomes using a transoral robotic technique in combination with palatal surgery. The potential confounding factors of these additional procedures presents us with a difficulty in interpretation of these results, yet additionally places further value on the evolving concept of multilevel surgery when the outcomes are reviewed.[110] The peri-operative management for these patients varies between centres but increasing experience in the technique and knowledge of the potential complications has led to a drive away from a prophylactic or 'covering' tracheostomy as standard part of the patient pathway.

Lin et al.[111] demonstrate the use of a TORS technique in isolation for tongue base obstruction, excluding patients who received additional forms of upper airway alteration. This case series is small, with only 12 patients, yet a statistically significant reduction in AHI is demonstrated from this preliminary data.

A robotic surgical approach to hypopharangeal obstruction is likely to be applicable to a small subset of patients with severe obstructive sleep apnoea. Present case series analysis suggests that, for adequately selected individuals, a robotic approach may yet prove an appropriate treatment modality within specialist centres with the requisite equipment and experience.

Less performed procedures

CAUTERY ASSISTED PALATAL STIFFENING OPERATION

Cautery assisted palatal stiffening operation (CAPSO) involves the use of an electrocautery needle to remove a 2 cm inverted 'U' area of mucosa from the soft palate, in addition to the mucosa and part of the uvula. It is left to heal by secondary intention to stiffen the soft palate.[112] There are no controlled studies to evaluate this technique, but the few studies there are suggest a success rate similar to UPPP, with minimal complications.[113]

INJECTION SNOREPLASTY

The injection of 2 ml of a sclerosing agent in the midline of the soft palate above the base of the uvula was reported to invite enough scarring to make it stiffer. In the literature, 3% sodium tetradecyl sulphate, 50% ethanol and doxycycline were used in selected patients. The procedure is performed in the outpatient setting under local anaesthesia and can be repeated within 2 years if it does not improve the snoring. Although two cases of palatal fistulae were reported, they healed spontaneously and no other complications were noted.[114]

PILLAR IMPLANTS

In this technique the palatal stiffening is achieved by the implantation of woven Dacron mesh into pockets dissected in the soft palate.[115] A systematic review of four studies showed subjective improvement in VAS scores up to 53%, but no significant difference was reached in any objective snoring indices. It is associated with mild pain with a rate of extrusions of 0–11%.[116]

MANDIBULAR AND MAXILLARY SURGERY

A number of procedures were described in the literature aimed at dilating the hypopharynageal airway, including genioglossus advancement, tongue base suspension suture, hyoid suspension, maxillomandibular advancement and laser midline glossectomy. Most of the reports describing these procedures are pilot studies with no standardized comparison of other techniques used in the treatment of OSA. The reported success rate of some of these procedures approaches 60% in the short term. These procedures are associated with relatively high complication rates, such as swallowing problems, taste change, tongue oedema, tooth numbness and mandibular fractures. The midline laser glossectomy was associated with a high incidence of post-operative bleeding.[117]

TRACHEOSTOMY

Surprisingly enough, tracheostomy was the first surgical intervention in patients with OSA even before the disease was fully recognized. In 1980, Guilleminault et al. reported the long-term results after tracheostomy as a single intervention for OSA with resolution of the clinical symptoms and return to full activity.[118] However, the advent of the above mentioned surgical interventions have meant that tracheostomy is rarely indicated for the management of OSA. The American Academy of Sleep Medicine (AASM) has published a recent update on practice parameters for the management of OSA, emphasizing that tracheostomy should be considered only when other options do not exist, have failed or are refused, or when this operation is deemed necessary by clinical urgency.[119]

HYPOGLOSSAL NERVE STIMULATION

Experimental research in both humans and animals has demonstrated an increase in pharyngeal neuromuscular activity during sleep in obstructive sleep apnoea patients but at an insufficient level to overcome airway collapse. As such, there has been a focus on selective stimulation of upper airway dilator muscles (e.g. genioglossus) to improve airway patency without arousing patients from sleep. An implantable neurostimulator to synchronize hypoglossal nerve stimulation with inspiration has shown early promise in a single arm feasibility study.[120, 121] Twenty-one patients were recruited with moderate to severe OSA who had failed to tolerate CPAP. A significant decrease in OSA symptomology and in-laboratory polysomnography was established at 6 months post-implantation. Two device-related 'serious' adverse events occurred in this cohort, necessitating removal or replacement. Long-term safety and efficacy of this treatment warrants further clinical evaluation but it remains a treatment modality with high expectations for future benefit given the technological advances in this area.

CONCLUSION

Patients with sleep-related breathing disorders are best dealt with using a multidisciplinary approach. Lifestyle changes, appliances and surgical intervention are all treatment modalities that are available for these patients and a combination of these treatment options may be required to adequately resolve their problem. Thorough assessment and careful patient selection, particularly for surgical treatment, is essential for a successful outcome.

KEY POINTS

- Treatment of sleep-related breathing disorders require a multidisciplinary approach.
- Lifestyle changes and appliances should be utilized before surgery is considered.
- Careful patient selection for surgery is necessary.
- SNE is useful in tailoring site-specific treatment.
- Multilevel problems are very commonly seen therefore multilevel surgery may be required.
- It may be necessary to use appliances in conjunction with surgery.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: stenosis, subglottis, laryngotracheal, reconstruction, resection, tracheal, granulomatosis, vasculitis, sarcoid, bilateral, cord and stents.

INTRODUCTION

The upper aerodigestive tract, larynx, trachea and bronchi form the conduit between the external environment and the lungs to facilitate gas exchange. The larynx acts to protect the airway from aspiration during swallowing. It is the primary organ for phonation but also provides important sensory feedback and movements that are critical to the control of ventilation. The narrowest site of the adult airway is the glottis, whereas in infants it is the subglottis.

In the middle of the last century, the discovery of antibiotics and the ability to ventilate patients for prolonged periods meant that infections were no longer the principle cause of laryngotracheal stenosis (LTS). A period of ventilation on the intensive care unit (ICU) is now the most common cause of laryngotracheal injury and stenosis. Approximately 50% in our series of adult airway stenosis is post-intubation (**Table 76.1**, authors' series) and this figure is higher in children.[1] Risk factors include duration of ventilation, sizing of ventilation tubes, excessive cuff pressures, irritation from orogastric secretions, infections, immune disturbance and the patient's response to injury and healing biology.

Abnormal narrowing of the laryngotracheal complex causes breathlessness, especially during physical activity, and retention of pulmonary secretions may lead to lung infection or collapse. Laryngeal stenosis can also interfere with phonation and a dysfunctional larynx can impair swallowing safety. The exact physiology of dyspnoea is not known but the extra effort of breathing, tendency towards carbon dioxide retention and afferent signals from the respiratory tract must play a part.

TABLE 76.1 Aetiology of laryngotracheal stenosis in 600 consecutive referrals to the National Centre for Airway Reconstruction

50.3% Acquired laryngotracheal stenosis	• 34.3% subglottic stenosis • 16% tracheal stenosis
16.67% Bilateral vocal cord mobility impairment	(Nerve injury, scar/fixation, rheumatoid arthritis)
10.0% Wegener's granulomatosis	
8.67% Idiopathic subglottic stenosis	
5.70% Supraglottic stenosis	(2.7% sarcoid, 3.0% other)
2.33% Previous papillomatosis treatment	
2.33% Glottic web	
1.33% Tracheomalacia	(0.67% relapsing polychondritis)
1.17% Vascular lesion	
0.83% Amyloidosis	
0.67% Subglottic stenosis congenital	

Although the incidence of post-intubation LTS is unknown, one series reports significant airway injury in 47% of patients bronchoscoped at extubation.[2] Long-term airway compromise has been estimated at between 1% and 4%.[3–6] This means that the initial fibro-inflammatory injury appears to resolve in the majority of cases and only in some patients, through healing by fibrosis and wound contracture, does it lead to persistent airway narrowing. However, it is also possible in the absence of high quality follow-up data that some patients live with dyspnoea after the ICU and their LTS is never diagnosed.

PATHOPHYSIOLOGY OF LARYNGOTRACHEAL STENOSIS

In laminar airflow, airway resistance is dictated by the diameter of the airway and by the density of the inspired gas (Poiseuille's law):

$$R = \frac{8nl}{\pi r^4}$$

where:

- R = resistance
- n = viscosity
- l = length
- r = radius.

The resistance to airflow, by a stenotic segment of airway, is proportional to its length but inversely proportional to the fourth power of its radius. Turbulence, although difficult to calculate, is also inversely proportional to the airway diameter and will further add to resistance to airflow.

During inspiration, the intrathoracic airways expand along with the expanding lungs. However, the extrathoracic trachea will have a reduced lumen during inspiration because the intraluminal pressure is lower than atmospheric. The reverse happens during expiration. A variable obstruction of the airway also changes size with breathing. Hence, an extrathoracic variable tracheal stenosis will limit inspiration whereas an intrathoracic variable lesion will limit expiration. A fixed obstruction, whether intrathoracic or extrathoracic, will limit peak airflow on inspiration and expiration in equal proportions and produce a characteristic flow volume loop (**Figure 76.1**).

DIAGNOSIS

Diagnosis of LTS starts with the history. Previous prolonged ventilation, duration of shortness of breath and coexisting medical problems such as vasculitis or sarcoidosis are relevant. Symptoms of dyspnoea, voice changes and chronic cough are common but questions should also be directed to determine impairment of swallowing function and history of laryngopharyngeal reflux.[7] Exertional dyspnoea is the main symptom and patients compensate by reducing their physical activity. Patients can compensate over time for chronic progressive airway stenosis whereas the same level of stenosis occurring acutely may result in significant disability and even death. Chronic airway obstruction is sometimes misdiagnosed as asthma or chronic obstructive pulmonary disease.

Examination should document the severity of stridor, chest recession, body morphology (body mass index) and neck scars. Fibre-optic nasal endoscopy will help assess vocal cord mobility, evidence of laryngopharyngeal reflux, pooling of secretions in the hypopharynx and the degree of stenosis if it lies within the larynx or cervical trachea. If a tracheostomy is in place, the lower airway can also be assessed with the same flexible endoscope and sometimes a retrograde examination of the subglottis is also possible if the patient will tolerate temporary removal of the tracheostomy tube.

Investigations include imaging using high definition tomography (CT) but care should be taken when interpreting these scans. As the scans reconstruct the image from 'cuts' taken at intervals, if these cuts miss the apex of the stenosis than they will underestimate or even miss the problem. Conversely if there are secretions over the stenosis then overestimation of stenosis may occur. Respiratory function testing is essential to determine the severity of airway compromise but also to monitor the response to treatment. The minimal requirement is spirometry and flow

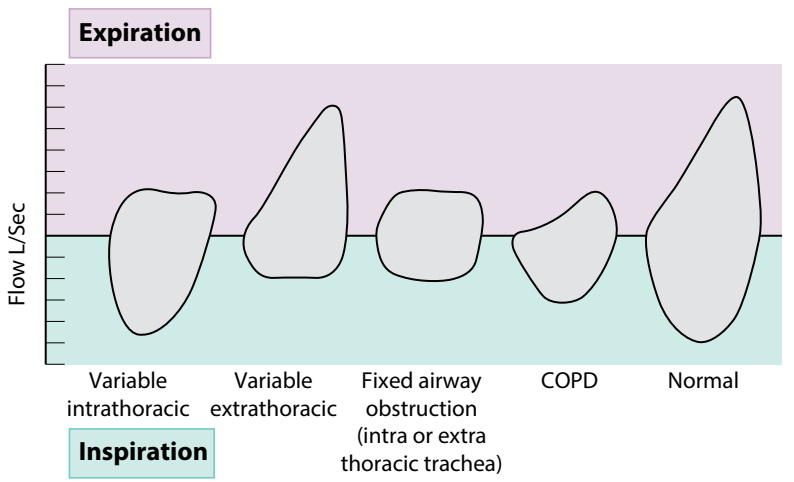

Figure 76.1 Characteristic flow volume loops. (Left to right): soft intrathoracic stenosis, soft extrathoracic stenosis, fixed stenosis anywhere in larynx or trachea, chronic obstructive pulmonary disease and a 'normal' flow volume loop.

volume loops and ideally cardiopulmonary exercise testing. If there is any evidence of disordered swallowing, then fibre-optic endoscopic evaluation of swallowing (FEES) or videofluoroscopy is essential. There are poor outcomes reported in patients with even minor aspiration, following airway reconstruction.[8] Although the majority of our patients are prescribed antireflux advice and therapy (once or twice daily proton pump inhibitor with an alginate suspension after the evening meal), it is still of value to investigate for laryngopharyngeal reflux in the symptomatic patient in case antireflux surgery is indicated.

Patients with airway stenosis must be managed by a multidisciplinary team that includes an ENT and thoracic surgeon, pulmonologist, anaesthetist, radiologist, pathologist and speech and swallowing therapist as well as a dietician. Bariatric services should also be available as there is an increase in the resting metabolic rate in obesity as well as decreased respiratory performance and exercise tolerance. Outcomes of airway surgery are also poorer in the overweight patient.[8]

INTRA-OPERATIVE ASSESSMENT OF POST-INTUBATION LARYNGOTRACHEAL STENOSIS

Paediatric LTS is a well-researched area of otolaryngology. Paediatric LTS nearly always involves the subglottis[9] and prolonged endotracheal intubation is by far the most common cause. Treatment strategies include airway augmentation with rib grafts as well as tracheal and cricotracheal resections. The lesional anatomy and pathology behind paediatric LTS differs greatly from the adult group. Adult LTS has been poorly researched and the surgical options include tracheostomy, tracheal resection or cricotracheal resection.[10] Some surgeons still use primary cartilage grafts to augment the adult airway. There appears to be poor appreciation of the fact that there is a high incidence of ischaemic necrosis of primary rib graft in adult patients.[11] Furthermore, the quality and quantity of rib cartilage that can be harvested diminishes with age.

The definitive airway assessment is airway endoscopy. Endoscopic airway assessment is performed by respiratory physicians, thoracic surgeons and otolaryngologists. Pulmonologists and thoracic surgeons are usually trained to use both flexible and rigid bronchoscopes. Flexible bronchoscopy is most commonly performed in the spontaneous breathing and sedated patient who has had topical anaesthetic applied to the upper aerodigestive tract. This technique allows assessment of the dynamic airway, the trachea and bronchi with the ability to perform the full spectrum of interventions. However, with a flexible bronchoscope placed through a narrow stenosis, the patient's airway can become obstructed. Attempted airway dilatation also leads to temporary airway obstruction. Use of the rigid ventilating bronchoscope requires the patient to be paralyzed and ventilation maintained by a face mask, laryngeal mask or endotracheal tube until the bronchoscope is inserted. For assessment of the airway beyond an area of stenosis, the rigid bronchoscope may need to be forced through the stenosis. This has the effect of dilating the stenosis, but also causes stripping of the mucosa. Neither flexible nor rigid bronchoscopy allows prolonged access or endoscopic surgery on the larynx or subglottis. The otolaryngologist is able to utilize suspension microlaryngoscopy, with supraglottic high frequency jet ventilation, in a patient receiving total intravenous general anaesthesia. The microscope provides binocular vision (hence depth of field), better illumination, two hands free for surgery and use of the carbon dioxide laser using a line-of-sight technique. The laryngoscope also allows the use of rigid and flexible endoscopes, fibre lasers, pulmonary balloon dilators, microdebriders and stents. In the event that the patient's oxygen saturations 'dip' an endotracheal tube can be passed via the larynx to achieve positive pressure ventilation. The endotracheal tube is removed to allow completion of airway surgery.

It is important at endoscopy to assess vocal cord mobility and map the stenotic segment. The tip of the endoscope is placed at the lower end of the stenosis and a mark is placed on it at the level of the mouth of the laryngoscope. The endoscope is withdrawn so that its tip lies at the top of the stenosis and again so that its tip lies at the level of the glottis. Each of these points is marked and, with the use of a ruler, the length of the stenosis and its distance from the glottis can be determined. There are techniques for accurately calculating the size of the airway at the level of the stenosis;[12] however, for most purposes the Myer–Cotton grading system[13] allows stratification of airway stenoses to plan treatment (**Figure 76.2**).

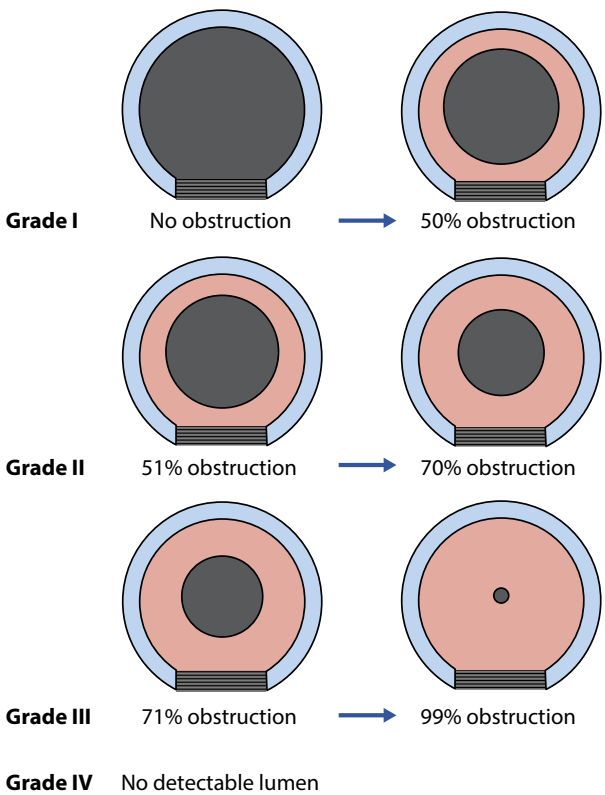

Figure 76.2 Myer-Cotton grading system for subglottic stenosis.

Although the first endoscopy is a staging procedure, some form of surgery is usually possible. Through a combination of imaging (CT) and endoscopy, a decision needs to be made as to whether there is significant damage to the cartilaginous support of the airway at the site of the stenosis. If this is the case then an endoscopic approach, including stenting, will only bring temporary relief of symptoms and an open surgical approach, such as a tracheal, or cricotracheal, resection or laryngotracheal reconstruction (LTR), needs to be considered.

SURGERY FOR POST-INTUBATION LARYNGOTRACHEAL STENOSIS

The majority of patients with post-intubation LTS start with an airway injury that is inflammatory or fibro-inflammatory (**Figure 76.3**).

These types of injury respond well to an endoscopic approach.[14] Using suspension laryngoscopy and supraglottic jet ventilation, up to three millilitres of Depo-Medrone (40 mg/ml) can be injected into the stenosis. Three to four radial cuts are then made into the stenosis using a carbon dioxide laser (8–10 watts) delivered through the operating microscope. The lesion is then dilated, using a pulmonary balloon dilator system, to the size of the adjacent normal airway.

More commonly, at presentation, the majority of cases of airway stenosis have already evolved into mature fibrotic lesion. Intralesional steroids are of limited value if the cartilaginous framework of the airway is intact; in this scenario, an endoscopic approach using radial laser cuts, balloon dilatation and topical mitomycin-C application may still be effective. The procedure usually needs to be repeated every 3–4 weeks until the airway has stabilized. By the third procedure, it is clear to the surgeon if the technique is going to work or whether an open procedure needs to be considered. Overall the endoscopic approach is successful in approximately two-thirds of cases of post-intubation LTS.[14] Failure occurs in cases of significant cartilage framework damage, stenosis length greater than 3 cm, obesity and in patients with swallowing impairment who tend to have persistent airway inflammation. The options are then tracheal (**Figure 76.4**) or cricotracheal resection. Unfortunately, in the adult patient, the maximum length of resection possible is 4–6 cm even with laryngeal and pulmonary release procedures.[15]

SURGERY FOR POST-TRACHEOSTOMY AIRWAY STENOSIS

A less common variant of post-ventilation tube related tracheal stenosis is seen in a small number of tracheostomy patients. This is probably due to over-resection or fracturing of anterior tracheal rings during insertion of a tracheostomy. At decannulation, there is scarring and contracture at the stoma site, which pulls in the lateral tracheal ring remnants leading to a 'lambda-shaped' stenotic deformity and airway compromise. The lesion usually extends over 1–2 tracheal rings with a normal proximal and distal trachea.[16] The trachealis is not involved and there is usually a small anterior bridge not contributing to the stenosis (**Figure 76.5**). Tracheal resection and anastomosis has been recommended for this condition,[17] but this is a major operation with associated morbidity and a small mortality rate.

The lesion can be treated using a CO_2 laser, delivering 8–10 W superpulsed, deployed through a micromanipulator attached to the microscope using a 'line-of-sight' technique. The proximal and distal trachea is used to guide the limits of the resection and the encroaching cartilage is vapourized. A pulmonary balloon dilator may be used to expand the airway. The mucosa over the trachealis and the apex of the Lambda must be preserved, as a circumferential injury with the laser will risk re-stenosis. The patient is usually discharged from hospital the following day with a short course of broad-spectrum antibiotic. The airway is

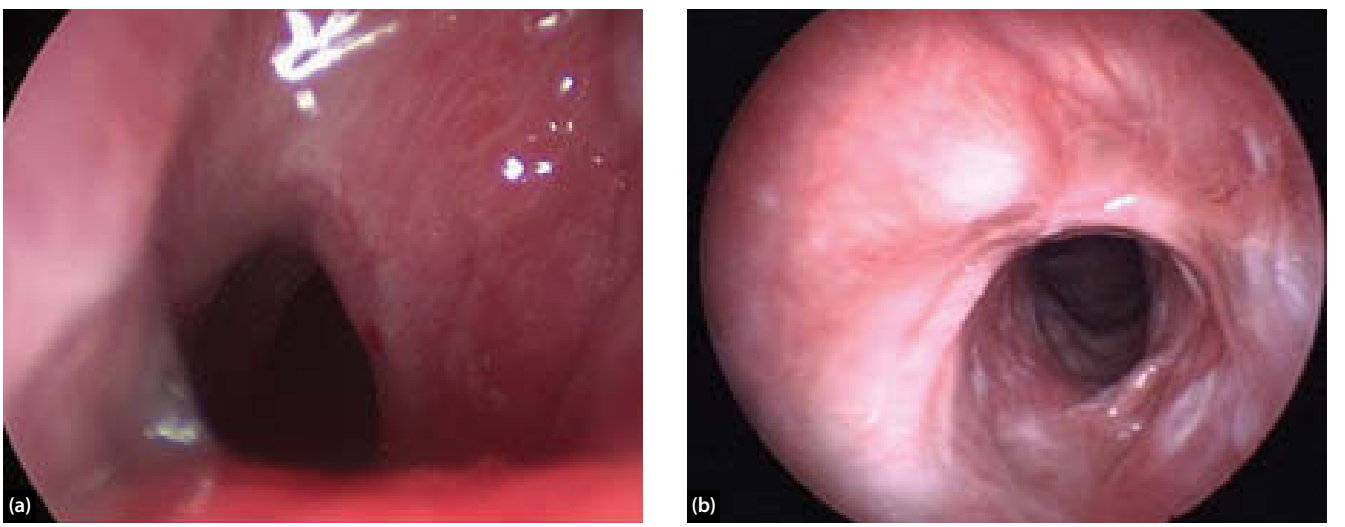

Figure 76.3 A very inflammatory airway stenosis as seen immediately post extubation (a). Stenosis has evolved to be more fibro-inflammatory **(b)**.

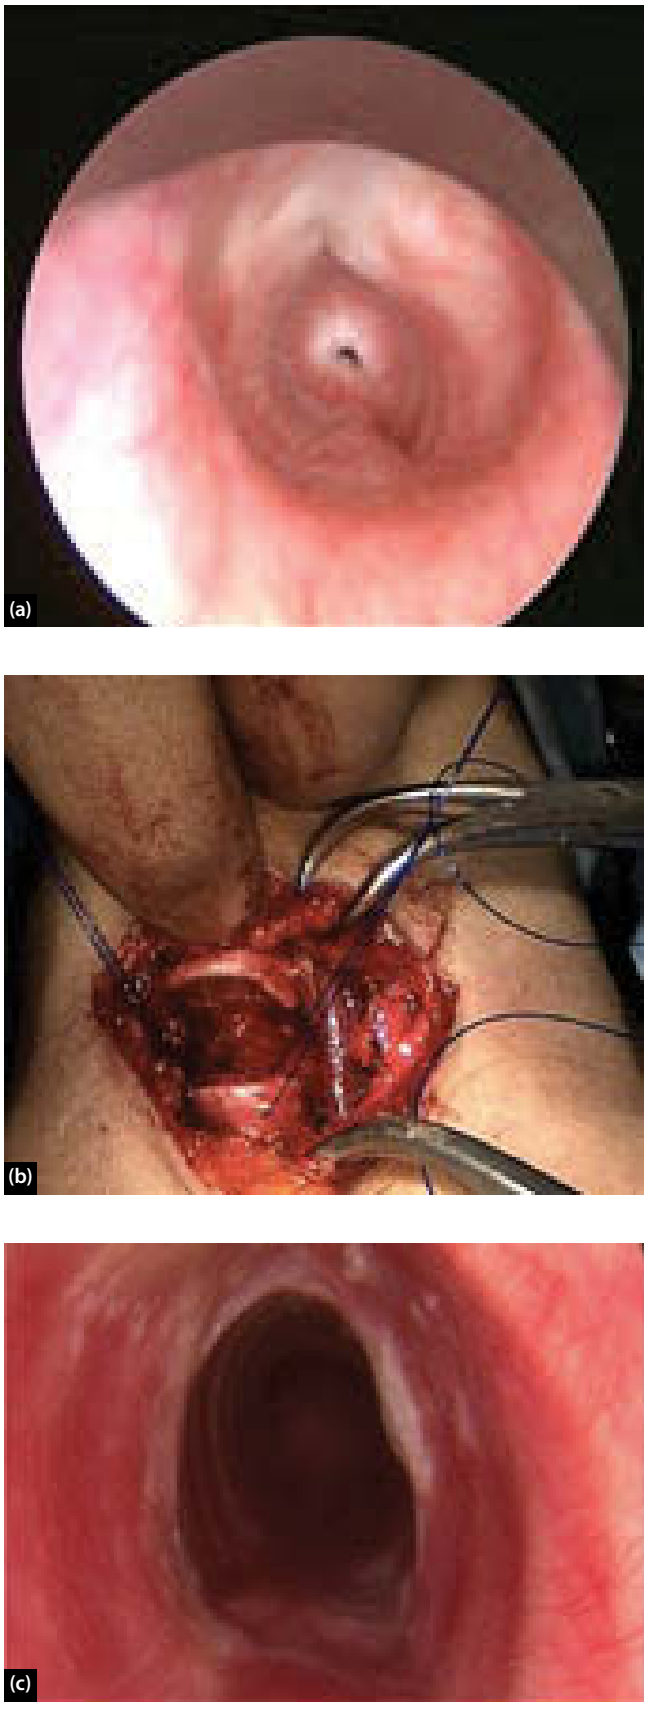

Figure 76.4 A cervical tracheal stenosis that is mature and fibrotic but also with loss of cartilaginous support (a). During a tracheal resection before anastomosis **(b)**. The same patient a few weeks after tracheal resection **(c)**.

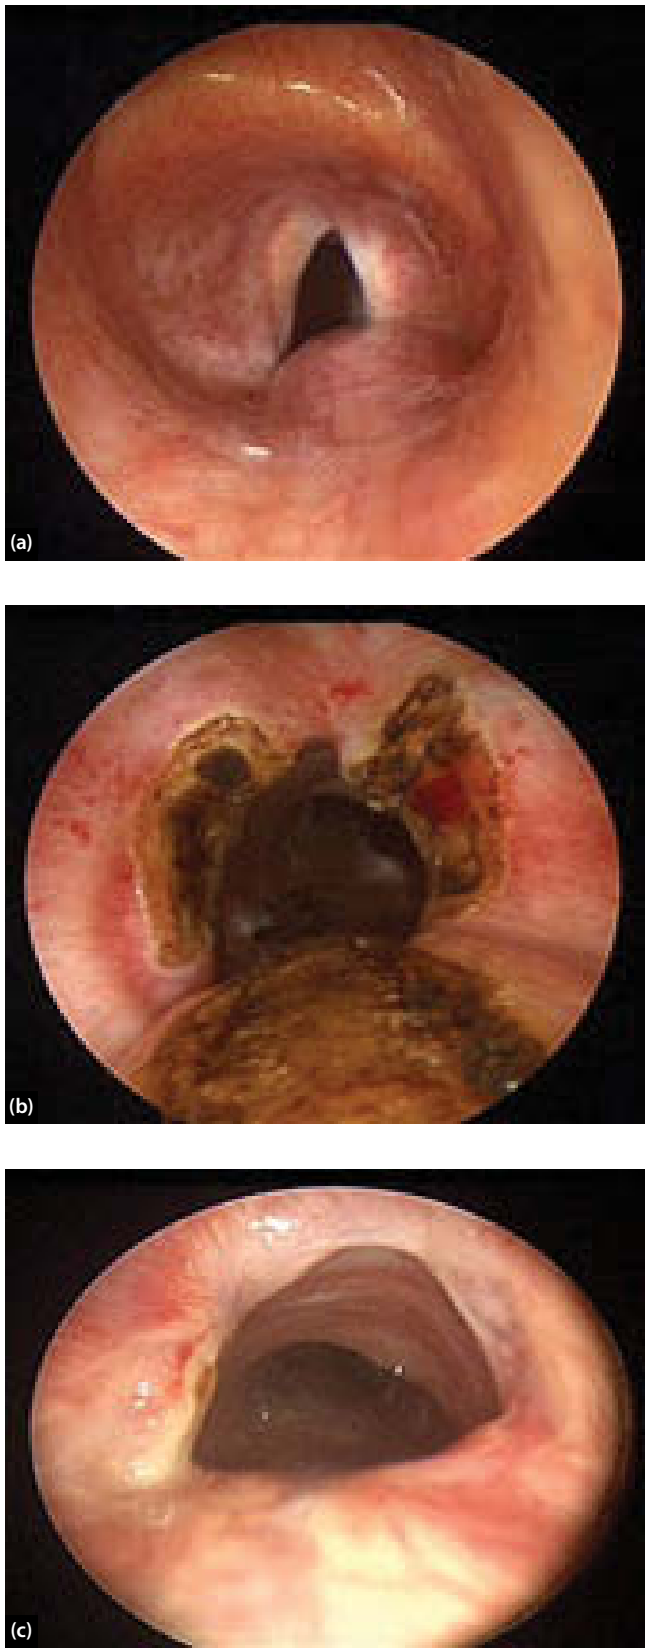

Figure 76.5 'Lambdoid' tracheal stenosis following decannulation (a). Intra-operative view after resection of tracheal cartilages with the CO_2 laser **(b)**. The bulging trachealis is managed with a gentle surface laser. Note bridges of normal mucosa between each site that is lasered. The same patient 3 months after surgery **(c)**.

reassessed, in theatres, at 3–4 weeks. Any residual cartilage or granulation is removed. It is unusual for a patient to require more than three endoscopic interventions for this condition. In these circumstances an open approach to tracheal resection should be considered.

TRACHEOBRONCHIAL STENTING

Charles Thomas Stent was a British dentist in the late 19th century. He developed dental impression material that was used as a template to support skin grafts for repair of oral trauma. Today, the term is used to describe devices for maintaining the patency of tubular structures, including the tracheo-bronchial tree. There is currently a variety of silicone and expandable metal stents for the airway (**Figure 76.6**). The metal stents can be uncovered, covered or partially covered (hybrid). Wire stents tend to be covered with polyurethane, although Teflon sheeting is used in some designs. The next generation of stents will be reabsorbable or bioengineered in other ways, negating the need for subsequent removal.

In benign and malignant disease, stents have been used to palliate the effects of large airway obstruction caused by extrinsic compression, endoluminal disease or loss of cartilaginous support. Indications in benign disease include long length stenoses, failed previous repair, patient comorbidities that restrict reconstructive surgery, or patient preference. Stents are also used temporarily following airway surgery.

Although patients with metal stents enjoy immediate palliation of symptomatic tracheal stenosis, metal stents are associated with a high incidence of obstruction with granulation.[18] They are also susceptible to metal fatigue and fracture over time. The authors recommend that uncovered or hybrid metal stents should only be used in a select group of patients with a short life expectancy.[19] If these stents are not removed within the first few weeks of deployment, they become a permanent fixture in the airway. They can fragment over time and cause granulation and bleeding. Silicone stents are easier to remove but have a higher incidence of migration unless sutured in place.[20] There is a high incidence of bacterial colonization of all stents, which can lead to granular tissue formation,[21, 22] the most common organisms being *Staphylococcus aureus* and *Pseudomonas aeruginosa*. It is widely accepted that wire stents have a higher incidence of granulation formation, especially at their ends. Some authors report that silicone stents have a higher incidence of mucus plugging than wire stents.[18] However, this experience largely relates to the use of stents in the bronchi. In the upper trachea, biofouling and mucus plugging is much greater in wire stents than in silicone stents. This may be due to the relative lower humidity in this area. The incidence of stent migration is widely reported as being higher in the subglottis than in the remainder of the tracheo-bronchial tree. The reason for this appears to be due to the fact that the subglottis is a fixed structure, without the expansion allowed by trachealis.

Usually silicone stents usually have to be placed under general anaesthesia, using a ventilating rigid bronchoscope. The authors use a technique of suspension laryngoscopy with supraglottic jet ventilation and placement of a silicone stent with rigid stent forceps. Visualization is assisted by a 0 degrees, 30 cm Hopkins optical endoscope, which is 4 mm in diameter or a flexible bronchoscope. Wire stents arrive preloaded in delivery devices and can be passed parallel to a flexible bronchoscope

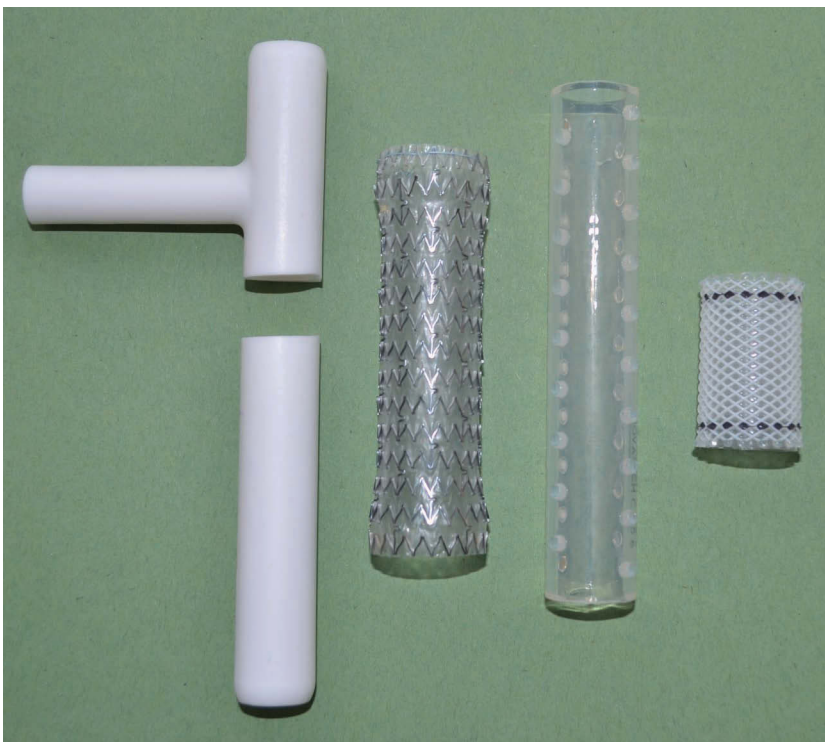

Figure 76.6 Left of image is a silicone stent fashioned from the vertical limb of a T-tube that has to be stitched into the airway. Centre left is a fully covered wire stent. Centre right is a silicone stent with external studs, which are to prevent migration. On the right is a covered mesh stent where the mesh is also made from a plastic polymer.

in a spontaneously breathing, sedated patient, or using fluoroscopic screening techniques. Wire stents can also be inserted under general anaesthesia. Stent removal is easiest using a general anaesthetic technique. This allows the use of rigid biopsy or grasping forceps to firmly grip the stent even if embedded in granulation. Uncovered wire stents that have been in place more than 3 months will usually require an open surgical approach for removal.[18]

Post-operatively, all patients with stents are prescribed daily saline nebulizers. Carbocysteine is added in those patients where there is evidence of mucus plugging.

IDIOPATHIC SUBGLOTTIC STENOSIS

Idiopathic subglottic stenosis (ISS) is a rare, slowly progressive, fibro-inflammatory process of unknown aetiology, leading to narrowing of the airway in the subglottis but also involving the first and second tracheal rings. Embryologically, there does not appear to be any developmental significance to this anatomical site, although it is an area of intense immune activity. ISS should strictly be called idiopathic LTS as it involves the proximal trachea and can extend up to the glottis.

It occurs predominantly in post-pubertal women, but has been reported in males,[23–26] and the majority of reported patients are Caucasians. The diagnosis is one of exclusion. The condition must follow the anatomical description above. There must be no history of intubation or tracheostomy in the last 2 years, no neck trauma or surgery and no neck radiotherapy. In each case, the antineutrophil cytoplasmic antibody (ANCA) and angiotensin converting enzyme (ACE) tests have to be repeated at intervals and prove negative. Tissue for histology is also sent at each surgical procedure to rule out other inflammatory conditions or a low-grade neoplasm.

The treatment approach varies from cricotracheal resection to repeated endoscopic procedures. The majority of patients can be managed with endoscopic airway surgery once or twice a year as described below. Examination under anaesthesia, using suspension laryngoscopy, supraglottic jet ventilation and rigid endoscopes, allows for the dimensions of the lesion to be determined. Up to 3 mL of methylprednisolone acetate is injected into the lesion using an appropriate needle. Three or four radial incisions are made into the lesion using the carbon dioxide laser set at 8–10 Watts. This laser is deployed through a micro-manipulator attached to the operating microscope. Following these radial cuts, the lesion is dilated using a pulmonary balloon dilatation system and the lesion is dilated to 15–16 mm (**Figure 76.7**). A deep tissue biopsy is taken at this stage using microcup forceps and haemostasis is achieved using topical adrenaline.

Aggressive laser ablation of the stenosis is not advised as this will risk more severe stenosis recurrence.

Cricotracheal resection has been used to treat this condition with reported good results[24] but others have failed to duplicate these outcomes.[26] ISS is primarily a mucosal disease that overlies healthy perichondrium and cartilage.[27] There is also concern that cricotracheal resection in a condition that predominantly affects females is likely to leave these patients with 'male-type' voices after the surgery.[28] Moreover, cricotracheal resection conceptually treats this condition as a benign neoplasm and, in our series, the disease often extends up to the glottis (**Figure 76.7**, left) and it is difficult to conceive how a resection could be performed within millimeters of the vocal folds without causing damage to this area.

With have described a different approach, which can be used to permanently treat all variations of this condition. A laryngofissure and posterior cricoid split is performed. The majority of the stenosed mucosa is removed and a piece of costal cartilage is placed as a 'spacer' to expand the posterior cricoid split (**Figures 76.8** and **76.9**).

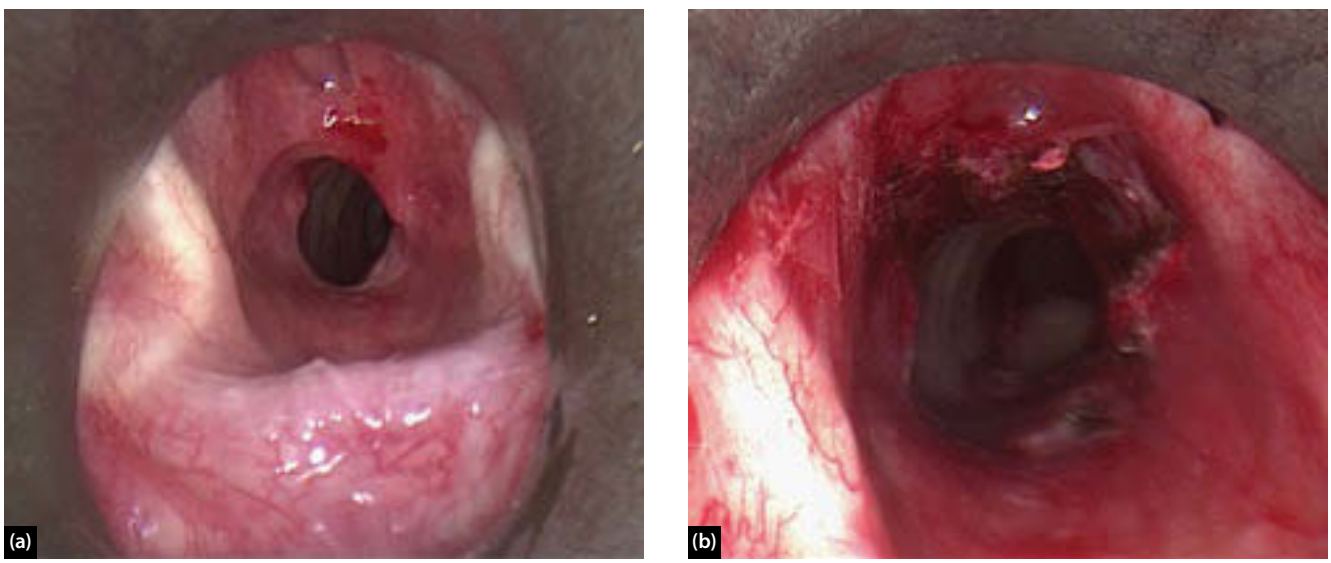

Figure 76.7 Idiopathic subglottic stenosis (a). The same lesion after steroid injection, radial cuts with the CO_2 laser and balloon dilatation **(b)**.

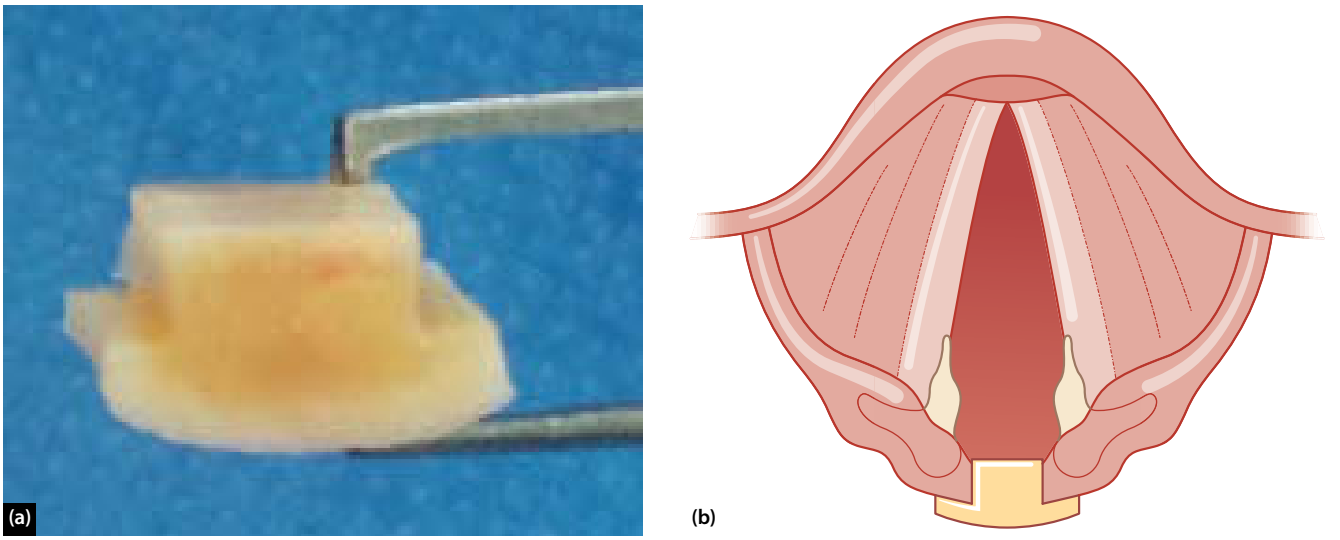

Figure 76.8 A costal cartilage 'spacer' (a), which is placed in a posterior cartilage split through a laryngofissure approach **(b)**.

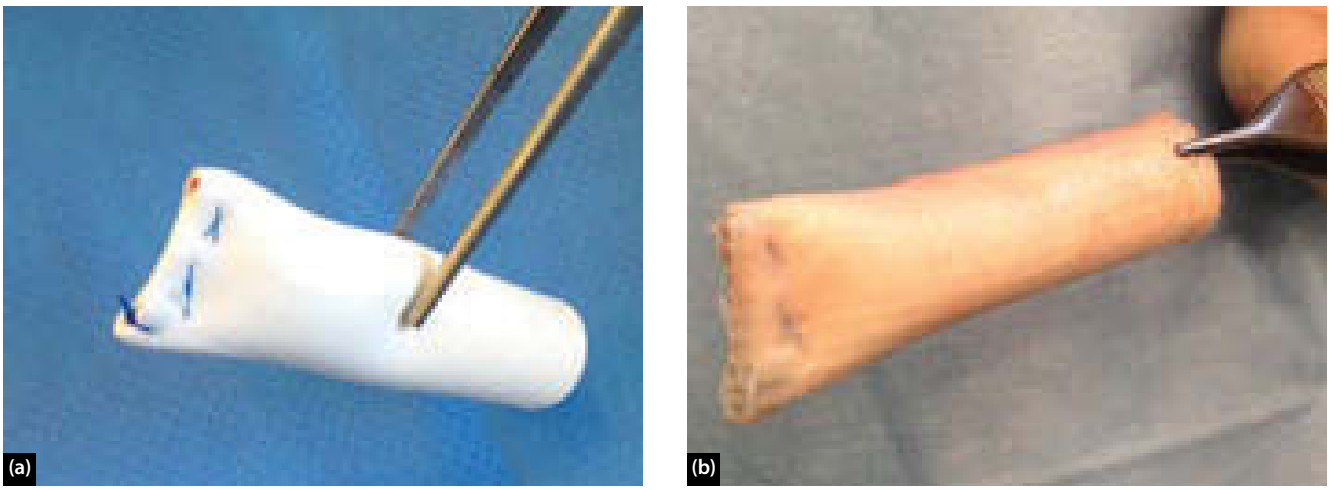

Figure 76.9 A section of silastic T-tube closed at one end with nylon suture (a). The same stent covered with superficial skin graft with epidermis against stent **(b)**.

A closed laryngeal stent, covered with a superficial skin graft is held in place with a single, strong, nylon suture.[20]

A temporary tracheostomy is required because there is no airway through the larynx once the laryngofissure is closed. Two weeks later the stent is removed endoscopically, followed by routine decannulation. The technique appears to work because keratinocytes colonize the parts of the airway where the diseased mucosa was excised and have a strong antifibrotic activity.

MITOMYCIN-C

Mitomycin-C (MMC) is derived from the *Streptomyces caespitosus* bacteria with the ability to modify wound healing at the molecular level and has been used to inhibit post-surgical scar formation. Available since the 1960s as a systemic chemotherapeutic agent in the treatment of solid tumours, MMC was first applied topically for the treatment of superficial bladder tumours. It was first reported in the ENT literature for the treatment of tracheal scarring after tracheal reconstruction in a small case series.[29] Several randomized prospective animal studies have shown impressive results in prevention of postoperative glottic and subglottic stenosis following surgery to the airway.[30–33] Its use in airway surgery has become fairly routine, despite no randomized controlled trials proving its efficacy. The authors have used MMC at concentrations of 1 mg/ml applied topically for 3 minutes in many hundreds of airway cases. Owing to lack of clear evidence of improved outcomes and continuing uncertainty about long-term toxicity we have stopped use of the drug.

GRANULOMATOSIS WITH POLYANGITIS

Granulomatosis with polyangitis (GPA) was formerly called Wegener's granulomatosis (WG) and is an immune disorder characterized by inflammation of small and

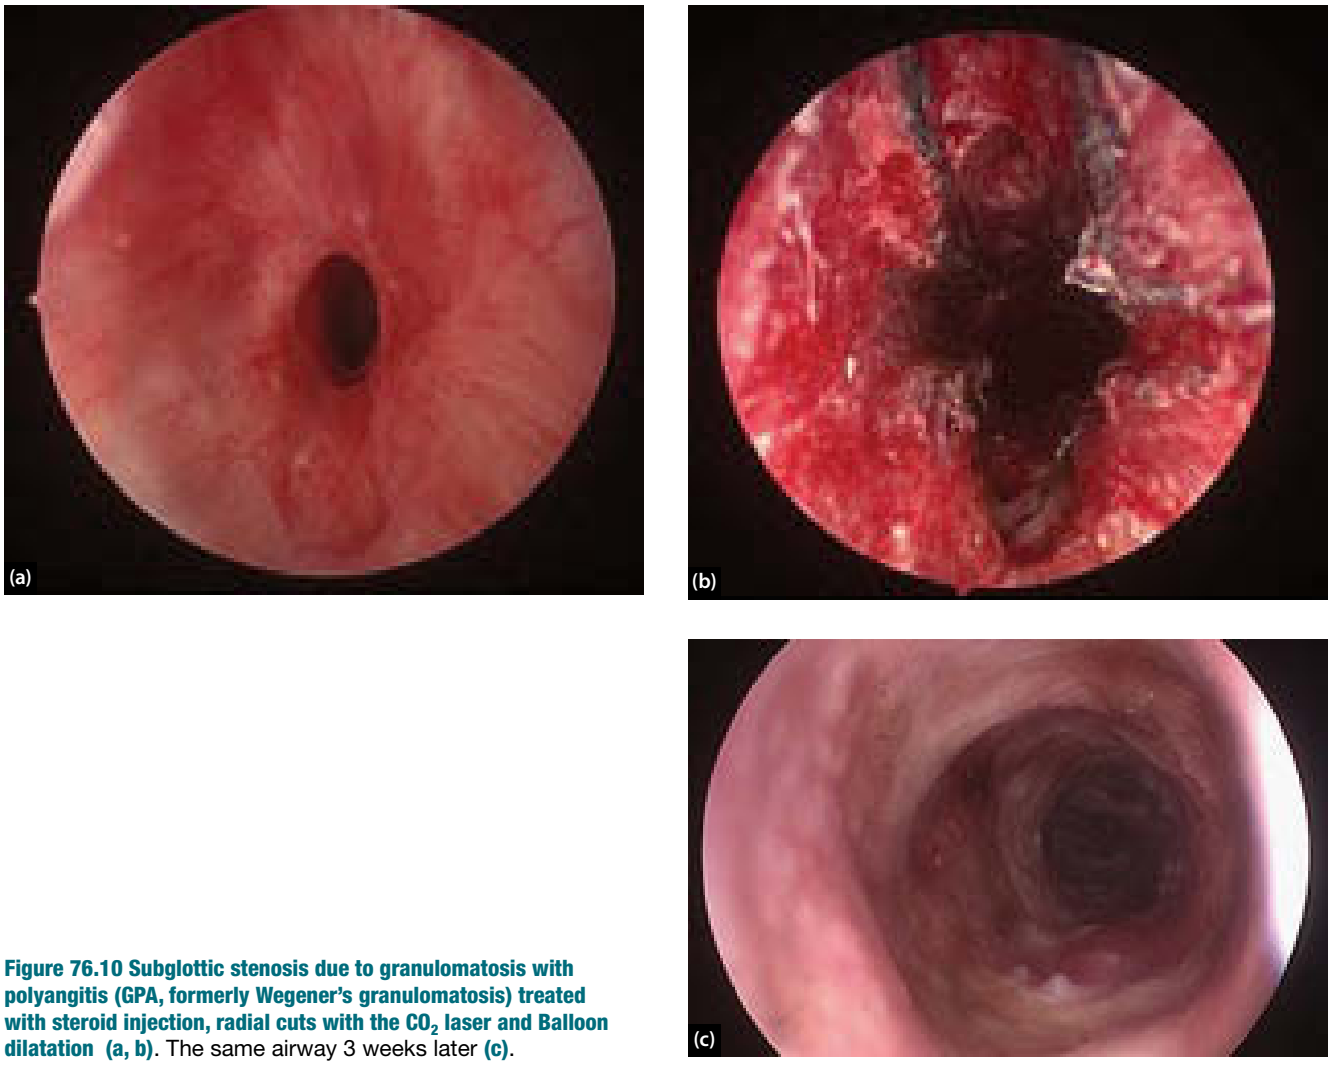

Figure 76.10 Subglottic stenosis due to granulomatosis with polyangitis (GPA, formerly Wegener's granulomatosis) treated with steroid injection, radial cuts with the CO_2 laser and Balloon dilatation (a, b). The same airway 3 weeks later **(c)**.

medium sized vessels. Most patients have some otolaryngological manifestations but also involvement of the lungs and kidneys and there may be an element of renal failure. The presence of a positive cytoplasmic antinuclear cytoplasmic antibody (cANCA) test may aid in the diagnosis, but positivity is not conclusive and negative ANCA results are not sufficient to reject the diagnosis. The diagnosis is sometimes made on clinical presentation when a patient has had the appropriate symptoms for a prolonged period. A definitive diagnosis of GPA can be made by a biopsy of suspicious lesions (demonstrating granulomatous inflammation) in conjunction with positive serological analysis. However, it must be recognized that up to 20% of patients with untreated active GPA lack cANCA[34] or may show positivity later on in the disease history.

Approximately 25% of patients have involvement of the larynx, trachea and bronchi causing localized narrowing. Intra-lesional corticosteroid injections, radiate lesion cuts and dilatation (**Figure 76.10**) will treat the majority of new stenoses.[35]

The use of tracheostomies and long-term stents can lead to airway complications that are difficult to treat.[10, 36]

SARCOIDOSIS

Cesar Boeck of Christiania, Denmark was the first to describe this multi-system disease in 1899.[37, 38] The disease is a non-caseating granulomatosis disorder with a worldwide distribution and can affect any race, ethnicity, gender or age group. Patients are typically aged 20–40 years, and there is a female to male ratio of 2 : 1 and a predilection for black African Americans.[38] Otolaryngologic involvement occurs in < 3% of cases and can occur in isolation or as part of a widespread disease.[39] Laryngeal sarcoidosis may be underdiagnosed and has a variable incidence reported between 1% and 5%.[40–43]

The pathophysiology behind sarcoidosis remains unknown. Current hypotheses propose sarcoidosis to occur in generally susceptible individuals through alterations in immune responses after exposure to various 'triggering' agents. The diagnosis of sarcoidosis depends on the presence of typical clinical features and non-caseating granulomatous inflammation on biopsy of diseased tissue with the exclusion of other known causes of granulomas, including tuberculosis, leprosy, syphilis and fungal disease.

Figure 76.11 Supraglottic larynx in sarcoidosis. Demonstrating epiglottis and aryepiglottic folds 'swollen' with disease. Below is the subglottic jetting cannula in place during suspension laryngoscopy.

Anatomically, laryngeal sarcoid has a predilection for the supraglottic region, particularly the epiglottis, aryepiglottic folds and arytenoids (**Figure 76.11**). The macroscopic appearance of the supraglottis is diffusely thick, oedematous and characteristically pale or pink in colour. These features are considered pathognomonic for this condition.[40] Although exophytic, polypoidal, nodular and granulating lesions have been described, these are less common.[42] Isolated involvement of the glottis is exceedingly rare.[44] Vocal cord paralysis is also reported as a result of perineural invasion or multiple cranial nerve polyneuritis.[40] Laryngeal disease tends to progress slowly with a relapsing and remitting course. Macroscopically laryngeal lesions may appear to persist despite overall remission and this is thought to be due to tissue fibrosis.

High dose systemic steroids have been recommended as the first line treatment of laryngeal sarcoid. Endoscopic laser reduction has been used as a last resort where conservative therapy has failed. Our technique for managing laryngeal sarcoidosis has led to a reduction or cessation of systemic steroids and decannulation in the majority of cases.[45] The procedure is performed using total intravenous general anaesthesia with suspension laryngoscopy and a subglottic or supraglottic high frequency jet ventilation technique. The larynx and airway are visualized using a combination of microscope and a rigid optical endoscope. 1–3 ml Depo-Medrone (methylprednisolone acetate), at a concentration of 40 mg/ml, is injected into the lesion at multiple sites and evenly through its depth, using a microlaryngoscopy injection needle. The end point of injection should produce almost complete blanching of the lesion. Following infiltration volumetric lesion reduction is achieved using the carbon dioxide laser at a continuous setting of 8–10 W, delivered via the microscope. This brings about immediate airway improvements and the combination of healing and the steroid produce further reductions in disease bulk. Any pedunculated lesions encroaching into the airway are removed and sometimes radial 'releasing' laser cuts are necessary. It is important not to create a circumferential injury in or around the laryngeal inlet as this has the potential to produce airway narrowing through scarring. Multiple narrow pits are created with the CO_2 laser ('pepper pot' pattern) separated by 2–3 mm and extending to the depth of the lesion. Most patients require on average of two treatments (range 1–4) separated by 3–4 weeks.[45]

BILATERAL VOCAL CORD MOBILITY IMPAIRMENT

Bilateral vocal cord mobility impairment (BVCMI) can produce reasonable voice but with some degree of dyspnoea as the vocal cords tend to lie in the median or paramedian position. Bilateral abducted cords are usually seen in neurological conditions and management is aimed at preventing aspiration, see Chapter 56, Chronic aspiration.

There are three principal causes of impaired vocal cord function:

- bilateral laryngeal denervation (neck and chest malignancy or thyroid surgery)
- bilateral cricoarytenoid joint fixation (trauma or rheumatoid arthritis)
- inter-arytenoid scarring (following endotracheal intubation).

Surgery is directed at improving the aperture of the posterior glottis. For bilateral denervation injuries we have had significant success with an endoscopic partial posterior cordectomy and partial arytenoidectomy using the CO_2 laser. The resection can be unilateral or bilateral (**Figure 76.12**).

The voice does become 'breathier' but remains functional. Destructive laryngeal surgery should only be considered when the possibility of spontaneous recovery has been ruled out and the patient has a safe swallow. Where there is potential for recovery, and a severely compromised airway, a temporary tracheotomy may need to be considered or the use of vocal cord suture lateralization procedures,[46] each of which are reversible. Various reinnervation operations have been described and the most promising technique uses the accessory phrenic nerve and anastomosing to the posterior cricoarytenoid muscle.[47] Other groups are looking at reanimating the human larynx with implantable electrical stimulation devices.[48]

With fixed cricoarytenoid joints the only surgical option is some form of laser to the posterior cord or arytenoid as described above.

Posterior glottic injuries can result in interarytenoid scar tissue, which in turn can lead to cricoarytenoid joint ankylosis, unless identified and treated early. The most common cause for this type of injury is endotracheal intubation and this is a reason for early tracheostomies on the ICU. Attempts at repairing the posterior glottis have included posterior laryngeal mucosal flaps, advanced into the post glottis, after division of the scar tissue. Unfortunately, all the procedures to correct this problem

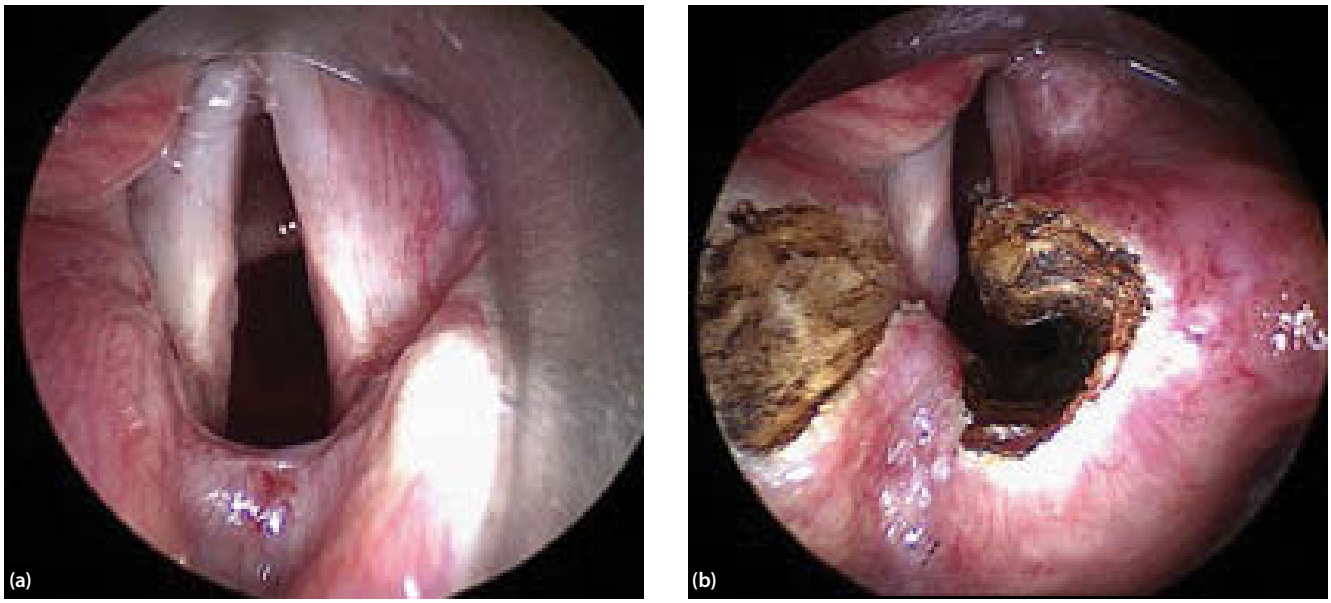

Figure 76.12 Larynx in bilateral cord palsy with the cords separated by the laryngoscope (a) Partial right laser arytenoidectomy with reduction of overhang from left arytenoid **(b)**.

lead to a compromise between voice airway and swallowing. Our preferred technique is the placement of a costal cartilage derived 'spacer' within a posterior cricoid split, through a laryngofissure approach.

FUTURE PROSPECTS

Up to 6 cm of trachea can be resected[17] in the adult with primary anastomosis. There is currently no solution to the repair of damaged tracheas beyond this length or where previous resections have failed. Tissue engineering[49] and tracheal allotransplantation[50] are two techniques that may provide future treatment options for these difficult cases. Laryngeal transplantation may be a solution to restoring the airway where this organ is dysfunctional or damaged beyond repair.[51]

Biotechnology may provide synthetic airways or scaffolds to deal with tracheomalacia and long length tracheal replacements in the more distant future. Biointegratable stents could be an even simpler solution for the management of airway stenosis.

Until these technologies are proven and widely available, prevention of laryngotracheal airway damage is important. This means appropriate sizing of endotracheal and tracheostomy tubes, monitoring cuff pressures and early change to tracheostomies in patients destined for prolonged ventilation. Also, early recognition and treatment of airway injuries, when they do occur, carries a greater chance of successful outcomes.

KEY POINTS

- The most common cause of laryngotracheal stenosis is a period of intubation and ventilation on the intensive care unit.
- The incidence of laryngotracheal stenosis is similar in patients who receive an earlier tracheostomy on the intensive care unit vs those that continue to be ventilated with an endotracheal tube. The difference is the stenosis is less likely to involve the glottis if the patient has a tracheostomy.
- Many of the cases of the stenosis due to systemic inflammatory diseases should and can be managed endoscopically, avoiding tracheostomies, stents and laryngotracheal reconstruction.
- Where an airway disease or trauma has damaged the cartilaginous framework of the larynx and trachea, endoscopic surgery is unlikely to restore a normal airway. These patients will usually require tracheal or cricotracheal resections, or laryngotracheal reconstruction.
- Airway stents are not a good long-term solution to laryngotracheal stenosis, as they are prone to migration, fouling and in the case of metal stents, fragmentation and granulation.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: laryngopharyngeal reflux, extra oesophageal reflux, laryngeal reflux, silent reflux, acid laryngitis and globus pharyngeus.

INTRODUCTION

Laryngopharyngeal reflux (LPR), caused by the backflow of gastric contents into the upper aerodigestive tract, is frequently diagnosed as a cause of throat symptoms in ENT patients, although there remains a degree of controversy surrounding the subject. The condition was first described by Koufman in 1991.[1] Since then, there has been a wealth of excellent basic science research describing the underlying disease process, but the diagnosis and management of this condition is less clear.[2]

In the oesophagus, a degree of gastro-oesophageal reflux is considered physiologically normal, as long as the exposure time does not exceed 5% in 24 hours. Although the oesophagus is lined by resilient stratified squamous epithelium, the tissue damage is thought to be acid mediated; however, mechanisms exist that physically remove and chemically neutralize the refluxed bolus. A proportion of gastro-oesophageal reflux disease (GORD) patients (possibly as many as two-thirds) have a variant known as non-erosive reflux disease (NERD) in which frank oesophagitis is absent.[3] In classical GORD, reflux typically occurs in the supine position.

In contrast, the larynx is lined in part by areas of very delicate squamous epithelium, and elsewhere by respiratory epithelium, both of which are far less resilient than the oesophageal mucosa. Refluxate, when present, is neither removed by peristalsis nor neutralized by bicarbonate. Tissue damage is thought to be mediated by activated pepsin, and can occur very rapidly following exposure times, which may be as brief as 30 seconds 3 times per week.[1] Reflux disease that affects the laryngopharynx (LPR) is one form of extra-oesophageal reflux (EOR). LPR events often occur in the upright rather than supine position.

Although GORD and LPR may exist independently, as disease severity increases the likelihood of both types being present increases.[4]

This chapter will concern itself mainly with the management of LPR. Other forms of EOR have been described, including reflux-associated cough, nasal and sinus disease, and glue ear. Manifestations of reflux disease in paediatric ENT practice are described in Volume 2, Chapter 44, Reflux and eosinophilic oesophagitis.

PATHOPHYSIOLOGY

Gastric refluxate is often considered solely in terms of its acid content, but in addition to hydrochloric acid it also contains enzymes (notably pepsin), food residues, bile acids and bacteria. Reflux episodes may involve significant volumes of liquid gastric contents, particularly in the lower oesophagus, but in the laryngopharynx may be mainly gaseous, containing a fine aerosol of droplets.[5] Such episodes may be triggered by transient lower oesophageal sphincter relaxations. Once the aerosol has reached the laryngopharynx, it then has easy access to the nose, nasopharynx and lower respiratory tract.

Pepsin

Pepsin is secreted in the form of pepsinogen, which is physiologically inactive. It is activated by cleavage in an acid environment (pH < 4). It had long been thought that pepsin was only active in a highly acidic environment (pH < 4), but recent research using human rather than porcine pepsin shows that, once activated, significant activity remains almost up to neutrality (pH = 7).[6] Even at this level, the enzyme is not damaged, and can be reactivated by a fall in pH. It is not irreversibly deactivated until pH > 8. Pepsin binds to mucosa, and is even taken up into epithelial cells by endocytosis. If the pharynx or larynx is coated with refluxate after a reflux event, pepsin activity gradually decreases as the pH drifts toward neutrality, but can be quickly reactivated by another event, or by ingestion of an acidic bolus. Cola drinks, for instance, have a pH of < 2. As pepsin is active at higher pH levels than previously thought possible, investigation techniques that rely on a pH threshold of 4–4.5 may miss weakly acid or non-acid episodes that can cause tissue damage.

Other components of refluxate

Hydrochloric acid may be present in concentrations that can be affected by medication, notably proton pump inhibitors (PPI). Pancreatic proteases (especially trypsin) may be present, especially in patients who have had gastrectomy or gastroenterostomy, or who are taking PPIs. Bile acids are mainly in conjugated form, but free bile acids can cause tissue damage.[6] Partly digested food residues and bacteria, notably *Helicobacter pylori*, may have some relevance.

LPR DIAGNOSIS

Most patients with LPR are diagnosed on clinical grounds, following outpatient assessment including history taking and examination with flexible or rigid laryngeal endoscopy.[7] In the UK, further investigations for clinically diagnosed LPR are usually reserved for a subset of patients in whom the diagnosis is in doubt, or there is failure to respond to treatment.

SYMPTOMS

LPR symptoms are shown in **Box 77.1**. It is recommended that a structured symptom questionnaire is used at each consultation, and the score documented. The document in most widespread use is the Reflux Symptom Index (RSI).[8] Although it is fairly sensitive, it has limited specificity, as other conditions that produce laryngeal inflammation will also produce a high score. Other causes of laryngeal inflammation are shown in **Box 77.2**. It must always be borne in mind that LPR is only one cause of an inflamed larynx. Most patients with LPR will have a combination of throat symptoms, which will be demonstrated by the RSI. Those with a single symptom, for example globus pharyngeus, will produce a low RSI score and be less likely to have significant LPR (**Box 77.3**).

BOX 77.1 LPR symptoms

- Dysphonia
- Swallowing difficulty ('pseudodysphagia')
- Globus/feeling of lump in throat (FLIT/FOSIT)
- Throat clearing/tickle in throat
- Sore throat
- Cough/choking
- Thick mucus in throat, 'post nasal drip' or 'catarrh'
- Laryngospasm/cough syncope

BOX 77.2 Causes of laryngeal inflammation

- Reflux disease
- Smoking/inhaled irritants
- Alcohol
- Allergy
- Virus infections
- Voice abuse

BOX 77.3 RSI scores

Hoarseness or problem with your voice	0–5
Clearing your throat	0–5
Excess throat mucous or postnasal drip	0–5
Difficulty swallowing food, liquids or pills	0–5
Coughing after you have eaten or after lying down	0–5
Breathing difficulties or choking episodes	0–5
Troublesome or annoying cough	0–5
Sensations of something sticking in your throat or a lump in your throat	0–5
Heartburn, chest pain, indigestion or stomach acid coming up.	0–5

Score: 0, no problem; 5 a severe problem. Total score: >10 may indicate a problem with LPR[8], >20 moderate and >30 severe.

EXAMINATION FINDINGS

The clinical examination of a patient with symptoms suggestive of LPR will include an outpatient fibre-optic endoscopy of the larynx and hypopharynx.

A variety of features have been described as being attributable to the effects of LPR. In general, elements of erythema and/or oedema seen in various locations throughout the laryngopharynx may be caused by LPR.[9] These have been summarized in the Reflux Finding Score (RFS) (**Box 77.4**).[10] Each of the items is scored by an observer. Out of a potential score of 26, Belafsky et al. consider a score of >7 to indiceate LPR.[10]

Some authors report the RFS as demonstrating a reliable correlation with symptoms and response to treatment,[10] although there remains some controversy as to its reproducibility as an accurate tool as others report less reliable correlation.[9]

BOX 77.4 Reflux Finding Score (RFS)

- Infraglottic oedema (*pseudosulcus vocalis*)
- Ventricular obliteration
- Erythema/hyperaemia
- Vocal fold oedema
- Diffuse laryngeal oedema
- Posterior commissure hypertrophy
- Granuloma or granulation
- Thick endolaryngeal mucus

A review of data from meta-analyses reveals laryngeal mucosal findings in 38.2–51.2% of patients with symptoms of reflux laryngitis.[11]

Other studies, however, have noted these findings to be prevalent in the general population with a high rate of abnormal findings in asymptomatic people. A recent review of mucosal signs in LPR highlighted similar proportions of normal and patient populations with reported laryngeal mucosal changes – or increased RFS.[12]

Similarly, laryngeal abnormalities have also been reported in 64–86% of normal controls.[13] In addition, the non-specific nature of these signs means they can also be seen secondary to several other causes: smoking, infection, alcohol, allergies, asthma and voice abuse.[14] A recent study of asymptomatic singers identified a high percentage of laryngeal abnormalities, thus recommending caution when using mucosal signs alone to diagnose LPR.[15]

Similarly, laryngeal findings are seen in patients with GORD (18.9–85%) with posterior larynx and posterior pharyngeal wall findings being the most common.[11]

No single sign appears to be pathognomonic of LPR; however, the presence of pseudosulcus or Reinke's oedema in *symptomatic* patients may be an indicator of LPR. (Positive predictive value (PPV) 67–90% for pseudosulcus in the presence of laryngeal symptoms.)[16] Recent work also suggests a possible new sign of a mucosal white line in the nasopharynx may be useful in identifying the presence of reflux affecting the pharynx.[17]

There remains, therefore, a significant amount of controversy around the reliability of examination findings in making the diagnosis of LPR.[11] Clinical symptom reporting, including the use of symptom scores such as the RSI, may correlate better with this subjective condition.[18] While the use of RFS has shown some inter-rater reliability, one must exercise caution when using mucosal signs alone to make the diagnosis of LPR. Using these examination findings to complement information gained from clinical history and symptom scores, as well as a tool to monitor the patient response to treatment, is probably a more reasonable approach.

INVESTIGATIONS

Following appropriate clinical assessment supplemented by appropriate questionnaires, several investigations have been reported in LPR.

Imaging

Barium swallow has traditionally been used for assessment of throat symptoms, including globus pharyngeus and those associated with LPR. It is no longer very widely used in this setting as swallowing a large bolus of dense liquid on an empty stomach and then tilting the patient head down to see if reflux occurs is probably not physiologically representative of events in normal life. It is still useful if dysphagia for solids is present, and is the investigation of choice if pharyngeal pouch is suspected. Videofluoroscopy is a valuable investigation for neuromuscular swallowing disorders, but not usually for LPR.

Functional tests

The Bernstein acid perfusion test involves passing a nasogastric tube into the lower oesophagus and instilling 0.1 M hydrochloric acid solution. If the patient then reports chest pain similar to his/her symptoms, then this would confirm that the cause is GORD rather than cardiac disease. It is no longer used for this purpose but has re-emerged as a research tool in recent years for reflux-related lower respiratory tract symptoms.

Pepsin testing

As LPR is thought to be pepsin mediated, testing for its presence in the larynx and pharynx is a logical development. Biopsy specimens can be stained for the presence of pepsin, but this requires an invasive procedure and is not used outside research programmes. A test is now available for the presence of pepsin in pharyngeal secretions (Peptest; RD Biomed Ltd, Hull, UK). This test is entirely non-invasive, and is easy and relatively cheap to perform. The patient expectorates pharyngeal secretions into a specimen tube containing a citric acid buffer. After mixing and centrifugation, the specimen is placed on a test strip and read after approximately 15 minutes. A positive result is strongly predictive for the presence of LPR, although a negative result does not exclude.[19] Examination of more than one specimen for each patient may increase diagnostic accuracy. Pepsin can also be detected in nasal secretions and exhaled breath condensate in ventilated patients using the same technique.

Manometry

Although oesophageal manometry is not itself helpful in the diagnosis of LPR, it is usually performed prior to pH monitoring (see the next section) to identify the position of the upper and lower oesophageal sphincters to aid electrode placement. High-resolution techniques give more detailed information on oesophageal function. Some patients with symptoms of LPR who do not respond to treatment will be found to have oesophageal dysfunction as their underlying problem.[20]

pH and impedance monitoring

For some years the 'gold standard' investigation was thought to be 24-hour dual-channel pH monitoring, with electrodes at the level of the upper sphincter, and in the lower oesophagus just above the lower sphincter.[21] A range of normative values have been published, with some authors suggesting that 4 episodes/24 hours at the

upper electrode are required for LPR diagnosis, and others suggesting that a single episode is sufficient. In practice, many patients have multiple episodes, enabling the diagnosis to be made easily, with only a small number falling into the 1–4 episodes/24 hours range.

The main limitation of pH monitoring alone is that the pH threshold is set at pH4 or 4.5: this test will therefore fail to identify weakly acid (pH4.5–7) or non-acid (pH>=7) events. Multichannel intraluminal impedance (MCII) monitoring, which adds an array of electrical impedance electrodes to the test catheter, can be added to dual channel pH monitoring, and may increase diagnostic accuracy by recording all reflux events. Once again, normative data are not standardized and like pH monitoring, MCII is an invasive and expensive test that some patients cannot tolerate.

A less expensive and better-tolerated technique is airway pH monitoring (Restech; Respiratory Technology Corp., San Diego, CA, USA). This uses a small catheter with a probe placed at the level of the soft palate, which is used to produce a 24-hour recording. Although results were initially promising,[22] more recent work has cast doubts on the reliability of this method.[23]

TREATMENT

Possible treatments for LPR include dietary and lifestyle measures, medical treatments and antireflux surgery.

Diet and lifestyle

There is good evidence that alteration of diet and lifestyle can improve LPR symptoms,[24] and this aspect of treatment should be stressed to all patients. The main points are shown in **Box 77.5**. Consumption of alkaline water has recently been advocated but is as yet clinically untested.[25] An advice session from a suitably trained speech and language therapist (which may be delivered on a group or individual basis) can improve compliance[14] and, if hoarseness is a significant symptom, voice therapy can also help.[26] As well as giving patients written advice on lifestyle measures, online resources are also available.

Medical treatments

This is perhaps the most contentious issue in relation to LPR. There is, as yet, no drug that acts directly against pepsin, which is thought to be the causative agent. Drugs currently available to prevent reflux episodes and improve oesophageal function (metoclopramide, domperidone) are much less effective than cisapride, which is no longer available due to toxicity problems, and recently limitations have also been imposed on the use of domperidone. Antacids alone have little effect, and the role of acid suppressant drugs (particularly PPIs) is controversial,[27] with some authors advocating their use[28] and others claiming they are ineffective.[29] PPIs are the treatment of choice for patients with GORD, which is thought to be acid mediated, but in LPR their effect is at best indirect by raising gastric pH to reduce activation of pepsin by cleavage of pepsinogen. Simply telling a patient that their symptoms are due to LPR and issuing a prescription for PPIs is unlikely to achieve a good outcome. Barrier agents (such as alginate) can be used to protect the mucosa of the oesophagus and upper aerodigestive tract.

BOX 77.5 Diet and lifestyle advice

- Give up smoking.
- Reduce alcohol intake. Spirits, white and rosé wine are particularly irritant.
- Avoid carbonated drinks (even carbonated water) and fruit juice.
- Reduce caffeine intake.
- Avoid fatty foods (anything fried, chips, cheese, pastry, chocolate).
- Elevate the head of the bed at night.

Proton pump inhibitors

Proton pump inhibitors (PPIs) are in common usage for treatment of LPR, particularly as part of a combined management strategy including diet and lifestyle advice as described earlier. An example of such a strategy is given in **Figure 77.1**. Although clinical trials have so far produced conflicting results as to the benefits of using PPIs, they are cheap (in the UK, generic pantoprazole currently costs approximately £1.30 for a box of 20 mg tablets) and generally well tolerated, although diarrhoea may be more of a problem with lansoprazole than other agents. In longer-term use, and particularly in high dosage, increased incidence of pneumonia, *Clostridium difficile* infection and osteoporosis have been described.

PPIs exert their effect by blocking the production of H^+ by the gastric glands. In GORD, they are highly effective at controlling symptoms in once-daily dosage. As described above, this is an acid-mediated disease, and the oesophagus can tolerate an acid pH for up to 5% of each day.

In LPR, by contrast, the aim of PPI therapy in LPR is to prevent the activation of pepsin. As mucosal damage can occur with short-lived reflux episodes, 24-hour coverage is necessary, and twice daily dosage is needed to achieve this as the drugs currently available are only active for 12–14 hours after each dose. PPIs are most effective if taken before food, as the drug needs to be present in the plasma when the proton pumps of the gastric glands are activated. It is therefore recommended that, if used, PPIs are given 30 minutes before breakfast and evening meal. Symptomatic improvement may take much longer than in GORD, and so a treatment trial of at least 2–3 months is required. A total treatment time of approximately 6 months has been advocated for responders,[30] and with the recognition of acid rebound if PPI therapy is discontinued abruptly,[31] tapered withdrawal may be more appropriate (**Box 77.6**).

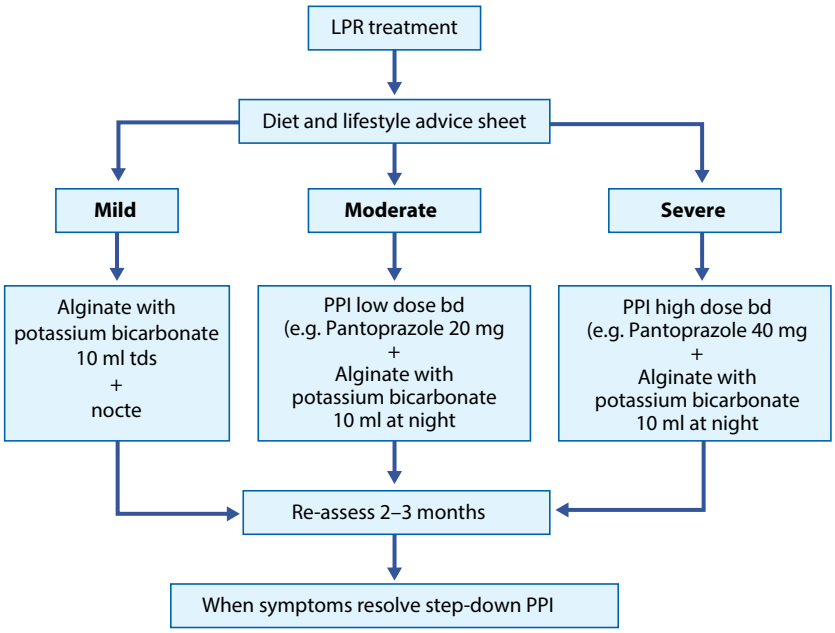

Figure 77.1 Combined treatment strategy.

BOX 77.6 PPI dose reduction schedule

- Pantoprazole 40 mg bd
  ↓ 2 months
- Pantoprazole 20 mg bd
  ↓ 2 months
- Pantoprazole 20 mg od
  ↓ 2 months
- Stop regular pantoprazole
- Consider providing a supply for prn use (e.g. before going out for a meal in a restaurant)
- Most patients do *not* need to be on long-term PPIs; only a small number need maintenance therapy.
- Gaviscon Advance and dietary advice are more suitable long-term measures in the treatment of reflux disease.
- Rebound symptoms are common on stopping PPI therapy; Alginate with potassium bicarbonate, 5 ml tds after meals and 10 ml at night for 2 weeks will help to reduce these.

Alginate

Alginate preparations have traditionally been used in the treatment of GORD symptoms such as heartburn, and there is evidence for the effectiveness in LPR of one alginate preparation that is currently available in the UK and Europe,[32] but not in the United States. Alginate is a non-systemic treatment derived from seaweed, and has little in the way of side effects, although some individuals find liquid preparations difficult to tolerate due to the thick consistency. Tablet formulations are available but the tablets are large and need to be sucked or chewed; they have a chalky texture.

Alginates are normally given after meals and/or just before retiring at night. They can also be used for breakthrough symptoms such as cough or globus. They may be helpful just before activities that can cause reflux, such as vigorous exercise or singing. They can be used as part of a combined management strategy involving diet and lifestyle advice and possibly PPI prescription, as described above.

MANAGEMENT OF NON-RESPONDERS

Published response rates to the medical therapies described in this chapter vary widely. For those patients who do not respond, the following need to be established:

- Is the diagnosis correct?
- Is the treatment regime reasonable, and is the patient complying with it?

If the diagnosis of LPR is not clear, then further investigations should be performed in order to confirm or refute it. Even if the diagnosis is clear, confirmation prior to referral for further management (particularly antireflux surgery) may be needed. Pepsin testing of pharyngeal secretions, 24-hour dual channel pH monitoring and MCII monitoring should be considered.

A recent study examined 23 consecutive treatment non-responders using MCII and high-resolution oesophageal manometry.[20] All patients had failed 3 months of high-dose twice-daily PPI therapy. Breakthrough acid reflux was found in 5/23 (22%) and significant non-acid or weakly acid reflux in 12/23 (52%). Active reflux disease was therefore present in 17/23 (74%) of the non-responders, with >80% of the reflux episodes occurring in the upright position. In addition, manometry showed significant oesophageal dysmotility in a 5/23 (22%).

Therefore, it is clear that many patients who fail medical treatment do actually have LPR. A close check should be made on the treatment regime to confirm compliance. Has the patient complied with diet and lifestyle measures (**Box 77.5**)? In particular, check smoking status and consumption of alcohol, carbonated drinks (especially cola), fruit juice and acidic fruits, as well as sleeping position. Has the prescribed medication been taken as instructed, in adequate dosage and for a sufficient period? With PPIs, some patients may respond better to one drug than another, so trial of a different agent can be considered. If alginate has not been used so far, it can be prescribed. If there is significant reflux present and the patient has persisting symptoms, referral to a gastrointestinal surgeon for antireflux may be appropriate.

ANTIREFLUX SURGERY

Surgery for reflux disease usually involves one of several forms of laparoscopic fundoplication, although some procedures implant a prosthesis to prevent reflux episodes.

Surgery may be considered either for LPR that does not respond to medical treatment, or for patients who require long-term high-dose PPI treatment to control symptoms, particularly at a young age. Surgery has been shown to produce better results in those who have GORD symptoms as well as LPR, or who have positive findings on pH monitoring, as well as those who respond well to PPIs.[33]

FUTURE RESEARCH

➤ Management of LPR patients will be improved when the diagnosis can be made with confidence by means of quick, cheap, reliable non-invasive tests, and medical treatments are available that prevent the activation or function of pepsin. Development of clinical guidelines would help to standardize treatment at an acceptable level.[34]

KEY POINTS

- Laryngopharyngeal reflux may cause throat symptoms.
- The evidence base is limited.
- Acid and pepsin are present in the refluxate.
- Symptoms and examination findings are subjective.
- Lifestyle changes and anti-reflux medication may help.
- Anti-reflux surgery may be considered in resistant cases.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: vocal fold paralysis, recurrent laryngeal nerve, laryngoplasty, thyroplasty, and laryngeal re-innervation, and focusing on evaluation and management.

INTRODUCTION

Paralysis of one or both vocal folds may impair the important physiologic functions of the larynx: breathing, swallowing and voicing. Individuals with laryngeal hemiparalysis typically complain of a broad range of symptoms reflecting variable degrees of glottic insufficiency. The most prominent of these are breathy dysphonia and dysphagia, particularly to liquids. Breathlessness while speaking and breathlessness during physical exertion may also be present. When both vocal folds are affected by the paralytic process, patients generally complain of symptoms of glottic obstruction such as stridor and dyspnea. This distinction in symptoms between unilateral and bilateral paralysis reflects the contrasting valving tasks of the larynx: glottic opening for respiration and glottic closure for airway protection, thoracic stabilization during effortful activity, and phonation.

The first important clinical task is establishing the cause of paralysis if possible. Effective management of symptoms follows. Some cases of paralysis improve symptomatically without intervention, while others fail to recover. Distinguishing between these two groups remains a challenge, and many otolaryngologists consequently choose to delay treatment until the possibility of spontaneous recovery is judged remote.

PATHOPHYSIOLOGY

Most cases of laryngeal paralysis result from peripheral nerve damage. Because the degree and pattern of neurological impairment varies, laryngeal paralysis is a heterogeneous condition with respect to symptoms, vocal fold position and electromyographic evidence of the degree of nerve damage.[1, 2] Unless due to severe trauma-like transaction, each case differs from the next in degree of neurologic impairment, and features a mix of injury types among its nerve fibres. This latter aspect is a principal reason why standard classifications of peripheral nerve injury are not entirely useful in vocal fold paralysis.

Both human and animal studies have shown that the larynx has a strong propensity for re-innervation,[2–4] which appears to be the rule rather than the exception. However, regeneration of the recurrent nerve is more problematic than that of most peripheral nerves because it carries a mixed population of adductor and abductor fibres. Re-innervation is often dysfunctional and does not yield physiologic motion. This neural dysfunction extends beyond traditional notions of synkinesis, in which balanced co-contraction of adductor and abductor fibres were theorized to produce an absence of net vocal fold motion. In fact, dysfunctional re-innervation may also occur when nerve regrowth is appropriately directed but insufficient, which may result in decreased force of contraction, loss of motor unit specificity, increased muscle fatigability and possibly changes in peripheral and central neural organization.[5] Nevertheless, the natural tendency for re-innervation accounts for the general trend for voice to improve over time in unilateral paralysis. Because of the predominance of adductor fibres, re-innervation tends to restore or preserve muscle bulk and tone, occasionally to the point that phonatory glottic closure is restored and conversational

voice sounds normal despite persistent vocal fold immobility. This explanation, well supported by electrophysiologic evidence,[1, 2] is probably closer to reality than the notion of gradual contralateral compensation.

For most of the last century, vocal fold position was erroneously thought to reveal the site or type of lesion, a prevailing belief that has since been invalidated by careful clinical and laboratory work.[6–8] Differing degrees and patterns of innervation probably account for variability in the position of the paralyzed vocal fold.

AETIOLOGY OF LARYNGEAL PARALYSIS

Most sources of nerve injury fall into three broad categories: mechanical damage from surgery or other trauma; functional compromise from a range of medical conditions; and other factors yet to be completely identified, designated 'idiopathic'.

The reported relative frequency of causes of laryngeal paralysis varies considerably (**Table 78.1**). In most series, laryngeal paralysis tends to affect men more often than women, probably reflecting the underlying gender distribution of thoracic malignancy. Uniformly, the left vocal fold is affected more often than the right, in approximately a 60:40 ratio or greater, due to the greater length and more profound descent into the thorax of the left-sided nerve, and its consequent greater vulnerability to disease and surgery.

Iatrogenic sources of injury have multiplied over time. In addition to thyroidectomy, still a main source of iatrogenic laryngeal paralysis, anterior approach to the cervical spine, carotid endarterectomy, and various cardiac and thoracic procedures have all become significant sources of laryngeal nerve injury (**Table 78.2**). The potential for recurrent nerve damage from the cuffed endotracheal tube is recognized and continues to account for cases of vocal fold immobility that are demonstrably neural in origin rather than the result of cricoarytenoid joint disruption.

A number of neurologic conditions remain relevant, albeit unusual causes of laryngeal paralysis. In contrast to other causes, some of these may be through a central mechanism. Vocal fold paralysis may appear in the wake of a stroke, almost always in conjunction with other deficits. Lateral medullary infarct (Wallenberg syndrome) is a complex of neural injury featuring vocal fold paralysis, dysphagia, vertigo, ataxia, Horner syndrome and hemifacial sensory deficit and/or pain. The vocal fold paralysis tends to improve with time, although measures may be needed in the short term to prevent aspiration. The vocal fold paralysis of Arnold-Chiari malformation tends

TABLE 78.2 Surgeries and procedures that place laryngeal nerves at risk

Cervical surgery	Thoracic procedures	Other surgery	Other medical procedures
• Thyroidectomy/parathyroidectomy • Anterior approach to the cervical spine • Carotid endarterectomy • Implantation of vagal nerve stimulator • Cricopharyngeal myotomy/repair of Zenker diverticulum	• Pneumonectomy and pulmonary lobectomy • Repair of thoracic aortic aneurysm • Coronary artery bypass graft • Aortic valve replacement • Esophageal surgery • Tracheal surgery • Mediastinoscopy • Thymectomy • Ligation of persistent ductus arteriosus • Cardiac and pulmonary transplant	• Skull base surgery • Brainstem surgery, or neurosurgery that requires brainstem retraction	• Central venous catheterization • Endotracheal intubation

to be bilateral, and it is important to recognize promptly because it is reversible with timely hindbrain decompression. Charcot–Marie–Tooth disease and its variants are a heterogeneous group of hereditary motor and sensory neuropathies that may involve the laryngeal nerves. Neural compromise of the vocal fold appears to evolve slowly but relentlessly and is usually bilateral. Postpolio syndrome, a degenerative neurologic condition seen many decades after the acute disease, may present as a complex of bulbar deficits resulting in dysphagia, dysphonia and dysarthria. A similar presentation may be seen in multisystem atrophy, a degenerative parkinsonian condition where laryngeal neurologic dysfunction may contribute to mortality by creating respiratory obstruction. Laryngeal weakness may also figure in oculopharyngeal dystrophy and inclusion body myositis, although the mechanisms of nerve involvement are not fully understood in those conditions.

The incidence of idiopathic paralysis had remained approximately unchanged over the past century, unaffected by the introduction and refinement of computed tomography and magnetic resonance imaging. Based on serologic studies, cases have been attributed to Lyme borreliosis, herpes zoster and simplex, Epstein–Barr virus and even the West Nile virus. However, the cause of many cases of vocal fold paralysis in which serologies are normal and there is no history of antecedent viral disease are yet to be elucidated.

UNILATERAL VOCAL FOLD PARALYSIS

Clinical evaluation

HISTORY

Patients with unilateral laryngeal paralysis typically experience hoarseness and hypophonia. These can range from subtle vocal fatigue to near-total aphonia, reflecting the degree of glottic insufficiency, which varies from affected individual to individual. Dysphagia with possible frank aspiration may also be reported, albeit less often than voice complaints. Dysphagia-related complaints are more frequent in cases of 'high' vagal injury, affecting both superior and recurrent laryngeal nerves, which adds hemilaryngeal anaesthesia, pharyngeal constrictor atony and cricopharyngeal muscle hyperfunction to glottic insufficiency from the immobile vocal fold. Situations in which laryngeal anaesthesia exists alongside other cranial nerve deficits, as in jugular foramen syndromes, after stroke and after skull base surgery also carry increased dysphagia risk. Surgeries affecting pulmonary reserve, as do most thoracic procedures, appear to carry a higher risk of aspiration, and age may be an independent risk factor.[23]

Some patients will demonstrate a characteristically 'wet' vocal quality arising from pooled secretions, which interfere with phonation. By definition, such secretions have at least penetrated into the laryngeal introitus; these patients should attract the otolaryngologist's attention as being at risk for aspiration. More subtle symptoms include laryngospasm resulting from reaction to unexpected penetration or aspiration. This may occur in patients with surprisingly small degrees of glottic insufficiency and reasonably good voice quality.

Occasionally, patients may complain of phonation- or activity-induced shortness of breath. Careful questioning will reveal that this is not obstructive dyspnea, but rather breathlessness that results from excessive air escape during voicing, or from compromise of the thoracic fixation (Valsalva) manoeuvre during effortful activity. Pulmonary function testing will inevitably reveal an extra-thoracic obstruction; this, plus a lack of insight into laryngeal physiology, may lead the physician away from laryngeal intervention.

The otolaryngologist should also inquire regarding smoking history, the most recent chest imaging, and antecedent illness. A review of systems should focus on conditions likely to affect the larynx. Relevant factors include: neurologic symptoms like weakness, tremor and dysarthria; pulmonary symptoms suggestive of tuberculosis or malignancy; and exposure to neurotoxic agents like solid tumour chemotherapy (vincristine, vinblastine and cisplatin) or organophosphates found in pesticides. Unilateral vocal fold immobility is rarely mechanical in nature, but the possibility should not be dismissed in cases that are identified in the wake of clearly traumatic intubation or external trauma, or in the presence of arthralgias or known inflammatory joint disease.

PHYSICAL EXAMINATION

The examination should include palpation of the neck for lymphadenopathy or thyroid enlargement. The remaining cranial nerves should be evaluated, with special attention to the spinal accessory and glossopharyngeal nerves, which share the jugular foramen with the vagus. Other branches of the vagus should be examined as well. Finally, the presence of ipsilateral tongue deviation, palate droop or Horner syndrome should raise the suspicion of a cranial base lesion.

The larynx itself should be examined across a variety of laryngeal tasks. Flexible nasolaryngoscopy probably offers a more accurate impression of laryngeal function than rigid techniques, as the tongue traction necessary for the latter probably introduces some confounding biomechanical factors.

A hypomobile vocal fold may occasionally be difficult to appreciate; in such cases, asking the patient to alternate sustained vowel phonation and sniffing ('eee-sniff' manoeuvre) should bring any asymmetry into evidence. The examiner should not be misled by small amounts of vocal fold motion that may be caused by the interarytenoid muscle, receiving innervation from the contralateral nerve, by an intact cricothyroid muscle, or even by passive lateral displacement of the denervated arytenoid by its pair during adduction.

We have seen that the position of the paralyzed vocal fold carries no significance with respect to the site of the injury or prognosis. Nevertheless, careful examination can reveal features that may inform clinical care. Occasionally, increasing tension and length of the paralyzed vocal fold upon raising the pitch of the voice may

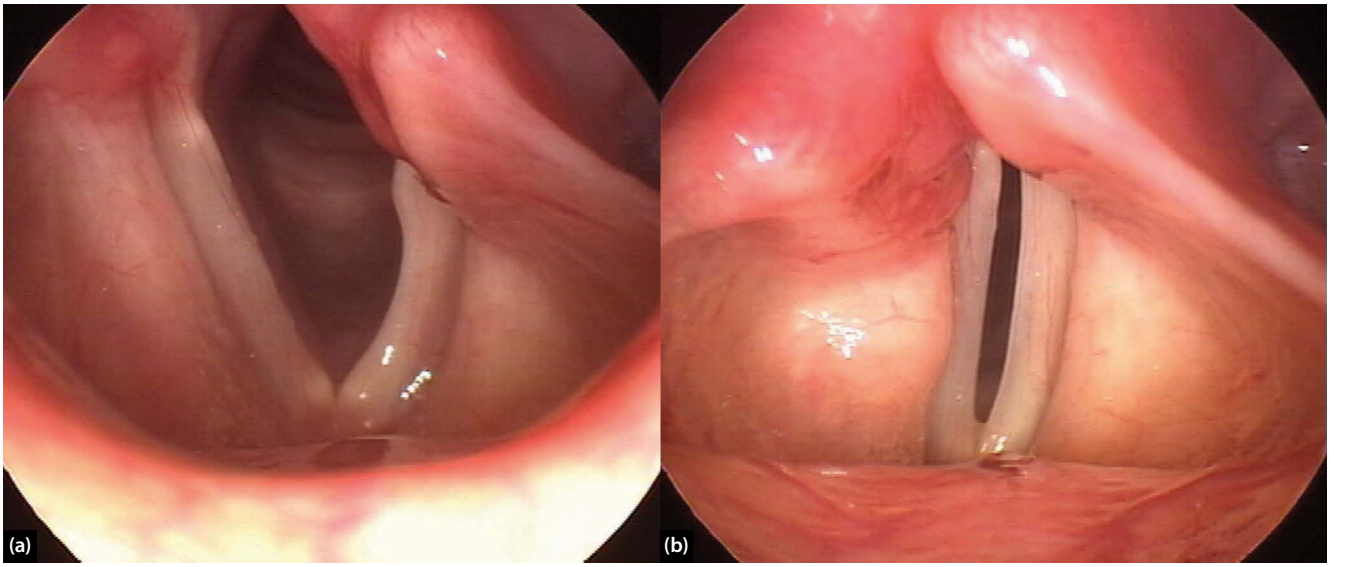

Figure 78.1 In this case of left vocal fold paralysis following anterior approach to the cervical spine, comparison of left vocal fold tension during quiet respiration (a) and phonation **(b)** suggests the superior laryngeal nerve is intact.

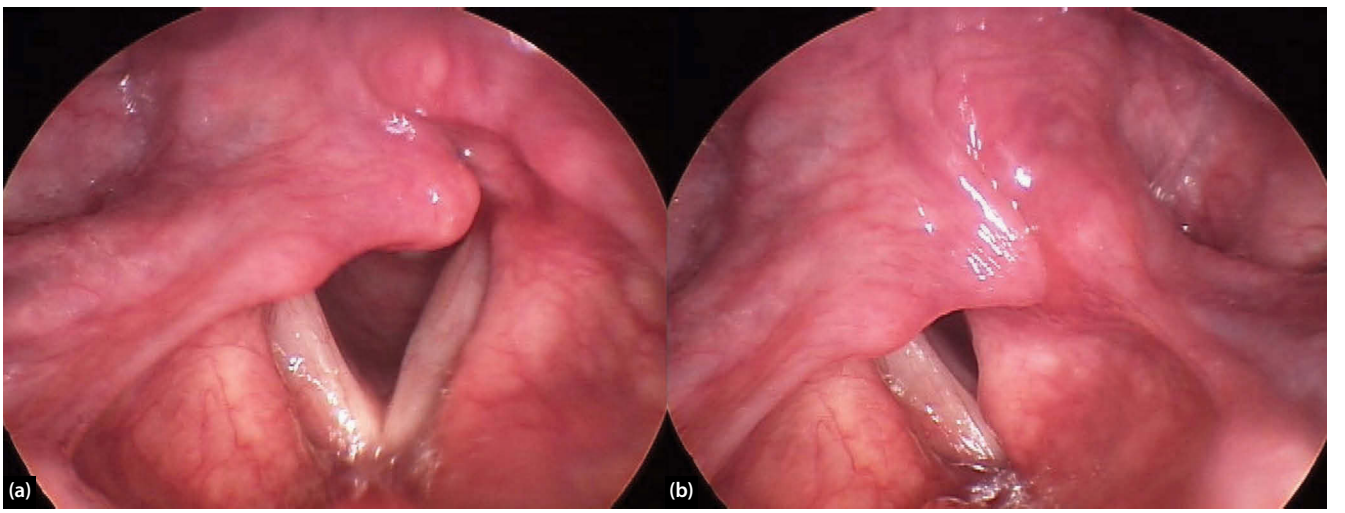

Figure 78.2 The right arytenoid is prolapsed into the laryngeal introitus in this case of idiopathic vocal fold paralysis, confirmed by electromyography (a). In adduction **(b)**, it interferes with the opposite cartilage and impedes closure. Rehabilitation without arytenoid repositioning surgery would very likely be suboptimal.

suggest an intact superior laryngeal nerve. Sometimes, patients may take advantage of intact cricothyroid function to improve voice projection by increasing vocal fold resistance to exhaled air (**Figure 78.1**); this pitch-raising phenomenon generates a characteristic voice described as 'paralytic falsetto'. The presence of supraglottic hyperfunction during phonatory effort should raise the possibility of glottic insufficiency. The ventricular folds serve as an accessory valving mechanism that tends to be engaged without deliberate effort when the vocal folds proper do not close effectively.[24]

Vocal fold adduction and abduction do not take place in two dimensions; the folds tend to abduct in a cephalad direction (into the ventricles) and adduct caudally. Thus, a paralyzed vocal fold may not rest in the same plane as its partner. Such three-dimensional judgements are difficult to make on laryngoscopy, but height mismatch is important to identify, as simple medial displacement of the paralyzed fold may not suffice for proper apposition during phonation.

Asymmetry of the arytenoids, with displacement of the cartilage on the paralyzed side forward into the laryngeal introitus (i.e. a 'prolapsed arytenoid'), is not a rare finding in laryngeal paralysis (**Figure 78.2**). This is not a sign of cricoarytenoid dislocation but does, however, suggest profound denervation with loss of muscular support for the cartilage. In addition, it strongly suggests a height and tension mismatch between the vocal folds. These factors argue for an arytenoid stabilization procedure should surgical rehabilitation be contemplated.

The incidence of cricoarytenoid dislocation as a cause of vocal fold immobility has been the subject of much debate. Experimental study has shown the cricoarytenoid joint to be strikingly robust and resistant to disruption.[25–27]

A problem-free intubation is unlikely to cause a joint injury, which usually follows obvious trauma, be it from intubation or external sources. The presence of arytenoid oedema and erythema, and the absence of a 'jostle sign' are suggestive of cricoarytenoid joint injury and should prompt further investigation (The Jostle sign is when the arytenoid cartilage on the side of the paralyzed cord, is passively displaced laterally on contact with the arytenoid on the normal side during phonation).

In hemilaryngeal paralysis, the glottal gap may be of two principal configurations. It may be essentially spindle-shaped, involving principally the membranous portion of the vocal fold, or V-shaped, marked by greater distance between the vocal processes of the arytenoid cartilages (**Figure 78.3**). This latter configuration is called a posterior gap, although the term does not refer to the absolute distance between vocal processes. The presence of a posterior gap should also cause the otolaryngologist to consider an arytenoid stabilization procedure for rehabilitation because implant medialization alone or injection augmentation is predictably poor at correcting this deficit.

Although there is no single metric of severity of symptoms of vocal fold paralysis, several simple clinical tools may help grade features of the history and examination. The Voice Handicap Index (VHI) and the voice-related quality of life (V-RQOL) are validated patient-completed self-rating scales that measure various aspects of vocal disability. The Consensus Auditory Perceptual Evaluation of Voice (CAPE-V) and the older grade, roughness, breathiness, asthenia, strain (GRBAS) scale are perceptual scales completed by the healthcare professional based on voice quality. The maximum phonation time (MPT) is the longest duration of sustained vowel phonation; for example, typically an /i/, which the patient can sustain, and is approximately inversely proportional to the degree of glottic insufficiency. The s/z ratio compares the MPT of a voiced (/z/) and unvoiced (/s/) sound. Under normal circumstances, the duration of the unvoiced sound should far exceed that of the voiced (the s/z ratio should be large), but with glottic insufficiency, the duration tends to become approximately the same (the s/z ratio tends to decrease).

ADDITIONAL INVESTIGATIONS

Fundamentally, diagnostic testing beyond the history and physical is intended to uncover causes of vocal fold paralysis. In cases temporally related to surgery that places the vocal folds at risk, no additional investigation is required. In others, malignancy is the principal pathology not to be overlooked. Imaging of the entire course of the affected laryngeal nerves is obligatory, including the mediastinum and the pulmonary apices.

Computed tomography (CT) from base of skull *through* the arch of the aorta or the right subclavian, as appropriate, is the minimum recommended study for laryngeal paralysis. In cases where a 'high vagal' paralysis is suspected according to criteria reviewed earlier, magnetic resonance imaging (MRI) may offer a more reliable means of imaging the skull base or central nervous system.

While serologies used to be ordered routinely, systematic examination has demonstrated a 0% yield in a series of 84 patients;[28] therefore, serologic testing is probably useless unless there is a specific clinical suspicion of an underlying illness.

Modified barium swallow is useful if a question of aspiration exists. The potential of morbidity related to dysphagia is a key element in determining the need for treatment.

Laryngeal electromyography (LEMG) measures the integrity of laryngeal innervation by means of percutaneous needle electrodes. It can provide unambiguous evidence of denervation and re-innervation, yet its utility in cases of vocal fold paralysis has been hotly debated. LEMG has been criticized for being a subjective study. In this respect, however, it does not differ

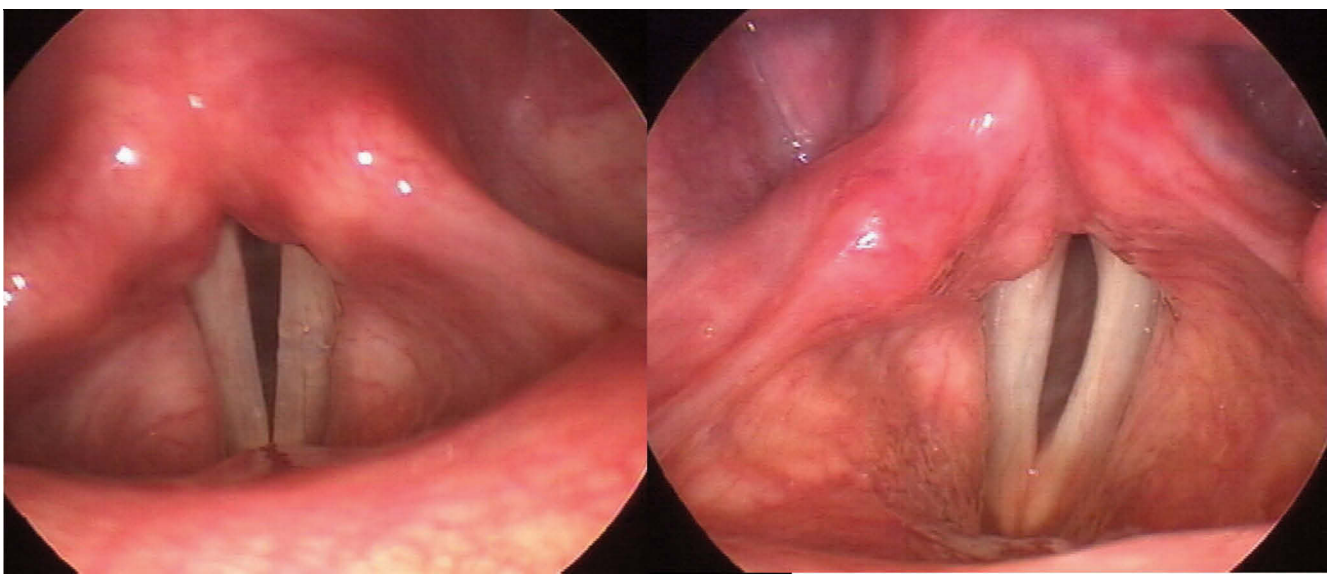

Figure 78.3 The case on the right, a left vocal fold paralysis following a thyroidectomy, demonstrates a posterior gap. On the left, a vocal fold paralysis from malignant mediastinal lymphadenopathy, closure at the vocal process is good. Compare also with the case in **Figure 78.2**, which also demonstrates a posterior gap.

TABLE 78.3 Laryngeal electromyography and prognosis in vocal fold paralysis of less than 6 months duration

from laryngoscopy and stroboscopy, except inasmuch as training and familiarity has allowed otolaryngologists to use these latter modalities more comfortably. In fact, LEMG exceeds both of these in its ability to definitively and objectively diagnose vocal fold paralysis, as opposed to immobility.

The practical clinical difficulty in the use of LEMG for prognosis has been that the appearance of electromyographic signs of re-innervation does not always lead to a return of vocal fold function, for pathophysiologic reasons reviewed earlier. Therefore, the utility of LEMG in prognosis in cases of vocal fold paralysis has been uneven. The available literature suggests that LEMG may be more useful as a predictor of poor outcome (**Table 78.3**), principally because electromyographic signs such as fibrillations and positive sharp waves, providing evidence of an absence of re-innervation, offer no physiologic ambiguities.[29] For now, LEMG clearly offers a reliable way to distinguish neurogenic from mechanical vocal fold immobility, and may offer variable prognostic information when used less than 6 months from the onset of paralysis.

Treatment

The management of glottic insufficiency in unilateral vocal fold paralysis is guided by concerns regarding morbidity from dysphagia and aspiration, the patient's own perception of the severity of the vocal handicap, and expectations about the eventual outcome without treatment. In turn, outcome expectations are influenced by the apparent cause of the paralysis and the time elapsed since onset.

OBSERVATION

Patients with hemilaryngeal paralysis, especially of short duration, may simply be observed. Factors favouring observation include:

- no evidence of aspiration
- injured laryngeal nerve(s) is (are) structurally intact and potential for recovery remains
- minimal vocal disability and/or minimal vocal demand
- comorbidities that discourage or prevent intervention.

Voice and swallowing therapy may be used as needed during the observation period. As with many interventions for this condition, the natural tendency of glottic insufficiency to improve over time makes it difficult to evaluate efficacy, and there is no convincing evidence that voice therapy affects the course and symptoms of vocal fold paralysis. Nevertheless, a skilled voice therapist may offer the patient insight into the condition.

The presence of severe dysphagia, history of aspiration pneumonia or observed aspiration during clinical evaluation effectively trumps other factors and demands intervention.

INJECTION LARYNGOPLASTY

Patients may opt for temporary relief of their symptoms, even when eventual recovery is expected. This is accomplished by injection of an absorbable bulking substance into the paralyzed fold to improve the glottic insufficiency. Such substances include various hyaluronic acid preparations, calcium hydroxylapatite paste, micronized human dermis, autologous fat and carboxymethylcellulose-glycerine gel. Factors favouring injection augmentation include:

- dysphagia
- high degree of vocal disability or high vocal demand
- good or indeterminate functional prognosis
- small glottic gap (2 mm to 3 mm)
- no posterior glottic gap
- short life expectancy.

Injection laryngoplasty may be performed via direct laryngoscopy, or perorally or transcutaneously under topical anaesthetic in the office, provided the patient is cooperative and committed. Office use in the awake patient is a major advantage of the technique. Selection of the substance to be injected depends on the surgeon's evaluation of its tissue properties, experience and preference.

Injection augmentation is regarded as temporary since the abandonment of polytetrafluoroethylene polymer (Polytef, Teflon™) because of well-known adverse tissue response. Calcium hydroxylapatite particle paste has been introduced as a durable injectable with effect around one year.

Injection augmentation has inherent limitations. It will not effectively reposition the arytenoid to rectify a height discrepancy or close a posterior glottal gap and is not ideal for large glottic gaps. Most injectates require overinjection to allow for reabsorption, rendering fine adjustment of vocal fold position impossible. In addition, should the injectate infiltrate into an unintended site – typically the superficial layers of the vocal fold, impairing mucosal phonatory vibration – corrective intervention is challenging and patients may have to await natural resolution over weeks to months. It should be noted that no substance today is ideally suited for use in the lamina propria; all currently available substances will stiffen this tissue.

LARYNGEAL FRAMEWORK SURGERY

Framework surgery is generally reserved for treatment of glottic insufficiency from unilateral paralysis that is not expected to improve. Favourable factors are:

- dysphagia
- high degree of vocal disability or vocal demand
- poor functional prognosis
- large glottic gap (2 mm to 3 mm)
- posterior glottic gap
- shortened life expectancy.

In its simplest and most common form, framework surgery consists of medialization thyroplasty, the surgical insertion of an implant, made of silicone, expanded polytetrafluoroethylene (Gore-Tex®), formed calcium hydroxylapatite, or other biologically inert material, into the paraglottic space to displace the paralyzed vocal fold medially (**Figure 78.4**). Typically, this operation is performed under a local anaesthetic, with or without additional intravenous sedation. The surgeon, guided by patient phonation and endoscopic visualization, may thereby size and position the implant for optimal correction of the patient's glottic insufficiency without functional restriction of the airway. The critical anatomic task is to identify the level of the vocal fold in relation to the thyroid lamina, so that the thyroid cartilage aperture through which the implant is inserted can be placed appropriately. Medialization via thyroplasty, in contrast to injection, is precise, predictable and durable. Often considered more aggressive treatment than injection, medialization thyroplasty under local anaesthesia can be safer and better suited to high-risk patients than injection under general anaesthesia.

Serious complications include airway obstruction and perforation into the laryngeal lumen. Necessarily, medialization narrows the airway and, in combination with post-operative oedema and haematoma, can cause airway obstruction. For this reason, some surgeons prefer to observe patients in the hospital for one night following the procedure. Rarely, patients undergoing medialization thyroplasty have been reported to require intubation or tracheotomy in the immediate post-operative period.[36] Perforation of the laryngeal mucosa increases the likelihood of infection and subsequent extrusion of implanted material.

The most common complication, however, is suboptimal voice outcome. This is typically due to technical factors, and revision rates of 5.4% to 14%, to even as high as 33% when adjunctive procedures such as fat injection are included, have been reported.[36–38] Common causes of poor voice result include persistent posterior gap, undermedialization and implant malposition, generally in too anterior or too superior a position (**Figure 78.5**).

Arytenoid repositioning procedures may be added to medialization thyroplasty when there is a poorly supported arytenoid or a posterior gap (**Figures 78.2** and **78.3**). This configuration is difficult to remedy with thyroplasty alone. Arytenoid repositioning surgery is designed to internally rotate and/or suspend the arytenoid in physiologic phonatory position. Most commonly, the muscular process of the arytenoid cartilage is approached through the inferior constrictor muscle and around the back of the thyroid lamina. A non-absorbable suture is passed through this structure and secured to the thyroid lamina to exert anterolateral traction on the muscular process and thus rotate the vocal process medially and slightly caudally. This is known as arytenoid adduction.[39] Adduction arytenoidopexy, a less common approach, involves opening the cricoarytenoid joint capsule and suturing the arytenoid in optimal position directly to the crest of the cricoid.[40]

These procedures are technically more challenging and time-consuming than thyroplasty alone, and have a higher incidence of complications, largely because oedema or bleeding into the paraglottic space can cause airway obstruction. Despite these problems, for the experienced phonosurgeon, arytenoid procedures are an essential adjunct to medialization thyroplasty in achieving an optimal voice outcome.

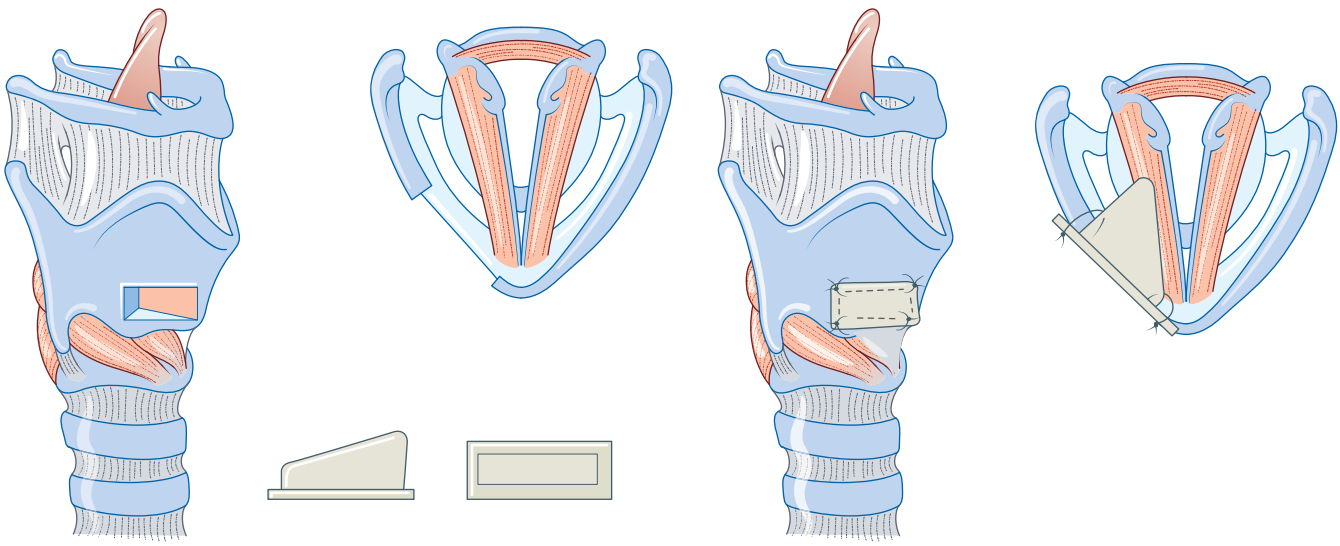

Figure 78.4 In medialization laryngoplasty, a medialization shim of biologically inert material is inserted into the paraglottic space through a thyroid cartilage window to displace the vocal fold towards the midline. Published with permission, from Bielamowicz.[35]

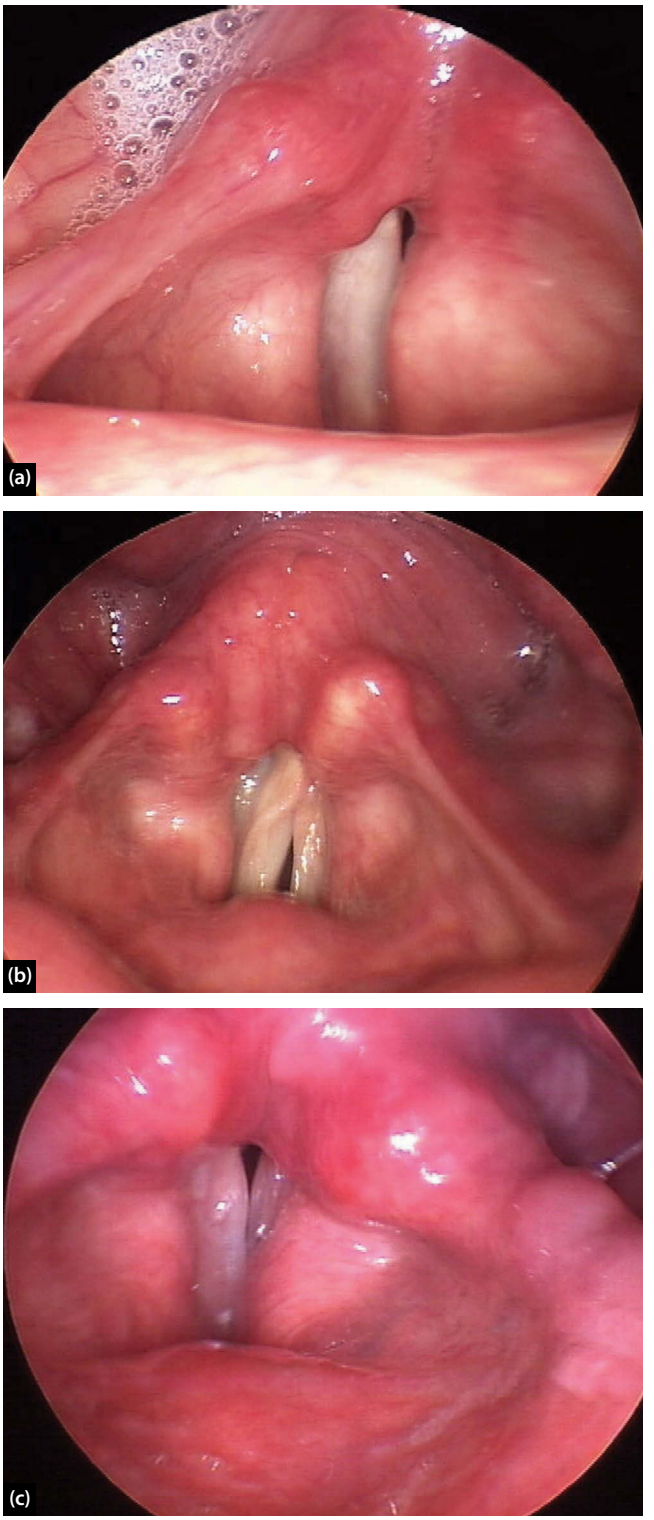

Figure 78.5 Suboptimal outcomes of medialization laryngoplasty. **(a)** Superior implant malposition in this case of left vocal fold paralysis after irradiation of a glomus tumour causes the ventricular fold to obscure the vocal fold, which is not well adducted. This is not supraglottic hyperfunction. **(b)** Inadequate medialization of the left vocal fold in a case of idiopathic paralysis results in persistent midfold glottic insufficiency and compensatory supraglottic hyperfunction. **(c)** Inadequate arytenoid medialization in this case of idiopathic right vocal fold paralysis causes persistent posterior gap. Note supraglottic hyperfunction on the normal (left) side.

RE-INNERVATION

Re-innervation using nearby nerves – both the *ansa cervicalis* and the hypoglossal nerves have been studied[41] – would seem to be an attractive and logical approach to vocal fold paralysis. However, it is subject to the same limitations as spontaneous recovery. Because of the complex innervation of the vocal fold muscles, re-innervation generally stands to improve the bulk and tone of vocal fold muscle but will not restore physiologic motion. Re-innervation is ideally suited when the vocal fold is known to be completely denervated (e.g. if the recurrent nerve or vagus has been sectioned). In fact, in cases of nerve section recognized during surgery, immediate re-anastomosis, or re-innervation if tension-free nerve re-anastomosis is not possible, is the treatment of choice. However, when considering re-innervation later in the course of paralysis, the surgeon should be reasonably confident that he or she is not depriving the vocal fold of existing re-innervation by sectioning a partially recovered recurrent nerve to use the distal stump. The patient must be counselled that symptom improvement may take weeks or months. For this reason, re-innervation has sometimes been combined with other rehabilitation techniques.

BILATERAL VOCAL FOLD PARALYSIS

Virtually any condition that can cause unilateral laryngeal paralysis may affect both recurrent laryngeal nerves to cause bilateral paralysis. Thyroidectomy remains the leading surgical cause;[42] both nerves are also at risk at esophagectomy, tracheal resection, thymectomy and other mediastinal procedures. Similarly, tracheal, esophageal and thyroid malignancies may compromise both nerves. Neurologic disorders tend to cause diffuse involvement of the peripheral nervous system. Amyotrophic lateral sclerosis, post-polio syndrome, Charcot–Marie–Tooth neuropathy, Arnold Chiari malformation and Guillain-Barré syndrome have been documented causes of bilateral paralysis. Some bilateral laryngeal paralyses are idiopathic, attributed to the same infectious agents as unilateral paralysis.

A clinician encountering bilateral vocal fold immobility should consider the possibility of joint fixation or posterior glottic scar, particularly when the condition follows intubation. In such cases the vocal folds are not denervated but merely appear to be, because of mechanical limitation. Careful inspection, sometimes requiring operative laryngoscopy, radiologic investigation and/or electromyography should be used to clarify the diagnosis, as mechanical limitations may be correctible.

Patients with bilateral vocal fold paralysis typically complain of dyspnea, noisy breathing and exercise intolerance. The severity of these respiratory symptoms is inversely proportional to the size of the glottic aperture between the two immobile vocal folds. Respiratory noise is worse on inspiration, as negative pressure pulls the denervated vocal folds into closer approximation. Voice may not be greatly altered, and swallowing is usually not affected.

In acute bilateral vocal fold paralysis, symptoms may be dramatic and even life-threatening. The typical scenario is unexpected respiratory distress after extubation from thyroid surgery and, in such a case, securing an adequate airway is the only consideration. In progressive cases, as found in certain neurologic diseases, patients may compensate as the paralysis becomes denser, and may tolerate unexpectedly small glottic airways. Close questioning about noisy inspiration or limitations in physical activity will suggest that paralysis has been present for some time.

Investigation includes radiologic imaging in the manner of unilateral vocal fold paralysis, with special emphasis on the mediastinum and infra-laryngeal neck, as well as the central nervous system. The degree of airway obstruction may be quantified using a flow-volume loop (see Chapter 76, Laryngeal stenosis in adults). Bilateral paralysis typically shows a variable (rather than fixed) extra-thoracic obstruction, as the vocal folds will passively adduct during inspiration and abduct with positive expiratory air pressure.

Treatment is guided by the degree of airway limitation; except in situations of acute airway distress, the patient may be the best judge of functional handicap. Tracheotomy is frequently performed emergently and may be a reasonable treatment option for the long term as well, as it guarantees airway with minimal compromise of phonation and deglutition. Often, though, patients prefer to avoid the inconveniences of tracheostomy if possible. Other treatment options include lateralization of the vocal fold or removal of arytenoid and/or vocal fold tissue to enlarge the glottic aperture (for more information, see Chapter 76, Laryngeal stenosis in adults). Effort is made to preserve the membranous vocal fold to the greatest extent possible in these procedures, but voice and sometimes swallowing may be adversely affected. Some of these procedures are destructive and irreversible, so the otolaryngologist should be sure that any reasonable possibility of spontaneous improvement has been exhausted before they are considered. Laryngeal pacemakers are currently being evaluated in human trials.[43]

VOCAL FOLD PARESIS

A sophisticated understanding of pathophysiology reveals that vocal fold paralysis is not an all-or-none phenomenon. Paresis, or incomplete paralysis in which some gross vocal fold mobility is preserved, exists alongside complete paralysis as a clinical entity. Symptoms of paresis are predominantly those of glottic insufficiency, even with bilateral involvement. This is because it is rare for paresis to be so dense that it impairs abduction to the extent that the airway is meaningfully narrowed. On the other hand, phonatory glottic function is affected by even mild asymmetries in neural input. Even when glottic closure appears grossly adequate, asymmetries in vocal fold tension may affect pitch, vocal stamina and high or low intensity phonation. Diagnosing paresis may be challenging because preserved gross vocal fold mobility may lull the examiner into overlooking subtle glottic insufficiency or limitations in motion. Perhaps the most difficult task is distinguishing paresis from innocent asymmetries in vocal fold motion, which are probably present in many individuals. Stroboscopy may occasionally be helpful, as subtle decrease in muscular tone affects the amplitude and frequency of the mucosal wave during phonation. LEMG must be used with as much judgement as laryngoscopy, as it probably lacks sensitivity. Because of the diagnostic challenge, there is a role for treatment trials in the form in injection augmentation in patients in whom the diagnosis remains ambiguous.[44]

Most aspects of laryngeal paresis, including prevalence, natural history, laryngoscopic and stroboscopic signs, and relation to other pathology such as mucosal lesions, continue to require clarification.

CONCLUSIONS

Laryngeal paralysis usually results from peripheral nerve injury of one or more laryngeal nerves, and results in clinically significant changes in phonation, swallowing and/or respiration. Often thought of as an all-or-none phenomenon, laryngeal paralysis represents a spectrum of nerve injury and re-innervation, which accounts for the variability in its clinical presentation. Investigation is aimed at discovering underlying causes. Because of the strong laryngeal propensity to re-innervation, paralysis tends to improve over time, and sometimes resolves spontaneously. When it does not, numerous surgical options are available to remedy dysphonia and dysphagia from the glottic insufficiency of unilateral laryngeal paralysis. Respiratory restriction from bilateral paralysis is a greater challenge, however, since most surgical measures are destructive, irreversible and stand to impact voice and swallowing adversely.

FUTURE RESEARCH

- Further identification of factors underlying idiopathic vocal fold paralysis.
- Improved characterization of laryngeal neurophysiology and recurrent laryngeal nerve recovery process.
- Development of reliable quantitative measures in laryngeal electrodiagnostics.
- Development of reliable and stable permanent injectates for definitive office augmentation.
- Dynamic rehabilitation of laryngeal paralysis, including electrical pacing and functional re-innervation.

KEY POINTS

- Vocal fold paralysis can be unilateral or bilateral, either scenario having different clinical implications.
- When facing vocal fold immobility, it is important to distinguish neurogenic paralysis from mechanical fixation.
- Most cases of vocal fold paralysis are caused by peripheral nerve injury.
- Spontaneous nerve recovery is the norm, but not return of function, due to the complex specificities of laryngeal neurophysiology.
- Beyond the treatment of an identifiable cause, management is mainly symptom-driven to address laryngeal dysfunction.
- A wide range of interventions is available to improve most patients' functional deficits.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: office laryngology, outpatient procedures, laser surgery and transnasal oesophagoscopy.

INTRODUCTION

There have been significant advances in the technology of flexible and rigid video endoscopy, along with innovative techniques that now provide the otolaryngologist with the ability to perform office-based laryngeal procedures. This has enabled surgeons to take the patient from a hospital admission with general anaesthesia and associated risks and downtime, to an office-based setting. Here, the same procedure is performed entirely under local anaesthetic without sedation. With careful patient selection and realistic expectations for outcome, a proportion of the pathology that occurs in the larynx can be well treated in the office through awake unsedated laryngeal surgery (AULS).

Performing AULS provides advantages to both patient and surgeon. The patient can drive themselves to and from the office procedure, can return to work on the same day if necessary and can avoid day hospital admission and general anaesthesia with its inherent risks. In addition, the need to allow diseases such as dysplasia, leukoplakia and papilloma to progress to substantial severity to justify the risks of general anaesthesia is obviated. Instead, patients can undergo a low-risk, simple office angiolytic laser treatment of laryngeal papilloma as an awake procedure in 10–15 minutes with a rapid recovery and minimal downtime. Such office procedures can be performed as frequently as clinically indicated. In addition, in some countries, there is a substantial cost saving for AULS.[1]

It should be stressed that the term 'office-based' and 'outpatient' are often used interchangeably. The critical point is that the patient remains unsedated and is in a totally cooperative state. As such the patient can undergo the procedure either in the surgeon's office or, at times, in the operating theatre.

The more commonly performed laryngeal procedures include laryngeal injection, endoscopic fibre-based laser procedures, transnasal oesophagoscopy (TNO) and panendoscopy, with numerous studies showing adequate patient safety profiles, high patient satisfaction rates and treatment outcomes for laryngeal pathology.[2–6]

HISTORY

The field of laryngology has developed extensively from its inception in the late 1800s. The first laryngology society was formed in the United States and held its inaugural meeting in 1879.[7] Prior to this there had been a tremendous interest in both the anatomy and physiology of voice production and deglutition, with reports of dental mirrors being used to examine the oral cavity as far back as the Roman era. The earliest, most extensive work on the anatomy of voice and hearing, written in CE 1600, came from Julio Casserius.[8, 9] In this text are found eloquent descriptions of the anatomy of both humans and animals. In the mid-19th century, Manuel Garcia,[10] a prominent singer and teacher, perfected mirror laryngoscopy well before it was common practice for

physicians. After rapidly growing fascination in laryngeal anatomy and function, many physicians in the late 19th century became very skilled at mirror examination of the larynx and began to adopt simple procedures that included removal of growths and foreign bodies.[11, 12] In the 1880s, topical anaesthesia with cocaine became available, which greatly aided office laryngeal procedures.[13] At the turn of the 20th century, Chevalier Jackson pioneered the new era of laryngology. It was shortly thereafter, with the use of general anaesthesia and airway cannulation, that laryngology procedures were taken from the physician's office into the operating theatre. In the late 20th century, as technology advanced exponentially, there was a move of laryngology procedures back toward the physician's office as AULS. Today, the modern laryngologist has rigid and flexible high-definition endoscopy and a wide range of rigid and flexible instrumentation to enable safe and effective outpatient laryngeal procedures to be performed.

OUTPATIENT LARYNGEAL PROCEDURES

Table 79.1 lists the various outpatient laryngeal procedures, the more commonly performed being laryngeal injection and endoscopic laser. Injection laryngoplasty is discussed in greater detail in Chapter 67, Phonosurgery and Chapter 78, Paralysis of the larynx. Other less commonly performed procedures include TNO, panendoscopy, removal of foreign bodies, treatment of glottic webs, biopsy and even balloon dilation for stenosis.

Patient preparation

With today's technology affording the ENT surgeon unprecedented abilities to perform both simple and advanced laryngeal procedures in the office or outpatient setting, patient selection and preparation is paramount to minimize risks of cardiorespiratory complications.[14] As with any surgical intervention, establishing a sound rapport with the patient is critical. The ability for a patient to undergo an office-based procedure is greatly enhanced when they have a high comfort level with the treating surgeon and feel confident in his or her care. To this end, informed consent plays a key role in the pre-procedure preparation. A discussion with the patient about the way the procedure is done, the goal(s) of the procedure and the expected and unexpected outcomes are all discussed.

TABLE 79.1 Common outpatient/office-based laryngeal procedures

Laryngeal injection	Injection laryngoplasty	Glottal gap from unilateral vocal fold paralysis, presbyphonia, surgical defect
	Chemical injection	Botulinum toxin, bevacizumab, saline, cidofovir
Laryngeal laser	KTP, PDL, CO_2, Thulium, Gold	Dysplasia, keratosis, papilloma, ectasias, varices, glottic web, granulation tissue, vocal process granuloma
Panendoscopy/ transnasal oesophagoscopy	Diagnostic	Therapeutic

The surgeon must ensure that the patient is a suitable candidate for office-based laryngeal surgery. Contraindications include patients with significant comorbidities, significant airway narrowing, heightened anxiety or extremes of age. For most office laryngeal procedures, patients who are on anticoagulants do not necessarily need to cease them pre-operatively. In the author's experience of over 400 office procedures, there have been 38 procedures performed with patients on anticoagulants (including warfarin). None of these patients have had any bleeding that has been significant, either during or after the procedure.

Local anaesthesia

Inadequate topical anaesthesia for AULS is destined to produce a suboptimal outcome, even despite the surgeon's advanced skill level and highly developed imaging and instrumentation. With this in mind, having a relaxed and well-anaesthetized patient is the critical starting point for successful AULS. The technique for topical anaesthesia will depend on whether the main instrumentation is done transnasally, transorally or transcutaneously.

The most commonly used of all of these is lidocaine due to its rapid onset of action and duration of effect. Although it is relatively low potency in comparison to other local anaesthetic agents, it has an onset of action in as little as 90 seconds and the duration of effect can range from 45 to 60 minutes. With any agent, knowledge of the appropriate dose is critical. The author mainly utilizes 4% lidocaine, representing 40 mg/mL. Toxicity occurs when the dose exceeds 3–5 mg/kg. In an average 70 kg male, the safe dose would be up to 300 mg, equating to 7.5 mL of 4% lidocaine. The maximum volume the author has used in any of the procedures performed has been 4 mL. For most procedures, between 2 mL and 4 mL is adequate to topically anaesthetize the laryngeal mucosa for the range of office procedures to be described.

Lidocaine toxicity must be identified at its earliest signs to enable prompt intervention and treatment. The signs of toxicity include peri-oral and distal upper limb paraesthesia, tinnitus, vertigo, visual disturbance, slurred speech, tremor, tonic-clonic seizures and coma. At the first suspicion of toxicity, the procedure should be halted and emergency management should be commenced.

Patient selection

In the author's experience, approximately 2% of AULS cannot be performed despite adequate preparation. The common reasons for this are intractable gagging despite aggressive local anaesthetic application and severe oropharyngeal crowding. A Friedman Grade 3 or 4 patient[15] can make the procedure difficult and occasionally will need conversion to a transnasal procedure. In some

patients, 10 mg of diazepam can be prescribed if there is a degree of anxiety or heightened gagging, and they will thus have their outpatient laryngeal procedure performed in the operating room.

Patient position

The ideal position for the patient is to be sitting in a typical ENT exam chair that would have them partially flexed forward at the hips. Placing a pillow behind the shoulders can assist in obtaining this position. **Figure 79.1** shows a typical approach for a transoral procedure. The height of the chair can then be raised to suit the surgeon's preference. If a laser procedure is being performed, a small suction catheter is placed transnasally with the distal tip sitting in the oropharynx. The catheter extends across the cheek and is taped securely in place. For any laser procedure the standard laser precautions are observed, which include, but are not limited to, protective eyewear with suitable protection for the wavelength being used and laser-rated surgical mask. Although many procedures can be done as a sole operator without the need of assistance, it is generally advisable to have a nurse, resident, registrar or other assistant at hand.

Transnasal approach

If the procedure is to be done entirely in a transnasal route then simple topical anaesthesia into the nasal cavity and down into the hypopharynx and larynx is sufficient.

Transnasal anaesthesia begins with aerosolized lidocaine mixed with oxymetazoline sprayed into at least one nasal cavity. Techniques often describe spraying both nasal cavities but a careful nasendoscopy prior to the anaesthetic should indicate which nasal cavity is more patent to accommodate the endoscope. In this setting, by only anaesthetizing one nasal cavity, the surgeon can limit the total amount of local anaesthetic used. After waiting the minimum of 3 minutes for adequate anaesthesia and vasoconstriction to take place, the flexible nasendoscope can then be passed, visualizing the entire nasal cavity. As the distal tip nasal endoscope with a working channel is passed into the oropharynx, again careful inspection of all mucosal surfaces takes place. With the endoscope tip sitting approximately level with the tip of the epiglottis, the patient is asked to sustain an 'eee' sound while 2 mL of 4% lidocaine is slowly dripped onto the vibrating larynx. The vibrations disperse the lidocaine to most of the laryngeal mucosal surfaces, providing wide coverage of anaesthesia. At that point the larynx is appropriately anaesthetized and the desired procedure can be performed.

Transoral approach

Due to the superior image quality of rigid transoral endoscopy, most of the author's office procedures utilize a 70 degrees rigid telescope and 1080 p high-definition endoscopy displayed on a 50-inch true high definition plasma monitor. The transoral route is well tolerated in the majority of patients when adequate anaesthesia is administered. The initial delivery of 4% lidocaine is through an atomizing device (**Figure 79.2**) where approximately 0.5 mL is sprayed to cover the tongue base, posterior pharyngeal wall and soft palate. Following this, the tip of the atomizer is angled to 70 degrees (**Figure 79.2** inset) and, with gentle tongue traction, a further 0.5 mL of lidocaine is atomized onto the vallecula, epiglottis and remaining supraglottis. Some lidocaine does contact the glottic surface and into the upper trachea. The endpoint of adequate anaesthesia is when the patient ceases coughing with subsequent topical administrations, keeping in mind the maximal safe volume of 4% lidocaine to use.

Using the rigid telescope in one hand and with either the patient or an assistant providing tongue traction, a curved orotracheal injector is introduced with the other hand. A further 1 mL of 4% lidocaine is slowly dripped onto a vibrating larynx sustaining an 'eee' sound similar to the preparation for transnasal procedures. There is now adequate anaesthesia of the larynx and the planned procedure can be performed. To date, the author has never required more than 4 mL of 4% lidocaine for an AULS.

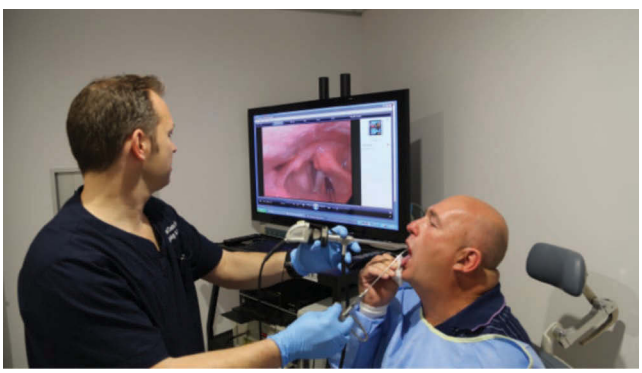

Figure 79.1 The patient sits upright leaning slightly forward flexing at the hips and with slight chin elevation. For the transoral injection laryngoplasty the patient is seen providing traction on their own tongue. This allows the surgeon to use the dominant hand for the injection and the non-dominant hand for the telescope. An assistant is optional, so the procedure can be performed solely by the surgeon.

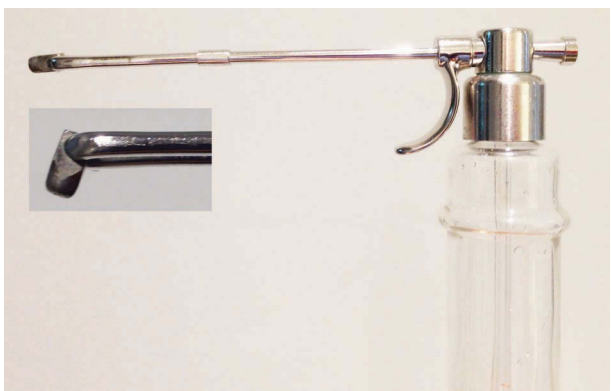

Figure 79.2 An atomizer enables extensive mucosal anaesthesia delivered to the oropharyngeal surfaces. Having graduations marked on the glass bottle can allow a known volume of 4% lidocaine to be used. The inset shows the delivery tip being angled to 70 degrees, which allows excellent mucosal anaesthesia delivery to the hypopharynx, supraglottis and glottis.

Occasionally a bilateral superior laryngeal nerve block is required. The superior laryngeal nerve is found at the midpoint between the superior aspect of the thyroid cartilage and the inferior edge of the hyoid bone laterally. One mL of 4% lidocaine to each side is adequate to achieve sufficient anaesthesia. As with other peripheral-type nerve blocks, approximately 10 minutes is required to have a reasonable effect. Another useful adjunct to topical anaesthesia is administration through a cricothyroid membrane puncture. This universally generates significant coughing and as long as the patient is aware of this pre-injection, they usually find it bearable. The coughing helps distribute the local anaesthetic to benefit the procedure.

LASER LARYNGEAL PROCEDURES

Since the introduction of the carbon dioxide laser into laryngology in the early 1970s,[16, 17] there has been a steady evolution and refinement of the processes for optimizing laser treatment of laryngeal pathology. In the past 15 years there has been an exponential increase in the use of angiolytic lasers in laryngology, both in the operating theatre and in the office. These lasers act by photoablation of the intra-lesional microcirculation through a process termed photothermolysis.[18, 19] Although it has been 30 years since the original description using pulsed dye laser, the modern angiolytic laser industry includes numerous lasers. A list of commonly used office lasers can be seen in **Table 79.2**.

The most commonly used angiolytic laser today in laryngology is the 532 nm potassium titanyl phosphate (KTP) laser. The absorbance of haemoglobin has peaks at approximately 541 nm and 577 nm,[20] allowing the KTP laser energy to be absorbed into the pathology, such as papilloma or dysplasia, with no collateral injury to surrounding normal tissue (**Figure 79.3**). The angiolytic parameters of the KTP laser were studied in the avian chorioallantoic membrane indicating that 35 watts, 15 millisecond pulse width and 2 pulses per second achieved ideal photoablation without surrounding collateral damage. **Figure 79.4a** shows the typical avian chorioallantoic membrane model with its vasculature. **Figure 79.4b** is demonstrating ablation of a single 100 micron vessel without vessel rupture or collateral damage.[20] Findings of this study translated seamlessly to the vocal fold mucosa and remains the author's most frequently used KTP laser settings. In the delicate and highly specialized layered microstructure of the vocal fold, maximal preservation of normal tissue surrounding a lesion is critical to minimizing any vocal deficit.

The 585 nm pulsed dye laser and 980 nm Gold angiolytic laser are less commonly used.[21, 22] All lasers in this class utilize a fibre delivery system, providing the surgeon with a close proximity interface with the laryngeal pathology being treated. Unlike the traditional CO_2 laser through a micro-manipulator using line of sight, fibre delivery office-based angiolytic lasers offer the surgeon safe and effective treatment options for many pathologies encountered. Common lesions suitable for angiolytic laser AULS are listed in **Box 79.1**.

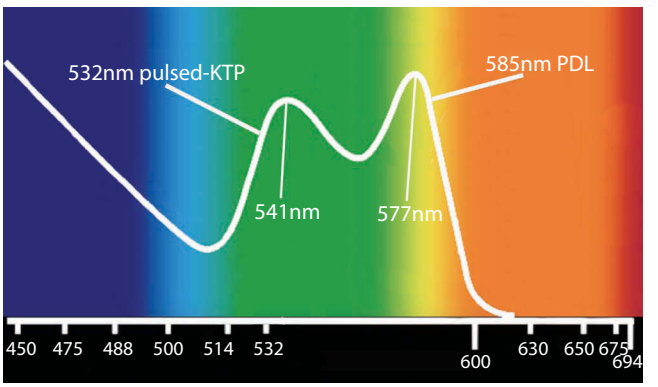

Figure 79.3 The absorbance curve for oxyhaemoglobin shows the peaks of absorbance at 541 nm and 577 nm (thin white lines). Note that the KTP (532 nm) and the pulsed dye (585 nm) angiolytic lasers have wavelengths (thick white lines) in close proximity to the absorbance peaks. This enables maximal absorption of laser energy into the microcirculation of the pathology resulting in photothermolysis.

TABLE 79.2 Angiolysis/fibre-based lasers in comparison

Laser	Wavelength	Chromophore	Advantages	Disadvantages	Fibre size (microns)
KTP laser	532 nm	Haemoglobin	• Haemostatic pulsed and continuous cuts similar to CO_2 • Low cost	• None	300–600
Pulsed dye laser	585 nm	Haemoglobin	• Haemostatic	• Dye kit unreliable	600
Gold laser	980 nm	Haemoglobin	• Haemostatic	• Limited data	300
Thulium laser	2010 nm	Water	• Haemostatic • Smallest fibre	• Increased heat	260–600
CO_2 laser	10600 nm	Water	• Clean cutting	• Increased heat • Large fibre • Cost • Non haemostatic	1210

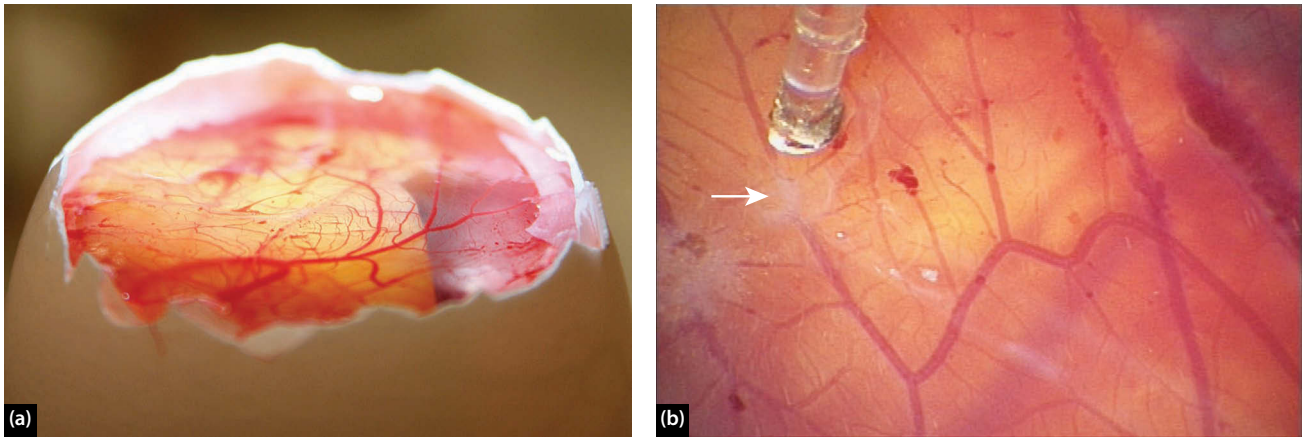

Figure 79.4 The chorioallantoic membrane of a leghorn chicken has been exposed in a day 9 fertilized egg and shown in (a). It provides an established model for simulating vocal fold angiolysis. **(b)** demonstrates the ablation of a second order vessel with no collateral damage to the albumin. The KTP laser was used with a 300 micron fibre, 35 watts, 15 millisecond pulse width and 2 pulses per second.

BOX 79.1 Laryngeal pathology suitable for treatment by awake unsedated laryngeal surgery (AULS)

- Dysplasia
- Keratosis
- Papilloma
- Ectasias
- Varices
- Granulation tissue
- Vocal process granuloma
- Polyp

As the target chromophore is haemoglobin, angiolytic lasers are extremely haemostatic and selected patients can be treated without ceasing anticoagulants. This can significantly simplify management of some patients who may be on warfarin and have laryngeal papillomatosis requiring multiple treatments per year. In contrast, traditional management includes repeated microlaryngoscopies under general anaesthesia, often using the microdebrider or cold steel and therefore necessitating cessation of antiocoagulant therapy. Although not in the angiolytic class, the CO_2 laser can now be used through a fibre delivery system.[23, 24] The BeamPath™ ENT fibre (Omni-guide, Cambridge, Massachusetts, USA) has a spot size of 320 microns but the outer diameter is quite bulky at 1.21 mm. When placing a fibre in the working channel of a flexible endoscope, smaller fibres (such as 300 microns for KTP laser) enable more efficient suctions around them than a larger fibre such as the Omniguide (**Figure 79.5**). Another non-angiolytic fibre-based laser is the 2010 nm thulium laser (Revolix Jr, Lisa Laser, Pleasanton, California, USA). With the chromophore being water, it is highly versatile and haemostatic although it does produce somewhat more heat than the KTP laser.[25–27] The thulium laser has the smallest available fibre, being 260 microns, and has benefits over the CO_2 laser in reduced cost for the laser unit, smaller fibre diameter and – being a solid-state laser – is markedly more reliable (see **Table 79.2**).

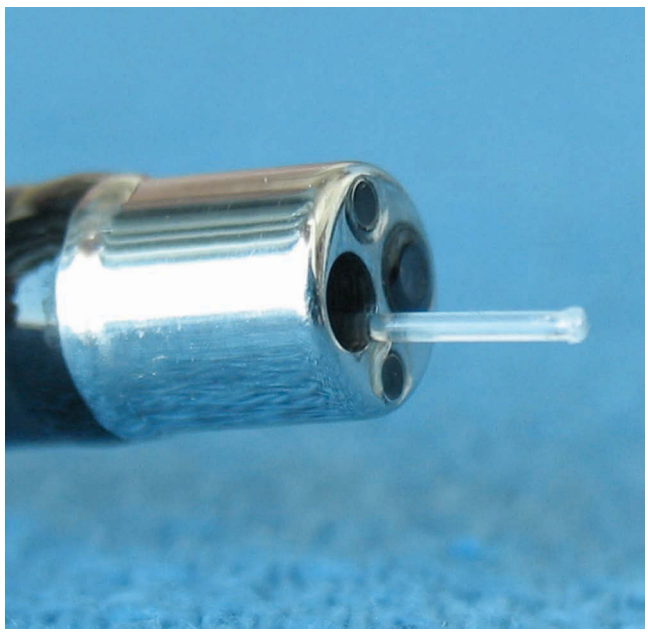

Figure 79.5 The smallest fibre appropriate should be used as this maximized the available space within the working channel of the endoscope for suction. Musocal secretions can become quite viscous and the less space occupied by the fibre in the working channel, the better. A 300 micron KTP laser fibre is seen protruding from the distal chip endoscope with significant suction space around the fibre.

LARYNGEAL PATHOLOGY SUITABLE FOR AWAKE UNSEDATED LASER LARYNGEAL SURGERY

Laryngeal pathology with prominent microcirculation can be well treated in the awake unsedated patient with fibre-based laser systems. (**Figure 79.6** and **Box 79.1**)

Laryngeal dysplasia

Many patients with field change to the glottic mucosal surfaces require careful and frequent office review to monitor

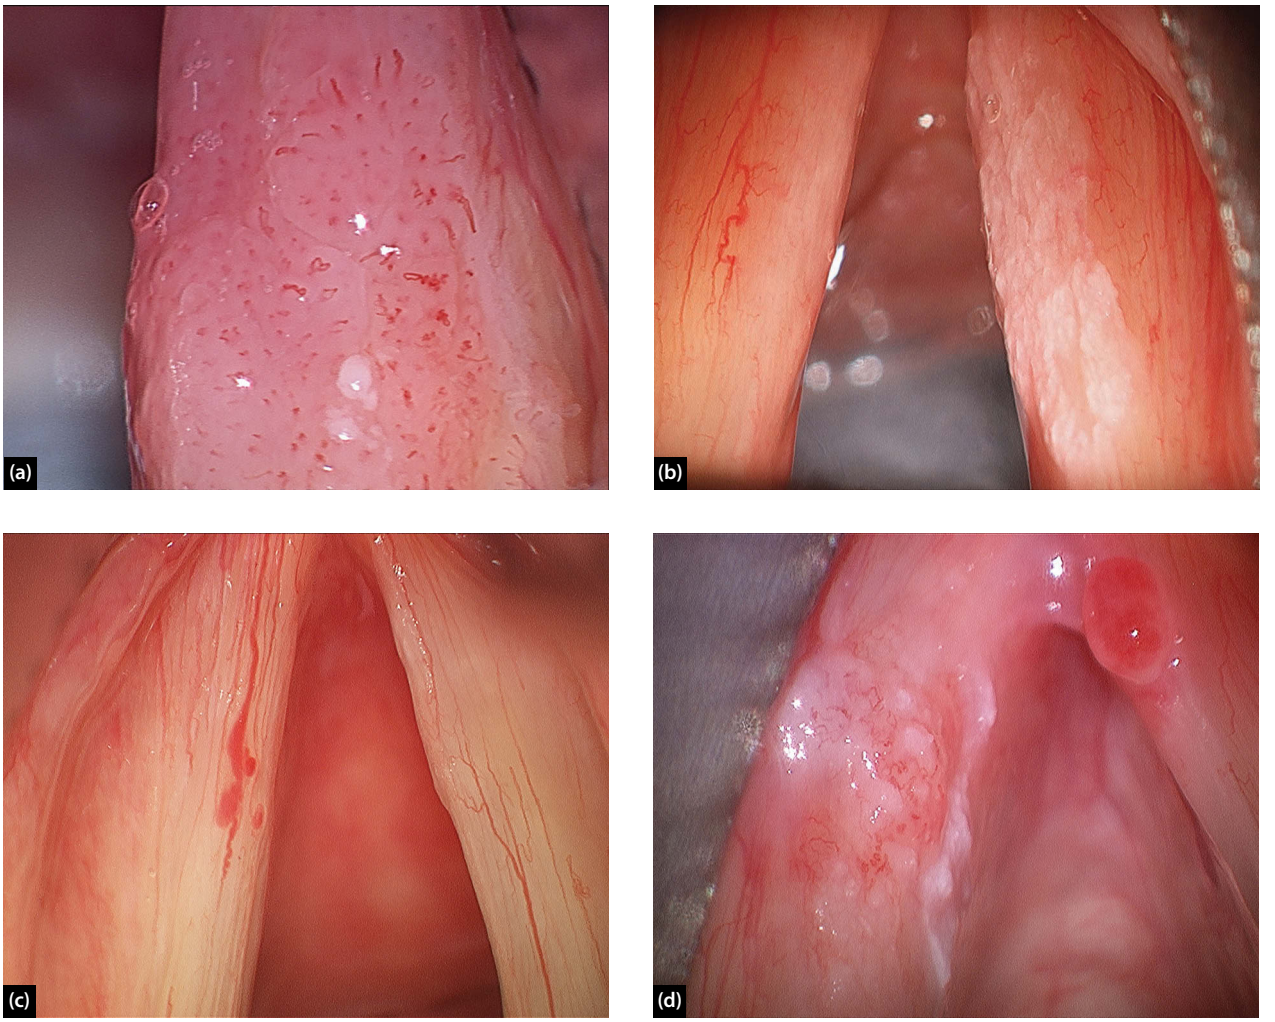

Figure 79.6 Angiolytic lasers are particularly effective for AULS due to the prominent microcirculation within some laryngeal pathology. Laryngeal papillomatosis in **(a)** demonstrates the aberrant angiogenic pattern. **(b)** shows left vocal fold ectasias with right vocal fold dysplasia. A varix and ectatic vessels are seen in a professional opera soprano in **(c)**. A small T1a squamous cell carcinoma in **(d)** further highlights the aberrant vessel growth pattern with these lesions. In all pathologies depicted, the angiolytic laser energy is absorbed by the microcirculation leading to lesion ablation with maximal preservation of the surrounding layered microstructure of the true vocal fold.

the extent of the dysplasia and keratosis and for possible malignant transformation. With the high resolution of endoscopy and fibre-based laser systems, many of these patients can now be managed with AULS procedures. In this setting, angiolytic laser ablation of regions of keratosis or dysplasia is performed and small biopsies can be taken. The procedure is generally very well tolerated and avoids the frequent hospital admission, general anaesthesia and multiple biopsies with traditional management. This in turn avoids the risks of permanent voice impairment and repeated general anaesthesia. The angiolytic epithelial ablation allows for subsequent re-epithelialization of the laryngeal mucosa tending to normalize this layer. Such a result can be seen in **Figure 79.7a** and **79.7b**. A typical glottic mucosal picture is seen with keratosis and dysplasia (**Figure 79.7a**). After a single office KTP laser ablation and more than 2 years following the procedure, the vocal folds still appear normal (**Figure 79.7b**) and the voice remains markedly improved. The concept of proactive management in field change keratosis/dysplasia is a substantial step forward in managing this difficult condition. It moves the surgeon away from the traditional 'wait and see' approach, where periodic microlaryngoscopies under general anaesthesia with biopsies cumulatively destroy the voice in managing benign disease. Benefits of this paradigm shift include preservation of the voice by avoiding multiple glottic biopsies and reduced burden on the outpatient clinics as close follow-up of field change is no longer applicable.

Laryngeal papillomatosis

Patients with laryngeal papillomatosis are well known to require multiple hospital admissions under general anaesthesia to manage this condition. The goals of treatment are to maintain airway patency and for voice preservation. It must be stressed that papilloma arises from the epithelium and as such, treatment should be confined to a depth

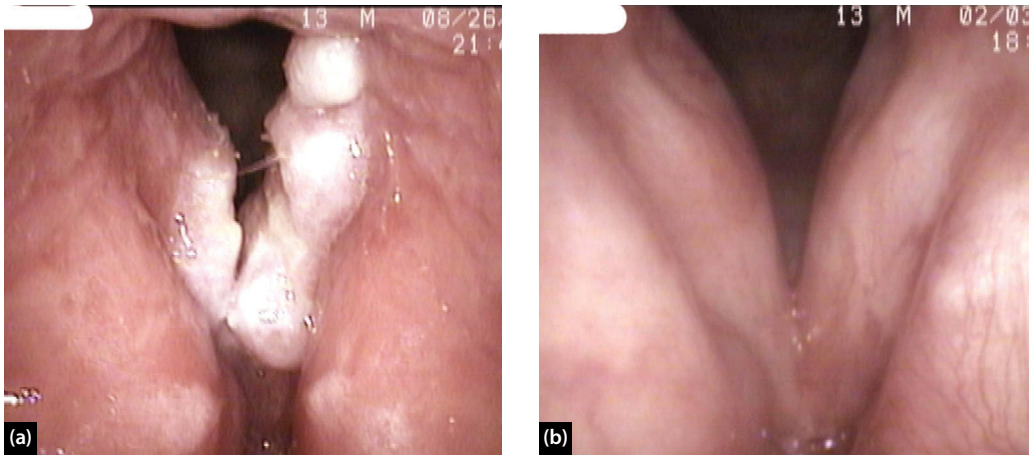

Figure 79.7 A typical patient with extensive keratosis and dysplasia is depicted in (a). This patient was medically unfit for general anaesthetic and was initially offered curative intent radiation for a presumed glottic cancer by the multidisciplinary team. He was then treated by the author with AULS utilizing KTP laser. Biopsies showed dysplasia but no cancer and after two office treatments the entire glottic surfaces normalized as, did his voice with follow-up now at 3 years **(b)**. This is a typical outcome for such a patient and avoided unnecessary radiation.

no more than the epithelial layer. Under traditional management the patient typically undergoes repeated general anaesthaesia and use of the microdebrider or non-angiolytic lasers to control the disease. To limit the number of general anaesthetics, procedures tend to be scheduled before there is substantial regrowth. In this setting, with the loss of many landmarks, it is not difficult to stray deep to the epithelial layer of the vocal folds and permanently denude the superficial lamina propria (SLP). As this can occur over many treatments with time, many patients become vocal cripples. As a paradigm shift, these patients can be initially controlled in theatre with angiolytic lasers and then transferred to the office setting for maintenance treatment with angiolytic lasers.[28, 29] Performing office procedures to control laryngeal papillomatosis can also limit the risks associated with frequent general anaesthesia and airway surgery.

In a typical initial presentation in a patient with extensive disease, treatment is first undertaken at microlaryngoscopy in theatre with general anaesthetic. In this setting, the author uses KTP laser ablation of all laryngeal papillomatosis. It is critical under the operating microscope to identify all mucosal areas of papilloma and treat them. For very early disease, the most subtle finding for papilloma is loss of the linear blood vessel growth pattern in normal mucosal. One can clearly see the loss of this normal pattern in **Figure 79.8** as the epithelium thickens and the vessels become aberrant with papilloma growth. Once this visual sign is noted, the surgeon can quickly identify areas of abnormal epithelium both under the operating microscope and using office-based high definition endoscopy. In both settings, angiolytic laser ablation can then be carefully directed to the diseased surfaces. With the appreciation of the subtle vascular changes seen clearly under high definition office endoscopy, there is little need for additional expensive endoscopy devices such as narrow band imaging.

At microlaryngoscopy, careful inspection of the ventricles is critical. On numerous occasions in tertiary referral cases, the author has found papilloma filling the ventricles that had not been noted at the referring ENT centre. In a setting such as this, seen in **Figure 79.9**, endoscopic removal of the false cords exteriorizes the ventricles and allows for both subsequent surveillance and treatment of recurrent papillomatosis. Having adequate access to all laryngeal mucosal surfaces is invaluable in the office-based setting to manage recurrent laryngeal papillomatosis.

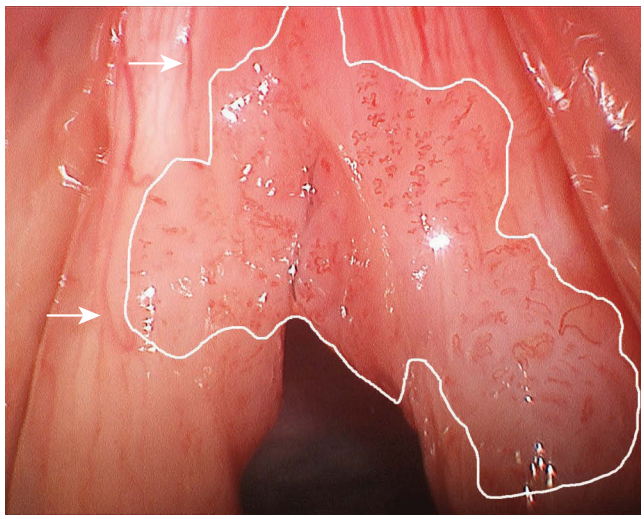

Figure 79.8 The loss of normal linear vascularity of the true vocal fold mucosa is seen clearly, outlined in white, by papilloma growth. The mucosa thickens and aberrant angiogenesis leads to the typical papilloma appearance, which can be clearly defined from the surrounding normal tissue. Being acutely aware of this interface appearance can allow the astute surgeon to easily identify abnormal regions of papilloma in the office setting and deliver target-specific angiolysis.

After office-based angiolytic ablation of the papillomatosis, subepithelial tissues are injected with bevacizumab.[30,31] Bevacizumab (Avastin®), a vascular endothelial growth factor inhibitor, appears to reduce the angiogenesis critical to papilloma regrowth, and can reduce the frequency of procedures and extent of papilloma recurrence. In some patients, the disease has remained in remission.[32]

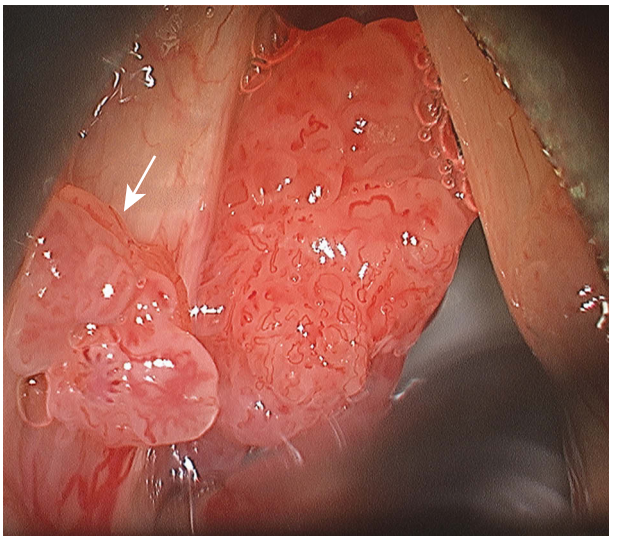

Figure 79.9 It is crucial in managing papilloma to closely inspect each ventricle at the time of microlaryngoscopy. This allows clearance of the entire ventricular disease, such as that shown by the white arrow. The false cord is also removed exteriorizing the ventricle. This enables unobscured surveillance of all laryngeal mucosal surfaces and enables easy access to the ventricle should disease recur.

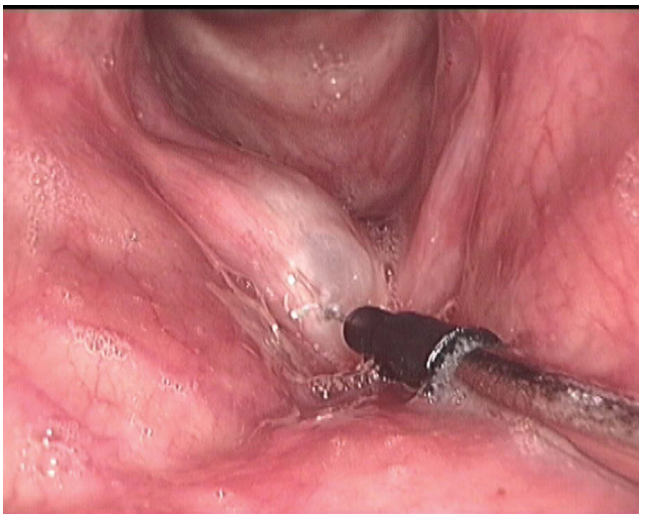

Figure 79.10 A simple office-based injection into the superficial lamina propria (SLP) can be performed as adjunctive treatment to angiolytic laser ablation of laryngeal papilloma. Note the distention of the SLP from the bevacizumab injection at 25 mg in 1 mL. This 10-minute awake procedure greatly simplifies managing some laryngeal conditions avoiding repeated microlaryngoscopies.

The half-life for bevacizumab is approximately 1 month. Given this, office-based injections are likely to be most effective when the supposed angiogenic 'switch' occurs within that month. **Figure 79.10** shows a typical injection in the office setting of bevacizumab, avoiding the need for general anaesthetic for such a short and simple procedure.

Patients with more aggressive or frequent recurrences tend to respond better to bevacizumab injections. Doses typically used are 25–50 mg (25 mg/ml).[30–32] Since first using Avastin in 2009, the author has noted many patients to have total eradication of the disease, who prior to commencement on bevacizumab, underwent multiple procedures per year. The only change associated with the eradication of papilloma has been the addition of KTP laser and bevacizumab to the management.

Laryngeal ectasias and varices

Some patients may present with a small vascular anomaly of the vocal fold and the only treatment necessary is removal of the lesion. For a simple ectasia or varix that is causing recurrent haemorrhage in a professional voice user, ablation of the lesion is required. Although this is typically done in the operating theatre under general anaesthesia with microlaryngoscopy, in suitable patients where there is no additional underlying pathology (e.g. nodules) the surgeon can ablate the lesion in the office setting safely with an angiolytic laser with maximal preservation of the layered microstructure of the true vocal folds.[21, 28, 33–35]

Figure 79.11 shows a typical lesion in a 62-year-old male causing recurrent haemorrhage. It was easily ablated with the KTP laser (settings: 35 watts, 15 ms pulse width, 2 pulses per second) as an awake unsedated office procedure with no recurrence at 1-year follow-up.

Arytenoid granuloma, laryngeal granulation, polyps and glottic web

There are numerous other entities that can be treated in the awake unsedated patient. This can be an attractive alternative when risks of general anaesthesia to the patient are high or there is patient preference for avoiding general anaesthesia or hospital admission. The lack of precision in treating these entities during an awake procedure when compared to suspension microlaryngoscopy and general anaesthesia needs to be explained to the patient.[36, 37] However, treating an arytenoid granuloma, polyp or granulation is a debulking procedure and high level precision is not critical. In polyp management, reports indicate reduction in size can be achieved with office laser treatment. Mallur et al. reported all lesions to have regressed over a 1-year follow-up.[38] Ivey et al. reported that office pulsed dye laser was able to reduce the polyp size by greater than 70% in approximately one-third of cases. It was also reported that up to 40% of patients did proceed to phonomicrosurgical resection as definitive treatment.[36] Although polyps can be debulked in this setting, it is more in the patient's best interest to elect for a near 100% success rate by treating a vocal fold polyp in theatre with microlaryngoscopy utilizing phonomicrosurgical techniques rather than accepting a simple reduction in lesion size through an office debulking procedure, which can sometimes involve multiple procedures.

Techniques for awake unsedated laser laryngeal surgery

As discussed under the injection section, the approach for laser treatments in the awake unsedated patient can be either transnasal or transoral. The author's laser preference is the

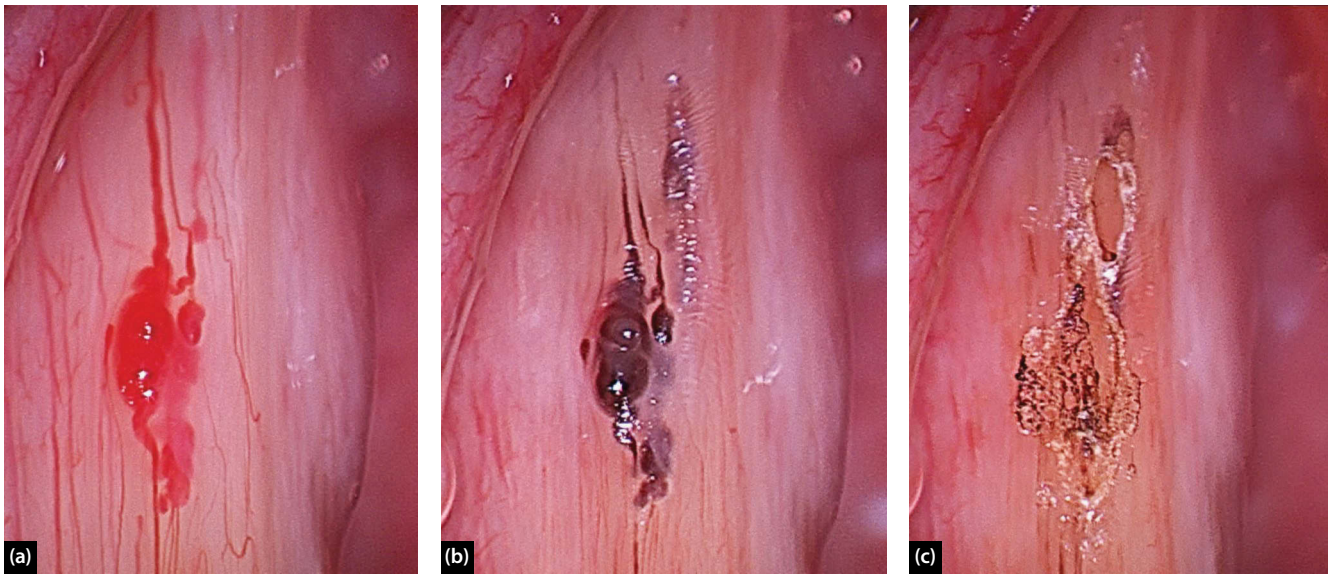

Figure 79.11 A 62-year-old male with recurrent true vocal fold haemorrhage from a large left vocal fold varix. (a) This can be easily ablated with an angiolytic laser (KTP laser in this case). Note the coagulum formed before final ablation **(b)** and no collateral injury to the true vocal fold layered microstructure **(c)**. After 1 week of voice rest, review showed complete resolution and at 2 years there remains no recurrence.

532 nm KTP laser (Aura XP, American Medical Systems, Minnetonka, MN) due to its small fibre size (300 microns), solid state, relative portability, variable power, pulse width and pulse frequency, and reasonable price.

In the transnasal approach, the patient preparation and distal chip flexible endoscopy placement is identical. For simple lesion ablation such as papilloma or ectasias, the fibre is brought into view and the laser is engaged. Initial blanching of the lesion will occur before it is completely ablated. **Figure 79.12** shows the glottic papilloma being ablated with the KTP laser. After the lesions blanch and are suctioned free, the underlying surface heals cleanly. If papilloma is being treated, then after ablation, the fibre tip or endoscope tip can be used to dislodge treated disease. After this, the under surface can be inspected and treated if necessary. Although lidocaine can have a 45–60 minute duration of anaesthesia, only approximately 15 minutes of adequate anaesthesia time for an awake procedure is available. Despite this, the majority of papillomatosis in a patient's larynx can be successfully treated in one setting, while occasionally a staged procedure is required for extensive disease.

For an arytenoid granuloma, granulation tissue or a polyp, the laser fibre is held in contact mode and the lesion ablated. Suction or the tip of the scope can be used to manually debulk the lesion further as treatment is completed. **Figure 79.13** shows the treatment of a vocal process granuloma with KTP laser and botulinum toxin injection in the office setting. The procedure took 10 minutes and the patient was able to drive himself home shortly after (**Figure 79.13**). These lesions can also be treated using the CO_2 or thulium lasers with fibre-based delivery. Both are highly efficient at removing such tissue and the latter is highly haemostatic. If using these lasers, care must be taken not to overtreat the base of the lesion at its interface with any SLP. These lasers have a markedly higher likelihood of creating thermal damage to the underlying SLP with subsequent fibrosis and scarring resulting in dysphonia.

TRANSNASAL OESOPHAGOSCOPY, PANENDOSCOPY AND BALLOON DILATION

ENT surgeons have long been competent in rigid oesophagoscopy and bronchoscopy in the theatre setting under general anaesthetic. In the office setting, hundreds of times each year, ENT surgeons use flexible nasopharyngoscopes to assess the upper airway. With improvements in distal chip image quality and narrow endoscopes with a working channel, the surgeon can progress forward to a more comprehensive aerodigestive tract assessment. Building on the highly familiar nasopharyngoscopy technique, the ENT surgeon can now pass the endoscope safely into the oesophagus and trachea for close-proximity assessment and treatment.

TNO is increasingly being used by otolaryngologists, with the advantage of avoiding hospital admission and sedation, which is traditionally performed in endoscopy suites. Although TNO can be performed with a bronchoscope, dedicated endoscopes are available for the purpose. The outer diameter ranges from 3.1 mm to 5.3 mm. A port or working channel is required (2 mm diameter) for suction, biopsy forceps, injection device or a laser fibre. An alternative model is to use a sheath around the endoscope that incorporates insufflation and instrumentation channels. The advantage of the sheath technique is that the endoscope does not need to go through a full sterilization cycle and several patients can be assessed in a single setting.

Common indications for TNO (listed in **Box 79.2**) include laryngopharyngeal reflux, dysphagia, monitoring

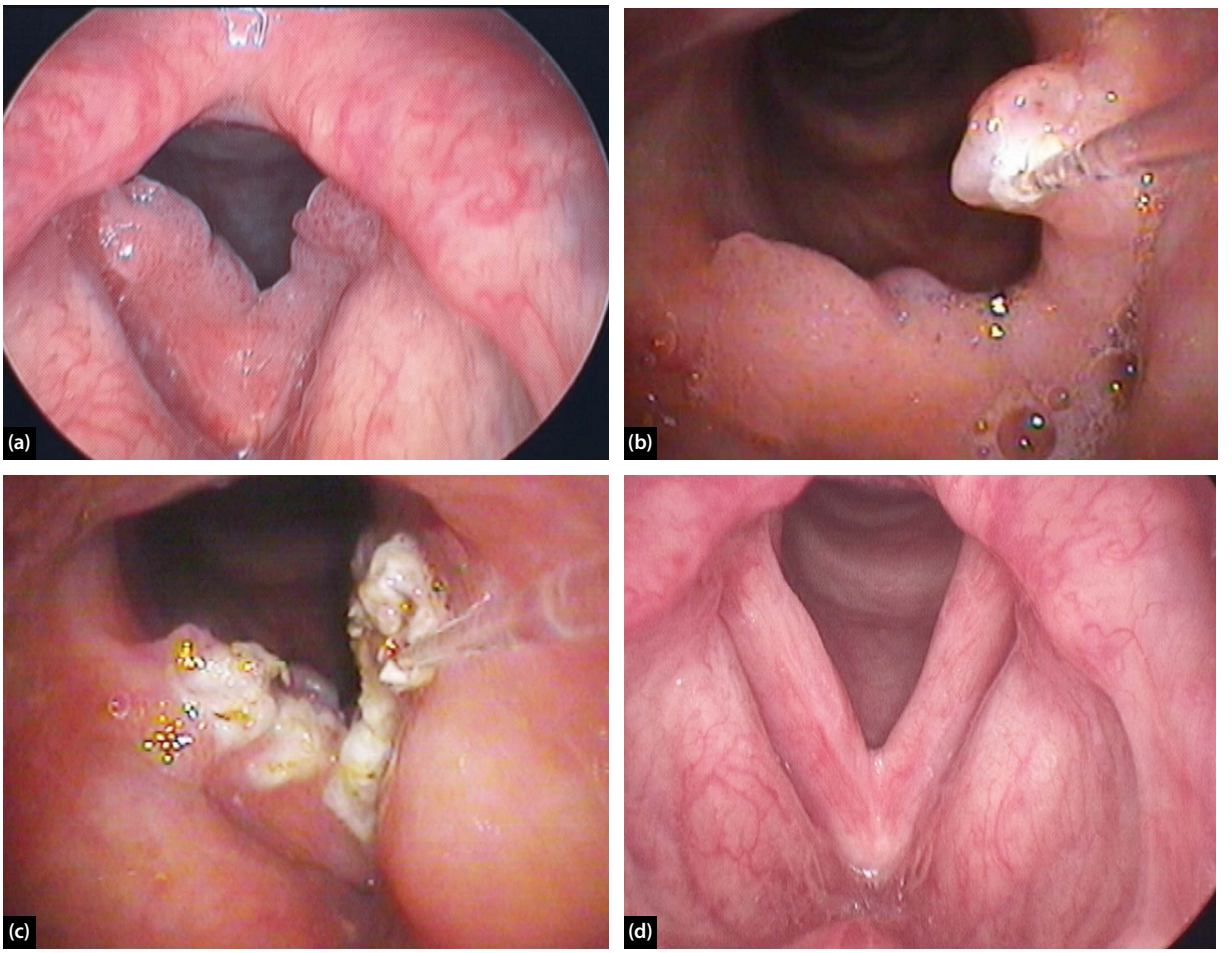

Figure 79.12 Typical glottic papilloma is seen covering both vocal fold surfaces in (a). Initial ablation with a 300 micron KTP laser fibre (settings: 35 watts, 15 ms pulse width, 2 pulses per second) of the posterior left papilloma is seen in **(b)**. As the procedure continues, **(c)** shows the majority of the papilloma is now ablated and can be scraped free with the fibre tip or the endoscope tip. After two office treatments and 2 years later, the patient remains free from papilloma **(d)** and with markedly improved voice. This patient had undergone previous microlaryngeal surgery with severe anaesthetic reactions. He refused microlaryngeal surgery offered prior to his referral to the author but agreed to AULS. Note the absence of any bleeding in the procedure due to the significant haemostatic nature of the KTP laser.

of Barrett's oesophagus, screening for head and neck cancer, chronic cough and procedural (injection Botox, balloon dilation, tracheo-oesophageal puncture and placement of pH probes). It is important to note that, in skilled hands, there is no measurable difference in diagnostic accuracy rates between conventional oesophagoscopy and the newer TNE.[6, 38–45] In addition, for TNO the patient tolerance is very high and risks are minimal. Rates of epistaxis are below 2% with vasovagal events being even less common.

Aside from TNO, the same endoscope can be used to perform panendoscopy in the office setting,[45] although routine bronchoscopic evaluations are not performed these days owing to the availability of high resolution CT scans. In a primary workup, for example of a small vocal fold tumour, a 15-minute in-office panendoscopy can safely provide the necessary information. Traditionally, a head and neck cancer patient would undergo a hospital admission, general anaesthesia with biopsy and panendoscopy (microlaryngoscopy, oesophagoscopy and bronchoscopy) for assessment of the disease extent. In selected patients this can be safely done in the awake unsedated patient in the office. Utilizing AULS, equivalent information is gained when compared to the traditional panendoscopy but it does spare the patient the downtime of a hospital day/overnight admission and the general anaesthetic. This is particularly attractive to patients who may be returning in a week or two for definitive surgery and minimizes their time in the hospital system and number of procedures. If a biopsy is required, in selected patients this can be done with a cup forceps through the channel of the endoscope or with a transoral approach using curved biopsy forceps, seen in **Figure 79.14**.

Reports have emerged of in-office balloon dilation for upper tracheal or subglottic stenosis.[46, 47] Although there appears to be reasonable safety, temporarily occluding a patient's airway in the office must be cautioned against. This can be simply performed in theatre and dramatically reduce patient risks. Achker et al. reported on a subglottic stenosis treated under general anaesthetic in which the balloon catheter failed to fully deflate. The catheter, while under traction maintaining the balloon in the desired location, tore and left a partially deflated balloon lodged in the trachea. Fortunately, during the general anaesthetic the balloon could

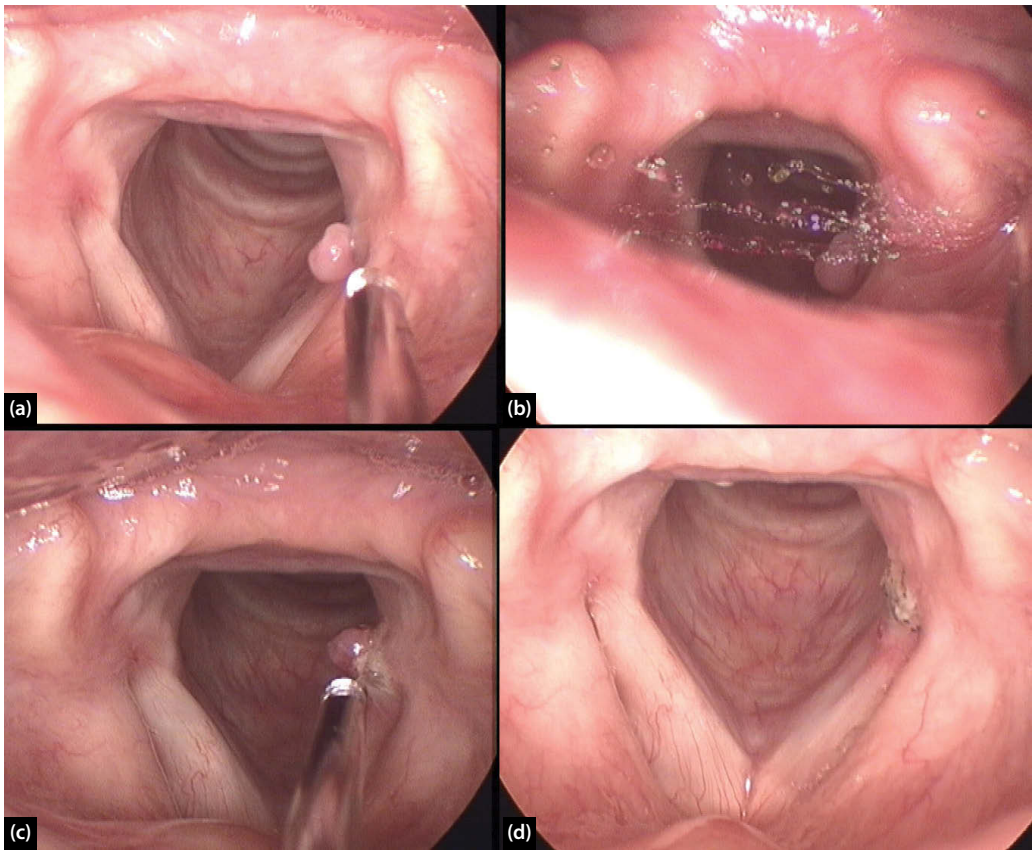

Figure 79.13 Although not routinely required in the author's practice, debulking of an arytenoid granuloma can be performed with AULS. **(a)** shows the left arytenoid granuloma; **(b)** demonstrates the dripping of 4% lidocaine for topical anaesthesia; **(c)** shows the KTP laser fibre delivered transorally through an oro-tracheal injector to ablate/debulk the lesion; **(d)** highlights the minimal collateral thermal injury by angiolytic lasers and the patient then underwent botulinum toxin injection into each thyroarytenoid and lateral cricoarytenoid muscle as part of the procedure. There was total resolution of the lesion by 1 month and he has remained granuloma-free for over 2 years.

BOX 79.2 Indications for transnasal oesophagoscopy (TNO)

- Diagnostic:
  - dysphagia, globus, laryngopharyngeal reflux
  - monitoring Barrett's oesophagitis
  - head and neck cancer surveillance
  - panendoscopy + biopsy
- Therapeutic:
  - balloon dilation
  - angiolytic laser therapy
  - tracheo-oesophageal puncture
  - botulinum toxin injection
  - foreign body disimpaction

be fully deflated and removed with no adverse patient outcome. If that occurred in the office setting, patient death would have been the likely consequence.[48]

Patient preparation and position

Patient position and topical anaesthesia for TNE or panendoscopy is identical to that described for transnasal laser or injection procedures. In addition, however, the patient is asked to be nil by mouth for 3 hours pre-procedure. The distal chip endoscope is passed into the nasal cavity and advanced to the hypopharynx, inspecting all mucosal surfaces on the way. The patient is then asked to lean with chin forward and down, as if looking over a fence, while the endoscope tip is advanced into the pyriform fossa. At this point, the patient is asked to swallow and gentle caudal pressure on the endoscope will allow it to pass into the upper oesophagus. Air insufflation is then used to dilate the oesophageal lumen and mucosal inspection is carried out as the endoscope moves caudally into the stomach.

There are three anatomical narrowings in the oesophagus that should be anticipated:

1. Aortic arch, at 26 cm, identified by pulsations on the left anterolateral wall
2. The left mainstem bronchus, which can be seen on the anterior wall at approximately 2 cm below the aortic arch
3. The lower oesophageal sphincter at the distal oesophagus.

After inspection of the stomach and retro-flexion to view the gastro-oesophageal junction and antrum, the scope is retracted. Further inspection occurs with withdrawal of the scope, noting the squamo-columnar junction. The endoscope can then be passed through the anaesthetized

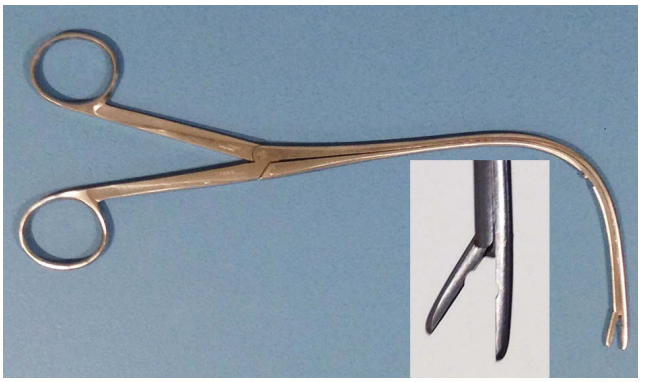

Figure 79.14 During a panendoscopy a lesion can safely biopsied in selected patients with a transoral biopsy cup forceps as shown. Note the cup jaws in the inset that enable a generous biopsy to be taken under direct vision.

vocal folds to inspect the subglottis, trachea and main stem bronchi. Following this procedure, the patient remains nil by mouth for 1 hour to minimize aspiration.

SUMMARY

With significant improvements in endoscopic technology and instrumentation of the upper airway there has been an exponential increase in AULS performed in the operating theatre or office setting. Although the majority is performed in the office, reimbursements can drive patients to the operating theatre for AULS.

Injection of a wide array of substances can be safely and reliably performed in patients in the office setting, managing a range of pathologies including vocal fold paralysis, presbyphonia, glottic defects from cancer resection, botulinum toxin, bevacizumab and saline. Angiolytic lasers (commonly the KTP laser) delivered by small flexible fibres can be used to treat a vast range of laryngeal pathology and obviate the need for hospital admission and general anaesthetic in selected patients. Patient selection and preparation, together with realistic expectations for the surgical outcome, are critical in utilizing this newly established approach to patient management.

KEY POINTS

- With improvements in technology, significant experience has accumulated worldwide in outpatient laryngology.
- This skillset is especially valuable in managing patients who may be unsuitable for general anaesthetic assessment of the larynx (poor general health or anatomical reasons that hamper access).
- A variety of basic and advanced laryngeal interventions can be performed in the outpatient setting (biopsy, cord injection for medialization, botulinum toxin injection and laser surgery.
- A robust emerging body of evidence supports incorporating transnasal oesophagoscopy into ENT practice, a procedure that has also found favour among gastroenterologists.
- The transnasal oesophagoscope can also be used for interventions such as tracheoscopy and oesophageal dilatations.

SEARCH STRATEGY

Data in this chapter may be updated a Medline search using the keywords: rhinoplasty, trauma, saddle nose deformity, deviated nose nasal septal reconstruction, nasal valve.

INTRODUCTION

Nasal fractures are the commonest facial fracture and occur at all ages. Forty per cent of facial fractures affect the nasal bones, and many of these involve damage to the nasal septum. It must be remembered that external forces sufficient to create a bony or cartilaginous deformity also damage the overlying skin and soft-tissue envelope, commonly leading to a scar or contour abnormality.

Both functional and aesthetic problems occurring after injury may prompt a patient who might not otherwise consider operations to seek treatment and the variation and variety of defects require a very extensive knowledge of septal and rhinoplasty surgery to correct these deformities adequately.[1]

A distinction should also be made between childhood and adult fractures, as any injury in the growing nose will likely have consequences for future nasal development. Growth in the facial skeleton is more often than not asymmetric and may result in the appearance of a 'damaged nose' even when there is no history of prior significant trauma.[2] Trauma, however, can be superimposed on pre-existing deformities or in a patient who has had a previous rhinoplasty such that the patient attributes the whole deformity to an injury, so it is essential to enquire about pre-injury status functionally and aesthetically – if possible with old photographs.

ASSESSMENT

It should be clearly documented whether the primary issue is functional, aesthetic or both. In addition to the standard clinical rhinoplasty photographs, a head-down photograph is very useful in determining displacement or deviation of the normal dorsal aesthetic lines. Each third of the nose should be examined, looking for irregularity, asymmetry or deviation. In the basal view, particular attention should be paid to the caudal septum, nostril symmetry and any insufficiency of the nasal sidewall.[3] There is often valve dysfunction following trauma and particular attention needs to be paid to each of the four plains of the nasal valve, both medially and laterally. Endoscopy is very useful in evaluating the dynamic status of the nasal airway in both the natural and decongested mucosa and particularly to assess any turbinate hypertrophy.

Treatment of acute nasal injuries frequently results in persistent asymmetry or deformity, often necessitating secondary reconstructive surgery. Lateral blows to the nose may produce a simple, depressed nasal bone, displacement of the bony/cartilaginous pyramid or deviation of the nasal axis in the lower two-thirds due to vertical fracture of the cartilaginous septum. Frontal blows may produce a simple fracture of the tip of the nasal bones, injury to the cartilaginous vault with widening of the bridge and, in more severe injury, horizontal fracture or fractures of the septum leading to loss of height either in the middle third or at the anterior septal angle. This is the

TABLE 80.1 Possible residual deformities following nasal trauma

Area of nasal trauma	Possible residual deformity			
Upper third	Depression of bridge – central or unilateral	Lateral displacement	Asymmetric lateral displacement	Vertical displacement of bone(s)
Middle third	Upper lateral cartilage collapse – loss of septal height	Lateral displacement with septal dorsal line	Asymmetric displacement	
Lower third	Loss of projection (septal angles) Dome asymmetry, bossa	Collapse of nostril margin, deviation of tip, caudal septal dislocation	Soft-tissue loss/ scar- notching irregularity	Lengthening of upper lip, acute columella/ labial angle
Skin envelope	Scar, tattooing, contour loss			
Nasal valve dysfunction	Septum angulation Septal loss, perforation	Lateral nasal sidewall insufficiency	Synechiae	

saddle nose deformity. **Table 80.1** illustrates the various types of residual deformity following trauma.

TIMING OF SURGERY

Primary management of trauma

The window to reduce a nasal fracture is variable but most advocate closed reduction within 2–3 weeks, possibly earlier in children. Early reduction is indicated for upper-third bone deformities and this may range from simple elevation of a depressed bone to a four-step manoeuvre in an impacted deviated pyramid. Here, the deformity is exaggerated using a Walsham type forceps to disimpact the vertically placed bone further outwards, the opposite (depressed) bone is then lifted out away from the deviated side, before a straight Ash forceps lifts the central vault of the pyramid including the upper septum and moves it back to the midline before manually pushing the sidewalls inwards to close the roof. Unstable pyramids should have an external splint applied for a week and an internal splint if concomitant disimpaction of the septum is required via a submucosal approach.[4]

Post-trauma rhinoplasty can be undertaken in the acute or subacute period or at an interval following the main injury. The main indication for early rhinoplasty (open reduction of nasal fracture) is for treatment of an acute saddle deformity to reconstruct septal height or in complex nasoethmoidal fractures where the nasal bones need to be stabilized (see Volume 1, Chapter 107, Nasal and facial fractures). Rhinoplasty techniques applicable in the acute phase are those usually to restore the height of the dorsum from a frontal blow such as falling forwards against an edge. In this scenario, as well as the nasal bone widening, there is collapse of the septum under the upper laterals. This is difficult to restore at a later date once scarring and fibrosis are established.[5] Fixation of the dorsal keystone area may be required using drill holes in the thicker part of the nasal bones and suture fixation to hold the perpendicular plate/quadrilateral cartilage together, with repair to the upper laterals (**Figure 80.1**) A supporting piece of posterior perpendicular plate with perforations or cartilage may need to be sewn to support the fragments of the lower two-thirds of the septum.

Lacerations to the skin over a compound fracture need to be closed primarily but may provide access enabling primary reduction of displaced nasal bones. In general, reconstructive rhinoplasty apart from manipulations is usually deferred until the soft-tissue envelope has healed.

'The missed opportunity' – sub acute

Where the nasal bony pyramid is displaced but the time from injury has passed that of closed manipulation, reopening the fracture lines usually with a 2 mm osteotome endonasally or via stab percutaneous approach can remobilize the fragments and allow better realignment. In this instance classical osteotomies are not performed, only those that reopen the partially healed fractures. If there is a history of pre-trauma deformity, then adequate realignment is unlikely, and it is probably wiser to counsel the patient to let the fractures and the skin envelope settle and consider a formal rhinoplasty after 6 months.

POST-TRAUMA RHINOPLASTY

General principles

This covers soft-tissue envelope damage, acquired nasal deviations, sidewall deformity/asymmetry, dorsolateral contours and the nasal septum.

The key structure to repair is the septum, especially when there are high septal deviations such as occur in Chevallet fractures, loss of the septal angles or where there has been septal cartilage necrosis due to haematoma. The important principle is to create a stable dorsal line connected to the nasal bones and then correct the position of the anterior and posterior angles as these two important points determine the support of the tip cartilages, nostril shape and the columella–labial profile. Being the least supported part of the nose, the caudal/dorsal free septum is the most frequently damaged. Simple oblique fractures can be released and the fragments secured by batons or pieces of perforated

Figure 80.1 (a–d) Acute saddle nose deformity following a frontal blow to the mid dorsum. **(e–h)** Post treatment.

perpendicular plate sutured usually on the more concave side. Curvature of the leading edge of the dorsum will usually require reinforcement: bilateral spreader grafts (often asymmetric) provide a secure compression that is not always possible with a unilateral graft.[3]

If the deformity is severe and the cartilage scarred or of poor quality, it is better to replace the dorsal or caudal septum. Invariably, wide exposure via the external approach with full septal dissection gives the best control to evaluate the deformity and to reconstruct. A graft, either from more posteriorly in the septum or from costal cartilage, is required (and spreader grafts are also needed to stabilize the dorsal line), so an adequate source of durable material is required. Rib cartilage can be difficult to use and choosing the more horizontal sixth or seventh rib via a medial inframammary approach gives a straighter graft. Grafts should be thin, and the most effective way to reduce warping is to laminate two pieces that have opposite curvature.[6] This technique produces a stable, straight construct that in the long term minimizes the risks of deformity. Another technique is obliquely sectioning the rib cartilage to include cortex and medulla, thereby having a balanced graft,[7] although this may not produce adequate lengths for extended spreader grafts.

The most important fixation point is to the nasal spine, which should be midline. If not, the spine may need to be modified and a specific drill hole should be made for firm suture fixation, not relying on periosteal attachments. The dorsal and posterior quadrilateral cartilage needs to be secured to the residual dorsal septum or affixed to the perpendicular plate and nasal bones. The reader is referred to the references for further reading.[8] Where the existing frame is unusable, a new L-shaped strut has to be created, usually as two or three individual cartilages pieces cut to lock together and fixed with PDS sutures. This gives the option to extend the caudal septum forward to act as a 'tongue in groove' with relatively rigid fixation for the medial crura and will correct columellar retraction. Alternatively, a septal extension graft fixed between two extended spreader grafts and sutured to the caudal septum will achieve the same objective. The leading edge, however, must be in the midline.[9]

Upper third

Modern appreciation of dorsal anatomy recognizes that there is a nasal bone cap covering the upper lateral cartilage/septal cartilages with an average of 7–8 mm,[10] so deformities in the upper third invariably involve cartilage as well as bone. Common deformities include a depressed fracture of one bone with attached upper lateral, depression of one bone with fracture of the upper septum and overriding of the contralateral bone, or a lean of the whole osseocartilaginous vault away from the midline. Fracture of the tip of both bones with loss of height of the underlying septum creates a middle vault saddle with a 'pseudo hump' above. These deformities can be very difficult to correct by traditional osteotomies and need a different approach with more controlled sculpting of the bones by fine rasps or, better, by modern power tools or Piezo surgery.[11]

Creating predictable fractures with osteotomes is difficult because old fracture lines reopen and comminution of bones can occur. Pre-operative CT facial bone scanning with 3D reconstruction allows more accurate planning. If the nasal bone sidewalls are straight, an open–close book osteotomy sequence including the central upper bony septum will realign the nasal sidewalls, the excess height being reduced from the oblique bone as it is orientated more vertically.[12]

With irregular thickness or shape of the nasal bones, rather than comminution, resculpting with Piezo or a power tool to create better bone shape, changing convexity and permitting a controlled movement minimizes the risk of residual irregularity. The use of securing sutures through the bone and upper septum allows a more satisfactory repositioning than leaving flail segments with little control of how they heal.[13] This requires a different approach from what has been practised since the time of Jaques Joseph of multiple comminuting osteotomies and prolonged splinting, internally and externally.

Contrary to previous teaching, the whole soft-tissue envelope can be raised from maxilla face to maxilla face. Collapse or loss of the nasal bone does not occur when the internal periosteal lining is preserved and this is a significant advantage in using the Piezo device, which will not damage soft tissue. It is not advisable to perform such a wide dissection, however, if traditional osteotomes are used as the internal lining support cannot be guaranteed.

Final contouring of defects or concavities can be done with autologous tissue, such as diced cartilage, either free like a paste, with a fascia wrap (diced cartilage wrapped in fascia – DCF)[13] or moulded using a physiological glue (e.g. platelet-rich fibrin).[14] The use of shavings of cartilage for small volume contours is well established and there is evidence of improved survival of these grafts using them together with platelet-rich fibrin.

Because of the relationship with the cartilage of the mid third, cranially extended spreader grafts between the nasal bones may be used as the solid foundation to widen a narrow upper third over which a more flexible graft can be placed to give a smooth contour.

Middle third

The middle-third support is important to the function of the nose as this is part of the complex area of the nasal valve. A depressed fracture of the nasal bone laterally with the attached upper lateral, internal synechiae across the valve angle, weak vertically placed upper laterals, high septal deviations, loss of height of the septum at its attachment to the upper lateral or damage at the scroll area will all impact on the valve function. Indeed, it is often easier to reconstruct the mid-third contour aesthetically with spreader grafts than to establish a normal functioning valve from collapse.

The lateral middle third is one area that needs to be tensioned between the attachments at the pyriform aperture and the dorsum to prevent dynamic collapse. The principle after adequate septal repair is to support the junctional roof, which is naturally vaulted cranially and caudally presents an angle said to be about 10–15 degrees. Spreader grafts are the mainstay of treatment here for the damaged nose and can be placed at the same level as the septum, just below to act as a pedestal to allow tensioning of the upper lateral sidewall or above the septum if an increase in height is needed and the septum is not being replaced. They are usually asymmetric in size to allow correct contouring of the neodorsum. In the approach to conservation and reorientation, if one upper lateral is large, it may be folded to be used as a turn-in flap (spreader flap), particularly on the oblique side of a deviated nose. Addition to the mid third by onlay grafts to produce the correct contour may also be considered.

Nasal tip/lower third

Fracture, buckling or loss of cartilage can produce multiple deformities in the tip, commonly with associated soft-tissue damage. Through and through scars in the envelope or previous areas of skin loss pose particular challenges in trying to create a smooth contour, especially when involving the rim. It is helpful to consider the dorsal septum/anterior angle position with the tip cartilages as this is the foundation for any repair. Loss of tissue volume usually requires reconstruction with grafts; the ear is a good source as appropriate curved pieces of cartilage either alone or as composite grafts with skin can be tailored. Defects in otherwise healthy tissue up to 2 cm can be composite grafted successfully. With an undamaged envelope, tip repair can be achieved by endonasal techniques if only one area needs attention, but with a more complex problem, especially when the septum is to be reconstructed, the open approach permits wide exposure, release of contractions and accurate repair or grafting.

Commonly used grafts of cartilage are strut grafts between the medial crura, shield and cap grafts, rim grafts for nostril sidewall stability and lateral crural grafts, either to augment or to replace a lost framework.[15] For details of repair of the nasal skin envelope, the reader is referred to Chapter 85, Nasal reconstruction.

The damaged nasal valve

The nasal valve is the flow-limiting segment of the upper airway and has an important function in directing airflow to the middle nasal meatus, as well as providing eddies of air for antegrade olfaction. Interference of the normal airflow may result from damage to the lining with synechiae, and insufficiency of the nasal sidewall either with a fixed deformity at the pyriform or a dynamically unstable sidewall. The addition of active rhinitis or the compensatory hypertrophy of the turbinates either inferior or middle needs to be considered. There are also the medially based deformities related to the nasal septum and the conjoined upper laterals.

The surgical goals need to be defined by identifying the specific areas of deformity medially, laterally, at the vaulted roof and occasionally the sill of the nose. CT scanning with modelling of the valve can assist in planning but assessment by direct vision endoscopically remains the usual examination.

The accuracy needed to maintain the correct septal height and width as well as maintaining the roof/sidewall stability cannot be overemphasized. Often the difference between success and failure is a millimetre in this complex zone, and it is important with any graft not to lose in bulk what you gain in strength.

Whichever method is chosen to repair the wall, it is the author's belief that a customized intranasal splint is essential in the first week, particularly if a three-layer dissection has been undertaken (i.e. skin, cartilage and vestibular lining having been released in the lower two-thirds of the nasal sidewall).

The skin envelope

The variable thickness of the envelope is considerable in the nose. Probably the most frequently traumatized area is at the rhinion where the skin is thinnest. Lacerations, stellate splits and grazing injuries should be cleaned and dressed primarily to prevent tattooing. Subsequent scars and loss of the subcutaneous tissue may fix the skin to the framework of the nose. If this is a risk, massage of the skin using moisturizer will help once the skin has healed. Adequate sun protection of scars and use of silicone gel daily all contribute to good cosmetic scar result. In thin, damaged skin and severe subcutaneous tissue loss, fat grafting to the nose will improve the contour and in atrophic skin add stem cells to improve the quality. This may be considered before definitive repair of the nose using fine cannulae.

Camouflaging the dorsum skeleton at the time of surgery in the presence of thin skin may be achieved by using autologous temporalis fascia, perichondrium from rib or rectus abdominis fascia. Both of these provide a uniform sheet to thicken the envelope and are easier to prepare than periosteum from the retroauricular area. If used over large areas, it is important to suture the sheet with fine absorbable sutures. This type of graft is particularly useful to cover reconstructed cartilage domes in the nasal tip.

REVISION SURGERY

Surgery for the traumatized nose by definition involves repair of damaged tissue. Predictability of outcome should be discussed with the patient, particularly where complex grafting is undertaken as there is a greater need for further, usually minor, revision. This is particularly so when dealing with both functional and aesthetic issues and it is wise to discuss this before any repair.

Infection is a major cause for creating a poor result through loss of tissue, so careful pre-operative evaluation including microbiology culture of the vestibule to exclude MRSA and appropriate advice on post-operative care are considered essential.

Common causes for revision may involve nasal valve disorders (e.g. thinning a wide rib graft caudal septal reconstruction), resuspending a sidewall collapse or a contour problem (e.g. minor saddling, especially at the central keystone area). As with all rhinoplasty revisions, if the skin envelope needs to be fully raised, an interval of about a year is advised. Singe-area deformities can be revised earlier dependent on the skin quality and extent of the area to be augmented/reduced. Alar base correction may be undertaken safely at an early point after the major repair.

NASAL TRAUMA AND CHILDREN

It is recommended that children with trauma requiring reconstruction are referred to specialist centres as often orthognathic and orthodontic services are required parallelling nasal repair.

Children's nasal injuries are common and have the potential to disrupt normal growth, particularly with loss of septal cartilage, as happens with a septal abscess.

Oblique fractures usually heal with fibrous union so continued growth will often produce a deviation from the rhinion. In general it is best to defer surgery at least until after puberty and as close to maturity as possible. This deformity increases with age and it can be difficult to resist pressure to operate early before nasal maturity. The timing is variable between sexes and in individuals and requires a judgement of skeletal maturity and mental maturity in planning the repair, but in general the repair should be as close to skeletal maturity as possible. Osteotomies do not disturb growth of the nose but damage to the growth centres in the septal cartilage does.[16] The septodorsal cartilage and the sphenospinal cartilage should not be disturbed, but conservative relocation on the spine or release of an angulation may be necessary.[17] The patient's parents need to be warned of a possible second operation when growth has stopped.

Where a saddle occurs, replacement by autologous cartilage is preferred as continued growth may then occur. Expansion of the skin envelope by serial placement of Custom silastic dorsal implants replaced every 18–24 months will prevent the problems of the short nose with a tight envelope and allow a definitive correction later, usually employing rib cartilage.

BEST CLINICAL PRACTICE

- ✓ Nasal trauma is a complex issue needing specialist assessment.
- ✓ Childhood injuries need to be monitored to assess growth.
- ✓ Early reduction and alignment of fractured nasal bones with or without septal release should be carried out within 2-3 weeks and acute saddles require early surgical intervention to restore septal height.
- ✓ Cartilage depleted noses will usually need rib grafts for reconstruction and the basis for a stable nose with good breathing is a reconstructed septum and a properly tensioned sidewall.
- ✓ Secondary procedures are common in repair of damaged noses. Finally the soft tissue envelope may also need augmentation.

KEY POINTS

- A suitable referral pathway needs to be established for early assessment of nasal trauma.
- Nasal endoscopy and cone beam CT scanning are helpful in assessment and planning repair.
- External approaches and grafting techniques are usually required.
- Patients should be consented for all graft harvest sites.
- Regenerative surgical techniques may enhance graft survival and improve the quality of damaged skin

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: facial proportions, facial, aesthetics, nasal, examination, assessment and rhinoplasty.

INTRODUCTION

Rhinoplasty is one of the most challenging procedures in facial plastic surgery and consideration must be given to both facial aesthetics and nasal function. It is technically difficult to achieve consistently excellent results and, as the surgery is on the most prominent part of the face, the aesthetic outcome is visible to all. Meticulous planning is therefore essential.

This chapter outlines a systematic approach to the assessment of patients for rhinoplasty/septorhinoplasty that will enable appropriate patient selection and facilitate surgical planning. Assessment should include:

- consideration of the patient's motivations, anxieties and expectations
- analysis of the face
- analysis of the nose
- examination
- photography.

THE PATIENT

It is essential to obtain a clear history of the patient's complaint and symptoms. Identification of any structural, congenital, traumatic, cosmetic and/or functional issues is crucial. Any past history of nasal surgery, sinonasal disease, diabetes, psychopathology, anticoagulant medication, smoking or cocaine use should be elicited.

It is critical to understand the patient's motivations, anxieties and expectations. Why is a patient prepared to undergo the risk and inconvenience of an operation to correct often seemingly minor deformities? Many people have nasal abnormalities but would not consider surgery, so what makes a patient choose to have surgery? For many rhinoplasty patients, their focus on their nose stems back to puberty and daily reflection in the mirror leads to increasing dissatisfaction in their appearance.[1] Studies have shown higher levels of dissatisfaction in personal appearance in patients seeking rhinoplasty than those seeking other aesthetic procedures.[2, 3] In the majority of rhinoplasty patients the motivation for surgery comes from a desire to change or from witnessing favourable outcomes in others.[4] For most it is not the severity of their deformity that leads them to surgery[5] but their perceived difference from the norm in their social environment. The timing for rhinoplasty often coincides with a loss in self-esteem. Rhinoplasty has been shown to have a positive effect on the patient's body image, which is found 3 months post procedure and is still evident 2 years following the procedure.[6]

Identifying high-risk patients

It is important that surgeons recognize potentially problematic patients, as high-risk patients are unlikely to be satisfied with surgical results. A number of unsuitable personality attributes have been described in the literature. Examples commonly referred to are patients with body dysmorphic disorder (BDD), those who are unreasonably demanding or overly flattering, patients who insist on secrecy, the so-called surgiholic, as well as obsessive, perfectionist and impolite patients. The simplified acronyms SIMON (single, immature, male, overly expectant/obsessive, narcissistic) and SYLVIA (secure, young, listens, verbal, intelligent, attractive) describe some of characteristics of the high-risk and the ideal patient respectively.[7–9]

Body dysmorphic disorder

BDD describes an altered perception of one's own appearance that results in distress. It is a subjective feeling of ugliness or physical defect which the patient feels is noticeable to others, although the appearance is within normal limits.[10] Its occurrence is summarized in **Box 81.1**.

The onset of BDD is typically in late adolescence; it is a chronic rather than episodic condition and affects both genders equally. Picavet et al found that 33% of patients seeking rhinoplasty had moderate symptoms of BDD. Only 2% of those seeking rhinoplasty for a medical reason had BDD whereas 43% of those seeking rhinoplasty for purely cosmetic reasons had BDD.[12]

Three questions to ask patients, based on the DSM-IV criteria, have been developed to help surgeons screen for BDD:

1. Are you worried about your appearance in any way?
2. Does this concern or preoccupy you? That is, do you think about it a lot and wish you could worry about it less?
3. What effect has this preoccupation with your appearance had on your life?[13, 14]

A number of both specific and generic questionnaires are available that can help identify patients with BDD (**Box 81.2**). These are designed to be used with those patients with behaviours suggesting BDD. Particular 'red flags' are shown in **Box 81.3**.

BOX 81.1 Body dysmorphic disorder: by the numbers[11]

BDD occurs in approximately:

1%	Adult population
2.3–13%	Students
13%	Psychiatric patients
14–42%	Outpatients with atypical major depression
11–12%	Outpatients with social phobia
39%	Inpatients with anorexia nervosa
6–20%	Patients seeking cosmetic surgery

BOX 81.2 General and specific questionnaires and questions for patients

Specific questionnaires:
- Cosmetic Procedures Screening Scale[15]
- Body Dysmorphic Disorder Questionnaire[16]
- Yale–Brown Obsessive Scale modified for BDD[17]
- Dysmorphic concern questionnaire[18]

General questionnaires:
- Derriford Appearance Scale[19]
- Brief Fear of Negative Evaluation Scale[20]
- Hospital Anxiety and Depression Scale[21]

Body image concerns:
- What is the nature of your appearance concern?
- What do you dislike about your appearance?
- Is this a cause of distress or preoccupation?
- When does the feature bother you most?
- Does this impact on your daily functioning?
- Have you had previous treatment to improve your appearance?
- Do you have other body areas of concern?

BOX 81.3 Red flags

Body image concerns that are difficult for others to see
Unrealistic expectations of treatment outcomes
Worrying about body image repeatedly throughout the day or for long periods
Use of camouflaging and cover-up strategies
Constant requests for reassurance
Mirror checking or avoidance of mirrors
Avoidance of social situations
General reduction in quality of life (e.g. no longer socializing)
Disruption in daily activity
Patient presents with numerous photos (of self or of models/celebrities)
Patient presents with detailed ideas of how to improve appearance
Patient has other areas of body image concern
Patient reports multiple previous 'ineffective' consultations or treatments

Further evaluation and treatment

A pre-operative psychological assessment is essential for patients in whom BDD is suspected.[10, 22] If BDD and other psychopathology are ruled out, the patient can then be counselled regarding surgery. If the surgeon still has significant concerns, however, it may be necessary to obtain a second opinion.

Expectations

Determining pre-operative expectations is crucial as poor results are often based on emotional dissatisfaction rather than technical failure.[23] It is therefore important to ask:

- What are your outcome expectations?
- How do you anticipate your life will be different following treatment?
- What if your expectations are not met?

Surgeons must be able to explain to patients how anatomical variations are causing their nasal problem and discuss what surgery can achieve. Through this discussion the surgeon can determine if the patient has realistic expectations.

The use of the rhinoplasty improvement scale is helpful in explaining and counselling patients about realistic post-surgical expectations (**Figure 81.1**). Patients should be informed that moving up one point on the scale is realistic but anything more is unlikely.

ANALYSIS OF THE FACE

In assessing a patient prior to rhinoplasty the analysis should consider the entire face and not simply view the nose in isolation. The analysis begins as soon as the patient enters the consultation room and is formally assessed prior to a detailed assessment of the nose. Attractive faces are deemed to have ideal measurements and angles, which are reportedly based on the dimensions first described by Leonardo da Vinci.[24, 25] This concept has since been extended by Albrecht Duerer,[26] Powell and Humphrey.[27]

Facial symmetry is reported to be the basis for a beautiful face, although minor asymmetry may be associated with the perception of beauty.[28] Many patients are unaware of minor facial asymmetries and, if they discover these in the post-operative period, it could lead to dissatisfaction and misunderstanding. It is therefore important to raise these concerns with the patient and document them pre-operatively.

While a rhinoplasty on an asymmetrical face can lead to dissatisfaction post surgery, correcting an asymmetrical nose which causes the illusion of facial asymmetry can lead to improved facial symmetry without the need for any other surgical procedure.[29, 30]

Symmetry is assessed using midline facial landmarks: a line running through the mid-philtrum of the upper lip, the midpoint of the glabella and the midpoint of the chin indicates a symmetrical face.

Analysis of facial proportions is performed using the 'rule of thirds' and the 'rule of fifths' to assess the face from a frontal view (**Figure 81.2**).[25] Horizontal facial thirds should be approximately equal; the landmarks defining each third are the trichion to glabella, glabella to subnasale and the subnasale to soft-tissue menton. The rule of fifths describes the ideal transverse proportions of the face vertically divided into equal fifths, each fifth approximately equal to the width of one eye; the alar base is equal to the intercanthal distance. The nose ideally occupies one-third of the length of the face and one-fifth of its width. The terms used to describe the constant landmarks of facial anatomy are defined in **Box 81.4**. Other elements to consider are the fullness and position of the lips and protrusion of the chin.

Powell and Humphrey described the ideal angles of the facial aesthetic triangle (**Figure 81.3**).[27] The accepted dimensions of each of the facial angles are:

- nasofrontal angle 115–135°
- nasofacial angle 30–40°
- nasomental angle 120–132°
- mentocervical angle 80–95°.

Facial proportions act as a guide and are helpful in planning procedures but should not be taken as absolute. Each rhinoplasty should respect the individual's wishes, gender and character. It is important to recognize, too, that these ideal measurements vary between ethnicities.[31]

Finally, the analysis of the face should involve inspection of skin type utilizing the Fitzpatrick classification, which divides the skin type based on its colour and its reaction to the first summer exposure (**Table 81.1**).[32] The

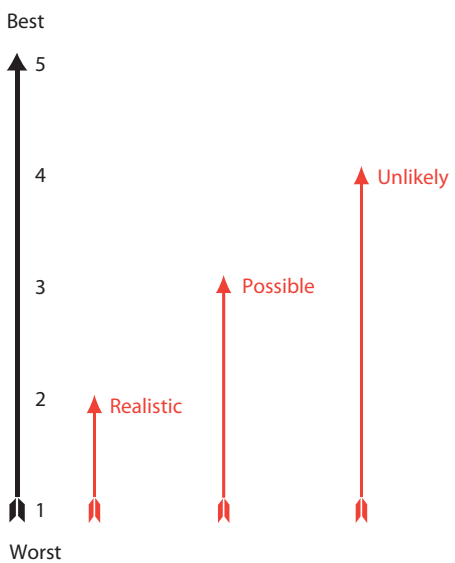

Figure 81.1 Rhinoplasty improvement scale used by the senior author.

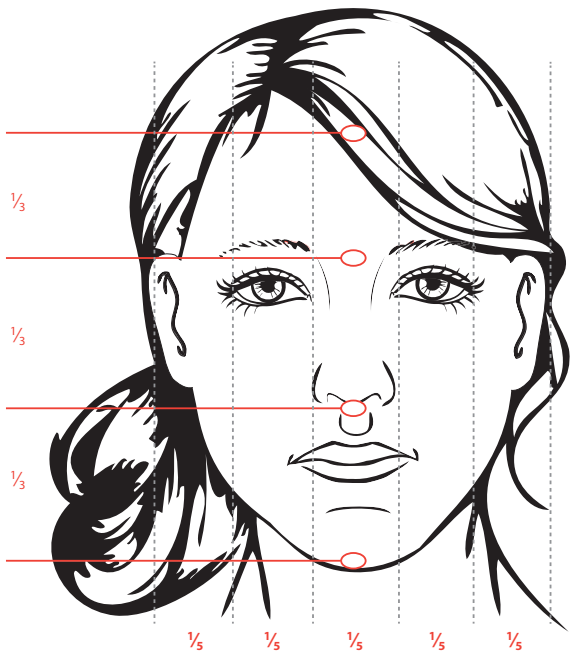

Figure 81.2 The concept of dividing the symmetric face into thirds and fifths.

BOX 81.4 Terminology of facial landmarks

Trichion	Anterior hairline in the midline
Glabella	Most prominent point of forehead in mid-sagittal plane
Nasion	Deepest point of frontonasal angle
Rhinion	Midline point of junction of nasal bones and upper lateral cartilages
Pogonion	Deepest point on outer cortex of mandible
Gnathion	Most inferior point of the chin
Gonion	Most inferior/posterior point of mandible
Menton	Lowest point of mandibular symphysis
Subnasale	Junction of columella and upper lip in mid-sagittal plane

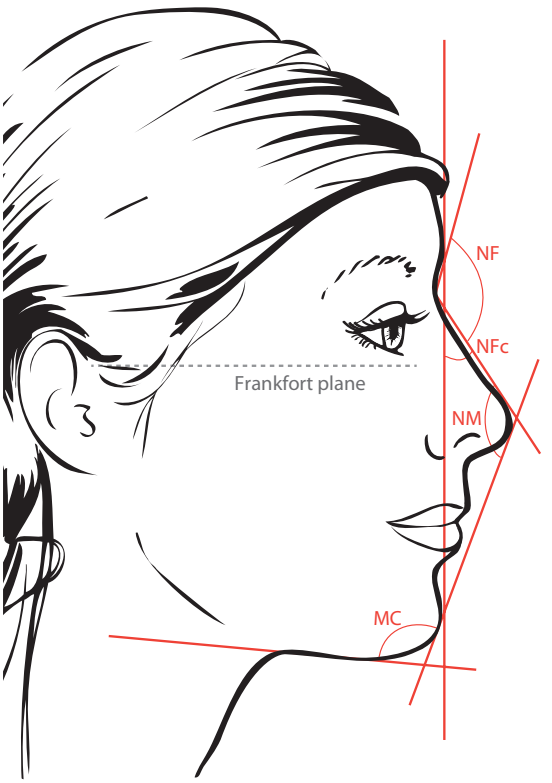

Figure 81.3 Triangles of Powell and Humphrey. Angles of the aesthetic triangle: nasofrontal (NF) = 115–135°; nasofacial (NFc) = 30–40°; nasomental (NM) = 120–132°; mentocervical (MC) = 80–95°.

TABLE 81.1 Fitzpatrick classification of sun-reactive skin types

Skin type	Colour	Reaction to sun
I	Very white or freckled	Always burns
II	White	Usually burns
III	White to olive	Sometimes burns
IV	Brown	Rarely burns
V	Dark brown	Very rarely burns
VI	Black	Never burns

surgeon should also consider the wrinkles on the face both with and without expression. The Glogau classification can be used to characterize progressive degrees of photo damage.[33]

ANALYSIS OF THE NOSE

Analysis of the nose comprises pertains to areas: inspection of the external nose, inspection of the internal nose and palpation.

Inspection of the external nose

Detailed inspection of the external aspects of the nose provides information about the individual nose as well as a comparison to accepted ideal measurements.

- **Skin quality:** This is variable and an assessment of whether the skin is thick and sebaceous or thin is required. Thin skin is unforgiving and minor irregularities are easily detectable; refining and narrowing the nasal tip can be challenging where there is thick skin.
- **Deviations:** The nose is divided into upper, middle and lower thirds. The upper third corresponds to the bony vault, the middle third to the upper lateral cartilages and dorsal septum, and the lower third to the lower lateral cartilages, caudal septum and alar base. Deviated noses are described on the basis of direction of the deviation of each third, e.g. classically described C-shaped, one-sided or S-shaped deviations (**Figure 81.4**). This provides an anatomical assessment of the aetiology of nasal deviation, which is key to surgical planning.
- **Length of the nose:** Nasal length is measured from the nasion to the tip, which is equal to the distance between the stomium and the menton. This can also be calculated mathematically as the distance from the nasal tip to the stomium multiplied by a constant of 1.6. nasal length: NT = TS × 1.6 (**Figure 81.5**).
- **Tip projection:** This is a measure of how far the nasal tip lies anterior to the face. Ideal projection is determined using Goode's ratio, where a line drawn from the alar–facial groove to the nasal tip measures 0.55–0.60 of the distance from the nasion to the nasal tip. A ratio less than this equates to an underprojected nose and greater than this corresponds to overprojection (**Figure 81.6**).
- **Lip–chin relationship:** The horizontal distance from the surface of the upper lip to that of lower lip is normally around 2 mm. The anterior surface of the upper and lower lips rest on the nasomental line in an aesthetic face (**Figure 81.7**).[34] When the chin lies posterior to this line, it is described as retrognathic; when it lies anterior to this line, it is described as prognathic. A retrognathic chin can give the illusion of an overprojected nose and the reverse applies to a prognathic chin. Genioplasty or chin implant procedures are therefore often used in conjunction with rhinoplasty.[35]
- **Dorsum:** The dorsum is inspected from both frontal and lateral views. Tracing the lateral aesthetic lines (also known as the brow–tip line) should reveal

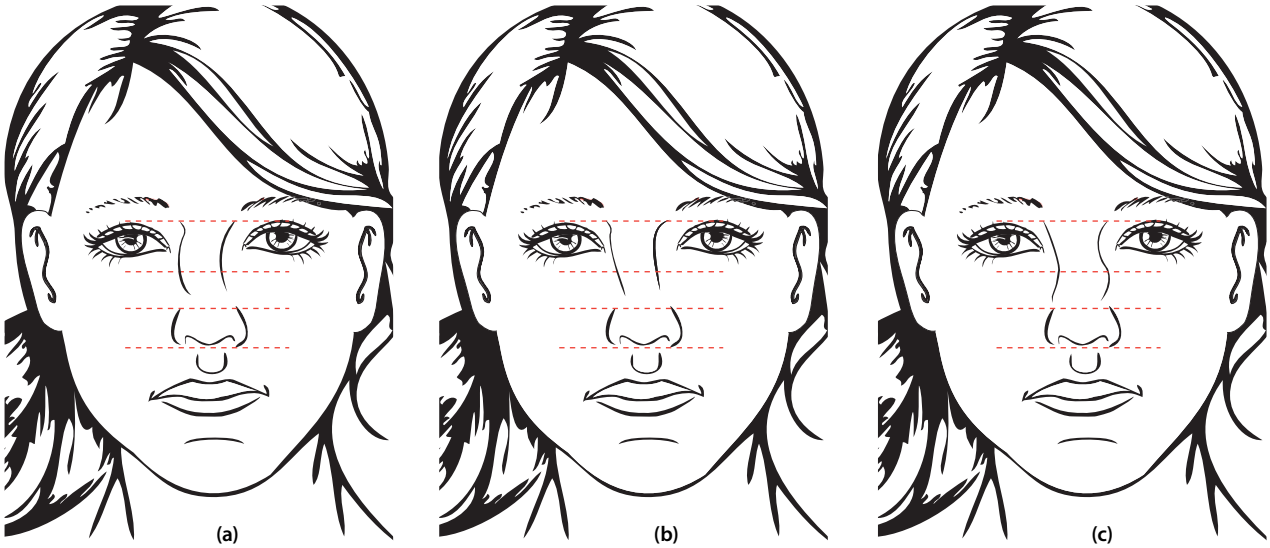

Figure 81.4 Classifying classic nasal deviations using thirds. **(a)** C-shaped, **(b)** one-sided, **(c)** S-shaped.

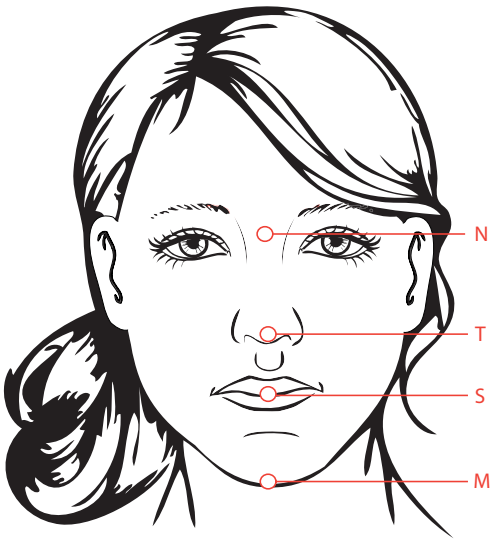

Figure 81.5 Nasal length (NT) = stomium to menton (SM) = 1.6 × TS.

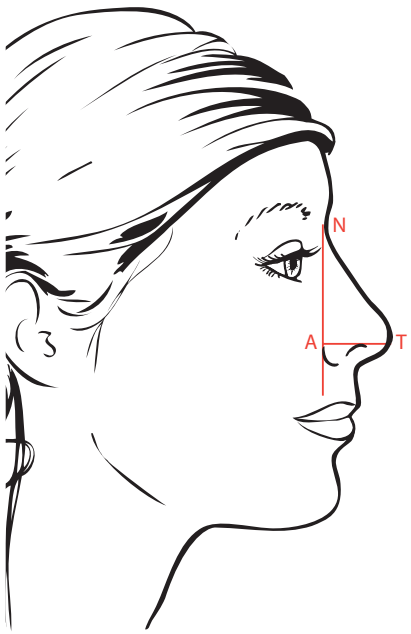

Figure 81.6 Determining tip projection by using Goode's ratio.

a smooth curvilinear line connecting the eyebrow superiorly to the nasal tip inferiorly (**Figure 81.8**). Identification of any irregularities in this smooth curve highlights sources of nasal deformity. In the lateral view, the height of the dorsum is assessed; the dorsum is a straight line in men and in women gently curves with a supratip break delineating the dorsum from the nasal tip. There is wide variation in dorsum height and it often characterizes different ethnicities.

- **Tip configuration:** There are four tip-defining points identified by light reflection (**Figure 81.8**). These represent the domes, the supratip and the infratip. The size and shape of the lower lateral cartilages are assessed, as are asymmetry, bifidity and rotation. Various tip configurations are generally related to these characteristics and to skin thickness. **Figure 81.9** depicts a commonly encountered selection of tip appearances: normal, boxy, bifid, bulbous and amorphous.
- **Tip rotation:** This describes the position of the tip along an arc with its radius centred on the nasolabial angle. The ideal dimension of the nasolabial angle in men is 90–95 degrees and in women is 95–105 degrees (**Figure 81.10**).[36]
- **Columellar show:** The relationship between the ala and the columella is assessed in the lateral view. The amount of visible caudal septum is ideally limited to 3–5 mm (Figure 81.10). This is the distance between two parallel lines drawn from the most anterior and the most posterior parts of the nasal vestibule. A degree of columellar show greater than this may be due to either a hanging columella or abnormalities in the alar margins such notching or retraction.

- **Basal view:** The width of the alar base approximates to the intercanthal distance. The ratio of the width of the dorsum of the nose relative to the alar base should be equal to 80% (see **Figure 81.2**). From the basal view, the nose can also be divided into thirds. The upper third corresponds to the lobule and the lower two-thirds correspond to the columella. A line that transects the columella at the area of medial crural footplate diversion divides the base into two halves (**Figure 81.11**). The overall basal view outline conforms to an isosceles triangle with pear-shaped nostrils lying at an angle of 45° to the vertical.[37] Multiple ethnic variations exist in alar base configuration.

Inspection of the internal nose

Examination of the internal nasal cavity is an essential component of assessment of rhinoplasty in the identification of abnormalities and assessment of donor cartilage sites. Anterior rhinoscopy and nasal endoscopy should be performed.

- **Septum** inspection should be made, looking for deviation, spurs, perforation or the presence of a septal button.
- **Lateral nasal wall and turbinates** inspection can identify congestion, hypertrophy and asymmetry.
- **Internal nasal valve** assessment should be carried out during normal quiet respiration at rest, as exaggerated effortful breathing is likely to precipitate transient internal nasal valve collapse in the normal individual.

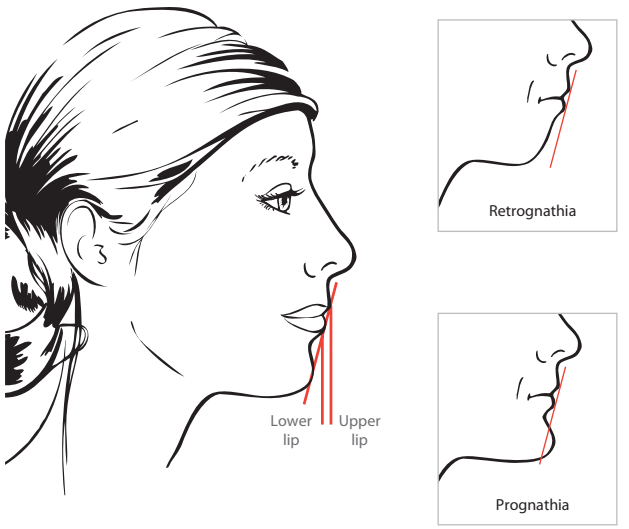

Figure 81.7 Lip–chin relationship.

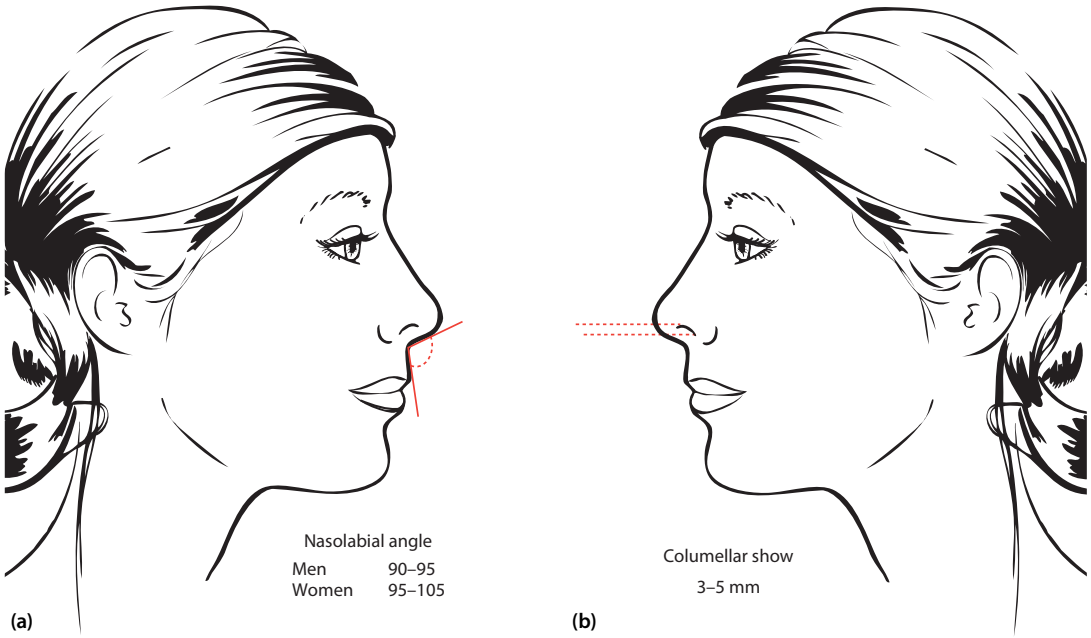

Figure 81.10 (a) Nasolabial angle in men and women. **(b)** Normal columellar show. Labels (a) and (b) angle/show lc a/s.

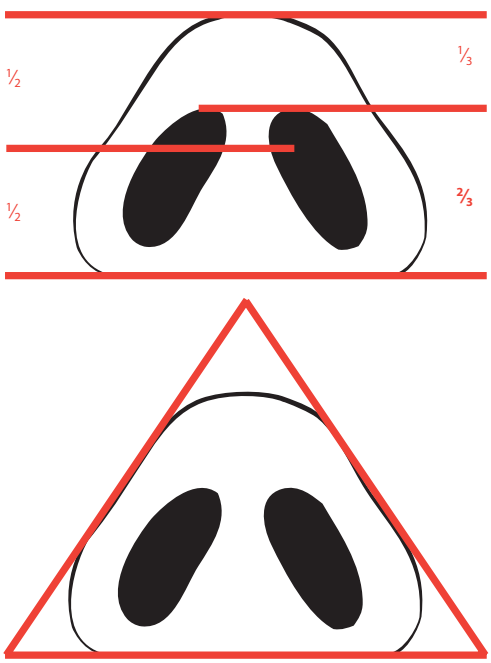

Figure 81.11 Basal view.

- **Cottle's manoeuvre** of opening the internal nasal valve by pulling on the soft tissues of the cheek is non-specific. A better test is to place a Jobson Horne probe in the internal nasal valve to prevent the collapse of the upper lateral cartilage and detect its effect on inspiration.
- **Alar collapse** is a measure of external nasal valve collapse and must be identified pre-operatively. The external nasal valve is not a true valve and is identified by the area bounded by alar cartilages, septum and columella.
- **Endoscopy** can exclude polyps, purulent discharge or residual adenoidal tissue.

Palpation

- **Skin:** Palpate for an assessment of skin texture and elasticity.
- **Irregularities:** Palpate for underlying irregularities that may be due to skin, soft tissue, cartilage, bone or previous graft material.
- **Nasal bones:** Assess the size, position and presence of palpable steps.
- **Tip recoil:** This is an assessment of the strength of the lower third of the nose and provides a palpable measure of the degree of underlying tip support.[38]
- **Alar cartridges:** Palpate for thickness, strength and shape.
- **Spine and septum:** Assess tip support, and confirm the presence and quantity of septal cartilage.

FUNCTIONAL STUDIES

Studies of nasal function are not performed routinely in rhinoplasty assessment and are mainly confined to the research environment. Nasal inspiratory peak flow, acoustic rhinometry and rhinomanometry can be used as objective tests of nasal function and to quantify surgical results. However, the correlation between objective and subjective sensation of nasal patency remains uncertain.[39]

PHOTOGRAPH REVIEW

Standardized photographs are essential for pre-operative planning. They are useful during the discussion with the patient about the proposed surgery and as an intra-operative reference and they are essential for comparison with post-operative results. In order to achieve reproducible photographs a standard patient position is used patient where the Frankfort plane is parallel to the floor; the Frankfort plane is a line that runs from the cephalic tragus to the lower orbital margin (see **Figure 81.3**). The standard photographic views obtained for rhinoplasty are frontal, left and right lateral, left and right oblique and basal. Additional views, which can be of use, are the close-up frontal view, superior view, base–radix view and bird's-eye view.[40–42]

Computer imaging

Computer morphing of the pre-operative photographs has been found to enhance communication with the patient and is associated with higher patient satisfaction.[43] It can also help in judging patient expectations and identifying BDD.[44] However, it is essential to clarify to the patient that image manipulation is only a means of communication and does not imply a specific guaranteed outcome.

CONCLUSION

Following the systematic assessment and examination of the patient, the proposed surgery can be effectively planned with clear surgical steps. It is good practice to commit the surgical steps to a written plan (**Table 81.2**).

TABLE 81.2 Summary of rhinoplasty assessment

Analysis	Assessment	
Patient analysis	What does the patient want? Is it realistic?

Surgical plan		

BEST CLINICAL PRACTICE

- ✓ First assess the patient, then the face and finally the nose.
- ✓ Develop an operative plan based on the patient's concerns and the results of your analysis.
- ✓ Carefully communicate the operative plan with the patient.

FUTURE RESEARCH

Appropriate patient selection is the ultimate key for successful rhinoplasty. Current research focuses on developing tools that help the surgeon in making that decision. There have been some recent attempts at developing questionnaires to identify those patients who would not benefit from surgery because of unrealistic expectations and to exclude those with suspected body dysmorphic disorder. To date, there has been no consensus and this is the subject of future research.[45–49]

KEY POINTS

- Rhinoplasty is a technically challenging procedure for which both the aesthetics and the function of the nose must be considered.
- Meticulous planning is essential to ensure the best surgical outcomes.
- Successful surgery requires realistic patient expectations, careful consideration of facial aesthetics and a detailed examination of the nose.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: external, open and rhinoplasty together with review publications and textbooks.

INTRODUCTION

The external or open approach is a firmly established and important technique in rhinoplasty surgery. Its key advantage over endonasal approaches is to afford the ability to assess anatomical deformities by direct inspection of the nasal cartilaginous and bony framework. This in turn allows for easier bimanual sculpturing of the underlying skeletal components and application of sutures and grafts under direct vision. While not an indication for the external approach, there is also a definite advantage for teaching where trainees are able to visualize surgical techniques with ease and these may also be captured satisfactorily with video and photography without the overlying skin and soft-tissue envelope hindering the view.

Limiting surgical tissue dissection to a minimum, as with an endonasal approach, reduces the risk of vascular compromise of the skin–soft-tissue envelope and this approach may therefore be favoured for correction of minimal structural bony dorsal irregularities and minor tip problems. However, the external approach's need for more soft tissue dissection is balanced by the unparalleled view of the nasal structure. In revision surgery, in particular, it facilitates accurate diagnosis in cases where the underlying anatomy is not obvious due to prior surgical resection and scar tissue formation.

The author personally favours this approach for most reconstructive revisions and where the nasal tip needs addressing in primary surgery. Incision refinements and surgical technique have overcome some of the earlier criticisms of a columellar scar and delay in resolution of the supratip skin oedema, and any potential loss of tip projection can be countered by placement of a columellar strut or septal extension graft to maintain support.

The choice of an external approach thus depends not only on the specific pathological anatomical findings but also on the philosophy of the surgeon. However, in deciding to use the external approach, the possible related sequelae should be considered, bearing in mind that the attainment of a predictable satisfying result demands the most atraumatic surgical procedure.

This chapter aims to present some historical aspects and principles of the external approach, outline relevant anatomy and emphasize technical aspects. Advantages with particular reference to grafting of the nasal skeleton and to specific extended indications such as revision rhinoplasty, the deviated nose, nasoseptal perforations, cleft-lip nasal deformities and nasal dermoids are discussed. Pitfalls related to this approach are outlined with the goal of shortening the long and arduous path of the learning process in rhinoplasty.

Mastery of this technique and exploitation of its specific advantages can bring a distinct range of opportunities to the rhinoplasty surgeon.

HISTORICAL ASPECTS

Early references to the elephant trunk incision[1] were made as early as the 1920s and subsequent papers named the approach as the transcolumellar incision,[2] the decortication technique,[3] and finally the external approach,[4] and open or external rhinoplasty.[5, 6] As most texts have adopted the latter three terms, we use them interchangeably in this chapter.

External incisions in rhinoplasty have been used in one form or another in all early descriptions of this procedure. The first such description is believed to have stemmed from India in 600 BC, in which external incisions and an open approach were practised. The first description of an external rhinoplasty via a transcolumellar incision was given by Rethi[2] in 1934 and subsequently by Sercer.[3] In 1974, Goodman advocated the external approach and described a modified transcolumellar incision – the well-known 'butterfly' incision.[4] His original description featured all the key points of incision placement, development of flaps and other surgical techniques. Publications thereafter have mainly served to emphasize the salient points he described. Refinements regarding incision placement, suturing and surgical technique have largely overcome the earlier problems encountered.

HISTORY AND EXAMINATION

The importance of pre-operative assessment in patients seeking rhinoplasty surgery cannot be overemphasized. It is beyond the scope of this chapter to discuss full facial analysis in detail and it is assumed that the rhinoplasty surgeon has a comprehensive knowledge of the relevant concepts.

A complete and discerning history regarding the cosmesis and function, any prior procedures and accurate chronological detailing of post-operative changes is important. Patient anxieties and expectations should be elucidated early in the consultation. The evaluating specialist needs to ensure that such expectations are true and achievable and that the patient's desires are realistic and in keeping with predictable likely post-operative outcomes. Where any doubt exists, sensitive counselling of the patient and referral for psychiatric review is always prudent and surgery is deferred pending this.[4, 5] Pertinent decisions about indications for surgery and potential improvements can then be made.

Diagnosis of the underlying anatomical deformity is essential prior to embarking upon the surgical plan. Inspection and palpation are equally important, particularly when assessing the skin and soft-tissue envelope and minor dorsal irregularities. Within these areas, a further subdivision of underlying skeletal support, soft-tissue thickness and scarring and overlying skin texture will help elucidate anatomical and structural deformities. Intranasal examination may be complemented with endoscopic evaluation to identify the presence of septal deviations, adhesions, nasal valve problems and mucosal disease. Assessment with Cottle's manoeuvre is often advocated but can be non-specific, and lateralizing the upper lateral cartilage with a probe or cotton bud may be a better evaluator.

Approach and technique planning is then discussed with the patient and documented. Standard 2D/3D photography is performed and digital manipulation software can help in discussing potential post-operative changes. This subject is covered in detail in Chapter 81, Pre-operative assessment for rhinoplasty.

INDICATIONS

As has already been indicated, the choice to perform an external rhinoplasty will in many cases be dependent on the training and philosophy of an individual surgeon, recognizing that it is merely an approach to the underlying skeletal structures and not a surgical technique to correct deformity.

However, specific indications for the external approach in rhinoplasty may include:

- congenital deformities such as the cleft lip nose
- extensive revision surgery
- severe nasal trauma
- marked tip deformities including significant rotation and projection issues
- significant septal deviations, especially where high dorsal deviations are present
- situations where assessment of the exact underlying pathology is difficult.

Extended applications of the external approach exploit the excellent exposure of the nasal skeleton and the advantages this affords. It has been advocated for septal perforation repair,[8] access to the nasal dorsum for treatment of nasal dermoids.[9]

ANATOMY

It is important to emphasize salient aspects of the external approach anatomy. **Figure 82.1** shows the anatomical subunits of the nose, which are conveniently divided into thirds. The upper third bony pyramid consists laterally of the nasal bones and the ascending (frontal) processes of the maxilla and the bony septum in the midline. The middle third ('vault') area is formed by the paired upper lateral cartilages inserting just under the caudal end of the nasal bones and their fusion with the midline cartilaginous septum in a T-type configuration. The scroll attachment of the caudal aspect of the upper laterals to the cephalic aspect of lower lateral (alar) cartilages forms the boundary to the lower third of the nose. The upper lateral cartilages thus effectively lie at a slightly lower level to both the nasal bones and lower lateral cartilages. The paired lower laterals form the lower third of the nose, the nasal tip region, and are traditionally divided into

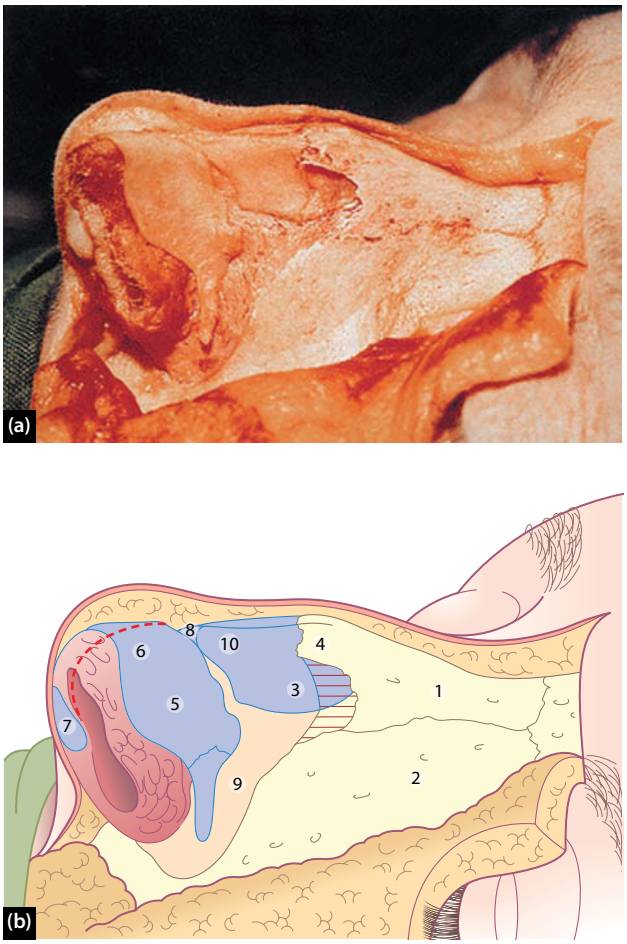

Figure 82.1 **(a)** Lateral view demonstrating the constituents of the anatomical subunits of the nose. **(b)** 1, nasal bone; 2, frontal process of the maxillary bone; 3, upper lateral cartilage; 4, area of overlap of upper lateral cartilage by nasal bone; 5, lateral crus of lower lateral cartilage; 6, dome area within intermediate crus; 7, medial crus of lower lateral cartilage; 8, quadrilateral cartilage; 9, connective tissue; 10, scroll region; 11, shaded area showing removed nasal bone.

the lateral, intermediate and medial crura. It is important to understand that the lateral crura extend laterally but also somewhat cephalically, leaving the most lateral aspect of the nostril's alar margin as being soft tissue alone, devoid of cartilaginous support. The domes and tip-defining points lie within the intermediate crus. The medial crural footplates extend to the lower aspect of the columella and lie just anterior to the caudal aspect of the nasal septum.

The superficial musculoaponeurotic system (SMAS) layer provides a vascular-rich covering to the underlying skeleton, with arterial supply derived from the superior labial and facial artery branches and corresponding venous and lymphatic vessels accompanying these. Exposure of all three parts of the nasal skeleton to some degree with subsequent identification of anatomical anomalies and asymmetries is the key advantage of the external rhinoplasty compared with an endonasal approach.[11]

BASIC PRINCIPLES OF THE EXTERNAL APPROACH

External rhinoplasty lends itself well to a philosophy of conservation of the structural support of the nose by full exposure of the underlyng structures and allowing open access for corrective surgical manoeuvres. It promotes emphasis on augmentation and reorientation of the supportive structures as opposed to reduction and resection.[12] However, certain general points need to be considered. Correct incision placement and meticulous wound closure are essential as the resultant scar should not be an overriding factor in the process of deciding which surgical approach to adopt.

The basic premise is that of a mid-columella incision connecting to bilateral marginal incisions; indeed, it is only this incision that separates it from a delivery-type endonasal approach. Those trained in endonasal rhinoplasty initially often choose to make the marginal incisions first and then join them with the columella incision. It is the author's preference to perform the incision first and then indentify and follow the medial crura outward into the intermediate and subsequently lateral crural areas.

Dissection in the subperichondrial and subperiosteal plane leaves as much soft tissue as possible on the skin flap, thus preserving its viability. In this way the lower and upper lateral cartilages together with the bony dorsum can be exposed to the nasofrontal angle in their undisturbed positions.[13, 14]

Division of the medial intercrural tissue offers access to the caudal septum and premaxillary spine, but it should be left intact if exposure is not indicated, as this intercrural attachment is one of the support mechanisms for the nasal tip. By dividing the upper laterals from the quadrilateral cartilage, the whole of the septum is accessible from the cephalic as well as the caudal aspect, allowing treatment of nasal valve problems, dorsal septal deviations and septal perforation repair.

As intercartilaginous incisions are not used, the valve area is preserved and the important major tip support mechanism of the scroll area is not disrupted. It is, however, important to appreciate that, while the major tip support mechanisms are respected in the external approach, the disruption of the skin soft-tissue envelope from the lower lateral cartilages and the division of the medial intercrural ligamentous fibrous tissue may lead to loss of some of the minor tip support mechanisms, and therefore some tip ptosis should be anticipated in all cases.

SURGICAL TECHNIQUE

Incisions

Fundamental plastic surgery principles dictate that a broken line transcolumellar incision will leave a less visible scar, rather than a single line horizontal incision which will be both more noticeable and prone to contraction. Commonly used incision variations include the step, gullwing and inverted V-type configurations. The author prefers the latter approach as this gives a near inconspicuous scar when properly closed.[16] If the columella is deemed too short in relation to the intended tip projection, as may occur, for example, in

cleft-lip rhinoplasty, a V incision made at the base of the columella to perform a V–Y lengthening procedure may be indicated.[17] An alternative forked flap has also been described.[18]

The columella incision should be situated in the upper two-thirds, normally at its narrowest point, to ensure the medial crural footplates provide adequate support, thus preventing a depressed scar (**Figure 82.2a**). In the lower third of the columella, the medial crura bend backward towards their attachment to the caudal septal area and thus the skin of the columella in this area is unsupported. It is essential to protect the integrity of the caudal end of the medial crura just beneath the incision to prevent post-operative notching in this area. This may be done by initially making only a very superficial columellar incision, cutting just through the skin; the vertical columellar parts of the marginal incisions are then placed 1.5–2 mm inside the vestibule and joined by careful undermining of the columellar skin with sharp dissecting scissors. These blades of the scissors can then be used as a guard upon which the columella incision is completed.

The midline aspects of the medial crura are now identified with sharp dissection and this is used to extend the incision upward towards the intermediate crural region. Ensuring adequate exposure of the cartilage, ideally in a subperichondrial plane, the marginal incision is then continued more laterally using angled Converse/Walter scissors with a spreading movement hugging the caudal aspect of the cartilage, followed by cutting of the overlying soft tissue (**Figure 82.2b** and **c**). To obtain adequate exposure of the nasal skeleton, the marginal incision should be extended at least halfway along the lateral crus but can be extended further laterally if dissection of the lateral most aspect of the lateral crus will be required.

Dissection of the soft-tissue envelope

Dissection of the soft-tissue envelope in the subperichondrial and subperisoteal plane is desirable to ensure minimal bleeding. Dissection after exposure of the medial crura should be continued in a lateral direction up to the hinge area, hugging the lower lateral cartilage, with further extension in a cephalic direction to the scroll area (**Figure 82.2d**). To free the cartilaginous vault, it is easy to make a false passage into the SMAS. To prevent this, dissection should be commenced in the midline between or just cephalic to the domes. It can be helpful to incise the perichondrium at the caudal end of the cartilaginous vault vertically in the midline, after which subperichondrial dissection can proceed from medial to lateral and in a cephalic direction. This can leave a useful subperichondrial flap that can be resutured in the midline, if required, to help with camouflage of underlying irregularities, particularly in thin skin noses.

Conversely, a thick supratip soft-tissue envelope can be thinned at a later stage if required, although this is done very conservatively to prevent compromise of the vascular supply to the overlying skin. A potential complication of the external approach is prolonged supratip oedema and occasionally a soft-tissue pollybeak as a result of dissection in the wrong plane disturbing the integrity of the transverse nasal muscle.

Dissection of the soft tissue of the bony pyramid in a subperiosteal plane starts with an incision made 2–3 mm parallel to and above the caudal end of both nasal bones. It is of great importance to palpate the edge of the nasal bone before making the incision, to prevent separation of the upper laterals from the bony pyramid, a pitfall that can only be corrected with a camouflaging onlay graft. The sharp side edges of a Joseph periosteal elevator are engaged along the incision to facilitate the raising of a subperiosteal flap over the bone.

The aim of the open approach is to identify and adequately expose underlying anatomical deformities and facilitate correction, and raising of the skin and soft-tissue envelope need only to extend to the areas of concern. More extensive dissection laterally over the doral bony skeleton has been advocated recently (an extended open approach) to facilitate powered instrumentation to create precise lateral osteotomies.

A potential disadvantage of the external approach is the difficulty assessing the supratip area and the desired tip projection, due to the lack of traction of the soft tissue prior to closure of the columella incision. Final assessment of these areas should thus be made after preliminary closure of the incision. Adjustment is still possible either by cartilage vault reduction and, if insufficient tip projection, by adding an onlay tip graft through the marginal incision or a shield graft, which can be sutured into place after reopening the transcolumellar incision.

In case of grafting procedures for augmentation, care should be taken that the overlying soft tissue has sufficient viability. Blanching of the skin over an augmentation graft is a warning sign which should not be neglected. A slight reduction of the graft size will prevent possible skin necrosis.

Access to the nasal septum

The nasal septum can be accessed by division of the soft tissue between the medial crura of the lower lateral cartilages, effectively dividing the membranous septal area (see **Figure 82.2f**). This will, however, disrupt one of the minor tip support mechanisms so may be best avoided if no cartilaginous material is available to provide structural support to maintain post-operative tip projection. An alternative exposure can be gained by a traditional separate hemitransfixion or Killian's incision.

Provision of a stable cartilaginous base is critical in all nasal tip surgery. If a columellar strut or septal extension graft is required, it is placed in a well-defined pocket between the crura, and extends from 2 mm above the anterior nasal spine to the angle between the medial and intermediate crura. The sandwich construction is fixed by mattress sutures which must not be placed above this angle in order to prevent loss of the columella–lobular ('double break') angle.[19, 20] To prevent asymmetry at the caudal plane of the columella and in dome height, it is important to fix the medial crura in the right parallel position temporarily with a needle after which final fixation with mattress sutures is accomplished (**Figures 82.2g** and **82.3**). The cartilaginous strut may also be used to correct buckled medial crura, strengthen weak medial crura, correct tip asymmetries and provide a stable base for the application of tip grafts.

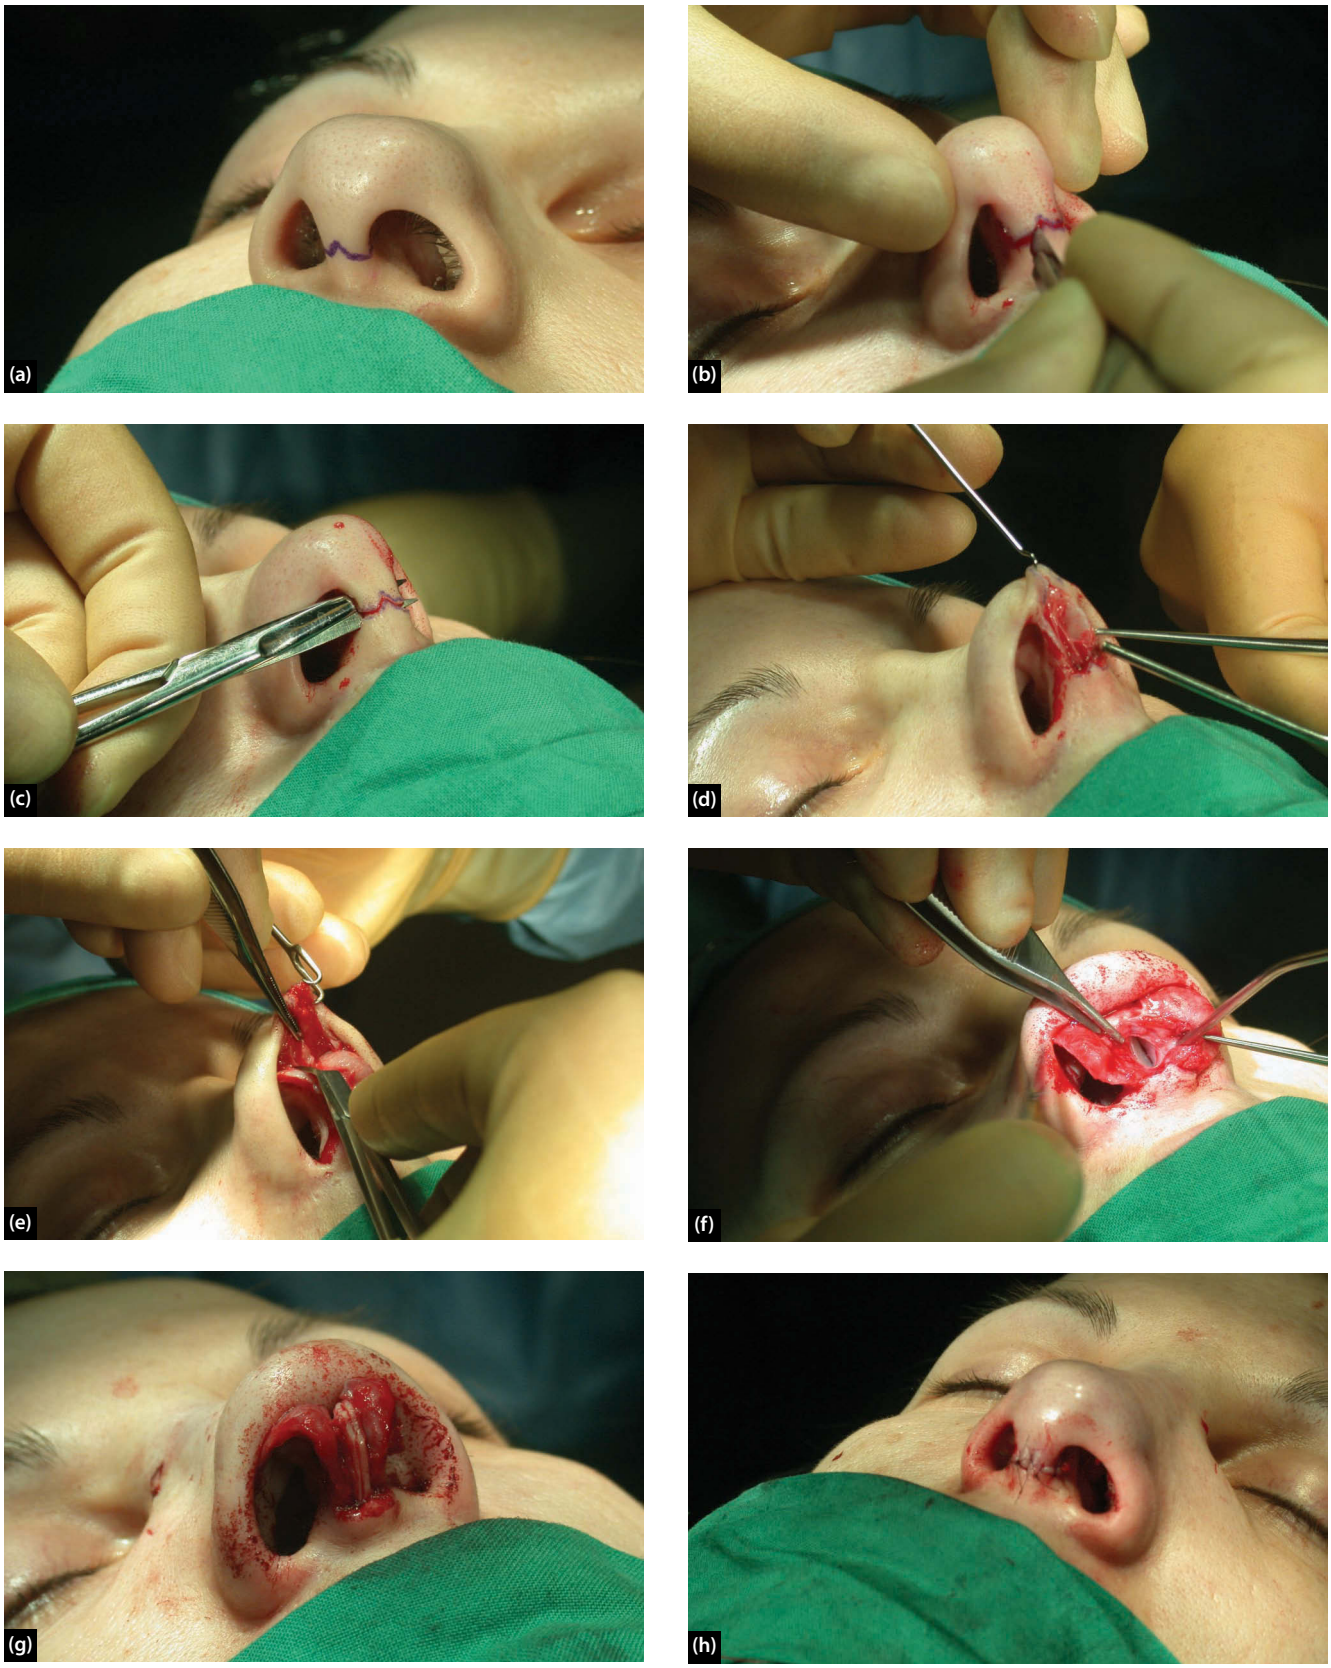

Figure 82.2 External rhinoplasty approach to correct an underprojected, asymmetric bulbous tip. **(a)** Mid-columella inverted 'V' incision. **(b)** Superficial incision made through the columella skin. **(c)** Iris scissors placed behind the incision to protect medial crurae. **(d)** Exposure of the medial crurae with development of the columella skin flap. **(e)** Dissection over the nasal domes with converse scissors. **(f)** Exposure of the caudal septal cartilage by dissection between medial crurae. **(g)** Columella strut placed between medial crurae. **(h)** Closure of incision after correction of boxy tip deformity.

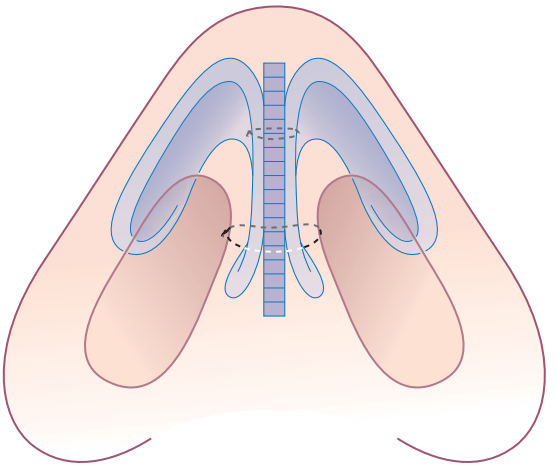

Figure 82.3 Columella strut of autogenous septal cartilage for extra tip support fixed by mattress sutures to the medial crura.

Closure of the transcolumellar incision

Meticulous closure is imperative with slight eversion of the wound edges (**Figure 82.2h**). Authors have favoured both fine non-absorbable suture material (6/0 ethilon or prolene) although the use of a rapidly absorbable suture such as 6/0 Vicryl Rapide negates the need for suture removal, which can prove very uncomfortable. To prevent tension, it can be helpful to place an initial subcutaneous absorbable suture, although this is not usually necessary. Between five and nine fine sutures are then used to close the incision with attention importantly focused to the lateral edges of the columella where irregularities may be most visible. The vertical incisions along the vestibular edge are closed and a single suture to approximate the lateral marginal incision normally suffices.

After closure of the incision, a smooth skin line of the columella from a basal and lateral view should be ensured. The skin sutures are removed, if required, 5–7 days postoperatively. While not favoured by the author, the use of tissue glue has also been shown to be an effective alternative method of closure.[21]

SPECIFIC APPLICATIONS

The bony pyramid in external rhinoplasty

Exposure of the upper third of the nose allows more accurate diagnosis and precise correction of dorsal abnormalities, thus avoiding irregularities that can arise from a closed procedure. The subperiosteal dissection should not extend more than halfway along the nasal bones.[22] The exception to this is when an extended dissection along the most lateral aspect of the bony vault to allow for powered lateral osteotomies such as with a Piezo device are planned.

A direct systematic examination is possible of the individual components of the bony vault. The size, shape and position of both nasal bones and bony septum, as well as the thickness of the overlying skin-soft tissue envelope in the region of the rhinion and nasion, are assessed individually and in relation to their effect on the nasofrontal angle and the width, height, dorsal profile and contour of the upper third.

The open approach allows the use of a burr or Piezoelectric device to deepen the nasofrontal angle. Conversely, the angle can be deepened or set in a more cephalic position by precise application of soft-tissue onlay radix grafts of temporalis fascia or slivers of autogenous cartilage. Such implants can also be secured in an accurate position via this approach.

The principles and techniques of bony dehumping together with lateral, medial oblique and intermediate osteotomies are the same for both the endonasal and open approaches although the latter has the added advantage of allowing direct vision, particularly when powered instruments are used. It can be easier, however, to remove medial bony wedges in a trapezoid bony vault with an open approach.

The middle nasal vault

The 'nasal valve area' is the smallest cross-sectional area in the nasal airway. Its boundary is formed by the caudal end of the upper lateral cartilage, the head of the inferior turbinate, the floor of the nose, the nasal septum and the intervening tissue surrounding the pyriform aperture. Rhinoplasty can compromise the nasal valve, particularly in patients with short nasal bones, a high bony–cartilaginous hump and weak upper lateral cartilages.[23] Frequently, there is an additional corresponding aesthetic defect of a 'sunken' or 'pinched-in' middle third. Such an inverted V-type deformity is a consequence of either excessive resection of or collapse of the upper lateral cartilages inferomedially due to inadequate support after removal of a dorsal hump. The nose displays a 'washed-out' appearance with prominence of the caudal edge of the nasal bones. There may be associated internal nasal valve collapse giving rise to nasal obstruction.

Placement of 'spreader grafts' to open up the nasal valve area and angle was initially described via an endonasal approach thereby improving both function and cosmesis (**Figure 82.4**).[24] The external approach allows easier and more precise placement and suture fixation of such spreader grafts, minimizing risk of displacement. These cartilaginous strips are placed longitudinally between the upper lateral cartilage and septum. The mucosa between these cartilages is often divided but, based on Sheen's original work,[32] this should be avoided and rather the spreader graft placed extramucosally. The functional improvement has been difficult to quantify objectively but subjective improvement is to be anticipated. Placement via an external approach allows for accurate visualization but, when required, can be equally well placed endonasally[33] into tight submucoperichondrial pockets and held with tissue glue or with percutaneous trans-septal sutures if needed. Unilateral placement of spreader grafts may also correct asymmetries of the dorsum.

'Autospreaders'/spreader flaps can be an effective and simple alternative and negates the need for a separate cartilaginous source (**Figure 82.5**). When lowering the

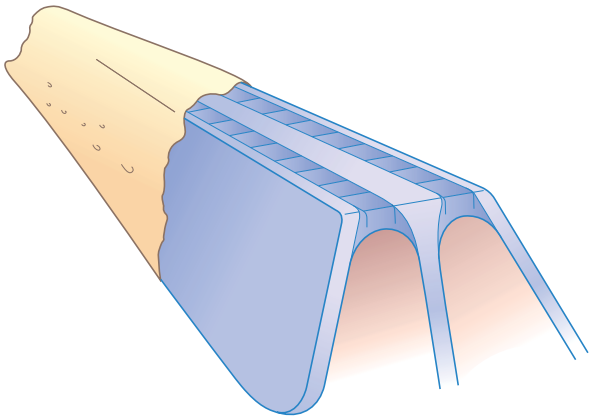

Figure 82.4 Shaded areas showing placement of spreader grafts.

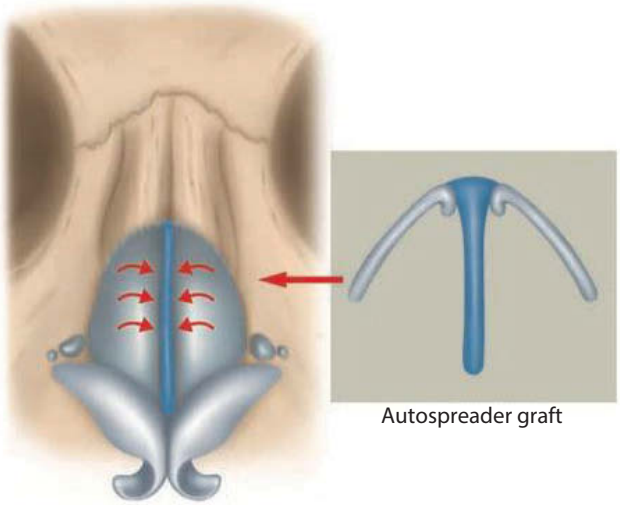

Figure 82.5 Autospreader graft/spreader flap created by turn in of upper lateral cartilages.

cartilaginous dorsum, the upper lateral cartilages are separated extramucosally from the septal cartilage and the superior-most aspect of its cephalic edge dissected off the underside of the bony vault. The midline septal cartilage is then lowered but the upper laterals are left intact and infolded to create such spreader flaps, mimicking the effect of spreader grafts. These can be an effective way of avoiding mid-vault narrowing but alone are unlikely to proffer any functional benefit.

The open approach exposure also facilitates extended roles of spreader grafts to include their use as part of lengthening an overly rotated nose with articulation onto septal extension grafts, maintenance or reconstruction of the dorsal nasal roof, straightening of a high dorsally deviated septum and recreation of the dorsal aesthetic lines.[25]

Nasal tip surgery

Nasal tip surgery has perhaps been the major beneficiary of the open approach since it exposes the structural components of the tip in their natural undisturbed position. It allows unparalleled diagnosis of the various deformities and asymmetries as well as facilitating precise surgical manipulation of the tip cartilages and suture fixation of grafts. In particular, it allows the visualization and correction of minor asymmetries, thus adding extra surgical finesse.

While it is beyond the scope of this chapter to discuss nasal tip techniques in detail, some highlights of tip surgery that benefit most by the open approach are featured. Altering tip projection and rotation by modelling the alar cartilages is based upon the 'tripod' theory.[5] This theory states that the structural framework of the nasal tip is based on the two lateral crura and the conjoined medial crura, each forming one leg of the tripod (**Figure 82.6**). This allows an understanding of the effect on the tip position by altering the size and position of the medial or lateral crura. For instance, if the medial and lateral crura are reduced in length, the tip is deprojected; if they are augmented, projection is achieved. Superior rotation is achieved by shortening the lateral crura or, alternatively, by lengthening the medial crura causing rotation at the 'hinge' region.

Problems encountered may be conveniently thought of as being due to under- or over-rotation, under- or over-projection, width problems or intrinsic tip deformities. Manipulation of any part of the tripod model normally leads to predictable changes in both the projection and rotation of the nasal tip and some examples are described below. All aspects of tip surgery can be performed in a more controlled fashion and with a high degree of symmetry by using the external approach.[7, 27, 28]

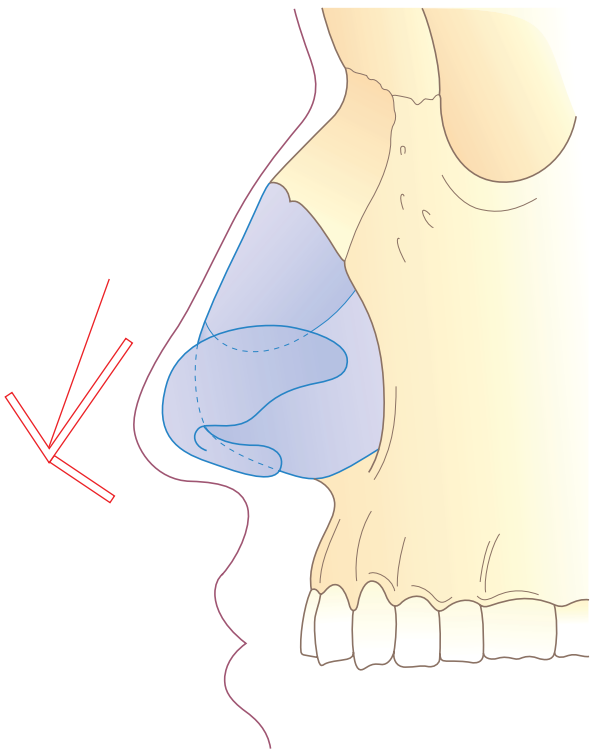

Figure 82.6 Tripod complex of the lower third of the nose. The conjoint medial crura comprise one leg of the tripod, while the lateral crura comprise the other two legs.

ROTATION DEFORMITIES

Correction of the under-rotated tip can be effected with various manoeuvres, based on the tripod theory. Rotation changes are usually linked with some associated projection change.

Lateral crural steal techniques with recruitment of the lateral crura medially using domal suturing creates tip projection and rotation. Conversely, resection and overlay of the lateral crura (lateral crural flap/overlay technique **Figure 82.7**) produce rotation with deprojection. Such a technique is generally used to shorten the nose as well when overprojection is problematic. Plumping grafts and columellar struts are also used to create an illusion of rotation.

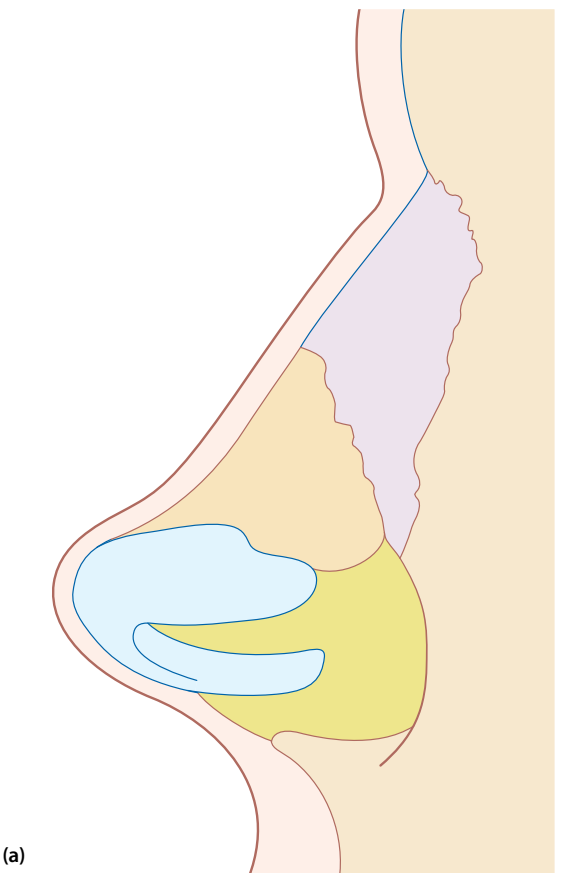
An overly rotated nasal tip is often challenging to correct, particularly when it is a result of prior surgery. It occurs most often due to a combination of factors at the original surgery such as resection of the anterior septal angle, or the visoring effect of excessive cephalic strip excision of the lower lateral cartilages perhaps together with other rotation manoeuvres involving the lateral crura. Options for correction are more limited with this situation and soft-tissue changes limit how much counter-rotation occurs. The mainstay of management is placement of a caudal septal extension graft to effectively lengthen the nose (**Figure 82.8**). Extended spreader grafts are then used to try to stabilize the septal complex and the lower lateral cartilages are then rotated downwards and fixed to the extension graft.

Again using the tripod theory, division and overlap of the medial crura will create counter-rotation although this does also deproject the tip. Finally, a graft in the tip/infratip area will give an illusion of counter-rotation and increased length of the nose and is best employed in addition to, rather than instead of, the other listed procedures when required. This is best avoided, however, in thin-skinned individuals where grafts in the tip region are potentially easily visible.

PROJECTION DEFORMITIES

Projection of the nasal tip is often desirable in rhinoplasty surgery. Both external and endonasal rhinoplasty approaches can create post-operative ptosis, so attempts to maintain adequate projection are important. Dome suturing, so often used to define the nasal tip by increasing triangularity and narrowing, may also act to project the tip somewhat. Used alone, a small amount of increased projection and rotation can be achieved. When further projection is required, the lateral crural steal is a workhorse technique that can also rotate the tip. It is important not to overtighten sutures as this can create a pinching effect.

The 'tongue-in-groove' technique of septocolumellar suturing is a further option and usefully allows setting of projection and rotation of the nasal tip (**Figure 82.9**). A disadvantage of this method is the rigidity and lack of mobility such a procedure imparts to the tip but it is



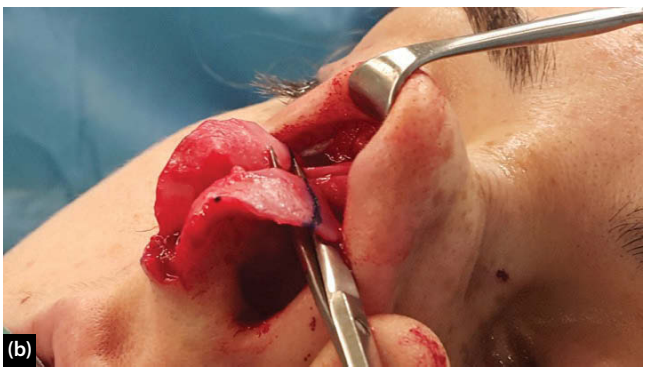


Figure 82.7 **(a)** and **(b)** Lateral crural flap/overlay – the lower lateral cartilage is divided laterally and overlapped to deproject the tip. This also creates a degree of rotation.

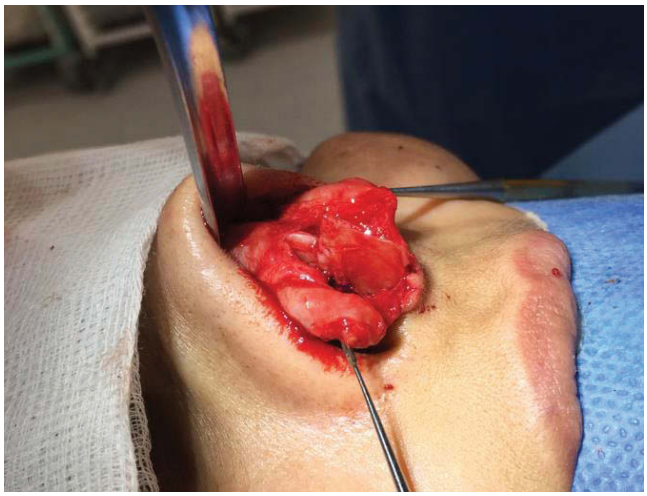

Figure 82.8 Septal extension graft placed in an 'end-to-end' fashion.

generally well tolerated in most patients. This technique can cause a degree of columellar retraction and over-rotation of the tip if the distance between the medial crura and caudal septum is excessive. A septal extension graft can be used to counter this, adding additional security of strength and base stability to the nasal tip complex. Columellar struts may help strengthen inherently weak medial crura, thereby creating projection, but they are generally best used in addition to other techniques as, alone, they may not be able to counter contraction post-operatively. Using a permanent suture between the upper lateral cartilages and columellar complex provides stability in this regard.

Grafts may also have a part to play. Shield and tip grafts work well in thicker-skinned patients and can create a final finesse to a poorly projected tip.

Deprojection of the 'tension' nose is a less frequently encountered problem in revision surgery. A full transfixion incision will divide the medial crural footplate attachment as they curve backwards to the caudal septum, thereby disrupting a major tip support mechanism, predictably creating some post-operative tip deprojection that is an easy initial step in correcting this deformity. This may need to be combined with division and overlay of the medial, lateral or both crura, depending on the rotation requirements. The 'lateral crural flap' alone creates deprojection and rotation and, in a similar way, the medial crural flap technique will deproject and counter-rotate the nose (see **Figure 82.7**). If the rotation needs no altering, an equal amount of overlapping in both areas can be performed, thus counterbalancing any rotation changes.

Excision of the anterior nasal spine has also been described[35] but risks bleeding and the potential for some columellar retraction.

INTRINSIC TIP DEFORMITIES

Pinched nasal tip deformity

By far the most common cause of a pinched nasal tip deformity is iatrogenic weakening of the lower lateral

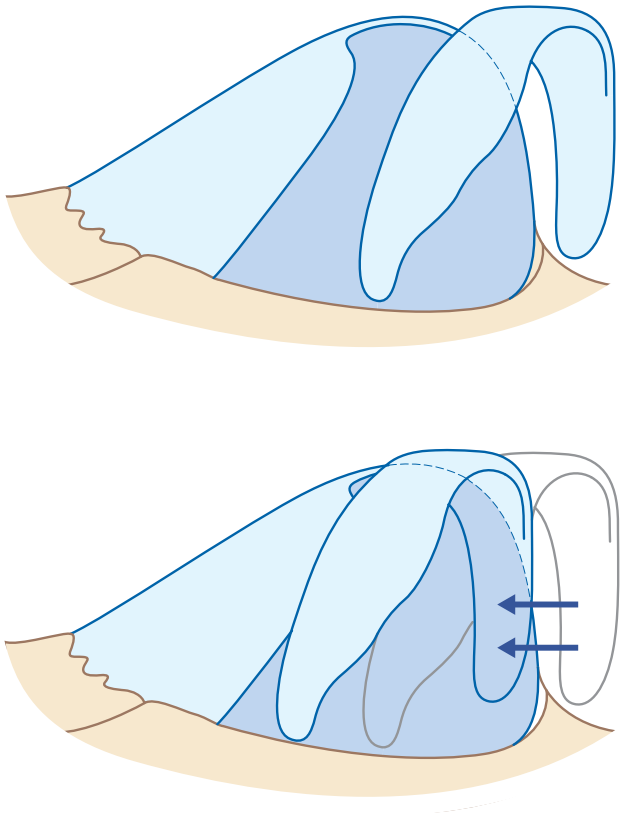

Figure 82.9 Tongue in groove technique of septocolumellar suturing.

cartilages due to over-resection of the cephalic edge of the lower lateral cartilages with subsequent weakening of the intact rim strip. The useful edict of leaving behind more cartilage than that resected should always be remembered; the author recommends an absolute minimum of 6 mm cartilaginous support but leaving more may be more favourable. The author now rarely resects the lateral crus cephalic cartilage but instead attempts to reorientate in such a way that the caudal edge lies at a higher level to the cephalic border. Aggressive domal suturing with its resultant alteration in tip orientation and dynamics can also cause notching in the dome region, predisposing to a pinched tip effect.

The lateral crura should have an outward convexity of the posterior alar rims and gentle rounding in the dome region; specifically, there should be no pinching of the lateral alar walls. While for minor deformities, an endonasal approach may prove adequate for placement of supporting grafts in primary surgery or to correct prior overzealous tip suturing, the open approach allows for accurate anatomical analysis of the underlying deformity of the lower lateral cartilages which can then be repositioned and modified as required. Small specific pockets allow batten grafts to be inserted to correct concavities caused by weakness of the cartilage. An isolated aesthetic deformity caused by inherent concavity of the lateral crus may be corrected by complete mobilization of the lower lateral cartilage from the vestibular skin. An incision is then made just lateral to the domal area and the lateral

crus flipped over such that the concavity now becomes a convexity. The rotated crus is then sutured to the medial segment (**Figure 82.10**).

The external approach remains the author's favoured method for accurate evaluation of the orientation, integrity and strength of the alar cartilages. Augmentation using septal or auricular cartilage to fashion alar battens or lateral crural strut grafts provides stability and strength to the weakened alar cartilages, thus correcting both aesthetic and functional aspects of the deformity. Alar rim grafts can further recreate convexity and rounding of the nasal tip contour as assessed on the frontal and basal views.

Bossae formation

Knuckling of the lower lateral cartilages in the domal area forms so-called 'bossae'. The inexperienced rhinoplasty surgeon may not be aware of the triad of thin skin, strong alar cartilages and bifidity of the tip which together predispose to their formation when there is an excess cephalic strip reduction and inadequate narrowing of the domes.[38] Post-operative scar contracture in this area causes the deformity.

Treatment options include trimming or resection of the knuckled areas with suture reconstruction of the lower lateral cartilages. Covering the area with a camouflage graft may also help correct any minor residual deformity.

Alar retraction

Overzealous cephalic strip resection can lead to alar retraction due to the visoring effect caused by contraction as healing occurs.[39, 41] An absolute minimum of 6 mm residual cartilage is recommended but, in the presence of an anatomically narrow alar cartilage, this may need to be revised. If vestibular mucosa is not preserved, this too can contribute to contracture and promote further retraction. Correction with cartilage grafting placed into a snug pocket fashioned through a marginal incision may improve minor defects. For a more severe deformity, a composite cartilage graft, usually fashioned from the concha of the opposite ear, is taken.[42] This is placed into a space created by dissection of the alar rim away from the residual lower lateral cartilage, allowing the alar rim to be displaced caudally. An alternative is to dissect space between the upper and lower lateral cartilages and place a firm (ideally septal or rib) spacer graft into this area, pushing the lower lateral crus caudally.

Hanging collumella and retraction

The hanging columella can be a very unaesthetic deformity. Options include resection of the caudal and/or membranous septum, which is the main cause. However, in the presence of prominent medial crura, resection of the caudal aspect of the crura or occasionally vertical division may resolve the deformity.[43] The 'tongue-in-groove' method of suturing the medial crura to the septum described previously can be an effective alternative.[36]

Columellar retraction is often a consequence of overresection of the caudal septum at primary surgery. The lack of support in this area causes gradual contraction with time. Placement of a columellar strut sutured between the medial crura is a treatment option, as are plumping grafts placed in the premaxillary area. More substantial retraction can be improved with cartilaginous septal extension grafts. These can be tailored to project either the whole retraction or variably the upper or lower part forwards, dependent on the need for rotation of the tip.

Revision rhinoplasty

Revision rhinoplasty is undoubtedly one of the most challenging operations undertaken by the facial plastic surgeon. The dawn of a social media generation has led to increased public awareness of all aspects of cosmetic surgery, including the need and desire for revision procedures, with the newly informed patient becoming more critical of post-operative results. An unprecedented number of media articles on aesthetic surgery appear to be increasing patient expectations. As contemporary techniques evolve, the modern rhinoplasty surgeon is constantly seeking an ultimate post-operative result that will please both the discriminative patient and surgeon alike.

Various authors have reported an increase in the number of revision cases, which may be a reflection of the greater popularity of rhinoplasty and the enhanced expectations and discrimination of both the surgeon and patient.[30, 31]

The key to successful revision procedures is the ability to correctly diagnose underlying deformity in the first instance with a view to formulating a surgical plan. Very often, this can be challenging given soft-tissue contracture following prior surgery. The open approach, of course, allows accurate visualization of the deformity and simplifies accurate correction, which may require advanced techniques, including augmentation procedures. Structural grafting and relocation of tissue with the aim of producing predictable favourable long-term results is facilitated. Scar tissue may also be more easily identified and excised.

The deviated nose

The external approach to the deviated nose lends itself well to accurate correction of such a deformity due to the added exposure it provides and the ability to place corrective grafts. When excising a bony hump in the presence of a bony pyramid deviation and unequal height of the nasal bones, the plane of the osteotome may be altered to allow this. Alternatively, the use of powered instruments such a Piezo device under direct vision will allow accurate reduction of the dorsal bone and cartilage alike. Osteotomies can also be performed sequentially under direct vision. For example, if the nose deviates to the right, the first step is to mobilize the left nasal bone and reposition it in its normal position; the next step is to position the bony septum in the midline; and, finally, the right nasal bone is repositioned in its normal position.[22] Again, with extended lateral dissection, a Piezo saw can be used under direct vision to create the lateral osteotomies.

Figure 82.10 (a) Unilateral concavity of lateral crus. **(b)** Dissection of lateral crus from underlying vestibular skin. **(c)** Concave lateral crus divided just lateral to dome. **(d)** Concave segment flipped over to create convexity. **(e)** Convexity now seen in final result.

A deviation of the lower two-thirds of the nose is usually due to a C-shaped dorsal deviation of the nasal septum, possibly complicated by previous surgery, which may have disrupted the union of the upper laterals to the septum. In mild cases, the dorsal aspect of the septum is shaved on the convex side and sutured to the upper lateral cartilage. If this is not sufficient to correct the deviation, a unilateral spreader graft is placed between the dorsal septum and the upper lateral cartilage.[20] The spreader graft acts as a stent as well as opening the nasal valve area. Any residual deformity is corrected by an onlay graft (**Figure 82.11**).

Dorsal augmentation

For grafting purposes, autologous septal or auricular cartilage remains the ideal standard and this appears to be supported by most authors. Options may be limited by prior surgery and the option of the autogenous or homologous irradiated costal cartilage must be considered. Alloplastic materials are reserved for cases where there is minimal residual cartilage available and the risks associated with infection and possible extrusion should be discussed with the patient pre-operatively.

Figure 82.11 (a–f) Pre- and post-operative images of a patient undergoing secondary rhinoplasty with residual septal and ear cartilage harvest. Septal L-strut reconstruction with an onlay diced cartilage and fascia graft, columellar strut graft with mild tip deprojection, and medial and lateral osteotomies were performed.

Grafts can be used as a solid implant, with careful fashioning and chamfering of its edges to reduce the risk of post-operative visibility. These can be placed into a 'hand-in-glove' type pocket to avoid movement post-operatively but the open approach allows for graft stabilization with sutures accurately placed. The same principles apply also to placement of diced cartilage in fascia grafts (**Figure 82.12**) where suture fixation will ensure that the graft remains secure and will not move in the post-operative recovery period.

Cleft-lip nasal deformities

Rhinoplasty in a cleft-lip patient is challenging due to the limitation of the final post-operative result.[38] The severity of primary nasal deformities is directly related to the severity of the cleft lip. The nasal and vestibular skin as well as the cartilaginous and bony skeleton is affected. Cleft-lip nasal deformities can be classified into unilateral and bilateral and form a characteristic pattern.[35] The secondary, and hopefully definitive, nasal reconstruction should be performed using the external rhinoplasty technique in the presence of severe tip asymmetry. The use of conservative techniques allows the procedure to be performed before puberty. However, the surgeon has to weigh up the psychological and future nasal directional growth benefits against possible inhibition of mid-facial growth,[35, 36] although studies have questioned whether septal surgery via an external approach truly has an effect on future nasal and midface development.[37] A V–Y procedure to lengthen the columella is usually needed in bilateral cleft deformities, and this should be considered when placing the incision. A complete cleft will be associated with hypoplasia and retropositioning of the maxilla on the cleft side. If mild, a cartilaginous graft can be used for support in order to relocate the alar base; in severe cases, a maxillary advancement will be needed. The key to correcting tip asymmetry is a stable and symmetrical base formed by the columella strut or, perhaps better still, a septal extension graft (see **Figure 82.8**). The lower lateral cartilage on the cleft side must first be dissected free, after which it can be repositioned and sutured to the cartilaginous columella support (more anterocephalic).[35, 40] This does not alter the lateral alar base displacement. A Z-plasty to reposition and to counter-rotate the ala at the cleft side is often required.[35] Finally, a shield graft may be positioned, which further increases tip projection, enhances tip definition and camouflages minor tip asymmetries.[39]

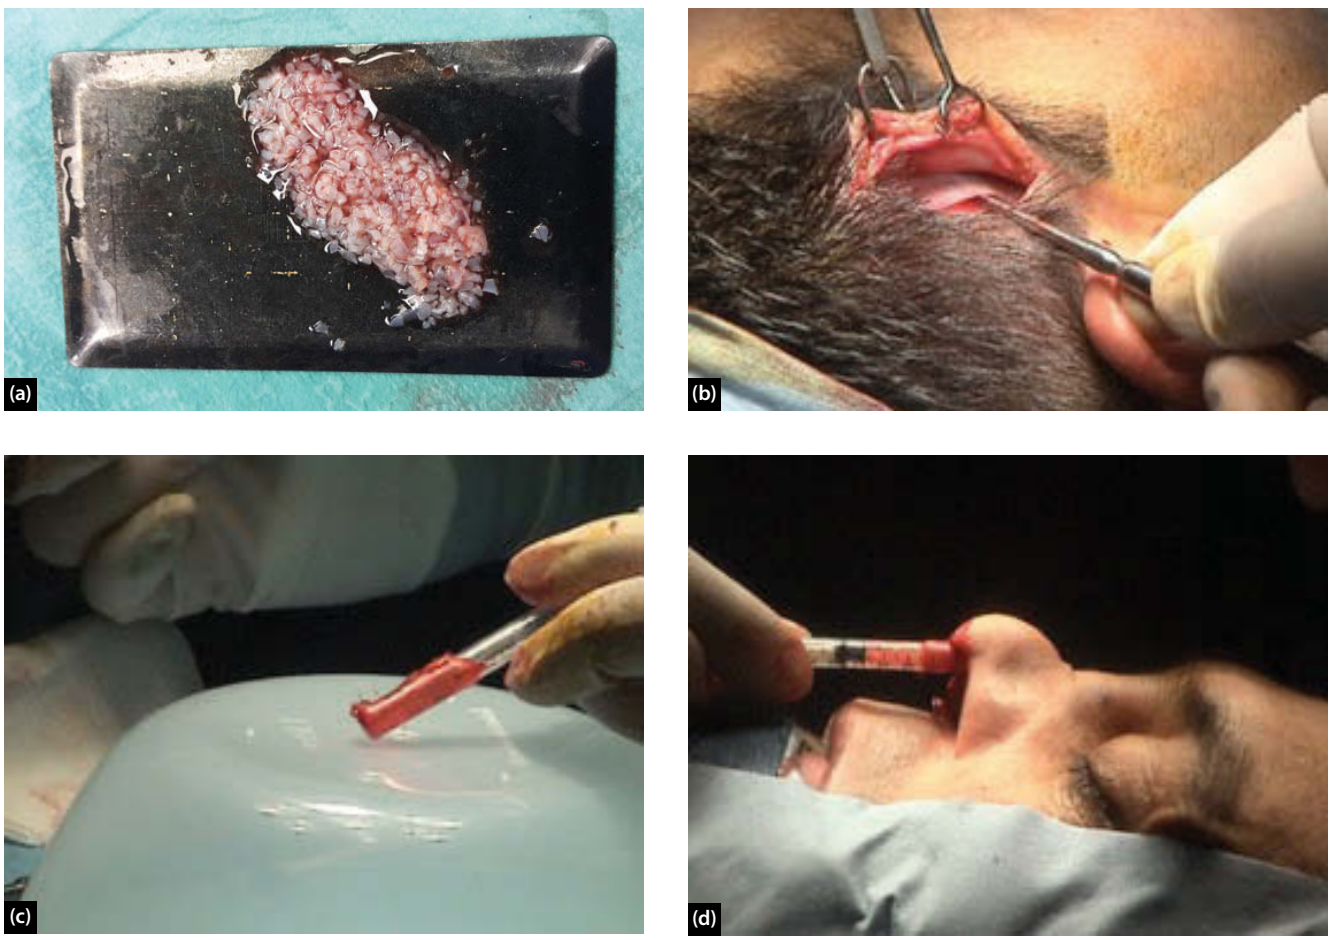

Figure 82.12 **(a)** Finely diced auricular cartilage. **(b)** Harvest of temporalis fascia. **(c)** Fascia wrapped around a 1 ml syringe. **(d)** Diced cartilage placed into syringe and injected with fascial wrapper onto dorsum.

Septal perforation repair

Contemporary techniques of septal perforation repair rely on mobilization of mucoperichondrial flaps to allow individual closure, usually with an interpositional graft. Such dissections are laborious and challenging and the external approach may be undoubtedly facilitating, particularly in the repair of large septal perforations.[8, 9] It allows unique exposure of the septum from both the cephalic and the caudal aspect and also aids any required conjunctive rhinoplasty. The septal flaps are then more easily released and advanced to allow for a tensionless closure, and suturing of the flaps is aided by the wide exposure.

Nasal dermoids

The poor cosmesis associated with a vertical midline scar required in total excision of a nasal dermoid may be avoided by use of the external rhinoplasty approach and its use has been advocated widely.[10] The dermoid can usually be dissected off the overlying skin although there may be a small of area of cutaneous resection required and, if particularly large, any excessive redundant skin may require resection.

CASE EXAMPLES

Figures 82.13 and **82.14** illustrate cases in which an external rhinoplasty approach was used to advantage for correction of specific deformities. The patient in **Figure 82.13** was a revision case in which there was need for significant grafting to allow improvement of both function and form. The open approach facilitated accurate diagnosis of the deformity and placement and suturing of the various grafts that were harvested from the residual septum and auricular region. The patient in **Figure 82.14** sought cosmetic

Figure 82.13 (a-f) This gentleman had prior surgery with overresection of the middle-third complex and lateral crura that resulted in an inverted-V deformity and lateral crural pinching. The patient underwent a secondary rhinoplasty with bilateral spreader grafts, morselized cartilage grafts over the upper lateral cartilages, an overlay diced cartilage graft, lateral crural strut grafts, and alar contour grafts.

Figure 82.14 (a-h) Pre- and post-operative photographs of a patient undergoing a reduction rhinoplasty. The patient had dorsal cartilaginous and bony reduction, insertion of bilateral but asymmetrical spreader grafts, medial and lateral osteotomies, tip rotation with a tongue-in-groove procedure, tip deprojection with a lateral crural overlay, and domal sutures.

improvement of the rather overprojected nose with reduction of the dorsal hump. Again the open approach allows simple placement of spreader grafts as well as the ability to use the tongue in groove and lateral crural overlay techniques effectively and precisely.

CONCLUSIONS

The external approach has proven to be a valuable part of the armamentarium of the rhinoplasty surgeon. Its unparalleled exposure and the ability to bimanually manipulate and handle underlying tissues gives a major advantage to endonasal techniques, particularly in more complex surgery, revision and post-traumatic deformity. It facilitates accurate resection and modelling of underlying bony and cartilaginous components and enables straightforward placement and suturing of graft material. Correct incision placement, dissection in the right surgical planes and meticulous suturing techniques prevent unnecessary sequelae of this approach, such as prolonged supratip oedema and aesthetically unacceptable transcolumellar scars. Relative disadvantages of increased operating time and difficulty of dorsal assessment are minor and should improve with the experience of the surgeon.

FUTURE RESEARCH

- ➤ There is much work being done presently with use of powered instrumentation, especially with the Piezoelectric devices.
- ➤ Popularity of powered instrumentation has grown in recent years but it will remain to be seen whether the additional extensive skin degloving required and the cost of the equipment will make these instruments a mainstay in the future.
- ➤ Additional research into powered instruments may shape future use of such devices.

KEY POINTS

- The external approach affords superior visualization of underlying deformities, allows bimanual handling of tissue and accurate placement of grafts and sutures.
- Modern techniques for tissue dissection planes and scar placement and suturing minimize the previously quoted disadvantages of this approach.
- The principle of limiting tissue dissection as much as possible remains and endonasal techniques may be employed in less complex cases.
- Structural grafting techniques to maintain long-term stability of the nose often necessitates an open approach.
- An appropriately placed broken line incision with meticulous closure allows for minimal visualization of the columellar scar with time.

SEARCH STRATEGY

Data in this chapter may be updated by searches of Embase, the Cochrane Library and PubMed using the keywords: secondary, revision, rhinoplasty.

INTRODUCTION

Rhinoplasty (in contrast to septorhinoplasty) focuses mainly on altering the appearance of the external nose for aesthetic reasons. In certain cases, for example in a tension nose or in alar insufficiency, rhinoplasty is performed to correct the nasal airways. A septorhinoplasty attempts to improve both the aesthetic appearance and the function of the nose. This combined procedure may add additional dynamics in the healing process and therefore revisions may be more common.[1] This chapter primarily deals with visible deformities after previous rhinoplasty, their types and frequencies, possible causes, their prevention and their correction. Unfavourable results may be the consequence of unpredictable healing, which is beyond the surgeon's control, and these are generally referred to as 'complications'. However, revisions may also be necessary because of an inadequate primary procedure, which is then termed a 'mistake'. In this situation, the patient usually blames the surgeon responsible for the ultimate outcome. For the surgeon, it is important to understand the difference between a complication and a mistake and to learn from revision surgery.[1]

The surgical procedures available for revision rhinoplasty are numerous[2–8] and are mostly based on the experience of the individual rhinoplasty surgeon. Because of this, only the more common techniques for the most frequent residual deformities will be discussed.

It is difficult to draw general conclusions from the literature. On one hand, reports on long-term results are very rare and most publications describe the number of revisions that are undertaken 1–2 years after primary surgery. It is possible that many problems that give rise to revisions may present much later. In addition, the patient population analyzed in an article will be non-homogeneous. The primary surgery can be performed by different surgeons with different experience and technical factors may contribute to post-rhinoplasty deformities. In addition, follow-up of patients operated on by a single surgeon may be incomplete. He or she may only see patients with minor deformities, who tend to return to the primary surgeon. Patients with major deformities, however, tend to seek an opinion from a second surgeon.[9] Comparing figures on types of post-operative deformities in different studies may also be of limited value. Noses, as well as surgical goals, may differ between countries and continents. What may be an acceptable result in one country may be an indication for revision rhinoplasty in another.

These factors do not facilitate the reporting of evidence-based data. This means that the figures presented can only represent a tendency and give support for a better understanding of the development of deformities after rhinoplasty, their prevention and revision techniques.

REVISION RATES

Most data from the literature describe revisions after aesthetic rhinoplasty, rarely for functional aesthetic rhinoplasty. This must therefore be taken into consideration when drawing any conclusions.

Reported revision rates are listed in **Table 83.1.** In general, a revision rate of 5–10% is to be expected.[14] Specialized surgeons will undertake more revisions because patients are more likely to be referred to them. In the large series by Parkes et al. of 1221 consecutive rhinoplasties,[14] the overall revision rate was approximately 14%. However, their own

*No consecutive series of primary or multiple rhinoplasties.

revision rate was only 5.3%. The frequency of having more than one revision lies between 20% and 23% of all revision cases.[9, 14, 15] Revision rhinoplasty is more commonly performed in females, with rates of 60–80%.[14, 15] In a series of 200 consecutive rhinoplasties undertaken by a single surgeon, 12% had revisions. Of these, more women (14%) than men (9%) were dissatisfied with the surgical result.[12] In contrast to these figures, the rate of dissatisfied patients in a population of 1062 patients who had undergone rhinoplasty and who then completed a questionnaire afterwards (468 responders) was higher among male patients (12.8%) than among female patients (4.6%).[16] Interestingly, a study cohort comprising 175 842 participants who underwent septorhinoplasty procedures showed an overall revision rate for any septorhinoplasty procedure of 3.3% (5775 of 175 842) (99% CI, 3.2–3.4%). After separating the patients into primary septorhinoplasty and secondary septorhinoplasty groups, the primary group had an overall revision rate of 3.1% (5389 of 172 324), while the secondary group had an overall revision rate of 11.0% (386 of 3518). Patient characteristics associated with an increased rate of revision include younger age (5.9% [633 of 10 727]), female sex (3.8% [2536 of 67 397]), a history of anxiety (3.9% [168 of 4350]) or autoimmune disease (4.4% [57 of 1286]), and surgery for cosmetic (7.9% [340 of 4289]) or congenital nasal deformities (8.9% [208 of 2334]).[20]

CLASSIFICATION AND FREQUENCY OF DEFORMITIES REQUIRING REVISION RHINOPLASTY

A systematic approach to revision rhinoplasty may be based on the type of surgical procedure needed or the type of the deformity to be corrected. Webster defined five categories of revision:[21]

- revision uncertain or unnecessary
- revision with skeletal reduction
- revision with skeletal augmentation
- external soft-tissue removal required
- revision in congenital anomalies, major trauma, etc.

Other authors have described the location of the deformity (**Table 83.2**). Cohen lists eight different groups of external abnormalities and also includes functional disturbances.[22] Stucker, however, divides the nose into thirds: the upper (bony) third, the middle cartilaginous third and the lower third.[23] These parts can be further subdivided (see **Table 83.2**).[24] Kamer and McQuown[9] include the severity of the deformity. They distinguished between major deformities, such as saddling, midnasal asymmetry, pollybeak, retracted ala and columella, and minor deformities, which included tip-bossae, wide nasal base, hanging columella, irregular or high nasal dorsum and acute nasolabial angle.

The frequency of different deformities as reported by the eight authors above is listed in **Table 83.2.** The risk for residual deformities increases from the upper to the lower third of the nose. Most frequently, dropping tips and pollybeaks were found. Uncorrected broad nasal tips and irregularities of the nasal dorsum are also relatively frequent causes of revision.

These figures demonstrate the particular importance of the nasal tip support and its dynamics in the healing process. As the supratip pollybeak and dropping of the tip are frequently combined, the rhinoplasty surgeon has to put special emphasis on maintaining adequate tip protection, as well as protection when approaching and mobilizing the nasal infrastructure. The common deformities that can occur following rhinoplasty are listed below in order of frequency of occurrence:

1. pollybeaks
2. dropping tips
3. uncorrected broad nasal tips
4. irregularities of the nasal dorsum.

FACTORS AFFECTING PREVENTION

Proper patient selection can influence the surgical result. For example, rhinoplasty with advancing age can be associated with the patient's own expectations and motivations. This may influence the surgeon to do more than is adequate. The result can be an overzealous rhinoplasty.

Safian[25] has described three basic rules to prevent any problems developing after rhinoplasty:

- Never change the normal basic anatomy or the anatomic relationships of the nose and never totally remove a component.
- Never allow the skin and lining membrane to meet or be left in contact.
- Never destroy nasal cartilage.

The revision concepts of Sheen[26] are based on a proper pre-operative diagnosis, limited dissection, use of

exclusively autogenous graft material when required and a well-defined pre-operative plan.

Webster's guidelines include an adequate interval before revision (normally 1 year). This acknowledges the effects of scar tissue and recognizes the differences between underdone and overdone noses, the use of autogenous tissue when dealing with the lining of the nose and the need to develop the aesthetic and reconstructive skills required for revision rhinoplasty.[21]

Constantian[17] reviewed 150 consecutive secondary rhinoplasties in a retrospective study to test the hypothesis that specific anatomic variants predispose to unfavourable rhinoplasty results. He defined four pre-operative variants and compared their incidence with a primary rhinoplasty group. The following conditions were found more frequently in revision patients:

- low radix, low dorsum (93%)
- narrow middle vault (87%)
- inadequate tip projection (80%)
- alar cartilage malposition (42%).

The 'triad' of the first three points was most common (40%), so patients with the combination of these deformities are at a higher risk for revision surgery (**Figure 83.1**).

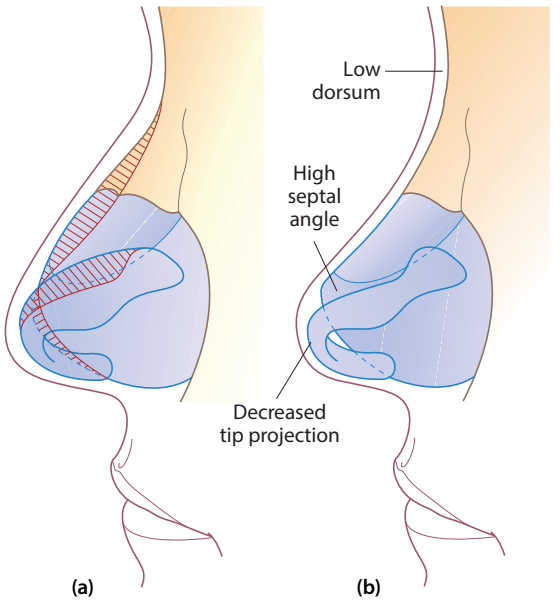

Figure 83.1 Predisposing factors for pollybeak deformity and profile changes: low radix, high dorsum, low tip projection. (a) Hump removal and resections of caudal septal end and lateral crura are marked; **(b)** post-operative result.

TREATMENT STRATEGIES

As already mentioned, techniques for revisions described in the literature are mainly based on the personal experience and preferences of the surgeon. Therefore, only principles and concepts for the most frequent causes for revisions are described here.

Pollybeak deformity

Although there may be cases with a soft-tissue thickening in the supratip area post-operatively, the majority of pollybeak deformities are caused by two effects (see **Figure 83.1**):

- dropping of the nasal tip (loss of tip projection and protection)
- an absolute or relative high septal angle.

The pollybeak deformity develops within months after surgery and this is because of the surgically induced loss of tip support mechanisms.[27] The end result will be a relatively high cartilaginous dorsum in relation to the position of the tip that is sometimes combined with a relatively low bony dorsum (**Figure 83.1**). In principle, there are three options for reconstruction:

- increase of tip projection
- reduction of cartilaginous nasal dorsum
- a combination of both.

The most reliable technique to increase tip projection and protection is a columella cartilage strut with fixation of the medial crura using an external approach (**Figure 83.2**).[28] If the nasal tip is still in a reasonable position after primary surgery, further reduction of the cartilaginous dorsum may be sufficient. In severe cases, both structures must

Figure 83.2 Deviation of the nasal dorsum and pollybeak deformity after three previous rhinoplasties. Low radix, narrow middle vault and alar cartilage malposition after dome division on the left side **(a–d)**. Revision via open approach (fourth operation): septal and columella reconstruction with autogenous rib graft, radix augmentation and spreader grafts. Reconstruction of left alar cartilage **(e–h)**.

be addressed. In principle, the dorsum must be adapted to the definite position of the nasal tip.

Irregularities of the nasal dorsum

These irregularities become visible after hump removal, especially in thin-skinned patients with prominent nose syndrome (tension nose). Very often they are found at the K-area where the nasal bones overlap the triangular cartilages. While minor bony ridges can be easily rasped, this technique is not possible for a cartilaginous deformity. The surface of the cartilage must be made smooth with scissors or a knife. In very thin skin, camouflage can be an excellent option. After further reduction of the nasal dorsum, tissue (mainly autogenous) is used to cover the whole distance from the radix to the septal angle. A crushed septal cartilage strut with delicate smooth edges is preferred (**Figure 83.3**). New insights came from using the technique refining the nasal dorsum with free diced cartilage.[29, 30] Ear cartilage and temporalis fascia are somewhat less suitable. Alloplasts, such as Gore-Tex, may be helpful in selected cases.

Crushed cartilage and free diced cartilage can be very useful to fill small depressions lateral to the nasal dorsum that give the appearance of a deviated nose. This camouflage is very often more effective than revision surgery with osteotomies.

Columella deformities

The acute nasolabial angle with retraction of the columella is often associated with a wide columella base. This can be caused by an over-resection or malposition of the caudal septal end, resection of the anterior nasal spine or creation of a columella pocket between the medial crura which allows the soft tissues to slide posteriorly. It can also be the result of an 'endorotation' of the nasal septum after mobilization during septoplasty.[31] The distance between columellar skin and caudal septum can be increased by inserting a cartilage strut after closing the space between the medial crura footplates with a non-resorbable 'U' suture. In case of a malposition of the septal cartilage after septoplasty, it can be repositioned ('exorotation') and fixed to the anterior nasal spine (**Figure 83.4**).

Overshortened noses

Although this deformity is not listed as a frequent cause for revision in Table 83.2, it is often cited in medicolegal cases. The wide open nasolabial angle in an over-rotated tip is extremely unpleasant and disturbing aesthetically. Very often, the surgeon's pre-operative analysis was inadequate. In a relatively long nose with a moderate hump, the decision was made to remove the hump and shorten the nose because it appeared even longer after hump removal (**Figure 83.5a**). Typical manoeuvres to shorten the nose include:

- resection of a triangular part from the caudal septum (with or without resections from the membranous septum, with or without columella pocket)
- resection of the cephalic margins of the lateral crura (with or without interrupted remaining cartilage strip)

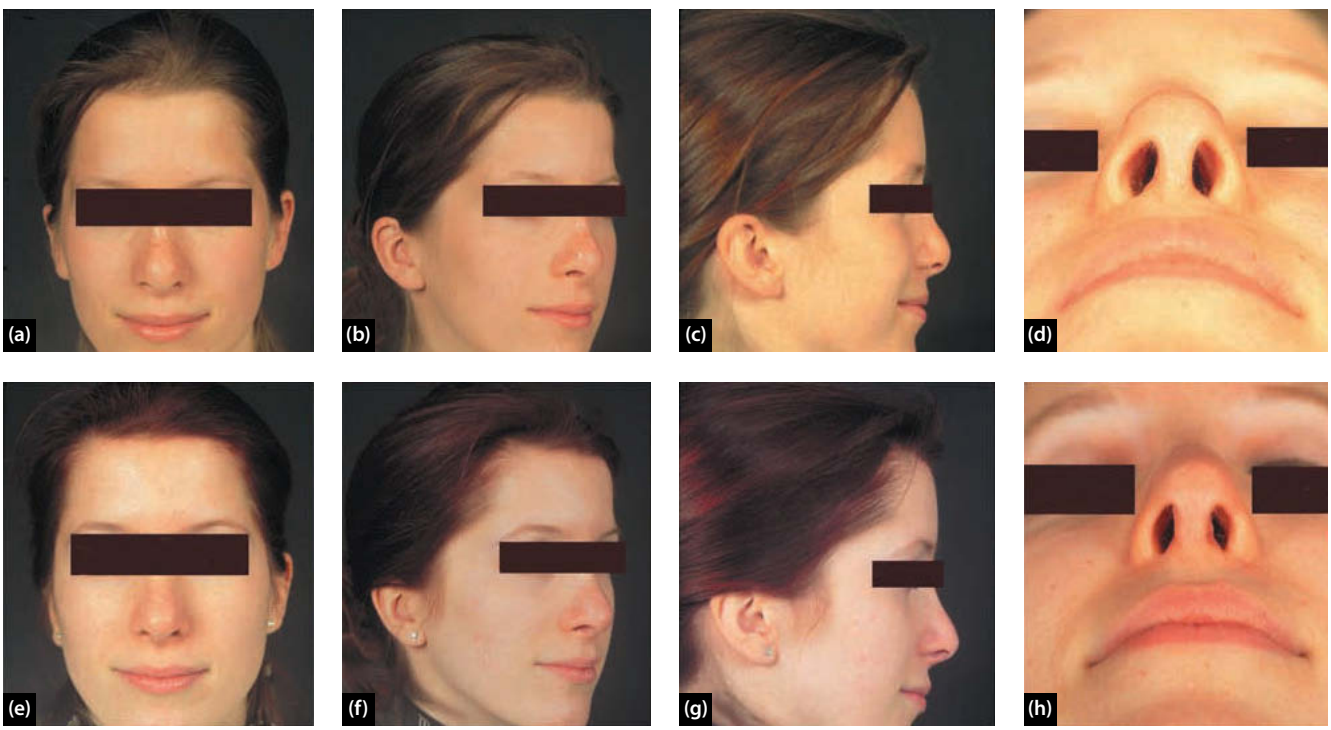

Figure 83.3 Narrow bony vault, irregularities of the dorsum and amorphous tip with pollybeak deformity after hump removal and tip surgery (delivery approach) (a–d). Revision via open approach: septal cartilage strut to the nasal dorsum, tip-suturing technique and tip graft **(e–h)**.

Figure 83.4 Sagging of the cartilaginous dorsum (bony pseudohump), loss of tip support and retracted columella after septoplasty and partial resection of the causal septal end (a–d). Reconstruction of the caudal septal end and repositioning of the septal cartilage. No removal of the pseudohump or nasal dorsal grafts **(e–h)**.

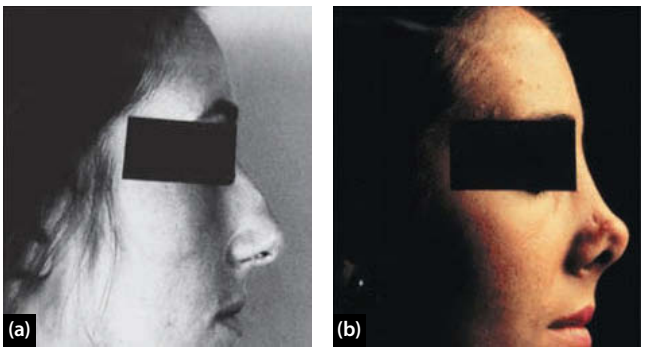

Figure 83.5 Overshortened nose and nasal base irregularities after reduction rhinoplasty. (a) Pre-operative analysis with moderate hump and nasolabial angle about 110°. Post-operative extremely open nasolabial angle and alar retractions after partial resections of alar cartilages and caudal septum **(b)**.

- sometimes resection of the inferior border of the triangular cartilages.

If the surgeon does not respect the nasolabial angle which was already close to 110 degrees pre-operatively (**Figure 83.5a**), then the result, if too much cartilage or even vestibular skin were removed from the lateral crura, is a foreshortened nose (**Figure 83.5b**).

Revision is very difficult in extreme cases. Normally, the limiting factor is not the nasal skin, which can be stretched if it is not too scarred. The problem comes with deficiencies in the inner lining, which is much more rigid than the external skin and can limit the lengthening of the dorsum and downward rotation of the tip. To reconstruct the retracted columella base can be impossible, since too many scars prevent the mobilization of the soft-tissue envelope. The new position of the soft tissues and the infrastructure must be secured by grafts. They can be applied following five principles:[32]

- flying buttress graft (spreader graft and columella graft) (**Figure 83.6**)
- caudal septal graft
- tip grafts
- radix grafts
- interposition grafts (between the upper and lower lateral cartilages).

Depending on the initial problem, revision surgery in an overshortened nose can improve the situation, but perfect reconstruction of all the deformities is uncommon (**Figure 83.7**). This means prevention is of utmost importance and the nasolabial angle should be checked carefully when tip rotation and shortening of the nose is planned.

CONCLUSION

The expected revision rate following primary rhinoplasty should be between 5% and 10%. Factors predisposing to

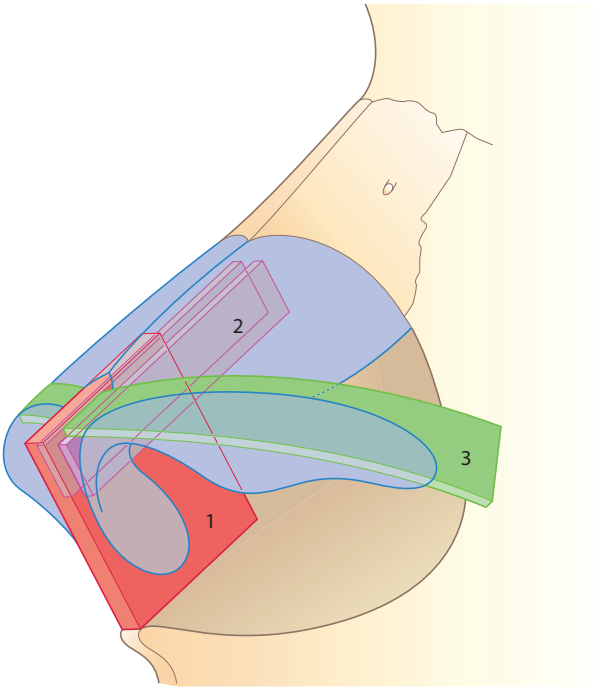

Figure 83.6 Grafts to lengthen an overshortened nose: combined septum and columella graft for downward projection of the columella (1); spreader grafts between the upper lateral cartilages to secure the length of the nasal dorsum (2); interposition grafts between upper and lower lateral cartilages for inferior projection of the alar rim (3).

revisions are thin skin, a low radix, the narrow middle vault and reduced tip projection. The most frequent deformities that may develop in these patients are the pollybeak deformity and irregularities of the nasal dorsum. Another frequent unfavourable outcome, especially of septoplasty or septorhinoplasty, is the cartilaginous saddle nose

Figure 83.7 Short nasal dorsum, low radix and retraction of columella base as a result of reduction rhinoplasty (a). Reconstruction with autogenous rib grafts. The nasal skin allows lengthening of the nasal dorsum, but downward projection of the columella base is limited because of the inner lining **(b)**.

with decreased tip projection and retracted columella. Overshortened noses tend to become medicolegal cases.

Although prevention during primary surgery can minimize the risk for post-operative sequelae, a planned second stage may be advocated and discussed with the patient in advance. However, the surgeon and patient must be aware that perfection is not always possible and revisions (especially when multiple) have a smaller chance of achieving the optimum result when compared with primary surgery.

The next generation of rhinoplasty surgeons and their patients will benefit from our experience. This experience, however, should not be based solely on personal opinion and the results of 'learning by doing'. We need more systematic evaluation and controlled studies than those available and cited in this chapter. All risk factors should be defined and prevention strategies developed, taking into account the outcome not only after 1–2 years but also after 10 years or more.

BEST CLINICAL PRACTICE

- ✓ Definition of standard surgical techniques for each nose deformity and anatomy for each surgeon.
- ✓ A systematic procedure for follow-up after one or more years is required to analyze post-operative results.
- ✓ Residual deformities or the development of other undesired sequelae should be clearly linked to the individual anatomy or the surgical technique used.

FUTURE RESEARCH

- ➤ Systematic evaluation of new surgical techniques (i.e. grafts, osteotomy) in rhinoplasty by specialized rhinoplasty centres before broad application in patients.
- ➤ Outcome research for evidence of nasal resistence measurements pre- and post-operatively.
- ➤ Development and establishment of specialized training centre and skills labs for rhinoplasty.

KEY POINTS

- Revision rates are between 5% and 10%.
- The most frequent deformities are pollybeak, dropping tip, broad tip and irregularities of nasal dorsum.
- Predisposing factors are low radix, narrow middle vault and inadequate tip projection.
- Patients with overshortened noses tend to take legal action.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: reduction and rhinoplasty. The author's own bibliography and library were also referred to. No references were found in the Cochrane database under rhinoplasty.

INTRODUCTION

The term 'reduction rhinoplasty' implies a formal, standardized approach to aesthetic nasal surgery. This concept has been inherited from Joseph[1, 2] and has been based for many years upon removing tissue from key anatomical nasal structures. His technique for cosmetic nasal surgery was developed in response to a case-mix predominantly comprising patients with abnormally large noses that invited ridicule.[3]

The classic Joseph reduction rhinoplasty is characteristically performed through intercartilaginous and full-length transfixion incisions and involves the following stages:[4]

- cephalic to caudal Joseph's saw bony hump reduction
- lowering of the cartilaginous dorsum
- triangular shortening of the caudal edge of the nasal septum
- use of a saw for lateral osteotomies with infracture
- alar cartilage cephalic rim reduction.

This generic approach to the oversized nose has been replaced by one that seeks to develop individual operative plans for each patient, tailored to careful pre-operative analysis of the anatomical variants. Sheen has championed a balanced approach to rhinoplasty which may involve augmentation of some areas of the nose as well as reduction of others.[4, 5] No longer in every patient is the tip reduced and then the dorsum lowered to fit the tip. Development of new rhinoplasty techniques has enabled surgeons to achieve the ideal tip position in relation to the ideal nasion height and position. These two landmarks then dictate the ideal height for the dorsum.[6]

The reduction rhinoplasty is still effective in selected cases, either in part or in whole. However, it should not be employed routinely in all oversized noses or in all patients with abnormal dorsal convexity related to tip–dorsum disproportion. In light of increasing patient expectation and the increasing attention paid to detail around every component of lateral profileplasty, this chapter will focus and reflect on the aesthetic dorsal reduction component of reduction rhinoplasty alone.

INDICATIONS AND AIMS

Aesthetic dorsal reduction rhinoplasty is indicated for the patient with an overprojected nasal dorsum relative to the nasion and/or the tip, resulting in a convex lateral dorsal profile. This dorsal convexity will be accentuated if the nasal tip is underprojected in relation to the nasion or vice versa (**Figure 84.1**). In the ideal nose the ideal nasion should project 10–13 cm from the anterior corneal plane. The ideal position of the nasal tip in females will be found at a point that intersects a line drawn from the ideal nasion at 34 degrees to the vertical facial plane, with a line drawn from the alar crease at 105 degrees to the vertical facial plane. In males the angles are 36 degrees and 95 degrees respectively. Oversized or cephalically malpositioned alar cartilages may contribute to supratip fullness and convexity. This chapter will not address techniques to correct these deformities.

Figure 84.1 (a–c) Pre-operative and **(d–f)** post-operative reduction rhinoplasty views with 12-month follow. Open approach. Composite dorsal reduction. Endonasal low-to-high lateral osteotomies and medial oblique osteotomies. Right spreader graft. Left autospreader graft. 2 mm cephalic trimes of the paradomal lateral crura. Bilateral dome creation sutures, a dome equalization suture and two tip position sutures.

Surgery to correct underprojection of the nasion and/or nasal tip which may contribute to lateral profile convexity will also not be presented in this chapter.

The aim of reduction rhinoplasty is a strong nasal dorsum in the lateral profile, which relates to the ideal nasion height. The tip-defining point should be projecting just above the dorsal line to create a supratip break, although in males the tip position may be on a straight line with the dorsum.[7] The aim is for a non-operated appearance with a 'handsome and patrician' look[8] and a high, strong dorsum.[9] Furthermore, achieving an attractive lateral dorsal profile with dorsal reduction must not result in loss of normal aesthetic dorsal lines. Normal nasal function must also be preserved.

CONTRAINDICATIONS

In the rare instance that both the nasion and the tip are underprojected, dorsal reduction may be contraindicated and surgical planning should consider radix augmentation and tip projection. When determining whether to reduce

Figure 84.2 (a–c) Pre-operative and **(d–f)** post-operative reduction rhinoplasty views with 15-month follow. Open approach. Composite dorsal reduction. Percutaneous low-to-low lateral and superior transverse and endonasal medial osteotomies. Bilateral spreader grafts. Deep temporalis fascia ball and apron graft inserted to augment the radix and to cover the upper dorsum and K area. The lateral crura were trimmed to leave intact 6 mm strips. Bilateral dome creation sutures, an intermediate crural suture and a dome equalization suture of 5/0 PDS were inserted.

the nasal dorsum and, if so, by how much, analysis must consider projection at the radix, the rhinion and the tip. The degree of hump reduction may need to be modified and balanced with radix augmentation (**Figure 84.2**) and techniques to increase tip projection.

Reduction of the dorsum to fit an underprojected tip will result in an unnatural, over-resected nose, which appears flat and broad in the frontal view and lacks height in the lateral profile. Dorsal reduction in these patients alone would be unlikely ever to achieve an aesthetic lateral profile in which the tip projects above the dorsal line. This is especially relevant in thick-skinned patients when skin elasticity and shrink are limited.

Just as a hump may only be a relative hump[5] due to underprojection of the tip, so pseudohumps may be apparent in patients with supratip depression characteristic of a saddle nose. Often saddle noses also have an underprojected tip, which further contributes to the appearance of a bony dorsal pseudohump. In such circumstances a natural dorsum is created by augmentation rather than reduction. If cartilaginous dorsal reconstruction is not performed and hump reduction alone is, dorsal aesthetic

lines in the frontal view will not be created and the nose will look flattened.

The same is often true in revision rhinoplasty for the soft-tissue pollybeak deformity. This results from primary over-resection of bony and cartilaginous dorsum in the thick-skinned patient and is exacerbated by techniques that also deproject the tip. Supratip dorsal reduction will achieve very little improvement and may exacerbate the problem by removing structural support for the skin.

Dorsal reduction must be very carefully considered and discussed with the patient who is happy with the shape of their nose but considers it too large for their face. Global reduction of the nose is required in such cases. Such surgery is complex and expects a lot from the skin with regard to shrinkage.

The overprojected radix in cases of dorsal convexity presents an anatomical area for which reduction may be contraindicated. A soft-tissue response of 25% reduction relative to skeletal resection has been demonstrated at the nasion.[10] It may therefore be more predictable to match the tip and dorsum to the nasion in these cases than to attempt aggressive nasion and dorsal reduction.

In all patients considering aesthetic rhinoplasty analysis must include detailed assessment to diagnose psychiatric disorders and personality types and traits that are associated with a high likelihood of surgery not meeting their physical or psychological expectations or of the patient not accepting or understanding unpredicatability.[11]

TECHNIQUES AND AVOIDANCE OF COMPLICATIONS

The patient is positioned in the reverse Trendelenburg with approximately 30 degrees of head up. The nasal mucosa is prepared topically with neurosurgical patties soaked in 1:1000 adrenaline solution and 5% lidocaine hydrochloride with 0.5% phenylephrine hydrochloride spray. Infiltration is performed with 2–4 mL of 2% lignocaine with 1:80000 adrenaline using a long, 27 gauge needle. The author most often uses an open approach. Infiltration is performed along the caudal end of the quadrilateral cartilage into the membranous septum and then deep to the perichondrium, particularly anteriorly and along the dorsal quadrilateral cartilage. Endonasally, infiltration is performed medial and lateral to the frontal process of the maxilla along the line of the lateral osteotomies, with the needle immediately adjacent to periosteum. Minimal infiltration is then placed laterally along the dorsum each side to avoid disguising the hump. Intradermal blebs of infiltration are raised along the incision lines and then injection is deep to the superficial musculoaponeurotic layer over the nasal skeleton that is to be exposed. The infiltration should be left for at least 10 minutes prior to surgery. During dissection, further infiltration is placed in the dissection planes, ideally subperichondrial and subperiosteal.

Surgery can be performed for dorsal reduction using a closed or open approach. Both must preserve tip projection when this is normal pre-operatively. An upper transfixion incision which avoids disrupting the relationship of the medial crural footplates to the quadrilateral cartilage and intercartilaginous incisions are used for the closed approach. When an open approach is chosen, the tip cartilages are not routinely separated for septal access. Their attachment to each other and the caudal septum is preserved. A hemitransfixion incision is used prior to opening the nose to access the septum. A superior submucoperichondrial tunnel is elevated bilaterally to expose the dorsal quadrilateral cartilage and adjacent upper lateral cartilages and the dorsal ethmoid plate deep to the nasal bones. If septal surgery is required or a septal cartilage graft is needed, the tunnels can be extended later in the procedure, after dorsal reduction and osteotomies. The author prefers to perform surgery in this sequence, with dorsal reduction and osteotomies preceding septal surgery. In this way the stability of the nose, particularly the keystone area, is best assessed after bone removal and fracture, which carry the greatest level of unpredictable disruption. This assessment of stability informs surgical decision-making with regard to septal procedures which could further destabilize the nasal keystone area.

If the open approach is chosen, three-way countertraction of the columella flap, alar rim and intermediate crus dome facilitates subperichondrial dissection of the lower lateral cartilages. In the midline the anterior septal angle is identified and subperichondrial dissection aided by infiltration, and hydrodissection proceeds along the cartilaginous dorsum. It is important to ensure that the anterior septal angle is well demonstrated so that the entire length of the nasal dorsum to the caudal limit of the hump to be removed is visualized. From the midline, subperichondrial dissection is continued laterally over the upper lateral cartilages. Perichondrial attachments in the scroll area may be adherent to underlying mucosa and the overlapping upper and lower lateral cartilages. Elevation is difficult here. This area is often also vascular. Good exposure of the upper lateral cartilages and their release from the superficial musculoaponeurotic system (SMAS) and perichondrium are necessary to facilitate precise medial edge resection, mobility and accurate reconstruction of the mid third later in the procedure.

At the pyriform aperture, sharp dissection is required to enter the subperiosteal plane over the bony dorsum. Lateral dissection over the bone should occur only as far as is required for bone removal. Maintaining skin and soft-tissue attachments to the majority of the frontal process of the maxilla minimizes the risk of excess medial movement after osteotomies.

The author prefers component dorsal reduction.[12] As described by Daniel,[13] the author prefers to begin reduction with bone removal. Incremental rasping is performed to uncap and leave intact the underlying cartilaginous upper lateral cartilages and their contiguous septal quadrilateral cartilage. The rasp is more predictable than an osteotome and graded rasps enable a graded reduction. The preserved upper lateral cartilages are then released flush from the septum in the midline with scissors or a 15 blade and the quadrilateral cartilage is incrementally reduced with an 11 blade. Rohrich[12] performs upper lateral cartilage release and incremental quadrilateral cartilage reduction prior to bone removal. Powered burrs,

rasps and blades may be used for bone reduction and may provide greater control and finesse.[14, 15] A decision then has to be made as to whether to trim the medial margins of the upper laterals incrementally to allow them to sit against the quadrilateral cartilage when retraction on the skin is released. The upper lateral cartilages tend to drop inferomedially when released from the quadrilateral cartilage. If resection is performed, it must therefore be conservative and also incremental. Daniel[13] terms release of the upper laterals and then incremental resection of the dorsal septum and upper laterals individually a 'vertical split-hump reduction'. He draws attention to the appreciation that excision of the dorsal septum lowers dorsal height while excision of the upper lateral decreases dorsal width.

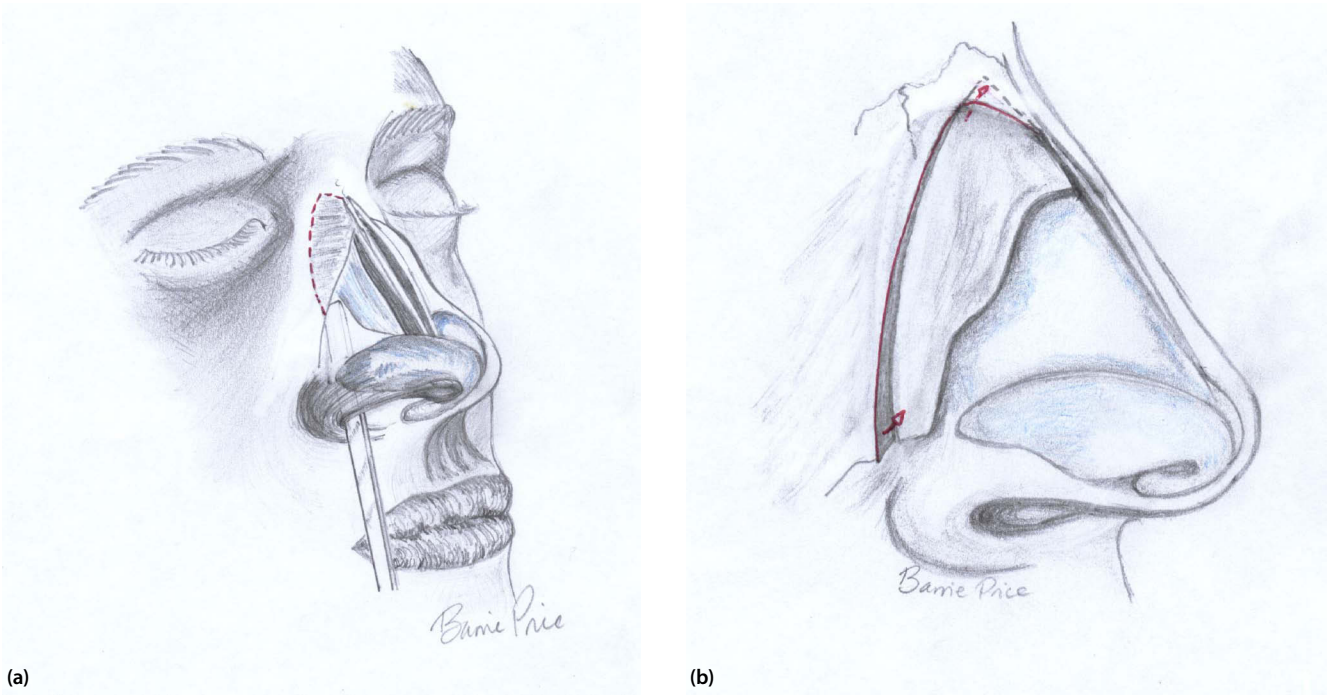
Tardy[16] describes incremental dorsal reduction but starting with retrograde shaving and removal of the intact upper lateral/quadrilateral cartilage hump from the bone–cartilaginous junction at the pyriform aperture to the anterior septal angle. The upper laterals are not released from the septum and therefore this resection will include the horizontal component of these cartilages as well as the dorsal septal quadrilateral cartilage. The bone is then reduced prograde with an osteotome from caudal to cephalic. This hump resection may be performed en bloc. Cartilage and bone are removed as a single unit with the bony and cartilaginous hump attached to each other.

Preservation of the upper lateral cartilages in their horizontal component both between the reduced edges of the bony dorsum and distally, caudal to the bones, maintains structure that can potentially be used to restore or maintain middle-third width and to bridge any gaps between the nasal bones after infracture. The medial edge of the upper lateral cartilages can be folded medially into the nose and sutured to the septum. These autospreader flaps[17] act to maintain mid-third width and are cartilage sparing, being an alternative to spreader grafts. Variations and refinements of these flaps have been described.[18] If the middle third requires width maintenance, there may be insufficient upper lateral to use as a flap. This occurs particularly if a small hump has been removed. In such cases spreader grafts are used. Spreader grafts may also be tailored to requirements better than autospreader flaps if the septum is curved or differential width restoration is necessary.[19] One or the other can be used on either side, depending on anatomical findings (see **Figure 84.1**). The author does not extend spreader grafts all the way to the anterior septal angle as this risks excess caudal mid-third width. There is no horizontal component to the normal upper lateral cartilages in their distal third. If spreader grafts are chosen and they extend to the keystone area, the horizontal component of the upper lateral cartilage in this region must be excised so that it does not sit up over the graft and cause a dorsal irregularity. This can be a technically difficult area to achieve a smooth contour for, particularly between the nasal bones. Preserved upper laterals can be sutured together in the midline after hump resection over spreader grafts.[20] This author also raises a perichondroperiosteal flap from the upper lateral cartilages and nasal bones to close over the dorsum after middle-third reconstruction with or without a contour refining onlay graft deep to the flap. If the middle-third width is good, as may be the case in conservative hump reduction with long nasal bones, spreader grafts or autospreader flaps may not be required. In these cases it is important to suture the upper lateral cartilages back onto the septum to maintain their length, tension and projection.[21] If mid-third vault width is not maintained or reconstructed, dorsal reduction will lead to an inverted V deformity seen in the frontal view. This results from medial and posterior relocation of the upper lateral cartilages and loss of a smooth continuous contour with the bony pyriform aperture.

While dorsal reduction may result in narrowing of the middle, cartilaginous vault, it will also result in widening of the bony vault. Osteotomies may therefore be required to narrow the bony dorsum. They may also be indicated if the bony base width is greater than the intercanthal distance. If middle-vault reconstruction is performed with spreader grafts or autospreader flaps, osteotomies are performed before these techniques are employed. We perform the lateral osteotomies first. These follow a 'low-to-high' path. A stab is performed in the nasal mucosa just superior to the insertion of the inferior turbinate bone onto the maxilla at the pyriform aperture. A 3 mm osteotome is engaged and passes in a gentle superoanterior arc to the level of the medial canthus. This osteotomy can be performed percutaneously. To control the cephalic position at which the lateral bony wall fractures, a 15-degree medial oblique osteotomy is performed from the lateral edge of the open roof to the superior extent of the lateral osteotomy (**Figure 84.3**).[22, 23] A paramedian, medial osteotomy, particularly if in the midline, risks a rocker deformity, either from the medial edge of each nasal bone becoming more projected or the cephalic margin pivoting laterally as the caudal margin is mobilized medially.

If the bony open roof does not extend to the level of the medial canthus, an alternative is to remove a cephalic wedge of bone that will extend the open roof to the level of the medial canthus.[24] A percutaneous, superior transverse osteotomy is then performed laterally from the apex of the open roof to join the cephalic end of the lateral osteotomy. Gentle pressure is applied either side of the dorsum to bring the bones together. Excess pressure at the bony nasal base is avoided to minimize the risk of moving the lateral nasal walls into too vertical a position, creating an unnatural, overly thin nose in the frontal view. Sheen described use of a low-to-high lateral osteotomy only, relying on digital pressure to create a short, superior fracture line along which the lateral wall hinged.[25] We prefer to use this technique only when the bony nasal dorsum is open cephalically to the level of the medial canthi. The technique also assumes that the open roof is wider caudally than cephalically. If this technique is employed for smaller open roofs, we feel it increases the risk of a visible step in the mid lateral nasal wall. In such cases no medial osteotomies will be required and superior, transverse osteotomies are performed to control the position of the superior fracture line as described above.

When the hump is removed, a slightly convex line of nasal bone and cartilage should remain. This allows for the differential thickness of the overlying soft tissues and



(a) (b)

Figure 84.3 **(a)** Endonasal low-to-low lateral and medial oblique osteotomies. **(b)** Movement produced by infracture.

will result in a straight external lateral profile. The author feels this point has been traditionally overemphasized and that any convexity should be slight.

If an open roof requires closing but the nasal base is narrow, infracture carries the risk of producing excess base narrowing. This is of particular concern if the nasal bones are short. Infracture carries the risk of producing excess mid-third narrowing and an inverted V deformity.[5, 26] In these circumstances the dorsum may be better reconstructed with spreader grafts,[5] an onlay spreader graft[27] or a dorsal onlay graft[28] and without osteotomies and infracture. Skoog described modification and replacement of the removed hump for dorsal reconstruction with or without lateral osteotomies.[29] The push-down operation and subsequent modifications have also been described in the management of the convex dorsum to avoid a skeletonized, inverted V deformity consequent upon dorsal reduction.[30]

If a small hump has been removed, an open roof defect may not result. The majority of the hump removed will have been cartilaginous, leaving no significant open bony defect. The upper lateral cartilages may still be contiguous with the quadrilateral cartilage as only the ridges of the bifurcated, 'Y'-shaped cartilaginous dorsum will have been shaved.[31, 32] In such instances, particularly in patients with thick skin and a nose with a narrow base, osteotomies and infracture may not be necessary.

Lastly, the author assesses the dorsum for irregularities with inspection and particularly with palpation using a wet finger. Achieving a smooth contour may require finesse achieved with the use of softened, small cartilage onlay grafts, 'scales' of shaved cartilage, scraped cartilage 'paste' or deep temporalis fascia (see **Figure 84.2**). The author avoids alloplasts.

The septum is quilted with 4/0 or 5/0 polyglactin (Vicryl®) and all incisions are closed with interrupted 6/0 polyglactin (Vicryl®). Great care must be taken with the columella closure to ensure skin-edge alignment and eversion. The author does not insert nasal packing. On induction of general anaesthesia, 8 mg of dexamethasone and a broad-spectrum antibiotic are given intravenously. The nose is taped and an external splint applied which remains for 1 week. Wounds are kept clean postoperatively using 3% hydrogen peroxide, and an antibiotic ointment is applied regularly for 1 week.

OUTCOME ASSESSMENT AND THE FUTURE

While not specifically reporting results of reduction rhinoplasty, several studies demonstrate psychological benefit from cosmetic rhinoplasty.[33–35] The functional sequelae of osteotomy with infracture in reduction rhinoplasty have been objectively studied. No change in nasal resistance using posterior rhinomanometry was detected in a series of 27 patients undergoing open rhinoplasty with osteotomies and infracture. However, patients in this study routinely underwent outfracture with or without submucosal diathermy of the inferior turbinates.[36] Total minimal cross-sectional area and minimal cross-sectional at the piriform aperture, measured with acoustic rhinometry, have been shown to change significantly following reduction rhinoplasty. In this study, 3 patients of 37 complained of postoperative loss of airway patency, which was normal before surgery.[37] No difference was detected between high or low insertion level lateral osteotomy in a 16 cadaver study performed by the same group.[38]

Outcome assessment in facial plastic surgery is a newly developing field looking at results from the patient's perspective. Expanded measures of both quality of life and health perception as well as satisfaction with appearance are studied rather than the surgeon's assessment of technical success.[39, 40] Specific instruments have been proposed for rhinoplasty.[41] International patient-reported outcome measure guidelines and criteria have been developed and from these have arisen patient-related outcome measurement tools that are procedure-specific, such as the FACE-Q.[42] A scale for rhinoplasty will be produced. Psychological screening tools will help us improve patient selection for surgery alongside measuring benefit.[43, 44] Three-dimensional imaging will further help with analysis, planning, communication, management of patient expectation and objective measurement of surgical change.[45]

Technical innovation will continue and will help the surgeon visualize the nasal skeleton better, and more precise techniques for osteotomy[46] and bone sculpting will develop further.

BEST CLINICAL PRACTICE

- ✓ Determine the ideal dorsal line from the ideal nasion and ideal tip-defining point.
- ✓ Use minimally traumatic techniques exploiting natural tissue planes.
- ✓ Fully expose the middle and upper nasal vaults in the midline.
- ✓ Perform dorsal reduction and osteotomies before septoplasty.
- ✓ Avoid aggressive over-resection.
- ✓ Ensure the middle vault is reconstructed.
- ✓ Meticulously assess the dorsum for irregularities after resection and infracture.

KEY POINTS

- Perform thorough pre-operative analysis of nasal deformity.
- Indications for reduction rhinoplasty are excess dorsal convexity relative to ideal height and position of the nasion.
- Aim for a strong, high nasal dorsum with tip projection above the dorsal line.
- Ensure middle vault support to maintain frontal view dorsal aesthetic lines and nasal function.
- Psychological benefit has been demonstrated in observational studies following cosmetic rhinoplasty.

SEARCH STRATEGY

Data in this chapter may be updated by Medline and Medscape searches using the keywords: nasal soft tissue defect, nasal obstruction, nasal skin cancer as specific or individual words that appeared as a keyword, in the title or abstract.

INTRODUCTION

Reconstruction of the nose poses several unique problems. The contours of the nose are variable, with convex and concave surfaces in close contact with each other, and the skin texture and colour is not easy to match. The human eye easily detects the slightest variation in contour or symmetry. Nasal defects can be reconstructed with local, regional, distal or free flaps. The primary aim of reconstruction is to restore the lost function and the secondary aim is to make the reconstructed part as normal in appearance as possible. The aetiology of nasal defects is shown in **Table 85.1.** Essentially, the surgeon confronted with a nasal deformity has to weigh up the alternatives available and select the correct one in order to obtain the best cosmetic and functional result with the minimum donor site morbidity. The selection of method is frequently based on personal experience, known effective procedures or individual bias.[1] Nevertheless, the principles laid out in this chapter and the key points should be of use whatever the choice of technique.

HISTORY

The history of nasal reconstruction dates back more than 3000 years. This operation developed in three phases. The first book on this subject is believed to be by Sushrutha[2] who lived approximately 600 BC. He used flaps from the cheek to reconstruct a lost nose. Later, Indian surgeons used a forehead flap, now universally known as the 'Indian method'.[3] Although this method continued to be used for centuries, it was not developed any further in India.

The next phase of development of nasal reconstruction took place in Italy during the Renaissance. In the mid 15th century, the Branca family in Sicily performed nasal reconstruction, possibly using the Indian method. This was later taken up by Tagliocozzi and published by him in 1597.[4]

TABLE 85.1 Aetiology of nasal defects

Defect type	Defects
Congenital	'Cleft nose', bifid or aplastic nose, proboscis lateralis
Traumatic	Iatrogenic: Septal surgery, scarring from endotracheal or nasogastric tube Thermal, radiation, chemical, mechanical, human bite, avulsion, frost bite
Inflammatory	*Autoimmune:* Wegener's granulomatosis, SLE, sarcoidosis, Sjögren's syndrome *Infection:* Syphilis, yaws, pinta, rhinoscleroma, leprosy, tuberculosis, histoplasmosis, mucormycosis, aspergillosis
Tumour	Basal cell carcinoma, squamous cell carcinoma, malignant melanoma

He used skin from the upper arm to rebuild the nose. Following the death of Tagliacozzi there is no information available to us on nasal reconstruction for two centuries.

After Britain established contact with India in the 18th century, the European surgeons absorbed and developed the 'Indian' operation. The first article that described the Indian method of rebuilding the nose was published in a lay journal called the *Gentleman's Magazine* in 1794.[5] Joseph Constantine Carpue began to perform similar nasal reconstruction after practising on cadavers, and he published his work in 1816.[6] Von Graef in Germany adopted this technique and performed an Indian type of reconstruction in 1816. Warren, a surgeon from Boston, came to Europe to study nasal operations. When he returned to the United States, he performed his first Indian-type nasal reconstruction in 1834.[7] During the 19th century, the Indian technique became widely accepted for rebuilding the nose in North America and even today it remains the basis for most reconstructive procedures.

The idea of rebuilding the nose with a single forehead flap with an inner lining of skin was reported by Natalie in 1842, Johann Friedrich Dieffenbach in 1845 and Ernst Blasius in 1848.[8] The use of composite grafts from the ear for reconstruction of a nasal defect was described by Konig in 1902.[9] In 1943, Gillies reported nasal reconstruction using a composite graft of auricular skin with attached conchal cartilage.[10] He transplanted a free composite auricular graft with epithelium on one side to a forehead flap. After healing took place, the forehead flap with graft was brought down to the nasal defect. Later, extensive work on the use of composite grafts in the head and neck region were reported by Walters.[11] In the 1960s and 1970s, Millard published a series of articles describing the paramedian forehead flap.[12] This helped provide a longer flap so that nasal tip defects could be corrected. More recently, Burget and Menick[13] have refined previous ideas and focused on methods that respect the aesthetic contours of the nose.

ANATOMY

The nose can be divided into upper, middle and lower thirds; the upper third is supported by the nasal bones, the middle third by the upper lateral cartilages and the lower third by the lower lateral cartilages. Contrary to what many believe, the lower lateral cartilages do not extend to the margins of the rim of the nostrils. The thickness and attachment of the skin and subcutaneous tissue to the bones and cartilages vary in different parts of the nose. Over the nasal bones the skin is loosely attached, whereas it is firmly attached to the upper and lower lateral cartilages. The skin over the lower third of the nose can be thick and sebaceous but in some women it can be so fine that the lower lateral cartilages can be seen through it.

AESTHETIC SUBUNITS

Gonzalez-Ulloa et al described the facial aesthetic units.[14] Aesthetic subunits are segments of contour broken by a change in undulation, skin quality or shadow. Different facial regions have their own colours, textures, mobility and contour. Every region is distinguished from other regions by its pattern of hair growth, quality and skin texture.[15] Scar placements along the border of the subunits can minimize visible alterations in contour and texture. The subunits comprise five convex and four concave units (**Figure 85.1**). They are the tip, dorsum, paired sidewalls, paired ala-nostril sills, soft triangles and columella.[16] In order to obtain an optimum cosmetic result, Burget and Menick[16] have advocated that the whole of the subunit is replaced. Defects that involve more than half a subunit should be repaired after removing the normal tissue in that subunit so that the whole subunit can be replaced.[16] Nasal defects may extend to

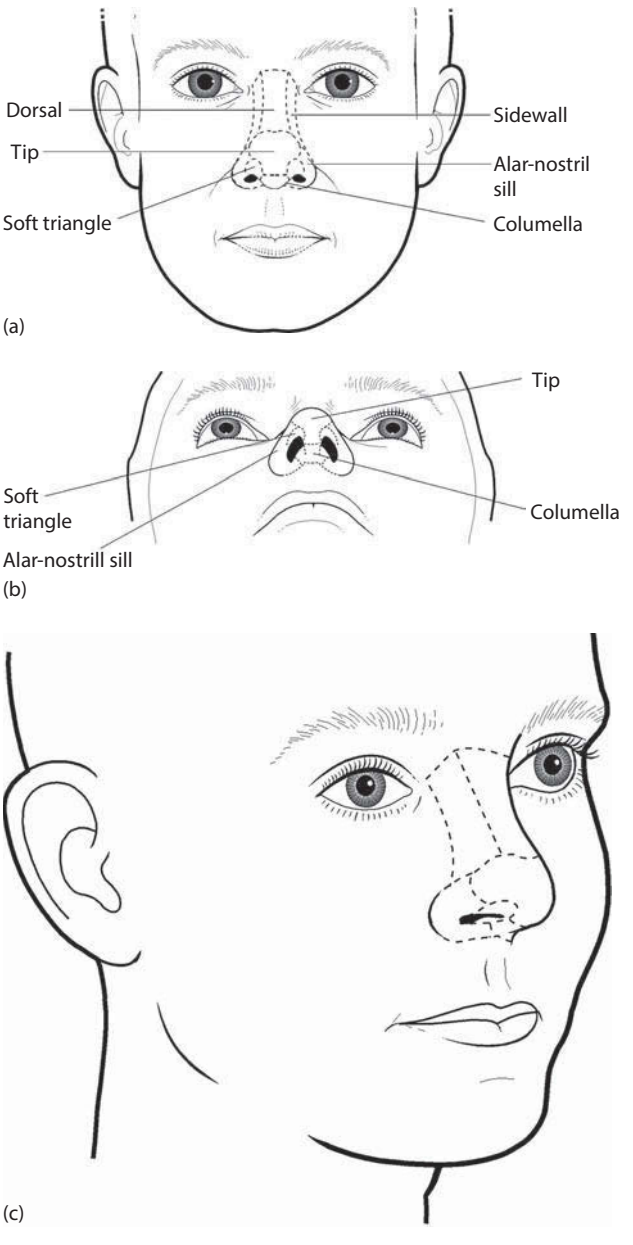

Figure 85.1 The aesthetic units of the nose.

adjacent facial units. The reconstruction of these facial units should ideally be carried out with a separate flap to maintain the segmental quality of the face.[16]

PRINCIPLES OF NASAL RECONSTRUCTION

After reconstruction, the nose must function and be aesthetically pleasing. The nasal valve, the inner lining of the nose and its supporting cartilages determine whether it works. Cosmesis depends on the cartilage and bony scaffolding, the quality of the skin, symmetry and the aesthetic compartments. Burget and Menick[13] have illustrated the primary principles in nasal reconstruction in an excellent text on this topic that is essential reading for any surgeon undertaking this work. They place particular emphasis on matching the contour of the unaffected side in unilateral defects, and respecting and reproducing aesthetic units wherever possible. They caution against using a forehead flap with any tissue excess as it will contract and 'bunch up' through contraction.[16] The fundamental principle of nasal reconstruction is to recreate the missing structures as closely as possible. Other principles include: avoid tension; replace whole aesthetic segment (where >50% loss); try to replace the exact amount of tissue, excess flap or graft may 'bunch up'; approximate vascularized tissue to any graft to avoid dead space.

During reconstruction of the nose, aesthetic segments must be respected as far as possible and the result is often better when the whole aesthetic segment, rather than part of it, is replaced. When the defect crosses aesthetic boundaries, more extensive reconstruction may be required. This is common in the nose and medial canthal regions, especially following Mohs' micrographic surgery for squamous cell carcinoma or morphoeiform basal cell carcinoma. A full-thickness defect of the nose also needs a lining, a scaffold and an external layer of skin of the same quality in terms of thickness, degree of sebaceous tissue and, if possible, colour, as the defect that is being replaced. Any cartilage that is removed needs to be replaced to avoid distortion and maintain symmetry. Another principle is to replace like with like so that the loss of an upper lateral cartilage should be replaced with cartilage of the same shape and thickness, if possible. In addition to this rule, a strut of cartilage should support the margin of the nostril where no cartilage normally exists, otherwise notching of the margins occurs. Extensive nasal defects that result from nasal malignancy require a combination of flaps and grafts as reconstruction will require an inner and outer layer, as well as supporting cartilage.

It is worth noting that, without the support of any septum, nasal reconstruction of the nose using any type of graft or flap is difficult. An osseointegrated replacement or prosthesis is another alternative. One possible technique to overcome this problem is the use of free bone and cartilage grafts sandwiched between a pericranial and paramedian forehead flap.[17]

PHYSIOLOGY

Factors influencing nasal reconstruction include:

- the aetiology of the defect and prognosis
- whether the patient has had previous radiotherapy, smokes, suffers from diabetes mellitus or has scarring from previous surgery
- the patient's nutritional status
- the patient's aesthetic needs and psychology.

Reconstruction is carried out using flaps or grafts. While flaps derive nutrition from their own blood supply, free grafts do not have a vascular pedicle. Grafts undergo three distinct, but overlapping, stages of healing.[18]

- **Stage one** is that of plasma imbibition. This stage begins at the time of graft placement and continues for the first 24–48 hours. Fluid is absorbed into the graft by capillary action, which draws the plasma into the graft itself. During this period, a fibrin deposit is being laid down between the graft and the recipient bed, which helps hold the graft in place. This process can be easily disturbed with the accumulation of clot or serum beneath the wound, separating the graft surface from the recipient bed.
- **Stage two** of graft healing begins approximately 24 hours after placement of the graft; the vascular components from the recipient bed start to meet with vessels randomly in the graft. At this point, circulation is beginning within the graft.
- **Stage three** includes vascular bud growth into the graft developing a vascular network. If anastamosis between the bed and graft is successful, true circulation begins within the graft and continued healing begins.

Direct interface between the graft and the recipient bed is important and this should be maintained during the first week.[19] Loose quilting may be necessary. Quilting should not be tight as post-operative swelling can cause excessive tension and lead to pressure necrosis.

The size of composite graft is important as blood vessels only develop from the edges. The vascularization of a composite graft is somewhat more tenuous and is dependent on limited surface contact along the edge of the graft and reducing any movement between the graft and its bed to a minimum.[10, 20] In larger grafts, survival depends on the rate of vascularization versus the rate of any destructive process.[20] The usual recommendation is that the centre of a free graft should not be more than 0.5 cm from the source of its blood supply. However, Converse[21] used an auricular composite graft up to 2.5 cm in diameter. The failure of a graft to survive in its new recipient area is more than a great disappointment to surgeon and patient, for the resorption of a necrosed cartilage transplant leaves a mass of scar tissue which renders further repair of the deformity much more difficult.[22]

TECHNIQUES FOR NASAL RECONSTRUCTION

Table 85.2 summarizes the techniques available for nasal reconstruction.

TABLE 85.2 Reconstruction of nasal defects

Area	Technique	Type
Skin and subcutaneous tissue	Primary closure	
	Secondary intention healing	
	Skin graft	Split thickness Full thickness, e.g. preauricular
	Local flaps	Advancement flap, e.g. cheek flap Rotation flap, e.g. dorsal nasal flap Transposition flap, e.g. bilobed flap, melolabial flap, nasolabial flap
	Regional flap	Pedicled, e.g. paramedian forehead flap Microvascular, e.g. dorsalis pedis free flap
Skeletal structure	Cartilage	Septal cartilage Conchal cartilage Rib cartilage
	Bone	Iliac crest Skull
Inner lining	Skin	Local flap Composite conchal graft 'Visa' of nasal vestibular skin
	Mucosa	Local flap Pedicled septal mucosal flap Composite conchal

Excision and primary closure

Small nasal lesions can often be excised and repaired by primary closure. Whole-thickness defects greater than 0.5 cm diameter repaired by this technique will often result in some asymmetry. Loss of skin and subcutaneous tissue, if minimal, can be closed after undermining either side down to the cartilaginous or bony skeleton. The advantages of this procedure are that it is a simple technique and single-stage.

Excision and healing by secondary intention

Healing by secondary intention is simple, does not require further surgery or hospitalization and it avoids donor site scarring and pain.[23] It also allows early detection of recurrence of cancer. Wounds allowed to heal by secondary intention do not necessarily give a bad scar.[24] In certain clinical situations, the scar from secondary healing will be better than a scar from a standard surgical repair. The variables to consider when deciding to opt for healing by secondary intention are the position, depth and size of the wound, skin colouration and patient age.[25] The most favourable sites are the concave surfaces of the nose, ear, eye and temple (NEET areas).[26] The disadvantages of this mode of healing are inconvenience due to a protracted healing time, infection, hypertrophic granulation tissue and scarring, hypopigmentation and distortion of adjacent structures through cicatrization.

Skin graft

Wounds that cannot be closed primarily or are not suitable for healing by secondary intention require repair with either a skin flap or a skin graft. An advantage of skin grafts is that they are the simplest and most predictable method of resurfacing a nasal defect not amenable to primary closure. Their disadvantage is a suboptimal cosmetic result due to contracture, poor colour match, a tendency to contract around the edges and donor site morbidity.[27] Split-thickness skin grafts contract more than full-thickness skin grafts post-operatively and their colour, texture and thickness will not readily match the surrounding skin. The full-thickness skin graft (Wolfe graft) contains most of the structures of the skin and is cosmetically superior to split-thickness grafts. The full-thickness skin graft is limited by its donor site availability and has an unpredictable 'take' over 2.5 cm. This can be used to resurface a defect of the upper two-thirds of the nose. The structural support should be intact. This graft often gives a poor result when used to replace the skin of the lower third of the nose as the smooth graft will contrast with the thick and sebaceous skin that is common in this area. For a full-thickness graft to take, the underlying periosteum and perichondrium should be healthy and vascular and the graft must remain immobile for vascularity to develop. The preauricular area is an ideal donor site as the graft often matches the skin of the upper two-thirds of the nose in colour, thickness and texture.

Local flaps

Local or adjacent skin flaps have many advantages. They have their own blood supply and, when designed well, the healing rate is high and the post-operative contraction is minimal. Local flaps are best for reconstructing the convex subunits of the nose. Depending on the vascularity, local flaps can be divided into random or axial. There are limits to the length and size of random local flaps that are based

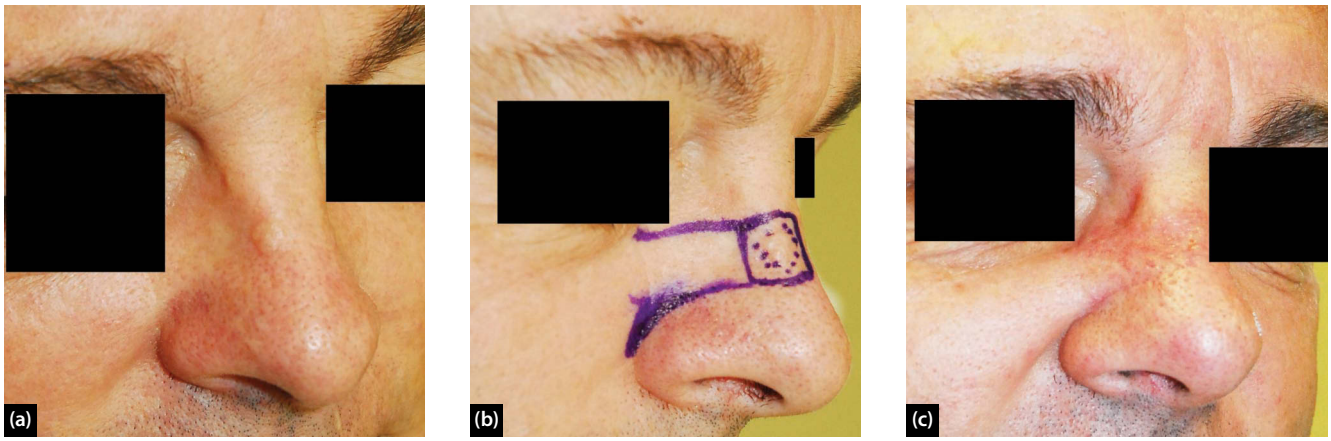

Figure 85.2 Advancement flap. **(a)** Nodular BCC of the nasal dorsum. **(b)** Excision margin and advancement flap marked. **(c)** Post-operative appearance after 6 months.

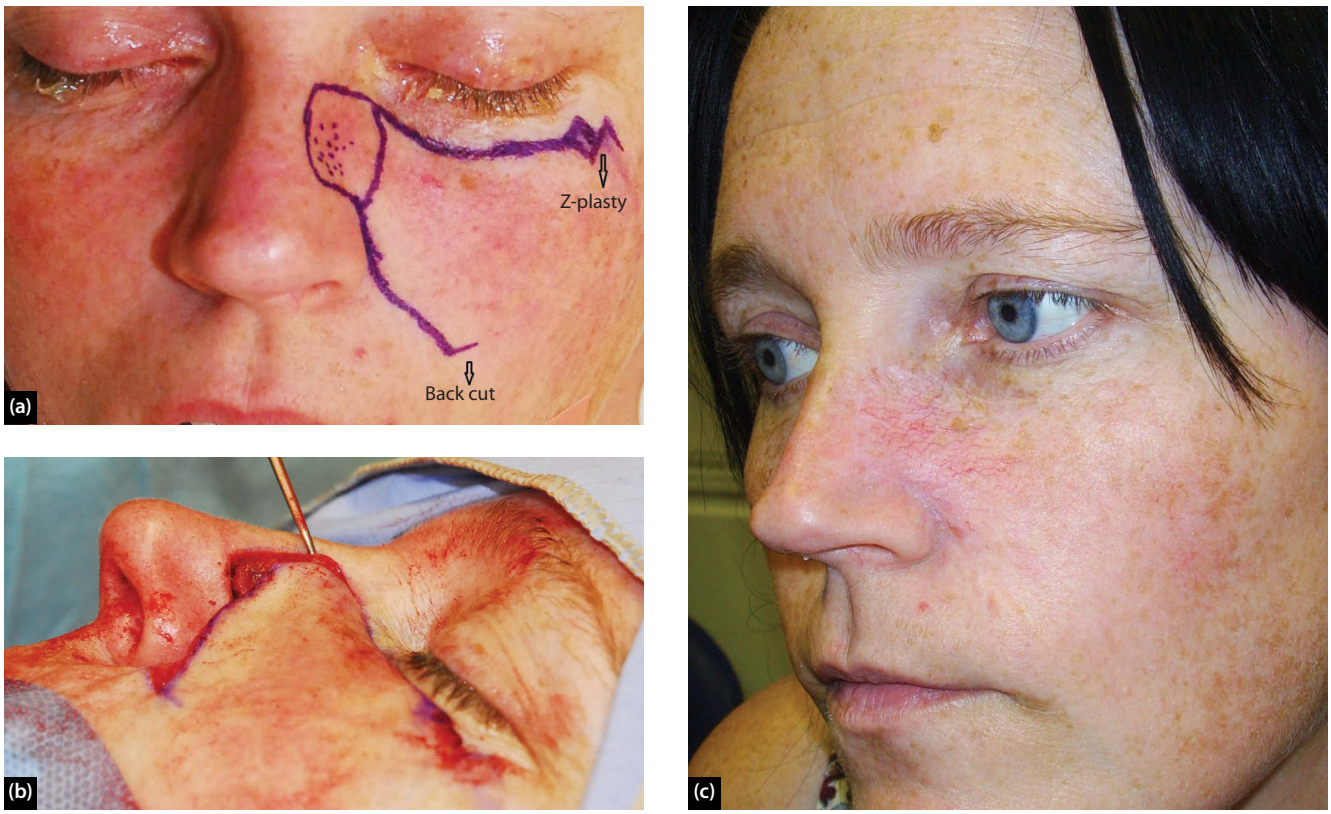

Figure 85.3 Cheek advancement flap. **(a)** Lentigo maligna of the nasal dorsum with cheek advancement flap marked with Z-plasty and back cut to lengthen the flap. **(b)** Flap raised and positioned. **(c)** Post-operative appearance after 1 year.

on random blood supply[28] but axial flaps based on named blood vessels can be larger. It is best to undermine below the subcutaneous musculoaponeurotic system (SMAS) in order to maximize the blood supply. Wide undermining is needed to reduce tension and increase the mobility of the skin and subcutaneous tissue. Based on their movement, local flaps are subdivided into advancement flaps, rotation flaps, transposition flaps and interpolation flaps.

ADVANCEMENT FLAP

Advancement flaps are the simplest of local flaps, being created when the tissue is undermined and advanced in a straight line in the same axis as the defect. An example of an advancement flap is the rectangular flap (**Figure 85.2**). Burrows triangles are excised to avoid 'dog ears', the cheek advancement flap and the V–Y advancement flap.[29] If the defect is large, two rectangular advancement flaps can be used to close the defect in an 'H' fashion. The reach of the advancement flap can be increased by using a 'Z'-plasty and/or a back cut (**Figure 85.3**). In a V–Y flap the flap is designed to be about twice the size of the defect (**Figure 85.4**). A bipedicled advancement flap can be used for closing a defect of the nasal dorsum (**Figure 85.5**).

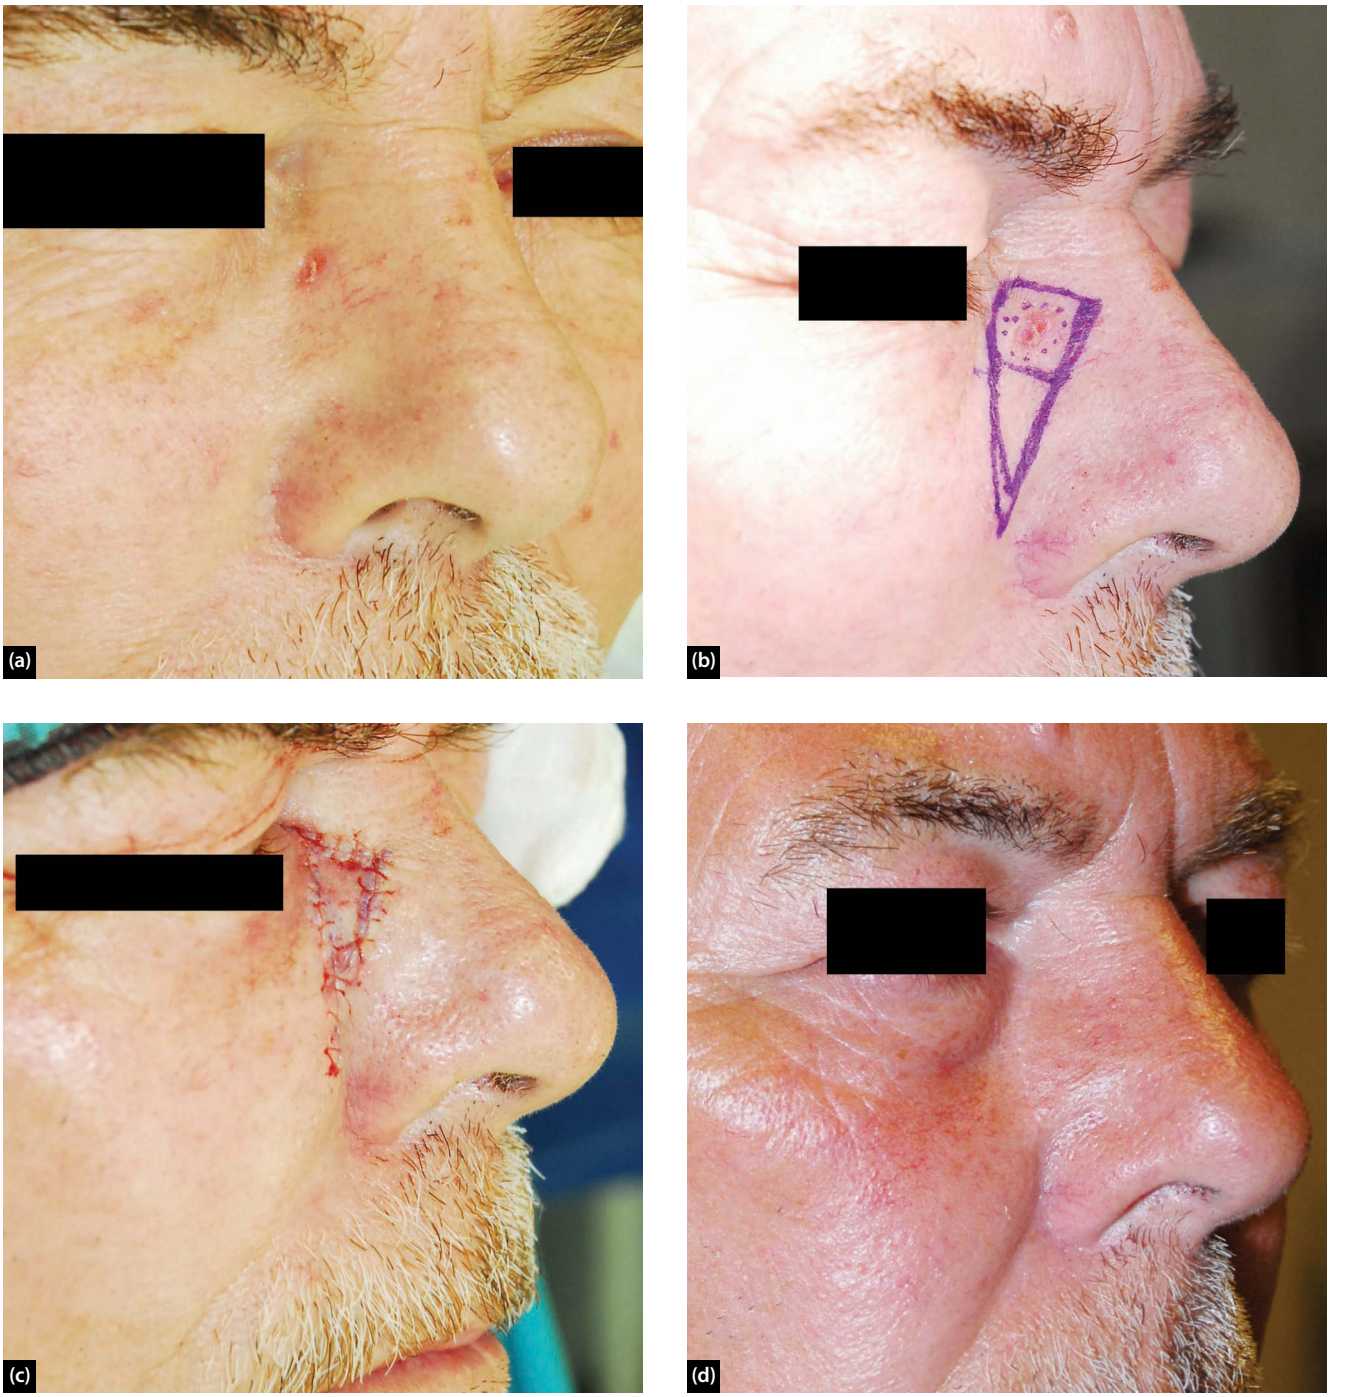

Figure 85.4 V-Y advancement flap. **(a)** Infiltrative BCC of the nasal side wall. **(b)** Margins and flap designed. **(c)** Flap sutured to the defect. **(d)** Post-operative appearance after 1 year.

ROTATION/PIVOT FLAP

A pivot flap is one whose axis rotates around a pivot to close the defect. As the degree of rotation increases, the effective length of the flap decreases. The entire flap and the surrounding skin need to be undermined in all directions. Failure to do this results in excessive tension during closure and buckling and will possibly compromise vascularity.[29] A bilobed flap is an example of a pivot flap. This is ideal for small defects (<1.5 cm) on the lateral side of the nose where local skin of the same thickness and colour can be used to fill a defect. If these flaps rotate skin through an arc of more than 110 degrees in the relatively inflexible thick skin of this region, it produces a prominent dog ear.

TRANSPOSITION FLAP

Transposition flaps are adjacent to the defect and do not have to cross an intact bridge of skin. They allow movement in more than one plane and examples include the 'note flap' and the rhomboid transposition flap.[18] A bilateral rhomboid flap has been described to reconstruct a supratip defect.[30]

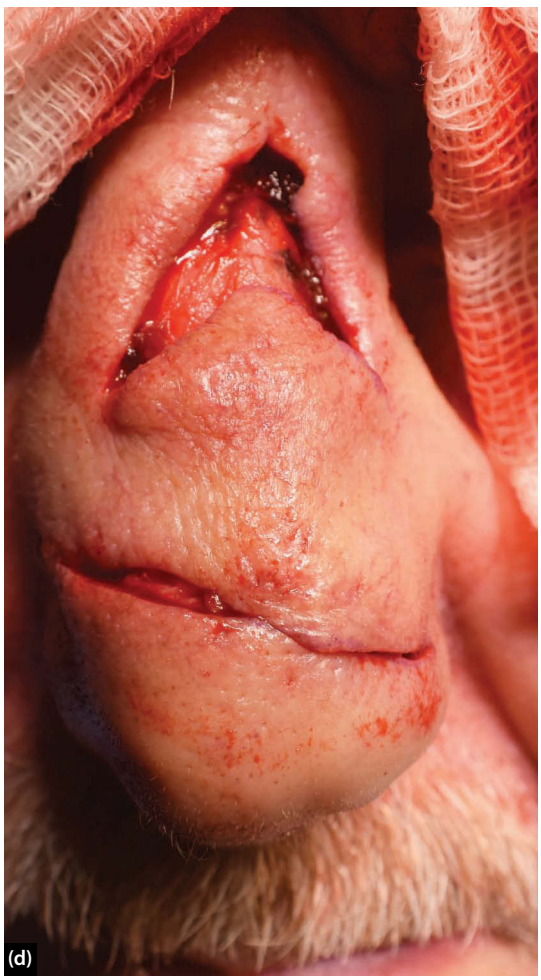

Figure 85.5 Bipedicle flap. **(a)** Nodular BCC of the nasal dorsum. **(b)** Margins of excision and flap marked. **(c)** After excision of BCC. **(d)** Bipedicled flap raised. **(e)** Post-operative appearance after 1 year.

INTERPOLATION FLAP

Interpolation flaps are not adjacent to the defect and they cross a bridge of intact skin to reach the defect. They will require a second stage to cut the pedicle once the flap has developed sufficient vascularity at the recipient site. Paramedian and nasolabial flaps are examples.

Bilobed flap (Zitelli's)

This is the flap of choice for defects of the lower third of nose 0.5–1.5 cm in diameter (**Figure 85.6**). There are five rules for the flap design to avoid problems of contour and vascularity.[31]

- The bilobed flap is used for defects up to 1.5 cm in diameter.
- Each lobe should not rotate more than 50 degrees.
- A piece of skin is excised between the defect and pivotal point of the flap before rotation to avoid a dog ear. The pivotal point is located away from the margin of the defect at a distance equal to the radius of the defect. It is never placed close to the medial canthus or alar margin.
- Lift the flap just above the level of the periosteum and perichondrium in order to preserve its blood supply and minimize scarring.
- The diameter of the first lobe is equal to the defect and the width of the second lobe is less than the first but large enough to close the donor defect comfortably.

Dorsal nasal flap

A dorsal nasal flap (**Figure 85.7**) can be used to cover a defect of the lower third of the nose but is not the ideal choice. The skin and soft tissue are elevated off the periosteum and perichondrium over the dorsum and side wall of the nose up to the glabella. This flap is slid down to cover the defect. The advantages are that the skin is brought from an area of excess, the glabella, to the lower third of the nose and the defect is covered by tissue similar to the lost one. However, it has three aesthetic disadvantages:

- The thick and pitted skin of the glabella slides downwards and may form an epicanthal fold.
- The flap does not coincide with the subunit excision lines.
- It forms a large dog ear that may not be corrected completely.[31]

Glabellar rotation flap

A glabellar rotation flap (**Figure 85.8**) is useful for defects of the upper third of nose and medial canthus. Excess skin from glabellar region is rotated down to cover the defect. Disadvantages are the same as for the dorsal nasal flap.

Nasolabial flap

A nasolabial flap (**Figure 85.9**) is suitable to correct the skin loss of the alar subunit. It can be used as the outer lining layer when a full-thickness defect of the alar subunit is being corrected. The flap can be based inferiorly or superiorly, and the pedicle divided at a second procedure. Alternatively, an island flap can be rotated into position.[32, 33] The perforating branches of facial and angular arteries supply this flap and an island flap can be rotated 180 degrees to allow primary closure. In order to obtain a groove around the alar margin, the nasolabial and cheek skin can be advanced a few millimetres more than might seem necessary and the rim left unsutured so that,

when healing takes place, the reconstructed ala contracts a little and rolls up to form a more natural edge.[34]

Note flap

The note flap (**Figure 85.10**) and adjoining defect appear similar to a musical note and hence the name. It is essentially a superiorly based nasolabial flap. A dog ear is removed and the flap moved to cover the defect. A second stage is not required.

Septal flaps

An anterior septal mucosal flap based on the septal branch of the superior labial artery, or alternatively a posterior flap based on the septal branch of the sphenopalatine artery, can provide an internal lining.[16] A septal flap produces a well-vascularized lining and, while it tends to crust for several weeks, it will eventually provide a normal lining. Squamous epithelium will tend to crust for many months when it is used to line the nose. One of the main limitations about using a septal flap is that, if both nasal vestibules need an internal lining, then a septal perforation will almost certainly be produced. Most septal flaps cause nasal obstruction as they fold over and this requires a secondary procedure. It is important to raise these flaps under the mucoperichondrium to give them strength.

Regional and distant pedicled flaps

When there are larger or more complicated defects, including a full-thickness tissue loss, regional flaps may be required. Complications can include: graft necrosis (rare in paramedian forehead flap); intranasal crusting; donor site morbidity; 'bunching up' due to contracture of excessive tissue; stenosis and nasal obstruction.

If pedicled regional flaps are not available, distant pedicled flaps can be used. However, distant pedicled flaps, like the pectoralis major myocutaneous flap and trapezius island paddle flap, do not provide a good colour or texture match for the nasal skin and are very bulky. Free flaps described for use in total nasal reconstruction are the radial forearm free flap, the dorsalis pedis free flap and the retroauricular free flap. The radial forearm free

flap is bulky, the dorsalis pedis free flap is thin, but it causes significant donor site morbidity and the retroauricular free flap has very small vessels and therefore has a precarious vascular anastamosis, limiting its application.

Large or complex defects with a full-thickness tissue defect require regional flaps in conjunction with free or local flaps and grafts. Free flaps have been described for use in total nasal reconstruction but they are bulky as the underlying fat is thick and it is difficult to thin it evenly, even after several stages.[35, 36] A pericranial flap has been described to provide an internal lining for total nasal reconstruction.[17]

The midline and paramedian forehead flaps are the pedicled flaps that are of most use in nasal reconstruction.

Midline forehead flap

For reconstruction of large defects of the nose above the columella, the midline forehead flap can be used, but extension onto the columella is limited. It can be used for subunit repair, heminasal reconstruction or total nasal reconstruction.[37] The midline forehead flap is based on the supratrochlear arteries[38] and consists of skin, subcutaneous tissue and frontalis muscle. A width of up to 4 cm has been described.[37] Recently, a midline forehead flap based on central artery has also been described.[39]

The advantages of this flap are the excellent colour and texture match with the skin of the nose, reliability and low morbidity, and the donor site deformity is low. The disadvantage is that the 180-degree twist in its base means that it has to extend to hair-bearing skin if it is to stretch to the columella without kinking its base. It is also unsightly until a subsequent procedure is carried out to divide the flap.[37]

Paramedian forehead flap

The paramedian forehead flap (**Figure 85.11**) is an improved modification of the midline forehead flap and is the best alternative in dealing with major nasal defects.[40, 41] The technique is very similar to that of the midline forehead flap except that the flap is positioned to one side of the midline based on the ipsilateral supratrochlear artery.

This flap is not only robust but the donor site often heals well, even when it is not possible to close its upper part and this is left to heal by secondary intention. One of the main problems of the flap is its thickness, particularly if it is used to reconstruct the alar margin. It is possible to thin this skin down up to 1.5 cm from its distal rim unless there are adverse factors affecting its vascular bed. A single-stage paramedian flap has also been described.[42]

Multiple flaps in large defects

When the defect is large, the use of multiple local flaps (**Figure 85.12**) can be considered for reconstruction if the patient is not keen on using larger flaps such as paramedian flap or cheek advancement flap. In such cases it may be advisable to use slightly larger flaps to compensate for the possible cicatrization at the junction of the flaps.[43]

Free cartilage grafts

Cartilage from the septum, conchal bowl or rib provides a useful scaffold and it is rare for it to resorb unless it is morselized or becomes infected. The scaffolding should be provided at the same time as the reconstruction. Delay in providing the support leads to scarring and contraction of the flap, causing difficulty in placing the scaffold as a second-stage procedure.[44] Burget and Menick have advocated placing the cartilage between the frontalis muscle and the skin of a forehead flap before any contraction of the flap has occurred,[45] but it can only be placed distally and this may compromise the distal vasculature. When alar subunits are reconstructed, the margin must be supported with a cartilage graft to avoid contracture. These grafts are kept between the inner and external lining to provide adequate blood supply. Even when the defect does not involve the alar margin, the cartilage-free graft has an important role in providing support if the lower lateral cartilage, upper lateral cartilage or quadrangular cartilage is lost.

Composite cartilage grafts

The free composite graft (**Figure 85.13**) consists of skin and greater or lesser amounts of attached subcutaneous tissue. Konig[9] first described the use of a composite cartilage graft from the ear. In his paper published in 1943, Sir Harold Gillies described the use of the composite graft to provide the inner lining of forehead flap used for nasal reconstruction.[10] Limberg,[46] Brown et al[47] and Dupertuis[48] reported the use of a free sandwich graft from the auricle for nasal reconstruction. The free auricular composite graft has been advocated for the repair of minor defects of the lower part of the nose for the following reasons.[48]

- The skin of the ear is similar in colour to the skin of the nose.
- The ear contains cartilage that gives good support with a choice of contours to match those of the ala.
- The auricular graft has only a slight tendency to contract after surgery.
- This method is economical because the length of hospitalization is much shorter.
- The secondary defect of the ear is inconspicuous and can easily be repaired.

Composite grafts up to 2 cm in diameter can survive free transplantation where the vascular bed has not been compromised by smoking, radiotherapy, scar tissue from previous trauma or surgery, diabetes or severe atherosclerosis.

The shape of the auricular composite grafts makes them suitable for use in nasal surgery.[49] These grafts have been used to correct small defects of the alar margins, especially those taken from the antitragal margin. The disadvantages noticed with the auricular composite graft are that, while its contour can often match that of the alar rim, it can rarely replace a whole aesthetic unit

and its skin quality is often different once it has bedded in and fibroblasts have led to some contracture.[50] The auricular composite graft from the conchal bowl can be used for lining the inner surface of the paramedian forehead flap and to provide skeletal support to the reconstructed area.[41] The defect can be filled using a pedicled postauricular island flap.[41] The benefits of a conchal cartilage graft to provide the internal lining and support for a paramedian forehead flap when both nasal vestibules need reconstructing are that it avoids a septal perforation[51] and nasal obstruction and there is little donor site morbidity. The morbidity of the donor region is small.

CONCLUSION

Various techniques are described for reconstructing defects of the nose. The surgeon chooses the technique depending on his or her preference and the nasal defect that requires correction. Whatever technique is used, it is essential to reconstruct all three layers of the nose. Whole aesthetic subunits must be reconstructed for a better aesthetic result if more than half of the subunit has been lost. Although different grafts and flaps have been described, in our opinion, the paramedian forehead flap (with composite conchal graft, if required) is robust and consistently gives good results in major nasal reconstruction.

Figure 85.13 Composite cartilage grafts. (a,b) Bilateral vestibular stenosis and notching of the alar margins secondary to pressure from the nasogastric tubes. **(c,d)** Post-operative view after inlay of conchal composite grafts.

BEST CLINICAL PRACTICE

- ✓ Reconstruction should only be undertaken when the surgeon is sure that the tumour has been removed.
- ✓ Mohs' micrographic surgery should be used for morphoeiform basal cell carcinoma or squamous cell carcinoma whose margins are unpredictable. If Mohs' is not available, then it is best to wait for the histological result from paraffin sections and dress the wound in the meantime.
- ✓ The slightest variation in contour or symmetry of the nose is readily seen and the aim should be to obtain as much symmetry as possible.
- ✓ The concept of replacing the whole of an aesthetic segment (a tissue plane with the same thickness, colour and contour of skin) if more than 50% of the segment has been lost is important in obtaining a good cosmetic result.
- ✓ Reconstruction requires an inner lining, scaffolding and an external layer otherwise the tissue will contract, roll up and become thick, firm and featureless.
- ✓ Incisions should be made at the junction of aesthetic segments in order to disguise them.
- ✓ If a defect requires three or more flaps to reconstruct adjoining aesthetic units, there can be unpredicted cicatrization at their junction. This particularly applies to the alar base and in these circumstances we recommended replacing the nasal defect with more tissue in the paramedian forehead flap than when the units of the nose are being reconstructed on their own.
- ✓ It is important for an individual's self-esteem and psychological well-being that they undergo counselling before embarking on nasal reconstruction.

FUTURE RESEARCH

- Many techniques have been described to reconstruct the nose and their success rate in both aesthetic and functional terms is difficult to quantify. The presence of numerous techniques means no one technique is good for all defects of the nose.
- A minority of authors have questioned the principle of resecting the remainder of an aesthetic segment if more than 50% has been lost[52] but these claims have not been supported by photographic evidence equal to that of the proponents of this principle. There are no good techniques available to reconstruct the nose if the septal support is lacking.
- Randomized control trials are unlikely to take place given the relative rarity of these conditions and the number of variables that would need to be controlled for. Nevertheless, the techniques described have stood the test of time and give good results when the principles outlined in this section are followed. These are not procedures that should be 'tried' by the occasional or inexperienced surgeon as a poor outcome makes it far more difficult to achieve a good result if revision surgery is needed.

KEY POINTS

- The concept of an aesthetic segment, a tissue plane with the same skin thickness and contour, is central to obtaining a good result.
- Try to keep the scars parallel to relaxed skin tension lines and at the junction of aesthetic subunits to make them less noticeable.
- Usually whole aesthetic segments should be replaced, even if this means removing good tissue – unless less than half of one segment has been lost.
- Respect and reproduce aesthetic units wherever possible.
- Sound reconstruction requires an inner lining, adequate scaffolding and an external lining with skin of the same thickness and colour as the contralateral side.
- If the alar rim is lost, a contoured girder of cartilage needs to support the soft tissue at its edge, otherwise it will tend to retract and collapse.
- Reconstruction should only be carried out when the surgeon is sure that the tumour has been removed. Mohs' micrographic surgery should be used for morphoeiform basal cell carcinoma or squamous cell carcinoma whose margins are unpredictable. If Mohs' is not available, then it is best to wait for the histological result from paraffin sections and dress the wound in the meantime.
- Symmetry is important.
- Avoid tension but remember that excessive tissue contracts and 'bunches up'.
- A composite cartilage graft can rarely replace a whole aesthetic unit and its skin quality is often different once it has bedded in and fibroblasts have led to some contracture.

ACKNOWLEDGEMENT

I would like to acknowledge the contribution of Professor Nicholas Jones who co-authored this chapter in the previous edition. I have benefited greatly from his advice, guidance and training. Much of this chapter is inspired by his writing in the previous edition.

SEARCH STRATEGY

The data in this chapter are based largely on the authors' personal experience as surgeons and teachers. Pinnaplasty techniques are extensively described in textbooks of operative surgery.

BACKGROUND

'Prominent ears' is a common presentation to the paediatric ENT clinic, and represents the commonest congenital deformity of the ear with an incidence of approximately 5–6%.[1] They can be associated with severe psychological distress and consequently affect academic performance and social development.[2] It is therefore important to address any associated psychological issues as well as manage the patients' and parents' expectations when discussing the potential outcome of surgery.

There is a spectrum of ear defects that require the surgeon to tailor the consultation and operative procedure to the individual but, as an umbrella term, pinnaplasty is the surgical procedure undertaken to correct this benign deformity.

The timing of surgery remains controversial. Some surgeons advocate operating on children as young as 3 years old in order to manage the condition prior to any psychological distress[3] while others argue that the individual should be able to give informed consent before undergoing treatment.

Since Dieffenbach first performed the procedure in 1845,[4] more than 200 different techniques of pinnaplasty have been described in the literature, indicating that no single approach is a 'panacea for all ills'. In 1968, McDowell thus proposed the main objectives for a successful pinnaplasty, enabling surgeons to blend various techniques and approaches (**Box 86.1**).[5]

ANATOMY

The external ear develops from the first and second branchial arches during the 6th week of gestation. The six hillocks of His rotate and fuse to form the pinna (**Figure 86.1**).

The aesthetically normal auricle lies with its long axis tilted posteriorly by 15–20 degrees. The top of the auricle is level with the eyebrow, and its width is approximately 60% of its height (range = 5.5–6.5 cm). A normal pinna

BOX 86.1 Objectives for a successful pinnaplasty

- Elimination of the protrusion in the upper third of the ear.
- The helical fold should be parallel to the antihelical fold but visible when viewing the patient from the front.
- The helix should have a smooth and regular contour.
- The post-auricular sulcus should not be distorted.
- The auricle should be an appropriate distance away from the mastoid.
- The difference between both auricles should be within 3 mm.

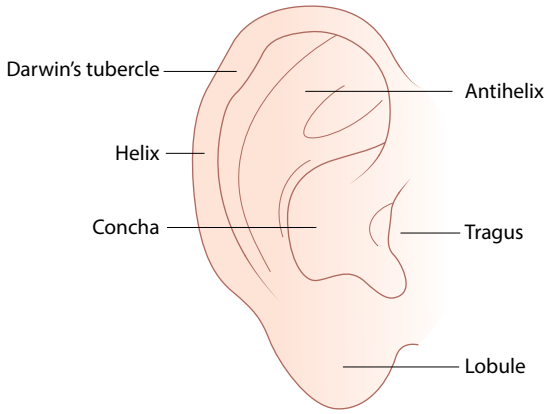

Figure 86.1 Anatomy of the pinna. (Based on a drawing by Mr Dutta, Pembury Hospital, Tunbridge Wells, UK.)

has an auriculocephalic angle of 25 degrees while protruding ears have an auriculocephalic angle greater than 40 degrees (**Figure 86.2**).

Prominent ears are an example of first-degree dysplasia, according to the classification of auricular deformities as first described by Weerda in 1988 (**Table 86.1**).[6]

Prominent ears are commonly due to one or a combination of the following defects:

- underdevelopment of the antihelical fold
- hypertrophy of the conchal bowl
- prominent lobule.

The constricted ear deformity appears as a small but prominent ear due to the small circumference of the helical rim. Stahl's ear deformity consists of an additional crus which transverses the scapha.

CONSERVATIVE METHODS

A number of non-surgical techniques have been developed for the treatment of protruding ears.

Simple moulding or splinting devices can be considered in children up to 6 months old. The high levels of oestrogen during the neonatal period allow for the cartilage to be more malleable and therefore respond to non-operative methods. The effectiveness of treatment is directly influenced by the age of the child and therefore referral of neonates with external ear deformities should be encouraged. Satisfactory results can be seen in up to 90% of patients if treatment is started within the first few days of life.[7]

OPERATIVE TECHNIQUES

Pinnaplasty can be performed under local anaesthetic or general anaesthetic as a day-case procedure although, with most patients being children, general anaesthetic is usually the preferred option.

Before surgery takes place, it is helpful to have at least two consultations with the patient/parents to confirm the need for surgery and photographs are essential for preoperative planning and for medicolegal purposes.

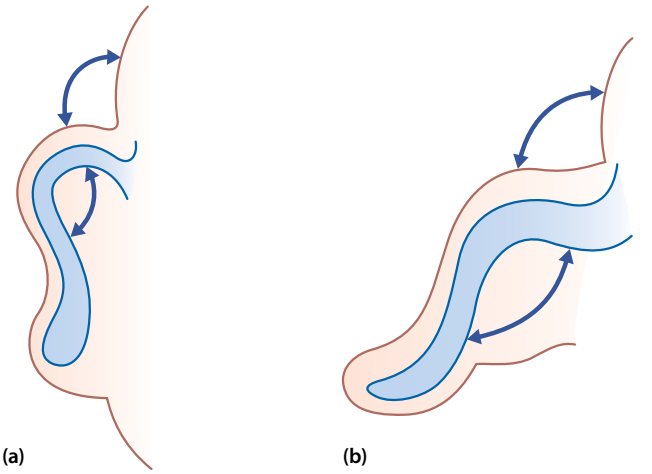

Figure 86.2 Anthropometric evaluation of a normal pinna. (Based on a drawing by Mr Dutta, Pembury Hospital, Tunbridge Wells, UK.)

TABLE 86.1 Classification of auricular deformities

Degree of dysplasia	Definition (example)
1st degree	All anatomical features present but minor≈deformities noted (prominent ears, macrotia, Stahl's ear)
2nd degree	Some anatomical features missing (cup ear, constricted ear)
3rd degree	No recognizable anatomical features (atresia)

Formation of the underdeveloped antihelical fold

Two techniques have defined the pinnaplasty operation and can be used in isolation or in combination:

- cartilage sparing/suturing technique
- cartilage excising/scoring technique.

At the start of the operation, the neo-antihelix is created by holding the helix against the mastoid. Each side of the neo-antihelix is then marked with methylene blue needle markings (**Figure 86.3**).

An elliptical skin incision is made in the posterior sulcus, which is then excised to expose the perichondrium (**Figure 86.4**).

The tattoo markings are identified posteriorly (**Figure 86.5**), and are used as landmarks for cartilage suturing or excising.

Mustardé first described the cartilage sparing/suturing technique in 1963.[8] Three or four non-absorbable mattress sutures are placed through the auricular cartilage and perichondrium using the methylene blue markers for precise placement (approximately 1 cm wide and 1 cm apart), thereby creating the new antihelical fold (**Figure 86.6**).

This technique reduces the trauma to the cartilage and, as a result, post-operative auricular irregularities rarely occur. It is widely considered to be an appropriate technique in young children with soft and malleable auricular cartilage.

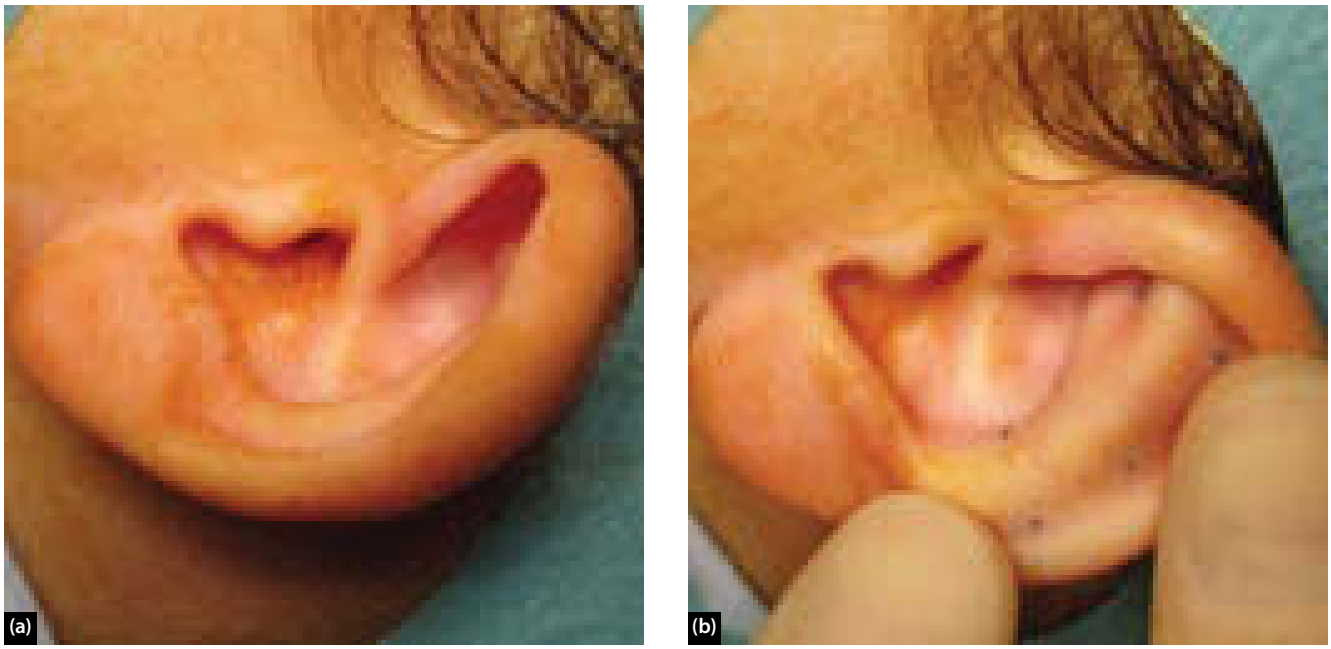

Figure 86.3 (a) A prominent ear and **(b)** the neo-antihelix with methylene blue markings.

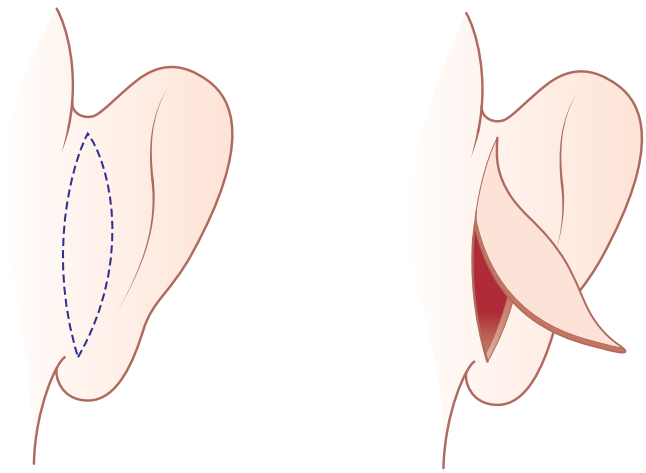

Figure 86.4 Postauricular elliptical skin excision. (Based on a drawing by Mr Dutta, Pembury Hospital, Tunbridge Wells, UK.)

It is advisable to use a non-absorbable suture such as Gore-Tex® to achieve a long-lasting result but with a minimum of reaction from the surrounding tissue (**Figure 86.7**).

Stenström described one of the initial cartilage incising/scoring techniques.[9] The scapha cartilage is incised in a 'C' shape and dissected off the anterior skin and perichondrium. The cartilage is then scored by making parallel incisions caudally from the inferior crus, which allows the antihelical fold to be developed. This technique can be used even when the cartilage is thicker in older individuals. With this technique, there is a greater risk of haematoma formation and infection due to significant skin elevation so intra-operative haemostasis and post-operative dressings are vital to prevent complications.

Usually, a combination of the two techniques allows for the disadvantages of the individual techniques to be minimized, thus reducing the potential for complications.

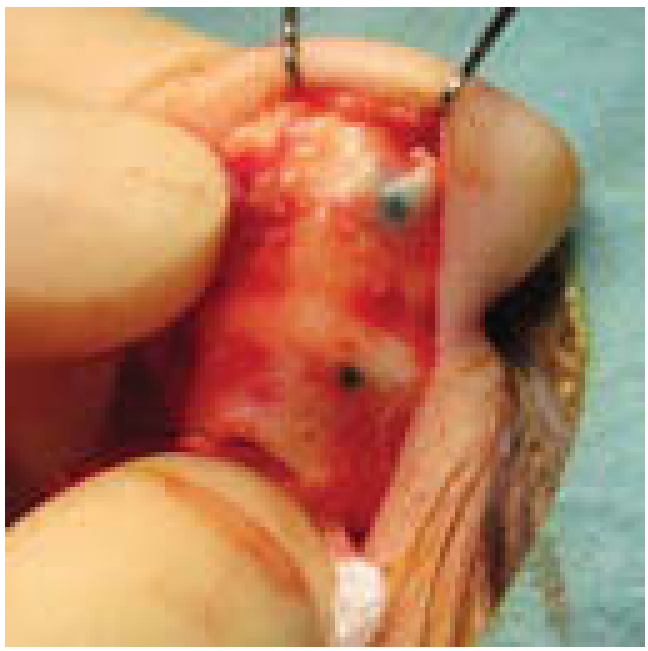

Figure 86.5 Methylene blue markings on the posterior aspect of auricular cartilage.

Additional techniques can be used as an adjunct to the conventional techniques. For example, a laterally based posterior auricular dermal flap or a bilateral fascioperichondrial flap can be used to prevent suture extrusion and decrease the rate of recurrence.

Without any particular 'gold-standard' procedure, novel techniques are continuously being developed, including cartilage-sparing methods without the use of sutures, and non-transfixing full-thickness incisions through the helix and antihelix that break the existing cartilaginous mould and therefore allow reshaping.

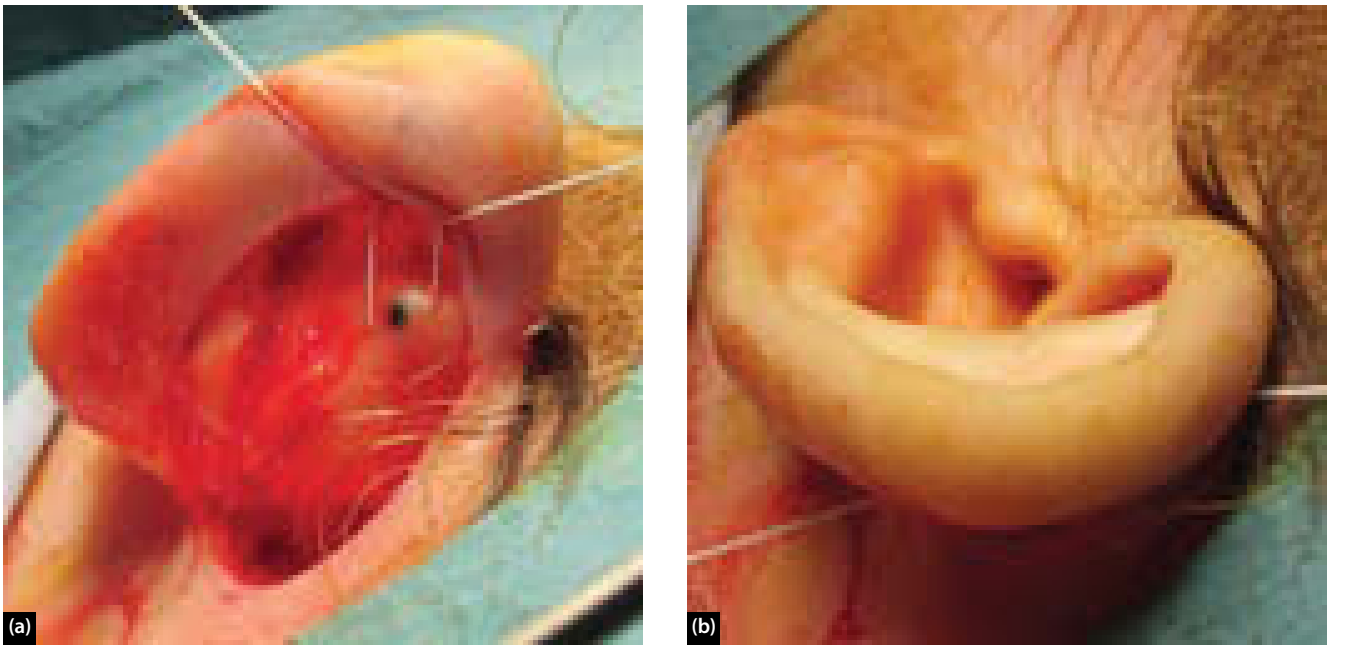

Figure 86.6 Mustardé suture.

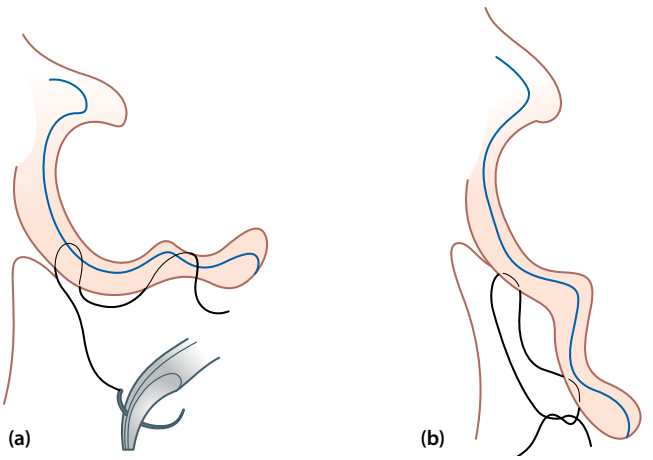

Figure 86.7 Technique of a Mustardé suture.

Correction of the conchal bowl hypertrophy

The angle between the concha and the mastoid can be reduced by a suture technique first described by Furnas in 1968 (**Figure 86.8**).[10] Care should be taken when placing the mastoid portion of the suture as placing it too close to the external ear canal may narrow the meatus when the suture is tied.

If the concha depth is more than 2.5 cm, excision of a full-thickness crescent of cartilage should be considered to correct the deformity, ideally being taken from the region of the conchamastoid sulcus.

Reconstruction of the lobule

A separate incision is made on the lobule to allow for a 'fishtail', 'wedge' or 'W-shaped' skin excision. The lobule can be repositioned by placing Goulian sutures (sutures that include postauricular skin, mastoid periosteum and posterior aspect of the lobule), therefore setting the lobule back towards the mastoid.

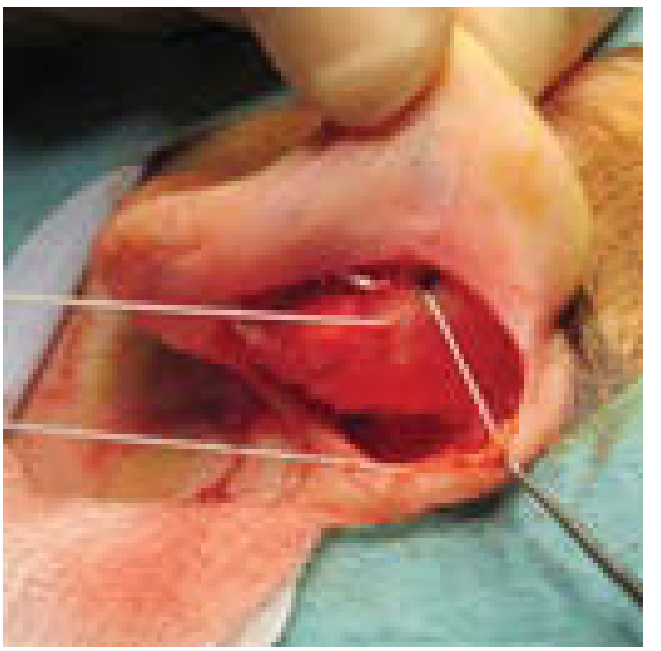

Figure 86.8 Furnas suture.

Other deformities

STAHL'S EAR DEFORMITY

The Kaplan and Hudson technique describes an incision being made along the helical rim and cartilage being

Figure 86.9 BIPP-soaked cotton wool dressing.

dissected off the skin. The affected cartilage, the extra crus, is excised and the skin is closed directly.

CONSTRICTED EAR DEFORMITY

The cup ear deformity requires elongation of the helical rim to allow the pinna to lie flat. An incision is made along the helical rim and the crus of the helix is fully mobilized and then advanced out of the concha. A standard pinnaplasty technique is then applied.

The postauricular wound can be closed with absorbable sutures, thus negating the need for removal (useful in younger children). A dressing such as BIPP-soaked cotton wool or paraffin gauze is applied to either side of the new antihelical fold and conchomastoid areas to reduce haematoma formation (**Figure 86.9**) followed by a dressing of heavy cotton wool and a crepe head bandage.

POST-OPERATIVE CARE

Head bandages in the post-operative period help to keep the dressings in place and also protect the ears. There is, however, no evidence to suggest that there is any clinical benefit conferred after 48 hours. Keeping the head up tends to reduce oedema.

COMPLICATIONS

- **Haematoma** is an early complication following pinnaplasty. It requires immediate evacuation to prevent necrosis of the cartilage. It is often signified by uncontrolled pain.
- **Infection** is a rare complication following pinnaplasty but requires early antibiotics in order to prevent chondritis and permanent deformity.
- **Keloid scarring** is a recognized complication of pinnaplasty, and patients and their families should be warned about this possibility.
- **Problems with sutures** can occur; they can extrude, and cause granulomas and hypertrophic scar formation.
- **Recurrence.** The rate of revision surgery is approximately 6% due to the pinna returning to its pre-operative position.
- **Overcorrection** is the most common complication of pinnaplasty and can lead to asymmetry or further deformity.

CONCLUSION

Many of the techniques for the correction of prominent ears are successful in achieving high satisfaction rates, despite significant variations in the techniques. Each technique has its own advantages and risks. The key to pinnaplasty is an awareness of each technique and applying the appropriate technique(s) to each individual case.

KEY POINTS

- 'Prominent ears' represents the commonest congenital deformity of the ear.
- 'Moulding' or 'splinting' is highly effective if commenced early and may avoid the need for surgery.
- Good quality pre-operative photography is an essential part of treatment planning.
- Timing of surgery varies, but most surgeons and parents prefer correction before the child goes to school or in the early years at school.
- Several operative techniques are available, each with benefits and drawbacks.
- Over-correction and asymmetry may lead to poor outcomes.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: cosmetic eyelid surgery, blepharoplasty, brow lift, dermatochalasis, midface lift and blepharoplasty complications.

INTRODUCTION

The term blepharoplasty is used to refer to an operation in which redundant tissues including skin, or skin and muscle, are excised from the eyelid, and in which fat may be excised, sculpted or repositioned. The appearance of the eyelids, and the periorbital region, plays a pivotal role in maintaining facial harmony through expression of human character, mood and emotions, and a successful outcome from this surgery requires great attention to detail.

A blepharoplasty can be performed for both functional and aesthetic reasons. A functional blepharoplasty aims to restore normal function and appearance to an eyelid that has been altered by trauma, infection, inflammation, degeneration, neoplasia or a developmental anomaly. A cosmetic blepharoplasty aims to improve the appearance of eyelid tissues that are histologically and functionally normal.

Patients who enquire about, or who are referred for, upper and lower eyelid blepharoplasty tend to present with a variety of aesthetic and functional complaints (**Figure 87.1**). These include:

- a tired look
- hooding of the upper eyelids
- 'drooping' of the upper eyelids
- 'eye bags'
- skin wrinkling
- skin folds
- a visual field defect
- headaches
- irritation of the upper eyelids
- lower lid 'dark circles'.

Female patients often complain of the inability to place make-up on the upper eyelid.

An upper eyelid blepharoplasty may involve the removal of skin alone, or skin and orbicularis muscle, or this may be combined with the removal or sculpting of herniated orbital fat. Occasionally an upper eyelid blepharoplasty will only involve the removal, sculpting or redraping of fat. The procedure may be combined with an eyebrow lifting or blepharoptosis procedure. The procedure may be performed for functional reasons to improve a patient's visual field restricted by dermatochalasis, or to improve symptoms of irritation from redundant skin hanging over the upper eyelid lashes, and/or for cosmetic reasons.

A lower eyelid blepharoplasty is more frequently performed for cosmetic reasons alone and may also involve the removal of skin and muscle alone or this may be combined with the removal and/or repositioning of herniated orbital fat, the resuspension of a ptotic orbicularis oculi muscle, a lateral canthal suspension, an orbital decompression procedure for thyroid eye disease or a midface or suborbicularis oculi fat (SOOF) lift. It may also be combined with skin-rejuvenating procedures (e.g. laser skin resurfacing, a chemical peel or the post-operative injection of dermal fillers).

Blepharoplasty is one of the most commonly performed cosmetic operations.

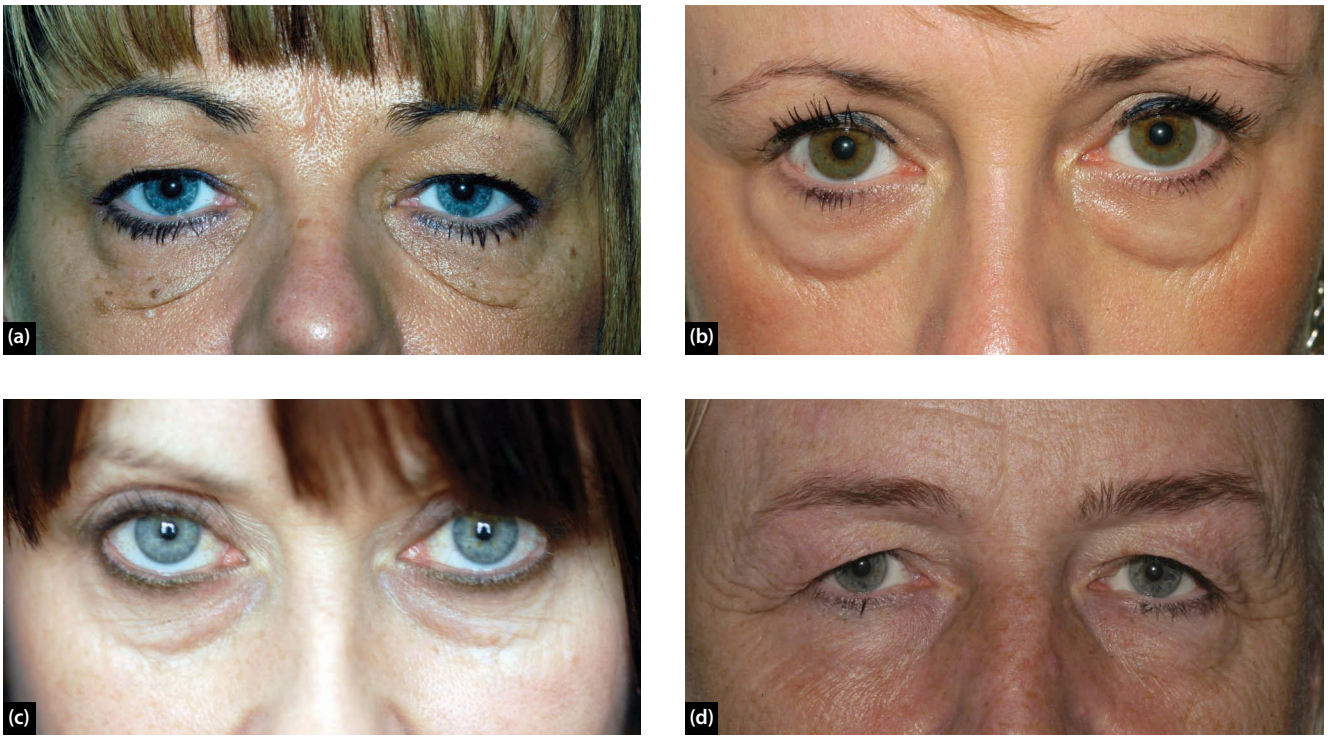

Figure 87.1 **(a)** A patient complaining of hooded upper lids with an inability to place make-up, and loose folds of skin in the lower eyelids. She was a heavy smoker. **(b)** A patient complaining of unsightly lower eyelid 'bags'. **(c)** A patient complaining of lower eyelid 'dark circles' creating a 'tired look'. **(d)** A patient complaining of a 'blinkered feeling' with a restriction of her visual fields.

APPLIED ANATOMY

A thorough understanding of the surgical anatomy of the eyebrows, eyelids and midface is essential prior to performing a blepharoplasty. This anatomy should be carefully reviewed. Additional aspects of surgically relevant anatomy are presented below.

The upper eyelids

The palpebral aperture is almond-shaped, with the lateral canthal angle lying slightly higher than the medial canthal angle. The lateral canthal angle is generally slightly higher in females than males and lies approximately 5 mm from the lateral orbital margin (**Figure 87.2**). The upper eyelid skin crease is usually approximately 5–6 mm above the lash line in males and 7–8 mm in females.

The distance between the inferior aspect of the eyebrow and the upper lid skin crease on downgaze should be approximately two-thirds of the distance from the inferior aspect of the eyebrow to the eyelid margin. Likewise, the distance from the skin crease to the eyelid margin in downgaze should be one-third of the distance from the inferior aspect of the eyebrow to the eyelid margin (**Figure 87.2**).

Figure 87.2 **(a)** The typical topographical anatomy of the periorbital region of a young female showing a skin crease at 6–7 mm above the eyelid margin and an arched eyebrow with the temporal aspect of the eyebrow lying at a higher position than the medial aspect. Note that the eyebrow has been plucked. It is important to take this into consideration when making measurements for skin resection. **(b)** The typical topographical anatomy of the periorbital region of a young male showing a skin crease at 5–6 mm above the eyelid margin and a flatter eyebrow contour.

Figure 87.3 A patient following an excessive resection of her left upper eyelid skin with worsening of her brow ptosis. She also has asymmetry of the upper eyelids and brows post-operatively.

In general, a minimum distance of 10–12 mm should be left between the inferior aspect of the eyebrow and the upper eyelid skin excision marking when performing an upper lid blepharoplasty and, again in general, approximately 20 mm of skin should be left between the inferior aspect of the eyebrow and the eyelid margin.

It is important to maintain these dimensions. If an excessive amount of upper eyelid skin is removed, reducing the distance from the skin crease to the brow in the presence of a brow ptosis, an unsatisfactory result will occur, with the appearance of the brow being attached to the eyelashes (**Figure 87.3**). This may also cause lagophthalmos (**Figure 87.4**).

It is important to differentiate prolapsed preaponeurotic fat from retro-orbicularis oculi fat (ROOF) that has descended into the upper eyelid (**Figure 87.5**). This may give rise to the appearance of upper eyelid 'fullness' (**Figure 87.6**). Although this descended fat can

Figure 87.4 (a) The same patient as in Figure 87.3 demonstrating severe lag on downgaze. **(b)** The same patient demonstrating lagophthalmos on attempted passive eyelid closure. She also shows very poor placement of the upper lid skin incisions and only 5–6 mm of skin between the left upper lid incision and the lowermost position of the eyebrow centrally.

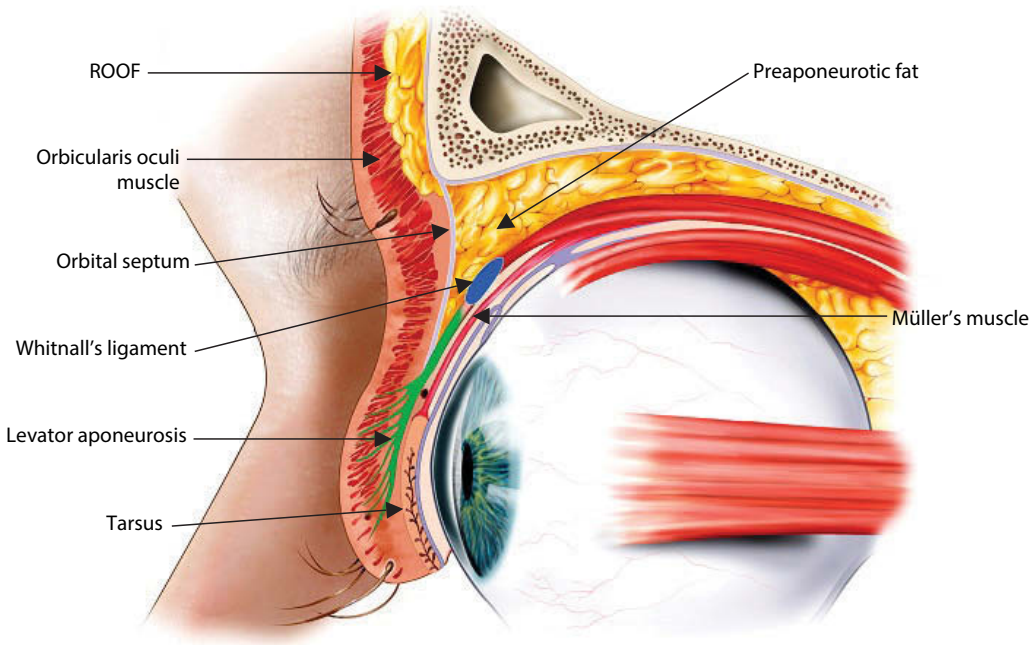

Figure 87.5 Diagram illustrating the position of preaponeurotic fat.

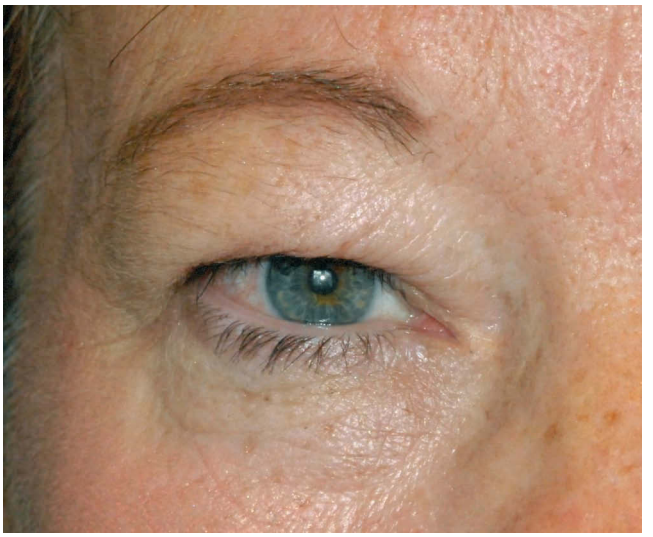

Figure 87.6 Fullness of the upper eyelid due to descent of the retro-orbicularis oculi fat (ROOF).

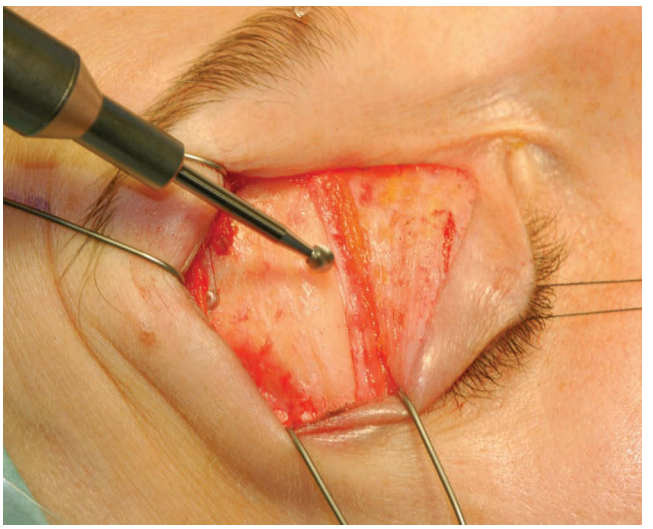

Figure 87.7 A burr is being used to reduce the prominence of the supraorbital margin in this patient.

Figure 87.8 A patient with bilateral lateral upper eyelid swellings due to spontaneous lacrimal gland prolapses.

be debulked, it is preferable to reposition it as part of a browlift procedure.

Some patients have very prominent superolateral bony margins that can also contribute to upper eyelid 'fullness'. This can be exposed and reduced with the use of a burr during the course of an upper eyelid blepharoplasty (**Figure 87.7**).

Subcutaneous thickening of this area in the dysthyroid patient must be recognized. This may not be amenable to improvement by standard blepharoplasty surgery. An overly aggressive upper eyelid blepharoplasty in a patient with thyroid eye disease can markedly worsen symptoms of corneal exposure.

It is important to recognize a prolapsed lacrimal gland that may be responsible for lateral upper eyelid 'fullness' or swelling (**Figure 87.8**). Prolapsed glands can be repositioned during the course of an upper eyelid blepharoplasty by suturing the gland to the periorbita of the lacrimal gland fossa (**Figures 87.9–87.11**).

Some patients develop orbital fat atrophy which creates an upper eyelid sulcus defect. The removal of preaponeurotic fat in such patients should be avoided to prevent a post-operative 'cadaveric' appearance. A prolapsed medial fat pad in such a patient can be debulked and the fat transplanted to lie evenly in the preaponeurotic space. In general, the removal of fat from the upper eyelid should be avoided in the majority of patients.

'Fullness in the medial aspect of the upper eyelid may be caused by a medial eyebrow ptosis. Elevation of the brow, or the use of botulinum toxin injections in the glabella, can be more successful at addressing this problem. Incisions in this area can leave unsatisfactory scarring. It is important to avoid the temptation to 'chase a dog ear' into this area beyond the medial limit of the skin crease during an upper eyelid blepharoplasty as the subsequent scarring can be very unsatisfactory. In such patients a gentle debulking of the medial fat pad can allow the skin to redrape with a more satisfactory aesthetic result, but over-resection of fat should be avoided. The fat should not be discarded as it may be required for use in the central aspect of the upper lid or may be of use to help to treat a medial tear trough defect in the lower eyelid.

The upper eyelid skin crease represents the most superior point of attachment between the skin and the levator aponeurosis. This position is just inferior to the insertion of the orbital septum onto the levator aponeurosis. The skin crease lies at a higher level in females, approximately 7–8 mm from the lash line, compared to 5–6 mm in males. It is important not to raise the skin crease in males to avoid a 'feminization' of the eyelid appearance.

The skin crease shows racial differences. In the oriental eyelid the orbital septum attaches to the levator aponeurosis at a lower level, allowing the preaponeurotic fat to descend into the lower reaches of the eyelid, preventing the levator aponeurosis from forming a high skin crease. A great deal has been written about the oriental eyelid and the oriental blepharoplasty. However, this detail is beyond the scope of this textbook.

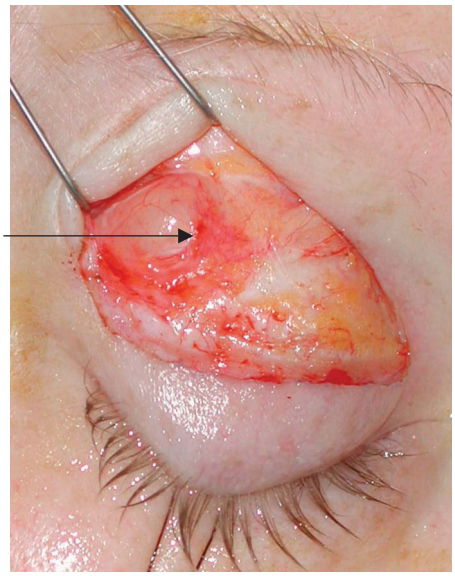

Figure 87.9 A right lacrimal gland prolapse as seen during an upper lid blepharoplasty.

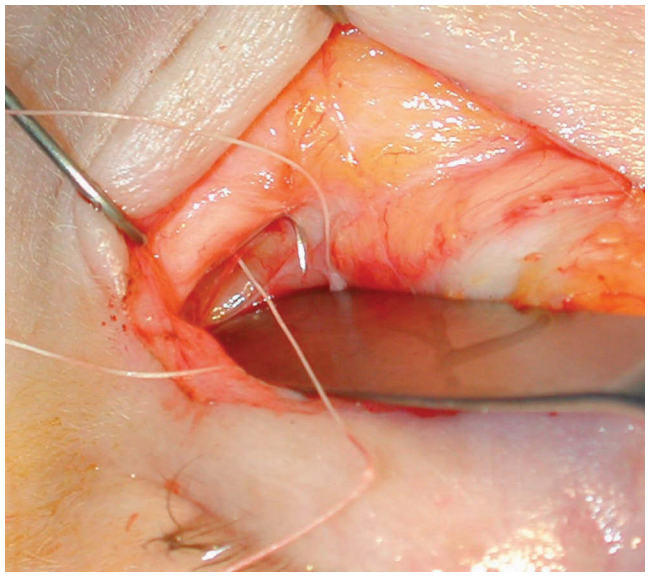

Figure 87.10 A double-armed 5-0 Vicryl suture is being placed through the periorbita of the lacrimal gland fossa.

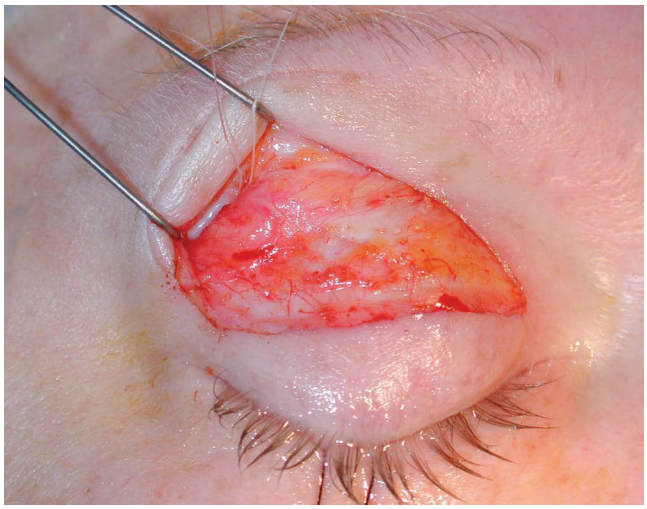

Figure 87.11 The Vicryl suture has been passed through the capsule of the lacrimal gland and tied, repositioning the gland into the lacrimal gland fossa.

The skin of the upper eyelid is very thin, without any subcutaneous fat. Beneath the skin lies the very vascular orbicularis muscle. Local anaesthetic injections should be placed immediately beneath the skin, avoiding the orbicularis muscle, to prevent the occurrence of a haematoma. Deep to the orbicularis muscle above the skin crease lies the orbital septum. This originates from the arcus marginalis along the superior orbital margin. This firm attachment can be utilized to differentiate it from the levator aponeurosis. The orbital septum is a multilayered structure with a very variable thickness.

Posterior to the septum lies the preaponeurotic orbital fat. Pressure applied to the lower eyelid can force the fat to prolapse, which helps to differentiate this from descended retro-orbicularis fat and from fatty degeneration of the levator muscle and/or Müller's muscle. The preaponeurotic fat is a key landmark in upper eyelid surgery. The levator aponeurosis lies immediately beneath it (see **Figures 87.5** and **87.12**).

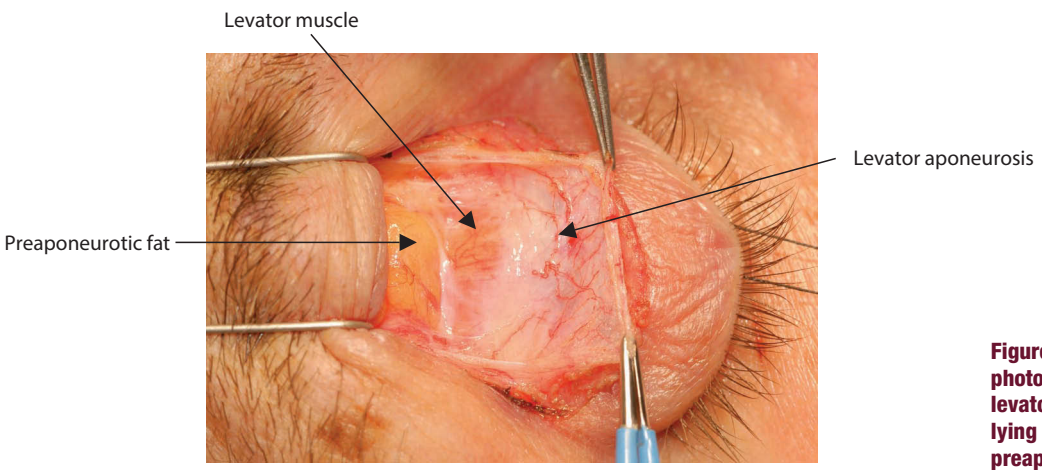

Figure 87.12 Intra-operative photograph demonstrating the levator muscle and its aponeurosis lying immediately beneath the preaponeurotic fat.

There are two main fat pads in the upper eyelid, a central pad and a nasal pad. The nasal fat pad is generally paler (**Figure 87.13**). It is extremely important to be able to distinguish the lacrimal gland from the orbital fat (**Figure 87.14**).

The levator muscle gives rise to the levator aponeurosis at the level of Whitnall's ligament. The aponeurosis inserts onto the anterior surface of the superior two-thirds of the tarsus. The medial and lateral horns of the aponeurosis insert in the region of the medial and lateral canthal tendons. The lateral horn divides the lacrimal gland into orbital and palpebral lobes. Intra-operative damage to the medial horn can give rise to a lateral shift of the tarsus with an eyelid peak lying temporal to the pupil.

Whitnall's ligament supports the levator muscle complex, acting as a fulcrum for the action of the levator muscle, and should not be disturbed during surgery. It is a variably developed structure that runs from the lacrimal gland to the region of the trochlea (**Figure 87.15**).

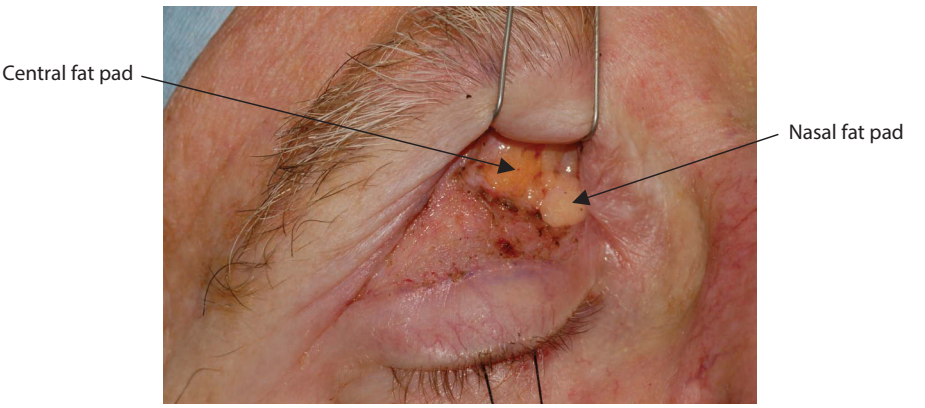

Figure 87.13 The nasal fat pad is paler than the central fat pad.

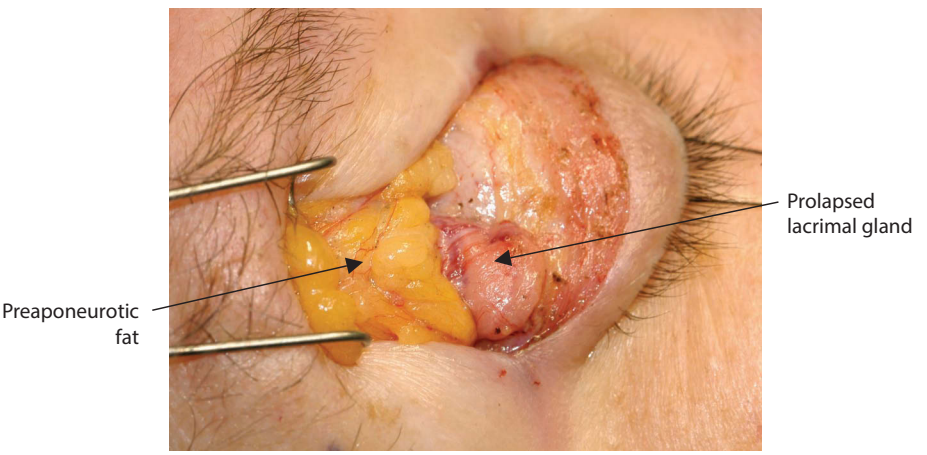

Figure 87.14 A prolapsed lacrimal gland.

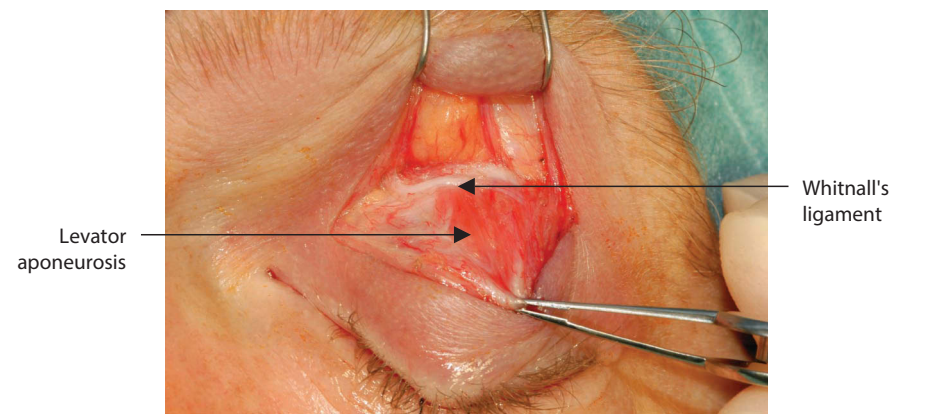

Figure 87.15 Whitnall's ligament.

The lower eyelids

The lower eyelid can be considered to consist of three lamellae:

- anterior – skin and the orbicularis oculi muscle
- middle – the orbital septum and the inferior eyelid retractors
- posterior – the tarsus and conjunctiva.

The lower eyelid skin crease is variable but is usually situated approximately 4–5 mm below the eyelid margin. The lateral canthal angle normally sits approximately 1 mm higher than the medial canthal angle.

The orbicularis oculi muscle is immediately deep to the skin of the lower lid. This muscle extends from just below the ciliary margin, past the inferior orbital rim and onto the cheek. Ptosis of the orbicularis oculi muscle commonly occurs over time and is responsible for the typical appearance of the malar crescent or malar mound in the aged face (see **Figure 87.23**).

Deep to the orbicularis oculi muscle lies the orbital septum, which serves to retain orbital fat within the orbit. The septum is composed of inelastic fibrous tissue. Atrophy of the septum with age permits orbital fat to herniate anteriorly creating typical lower lid 'bags' (see **Figure 87.1b**). The suborbicularis fascia, a plane of loose, fibrous connective tissue, lies between the orbicularis and orbital septum and provides a very good, relatively bloodless, dissection plane. The orbital septum extends from the inferior border of the tarsus to fuse inferiorly with the periosteum of the infraorbital margin. This inferior attachment of the orbital septum to the periosteum, where there is a condensation of tissue, is referred to as the arcus marginalis (**Figure 87.16**).

The arcus marginalis is strongest and best defined medially, where it attaches to the anterior lacrimal crest. As it extends laterally, it thins and weakens. It also assumes a more inferior and anterior insertion; thus, medially, it runs along the inner aspect of the rim but, laterally, it attaches approximately 2 mm inferior to the rim on the facial aspect of the zygomatic bone.

The tarsus in the lower eyelid is approximately 4–5 mm in height. The lower eyelid retractors are analogous to the levator aponeurosis in the upper eyelid. The smooth inferior tarsal muscle is analogous to Müller's muscle in the upper eyelid. The lower eyelid retractors, collectively referred to as the capsulopalpebral fascia, run from the inferior rectus muscle and split to envelop the inferior oblique muscle. This fascia then inserts into the inferior border of the tarsus (**Figures 87.16** and **87.17**). A deep layer of the fascia attaches to the conjunctival fornix as the suspensory ligament of the fornix.

Isolated shortening of the anterior lamella of the lower eyelid results in ectropion, of the middle lamella results in eyelid retraction with scleral show (**Figure 87.18**), and of the posterior lamella results in entropion.

There are three fat compartments in the lower eyelid: medial, central and lateral. Many delicate fibrous septa invest these compartments. The fat compartments lie between the capsulopalpebral fascia and the orbital septum. As the capsulopalpebral fascia (the lower eyelid retractor)

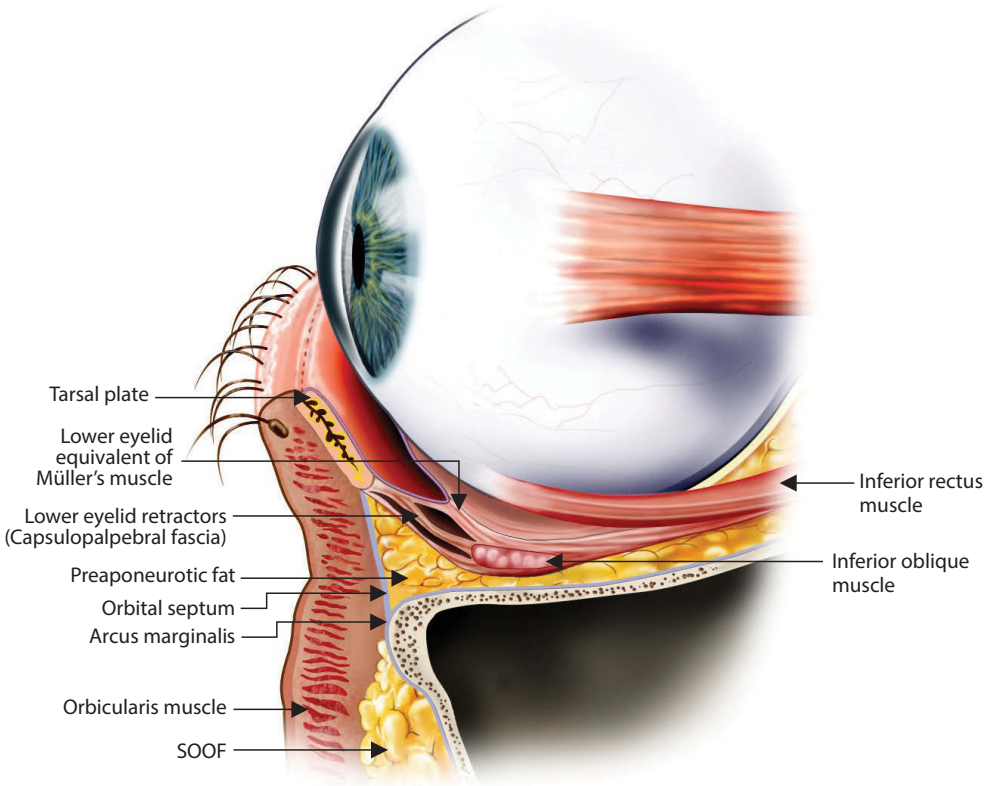

Figure 87.16 Diagram illustrating the anatomy of the lower eyelid region.

is analogous to the levator aponeurosis in the upper eyelid, the fat lying in front of the capsulopalpebral fascia can be considered to be analogous to the preaponeurotic fat in the upper eyelid. As in the upper eyelid, locating this fat is key to locating the eyelid retractor.

The inferior oblique muscle, originating from the anteromedial orbital wall, lies between and separates the medial and central fat compartments as it extends posterolaterally under the globe (**Figure 87.19**).

The arcuate expansion, an extension of the fascial sheath of the inferior oblique, continues laterally to attach to the lateral orbital rim and separates the central and lateral compartments (**Figure 87.20**). Subtle differences exist among the three orbital fat pads. The fat of the medial compartment is typically white and membranous, while that of the central and lateral compartments appears yellow and soft. The lateral fat compartment contains more septa than the medial and central compartments and is

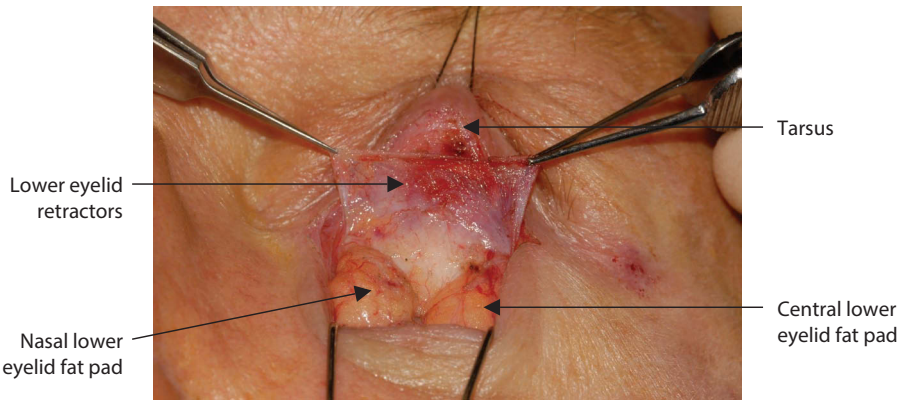

Figure 87.17 The lower eyelid retractors detached from the inferior border of the tarsus.

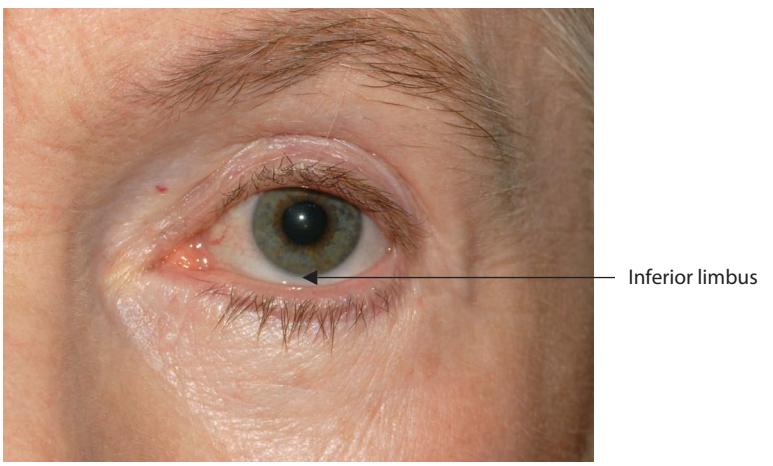

Figure 87.18 Middle lamellar scarring following a lower eyelid blepharoplasty resulting in lower eyelid retraction and scleral 'show' below the inferior limbus.

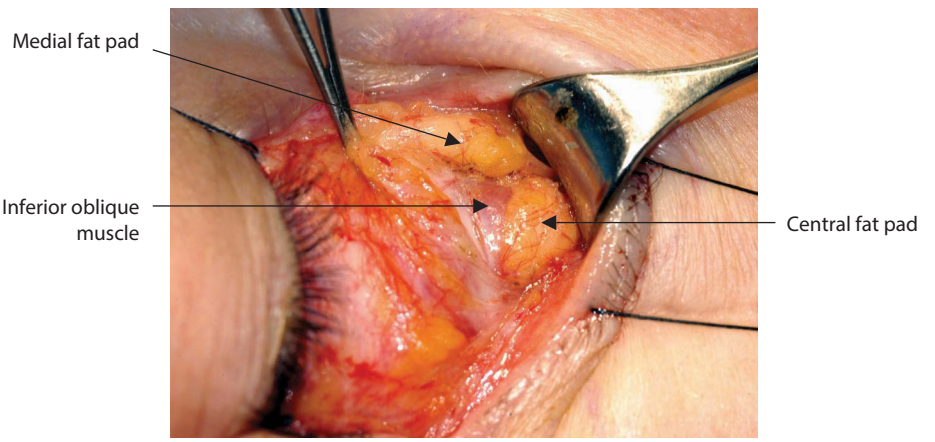

Figure 87.19 The inferior oblique muscle lying between the medial and central fat pads.

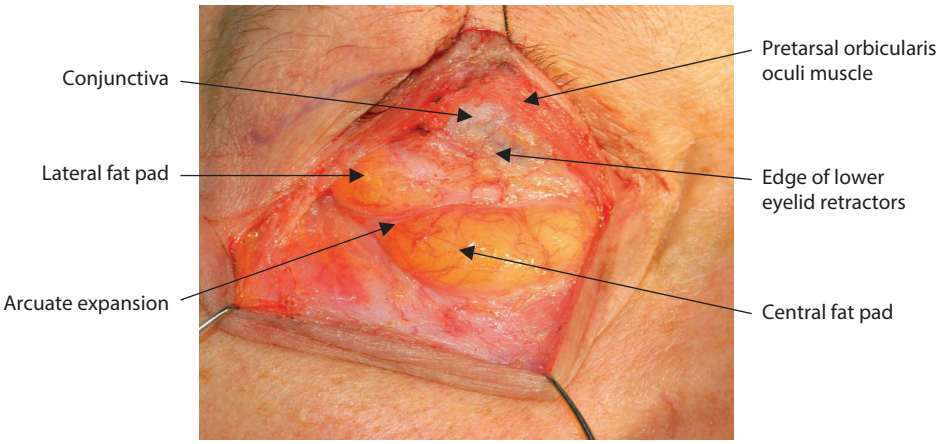

Figure 87.20 The arcuate expansion separating the central and lateral lower lid fat pads.

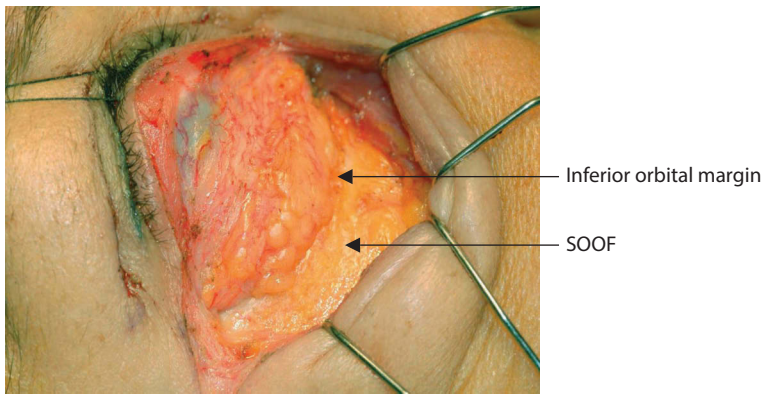

Figure 87.21 The suborbicularis oculi fat (SOOF).

therefore less prone to herniate anteriorly. It is important to note that inferior palpebral vessels travel directly through the medial fat compartment.

Fat seen below the inferior orbital margin posterior to the orbicularis oculi muscle and just anterior to the periosteum is the suborbicularis oculi fat (SOOF) (**Figure 87.21**).

With increasing age, the orbicularis oculi muscle and the SOOF move inferiorly, leading to a double convexity of the lower eyelid. The superior convexity is caused by a herniation of orbital fat through a weakened orbital septum above the inferior orbital margin (**Figure 87.22**). The orbital margin itself is responsible for the horizontal concavity and the SOOF, which has moved inferiorly, is responsible for the second convexity.

The midface

Knowledge of the anatomy of the midface is essential to the understanding of the morphological changes which occur at the lower eyelid–cheek junction with advancing age.

The prezygomatic space is a triangular space overlying the zygomatic and maxillary bones with its apex towards the nose and is limited superiorly by the orbitomalar ligament. It contains:

- fat overlying the orbital part of the orbicularis muscle
- the orbital part of the orbicularis muscle
- the SOOF
- pre-periosteal fat deep to the origin of the lip elevator muscles.

RETAINING LIGAMENTS

There are a number of retaining ligaments in the face which are condensations of fibrous connective tissue and which act to anchor the superficial tissue layers to firmer underlying structures. These ligaments are divided into true and false retaining ligaments.

- True retaining ligaments link the dermis to the underlying periosteum (zygomatic, orbital, orbitomalar and mandibular ligaments).
- False retaining ligaments link the deep facial fascia to the superficial facial fascia and the subcutaneous tissue (masseteric and platysma-auricular ligaments).

The zygomatic retaining ligament (McGregor's patch) arises from the zygomatic arch and from the body of the zygoma, passes through the superior aspect of the malar fat pad and inserts into the dermis of the overlying skin. The ligament is well-defined. The orbital retaining ligament lies over the frontozygomatic suture.

The orbitomalar ligament arises from a thickened area of periosteum a few millimetres below the inferior

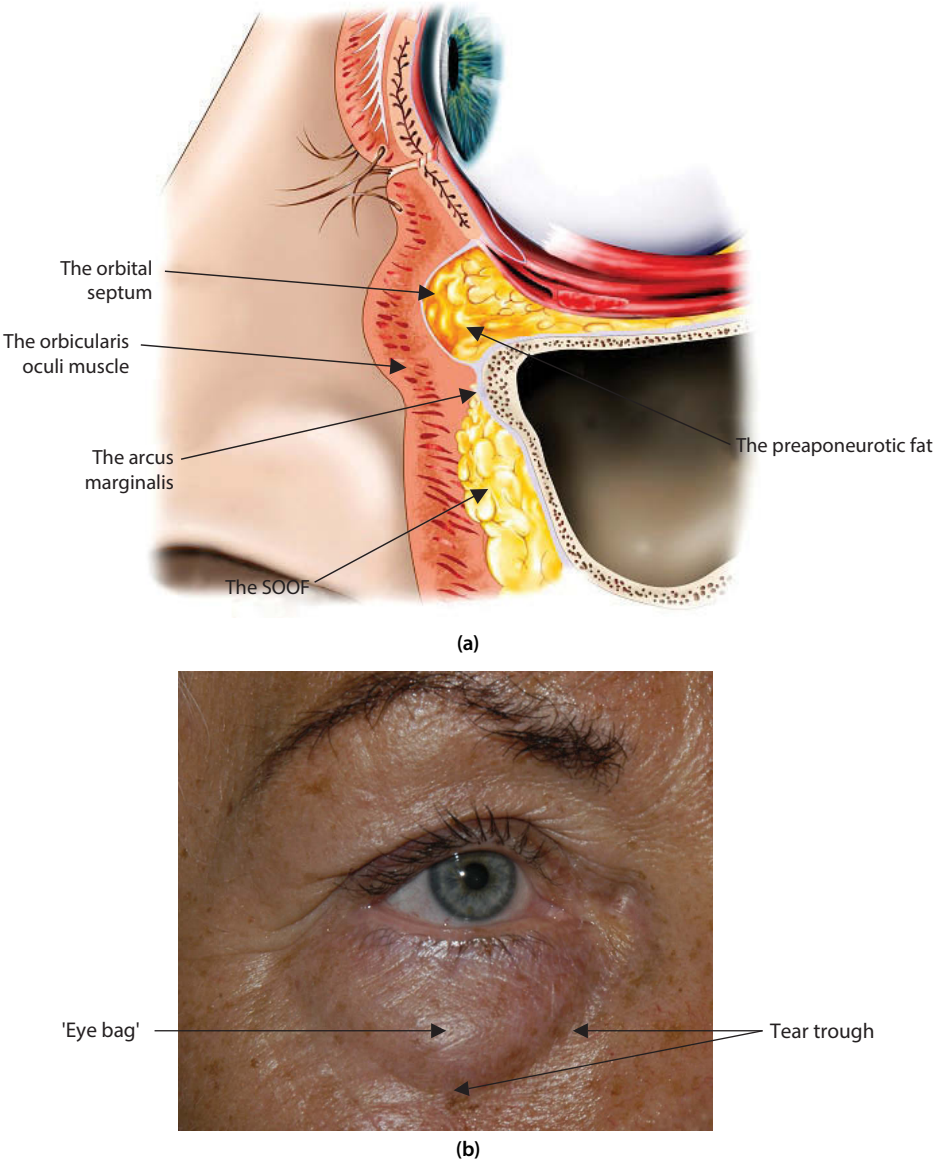

Figure 87.22 **(a)** A diagrammatic representation of bulging preaponeurotic fat through a weakened orbital septum with a secondary concavity over the inferior orbital margin responsible for the complaint of 'eyebags' and for a tear trough deformity or 'dark circle'. **(b)** A patient demonstrating the typical 'eyebag' and tear trough extending along the whole length of the inferior orbital margin.

orbital margin, and passes through the superficial musculoaponeurotic system (the SMAS) and overlying fat to insert into the dermis.

The orbitomalar ligament, the levator labii superioris and the levator alaeque nasi muscles are responsible for defining the tear trough. The tear trough extends into the upper central cheek as a triangular groove between these muscles as the malar fat descends with age.

'Malar mounds' are the result of oedema within the fat of the prezygomatic space (**Figure 87.23** below). The malar fat pad is subcutaneous, triangular and distinct from the 'malar mounds'. This fat pad contributes to the fullness of the midface. Elevation of the malar fat pad and the 'malar mounds' contributes greatly to the aesthetic appearance of the midface and can improve the appearance of the tear troughs.

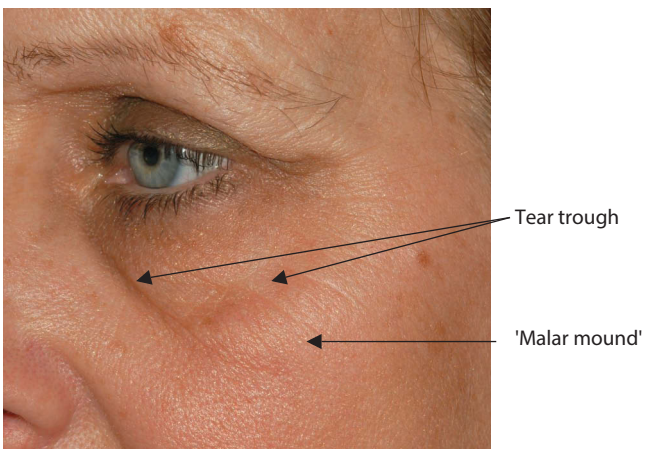

Figure 87.23 Typical age-related changes at the eyelid–cheek junction.

DERMATOCHALASIS

Dermatochalasis describes a common, physiologic condition seen clinically as sagging of the upper eyelid skin. It is typically bilateral and most often seen in patients over 50 years of age, but it may occur in some younger adults. Examination of these patients' eyelids reveals redundant, lax skin with poor adhesion to the underlying orbicularis oculi muscle. An excess fold of skin in the upper eyelid is characteristic, which obscures the normal upper eyelid skin crease which may be lost (**Figure 87.24**). This patient complained of visual field limitation and headaches towards the evening (due to frontalis muscle fatigue).

Dermatochalasis is often confused with blepharochalasis although the disorders are quite different in both their presentation and their aetiology. Blepharochalasis is a rare inflammatory condition that typically affects only the upper eyelids, and may be unilateral as well as bilateral. It occurs more often in younger patients. The condition is characterized by exacerbations and remissions of eyelid oedema, which results in a 'stretching' and subsequent atrophy of the eyelid tissue. The secondary effects of blepharochalasis include conjunctival hyperaemia and chemosis, entropion, ectropion, blepharoptosis, medial fat pad atrophy and thinning of eyelid skin.

Pathophysiology

The tissue changes seen in dermatochalasis are similar to the normal ageing changes of the skin seen elsewhere in the body. There is thinning of the epidermal tissue with a loss of elastin, resulting in laxity, redundancy and hypertrophy of the skin. The tissue changes of dermatochalasis appear to be due to repeated facial expressions combined with the effects of gravity over many years. A number of systemic disorders such as thyroid eye disease, Ehlers–Danlos syndrome, cutis laxa, renal failure and amyloidosis may hasten the development of dermatochalasis. In addition, some patients may have a genetic predisposition towards the development of dermatochalasis at a younger age.

In contrast, blepharochalasis stems from recurrent bouts of painless eyelid swelling, each instance of which may persist for several days. The swelling most likely represents a form of localized angioedema, although this remains speculative. Ultimately, after numerous episodes, the skin of the lids becomes thin and atrophic, and damage to the levator aponeurosis ensues. Blepharoptosis then develops (**Figure 87.25**). Blepharochalasis is idiopathic in most cases, though it has been linked to kidney agenesis, vertebral abnormalities and congenital heart defects in rare instances.

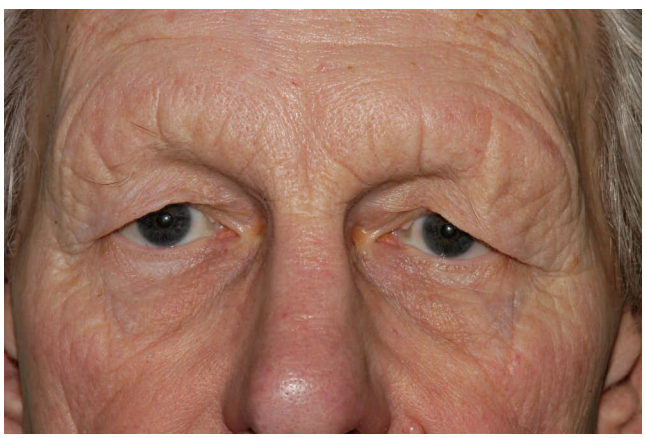

Figure 87.24 A female patient demonstrating bilateral brow ptosis and bilateral upper eyelid dermatochalasis.

Figure 87.25 A young female patient with blepharochalasis showing bilateral blepharoptosis with raised skin creases, thinning of the upper eyelid skin and atrophy of the preaponeurotic fat pads. She also demonstrates a bilateral pseudoproptosis from high axial myopia.

UPPER EYELID BLEPHAROPLASTY

The goals of an upper eyelid blepharoplasty are:

- to remove an appropriate amount of excess upper eyelid skin alone, or skin and orbicularis muscle, in order to achieve the best cosmetic and functional result for the patient
- to remove or sculpt herniated orbital fat only where appropriate
- to create a symmetrical upper lid skin crease at an appropriate height for the individual patient
- to avoid visible scarring
- to avoid a secondary lagophthalmos or an incomplete blink
- to avoid exacerbating an associated brow ptosis.

An additional goal in the oriental patient is to create a visible upper eyelid crease.

Pre-operative patient evaluation

HISTORY

A careful history should be obtained. The patient's complaints, goals and expectations should be determined. The patient may be concerned about:

- an overhang of excess upper eyelid skin causing a loss of the superior visual field
- excess upper lid skin causing cosmetic problems
- upper lid fat herniation

- upper lid 'fullness'
- 'hooding' of the upper eyelids
- 'drooping eyelids'
- headaches from frontalis muscle fatigue
- a tired appearance commented on by friends or relatives.

The complaint of droopy upper eyelids may simply be due to severe dermatochalasis causing a pseudoptosis with the underlying eyelid height being normal. The lid position should be carefully evaluated, however, as a true blepharoptosis may also be present. If a true blepharoptosis is present, the patient must be carefully evaluated to diagnose the underlying cause of the blepharoptosis, such as an aponeurotic dehiscence from contact lens wear, Horner syndrome, myasthenia gravis or chronic progressive external ophthalmoplegia. Similarly, a severe dermatochalasis, often combined with a brow ptosis, may obstruct the patient's superior visual field.

Patients who have a moderate to severe brow ptosis and dermatochalasis are obliged to use their frontalis muscle to overcome the superior visual field defect. Such patients commonly develop deep forehead furrows (**Figure 87.26**). This leads to fatigue of the frontalis muscle, which in turn can cause a headache.

Occasionally, upper eyelid dermatochalasis and a lateral brow ptosis can lead to a secondary mechanical misdirection of eyelashes causing chronic ocular discomfort.

The cosmetic effects of upper eyelid dermatochalasis and brow ptosis can lead to complaints of a tired appearance. Lower eyelid fat herniation can also lead to similar complaints (see **Figure 87.1b**).

Patients should be specifically questioned about previous eyelid surgery. Patients who have previously undergone a cosmetic blepharoplasty or a facelift may omit such information, particularly if accompanied by a new partner. A history of contact lens wear, dry eye, facial palsy or thyroid dysfunction identifies a patient at risk of exposure keratopathy symptoms following an upper lid blepharoplasty.

It is important to exclude a bleeding disorder, as a post-operative haemorrhage following a blepharoplasty can be potentially sight-threatening. The use of aspirin or non-steroidal anti-inflammatory agents should be discontinued 2 weeks pre-operatively if the patient's medical status permits this. Any other non-prescription medications or dietary supplements that may predispose to excessive bleeding should also be discontinued (e.g. vitamin E supplements).

Any allergies should be carefully noted.

EXAMINATION

The patient should undergo a complete ophthalmic examination.

- The patient's best corrected visual acuity should be recorded.
- The palpebral fissures should be measured and the position of the skin creases documented after lifting the upper lid excess skin.
- The height and curvature of the upper eyelids relative to the pupils should be noted, and the MRD-1 and MRD-2 should be measured and recorded, looking for any evidence of true blepharoptosis.

  (The marginal reflex distance-1 (MRD-1) is the distance between the centre of the pupillary light reflex and the upper eyelid margin with the eye in primary gaze. A measurement of 4–5 mm is considered normal. The marginal reflex distance-2 (MRD-2) is the distance between the center of the pupillary light reflex and the lower eyelid margin with the eye in primary gaze.)
- The amount of pretarsal skin 'show' should be measured and recorded along with the amount of skin present from the lash line to the lowermost portion of the eyebrow, medially, centrally and laterally. This can be difficult in patients who pluck or tattoo their eyebrows (**Figure 87.27**).
- Any asymmetries should be noted. (It is important to make the patient aware of any pre-operative asymmetries,

Figure 87.26 A patient with a severe bilateral brow ptosis and dermatochalasis causing visual field problems and headaches from frontalis overaction.

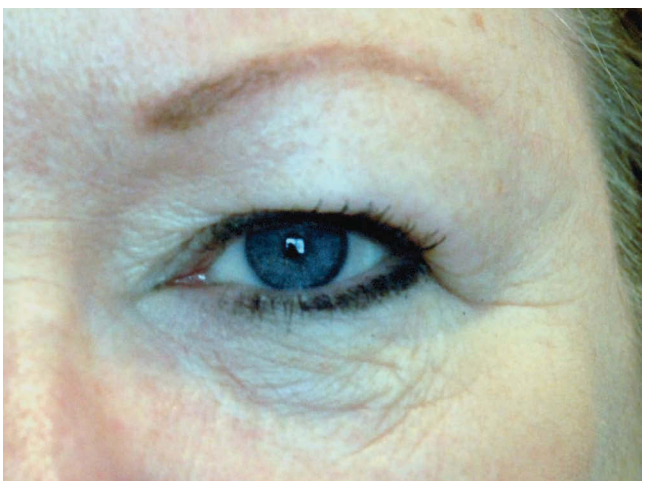

Figure 87.27 A patient with a plucked and tattooed eyebrow camouflaging the effects of a brow ptosis and a descent of the 'ROOF'.

which they may not have noticed. The patient will certainly notice asymmetries post-operatively!) Any frontalis overaction should be noted, and the position and shape of the brows observed after asking the patient to relax the frontalis muscle as much as possible. The secondary effects of brow ptosis on the upper eyelids must be recognized (see **Figure 87.24**).

- An assessment of the tear meniscus should be made using a slit lamp, and the tear film break-up time after the instillation of a drop of fluorescein should be documented.
- The upper lids should be everted to exclude the presence of any subtarsal lesions (e.g. papillae seen in atopy or with contact lens wear).
- The presence or absence of a Bell's phenomenon should be recorded.
- The degree of upper eyelid laxity is assessed to ensure that a 'floppy eyelid syndrome' is not overlooked. This is done by pulling downwards on the eyelid after grasping the eyelid margin and the eyelashes in the lateral aspect of the eyelid. Excessive eyelid laxity is also evident if eversion of the upper eyelid is very easy to perform.
- Any herniation of the medial and central preaponeurotic fat pads is noted in the upper eyelids, and of the medial, central and lateral preaponeurotic fat pads in the lower eyelids.
- The degree of excess upper eyelid skin is assessed and measured.
- The degree of any associated brow ptosis is noted along with any asymmetry. Any overaction of the eyebrow depressor muscles is also determined by noting the extent of glabellar frown lines and lateral canthal rhytids.
- The skin quality and degree of actinic damage is assessed. Specific dermatological disorders should be excluded (e.g. atopic dermatitis).
- The ocular motility should be assessed and recorded along with cover and alternate cover tests to exclude any horizontal or vertical ocular muscle imbalance.
- Any proptosis or pseudoproptosis due to axial myopia is noted. It may be much more difficult to achieve the desired surgical goals in such patients.
- The patient should be examined specifically to exclude the possibility of thyroid eye disease.

Pre-operative photographs must be taken. Pre-operative photographs are essential for patients who are to undergo any facial plastic and reconstructive surgery. They serve a number of useful purposes:

- a learning and teaching aid for the surgeon
- verification of the patient's disorder for healthcare insurance companies
- an aid to defence in a medicolegal claim
- to jolt the memory of the forgetful patient about their pre-operative appearance.

Written patient consent should be obtained before the photographs are taken. It should be made clear to the patient how the photographs are to be used.

The limitations of an upper eyelid blepharoplasty performed alone in the presence of significant brow ptosis should be explained. In these circumstances, an upper eyelid blepharoplasty should be very conservative in order to prevent further lowering of the brow and an unsatisfactory appearance. The patient should be carefully questioned to ascertain their expectations of surgery. Some patients with a mild degree of brow ptosis and upper lid dermatochalasis are better managed with the use of botulinum toxin injections, which, if used correctly, can create a satisfactory and pleasing brow lift. The injection can be given into the lateral rhytids and tail of the eyebrow (30–60 units of Dysport® per side given as four or five separate intramuscular injections), and can be combined with injections into the glabella (80–120 units of Dysport® given as four to six separate intramuscular injections) paralyzing the brow depressors and allowing the frontalis muscle to act unopposed. If an unwanted temporal peaking of the brows occurs, 5–10 units of botulinum toxin can be injected 1–2 cm above the lateral brow into the overacting frontalis.

If botulinum toxin injections are to be used as a trial prior to surgery, this should be undertaken 2 weeks beforehand. The injections should not be given at the time of surgery as post-operative oedema will cause the toxin to spread to other muscles (e.g. to the levator muscles), causing a blepharoptosis.

Where a brow ptosis is significant, it is far preferable to address this by one of a number of surgical approaches, depending on the degree of brow ptosis and the age and preferences of the patient. The options for a brow lift procedure include:

- direct brow lift
- 'gull wing' direct brow lift
- temporal direct brow lift
- internal suture browpexy
- transblepharoplasty Endotine implant brow lift
- mid-forehead brow lift
- subcutaneous forehead and brow lift
- pretrichial brow lift
- coronal brow lift
- endoscopic brow lift
- brow lift using dissolvable 'coned' suture devices.

Figure 87.28a illustrates the problem posed by a female patient requesting an upper eyelid blepharoplasty who demonstrates a bilateral brow ptosis. A blepharoplasty alone would be inappropriate. **Figure 87.28b** demonstrates her post-operative appearance 4 months following a bilateral upper eyelid skin/muscle blepharoplasty combined with a bilateral endoscopic brow lift.

INFORMED CONSENT

The advantages, disadvantages, risks and potential complications of the procedure should be discussed with the patient in great detail. The siting of incisions and anticipated scars should be explained. The risks and the incidence of complications need to be outlined in an open and

Figure 87.28 (a) A female patient with bilateral brow ptosis and upper eyelid dermatochalasis. **(b)** The same patient 4 months following a bilateral endoscopic browlift and upper lid blepharoplasty.

honest manner. The consequences of complications and their management should also be outlined. The patient should also be provided with a formal document which outlines the potential complications of blepharoplasty surgery, their management and the financial responsibilities that would be incurred.

The description of any blepharoplasty procedure as 'basic', 'straightforward', 'simple', 'minor' or 'routine' should be avoided.

Many patients seeking cosmetic blepharoplasty request that their general practitioner is not informed. A detailed letter outlining the patient's complaints, the clinical findings, the management options which have been discussed, the risks and potential complications of surgery, advice about the discontinuation of aspirin or anti-inflammatory drugs, the anticipated recovery period and aftercare instructions should, however, be sent to the patient and retained in their clinical records. The patient should be encouraged to give further consideration to the options discussed before making a decision to proceed with surgery. This also avoids any misunderstandings on the part of the patient. It may necessitate a further consultation or an attendance at a pre-assessment clinic to obtain fully informed consent and to answer any residual queries. The patient should not be asked to sign a consent form for an elective cosmetic procedure on the day of surgery.

Surgical technique

MARKING THE UPPER EYELID

Marking the upper eyelid skin crease with the patient sitting upright, before the injection of any local anaesthetic solution, is the first very important step in a successful upper eyelid blepharoplasty. A drop of proxymetacaine is instilled into each eye. The upper eyelid skin is cleaned with an alcohol wipe, and the skin crease marked with a cocktail stick that has been dipped into a gentian violet marker block. A calliper should be used to measure the height of the crease. The fellow eyelid should be marked simultaneously, ensuring precise symmetry. The skin crease should be marked at a lower level in a male patient.

Figure 87.29 Marking the eyelid. The skin just above the skin crease marking is gently pinched with toothed forceps to ensure that passive closure of the eye is not compromised. This is repeated medially and laterally and the proposed skin excision is marked.

The skin above the crease centrally is gently pinched with a pair of fine-toothed forceps. Great care should be taken to ensure that the eyelids can close passively. Any temptation to remove more than 8–10 mm of skin should be resisted, particularly in the presence of an uncorrected brow ptosis. The superior aspect of the pinched skin is marked and an ellipse is drawn (**Figure 87.29**).

The relative dimensions of this area divided into thirds should be remembered to maintain a good aesthetic appearance. (The distance between the inferior aspect of the eyebrow and the upper lid skin crease on downgaze should be approximately two-thirds of the distance from the inferior aspect of the eyebrow to the eyelid margin. Likewise, the distance from the skin crease to the eyelid margin in downgaze should be one-third of the distance from the inferior aspect of the eyebrow to the eyelid margin.) In general, at least 10–12 mm of skin should be left between the inferior aspect of the eyebrow and the superior skin excision marking (**Figure 87.30**). It is important

not to carry the incision markings into the medial canthal area to avoid webbed scars.

If there is no temporal hooding of skin, the lateral aspect of the incision should be kept within the orbital margin (**Figure 87.30**). If there is temporal hooding, a lateral wing can be added to the crescent leaving the resulting scar running in a horizontal direction (**Figure 87.31**). The patient should be warned that this lateral scar will be visible and will not be hidden with the upper lid skin crease.

ANAESTHESIA

The procedure may be undertaken under general anaesthesia, local anaesthesia or local anaesthesia with intravenous sedation. Local anaesthesia, preferably with carefully titrated intravenous sedation provided by an anaesthetist, is advantageous as it allows voluntary levator muscle function to be used to assist in the identification of eyelid structures. This is particularly important when an upper eyelid blepharoplasty is being performed in conjunction with a levator aponeurosis advancement procedure to correct blepharoptosis.

The patient should be kept in a semirecumbent position with the head elevated at least 30 degrees to reduce venous engorgement and bleeding. Normal saline sachets should be kept available in the refrigerator and used to moisten 4 × 4 gauze swabs, which are applied to the operated side while the fellow side is undergoing the same procedure.

Figure 87.30 Eyebrow–superior skin excision mark distance. Here 12 mm of skin has been left between the inferior aspect of the eyebrow and the superior skin excision marking.

Figure 87.31 Final markings. The desired position of the upper eyelid skin crease has been marked with a cocktail stick dipped into a gentian marker block. The skin above the crease has been gently pinched while asking the patient to passively close the eye at the same time as an assistant gently raised the eyebrow with a finger. The markings are not taken medially beyond the limit of the skin crease. Laterally a small 'wing' has been added in this patient to prevent a 'dog ear'. A distance of 10–12 mm has been left between the inferior aspect of the brow and the superior aspect of the skin resection all along the length of the skin marking.

SURGICAL PROCEDURE

1. Approximately 2–3 mL of 0.5% marcain with 1:200 000 units of adrenaline mixed 50:50 with 2% lignocaine with 1:80 000 units of adrenaline are injected just beneath the skin with a single pass of the needle if possible, avoiding the underlying orbicularis oculi muscle in order to prevent the occurrence of a haematoma. The needle is inserted temporally and advanced nasally while slowly injecting the solution. Immediate pressure should be applied for a few minutes. A pause of 10 minutes is allowed for the adrenaline to take effect.
2. The patient is prepped and draped, ensuring that the drapes do not place any downward pressure on the eyebrows.
3. A 4.0 silk traction suture is inserted along the grey line of the upper eyelid and fixated to the face drapes with a curved artery clip, providing downward traction on the eyelid. This makes the skin incision easier to undertake and provides protection for the eye.
4. The skin incision is made along the gentian violet markings with a Colorado needle.
5. A skin flap is developed and dissected off the underlying orbicularis oculi muscle (**Figure 87.32**). A strip of orbicularis muscle can then be dissected off the underlying orbital septum. If the patient merely requires the removal of excess skin, and any orbicularis muscle for functional reasons, the skin can be closed with simple interrupted 7-0 Vicryl sutures. This surgical procedure is quick and relatively simple to perform and does not expose the patient to the small risks of a postoperative intraorbital haemorrhage.

   In patients who are at an increased risk of exposure keratopathy, a simple skin excision alone can be performed, preserving the underlying orbicularis muscle. In some patients, however, this can result in some bunching of the orbicularis muscle with a less satisfactory aesthetic result. Alternatively, a central 3–5 mm strip of orbicularis muscle can be removed.
6. If the patient requires the removal, sculpting or redraping of orbital fat, the orbital septum is opened along its entire length.
7. The central preaponeurotic fat is allowed to prolapse. This can be sculpted with the Colorado needle using the coagulation mode and any larger vessels cauterized with bipolar cautery. The fascial septa around

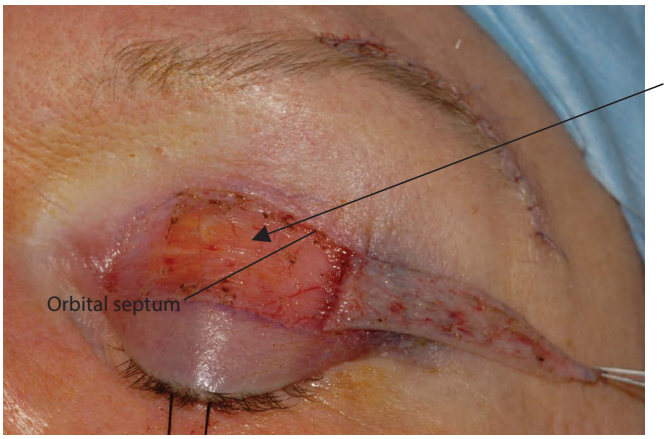

Figure 87.32 A skin flap has been created, exposing the underlying orbicularis oculi muscle. This patient has also undergone a temporal direct brow lift.

and within the medial fat pad can be gently opened and separated using the Colorado needle.

8. If fat needs to be removed, the fat should be carefully clamped using a small curved artery clip. The artery clip should be held carefully by the assistant. Great care should be taken to avoid anterior traction on the fat that can lead to rupture of posterior orbital vessels and a sight-threatening retrobulbar haematoma. The fat is removed using the Colorado needle on cautery mode. The artery clip should be released very slowly and carefully, and immediately reapplied if any vessels bleed. This is particularly important when removing fat medially. Great care should also be taken not to damage the medial horn of the levator muscle or the trochlea. It should be noted, however, that fat removal should be undertaken very conservatively, if at all, in the upper lid so as to avoid a secondary hollowing of the upper eyelid, which can result in a very aged appearance. The fat should be retained within a swab moistened with sterile saline as it may be divided into small fat pearls and used as a free graft in the opposite upper eyelid to address an asymmetry or in the lower eyelid to assist in the camouflage of a tear trough defect.
9. The skin is closed with interrupted 7-0 Vicryl sutures, taking bites of the very edges of the skin. The type of skin closure is determined by the type of skin crease that is required. If this is to be a soft, less well-defined crease, the skin can be closed as above. If a higher, well-defined crease is required, usually in a female, the skin is closed with interrupted 7-0 Vicryl sutures that incorporate a bite of the underlying levator aponeurosis. It is sometimes advantageous to remove a strip of orbicularis muscle from the inferior skin wound edge but this can lead to bleeding, particularly if the effects of the adrenaline have begun to wear off.

POST-OPERATIVE CARE

Post-operatively the patient is prescribed a topical antibiotic ointment to be applied to the upper lid wounds three times a day for 2 weeks and Lacri-Lube® ointment 1–2 hourly to the eyes for 48 hours and at bedtime. The Lacri-Lube® ointment is then changed to preservative-free topical lubricant drops to be used hourly during the day and Lacri-Lube® is continued at bedtime until the degree of lagophthalmos has improved. The frequency of the lubricants is then gradually reduced over the course of the next few weeks. The patient is instructed to sleep with the head of the bed elevated for 4 weeks and to avoid lifting any heavy weights for 2 weeks. Clean cool packs are gently applied to the eyelids intermittently for 48 hours. The patient should be reviewed in clinic within 2 weeks and again within 4–6 weeks. The upper lid skin sutures are removed at 2 weeks.

LOWER EYELID BLEPHAROPLASTY

The goals of a lower eyelid blepharoplasty are:

- to remove an appropriate amount of excess lower eyelid skin and muscle if required
- to remove or reposition herniated fat where appropriate
- to avoid middle lamellar scarring and eyelid retraction
- to address any associated lower eyelid or lateral canthal tendon laxity
- to avoid any post-operative ectropion and secondary epiphora.

An emerging concept in cosmetic surgery holds that the face develops the characteristics of ageing as a result of not only elastosis and sagging but also soft-tissue atrophy. The evolution of this concept is well illustrated in the field of lower lid blepharoplasty, in which the traditional approach to the surgical improvement of lower eyelid 'bags' has been to resect the herniating preaponeurotic fat. While this method can indeed remove 'bags', in many patients it may also eliminate the soft tissue that conceals the inferior orbital margins, creating a hollowed, skeletonized appearance. This is in contrast to the appearance of the youthful face, in which soft-tissue fullness creates a smooth transition from the cheek to the lower eyelid. The inferior bony orbital margin is concealed. The traditional approach of resecting orbital fat is therefore unlikely to produce a full, youthful lower lid contour and conflicts with the concept that facial ageing is partly a consequence of soft-tissue atrophy.

A number of alternative surgical approaches have been devised to address this problem. One such technique that has gained prominence is the arcus marginalis release, in which preaponeurotic fat is advanced and repositioned rather than resected, in order to reconstruct the soft tissue of the lower eyelids. This technique is designed to conceal the underlying bony structure of the inferior orbit in an attempt to impart a more youthful contour to the periorbital area. Alternatively, a SOOF lift or a midface lift may be undertaken in conjunction with a lower eyelid blepharoplasty in order to achieve the same goals, but the patient then has to accept a more extensive surgical dissection and a longer period of recuperation with more post-operative bruising and swelling.

Pre-operative patient evaluation

HISTORY

The patient's complaints, goals and expectations should be determined. The patient may be concerned about:

- loose folds of skin
- lower eyelid 'bags'
- dark circles beneath the eyes
- skin wrinkles and/or signs of photodamage
- malar mounds
- lower eyelid 'festoons'.

EXAMINATION

As for an upper eyelid blepharoplasty, the patient should undergo a complete ophthalmic examination.

- The patient's best-corrected visual acuity should be recorded.
- The palpebral fissures should be measured and the position of the lower eyelid with respect to the inferior limbus noted. The MRD-1 and MRD-2 should be measured and recorded.
- Any asymmetries or scleral show should be noted.
- The patient's lower lid appearance at rest and on smiling should be compared.
- The relationship of the globe to the inferior orbital margin should be noted, particularly the degree to which the globe protrudes beyond the inferior orbital margin in profile view. A globe which protrudes beyond the inferior orbital margin is referred to as a 'negative vector' configuration. Such patients are more at risk of post-operative problems with eyelid retraction and scleral show following a lower eyelid transcutaneous blepharoplasty.
- An assessment of tear production and the tear film should be undertaken using a slit lamp and the findings documented.
- Any 'herniation' of the lower eyelid fat pads is noted and their positions documented. The skin quality and degree of actinic damage is assessed.
- The degree of lower eyelid laxity is assessed. This can be quite subjective but, as a general rule, if the lower eyelid can be distracted from the globe by more than 6–8 mm or if the eyelid does not return to its position after release without a blink (a positive 'snap test'), the eyelid can be considered to have sufficient laxity to warrant a lower eyelid tightening procedure.
- Any proptosis or pseudoproptosis due to a large globe is noted. It may be more difficult to achieve the surgical goals in such a patient. The patient should be examined specifically to exclude the possibility of thyroid eye disease.
- The appearance of the infraorbital margin is carefully assessed. Almost any patient seeking a lower eyelid blepharoplasty with lower eyelid 'bags' and/or a skeletonization of the inferior orbital margin is a candidate for an arcus marginalis release. In contrast, however, younger patients with a congenital excess of orbital fat are less likely to benefit from this technique. These patients are better managed using a traditional resection of the excess fat via a transconjunctival approach, with the use of CO_2 skin resurfacing or a chemical peel to manage any associated lower eyelid skin wrinkling and photodamage.

Just as the upper lid cannot be properly assessed without also taking into consideration the position of the eyebrow, the lower lid should not be examined in isolation but account should be taken of any associated midface ptosis and midface fat atrophy. Such a patient may require a SOOF lift, or a midface lift and/or volume augmentation of the cheek and tear trough using dermal fillers or structural fat grafting.

INFORMED CONSENT

The guidelines for consent are as detailed in 'Upper eyelid blepharoplasty' above.

Surgical approaches

A lower eyelid blepharoplasty procedure should ideally be tailored to the individual requirements of a patient. The surgical approach selected depends on a pre-operative assessment of fat 'herniation', the degree of skeletonization of the inferior orbital margin, the presence of a lower lid double convexity, the amount of excess lower eyelid skin, the degree of static wrinkling and actinic damage, the degree of orbicularis oculi muscle ptosis, the presence and degree of midface ptosis and midface fat atrophy, the presence of 'malar mounds' or festoons, and the degree of lower eyelid or lateral canthal tendon laxity. The procedure may be performed in conjunction with another surgical procedure (e.g. an orbital decompression procedure in thyroid eye disease).

The patient should be carefully evaluated to determine whether alternative non-surgical treatments might be better suited to their needs. This will depend on the patient's individual circumstances and age. Some patients with the complaint of lateral canthal rhytids ('laughter lines') and lateral eyelid skin wrinkling alone may be better managed with botulinum toxin injections. These can be given into the lateral rhytids (30–60 units of Dysport® per side given

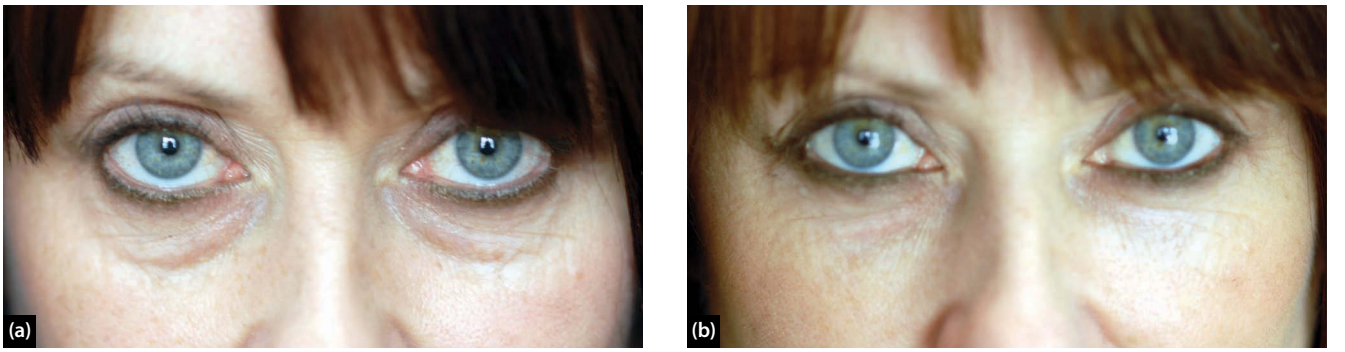

Figure 87.33 (a) Bilateral lower eyelid 'tear tough' defects. **(b)** The appearance of the same patient 2 weeks following the injection of a hyaluronic acid filler (Restylane®) along the inferior orbital margins.

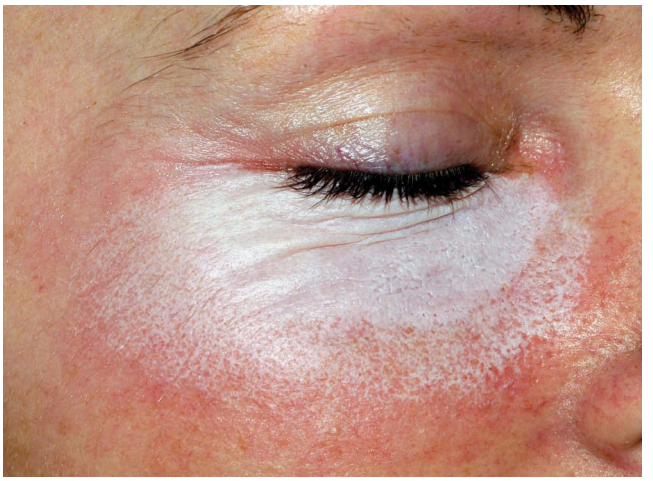

Figure 87.34 A lower eyelid 35% Jessner's/TCA peel.

as four or five injections) with the addition of tiny amounts to the lateral lower lid orbicularis muscle (two or three injections of 2–3 units of Dysport®). Injections should not be given in the medial aspect of the lower eyelid, as this is associated with the risk of spread to involve the inferior oblique muscle. In addition, higher doses should be avoided in the lower eyelid to avoid undue weakness to the orbital portion of the orbicularis muscle with the risk of the patient developing a malar 'bag'.

Hyaluronic acid filler injections (e.g. Restylane® or Juvéderm®) can be used to camouflage the tear toughs in suitable candidates (see **Figure 87.28**). Alternatively, a Jessner's/trichloroacetic acid peel (TCA) or CO_2 laser resurfacing can be considered to treat age- and solar-related skin wrinkling in the lower eyelids (**Figures 87.33** and **87.34**).

For patients who are better suited to surgical management there are two main surgical approaches:

- transcutaneous lower lid blepharoplasty
- transconjunctival lower lid blepharoplasty.

These procedures can be supplemented by other techniques to enhance the result:

- horizontal eyelid tightening procedure
- 'pinch' technique skin resection (in the case of a transconjunctival lower lid blepharoplasty)
- CO_2 laser resurfacing
- Jessner's/TCA peel
- botulinum toxin injections
- injection of dermal fillers or autogenous fat to provide soft tissue enhancement
- SOOF lift
- midface lift
- placement of a cheek implant.

A transconjunctival approach is preferred for patients with 'fat herniation' but no significant skin excess. This approach avoids an external scar and is also ideal for patients who have previously undergone a transcutaneous blepharoplasty but who require revision surgery for residual 'fat herniation'. It can be combined with CO_2 laser resurfacing or with a Jessner's/TCA peel to deal with skin wrinkling in those patients who are prepared to cooperate with the more onerous post-operative care and the avoidance of sun exposure (**Figure 87.35**).

Surgical technique

A lower eyelid blepharoplasty can be performed under general anaesthesia, local anaesthesia or local anaesthesia with intravenous sedation. Local anaesthesia affords the surgeon the opportunity of asking the patient to look up and to open the mouth to avoid excessive skin resection during a transcutaneous blepharoplasty. The patient should be draped using non-adhesive drapes to allow free movement of the lower eyelid and cheek. The upper lid skin crease may need to be marked or, if the procedure is to be combined with an upper lid blepharoplasty, the upper lid skin excision should be marked as described above.

TRANSCUTANEOUS BLEPHAROPLASTY WITH ARCUS MARGINALIS RELEASE, FAT REPOSITIONING AND ORBICULARIS OCULI MUSCLE SUSPENSION

The patient is advised pre-operatively that the lateral aspect of the lower eyelids will be unnaturally high for the first 2–3 weeks following this procedure. As the absorbable 5–0 Vicryl suture holding the orbicularis muscle flap in place begins to give way, the lateral aspect of each lower eyelid gradually assumes its normal position.

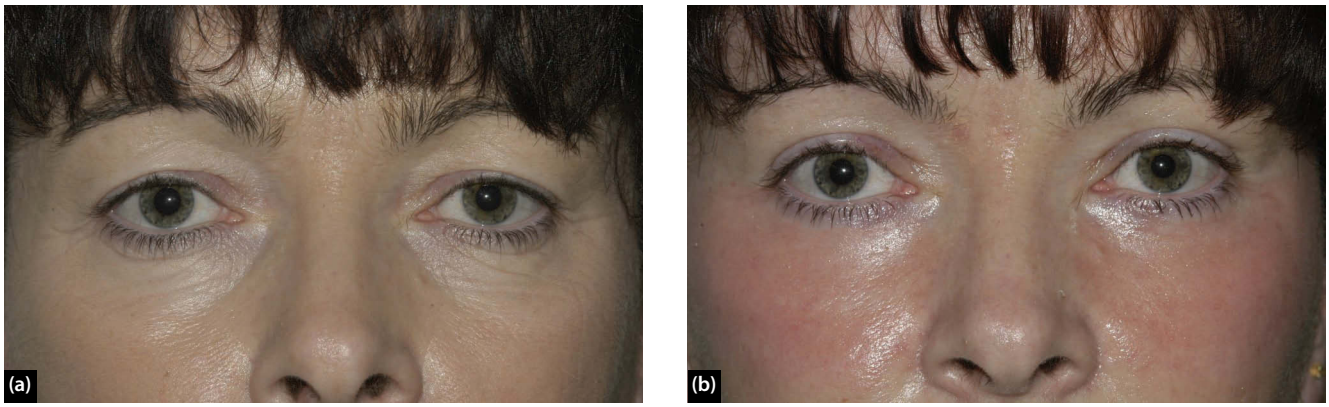

Figure 87.35 (a) The pre-operative appearance of a patient with moderate lower eyelid rhytids. **(b)** The post-operative appearance of the same patient 2 weeks following a bilateral upper eyelid blepharoplasty and lower eyelid CO_2 resurfacing (prior to the application of camouflage mineral make-up) demonstrating improvement in skin wrinkling but with typical post laser erythema.

Surgical procedure

1. Approximately 2–3 mL of 0.5% marcain with 1:200 000 units of adrenaline mixed 50:50 with 2% lignocaine with 1:80 000 units of adrenaline are injected with aouipl single injection just beneath the skin along the lower eyelid just below the tarsus and a further 2 mL is injected along the upper lid skin crease. The needle is inserted temporally and advanced nasally while slowly injecting the solution. Immediate pressure is applied. A pause of 10 minutes is allowed for the adrenaline to take effect.
2. The patient is prepped and draped.
3. A 4-0 silk traction suture is placed through the grey line of the lower eyelid and fixated to the head drape with a curved artery clip. A subciliary incision is made with a Colorado needle 1.5 mm below the eyelid margin to avoid damaging the eyelash follicles. This is commenced just beneath the inferior punctum and extends to the lateral canthus where it is continued within a lateral rhytid for a few millimetres (**Figures 87.36** and **87.37**). The dissection plane first passes subcutaneously for a few millimetres until the inferior margin of the tarsus is reached, at which point the dissection plane passes deep to the orbicularis oculi muscle (**Figure 87.37**). In this way, the pretarsal orbicularis oculi muscle is preserved, thereby minimizing the risk of denervation and, consequently, a paralytic eyelid ectropion.
4. A skin–muscle flap is dissected from the underlying orbital septum down to the inferior orbital margin.
5. Now exposed, the arcus marginalis is incised using the Colorado needle from a medial to lateral direction along the infraorbital rim, taking care to avoid the inferior oblique muscle and the lateral canthal tendon (**Figure 87.37**).
6. The septum and released preaponeurotic fat are then advanced over the inferior orbital margin. If necessary, the lateral fat pad may be trimmed as it may not be possible to reposition this adequately. It is very important to avoid undue traction on the fat pads in order to avoid tearing deep orbital veins which can in turn lead to a sight-threatening retrobulbar haemorrhage. The fat should not be discarded, however, as it can be placed over the inferior orbital margin and used to further recontour the nasojugal groove and the lateral tear tough. Likewise, fat removed during the course of a simultaneous upper lid blepharoplasty should not be discarded. Any fat removed should be kept in a swab moistened with saline and reimplanted without undue delay.
7. The fat pads may need to be sculpted to achieve a smooth contour. Meticulous technique is critical at this stage, since irregularities in the contour of the advanced fat pads are noticeable through the skin. The advanced septum and orbital fat are reset (as a unit) onto the periosteum of the maxilla inferior to the orbital rim with interrupted 5-0 Vicryl sutures (**Figures 87.38** and **87.39**).

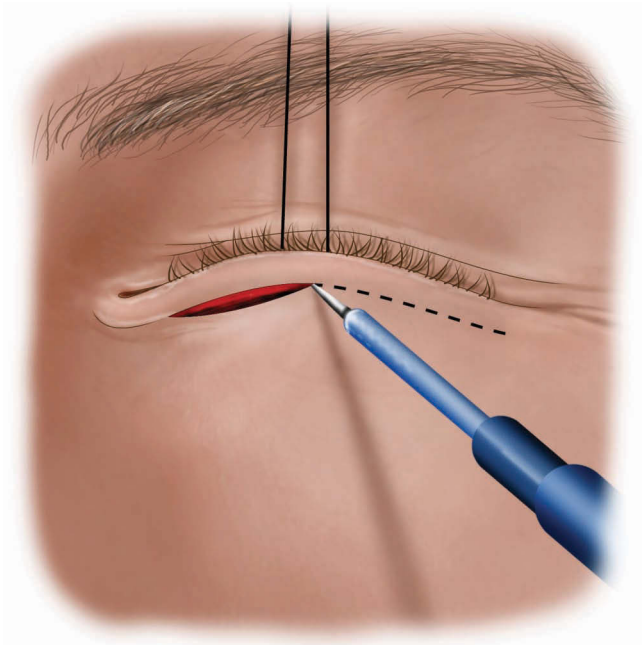

Figure 87.36 A subciliary incision is made with a Colorado needle with the lower eyelid placed on traction.

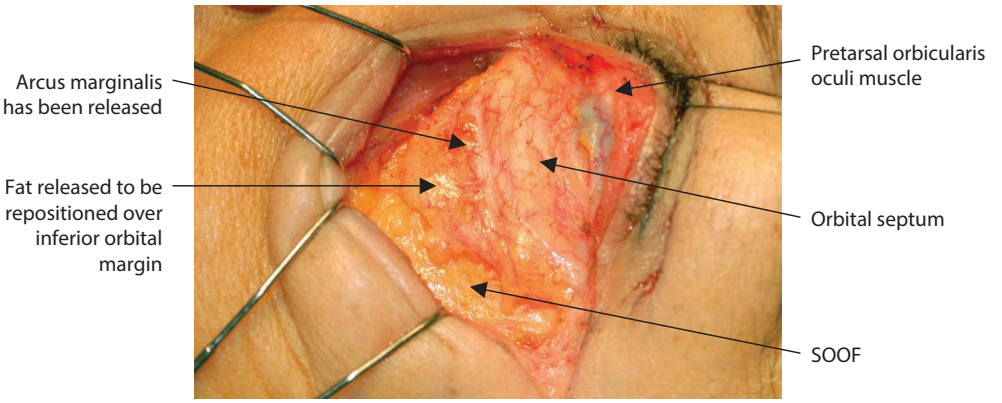

Figure 87.37 The anatomy of the left lower eyelid as seen during the course of a transcutaneous lower lid blepharoplasty.

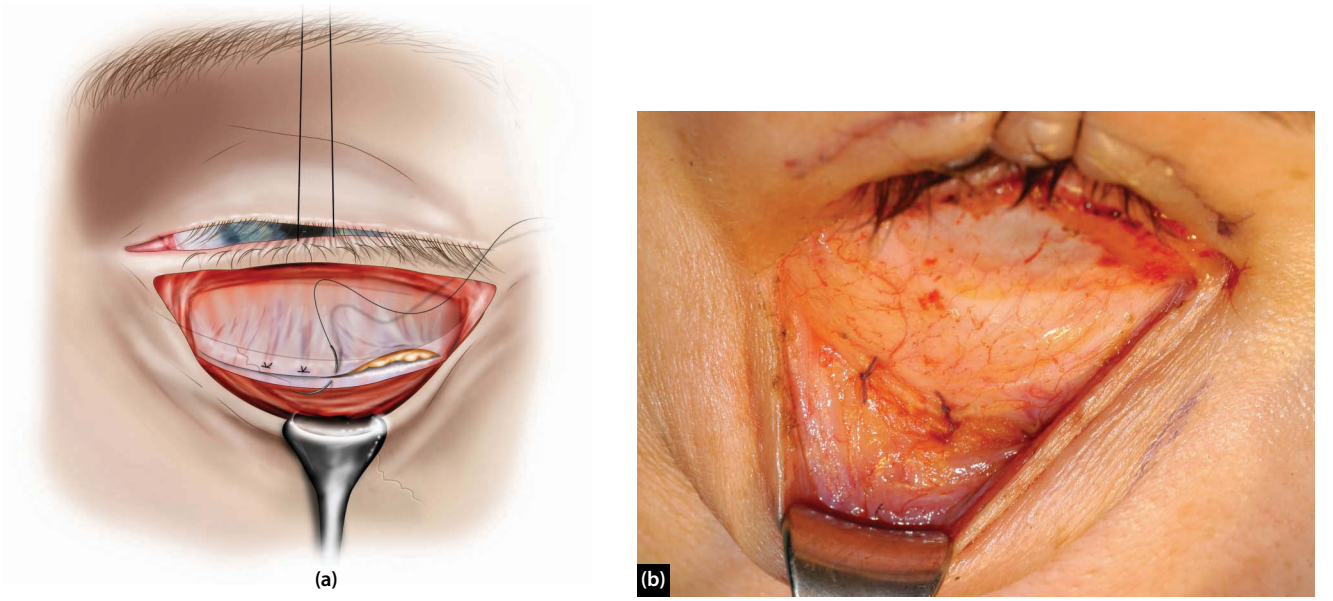

Figure 87.38 (a) Diagram showing the septum and fat being advanced over the inferior orbital margin and sutured to the periosteum just below the inferior orbital margin. **(b)** Intra-operative photograph of the septal reset procedure.

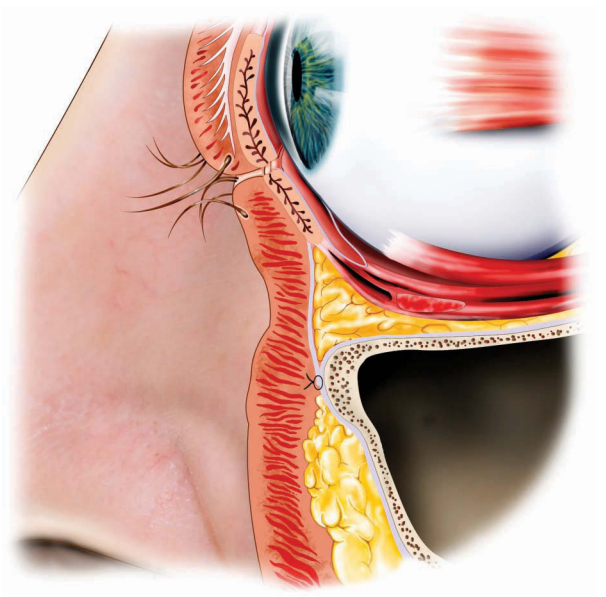

Figure 87.39 A more convex eyelid–cheek junction is created as the septal reset is performed and the orbicularis muscle is moved superolaterally.

8. The septum should be reset under minimal tension to avoid scleral show or an ectropion. If resetting the septum results in any eyelid retraction, the fat alone can be repositioned and sutured.
9. A lateral upper lid skin incision is made using the Colorado needle. The dissection is carried down through the orbicularis muscle to the orbital septum. This is then traced to the lateral orbital margin where the periosteum is exposed.
10. Stevens scissors are then used to bluntly dissect beneath the lateral orbicularis oculi muscle creating a tunnel (**Figure 87.40**).
11. A lateral tightening procedure may be required depending on the degree of lower lid laxity and should be performed before the septum is repositioned in order to establish and stabilize the position of the eyelid (**Figure 87.41**). (This is in fact very rarely required in patients under the age of 60 years.) Using a 15 blade, a tiny incision is made at the lateral commissure. A double-armed 5-0 Prolene suture on a round-bodied needle is passed through the incision, emerging through the lateral upper lid incision.

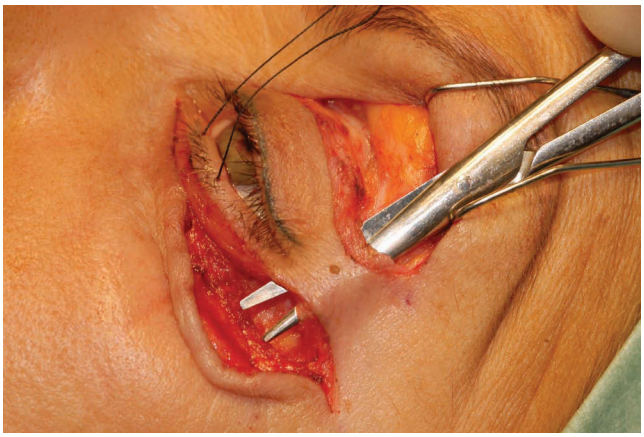

Figure 87.40 Stevens scissors are used to create a tunnel under the lateral orbicularis oculi muscle. In this patient, the lower eyelid blepharoplasty is being combined with an upper eyelid blepharoplasty.

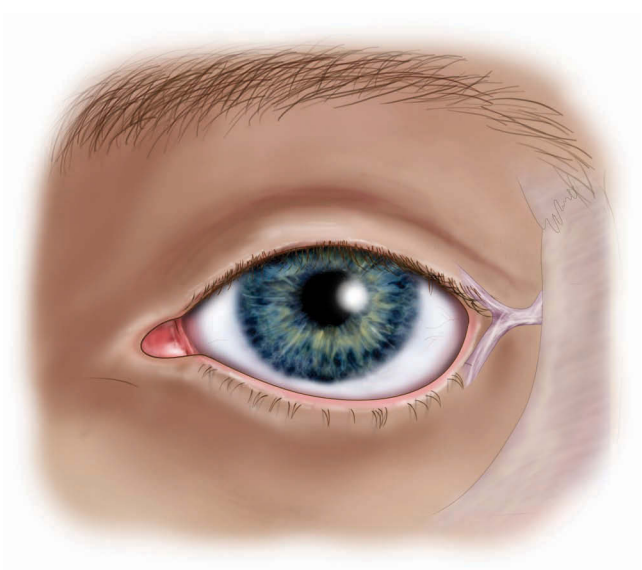

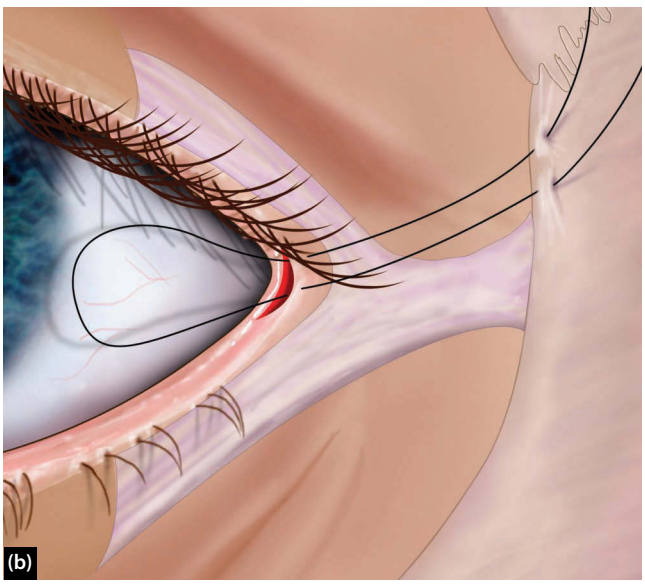

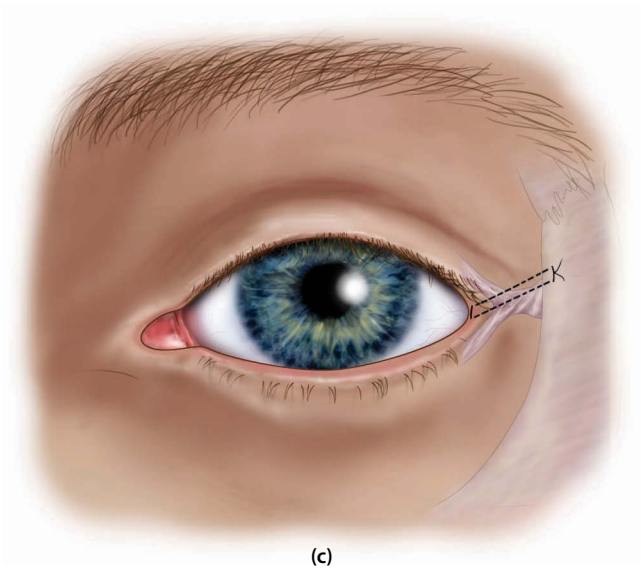

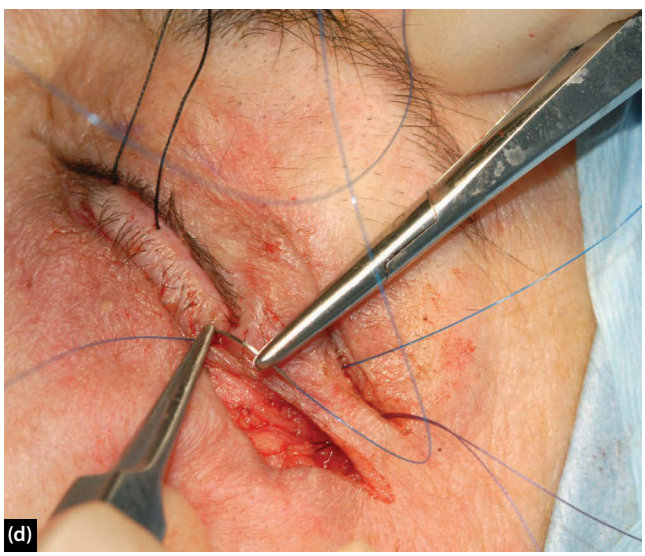

Figure 87.41 (a) Laxity of the lower eyelid with inferior scleral 'show'. **(b, c)** A lateral canthal tightening suture. The lateral canthal tendon and the lateral orbital margin are exposed via a lateral upper lid skin crease incision. **(d)** An intra-operative photograph showing the placement of the Prolene suture through a small incision at the lateral commissure. *(Continued)*

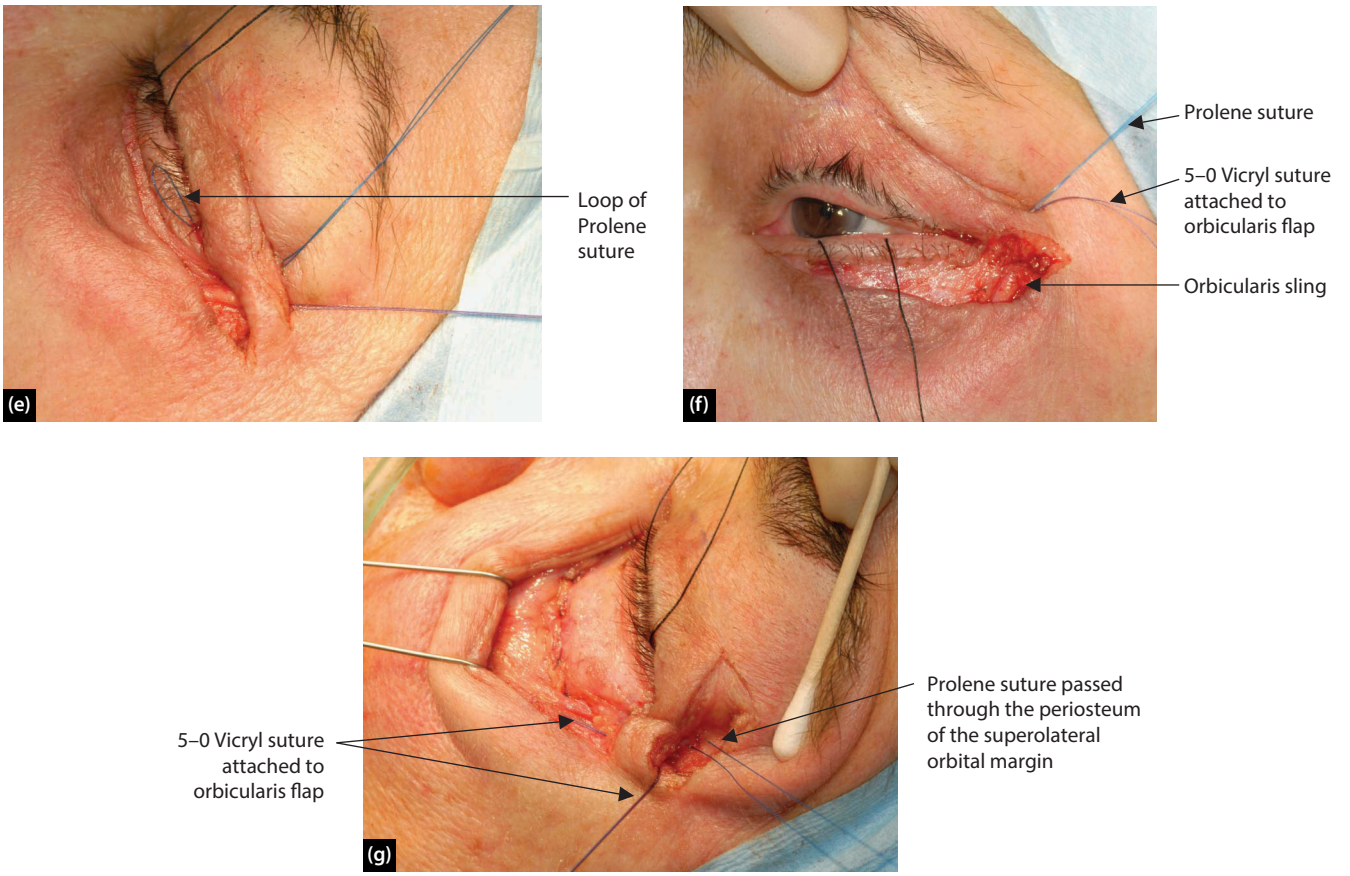

Figure 87.41 (Continued) **(e)** The loop of the Prolene suture is seen between the upper and lower eyelids laterally before the suture is tightened. **(f)** The Prolene suture has been tightened. The lower eyelid contour and height are checked to ensure that these are satisfactory. **(g)** The placement of the Prolene suture through the periosteum of the superolateral orbital margin is demonstrated.

Each needle is then passed through the periosteum of the internal aspect of lateral orbital wall in a medial to lateral direction and tied on the external surface of the lateral orbital wall, burying the knot (see **Figure 87.35**). Greater degrees of laxity of the lower eyelid and lateral canthal tendon should be addressed using a lateral tarsal strip procedure.

12. The orbicularis oculi muscle is now repositioned. With the use of this manoeuvre, lateral eyelid tightening is rarely if ever required in patients under the age of 60 years. From the dissection plane already created superficial to the septum and arcus marginalis, the lower lateral orbicularis is elevated off the underlying malar eminence with Westcott scissors, extending inferiorly in the submuscular plane as far as necessary to free the muscle's inferior border.
13. After separating the orbicularis oculi muscle from the skin of the lower lateral eyelid using Westcott scissors, a triangular muscle pedicle is created, with the base anchored inferolateral to the lateral canthus (**Figure 87.42**). Any redundant orbicularis muscle medial to the pedicle is removed with Westcott scissors.
14. A double-armed 5-0 Vicryl suture on a half circle needle is passed through the orbicularis flap and the suture is passed under the bridge of skin and orbicularis muscle at the lateral canthus.
15. The needles are passed through the periosteum of the superolateral orbital margin from medial to lateral and tied (**Figure 87.43**).
16. Moderate tension is maintained on the lower eyelid traction suture to prevent an over-resection of skin. If the surgery has been performed under local anaesthesia, the patient is asked to look up and to open the mouth to further assist in ensuring that an over-resection of skin is avoided. The skin is incised vertically at the lateral canthus using straight iris scissors. The redundant skin is then excised medial and lateral to the vertical incision using the same straight scissors (**Figure 87.44**). Care is taken to manage any residual dog ear at the temporal aspect of the wound. No skin should be removed from the medial two-thirds of the eyelid in the vast majority of cases. The skin resection should always be conservative.
17. The skin edges are then re-apposed using interrupted 7–0 Vicryl sutures.
18. The traction suture is removed.
19. The upper lid blepharoplasty wound is closed with interrupted 7–0 Vicryl sutures.

Post-operative care

Post-operatively the patient is prescribed a topical antibiotic ointment to the upper and lower lid wounds

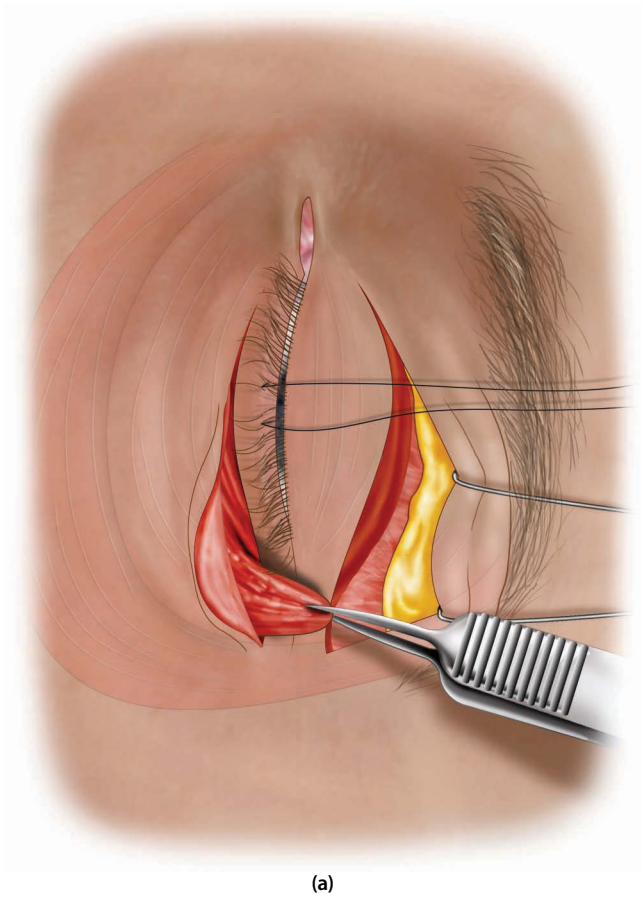

Figure 87.42 **(a)** Diagram demonstrating the creation of an orbicularis oculi muscle flap. **(b)** Intra-operative photograph showing a triangular flap of orbicularis oculi muscle being held with forceps. The redundant skin has been folded back on itself.

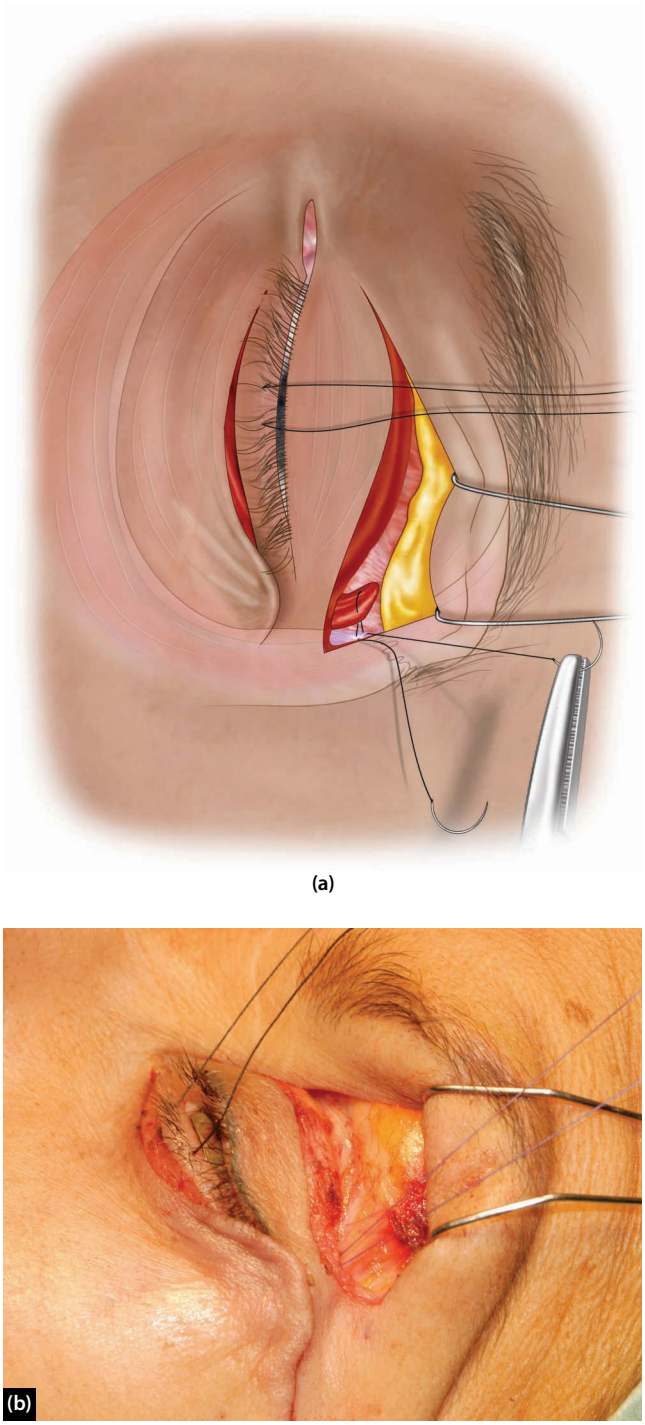

Figure 87.43 **(a)** Vicryl sutures with the attached orbicularis flap are passed beneath the intact bridge of skin and muscle laterally. The sutures are passed through the periosteum of the superolateral orbital margin. **(b)** Intra-operative photograph demonstrating the effect achieved when tension is applied to the sutures which are attached to the orbicularis flap.

three times a day for 2 weeks and Lacri-Lube® ointment 1–2 hourly to the eyes for 48 hours and at bedtime. The Lacri-Lube® ointment is then changed to a preservative-free topical lubricant gel to be used hourly during the day and Lacri-Lube® is continued at bedtime until the degree of lagophthalmos has improved. The frequency of the lubricants is then gradually reduced over the course of the next few weeks. The patient is instructed to sleep with the head of the bed elevated for 4 weeks and to avoid lifting any heavy weights for 2 weeks. Clean cool packs are gently applied to the eyelid intermittently for 48 hours. The patient should be reviewed in clinic within 2 weeks

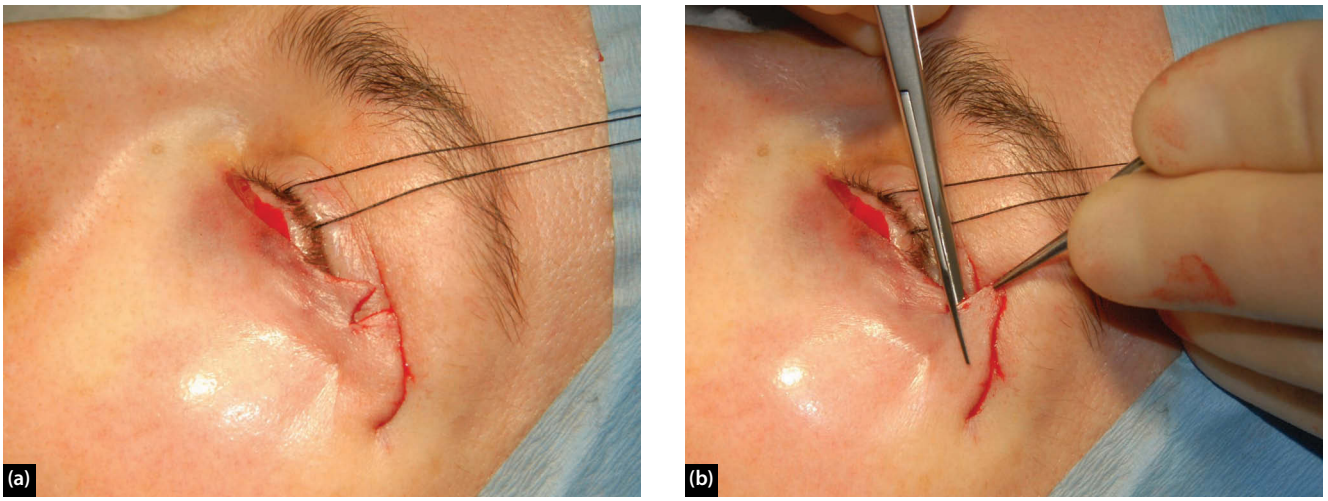

Figure 87.44 **(a)** A vertical incision is made in the central aspect of the lateral skin flap with straight iris scissors. **(b)** The excess skin is trimmed keeping some tension on the lower lid traction suture to prevent an inadvertent over-resection of skin.

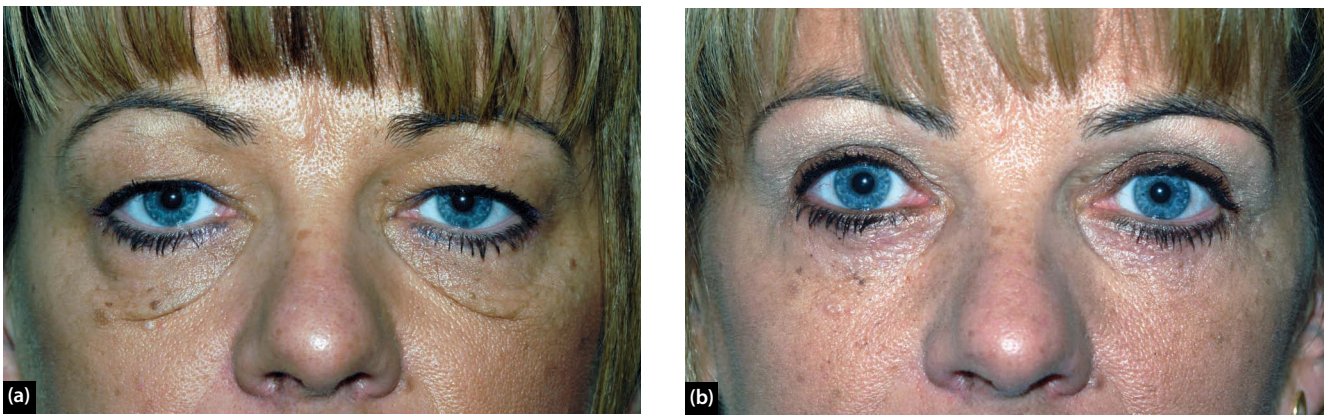

Figure 87.45 **(a)** Pre-operative appearance. **(b)** Post-operative appearance 4 months after undergoing a bilateral upper lid blepharoplasty with sculpting of the medial and central fat pads, and a bilateral lower lid transcutaneous blepharoplasty with an arcus marginalis release, fat repositioning and an orbicularis oculi muscle suspension.

and again within 4–6 weeks. The upper and lower lid skin sutures are removed at 10–14 days post-operatively. The patient is instructed to commence massage to the lower eyelids 2 weeks post-operatively. The patient should apply Lacri-Lube® ointment to the skin and massage in an upward direction for 2–3 minutes three times a day for 4–6 weeks. This is important to help to avoid lower eyelid retraction.

An example of a patient who has undergone this procedure is shown in **Figure 87.45**.

For patients who also have mild malar mounds, the lower eyelid transcutaneous blepharoplasty can be combined with a SOOF lift using the same incisions. Likewise, for patients with malar bags and a midface ptosis with descent of the malar fat pads, the transcutaneous blepharoplasty can be combined with a midface lift, again using the same incisions (**Figure 87.46**).

STRUCTURAL FAT GRAFTING

If structural fat grafting to the cheeks, temples or other facial areas is to be undertaken in conjunction with a lower eyelid blepharoplasty, this should be undertaken initially. It is important that the fat is injected as soon as possible after it has been harvested. This increases its chances of survival. The fat should be placed at different depths in the tissues by injecting only 0.1 mL of fat with each pass of the cannula. Multiple passes are required. The injection technique should be meticulous.

SOOF LIFT

Surgical procedure

1. This is undertaken after repositioning or removing lower eyelid fat.
2. The SOOF is mobilized by dissecting in the preperiosteal plane using blunt-tipped Westcott scissors, taking care to avoid damage to the infraorbital neurovascular bundle.
3. The SOOF is then sutured to the arcus marginalis and the periosteum of the lateral orbital margin with 4-0 Vicryl sutures (**Figure 87.47**).
4. The blepharoplasty is then completed as described above.

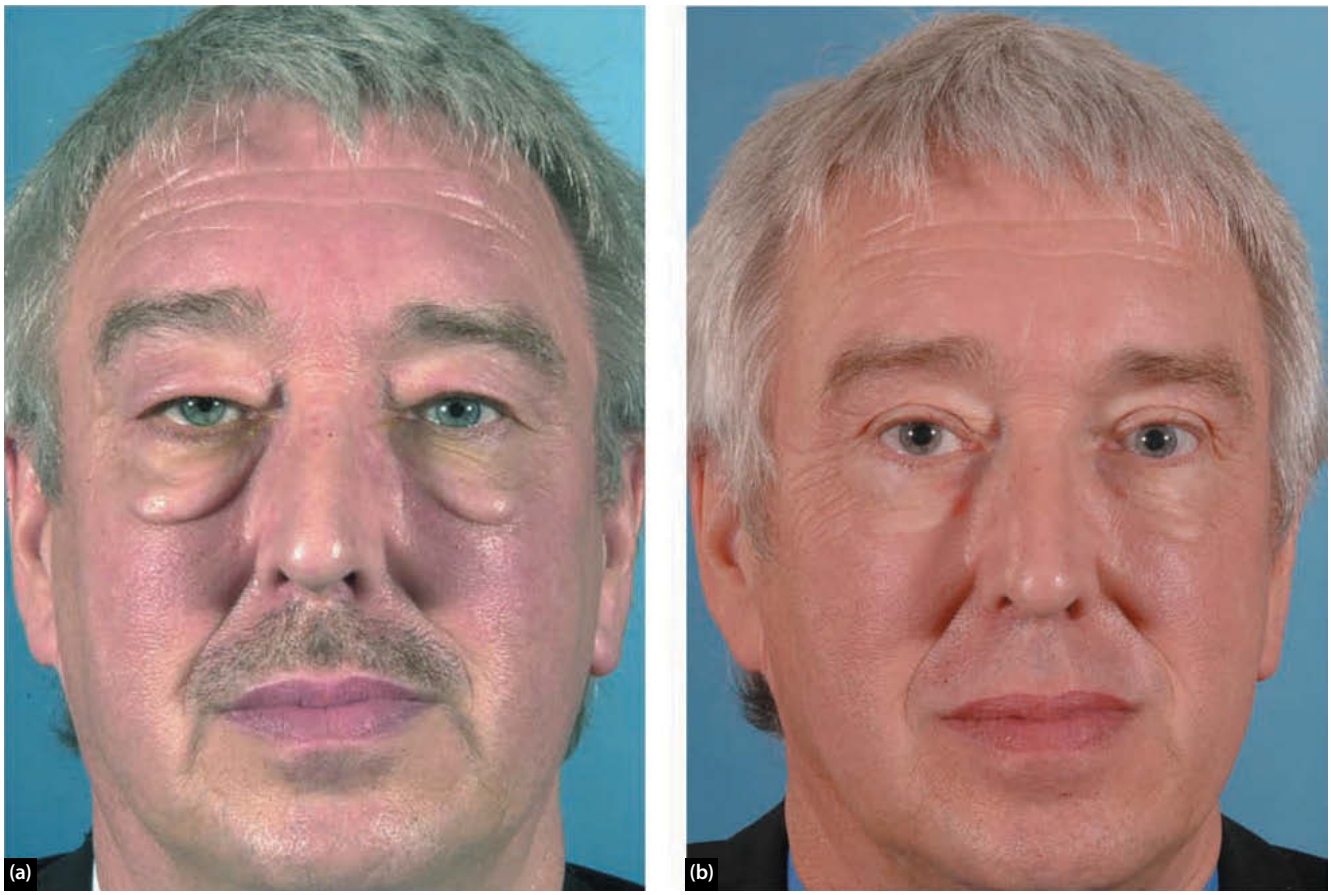

Figure 87.46 (a) The pre-operative appearance of a patient with marked bilateral lower eyelid festoons and bilateral upper eyelid dermatochalasis with no evidence of thyroid eye disease or other predisposing systemic disorder. **(b)** The post-operative appearance of the same patient 1 year following a bilateral upper lid blepharoplasty and transblepharoplasty internal browpexy and bilateral lower eyelid transcutaneous blepharoplasties combined with an orbicularis oculi muscle suspension. Note that this patient still has some lower lid festoons, which are extremely difficult to eradicate completely.

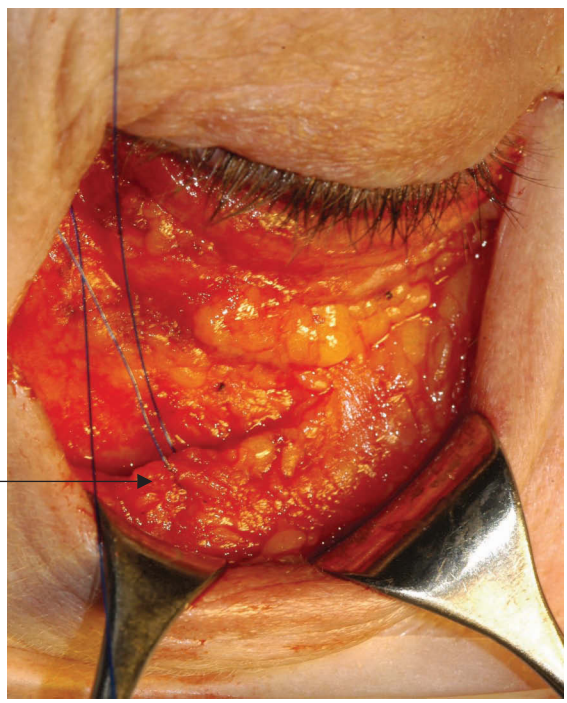

Figure 87.47 A 4-0 Vicryl suture has been placed through the SOOF.

MIDFACE LIFT

Surgical procedure

1. This is undertaken after repositioning or removing lower eyelid fat medially.
2. The periosteum is incised 2 mm below the inferior orbital margin and a subperiosteal dissection is performed using a Freer periosteal elevator, over the surface of the maxilla and zygoma, taking care to avoid damage to the infraorbital neurovascular bundle.
3. The periosteum is divided close to the buccal sulcus using Stevens scissors or the sharp end of a Freer periosteal elevator. In some patients, a buccal sulcus incision can be used to aid the subperiosteal dissection and mobilization of the midface.
4. Next, the periorbita is raised over the inferior and inferolateral orbital margin and into the orbit for a few millimetres using the Freer periosteal elevator.
5. Two or three drill holes are made through the inferior and inferolateral orbital margin, protecting the orbital contents with a malleable retractor.
6. A 3-0 Prolene suture is passed through the superior edge of the mobilized periosteum and through the ptotic malar fat pad. This suture is then passed

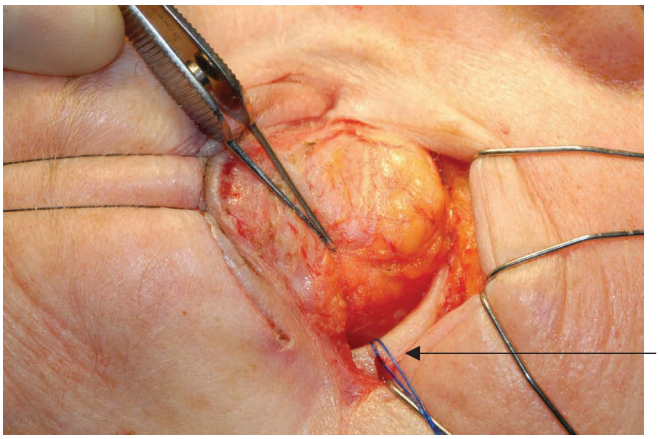

Figure 87.48 A 3-0 Prolene suture has been passed through a drill hole in the inferolateral orbital margin.

through the drill holes in the bony margin and tied (**Figure 87.48**). The suture knot is rotated into the drill hole. Additional sutures are placed as required.

7. The blepharoplasty is then completed as described above.

As an alternative option, the ptotic midface can be lifted with the use of a midface Endotine implant although this adds considerable expense to the procedure. The implant is positioned so that the tines at the inferior end of the implant engage the ptotic cheek fat pad and the other end is fixated to the lateral orbital margin using one or two titanium screws or biodegradable screws (**Figure 87.49**). The stem of the implant is then severed just above the securing screw using a 15 Bard Parker blade.

The Endotine implant gradually biodegrades over a period of approximately 6–9 months. The implant can provide a very powerful and effective midface lift. The patient should be warned that a midface lift can result in considerable post-operative swelling which can take 2–3 months to subside.

Post-operative care

This is as described above.

CHEEK IMPLANT

Although a variety of cheek implants are available (e.g. Medpor), and these can certainly provide augmentation of the midface, the author does not advocate the use of any cheek implants as these can lead to an unsatisfactory appearance after the patient has developed age-related soft-tissue deflation in the area overlying and adjacent to the implant after some years.

TRANSCUTANEOUS BLEPHAROPLASTY WITH FAT DEBULKING

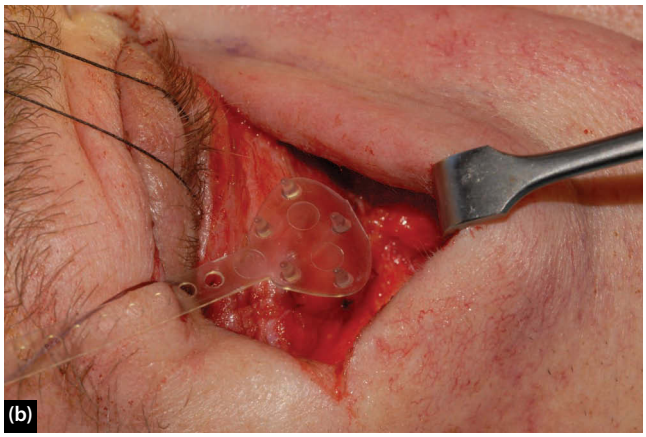
For the majority of patients seeking a lower lid blepharoplasty, usually in the age group 45–60 years of age, the transcutaneous blepharoplasty with arcus marginalis release, fat repositioning and an orbicularis oculi muscle suspension provides a very good cosmetic result with minimal risks. It is, however, time-consuming. For older patients with greater degrees of fat herniation, the fat will need to be formally debulked, paying very careful attention to haemostasis and avoiding traction on the fat. In such patients, a transcutaneous approach gives excellent access to the lower lid fat pads, which can be debulked with a very conservative removal of skin. An orbicularis muscle sling can be avoided but a lateral tarsal strip procedure will usually be required. This procedure is quicker to perform and the patients who are suitable for this procedure tend to be less demanding and critical of slight asymmetries.

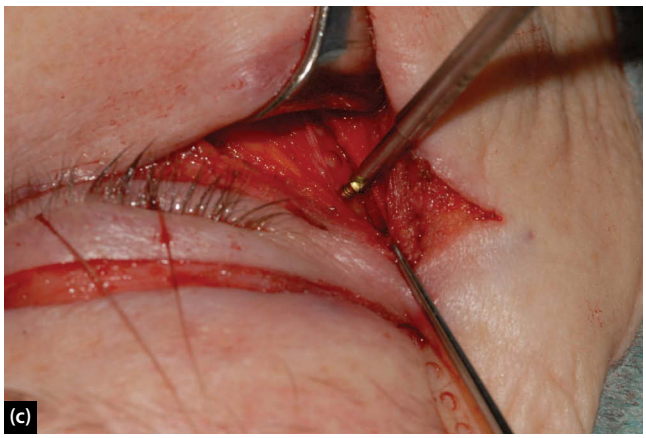
These older patients should also be carefully screened for systemic comorbidities, including undiagnosed essential hypertension. Such patients are at an increased risk of a retrobulbar haematoma with its potential visual morbidity.

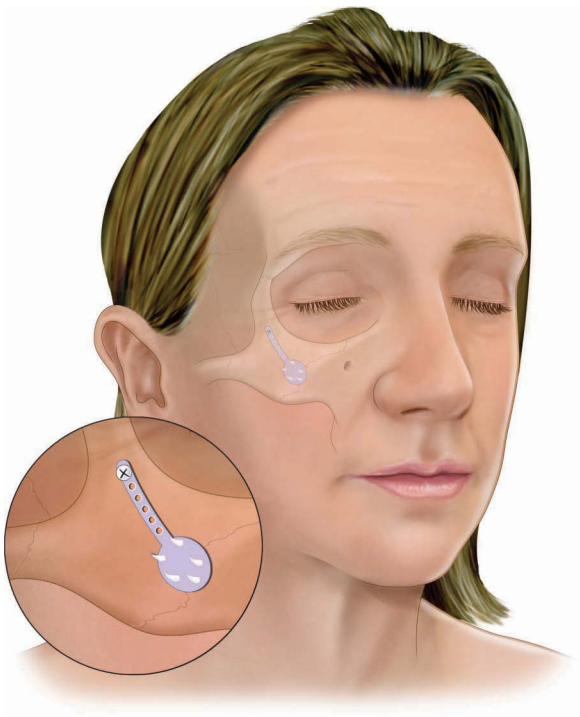
Steatoblepharon refers to a situation, usually in an older patient, where the orbital septum has become very lax with marked herniation of the lower eyelid fat pads (**Figure 87.50**). This can occasionally occur in younger patients as a familial trait. In older patients it tends to accompany dermatochalasis, eyelid laxity and ptosis. Prolapse of fat through a weakened Tenon's capsule may also accompany steatoblepharon. This fat can be resected via a lateral vertical conjunctival incision made directly over the prolapsed fat using Westcott scissors. The superolateral fornix should be avoided to prevent intraoperative damage being caused to the lacrimal gland ductules.

TRANSCONJUNCTIVAL BLEPHAROPLASTY

A transconjunctival blepharoplasty is ideally suited to the younger patient who has mild to moderate lower eyelid fat herniation but with no or minimal skin or eyelid laxity. It is also suited to the patient with thyroid eye disease and can be combined with an orbital decompression procedure. For patients who have marked fat pad enlargement, the fat can be debulked but, for patients with lesser degrees of fat herniation and who are concerned about the appearance of lower eyelid dark circles due to tear trough defects, fat can be repositioned over the inferior orbital margins.







(d)

Figure 87.49 **(a)** The head of the midface Endotine implant with the protruding tines. **(b)** The implant is about to be placed. **(c)** The implant has been placed. The stem of the implant has been passed under the lateral canthal raphé and brought out through the upper eyelid wound in this example. The stem is then pulled in a superolateral direction until the desired height and contour of the midface have been achieved. The stem is being secured to the lateral orbital margin with a 1.5 × 4 mm titanium screw. **(d)** Drawing showing the location of the Endotine implant.

Figure 87.50 **(a)** Steatoblepharon and upper lid dermatochalasis. **(b)** A prolapse of orbital fat through a weakened Tenon's capsule in the same patient.

The patient should be warned pre-operatively that post-operative chemosis is to be expected following this surgical approach, particularly in the patient with pre-operative conjunctivochalasis, and that this usually takes 1–2 weeks to resolve. In some patients, however, it can take several weeks to resolve.

Surgical procedure

The patient is examined in a sitting position and the prolapsed preaponeurotic fat pads are outlined using gentian violet. It is particularly important to outline a lateral fat pad as the position of the fat pad and the extent of the prolapse can be difficult to judge following the injection of local anaesthetic solution and with the patient in a semi-recumbent position.

Fat repositioning

1. Approximately 2–3 mL of 0.5% marcain with 1:200 000 units of adrenaline mixed 50:50 with 2% lignocaine with 1:80 000 units of adrenaline are injected with a single injection just beneath the skin along the lower eyelid just below the tarsus. The needle is inserted temporally and advanced nasally while slowly injecting the solution. Immediate pressure is applied. A pause of 10 minutes is allowed for the adrenaline to take effect. Local anaesthetic containing adrenaline is not injected subconjunctivally to avoid its effect on the pupil.
2. The patient is prepped and draped.
3. A 4-0 silk traction suture is placed through the grey line of the lower eyelid and everted over a medium Desmarres retractor.
4. A conjunctival incision is made with a Colorado needle 3–4 mm below the inferior border of the tarsus from the level of the punctum to the lateral canthus entering the plane between the orbital septum and the orbicularis oculi muscle. The orbital fat will remain contained behind the orbital septum as long as the incision is made above the line of fusion of the septum and the capsulopalpebral fascia.
5. 4–0 silk traction sutures are placed through the medial and lateral edges of the conjunctiva and the lower eyelid retractors and fixated to the head drapes using small curved artery clips in order to protect the cornea (see **Figure 87.44a**).
6. Dissection proceeds down the plane between the septum and the orbicularis and onto the anterior surface of the infraorbital rim. This bloodless dissection is greatly aided by the use of the Colorado needle.
7. A pocket is created beneath the orbicularis muscle over the anterior lacrimal crest.
8. The arcus marginalis is incised with the Colorado needle from medial to lateral along the infraorbital rim, taking care to avoid the inferior oblique muscle medially (located directly behind the medial third of the septum) and the lateral canthal tendon laterally (**Figure 87.51**).
9. Next a double-armed 4-0 Prolene suture is passed through the prolapsed fat medially. The needles are passed beneath the orbicularis muscle over the anterior lacrimal crest medially, through the full thickness of the eyelids to exit through the skin and are then tied over a silicone bolster, pulling the fat forwards and the orbicularis upwards over the inferior orbital margin. Further sutures are placed and passed just anterior to the periosteum over the anterior surface of the inferior orbital margin centrally and laterally (**Figure 87.52**).
10. The conjunctival retraction sutures are removed and the conjunctiva and eyelid retractors are re-apposed with 2–3 interrupted 7.0 Vicryl sutures.

An example of a patient who has undergone this procedure is shown in **Figure 87.53**.

Post-operative care Post-operatively the patient is prescribed a topical antibiotic ointment to the eyes three times a day for 2 weeks and Lacri-Lube® ointment 2 hourly to the eyes for 48 hours and at bedtime. The Lacri-Lube® ointment is then changed to a preservative-free topical lubricant gel to be used 2 hourly during the day and Lacri-Lube® is continued at bedtime until any

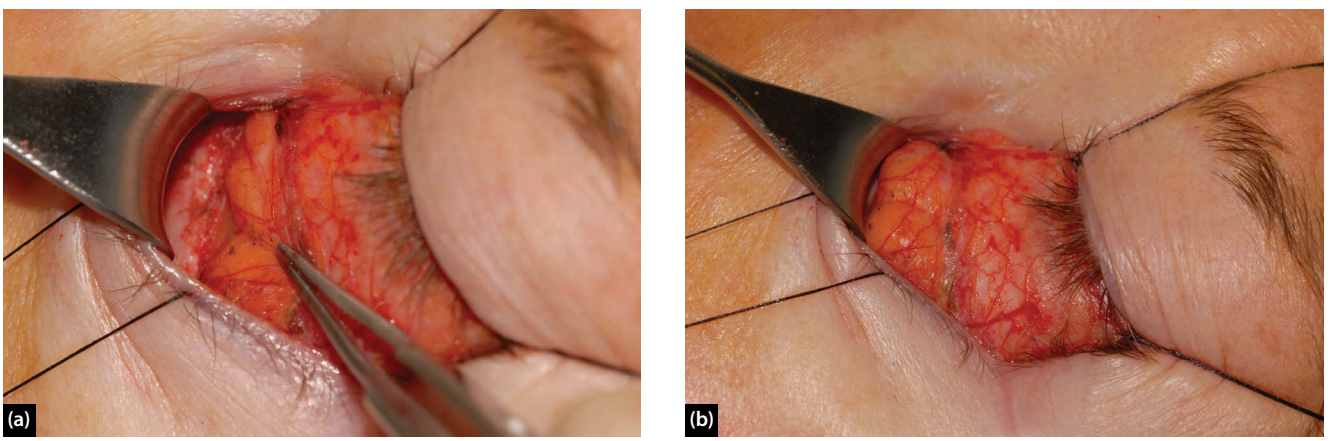


Figure 87.51 **(a)** The arcus marginalis has been opened allowing the preaponeurotic fat to prolapse. The inferior orbital margin has been exposed. **(b)** The fat is now prolapsing over the inferior orbital margin prior to placement of the double-armed Prolene sutures.

post-operative chemosis has resolved. Post-operative steroid drops are unnecessary. The patient is instructed to sleep with the head of the bed elevated for 2 weeks and to avoid lifting any heavy weights for 2 weeks. Clean cool packs are gently applied to the eyelid intermittently for 48 hours. The patient should be reviewed in clinic within 5 days when the Prolene sutures are removed, and again within 4–6 weeks. The conjunctival sutures should drop out spontaneously within 2 weeks. Massage to the lower eyelid/cheek junction for 3 minutes three times per day can be commenced using Lacri-Lube® ointment as soon as the Prolene sutures have been removed. This is continued for 2–3 weeks.

Figure 87.52 Three 4-0 double-armed Prolene sutures have been passed from the fat through the full thickness of the lower eyelids and tied over silicone bolsters.

Fat removal

In patients with a true fat excess a more traditional fat resection is required. In these patients gentle pressure is applied to the globe to allow the orbital fat pads to herniate into the wound.

The operation is as per stages 1–5 for fat repositioning above.

6. The orbital septum is opened using the Colorado needle over the points of maximum convexity caused by the bulging of the fat with pressure applied to the globe. The fat will prolapse through the openings in the septum.
7. The fat is then very carefully excised after clamping the fat with a curved artery clip. Strict attention is paid to meticulous haemostasis (**Figure 87.54**).
8. No undue traction should be exerted on the fat. The fat is removed commencing with the nasal fat pad, moving to the central and then to the lateral fat pads.
9. The residual fat should be left flush with the orbital margin to prevent over-resection with a subsequent 'skeletonized' look.

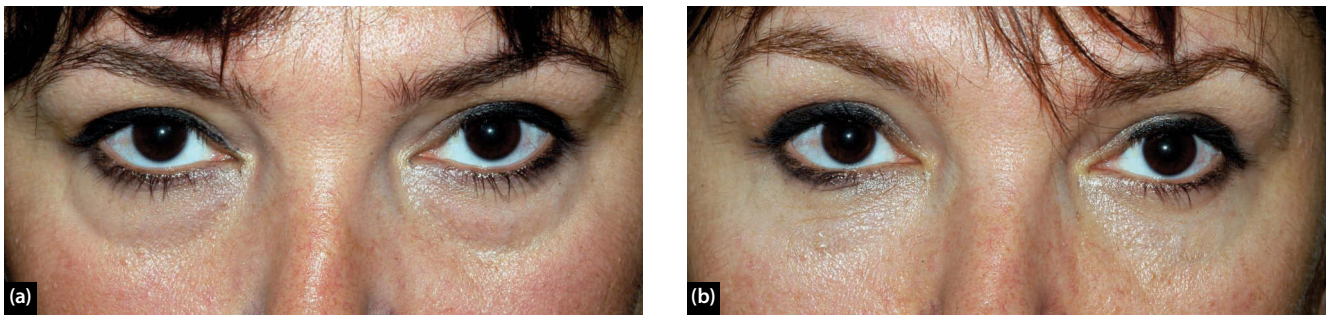

Figure 87.53 (a) Pre-operative appearance. **(b)** Post-operative appearance following a bilateral lower lid transconjunctival blepharoplasty with arcus marginalis release and fat repositioning.

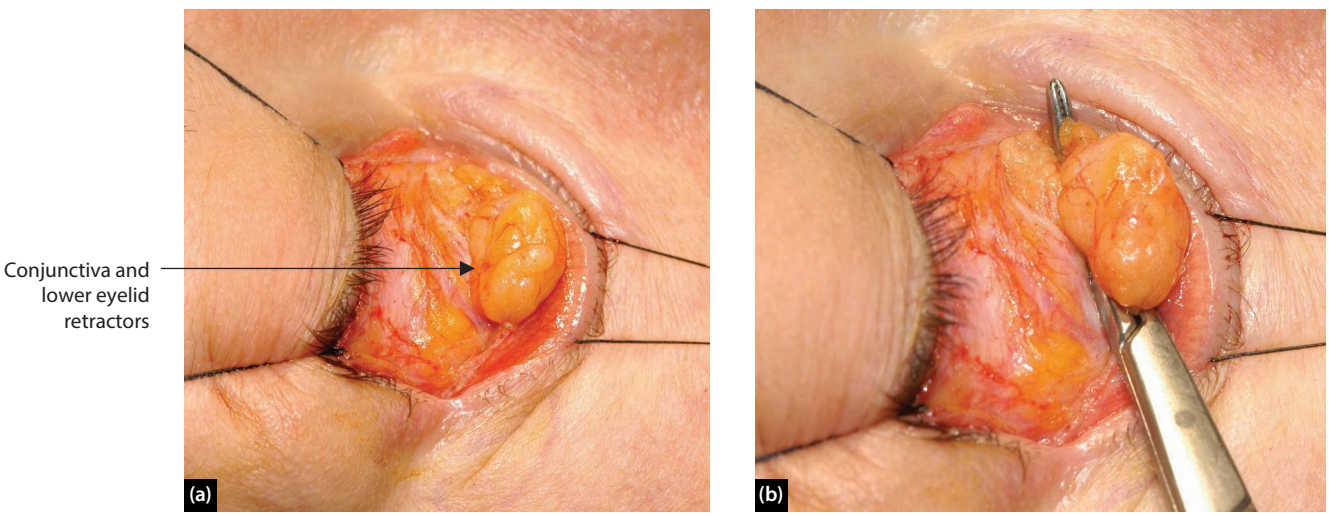

Figure 87.54 (a) The central eyelid fat pad has prolapsed into the wound after opening the orbital septum. **(b)** The central fat pad has been clamped with a curved artery clip.

10. The Desmarres retractor is removed and the eyelids inspected to ensure adequacy of fat removal and symmetry. If there is concern that too much fat has been removed, this can be replaced as a free graft over the inferior orbital margin.
11. The conjunctival retractor sutures are removed and the conjunctiva and eyelid retractors are reapposed with two or three interrupted 7-0 Vicryl sutures.

An example of a patient who has undergone this procedure is shown in **Figure 87.55**.

In some patients a minimal skin excess can be addressed at this stage by adding a simple 'pinch' skin resection. The lower lid skin is gently pinched into a fold in the lateral aspect of the eyelid using Castroviejo 0.3 mm toothed forceps and this is marked out using a cocktail stick impregnated with gentian violet solution, ensuring that the eyelid position is not affected even with upgaze and with mouth opening. The skin alone is resected with a Colorado needle and the skin edges reapproximated with interrupted 7-0 Vicryl sutures.

Post-operative care Post-operatively the patient is prescribed a topical antibiotic ointment to the eyes three times a day for 2 weeks and Lacri-Lube® ointment 2 hourly to the eyes for 48 hours and at bedtime. The Lacri-Lube® ointment is then changed to a preservative-free topical lubricant gel to be used 2 hourly during the day and Lacri-Lube® is continued at bedtime until any post-operative chemosis has resolved. Post-operative steroid drops are unnecessary. The patient is instructed to sleep with the head of the bed elevated for 2 weeks and to avoid lifting any heavy weights for 2 weeks. Clean cool packs are gently applied to the eyelid intermittently for 48 hours. The patient should be reviewed in clinic within 2 weeks, and again within 4–6 weeks. The conjunctival sutures should drop out spontaneously within 2 weeks. If a pinch skin excision has been performed, the skin sutures are removed in clinic after 2 weeks.

PATIENT AFTERCARE

If the surgery has been performed under general anaesthesia, it is wise to apply a compressive dressing for 30 minutes until the patient has recovered. This prevents oozing into the eyelids if the patient performs a Valsalva manoeuvre following extubation. The dressings are then removed and ice packs applied intermittently for 24–48 hours post-operatively. Significant post-operative pain is rare, and most patients are comfortable with a mild non-aspirin analgesic. Significant post-operative pain should, however, raise concerns about the possibility of a retrobulbar haemorrhage and the patient should be examined to ensure that this has not occurred.

Increased pigmentation from haemosiderin deposition is sometimes observed in patients with excessive bruising. To minimize this post-operative problem, patients should be instructed to avoid post-operative sun exposure until the ecchymosis has completely resolved.

Eyelids are extremely sensitive to allergenic insult, and any pre-existing atopy can be aggravated by surgery. Patients should therefore not use cosmetics for at least 10 days after surgery in order to avoid an allergic reaction. Mineral make-ups can be used 10–14 days post-operatively. Patients should also be made aware of the symptoms and signs of allergy to topical antibiotic ointments prescribed for application to the wounds at home after discharge.

For patients who have undergone a more extended lower eyelid blepharoplasty with resuspension of the orbicularis oculi muscle and a SOOF or midface lift, the patient and surgeon must be prepared to wait several weeks for post-operative swelling to resolve and healing to take place before judging the final outcome, since a complete recovery takes significantly longer after this procedure than after a more traditional blepharoplasty. Pre-operative counselling of the patient is vital to ensure that such a prolonged period of convalescence is acceptable to the individual patient.

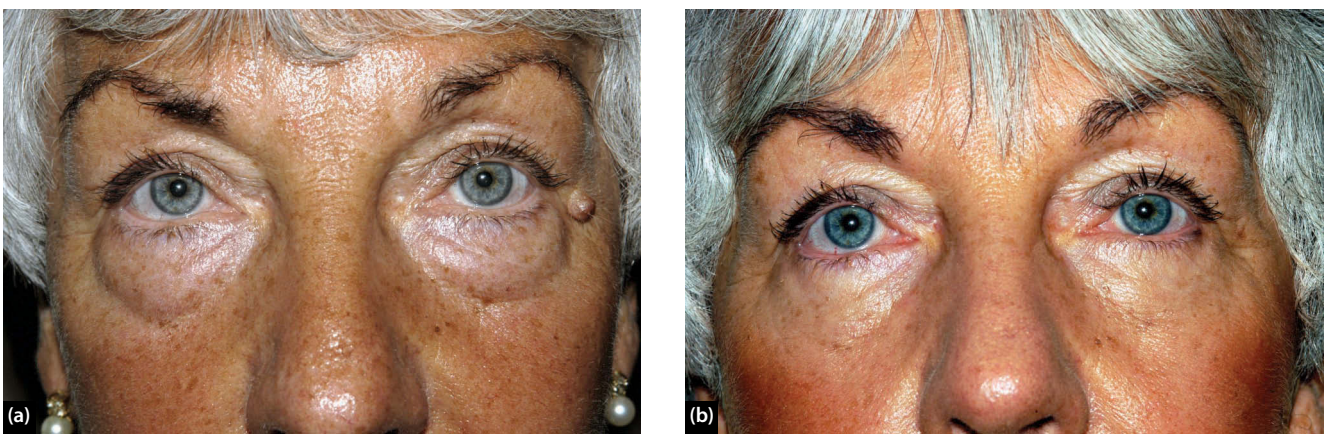

Figure 87.55 **(a)** Pre-operative appearance. **(b)** Post-operative appearance of the same patient 12 months following a bilateral transconjunctival blepharoplasty with fat debulking and removal of a left lateral canthal skin lesion.

COMPLICATIONS OF BLEPHAROPLASTY SURGERY

A number of complications can occur following blepharoplasty surgery (**Box 87.1**). Fortunately, serious complications are rare. The vast majority of complications are ophthalmic in nature and for this reason an increasing number of well-informed patients requesting blepharoplasty surgery seek the skills of appropriately trained and experienced oculoplastic surgeons for their pre-operative evaluation and for their surgery.

BOX 87.1 Complications of blepharoplasty

1. Blindness
2. Bradycardia or other dysrhythmias from the oculocardiac reflex
3. Dry eye
4. Lower eyelid retraction
5. Lower eyelid ectropion
6. Rounding of the lateral canthus
7. Hollowing of the eyelids
8. Epiphora
9. Lagophthalmos
10. Asymmetrical upper lid creases
11. Diplopia
12. Blepharoptosis
13. Chemosis
14. Corneal abrasion
15. Injury to branches of the facial nerve
16. Sensory loss in the distribution of the infraorbital or zygomaticofacial nerves
17. Irregular lower eyelid lumps
18. Fat necrosis

Many of these complications can be avoided by careful pre-operative patient evaluation and selection of the most appropriate surgical procedure for the patient, as outlined above.

- **Blindness** is by far the most serious complication of blepharoplasty surgery. This is usually due to the sudden occurrence of a post-operative orbital haemorrhage. Although rare (the precise incidence is unknown due to under-reporting of this complication but is estimated to be approximately 0.05%), this is a devastating complication of an operation performed most commonly to improve a patient's cosmetic appearance. The patient should be counselled about such a risk pre-operatively. The surgery must be meticulously performed with strict attention to intraoperative haemostasis. Undue traction on orbital fat must be avoided. It is important to ensure that all risk factors for bleeding are addressed pre-operatively. No patient should undergo blepharoplasty surgery involving the removal of orbital fat if hypertension is uncontrolled, if there is a history of a bleeding disorder or if the patient is taking antiplatelet drugs. The patient must be given post-operative instructions about restrictions on activity following surgery. The patient must be able to return to hospital immediately in the event of any sudden orbital pain, proptosis or decrease in vision. The patient with a retrobulbar haematoma usually complains of a steady, lancinating pain, similar to that of glaucoma. The patient may also report scintillating scotomas or complete visual loss and may exhibit mydriasis with a relative afferent pupil defect, proptosis with resistance to retropulsion, and haemorrhagic chemosis.

  If a patient develops a sudden orbital haemorrhage with proptosis, subconjunctival haemorrhage and decreased visual acuity, the wound must be opened immediately to drain the haematoma and a lateral canthotomy and inferior cantholysis should be performed to achieve an emergency orbital decompression. Because the consequences of a retrobulbar haemorrhage are so severe, aggressive intervention is required. If possible the surgeon should not wait for signs of optic nerve compression (i.e. reduced visual acuity, visual field loss, an afferent pupillary defect) to arise, because permanent damage may have occurred by that time. Rather, excessive pain and proptosis necessitate immediate surgical decompression. The incision should be opened and carefully explored. Medical decompression of the orbit with corticosteroids (methylprednisolone 100 mg i.v.), carbonic anhydrase inhibition (acetazolamide 500 mg i.v.) should be organized straight away and, if necessary, osmotic diuresis (mannitol 50–100 g i.v. over 30 minutes) may also be used. The patient's intraocular pressure should be monitored using a Perkins tonometer or a Tonopen and the patient's fundus should be examined to ensure patency of the central retinal artery.
- The **oculocardiac reflex**, characterized by intraoperative bradycardia or dysrhythmia, can be triggered by traction on the extraocular muscles or orbital fat pads. A profound bradycardia or even asystole can occur. Younger patients are more susceptible to the severe effects of this reflex. The anaesthetist monitoring the patient should be aware of the possibility of a dysrhythmia occurring and should alert the surgeon who should in turn release any tissue to which traction is being applied. Atropine or glycopyrolate should be kept drawn up in a syringe and available immediately in the event of a severe dysrhythmia.
- **Keratoconjunctivitis sicca (dry eye syndrome)** is most often seen in patients who have a pre-existing tear film insufficiency. This should be specifically examined for pre-operatively and the patient counselled accordingly. This can be particularly important in patients who have undergone corneal refractive procedures (e.g. LASIK) or who wear contact lenses. The consistent continued use of frequent artificial tears is imperative in these patients who may also require additional procedures at a later date (e.g. punctal plug placement or punctal cautery). Patients who require artificial tears more frequently than three or four times per day should use a preservative free preparation.

- Mild **lower eyelid retraction** may be managed conservatively with post-operative eyelid massage. The eyelid should be massaged in an upward direction after applying Lacri-Lube® ointment to the skin. A SOOF lift or midface lift combined with a lateral canthal resuspension may prevent the need for a full-thickness skin graft following an over-resection of skin leading to lower eyelid retraction. Middle lamellar contracture resulting in lower eyelid retraction (see **Figure 87.16**) may, however, require division of the scar tissue and placement of a hard palate graft or a dermal graft.
- A temporary **lower eyelid ectropion** can occur, particularly laterally, as a result of post-operative wound oedema, wound contraction and/or hypotonicity of the orbicularis oculi muscle. A frank ectropion occurs when significant lower eyelid laxity has not been addressed or where caution has not been exercised in resetting of the orbital septum or in the degree of skin resection. This will usually require a lateral canthal tightening procedure and in some patients this will have to be combined with a skin graft.
- **Rounding of the lateral canthus** occurs following the excessive resection of skin and orbicularis oculi muscle as a triangle laterally, particularly in a patient whose eyelid laxity has not been appropriately addressed. This can prove to be very challenging to correct, and may require a midface lift combined with a lid-tightening procedure.
- **Hollowing of the eyelids** occurs if too much orbital fat is removed, particularly in older patients with very thin eyelid skin. In the lower eyelids care should be taken to resect the fat flush with the inferior orbital margin and to avoid pulling the fat anteriorly during the resection. In general, fat removal from the upper eyelids should be avoided wherever possible. Hollowing of the eyelid can be addressed by the placement of fat pearls harvested from the periumbilical area, or by means of structural fat grafting.
- **Epiphora** is common in the first few post-operative days. Corneal irritation, which triggers hypersecretion of tears, and lower eyelid ectropion, which removes the inferior punctum from the surface of the globe, usually causes epiphora. Continued epiphora following blepharoplasty surgery may occur as a consequence of lagophthalmos with a secondary punctate keratopathy and hypersecretion of tears and/or a malposition of the inferior punctum. A subtle vertical positioning of the inferior punctum may result in epiphora. This is seen on careful slit lamp examination and may occur some years after surgery as the lower eyelid tarsoligamentous support becomes more lax. Conjunctivochalasis, a redundant fold of bulbar conjunctiva, may lie over the inferior punctum obstructing tear flow. This is again a subtle abnormality requiring careful slit lamp examination. It can respond to a conservative resection of the redundant conjunctiva. Persistent epiphora due to malposition of the inferior punctum requires further surgery to reposition the punctum.
- **Lagophthalmos** following an upper eyelid blepharoplasty is avoided by ensuring a conservative skin resection in the upper eyelids. Overzealous resection may require a skin graft if exposure symptoms do not respond to conservative treatment.
- The **appearance and symmetry of the upper eyelid skin creases** have a profound effect on the cosmetic outcome of an upper eyelid blepharoplasty. The skin crease should be higher in a female and well defined in contrast to a male in which this should be lower and more subtle. Complications are avoided by meticulous pre-operative planning and marking. Post-operatively it is easier to raise a skin crease which is unsatisfactory than it is to lower it.
- **Diplopia** is a rare complication following lower eyelid blepharoplasty. This is usually due to surgical trauma to the inferior oblique muscle. A good knowledge of anatomy, a meticulous surgical dissection and an avoidance of the excessive use of cautery should prevent such a complication. A permanent ocular motility disturbance caused by blepharoplasty is much rarer than a pre-existing phoria, which may decompensate following surgery. For this reason it is imperative to perform a detailed pre-operative ophthalmic examination in order to diagnose the problem and to protect the surgeon from unfair blame.
- **Blepharoptosis** may occur if the levator muscle, the horns of the levator muscle complex or Whitnall's ligament are damaged during surgery. These should be carefully identified and avoided. Any pre-existing ptosis should be addressed at the time of an upper eyelid blepharoplasty by means of a levator aponeurosis advancement. This should be performed under local anaesthesia to facilitate an intra-operative adjustment of the height and contour of the upper eyelid(s) with the benefit of the patient's cooperation.
- **Chemosis** (**Figure 87.56**), which is more commonly seen following a transconjunctival blepharoplasty, usually resolves after 10–14 days following the liberal use of topical lubricants. On very rare occasions it may last for some weeks post-operatively. The use of topical steroids to treat this should be avoided

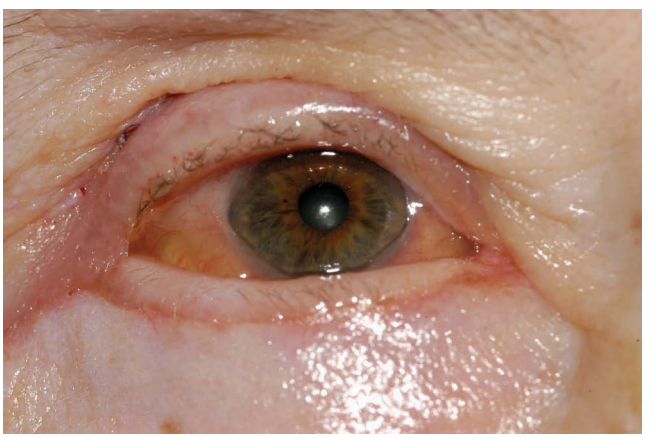

Figure 87.56 Post-operative conjunctival chemosis following a transcutaneous lower eyelid blepharoplasty.

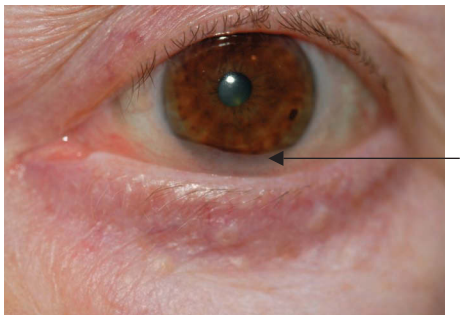

Figure 87.57 Conjunctivochalasis.

because of the risk of cataract, glaucoma and predisposition to infection. If the chemosis does not resolve, a redundant fold of forniceal conjunctiva may need to be removed and the cut edges sutured to the episclera using 8-0 Vicryl sutures. The occurrence of post-operative chemosis can be predicted in the patient who has pre-operative conjunctivochalasis (**Figure 87.57**). Such a patient should undergo the simultaneous resection of the redundant conjunctiva at the time of the blepharoplasty.

- All precautions must be taken to prevent a **corneal abrasion**, which can be extremely painful. Care should be taken when placing eyelid and conjunctival traction sutures to avoid causing a corneal abrasion. Most corneal abrasions heal rapidly without any long-term sequelae but in some patients a recurrent corneal abrasion syndrome can occur. Diabetic patients and patients with corneal dystrophies (which may have been previously undiagnosed) are at particular risk of a recurrent corneal abrasion syndrome. If an abrasion does occur, the patient must be treated with frequent topical antibiotics and should undergo a daily review with slit lamp examinations until the abrasion has completely healed. A topical lubricant ointment should be prescribed at night for a minimum period of 6 weeks to help prevent a recurrent corneal abrasion syndrome.
- **Injury to branches the facial nerve**, particularly the zygomatic branch to the inferior orbicularis, is a potential hazard of dissecting below the orbicularis oculi muscle. This can lead to a loss of tone in the muscle with loss of lower eyelid symmetry lower eyelid ectropion or lagophthalmos. A subperiosteal dissection minimizes the risk of this complication.
- **Sensory loss in the distribution of the infraorbital or zygomaticofacial nerves** is usually temporary. Care should be taken when cauterizing branches of the infra-orbital artery over the inferior orbital margin
- **Irregular lower eyelid lumps** can occur following fat repositioning. This is usually temporary and the lumps often respond to a period of post-operative massage. The use of steroid injections should be avoided.
- **Fat necrosis** is rare and manifests as small, painful, indurated nodules. Massage can hasten their resolution. Injection of steroids into the lesions is effective but carries the risk of subcutaneous atrophy and hypopigmentation.

Medicolegal pitfalls

Most complications of blepharoplasty surgery stem from an inadequate pre-operative patient evaluation. From a medicolegal perspective, a thorough history and meticulous ophthalmic examination, good documentation, informed consent with the provision of detailed information about the pros, cons, risks and potential complications and their management, and excellent patient communication are crucial.

FUTURE RESEARCH

Future research should focus on the improvements that can be made in addressing age-related facial and periocular volume deficits using refined methods of safe structural fat grafting and improvements in the quality and safety of dermal fillers, to help to achieve better and sustained results from blepharoplasty surgery.

KEY POINTS

Anatomy

- A thorough understanding of the surgical anatomy of the eyebrows, eyelids and midface is essential prior to performing a blepharoplasty.
- The distance between the inferior aspect of the eyebrow and the upper lid skin crease on downgaze should be approximately two-thirds of the distance from the inferior aspect of the eyebrow to the eyelid margin. It is important to maintain these dimensions. In general, a minimum distance of 10–12 mm should be left between the inferior aspect of the eyebrow and the upper eyelid skin crease when performing an upper lid blepharoplasty.
- It is very important to be able to distinguish the lacrimal gland from orbital fat.
- Whitnall's ligament supports the levator muscle complex and should not be disturbed during surgery.
- The inferior oblique muscle lies between the medial and central fat pads.

Blepharoplasty

- A history of contact lens wear, previous corneal laser refractive surgery, or a dry eye, facial palsy or thyroid dysfunction identifies a patient at risk of exposure keratopathy symptoms following an upper lid blepharoplasty.
- It is important to exclude a bleeding disorder, as a post-operative haemorrhage following a blepharoplasty is potentially sight-threatening. The use of aspirin or non-steroidal anti-inflammatory agents should be discontinued 2 weeks pre-operatively.
- The patient seeking or referred for a blepharoplasty should undergo a complete pre-operative ophthalmic examination and examined specifically to exclude the possibility of thyroid eye disease.
- The secondary effects of brow ptosis on the upper eyelids must be recognized.
- Pre-operative photographs must be taken. Written consent should be obtained before the photographs are taken and it should be made clear to the patient how the photographs are to be used.
- Botulinum toxin injections should not be given at the time of surgery.
- For purely elective, cosmetic procedures, the patient should be encouraged to consider the information carefully before making a decision to proceed. This may necessitate a further consultation or an attendance at a pre-assessment clinic to obtain fully informed consent and to answer any residual queries.
- The patient should not be asked to sign a consent form for an elective cosmetic procedure on the day of surgery. The risks and potential complications that have been discussed should be documented in the patient's records, on the patient's consent form and in a letter addressed to the patient. The patient should also be provided with a formal document which outlines the potential complications of blepharoplasty surgery, their management and he financial responsibilities that would be incurred.
- It should be noted that fat removal should be undertaken very conservatively, if at all, in the upper lid so as to avoid a secondary hollowing of the upper eyelid, which can result in a very aged appearance.
- No skin should be removed from the medial two-thirds of the lower eyelid in the vast majority of cases. The skin resection should always be conservative.
- Significant post-operative pain following a blepharoplasty should raise concerns about the possibility of a retrobulbar haemorrhage and the patient should be examined immediately to ensure that this has not occurred.
- By far the most serious complication of blepharoplasty surgery is blindness.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: rhytidectomy, facelift, facial rejuvenation, and facial fat grafting or autologous fat transfer.

INTRODUCTION

As populations expand and life expectancy increases, growing numbers of people are seeking methods to reverse the outward effects of ageing. Over the past decades, refinements in surgical techniques have enhanced our ability to achieve natural-looking results with an emphasis on facial harmony and avoidance of the stigmatized 'operated' look. This has allowed aesthetic facial surgeons to meet the high expectations of an increasingly astute patient population and permitted the practice to flourish. Central to the discussion on ageing face surgery is the evolution of facelift surgery, or rhytidectomy. This chapter will provide an overview of the history of facelift surgery and its techniques, and review the senior author's approach to ageing face surgery. The recent resurgence in interest in autologous fat grafting will also be reviewed.

HISTORY OF AGEING FACE SURGERY

The history of ageing face surgery begins with the advent of rhytidectomy, which can be traced back to the dawn of the 20th century. Average lifespans increased sufficiently around this time such that populations began to manifest recognizable signs of ageing. Existential issues of senescence became more salient in the minds of society. Confronted with this phenomenon, clinicians began honouring requests for procedures that would ostensibly slow or reverse the ageing process. Early pioneers of aesthetic plastic surgery were commonly referred to as 'featural surgeons', a pejorative reflecting the underlying sentiment of negativity towards what was considered unnecessary surgery. While many in the medical community shunned the practice of aesthetic surgery, a minority of others recognized the benefits of these procedures and practised in secret on growing numbers of hopeful patients. Unfortunately, public disdain curbed widespread acceptance of plastic surgery and stifled documentation of these early efforts.

Although there is historical debate on the matter, the German surgeon Erich Lexer (1867–1937) is frequently credited as the first individual to describe rhytidectomy, doing so in 1906. Using S-shaped incisions, Lexer excised skin paddles in strategic temporal and preauricular locations to remove lateral rhytids, or wrinkles, which became known as rhytidectomy. Skin excision was conservative and performed only to facilitate closure. Not surprisingly, Lexer's technique resulted in only a subtle improvement. In the ensuing years, other European surgeons including Hollander (1912), Passot (1919), Noel (1920) and Joseph (1921), reported their experiences treating the ageing face. American involvement in facelift surgery occurred at the same time, though virtually independently of European advancements. The first American to publish on the subject was Miller (1907), also one of the first to provide anatomical drawings guiding incision placement. Bettman (1920), another American, was the first to describe the

long incision connecting the pre- and postauricular regions that is now familiar to the modern facelift surgeon. He was also the first to present before and after photographs for publication, now a standard practice.

These early surgeries consisted primarily of limited skin excisions, with predictably limited results. The next step in the evolution of facelift surgery was the practice of wide subcutaneous elevation. This so-called 'long-flap' technique combined with Bettman's incision ushered in the era of subcutaneous rhytidectomy. The technique gained rapid popularity on account of being a technically straightforward operation with a good safety profile; however, it had significant drawbacks. Tension was placed exclusively on the skin flap, leading to a characteristic 'operated' look, and the results were also frequently short-lived due to what is now recognized biomechanically as skin creep and rebound stretching. Despite these flaws, essentially no other significant contributions were made during this early period. Innovations primarily centered on variations of the incisions, but the surgical concept remained unchanged. Subcutaneous rhytidectomy, therefore, remained the standard for nearly 50 years.

The 1970s witnessed two major advancements in ageing face surgery. The first was introduced by Skoog[1] in 1974, who demonstrated the existence of a safe dissection plane below a tough fascial layer spanning the face. His work showed that this plane is continuous with the subplatysmal plane in the neck. By developing a 'short flap' along this plane, the fascial layer could be used as a girdle to lift the skin and subcutaneous tissue together. Skoog reasoned that suspension of this composite unit would generate less tension on the skin, which translated into less visible scarring and more durable results. Indeed, subsequent biomechanical studies have demonstrated this, confirming less rebound relaxation and skin creep.[2] For the first time, Skoog demonstrated how the lower face and upper neck could be safely rejuvenated as one anatomical unit without detaching the skin.

The second major advancement was the description of the superficial musculoaponeurotic system (SMAS), by Mitz and Peyronie in 1976.[3] Their work resulted in a landmark publication confirming Skoog's fascial layer while detailing its anatomical relationship to other facial structures. They demonstrated the SMAS to be a condensed fibrous mesh layer contiguous with the platysma, situated below the subcutaneous fat and over the mimetic musculature and motor branches of the facial nerve. They also described a series of transverse fibrous septations between the SMAS and skin, allowing for the transmission of facial expression. Because the ageing process weakened elasticity of these fibrous septations, Mitz and Peyronie postulated that suspension of the SMAS could aid in re-establishing a youthful facial appearance.

These seminal works laid the foundation for modern approaches to facelift surgery, which are based on suspension of this deep layer. Modern facelifting techniques can be broadly categorized as either SMAS technique rhytidectomies or so-called 'deep plane' rhytidectomies. The SMAS rhytidectomy technique comprises a vast number of variations, from simple suture plication, to more extensive flap dissection and suspension. These techniques treat the subcutaneous and deep layers separately, as opposed to the 'composite flap' featured in deep plane techniques. SMAS procedures allowed for a more natural and durable rejuvenation, particularly of the lower third of the face, when compared to the prior generation of subcutaneous facelifts. The 'deep plane' facelift techniques arose directly from Skoog's 'short flap' technique.[4–6] The concept was pioneered by Hamra in an attempt to achieve a greater effacement of the nasolabial fold, which he felt was not adequately addressed by the SMAS techniques.[4] In the deep plane technique, dissection of the midface transitions from a subplatysmal plane to a deep subcutaneous plane in the cheek to include the malar fat pad. The transition point occurs over the zygomaticus musculature. Hamra later expanded this technique into the 'composite' facelift flap by incorporating the orbicularis oculi muscle in the flap via zygorbicular dissection through a separate subciliary incision. This was done in order to provide improvement of the malar region and address what he saw as disharmony between the adequately rejuvenated jawline and the insufficiently treated midface.

The continuing evolution of today's facelift reflects an increasing understanding of ageing in the critical midface and periorbital regions. In today's ageing face practice, surgeons seek not only to soften the nasolabial fold, but to achieve a smooth transition from the periorbital region, while re-establishing youthful fullness and projection of the cheek. A variety of techniques including suborbicularis oculi fat (SOOF) lifting, orbital fat repositioning or septal reset, and different forms of midface lifting have been developed to achieve these ends.[7–10] These innovations allow surgeons to create natural transitions between rejuvenated facial subunits as part of a balanced full-face surgical rejuvenation procedure.

A complementary though conceptually distinct approach to the ageing face from rhytidectomy is autologous fat grafting. The history of autologous fat grafting dates back to as early as 1893, when Neuber transplanted fat grafts for facial deformities resulting from tuberculous osteitis. Similar to facelift surgery, advancements in the field lay dormant until the 1970s, when a renewed interest in these techniques was born out of the advent of liposuction. Today there is a full-blown renaissance in facial fat grafting, fuelled in part by the work of Sydney Coleman and others, and a rapidly growing public interest in facial fillers in general. Coleman's lipostructure technique,[11, 12] in which large volumes of fat are injected in minute 'parcels' within the subcutaneous space, is regarded by some as a potential replacement for rhytidectomy altogether.[13] There is debate in current practice regarding technical aspects of fat harvest and transfer, but the technique is now widely accepted and in wide clinical practice. In addition, research into adipocyte biology has elucidated the presence of an abundance of growth factors and multipotent stem cells in the harvested lipoaspirates.[14] Therefore the cutting edge of fat grafting includes numerous applications in not only aesthetic surgery but also reconstructive surgery and multidisciplinary regenerative medicine.

BIOLOGY OF AGEING

Facial ageing involves a wide array of biological changes of both intrinsic and extrinsic aetiology. Atrophy is the central process of intrinsic ageing. The facial skin, subcutaneous fat and facial skeleton are each affected and contribute to the ageing face deformity.

Distinct atrophic histological changes occur within the dermis and epidermis. Within the epidermis, the density of keratinocytes and melanocytes declines significantly, creating thinning and abnormal pigmentation of the skin. Langerhans cells, a component of cell-mediated immunity, likewise decrease. Within the dermis, elastic fibres begin to disappear, creating a deficiency in tissue recoil that manifests as excess wrinkling, and there is also a significant decrease in collagen and ground substance. Retraction of dermal papillae and rete ridges causes flattening of the dermal–epidermal junction. In combination, these changes result in the decreased capacity to retain moisture, creating the dryness that typifies aged skin.[15]

Atrophy of subcutaneous fat is another hallmark of facial ageing. The supporting fascial attachments around the fat pads begin to weaken with age. Gravitational forces gradually redistribute these tissues in a more inferior and lateral direction. Consequently, entire subunits, such as the malar fat pad and jowl, become ptotic and contribute to a tired facial appearance.[16–20]

Continuous remodelling of the facial skeleton leads to volume loss with increased age.[20–22] Relative changes can be seen in terms of both volume reduction and expansion. An appreciable reduction in height occurs with modest increases in width and depth. For example, the vertical height of the maxilla decreases while the width of the orbital bones increases. Such changes lead to a disproportionate balance between the available bony surface area and soft-tissue coverage. This process further contributes to inferior displacement of the cheek pad and skin. This same process accounts for jowl formation and sagging along the neckline.

Extrinsic mechanisms of ageing most commonly involve skin damage sustained from solar exposure, known as photoageing. Ultraviolet radiation is well known to contribute to actinic damage through direct or indirect DNA damage. Whereas intrinsic ageing of the skin uniformly results in atrophy of the tissue, actinic changes tend to lead to thickening. In addition, photoageing causes disorganization of dermal elastic tissue fibres, termed elastosis, which contributes to further development of fine skin wrinkles and is a hallmark of the photoageing process.[23]

CLINICAL EVALUATION

Achieving success in ageing face surgery begins with proper patient selection. One of the most critical factors to consider is the patient's psychological motivation for surgery. Multiple studies[24, 25] demonstrate that patient psychology is a significant determinant of post-operative satisfaction in ageing face surgery. The patient who has a stable self-image and internal desire for a more youthful appearance is more likely to be satisfied with the post-operative result. In contrast, the patient seeking surgery to remedy a situational or social dilemma may have unrealistic expectations. This situation often heralds unhappy results.

It is imperative the patient and surgeon are in complete agreement on the indications for surgery and the resulting anticipated changes. Rhytidectomy is an excellent technique to correct visible signs of ageing in the lower two-thirds of the face and upper neck. This includes redundant facial skin and deep rhytids, jowling or loss of a well-defined mandibular contour, and modest improvement of prominent nasolabial folds. Patients should be counselled that rhytidectomy is not effective for superficial rhytids resulting from solar damage or minor depressions secondary to acne scarring. These abnormalities are more appropriately treated with adjunctive techniques, such as laser resurfacing or dermabrasion.

As with any elective procedure, overall good health is a prerequisite in ageing face surgery. Pre-operative evaluation includes a thorough history and review of systems to screen for potential complicating factors. Many patients consider rhytidectomy following significant weight loss. If further weight loss is planned or a history of repeated weight loss and gain is suspected, surgery should be delayed until a plateau is reached. Patients with a history of coronary artery disease, hypertension, pulmonary compromise and hepatic or renal insufficiency should be cleared by the appropriate medical specialist in advance. Relative contraindications to rhytidectomy include predisposition to poor wound healing, as seen in diabetes mellitus, chronic steroid use, connective tissue disorders (such as Ehlers–Danlos syndrome) and past radiation therapy. An absolute contraindication to surgery is a history of a bleeding diathesis.

All medications containing aspirin and non-steroidal anti-inflammatory agents are discontinued at least 3 weeks prior to surgery to minimize bleeding. It is important to enquire about use of supplemental vitamins (particularly vitamin E) and homeopathic preparations (including *Ginkgo biloba* and garlic). These medications are in widespread use but rarely disclosed voluntarily by patients and can contribute to unexpected bleeding.

A history of tobacco use is particularly relevant in the assessment of the ageing face patient. It has been estimated by Rees and Aston that smokers have a 12 times increased risk of skin slough following rhytidectomy compared with non-smokers.[26] This is attributed to a higher incidence of haematoma formation and vasoconstriction. Although long-term effects of smoking on skin cannot be negated by peri-operative cessation, surgical complications can be reduced by smoking cessation within 2 months of surgery.

There is no ideal age when considering timing for ageing face surgery. Chronological age alone should not be used as the qualifying criterion. More importantly, consideration is given to the visible degree of ageing in a particular individual. Patients demonstrating mild to moderate degrees of ageing are more likely to achieve a natural, rejuvenated appearance. Signs of advanced ageing, such as extreme skin sagging, are more difficult to correct and

will limit expected improvement. Rhytidectomy is often an operation of compromise. Dramatic improvement can be made in one region, but this may occur at the expense of suboptimal change in another. In patients with advanced signs of ageing, it is beneficial to strive for less dramatic but more natural change initially, with further refinement at a later date if necessary.

Physical examination begins with assessment of the patient's skin type. An ideal candidate for rhytidectomy is an individual with fair, medium-thickness skin. Dark patients usually have thicker skin and enjoy less dramatic improvement. The increased weight of their skin also results in more post-operative skin relaxation. The presence of a moderate amount of skin elasticity is beneficial. Less elastic skin can be tightened by rhytidectomy, but the duration of improvement may be less satisfactory. A modest degree of subcutaneous fullness is also desirable, particularly in the midface. This reflects a healthy adipose tissue layer and contributes to a more youthful look. This can be enhanced with the use of complementary fat grafting.

Facial skeletal structure can help predict a more or less favourable surgical outcome. Patients with a strong facial skeleton usually demonstrate more obvious improvement. Well-defined bony contours provide excellent support for skin redraping and accentuate desirable facial features. Patients with mid-facial hypoplasia are poor candidates for rhytidectomy alone and typically require adjunctive procedures. Similarly, patients with microgenia and poor chin definition require chin augmentation in conjunction with rhytidectomy to achieve enhanced results.

Many facelift patients express concern regarding skin laxity and fullness in the submental region. This is best appreciated on a profile view by assessing the cervicomental angle. The submentum should be palpated to determine relative contributions from redundant skin, fatty tissue and platysmal banding. Redundant skin alone can usually be addressed with standard rhytidectomy technique by suspension of the cervical skin. Excess fatty tissue is most effectively treated by submental liposuction. Patients with prominent platysmal banding require platysmaplasty to attain a more favourable cervicomental angle. In patients with extreme fatty deposition, platysmal banding may not be appreciated until after liposuction has been performed. Thus, patients should be counselled that platysmaplasty may be indicated in addition to submental liposuction. It is worth noting that a subgroup of patients has an inherent anatomic limitation to the degree of improvement that can be realized in the submental region. These patients have an abnormally low positioned hyoid bone and are considered less ideal candidates for surgery. Such patients should be thoroughly counselled that facelift surgery may not significantly affect their submental profile view, even in conjunction with liposuction and platysmaplasty.

Pre-operative photographs are taken with standardized 1:8 full-face frontal, lateral and oblique views. Digital imaging can be useful in demonstrating to the patient realistic changes that may be expected following surgery.

SURGICAL TECHNIQUES

This section outlines general steps in surgical technique for SMAS rhytidectomy, submental liposuction, platysmaplasty and autologous fat injection.

The patient is marked pre-operatively in the sitting upright position. Areas of special concern are highlighted, as well as anatomical landmarks such as the geniomandibular groove, mandibular border and submental triangle. A pre-operative intravenous dose of an appropriate anti-staphylococcal antibiotic is then administered.

We prefer to perform rhytidectomy under general anaesthesia, but local anaesthesia with intravenous sedation is well tolerated by the patient. Anaesthetic solution containing 1:100 000 epinephrine is infiltrated along the pre- and postauricular borders and in a fan-like fashion beneath the facial and upper cervical skin flaps. If the neck is to be addressed by either liposuction or platysmaplasty, local anaesthetic is additionally infiltrated throughout the submental region. The endotracheal tube is prepped into the surgical field and positioned to allow side-to-side movement during the operation. The entire face, neck and scalp are prepped and draped in sterile fashion.

Careful incision design and placement are vital to achieving natural-appearing results in rhytidectomy. The ideal incision camouflages scar formation, minimizes changes in the temporal and postauricular hairline and avoids distortion of the earlobe. An oblique incision begins in the temporal hair tuft region and varies for the individual patient. If a low temporal hairline is present, the incision is placed within the hair tuft to raise the hairline to a normal position post-operatively. If a normal or elevated temporal hairline is present, the incision is designed to run directly on the hairline to avoid elevating it further. The incision extends posteriorly 2–3 cm, gently curving into the temporal hair. It is then redirected inferiorly toward the root of the helix and into the preauricular crease.

A post-tragal incision is used in most female patients. The incision is positioned 2–3 mm onto the posterior tragal surface and not deep toward its base. It exits at the inferior margin of the tragus and transitions toward the lobule. Alternatively, a pre-tragal incision can be used that courses within the preauricular skin crease. In male patients this incision is placed approximately 1 cm anterior to the preauricular crease to avoid advancing hair-bearing skin too close to the auricle.

The lobule incision can be transposed according to individual need. In patients with a 'hanging lobule', the incision can be placed 1–2 mm below the lobule attachment and readily camouflaged. If a dependent lobule is not present, the incision is made at the junction of the lobule and infra-auricular skin. The lobule incision extends onto the posterior surface of the auricle coursing over the conchal bowl. Approximately 3–5 mm should remain between the incision and the postauricular sulcus. In the male patient, the incision rests within the sulcus to avoid displacing hair-bearing skin onto the ear. The incision extends to the level of the fossa triangularis before turning posteriorly. A less dependent skin flap can be created in patients with a smoking history by limiting the superior extent of this incision.

A V-shaped dart is created as the incision traverses the sulcus and minimizes post-operative webbing. The incision extends into the hair-bearing skin before coursing parallel to the occipital hairline (**Figure 88.1**).

Elevation of the skin flap begins in the postauricular region. The flap is elevated in an avascular plane while preserving the subdermal plexus and thin fatty layer on the undersurface of the skin. Elevation continues into the neck in a supraplatysmal plane. The preauricular skin flap is elevated in a similar manner. Near the zygomatic arch, dissection is limited to the posterior one-third of the arch to avoid potential frontal nerve injury. A full-thickness skin flap is elevated off the tragal cartilage. This facilitates redraping of the skin and helps maintain the natural tragal contour. The preauricular skin flap is elevated approximately 9 cm anteriorly and can be extended over the jawline into the neck. Dissection in the neck is most commonly performed in the subcutaneous plane. In many patients, liposuction of the neck can be performed without connecting the preauricular with the neck dissection.

Once the skin flap is elevated, the SMAS is identified. A horizontal incision is made in the SMAS just below and parallel to the zygomatic arch but limited to the posterior one-third segment. This connects to a vertical limb coursing 2 cm anterior to the tragus. The SMAS incision should not extend beyond the angle of the mandible because the marginal mandibular nerve is in close proximity. The SMAS flap is elevated approximately 3–5 cm (**Figure 88.2**). In many cases the platysma is incorporated as an extension of the SMAS. The SMAS flap is then advanced and primarily pulled in a superior vector with a slight posterior vector. Maximal pull should be avoided when suspending the first side as this may restrict mobility of the contralateral side and result in facial asymmetry. A triangular segment of SMAS is excised and the edges of the SMAS flap are then sutured to the dense fibrous tissue at the inferior margin of the zygomatic arch and the preauricular SMAS. Multiple 4-0 PDS and 5-0 nylon sutures can be used for this SMAS imbrication. In some patients, a postauricular SMAS flap can be dissected and suture plicated to the mastoid periosteum (**Figure 88.3**).

After tightening the SMAS, the skin flap advances easily over the face. The postauricular skin is pulled superiorly and slightly anteriorly, whereas the preauricular skin is pulled superiorly and slightly posteriorly. The postauricular skin is temporarily anchored at its superior margin with staples. Similarly, the superior margin of the preauricular skin is anchored to the temporal hairline. After careful

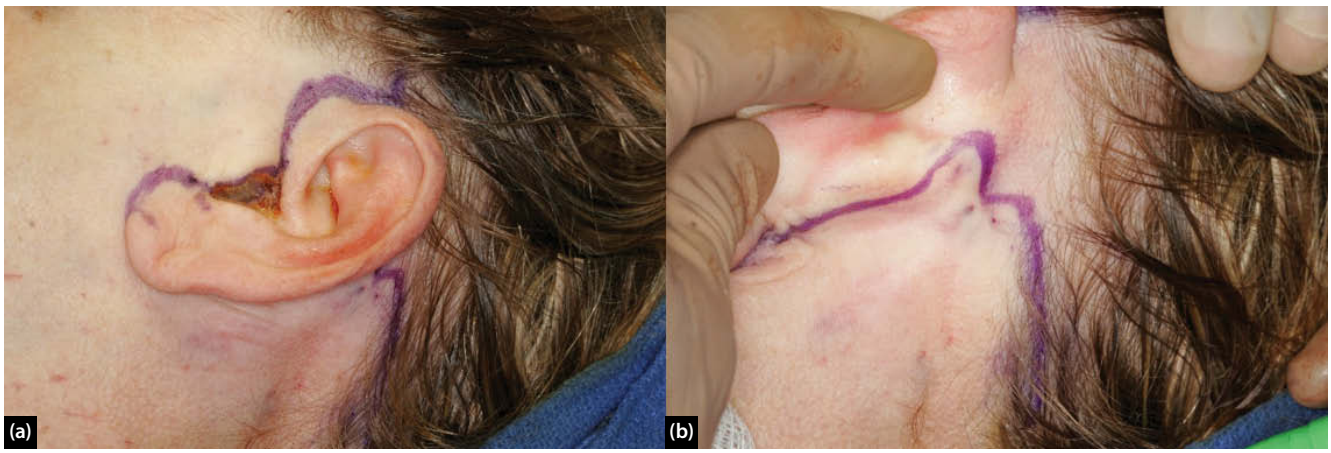

Figure 88.1 The post-tragal incision is placed just behind the tragal cartilage (a). Note how the outline of the tragus is defined by the incision. The postauricular incision **(b)** runs along the posterior surface of the conchal cartilage with a V-shaped dart in the posterior limb of the incision as it moves toward the hairline. This acts to break up the scar and prevent contracture.

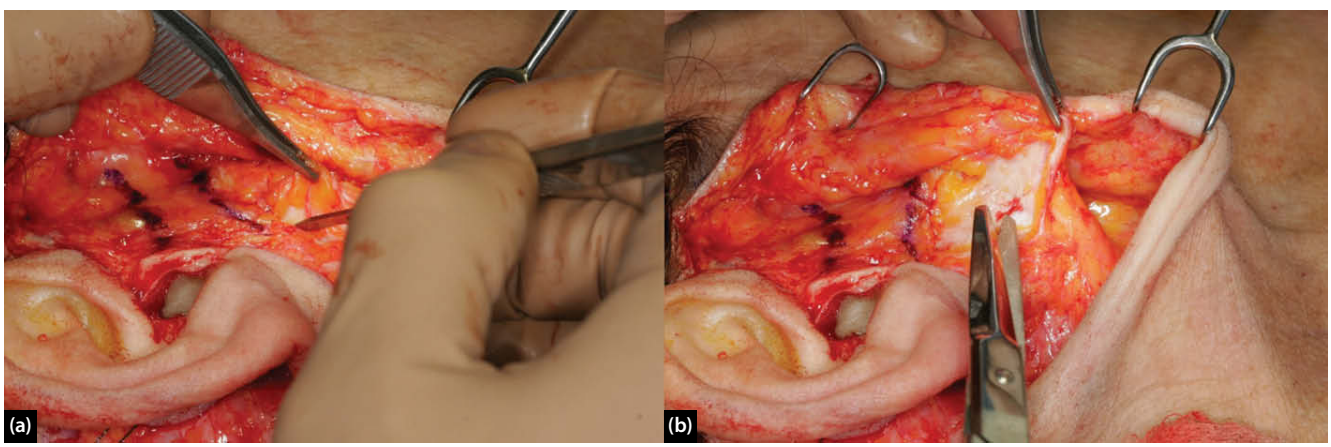

Figure 88.2 The SMAS is incised after elevation of a subcutaneous flap (a). A sub-SMAS flap is carefully elevated from below the zygomatic arch extending anteriorly and inferiorly **(b)**.

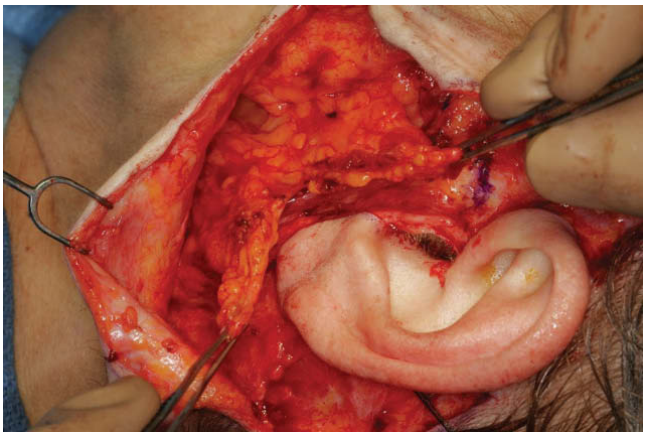

Figure 88.3 The SMAS flap is advanced superiorly and slightly posteriorly. In this case the flap was bifurcated and separately suspended to the preauricular SMAS below the zygoma, and to the mastoid periosteum.

measurement, the excess skin is sharply trimmed. The tragal skin flap should be thinned sufficiently to allow natural redraping over the cartilage. It is imperative to avoid excess skin tension as displacement of the tragus can easily result. Meticulous care should be taken to realign the occipital and temporal hairline.

Attention is then focused on the portion of the skin flap hammocking the lobule. The skin is sharply divided to 'release' the lobule, leaving a significant hammock effect on the lobule. This support on the lobule will help prevent a satyr ear deformity due to post-operative settling of the earlobe. The excess skin is trimmed to recreate a natural lobule contour. It is important to minimize tension placed on this closure.

The entire incision is closed in a layered fashion over a ¼-inch Penrose or suction drain. The subcutaneous layer is closed with 5-0 polydioxanone sutures. The temporal, preauricular and lobule skin segments are closed with 6-0 nylon vertical mattress sutures. The postauricular skin is closed with 5-0 fast-absorbing plain gut suture. Antibacterial ointment is applied to all incision lines followed by a dry gauze pressure dressing.

All rhytidectomy patients are observed overnight. The following morning, the drain is removed and a pressure dressing is reapplied. Antibiotics are prescribed for a total of 10 days post-operatively. Sutures are removed 7–10 days after surgery. Oedema resolves over several weeks and facial contour stabilizes at approximately 4–6 weeks after surgery. Erythema of the tragal incision should fade over several months (**Figure 88.4**).

SUBMENTAL LIPOSUCTION AND PLATYSMAPLASTY

When indicated, submental liposuction and platysmaplasty are performed prior to the rhytidectomy. A midline incision is made within the first well-developed submental crease posterior to the mandible. If liposuction alone is planned, this is limited to a 5 mm stab incision. If a wider incision is later needed for platysmaplasty, the stab incision should be made initially to maintain vacuum pressure during liposuction.

A wide variety of liposuction cannulas exists, ranging from flat to round-tipped with an array of suction port designs. Surface irregularities appear to be minimized with the use of smaller cannulas. We prefer pre-tunnelling with a 2 mm cannula followed by applied low suction. The cannula is inserted into the subcutaneous space between the dermis and platysma. The dominant hand controls movement of the cannula while the contralateral hand guides tip position. Pre-tunnelling involves limited dissection to facilitate passage of the larger cannula. Liposuction is performed by dissecting with the cannula in radial fashion away from the incision. One atmosphere (760 mmHg) of negative pressure is usually sufficient. The suction port should always be directed away from the skin to minimize dermal trauma and dimpling. Uniform suctioning is performed across the submental triangle down to the hyoid bone. Liposuction should be limited near the inferior border of the mandible to avoid injuring the marginal mandibular branch of the facial nerve. Periodic inspection of the skin using the 'pinch and roll' technique helps determine the degree and extent of liposuction required. A sufficient amount of fat should remain to preserve natural skin cushioning.

Platymasplasty requires creation of a slightly wider submental incision. Blunt scissor dissection is used to expose the medial border of the platysma muscles. Residual fat surrounding the incision and between the muscles is removed under direct vision. If minor platysmal banding is present, plication of the exposed muscle borders across a short distance is sufficient to improve the submental contour. In patients with severe platysmal banding, both muscles are horizontally incised at the level of the hyoid bone. The muscles are then plicated anterior to this incision, thereby recreating a well-defined cervicomental angle. The submental incision is closed in a layered fashion.

AUTOLOGOUS FAT TRANSFER

The patient is marked in the pre-operative holding area in an upright position with the patient in neutral gaze. Areas of volume deficiency are carefully noted. These typically include the nasojugal, submalar, malar, nasolabial and geniobuccal regions. Marionette lines and prejowl sulci can be filled to restore a more youthful shape. The submental crease can be augmented to ease the transition to a ptotic chin. Areas of concern are addressed based on extensive pre-operative discussion with the patient with the aid of digital photographs. Potential donor sites are examined. The most easily accessed harvest sites during an aesthetic facial surgery are those that do not require significant patient repositioning, including the abdomen, flanks and lateral thighs. The medial thigh is a potentially robust donor site but requires minor repositioning to a frog leg position to facilitate harvest. Quite frequently, autologous fat grafting is undertaken in conjunction with other

Figure 88.4 Patient treated by SMAS imbrication rhytidectomy with upper and lower lid blepharoplasty, submental liposuction, platysmaplasty and chin augmentation. Pre-operative views (top row). Post-operative views (bottom row).

aesthetic facial surgery to achieve an optimal result. Thus, it is most aptly considered a complementary procedure.

We usually undertake fat grafting as part of an extended procedure requiring general anaesthetic. However, fat grafting can be performed under the spectrum of anaesthetic options. During surgery, the donor sites are prepped into the sterile field. A small aliquot of local anaesthetic is infiltrated subcutaneously at the site of planned incisions. A 11 blade scalpel is used to create a 3 mm stab incision at the site of planned harvest. Incisions within the umbilicus are placed within a natural skin fold if present.

A tumescent liposuction technique is used to harvest the fat for transfer. Tumescent solution containing 20 mL of 1% lidocaine and 1 amp of epinephrine in 1 L of isotonic saline is infiltrated into the subcutaneous fat plane using a blunt-tip cannula. The tumescent solution is permitted to stand for a period of time prior to liposuction to allow for adequate vasoconstriction. Fat is then harvested using a liposuction technique similar to that described above. A 2–3 mm blunt multihole cheese grater type cannula is preferred for the harvest. Careful attention is paid to the plane of harvest to avoid irregular scarring of the dermis or entry into the abdominal cavity. The non-dominant hand continuously palpates the depth of the cannula and controls its movement. The amount of fat required for facial injections is typically well below the volume

performed in a standard liposuction procedure, which decreases the morbidity of the technique substantially. Patients should be counselled not to expect a significant aesthetic improvement at the donor site.

Once the fat is harvested, it is transferred from the suction cannister and placed in 10 mL Leuer-lock syringes. These syringes are capped and placed in a centrifuge in sterile sleeves and spun at 3000 rpm for 3 minutes. The infranatant is drained away and the fat is placed in 1 mL tuberculin syringes for injection.

For introduction of the injection cannula, 3 mm stab incisions are created with a 11 blade scalpel. A typical injection can be accomplished through three such incisions on each side, in the submalar region, the base of the nasolabial fold and the peak of the geniobuccal sulcus adjacent to the corner of the mouth. Additional incisions can be placed as needed. The premarked regions are then carefully injected with fat using a blunt 20 G injection cannula (**Figure 88.5**). Constant controlled motion and attention to the depth of injection help prevent irregularities. Microaliquots of fat are carefully deposited in multiple tissue planes. The volume is determined by the degree of deficiency and the patient's goals for rejuvenation. Special attention is paid to the depth of injection in the nasojugal region and along the orbital rim, where thin skin is very unforgiving of irregularities. The non-dominant hand protects the orbit during injections of the upper midface near the eyelid–cheek junction. When completed, the incisions can be closed with a single fast-absorbing gut suture. **Figure 88.6** shows pre- and post-operative photographs of a patient who underwent autologous fat grafting using the above technique.

COMPLICATIONS

Haematoma

Haematoma formation is the most common complication of facelift surgery. In most modern series, the incidence of haematoma is reportedly less than 4%.[27] A majority occur within 48 hours post-operatively and often within the initial 6–8 hours. Poor haemostasis, extended skin flaps and severe hypertension have all been purported to be influential factors.[28] Some haematomas are so small they are considered clinically insignificant and can be observed expectantly. Others result in a discrete pooling that should be addressed in a timely manner with aspiration using a large-bore needle. Alternatively, a small stab incision made within a well-developed skin crease will allow adequate drainage. Application of a pressure dressing may help in preventing recurrent formation.

An expanding haematoma is a surgical emergency requiring immediate attention. This is heralded by acute swelling, pain and discolouration along the buccal surface. All surgical dressings must be removed and the skin flaps inspected closely. If flap viability is in question, the immediate removal of consecutive sutures may temporarily restore adequate circulation. Exploration of the wound and evacuation of all visible clot, preferably in the operating room, is mandatory. In a majority of cases, the specific source of bleeding is never identified.[29] Nonetheless, failure to recognize and treat haematoma can result in abnormal pigmentation, alopecia, skin puckering and flap necrosis.

Nerve damage

Nerve damage resulting from rhytidectomy is a rare occurrence. Baker and Conley reported a 0.1% incidence of permanent nerve damage in a series of 6500 rhytidectomies.[30] The most commonly injured branch is the great auricular nerve. Mechanisms of injury include inadvertent dissection deep to the sternocleidomastoid fascia, plication of the postauricular SMAS and transmission of the thermal electrocautery. In most cases, the integrity of the nerve has not been disrupted and full return of sensation can be expected.

Branches of the facial nerve are the most commonly injured motor nerves in rhytidectomy. Proximity to the plane of dissection, especially during elevation of the SMAS, makes them particularly vulnerable to mechanical injury. The frontal nerve is most often injured during SMAS elevation near the zygomatic arch. Within this region, the frontal nerve becomes increasingly superficial as it courses over the middle segment of the arch. If surgical

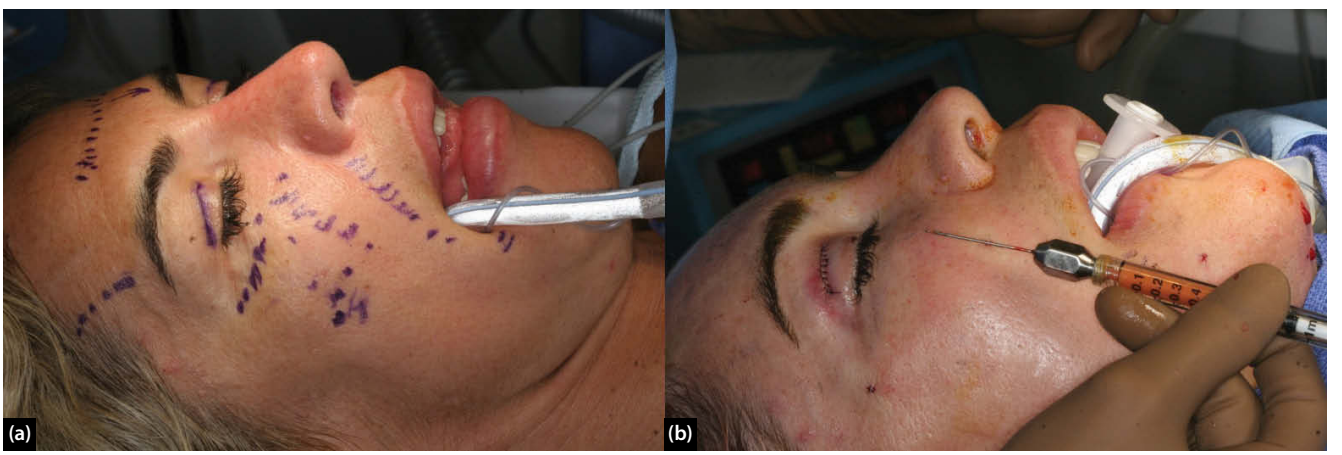

Figure 88.5 Markings for facial fat injection (a left). Intra-operative view during injection procedure **(b right)**. An injection cannula is used for infiltration.

Figure 88.6 Patient treated by facelift, endoscopic browlift and upper blepharoplasty with autologous fat injection. Pre-operative views (top row). Post-operative views (bottom row).

dissection is limited to the posterior one-third of the arch, risk to the frontal nerve branch is virtually negated. Injury to the marginal mandibular nerve typically results from transection of the platysma or excess SMAS retraction near the angle of the mandible. Fortunately, nearly 85% of paralyzed motor branches will recover spontaneously with minimal residual deficits.

Skin slough

Skin slough most commonly arises as a consequence of unrecognized and untreated haematoma. Excess skin tension and disruption of the subdermal plexus are also frequent causes. The toxic effects of smoking have long been recognized as another predisposing factor in skin sloughing.[31] The postauricular flap is at greatest risk because skin tension is typically highest in this region. Dependent flap length is also maximal and the skin is relatively thin along this surface. In general, expectant management with meticulous wound care is the rule for skin sloughing. However, frequent visits and repeated patient reassurance are necessary. Superficial epidermal sloughing typically results in an acceptable appearance after healing. In cases of full-thickness sloughing, eschar formation is

seen and serial debridement is required to promote healing by secondary intention. Invariably, patients with full-thickness loss can expect some degree of hypertrophic scarring and abnormal pigmentation.

Alopecia

Alopecia in the temporal region is a common complication of rhytidectomy and one that is easily avoided with careful incision design and placement. In some cases alopecia is a transient phenomenon, termed telogen effluvium, attributed to temporary follicular shock. In other instances alopecia is more permanent, for example when the hair follicles have been injured by thermal electrocautery. If no evidence of regrowth is noted after a waiting period of 4–6 months, hair restoration can be attempted using either micrografts or local skin flaps.

Satyr ear deformity

Satyr ear, or 'devil's ear' deformity, results from improper incision placement around the lobule and/or overzealous excision of the skin flap. Tension caused by post-operative relaxation of skin leads to an inferior displacement of the lobule and abnormal banding. This complication can be avoided by preserving a tight supporting margin of skin below the lobule attachment that actually pulls up on the lobule.

Complications of fat injection

When performed correctly, fat grafting by injection is a safe technique with few and rarely significant complications. Irregularities of contour are the most frequently encountered complication. These can range from a discrete focal irregularity that can be managed with simple excision, to generalized overcorrection, which is very difficult to manage. Intralesional steroid injection, ultrasound therapy and local massage all represent viable conservative treatment methods of minor focal deformities. The transplanted fat can be susceptible to changes in weight, particularly large amounts of weight gain, which lead to the overcorrection deformity. Pre-operative counselling should clearly address these issues, and a conservative approach to fat grafting is always preferable. Donor site morbidity can include haematoma, infection, bruising and dermal scarring. These can be minimized with careful harvesting technique.

The most serious complication of fat or other filler injection to the face is inadvertent intravascular injection resulting in embolism, which can lead to serious adverse events including blindness, stroke and local tissue ischemia or necrosis.[32] Marked local blanching of the skin is a warning sign and should lead to a heightened degree of suspicion. Immediate actions that can be taken include applying nitropaste locally, performing local massage and placing the patient in the Trendelenburg position.[13] Better still is to practise careful injection technique to minimize this risk, by using blunt-tipped cannulas with initial aspiration, low injection pressures, small volumes per pass, or local epinephrine to induce vasoconstriction. As always, the clinician should develop an injection plan based on a detailed understanding of the underlying facial vascular anatomy.

BEST CLINICAL PRACTICE

- ✓ A post-tragal facelift incision is used in most female patients, while a pretragal incision is used in males.
- ✓ Elevation of the skin flap and SMAS flap should be limited to the posterior one-third of the zygomatic arch to avoid injuring the frontal nerve branch.
- ✓ The postauricular skin flap is suspended superiorly and anteriorly, while the preauricular skin flap is suspended superiorly and posteriorly. It is imperative to avoid excessive tension on any portion of the skin flap.
- ✓ Submental liposuction and/or platysmaplasty should be considered in patients with neck fullness not attributed to excess skin alone.
- ✓ Post-operative haematoma formation requires timely assessment and intervention to minimize chances of a suboptimal aesthetic outcome.
- ✓ Facial fat injections must be performed carefully with proper technique to avoid complications.

FUTURE RESEARCH

- ➤ Advances in rejuvenation of the midface and upper third will allow for more natural surgical rejuvenation.
- ➤ Techniques and applications for fat grafting will continue to expand, particularly as the underlying biology is better understood.

KEY POINTS

- Sun damage to the skin, atrophy of tissues and the effects of gravity bring on the changes seen in the ageing face patient.
- Pre-operative analysis is critical to determine the specific needs of the patient.
- Incision placement is critical to help hide incisions and avoid deformity of the hairline.
- Patients must stop smoking cigarettes 3–4 weeks before surgery to avoid vascular compromise and necrosis of skin flaps.
- Dissection of the SMAS allows correction of jowling over the body of the mandible and neck deformity. Placement of tension on the SMAS plication takes tension off the skin closure.
- The most commonly injured nerve in facelift surgery is the great auricular nerve.
- The incidence of haematoma formation is less than 4%. An expanding haematoma constitutes a surgical emergency.
- Facial fat injection is a valuable adjunct to ageing face surgery, as it directly addresses facial volume deficiency associated with ageing.

SEARCH STRATEGY

Data in this chapter may be updated by a search of PubMed using the keywords: non-surgical face, look younger, hyaluronic acid fillers, collagen stimulation, polycaprolactone, botulinum toxin, botox, retinoids and chemical peels.

INTRODUCTION

Ageing transforms the face to create a look that often does not reflect the vibrant person inside. Maintaining a youthful appearance can have a profound effect on self-esteem and personal and professional relationships; the exponential uptake of facial aesthetic procedures requires no further explanation. In this chapter, an overview of the core non-surgical interventions which are recognized to be safe and effective is provided.

The causes of ageing in relation to facial appearance may be intrinsic or extrinsic. Intrinsic skin ageing is caused by the same genetic pathways that lead to ageing of all the other organs of the body; thin, atrophic, hypopigmented and fragile skin results from a total reduction in cell count and function. Intrinsic ageing of the subcutaneous tissues is also highly relevant as bone resorption, muscle atrophy and variable atrophy and hypertrophy of individual fat compartments leads to ptosis of the soft tissues, sagging, hollowing and rhytids.

Extrinsic skin ageing is caused by lifestyle and environmental factors. Notably, skin ageing is rapidly accelerated from excessive exposure to ultraviolet light and smoking; several observational and twin studies have demonstrated this. Recent evidence suggests that environmental hydrocarbon pollution and infrared light exposure may also be contributory to skin ageing. The results of extrinsic ageing are the presence of increased fine and deep lines from loss of elastin and collagen fibres, solar elastosis from the disorganization of elastin fibres creating a sallow colour tone, hyperpigmentation usually in the form of solar lentigines, and erythema from telangiectasias. These characteristics are often referred to as the signs of 'photoageing'.

It is important to establish the concerns of any patient considering non-surgical treatments. Typically, these are to improve the appearances of fatigue, to appear less angry and negative, and to brighten skin tone and freshness. In general, the desire to appear 'well' and optimum for chronological age, and to maintain this, is a frequent and realistic goal. Looking substantially younger or back to a certain stage in life is perhaps more unrealistic and must be addressed in the pre-procedure consultation.

Broadly speaking, non-surgical treatment modalities may be considered by anatomical layer depending on whether they address changes in the epidermis (e.g. topical treatments and chemical peels), atrophy and inelasticity of the dermis (e.g. topical treatments, chemical peels and fillers), dynamic facial lines caused the pull of the underlying muscles of facial expression (e.g. botulinum toxin injections), and loss of volume at sites of fat or bone resorption (e.g. fillers). Effective facial rejuvenation requires a treatment plan to fit the unique requirements of an individual patient, and providers ought to be familiar with a range of treatment modalities that allow this to be provided. All too often, many doctors, even those who specialize in facial aesthetics, are 'married to one therapy' and this may not be conducive to optimal outcomes.

TOPICAL TREATMENTS AND COSMECEUTICALS

Topical treatments are popular among consumers seeking improvement of cutaneous signs of ageing because of their convenience, low cost and excellent safety profile. While results may be modest, topical treatments often represent a starting point before progressing towards more invasive facial rejuvenation treatments. A myriad of products are available on the market and this causes confusion for consumers and physicians alike. The relative lack of regulatory restrictions on cosmetics has allowed a range of products categorized as 'cosmeceuticals' to flourish. These are cosmetic products which are purported to provide superior benefits to the skin compared to simple cosmetics while not affecting the structure and function of the skin, as this would otherwise classify them as drugs. The level of evidence required by cosmeceuticals falls significantly short of those required by medicinal products. A greater reliance on *in vitro* data, which is often extrapolated to human skin, is frequent for cosmeceuticals. This allows exemption from the heavy regulatory requirements that *in vivo* research may bring about and which may show changes to structure and function of the skin and cause products to be classified as medicinal instead.[1] Somewhat exaggerated claims of efficacy, often based on *in vitro* data alone, are also not uncommon, which further adds to the confusion.

It is unsurprising therefore that consumers often look towards their physician for advice and recommendations. The yield for physicians is also quite high as, aside from providing an opportunity to build a therapeutic relationship with appearance-conscious patients, 40% may go on to use physician-recommended topical products following initial consultation. Of these, one-third will undergo chemical peels and up to one-quarter will undergo facial injectable treatments in the future.[2] Topical treatments may therefore be considered the first rung of the non-surgical rejuvenation ladder. A topical treatment plan is tailored to the individual needs of a patient and may be designed to target one or more indications (**Table 89.1**).

A selection of topical agents, both medicinal and cosmetic, that a facial plastic surgeon may wish to become familiar with are discussed further here. An in-depth assessment of all available agents is outside the scope of this chapter and the reader is referred to the many excellent texts available on the subject.[3] Advice on the avoidance of lifestyle factors which cause accelerated skin ageing and increased perceived age, such as excessive sun or sunbed exposure and smoking,[4] should supplement and underpin a topical rejuvenation plan.

TABLE 89.1 Indications for topical treatments

Concerns	Clinical signs
Ageing	Fine lines, poor skin texture, photodamage, solar elastosis, atrophic skin
Pigmentation	Solar and post-inflammatory pigmentation
Inflammation	Dry skin, redness and sensitivity
Follicular disorders	Acne, rosacea, folliculitis, enlarged pores

Prescription topical products

RETINOIDS

Retinoids are found in medicinal preparations (requiring a prescription) or in milder forms in over-the-counter formulations (**Table 89.2**). Their use for the treatment of acne dates back to 1959. Kligman's seminal studies in the early 1980s first established the role of tretinoin for the reversal of skin ageing.[5] Since then, over 20 randomized studies have shown the benefits of tretinoin in photodamaged skin.[6] Prescription topical retinoids are the most powerful, effective and evidence-based topical anti-ageing product currently available. Consequently, topical retinoids should form the cornerstone of any topical rejuvenation plan.

The profound biological effect of retinoids on the skin results from their direct action on a family of nuclear hormone receptors, the retinoic acid receptors (RARs) and the retinoid X receptors (RXRs). These receptors are found in all cells, though the key targets are keratinocytes and melanocytes in the epidermis and fibroblasts in the dermis. Activation of retinoid receptors leads to a molecular chain of events that changes protein transcription and modifies cellular function. Histologically this leads to epidermal hyperplasia and impaction of the stratum corneum (producing smoother skin with a 'glow'), increased dermal collagen type I, III and VII synthesis, reduced collagen breakdown and normalization of elastic tissue organization (improving coarse wrinkling and crepe-like skin texture), and a reduction in melanin synthesis and transfer of melanosomes to keratinocytes (improving solar pigmentation).[6] Epidermal effects are seen within 6 months of use, while dermal effects may take a year or longer to become apparent. Treatment ought to be continued indefinitely for continued benefit.

A concentration of tretinoin of 0.025% is considered therapeutically effective while minimizing side-effects. Greater concentrations are associated with a higher incidence of cutaneous toxicity including erythema, scaling, pruritus and sensitivity, and may produce only marginal, if any, additional clinical benefit. Side effects may also occur at lower concentrations and are the most important cause of non-compliance. A typical regime involves the application of tretinoin 0.025% once at night. Strategies to minimize side-effects include using small quantities on

TABLE 89.2 Classification of topical retinoids

Availability	Topical retinoid
Prescription	Tretinoin (all-*trans* retinoic acid) Isotretinoin (13-*cis* retinoic acid) Adapalene Tazarotene
Over-the-counter	Retinaldehyde Retino (all-*trans* retinol, Vitamin A) Retinyl ester

alternate nights initially and gradually increasing this to 1–2 g every night, avoiding astringents, scrubs and detergent-based products, and frequently applying a moisturizer throughout the day. The thinner and more sensitive skin of the eyelids and neck is unlikely to tolerate tretinoin 0.025%, even with incremental exposure, and a compromise is to use an over-the-counter retinol-containing product to these areas. More modest effects are expected as retinol is 20 times less strong.[6]

Non-prescription topical products

HYDROXY ACIDS

The variety of compounds that constitute hydroxy acids is summarized in **Table 89.3**. Many of these have naturally occurring sources. The bathing of Egyptians in soured milk (lactic acid) for beautification over two millienia ago is likely the earliest documented evidence of the use of hydroxy acids for aesthetic skin enhancement.

Alpha-hydroxy acids (AHAs) are the most commonly encountered hydroxy acid in aesthetic formulations. When AHA is applied on pathologically scaly skin such as that found in hereditary ichythosis, the thick stratum corneum separates and a normal thickness epidermis results. The opposite occurs when it is regularly applied on atrophic and aged skin where the epidermis is noted to thicken over a period of several months and revert to a normal thickness.[7] Typically, over-the-counter formulations have concentrations of AHA in the range of 10–12% and are used once or twice a day. A 22-week double-blind randomized controlled trial showed superiority of 8% AHA cream over vehicle in improving the signs of photodamage and sallowness to the skin.[8]

Dermal thickness may also increase from the daily application of AHA because of increased deposition of glycosaminoglycans in the dermis.[7] In addition, glycolic acid has been shown to increase fibroblast proliferation and collagen synthesis.[9] Dermal effects are likely only to occur with higher concentrations of AHA (20–25%) which are available in prescription compounded preparations, though a greater incidence of irritant side effects is found. Higher concentrations still (>25%) constitute superficial chemical peels and are applied once, under the supervision of a clinician, and repeated after a period of time.

TABLE 89.3 Classification of hydroxy acids

Hydroxy acid group	Example	Found in
Alpha-hydroxy acid (AHA)	Glycolic	Sugar cane
	Lactic	Sour milk
	Mandelic	Bitter almond
	Citric	Lemon, orange
Beta-hydroxy acid (BHA)	Beta-hydroxybutanoic	Urine
Polyhydroxy acid (PHA)	Gluconic	Skin
	Gluconolactone	Skin
Aldobionic acid	Lactobionic	Lactose from milk
	Maltobionic	Maltose from starch
Aromatic hydroxyl acid	Salicylic	Winter green leaves

VITAMINS

The concept that vitamins may have a beneficial effect on the skin is very easy to grasp by patients, and additional topical vitamins may easily be introduced after establishing patients on a topical retinoid ('vitamin A cream').

Vitamin B3 (nicotinamide)

Nicotinamide (niacinamide) is the active form of vitamin B3 and is a precursor to a family of enzyme cofactors integral to cellular metabolism. In addition, nicotinamide inhibits poly (ADP-ribose) polymerase-1 (PARP-1).[10] When taken orally at a dose of 500 mg twice a day for 12 months, nicotinamide reduces the incidence of actinic keratosis, basal cell carcinoma and squamous cell carcinoma in individuals who have previously had non-melanoma skin cancer.[11] A 4% nicotinamide gel is available over the counter in the UK and has been shown to be effective for acne,[12] while 2% nicotinamide cream applied to the face for 4–6 weeks reduces sebum production, and improves facial shine and oiliness.[13] A split face study reported that 5% nicotinamide cream applied twice daily for 12 weeks improved fine lines and wrinkles, hyperpigmented spots, red blotches and sallowness while also improving skin elasticity.[14]

Vitamin C (ascorbic acid)

Vitamin C is a potent antioxidant and a cofactor in the collagen synthesis pathway. It may also inhibit tyrosinase and so prevent excessive melanin production, and improve hyperpigmentation. Topically, it is available in concentrations of 5–20%. A 5% cream applied for 6 months to the lower neck and arms of 20 women aged 51–59 years led to significant improvements in the visible signs of ageing though skin biopsy did not show altered levels of collagen.[15] A 23.8% preparation applied for 2 weeks improved several parameters including roughness, fine lines and hyperpigmentation without any significant side effects.[16] A 15% vitamin C may be more stable when combined with 0.5% ferulic acid, a plant-based antioxidant, and together with 1% vitamin E, this triple combination formulation doubles the dose of ultraviolet light required to cause sunburn.[17]

BOTANICAL PRODUCTS

Several hundred botanical remedies for skin disorders exist. There is a perception among the public that botanical products are safe, 'natural' and effective purely by virtue of their origin. The lack of high-quality clinical data makes it difficult to place the utility of botanical compounds into the context of day-to-day clinical practice. A selection of commonly found botanical compounds is included in **Table 89.4**. This list is by no means exhaustive.

TABLE 89.4 A selection of botanical ingredients found in topical preparations and their purported effects

Botanical ingredient	Effect(s)
Aloe	Antioxidant, anti-inflammatory
Arbutin	Skin lightening
Caffeine	Anti-ageing
Co-enzyme Q10	Antioxidant, anti-ageing, skin lightening
Green tea	Antioxidant, anti-inflammatory, anti-ageing, skin lightening
Kojic acid	Skin lightening
Lycopene	Antioxidant, anti-ageing
Polypodium leucotomas extract	Antioxidant, anti-inflammatory
Soy	Antioxidant, skin lightening

In summary, topical treatments are the least invasive of all cosmetic interventions, and providing these may facilitate the engagement of patients who are initially hesitant to have injectable or other more invasive treatments. The physician is under an ethical obligation to recommend products which are effective and in the best interests of the patient.

CHEMICAL PEELS

Chemical peeling is the topical application of chemical agents to cause controlled destruction of part or all of the epidermis, with or without the dermis. This leads to desquamation, liquefaction and coagulation of the affected layers, followed by inflammation, and finally regeneration of epidermal and dermal tissues.

Indications for chemical peeling include fine lines and wrinkles, pigmentation disorders such as solar lentigines and melasma, superficial acne scars and benign epidermal growths. Peels can be classified according to the chemical compounds used or the depth of chemical injury that is produced. Results, recovery time and complication rates vary according to the depth of peel.

Superficial chemical peels are limited to the epidermis and are popular among patients as they are effective while carrying low costs, low complication rates and minimal downtime. Safety in all skin phototypes has been established and recovery within 1–3 days is expected. Superficial peels can be performed with various compounds including trichloracetic acid (TCA) at concentrations of 15% and under, alpha hydroxy acids such as lactic and glycolic acid, and Jessner's solution (14% lactic acid, 14% resorcinol and 14% salicylic acid).

Alpha hydroxy acids, in particular glycolic acid (GA), are commonly used superficial chemical peeling agents. GA peels in concentration ranging from 20% to 70% have been shown to be effective in reducing facial hyperpigmentation and fine lines/wrinkles.[18] Salicylic acid peels have a similar profile, and may be more beneficial for acne-prone skin.[19]

Superficial peels are delivered at 2–4-weekly intervals (typically by an aesthetician), and patients frequently report smoother skin which 'glows', as well as tighter pores and fewer inflammatory acne lesions. Patients often 'feel' the results. Lightening or disappearance of solar lentigines and melasma is also possible. As the target of superficial chemical peels is the epidermis, true dermal changes are minimal (if any) and no number of superficial chemical peels can equate to the skin tightening and improvement in rhytids that a single, correctly performed medium-depth chemical peel may achieve.

Medium-depth peels produce chemical injury to the level of the papillary dermis or the very highest part of the reticular dermis. Due to their depth of penetration, medium-depth peels can produce tissue tightening and an improvement in lines and wrinkles produced by an increase in collagen production and reorganization of elastic bundles. The typical agent used for medium-depth chemical peeling is TCA at concentrations over 30%. TCA is a crystalline inorganic compound which causes coagulative necrosis through extensive protein denaturation. The degree of necrosis varies with the concentration of solution applied.

Monotherapy with 50% TCA may penetrate to the desired depth but carries a high incidence of scarring and should be avoided. A better strategy is to pretreat the skin with Jessner's solution, GA or carbon dioxide slush, to make the epidermis more permeable, and subsequently apply 30–35% TCA. This strategy reduces the risk of scarring from TCA substantially, though pigmentary changes are frequent in darker skin types and medium-depth chemical peels are best reserved of skin phototypes I–III. The reader is referred to an excellent review article on medium-depth TCA peeling by Herbig et al.[20]

BOTULINUM TOXIN

'Botox' has been the most revolutionary anti-ageing treatment in recent years. Doctors Jean and Alastair Carruthers noticed that, when they used botulinum toxin to treat patients with ocular spasms, the wrinkles around the eye disappeared. These results encouraged doctors to treat lines of facial expression such as frown lines, horizontal forehead lines, periorbital lines, nasal lines, perioral lines and platysmal bands.

Botulinum toxin type A (BTX-A) is produced by *Clostridium botulinum*. Synthesized as a single-chain polypeptide of ~150 kDa, BTX has relatively little potency until it is cleaved by trypsin or bacterial enzymes into two chains, a heavy chain of 100 kDa responsible for binding to the target structure and a light chain of 50 kDa known as the toxifying chain. These two chains are linked together by a disulfide bond. The light chain contains a Zn^{2+}-binding motif with enzymatic activity. BTX-A is a zinc-dependent endopeptidase.

When BTX is injected into a muscle, the heavy chain of the molecule binds to glycoproteins expressed specifically on cholinergic nerve endings. After internalization of the whole molecule by pinocytosis, the chains are cleaved within the cytoplasm. The light chain binds with high specificity to the soluble N-ethylmaleimide-sensitive

fusion (SNARE) attachment protein receptors essential for exocytosis of acetylcholine. BTX-A cleaves plasma membrane synaptosome associated protein (SNAP-25) that results in a blockade of vesicle fusion.[21]

Around 2–5 days after BTX is injected into a muscle, paresis occurs, which lasts for at least 3 months and gradually starts to wear off. When the muscle relaxes, it stops pulling on the skin and the wrinkle caused by the muscle pull fades away. The objective duration of action in a given patient seems to be stable, but there is a great variability between different people. Even very low doses produce some effect. By increasing the doses, a plateau is reached where further dose increases will not result in stronger effects. Dose-duration correlations exist to a lesser extent.

On the European market, three different branches of BTX-A are officially registered: Botox®/Vistabel® (Allergan), Dysport® (Ipsen)/Azzalure® (Galderma) and Xeomin®/Bocouture® (Merz). The units are not directly comparable. The products have different amounts of complexing proteins or are free of complexing proteins (i.e. Xeomin®/Bocouture®). The diffusion of the different drugs seems to be dependent on concentration. BTX-A has an excellent safety profile and has been used extensively for facial rejuvenation with a focus on hyperkinetic wrinkles and to improve facial wound healing after surgery.

Botulinum toxin for facial dysfunction and palsy

Similar techniques can also be employed for the dysfunctional paralyzed face so as to improve facial symmetry or in the scarred face to improve dermal contour with the use of fillers. Although facial reanimation surgery primarily relies on dynamic reconstructive techniques,[22, 23] it also draws upon adjunct techniques, such as botulinum toxin, which further augments a positive outcome. In our facial function clinic, BTX is used in a number of situations, primarily in the treatment of synkinesis and also to weaken the non-paralyzed side so as to improve symmetry. As can be seen in **Figure 89.1** botulinum toxin plays a large role in the treatment armamentarium of our facial function clinic and is used in nearly 50% of our patients. As a result, we now run two clinics simultaneously within the facial function clinic allowing the botulinum toxin treatment clinic to run parallel.

Acute facial palsy is the most frequent cranial nerve impairment encountered by otolaryngologists, often presenting as an acute idiopathic facial palsy or Bell's palsy as it is commonly known. Current evidence suggests that 71% of Bell's palsies recover completely and 29% do not. Of those reaching a full recovery, 85% do so within 3 weeks. In Peitersen's study contracture and synkinesis were seen in 17% and 16% of the patient cohort respectively.[24] Synkinesis refers to the abnormal involuntary facial movement that occurs with voluntary movement of a different facial muscle group. The pathophysiological basis of facial synkinesis is likely to be multifactorial although the predominant mechanism appears to be aberrant regeneration of facial nerve fibres to the facial muscle groups. Considering the facial nerve contains approximately 10 000 nerve fibres of which 7000 are motor and the remaining are a combination of parasympathetic efferents and sensory afferents, there is little wonder that disorganization can occur.

The preparation of botulinum toxin in the facial palsy clinic includes 500 units of Dysport which is made up to 5 mL of normal saline; this gives 10 units per 0.1 mL concentration. The Dysport is injected at an angle of 45 degrees using a 1 mL insulin syringe. Local anaesthetic

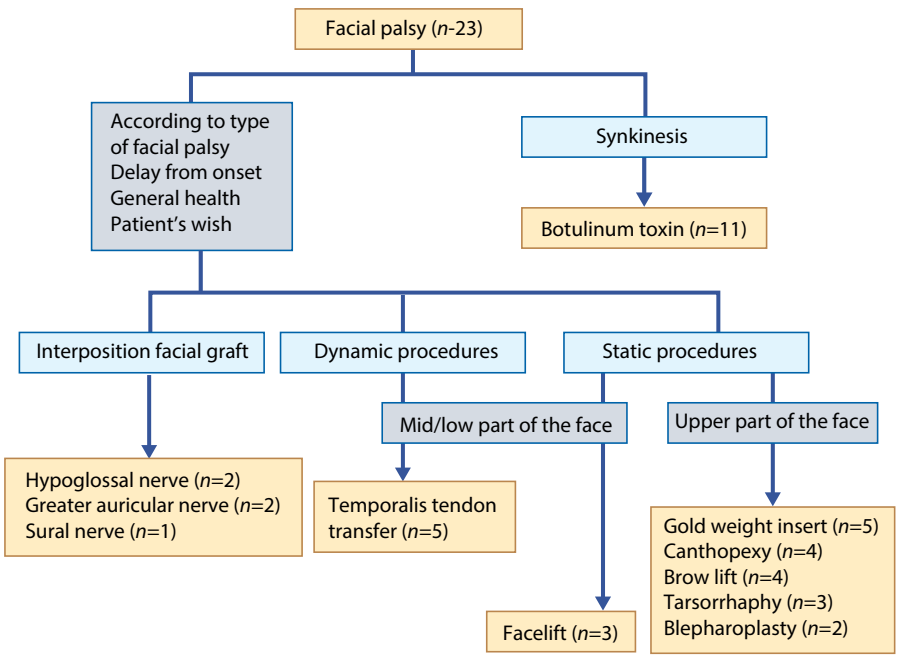

Figure 89.1 Synopsis of facial function treatments.

is not routinely used. In cases of synkinesis, an initial dose of 10 units is used at multiple points within the synkinetic muscle and, in our practice, botulinum toxin is judicially used on the first occasion and then adjusted at 6 months depending on response. We recommend caution when injecting around the orbicularis oculi muscle so as to avoid ptosis and double vision.

As well as for synkinesis we use botulinum toxin for facial contractures following Bell's palsy in particular. These patients can present with disfiguring and painful contractures which come on when stressed or talking, whereby the hemiface goes into contortion. In addition to reducing the contracture, it also helps with the pain. We also employ botulinum toxin in the unaffected overexaggerated side so as to improve symmetry. In a study looking at the use of botulinum injection on the unaffected side of a paralyzed face, the lower muscles of facial expression were injected. The aim of this technique was to reduce the unopposed action of the normal side. The average dose used was 30 units and the affects were first observed at 6 days and lasted up to 4 months.[25]

Botulinum toxin for facial rejuvenation

Temporary chemodenervation of facial muscles responsible for lines and furrows is a well-accepted practice. The commercially available products need to be diluted with 0.9% non-preserved sterile isotonic sodium chloride (saline solution). High dilutions have several disadvantages: more volume needs to be injected, which adds swelling and bruising, less precision as there is more chance of diffusion to adjacent muscles and shorter duration of action. After an informed consent is obtained, the dynamic facial lines are evaluated and standard photographs taken for the purpose of comparison after treatment. The medical history should include any pre-existing facial weakness. Botulinum toxin is contraindicated in patients with underlying neuromuscular junction disorder, allergy to any of its components (human albumin, botulinum toxin), pregnancy and breastfeeding. Aminoglycoside antibiotics and calcium channel blockers may potentiate the effect of the toxin and concomitant use is therefore not recommended.

A regional approach to injection of botulinum toxin facilitates the development of guidelines and injection doses. Total doses should be recorded. Injection of glabellar creases targets the procerus and corrugator muscles, which contribute to dynamic interbrow vertical lines. Asking the patient to frown is the best method for accurately delineating the span of the muscles. The frontalis muscle elevates the brows and creates the horizontal forehead lines. By avoiding the lateral forehead we avoid brow ptosis and a very rigid forehead. However, in patients with an overactive frontalis in the temporal region, undesirable brow arching or 'cocked' eyebrow may occur.

Periorbital lines or crow's feet are produced by the orbicularis oculi muscle, which has a sphincteric action and is responsible for squeezing the eyelids together. This circumferential muscle has three parts: the lacrimal portion assists in tear flow, the palpebral portion passes into the eyelid superficial to the orbital septum and the orbital portion is over the bony aspect and beyond. The lateral and superior aspect of this muscle causes brow depression so, when this downward pull is released, there will be a temporal brow lift. Unlike in glabellar and forehead lines where the injection was deep into the body of the muscle, the injection into orbicularis oculi needs to be superficial. We can strike a balance between the depressors (superior part of orbicularis oculi, corrugator and procerus) and elevators (paired frontalis) and alter brow position. Medial brow elevation can be achieved by treating the glabella, and lateral brow elevation can be achieved by undertreating the lateral forehead (frontalis) and injecting the superior lateral portion of orbicularis oculi.

Bunny lines or nasal scrunch is produced by excessive activity of the nasalis muscle. Patients develop radial lines on the nasal dorsum when they smile or laugh. Vertical and radial perioral lines occur in ageing-related skin changes and habitual lip pursing (as done during smoking). There is a potential side effect of oral incompetence and treatment is therefore not recommended in wind instrument players, vocalists or scuba divers. Angle of mouth or marionette lines are the result of hyperactivity of the depressor anguli oris muscle giving the patient a sad look or a downward curl of the lips. An excessive dose or injection at a site near to the orbicularis oris can weaken this muscle, producing lip drooling and an inability to pucker the lips.

Platysmal bands are the prominent vertical bands that may develop in the neck as part of the ageing process. These vertical bands are the anterior part of platysma and injection with the toxin softens them. A prominent mentalis muscle can produce a horizontal crease or a cobblestoned appearance on the chin. Masseter hypertrophy can cause a square jaw line, widening the face and giving what is considered a more masculine appearance. Injection of the muscle with botulinum toxin can give a more oval-shaped contour to the face.

FILLERS

Different products can be inserted under the skin in different layers to improve angles, lines, folds, scars and flaccidity. The idea is to replace an original volume lost by the ageing process or to create volume. Fillers can be temporary or permanent. Permanent fillers are in our view no longer recommended, as the long-term safety of their use has not been established conclusively. The filler with long-term effect is autologous fat grafting. This technique was popularized and modified by Coleman.[26] As certain faces age, they get thinner, and Lambros[27] does fat injections in every patient undergoing rhytidectomy.

There are, however, some issues surrounding fat transfer. Injected fat can grow – the greatest long-term problem with fat. We have seen increasing numbers of people who have gained weight after their fat injections and whose faces are growing in an unaesthetic manner. Fat is difficult to remove and fat grafts are not reliable. They work better in younger people and the adipocyte survival can be unpredictable, hence they may work better on one

side of the face than the other so touch-up procedures are often necessary. If we tell patients that fat grafting will give them a young-looking face that is smooth, round, full and wrinkle-free, we may end up ballooning the face and removing all the definition and delicacy of the face in a process that is not reversible. The most common complication of fat grafting happens when it is used in the lower lids. Fat survives very efficiently in this area, lumpiness occurs often and it is very noticeable. Around the eyes, temples and nose, temporary hyaluronic acid fillers last up to 3 years, making them a cost-effective, predictable treatment, which gives a smoother result.

Temporary fillers are metabolized by the human body and consist of different substances including collagen, hyaluronic acid, alginates and other polysaccharides. Substances such as polylactic acid and hydroxylapatite have a longer half-life. The most common temporary filler used today is hyaluronic acid (HA), a natural polysaccharide and a component of human dermis and epidermis. HA fillers offer excellent biocompatibility and provide the same structural and mechanical properties of normal subcutaneous tissue. Natural hyaluronan is rapidly broken down by hyaluronidase with a half-life of about 12 hours and eliminated through the lymphatics and by the hepatic metabolism to carbon dioxide and water. As HA is a normal extracellular component of skin, it can be used without skin testing, it has a high tolerability profile and corrections of displacement can easily be done by injection of hyaluronidase. Cross-linking gives HA fillers a life span of 6–18 months.[28] Factors that impact the longevity include the concentration, percentage of cross-linkage, type of cross-linkage, water-binding capacity and injection technique. The final proportion of cross-linked HA and the degree of cross-linking impacts the physical characteristic of the product. The product with a higher concentration and highest degree of cross-linking experiences the least amount of degradation by enzymes and free radicals.[29] The cross-linking agents also have an impact on connective tissue reaction to injectable fillers. Injection technique can play a role in longevity. Injection into the deep dermis has been shown to increase *de novo* collagen synthesis; as the HA is degraded, therefore, novel collagen synthesis replaces the HA, which results in longer lasting correction.

Although there is some evidence that HA stimulates new collagen, the main effect is from its hydrophilic properties. When not bound to other molecules, it binds to water, giving it a viscous quality similar to 'jello'. This is the main drawback of HA; it can give an unnatural overinflated look. Within the extracellular matrix, HA contributes to moisture, but collagen contributes to the scaffolding and keeps skin tight. A newer generation of biodegradable fillers have emerged which possess bio-stimulatory properties. Polycaprolactone (PCL) microspheres of 25 nanometres (30%) in diameter in a carboxymethylcellulose gel carrier (70%) combine durability and immediate outcome. The collagen stimulating effect of the PCL has been confirmed in human skin biopsies from treated subjects.[30] The PCL-based safety has been demonstrated in clinical studies and recommendation on injection techniques are provided for the upper, mid and lower face, and zone by zone for each of these areas.

In addition to manufactured fillers, a relatively new biotechnology autograft, concentrated growth factor (CGF), demonstrates significant stimulation and acceleration of soft-tissue formation. The efficacy of this therapy lies in the local delivery of a wide range and high concentration of growth factors and proteins, mimicking and supporting physiological wound healing, reparative tissue process and local infiltration therapy. The CGF technique was developed to achieve the optimal phase separation and concentrate the factors for maximum recruitment and biostimulation. The CGF therapy is an advanced, powerful anti-ageing treatment for the ultimate natural approach to facial rejuvenation; it is free from toxins and animal products and simply uses the patient's own blood.

CGF treatment may be effective in all aspects of facial aesthetics such as non-surgical facial augmentation, lip enhancement, and treating smile lines, the forehead, cheeks, neck and décolletage.

CONCLUSION

The field of anti-ageing and facial rejuvenation is advancing rapidly and new information and new therapies are discovered almost daily. As new technologies evolve, our goal should be focused on the patient, honesty and achieving a balanced look, which may be part of an overall programme of health and self-improvement. More often than not this is achieved by a combination of tools and we believe the best combination varies with the patient's face and not with what we like to use. Ultimately, while we can have our favourite treatment, it is counterproductive to be doctrinaire about it.

KEY POINTS

- Retinoids are the most powerful, effective and evidence-based topical anti-ageing products available.
- With Botulinum toxin less is more. Avoid creating unnatural folds and a frozen face.
- Manufactured fillers are extremely popular and whilst Hyaluronic acid is safe, it binds up to one thousand times its weight in water, it is a good lubricant 'jello' but when injected in the dermis it can give an overinflated look. The newer generation polycaprolactone-based collagen stimulators restores volume and redefines contours in a more natural way.
- Autologous platelet-rich plasma injections promote tissue remodelling by increasing the expression of Type I collagen in human dermal fibroblasts.

SEARCH STRATEGY

The information in this chapter is based largely on the authors' personal bibliographies, supplemented by reference to standard texts and articles on the history of surgery.

INTRODUCTION

In order to fully appreciate the current state of head and neck reconstructive surgery it is useful to understand its evolution and development. The word plastic is derived from the Greek work *plastikos*, meaning 'to mould' or 'to give form'. The origins of reconstructive head and neck surgery likely predate this linguistic root, as the early papyri of Egypt and the Sanskrit texts of India describe the use of reconstructive procedures to correct facial deformities. Reconstructive surgery over the past many centuries has largely been focused on the correction of deformities of the head and neck. Until the end of the 19th century, 'plastic surgery', as Harold Gillies described it (see The Great Wars, below), was focused on the returning the patient to a normal state, while the cosmetic or aesthetic surgery that developed in the 20th century was essentially focused on surpassing the normal.[1] This chapter will review the history of reconstructive head and neck surgery with a focus on the developments in the 20th and early 21st century.

EARLY HISTORY

Egyptian physicians can be credited with describing some of the first efforts at facial reconstruction. The Edwin Smith Papyrus, the origins of which are dated at approximately 3000 BCE, contains some of the first descriptions of surgical management of mandibular and nasal fractures. Arguably the first documented efforts of reconstructive surgery of the nose and ear are found in the Sanskrit texts of ancient India, written approximately 2600 years ago. During this period of Indian history, reconstructive surgery of the nose and ear was highly valued, as invaders from surrounding territories would often stigmatize their victims by amputating the nose or ear. The early Hindu justice system also imposed harsh penalties on those found guilty of being unfaithful to a spouse by amputating either the genitalia or the nose. It is therefore logical that the nose, a structure of dignity and unique personal identity, would become a focus of reconstructive efforts in the early history of reconstructive surgery.

In his *Sushruta Samhita* (Sushruta's compendium),[1] Sushruta, regarded as the 'Father of Indian Surgery', described a variety of surgical techniques for reconstruction of head and neck defects. Considerable controversy exists over the time period of his contributions, with dates ranging from 600 BCE to CE 1000. He contributed to many fields of medicine but is said to have laid the foundations for a variety of pedicled and rotation flaps. He was the pioneer of reconstructive rhinoplasty, and described more than 15 methods of nasal reconstruction.

ROMAN AND HELLENISTIC

Whether Hellenistic or Roman physicians were exposed to the Indian techniques through Alexander the Great's expedition to India in the 4th century BCE is of debate. Certainly Roman and Hellenistic physicians described

similar techniques to those described in India. Aulus Cornelius Celsus,[2] considered to be the greatest of the Roman medical authors and surgeons, also described a variety of techniques similar to those practiced in India in his medical text of the first century, *De Medecina*.

The royal Byzantine physician, Oribasius, wrote extensively about facial and nasal reconstruction in the 4th century. His comprehensive medical encyclopaedia, entitled *Synagogue Medicae,* followed Celsus. He described in detail the use of bi-pedicle advancement flaps for skin defects of the eyebrow, ala, cheek, nasal dorsum and columella. He described the concept of undermining of advancement flaps. His technique of alar reconstruction may have been the first description of the superiorly based nasolabial flap.

THE MIDDLE AGES AND THE RENAISSANCE

The development of facial reconstruction certainly continued in the Middle Ages. However, following the fall of Rome in the 5th century and the diffusion of Barbarians and Christianity throughout the Middle Ages, a significant decline in the advancement of all surgery, in particular reconstruction, occurred. This decline was certainly aided by Pope Innocent III, who prohibited surgical procedures of all types. It is interesting to note that physicians of the time considered surgery to be a manual skill and below their intellectual and societal stature. The concept of the barber surgeon appeared and the decline of the role of surgery and surgeons began.

The period of Renaissance in the 14th century signalled a rebirth of science, medicine and the world of surgery. In the 15th century the Branca family became prominent in wound reconstruction and the reintroduction of the Indian method of nasal reconstruction.[3] The family apparently zealously protected the techniques they had developed from outside observers and the surgical techniques were passed down through family members. Branca's son, Antonius, inherited this technique and modified it through the use of a delayed skin flap from the arm. This Italian method, as it became known, was eventually transferred to other families of surgeons.

Descriptions of these various techniques may have contributed to Gasparro Tagliacozzi's interest in nasal reconstruction. Tagliacozzi – incorrectly referred to as the originator of the Italian method – made significant contributions to facial reconstructive surgery. Working in Bologna in the latter half of the 16th century, Tagliacozzi described and refined the use of distant pedicled flaps for a variety of facial reconstructions.[4]

THE 17TH AND 18TH CENTURIES

In the late 1600s reconstructive surgery entered into a period of significant decline. This was largely based on misconceptions about transferred tissues, superstition and a lack of belief or understanding of the sciences.

Reconstructive surgery began to emerge in the late 18th century. An often-cited impetus of this renewal was a letter published in *Gentleman's Magazine* in London in 1984 by a British surgeon named Lucas. In this account, Lucas described the reconstruction of the nose of a British bullock driver whose nose was mutilated by the enemy for transporting supplies for the British forces. Lucas explained how a forehead flap was performed by an Indian man of the brickmaker caste. His account was read by a British surgeon, Carpue, who reasoned that if the procedure could be done in India it could be easily done in Britain. Carpue described his experience with two British soldiers for *Restoring a lost nose* in 1816.[5]

In 1818 the German surgeon, Carl Von Graefe, published his major work, *Rhinoplastik*.[6] Von Graefe's book described a variety of reconstructive approaches, including the Indian and Italian methods, as well as his own method utilizing a free skin graft from the arm. He also described techniques for palate reconstruction and blepharoplasty. Because of the breadth of his contributions he is regarded as one of the fathers of modern plastic surgery.

Johann Dieffenbach began his practice in Berlin in 1823, with a great interest in plastic surgery and nasal reconstruction. In 1840, following the death of Von Graefe, Dieffenbach assumed the chair at the University of Berlin and published extensively on reconstructive plastic surgery and in particular nasal reconstruction and reconstructive rhinoplasty.[7] He also made significant contributions in cleft palate repair and was one of the first surgeons to advocate the use of anaesthesia. Based on all accounts, Dieffenbach was a gifted technical surgeon and a charismatic communicator. His charm and humanitarian spirit captivated the hearts of his patients, colleagues and students. He died in his clinic while preparing for an operative procedure.

Jacques Joseph, a German orthopedic trained surgeon, is widely regarded as the father of modern rhinoplasty. His book *Nasenplastik und sonstige Gesichtsplastik*, published in 1928, remains one of the most comprehensive texts written on the subject.[8] Joseph developed a number of techniques and instruments that are still in use today.

SKIN GRAFTING

As applies to many of the reconstructive techniques used in head and neck surgery, the idea and practice of skin grafting appears to have originated in India; the Hindus reported the use of free skin grafts along with the use of forehead and other facial flaps for reconstruction. The modern interest in skin grafting likely began near the end of the 18th century when Baronio reported the use of skin grafts on sheep.

The first human skin graft was probably performed by Astley Cooper in 1817.[9] In 1869, Reverdin reported on his experience with small 2–3 mm epidermic grafts for serious burns he was treating at the Necker hospital in Paris.[10]

Ollier, who studied the work of Reverdin, emphasized the importance of the dermal component and coined the

Figure 90.1 Tagliacozzi refined the use of distant pedicled flaps for facial reconstruction.

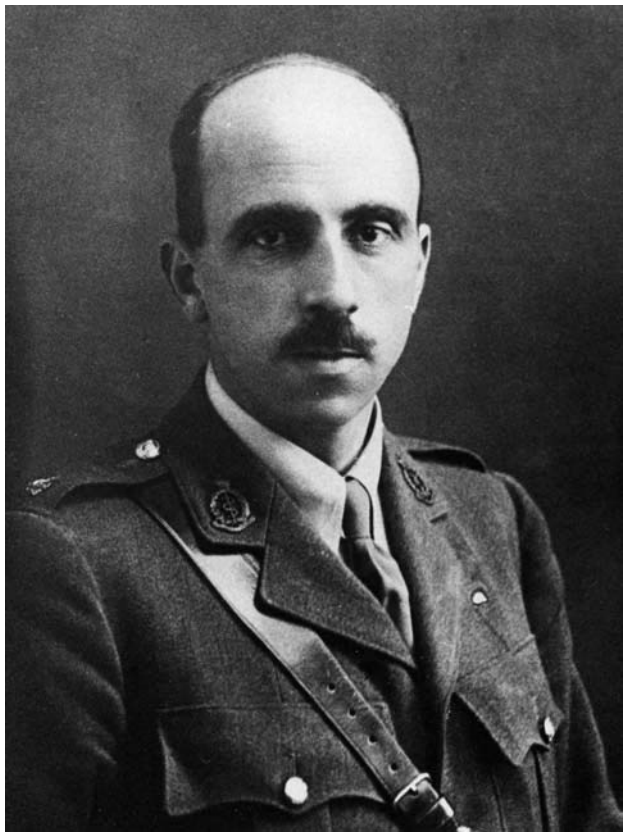

Figure 90.2 Sir Harold Gillies. Reproduced with kind permission from Andrew Bamji, Curator of Archives at the Frognal Centre, Queen Mary Hospital, Sidcup, UK.

term 'skin graft'. In 1872, Ollier performed the first successful full-thickness autograft to treat ectropion.[11]

In 1875, Wolfe described the concept of full-thickness skin grafting over a fresh surgical wound. Wolfe, an ophthalmologist by training, was given credit along with Krause for bringing this technique to clinical practice. The term 'Wolfe graft' is still used in the UK to describe a full-thickness skin graft.[12]

In 1929, Blair and Brown described the use of large split-thickness skin grafts of various thicknesses for different types of wounds characterizing the features of donor site morbidity and contraction.[13]

One of the greatest developments in reconstructive surgery was the development of the dermatome. Developed in 1939 by Padgett, a surgeon, and Hood, a mechanical engineer, it revolutionized the harvesting and application of skin grafting techniques.[14]

THE WORLD WARS

The two World Wars in the first half of the 20th century played a key role in the development of reconstructive head and neck surgery, particularly in plastic surgery, dentistry and maxillofacial surgery. The First World War presented a unique challenge for medical care because of the volume of injured combatants and the nature of the wounds (high velocity projectiles and explosions). On the first day of the Battle of the Somme the British expeditionary force suffered 60 000 casualties, 21 000 of whom were killed.

A number of surgeons had prominent roles in the primary management and reconstruction of these patients. Prominent among the French surgeons was Hippolyte Morestin. Born in Martinique, Morestin worked in the French army's surgical unit at the Val-de-Grace Military Hospital in Paris. He became well known for his expertise in local flaps, advocating the concept of wide undermining as well as developing techniques in z-plasty. Because of the nature of his work and his prominence, many surgeons went to observe his surgery.[15] Perhaps most prominent among these was Harold Gillies (1882–1960). Gillies (**Figure 90.2**) was born in Dunedin, New Zealand, and graduated in medicine from Cambridge. He trained initially in otolaryngology and in 1915 volunteered his services to the Red Cross and was sent to France. Fascinated by the reputation of Hippolyte Morestin, he went to observe his surgery. The nature of the work convinced Gillies to advocate for a specialty hospital for the treatment of facial and jaw injuries for British combatants. Interestingly, when Gillies made a return visit to observe Morestin, he was refused entry into the operating theatre.

In 1916, the British War Office established a unit at the Cambridge Military Hospital, Aldershot. The Aldershot facilities proved inadequate and in 1917 the unit was moved to The Queen's Hospital (renamed Queen Mary's Hospital in 1927) at Sidcup in Kent. Gillies treated and documented the care of numerous patients and developed his craft at Sidcup. Significant among his developments

were the refinement of the tubed flap and skin grafting for defects of the eyelid (**Figure 90.3**). Gillies' wartime experiences provided the material for his classic book, *Plastic surgery of the face*, published in 1920.16 This beautifully illustrated text set down Gillies' rules of reconstructive surgery and certainly cemented his reputation as one of the fathers of modern 20th-century plastic surgery. Gillies and Sidcup played a major role in the training of surgeons from around the world. Ferris Smith, also originally an otolaryngologist, became a prominent American plastic surgeon. Other prominent surgeons included Pickerill from New Zealand and Risdon from Canada. For his contributions to the care of the injured and his major contributions to the field, Gillies was knighted in 1930.

Between the wars, plastic and reconstructive surgery flourished in North America. In 1919, John Staige Davis published the first American plastic surgery textbook, *Plastic surgery – its principles and practice*, which became a classic in the field.[17] The 1920s and 1930s saw the development of many professional societies dedicated to plastic surgery in North America and a rapid expansion in the number of plastic surgeons in the United States.

The Second World War facilitated further developments in reconstructive surgery of the head and neck. In the UK there were only four plastic surgeons (The Big Four: Gillies, Kilner, Mowlem and McIndoe). At the beginning of the Second World War the emergency medical services in England set up nine centres for facial and jaw injuries. McIndoe was appointed to the Queen Victoria Hospital in East Grinstead, Sussex, and Gillies was sent to head the unit at Rooksdown House, Park Prewett Hospital, Basingstoke. Gillies continued to develop his expertise in facial reconstruction; McIndoe became famous for developing innovative treatment approaches for severe burns, including the face, and was well known both during and after the war for his expertise and compassionate care.

THE MODERN ERA

The expertise in soft tissue and bone reconstruction that evolved and developed during and after the World Wars changed its focus in the last 40 years of the 20th century. The emphasis on plastic and reconstructive surgery moved to the correction of congenital and secondary deformities and the reconstruction of defects following oncologic resections. Many plastic surgeons became increasingly interested in aesthetic surgery. In the 1950s and early 1960s, the majority of oncologic and post-traumatic reconstruction still utilized the techniques pioneered by Gillies and his contemporaries. In the 1960s, a number of surgical innovations changed the morbidity of head and neck reconstruction. The increasing use of axial pattern flaps made reconstruction of large oral cavity and neck defects more reliable and less costly to the patient in terms of prolonged hospitalization. Foremost among these were the descriptions of the forehead flap for oral reconstruction popularized by McGregor[18] and the deltopectoral flap described in the United States by Bakamjian.[19] In the late 1970s, the description of the pectoralis major myocutaneous flap by Ariyan[20] transformed head and neck oncologic surgery, as patients could be offered a single stage reliable reconstruction with minimal donor site morbidity. In addition, the ease of harvest and transfer of the pectoralis major flap made it a technique that any head and neck-trained surgeon could perform, broadening the scope of reconstructive surgery to other disciplines outside plastic surgery.

The late 1960s and early 1970s heralded the era of reconstructive microsurgery. The concept of free tissue transfer had been developed years earlier but was limited by the quality and availability of microvascular sutures, quality instruments and magnification. Jacobson and Suarez[21] first described the repair of vessels under 2 mm in 1960. The first free tissue transfer of a composite of skin was performed by Taylor and Daniels in 1973.[22] Subsequent developments in reconstructive microsurgery have resulted in the description of a plethora of free tissue

transfers available for head and neck reconstruction, championed by a number of extremely gifted reconstructive microsurgeons including Harii, Buncke, Manktelow and many others.

The more notable among these flaps are: the free forearm flap, described by Yang in 1983[23] and popularized for oral cavity and oromandibular reconstruction by Soutar;[24] the free fibular transfer, originally described by Taylor in 1973[22] and popularized by Hidalgo[25] for mandibular reconstruction in 1995; and the anterolateral thigh flap, described by Song[26] in 1984 and popularized for head and neck reconstruction by Wei[27] in 2002.

As experience has evolved with a vast array of free tissue transfer, creative surgeons from many disciplines and jurisdictions have developed new techniques for reconstruction of the mandible, maxilla, airway and numerous other head and neck sites. The application of these techniques has dramatically enhanced the ability of the head and neck reconstructive surgeon to deliver high quality reconstruction with preservation or restoration of form and function.

The community of specialties performing head and neck reconstruction has changed dramatically over the past 40 years. Head and neck oncologic surgery in the 1950s and 1960s was largely the domain of general and plastic surgeons, with the majority of reconstruction performed by plastic surgeons. In the last three decades of the 20th century, however, some major changes in the specialties treating defects of the head and neck evolved. Increasingly in Europe and North America, otolaryngologists with subspecialty training in head and neck surgery and reconstructive microsurgery began to develop an interest and expertise in head and neck surgery that extended beyond the treatment of laryngeal cancer. At the same time, in Europe, maxillofacial surgery began its evolution as a specialty and, increasingly, maxillofacial surgeons treated and reconstructed congenital, traumatic and oncologic defects of the head and neck.

FUTURE RESEARCH

➤ In the next 10 years, further refinements will occur in the application and evaluation of the various reconstructive microsurgical techniques. The areas of major innovation are clearly tissue engineering and transplantation. Tissue engineering may offer the potential to create composite tissue constructs that will replace the current approaches, including free tissue transfer and the associated donor site morbidity. The most notable and controversial use of tissue engineering in the head and neck site has been the airway work of Macchiarini et al.[28] Vascularized composite allografts (VCA) or transplantation clearly has the potential to dramatically change the field of reconstructive surgery of the head and neck. The recent experiences with face transplants, both in Europe and North America, have highlighted the potential of VCA as well as long-term sequelae of immunosuppression.[29, 30] As the understanding of immune surveillance and improved regimens for immunosuppression evolve, we will likely see a broader application of these techniques in head and neck reconstruction.

KEY POINTS

- Reconstructive techniques to repair facial defects and deformities have been found in ancient Egyptian and Sanskrit papyrus documents dating back over five thousand years.
- Techniques for nasal reconstruction following amputation of the nose developed in India, and were in widespread use until the middle ages.
- Pedicled flaps and free skin grafts were popularized from the late 18th-century onwards.
- Josef Dieffenbach (Berlin) is often referred to as the 'father' of plastic surgery.
- Harold Gillies pioneered techniques for facial reconstructive surgery in Britain, working mainly on servicemen with severe shrapnel injuries during the two World Wars.
- The operating microscope transformed plastic and reconstructive surgery, paving the way for free flaps.

INTRODUCTION

Defects following head and neck surgery can often be closed using the technique of direct suture. This, of course, applies not only to the skin but also to the mucous membranes of the upper aerodigestive tract. This technique is used when the defect is small and where local conditions mean that enough tissue is available. However, for larger defects or in situations where direct suture is neither applicable nor available, surgical defects in the head and neck can be reconstructed with grafts, local flaps, regional flaps or free-tissue transfer. Occasionally, a combination of these different reconstructive techniques is required as 'building blocks' to reconstruct more complex defects. A **graft** is a piece of tissue that has no blood supply of its own and its survival depends on it gaining a blood supply from the recipient bed. A **flap** is a piece of tissue that has its own blood supply and does not rely on the recipient bed for its survival. This chapter focuses on the use of grafts and local flaps in head and neck reconstruction.

RECONSTRUCTIVE LADDER

The reconstructive ladder is an important concept in reconstructive surgery. It begins with the simplest option first, which is to allow the wound to heal by secondary intention. As one advances up the rungs of the ladder, more complex reconstructive techniques are encountered, up to the highest rung, which is microvascular free-tissue transfer. When analyzing a defect to be reconstructed, the reconstructive surgeon would start at the bottom rung and work his way up, deciding which reconstructive method should be undertaken. There are some instances, however, where the 'reconstructive elevator' should be taken instead and some of the rungs in the reconstructive ladder can and should be skipped. An example of this would be in the reconstruction of a significant defect in the neck following primary tumour excision with exposure of the great vessels. In this case, although a skin graft could theoretically be used and probably would 'take', the risk of exposed vessels would warrant the use of a pedicled or free flap for reconstruction. An example is shown in **Figure 91.1**.

WOUND CLOSURE AND RELAXED SKIN TENSION LINES

Many defects in the head and neck region can be directly closed if they are small and enough tissue is available locally. For larger defects, closure of the wound can be achieved by the different rungs of the reconstructive ladder, dependent on the site, size and extent of the defect. The concept of relaxed skin tension lines is useful when considering where to place skin incisions. These are lines parallel to the natural skin wrinkles and tend to be perpendicular to

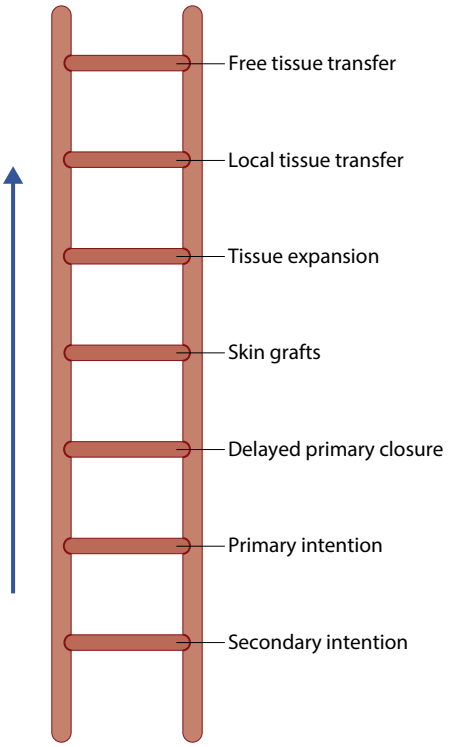

Figure 91.1 The reconstructive ladder.

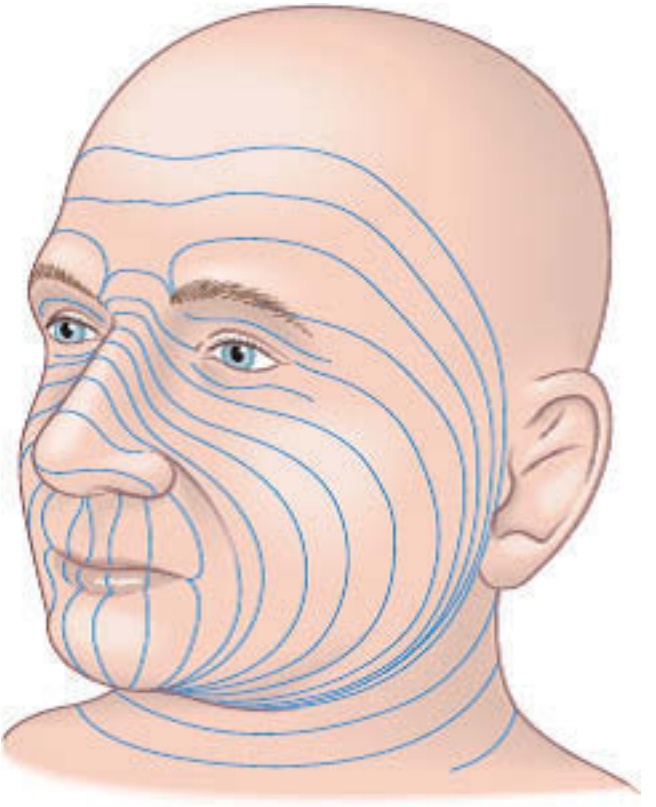

Figure 91.2 Relaxed skin tension lines.

the underlying muscle fibres (**Figure 91.2**). Scars placed parallel to these lines will be under the least amount of tension and therefore will result in the best possible scar. With regards to local flaps, these lines should be considered when closing the flap's donor site, again to minimize tension and allow easy closure.

Wedge excision

Lesions located at the free edge of tissues such as the eyelid, lips and helical rims can be excised as a wedge and repaired. The separate components of these composite tissues must be repaired individually to optimize function and appearance. These layers are, in the lip, the mucosa, orbicularis oris and skin; in the eyelid, conjunctiva, tarsal plate, orbicularis oculi and skin (**Figure 91.3**).

COSMETIC SUBUNITS OF THE HEAD AND NECK

The face is divided into multiple cosmetic subunits (**Figure 91.4**). These cosmetic subunits should be taken into account when reconstructing defects in the head and neck to optimize cosmesis. Ideally, individual subunits should be reconstructed separately and scars should not cross the subunits if possible. It is therefore preferable to use a graft or a flap to reconstruct one cosmetic subunit and a second graft or flap to reconstruct an adjacent subunit. If more than 50% of a cosmetic subunit is involved, it may be desirable to excise the entire subunit and reconstruct it to obtain an optimal result.

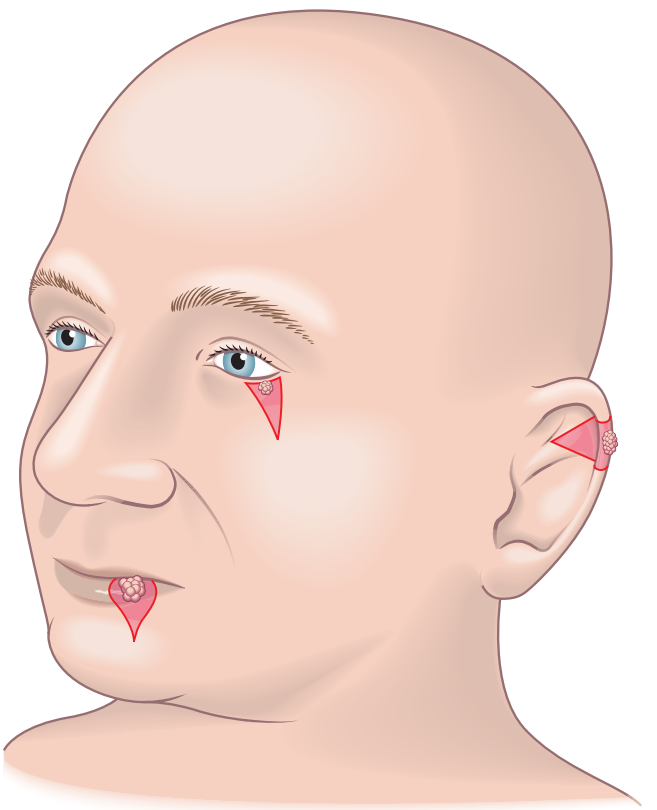

Figure 91.3 Wedge excision designs in different areas.

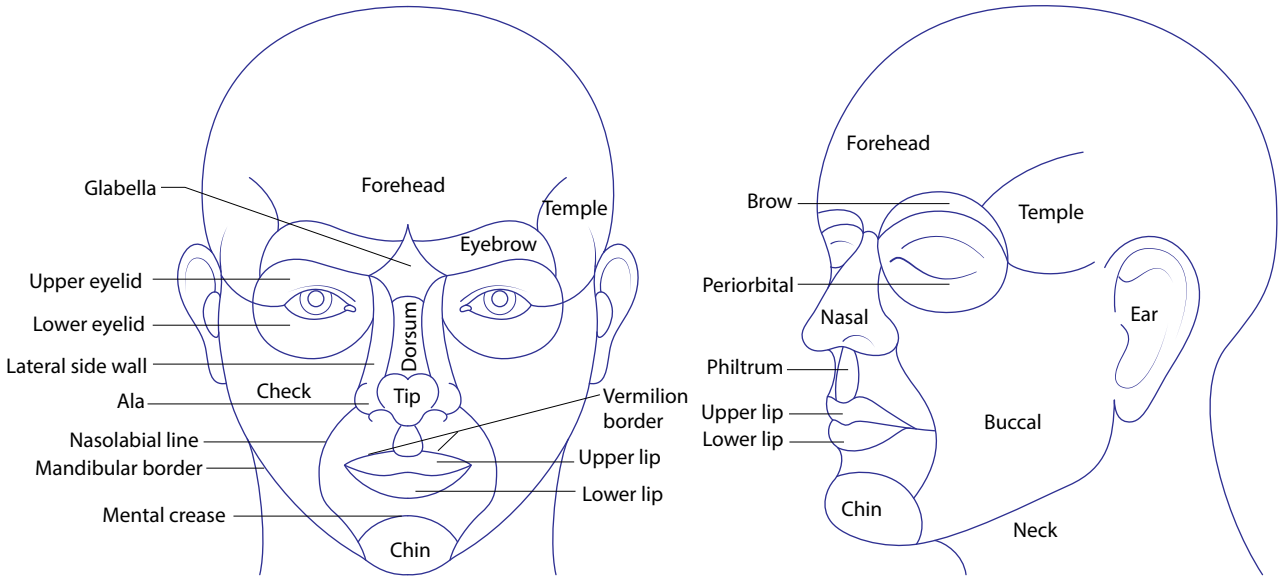

Figure 91.4 Facial cosmetic units.

SKIN GRAFTS

History

Grafting of skin originated in India over 3000 years ago when surgeons took skin grafts from the gluteal region to repair traumatic defects of the face.[1] The first report in the English language was in 1817 when Sir Astley Cooper grafted a full-thickness piece of skin from a man's amputated thumb onto the stump for coverage. Lawson[2] reported successful elective full-thickness skin grafting in 1871, which was followed by Ollier,[3] a French surgeon, describing a split-thickness skin graft in 1872. Thiersch,[4] from Germany, was the first to recognize the importance of recipient site for graft survival, and in 1875 Wolfe used a full-thickness skin graft taken from the patient's forearm to treat a traumatic ectropion of the lower lid following a gunpowder explosion. Full-thickness skin grafting of the eyelids is now a procedure with which Wolfe's name has become synonymous.[5] In 1929, Brown and Blair[6] differentiated between full-thickness and split-thickness skin grafts; they identified the advantages and disadvantages of each and, using their techniques, consistent, acceptable results were achieved. Medawar[7] studied the underlying biology of healing skin grafts in the 1940s. His work described the cellular changes in both the epidermis and dermis, giving the technique of skin grafting a scientific basis and laying the foundation of modern transplant immunology.[8]

Introduction

A **graft** is a piece of tissue that is transferred from one site to another, devascularizing it in the process. The area from which the graft is taken is known as the **donor site** and the area to which the graft is applied is known as the **recipient site**. Grafts can be classified according to their composition – skin, bone, cartilage, fat, mucosa, or composite grafts which consist of two or more different tissue types[9] (e.g. a septal mucosal graft consisting of septum and mucosa). They can also be classified according to their source. An **autograft** is a graft taken from one part of an individual's body and transferred to a different part of that same individual. An **isograft** is a graft transferred between genetically identical individuals, such as between identical twins. An **allograft** is transferred from one individual to another of the same species. A **xenograft** is a graft transferred between different species.

Skin grafts are of two types: **split-thickness** skin grafts (STSGs) or **full-thickness** skin grafts (FTSGs) dependent on the dermal content of the graft. FTSGs contain epidermis and all of the dermis whereas STSGs contain epidermis and a variable amount of dermis (thin, intermediate or thick) (**Figure 91.5**).

Skin graft healing

Once a skin graft has been harvested, it has been detached from its blood supply and is, temporarily, not viable. In order to survive permanently, it has to become reattached and obtain a new blood supply from its recipient site; this process is known as 'take'. Skin graft take is a continual biological process but, for convenience, it can be divided into four main stages (**Table 91.1**):

1. Skin graft adherence (immediate)
2. Serum imbibition (first 24–48 hours)
3. Revascularization (48 hours to 3 weeks)
4. Remodelling (3 weeks to 1 year)

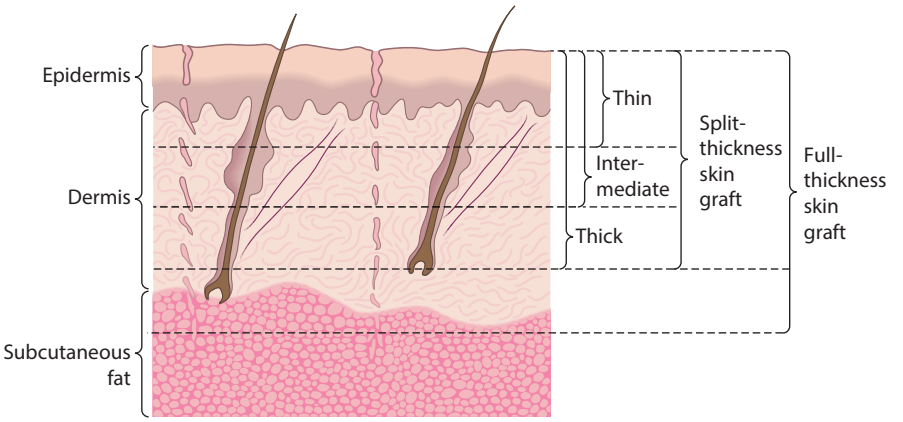

Figure 91.5 Skin graft thickness.

TABLE 91.1 Graft healing

Stages of graft healing	Time period	Mechanism
Graft adherence	Immediate	Graft adheres to recipient bed through formation of fibrin layer
Serum imbibition	Up to 48 hours	Graft survives via absorption of nutrients from a recipient bed
Revascularization	48 hours to 3 weeks	Inosculation – joining up of cut vessel ends in graft and recipient bed Revascularization – ingrowth of vessels into the graft producing new vascular channels Neovascularization – ingrowth of vessels down basement membrane
Remodelling	3 weeks to 1 year	Maturation and remodelling of the graft with collagen reorganization

Initially, when the graft is applied, it becomes adhered to the recipient bed by the formation of an intervening layer of fibrin.[10] Within 48 hours, the thin fibrin layer starts to break down and adhesion to the bed is maintained by the proliferation of fibroblasts and the deposition of collagen.[11] During this period of initial adherence, the skin graft survives through the passage of nutrients from plasma leaking from capillaries in the recipient bed. This is known as serum imbibition.[12] During this time, the graft gains weight and swells. The skin graft, however, cannot depend on serum imbibition indefinitely and, after 48 hours, revascularization of the graft begins to take place. There are several methods by which this occurs: namely inosculation, revascularization and neovascularization.

- **Inosculation** is the process of the joining up of the cut ends of the vessels in the recipient bed with the cut ends of vessels in the skin graft.[13]
- **Revascularization** is the actual ingrowth of vessels into the graft to produce new vascular channels.
- Alternatively, the endothelium of old cut vessels degenerate, leaving behind its basement membrane and this acts as a conduit for growth of capillary buds. This is known as **neovascularization**.[14]

All these processes continue for up to 3 weeks until revascularization of the graft is complete. Once the graft has become revascularized, it undergoes maturation and remodelling with collagen reorganization and increasing strength.

Factors affecting graft healing

Successful take of a skin graft is dependent upon the extent and speed at which vascular perfusion is returned to the graft. This is determined by graft factors, local and systemic factors. To obtain successful graft take, each of these factors must be optimized.

FTSGs have a higher metabolic demand due to their thickness and therefore have a higher chance of failure compared to STSGs. Local factors, such as the vascularity of the wound bed, are also an important determinant in graft take. Healthy granulation tissue, muscle and fascia act readily as recipient beds whereas fat is less suitable. Bone covered with periosteum will accept a graft but exposed bone and tendon will not. In some cases, exposed bone (such as the outer table of the skull) can be burred to cause pinpoint bony bleeding which will facilitate graft take.

In order for vascular channels to form between the recipient bed and graft, the graft has to be immobilized and in direct contact with the recipient bed. Shearing forces must be avoided and numerous methods such as tie-over dressings, the use of foam and sponges, and bandaging have been described to facilitate graft take. The most frequent cause of graft loss is the presence of a haematoma or a seroma which separates the graft from its recipient bed. Meticulous haemostasis and either meshing or fenestrating the graft to allow fluid to escape will help to prevent this. Infection is another common cause of graft loss and wounds that contain more than 10^5 organisms will not support a graft. Grafted beds which

become infected should be treated with systemic and/or topical antibiotic agents to reduce the risk of graft loss. Common pathogens include *Streptococcus pyogenes*, *Pseudomonas aeruginosa* and methicillin-resistant *Staphylococcus aureus*, which can all destroy fibrin and prevent graft adherence.[15]

In addition to these local conditions, systemic conditions of the patient can also influence skin graft take. These include diabetes mellitus, smoking, previous radiotherapy and chemotherapy, as well as nutritional status.

Split-thickness skin graft vs full-thickness skin graft

The amount of dermis included with the graft determines both the likelihood of survival and the degree of contraction. All skin grafts contract once removed from their donor site (primary contraction) and again following revascularization (secondary contraction). Primary contraction occurs as a result of the elastin within the dermis whereas secondary contraction occurs due to myofibroblast activity within the wound bed. STSGs can tolerate less vascularity than FTSGs, and undergo less primary contraction but more secondary contraction. They also tend to have abnormal pigmentation, are more susceptible to trauma and usually have poorer sensory recovery. STSGs are hairless due to the lack of hair follicles (see **Figure 91.5**).

FTSGs require a better vascular bed for survival than STSGs and they undergo more primary contraction but less secondary contraction. FTSGs also resists trauma better, tend to provide a better colour match and have improved sensory recovery due the greater availability of neurilemmal sheaths within the dermis. FTSGs also contain hair follicles and will demonstrate similar hair growth to the donor site. These differences are summarized in **Table 91.2**.

Composite grafts

Composite grafts are grafts which contain two or more different tissue types. An example that was used previously is a septal mucosal graft which contains septum and mucosa. Another example is a chondromucosal graft from the ear which contains cartilage and skin. These grafts are useful in reconstructing composite defects, either for complete reconstruction, as in the reconstruction of an alar rim or small defect of an ear, or as partial reconstruction of a more complex composite defect. An example of one such defect is the eyelid where three separate layers (i.e. the mucosa, tarsal plate and skin) need to be reconstructed. In this case, a septal mucosal graft can be used to reconstruct the mucosa and tarsal plate support and a cheek rotation flap can be used to reconstruct the skin defect (**Figure 91.6**).

TABLE 91.2 Advantages and disadvantages of STSGs vs FTSGs

Factor	STSG	FTSG
Amount of dermis	Variable	All of dermis
Chance of successful take	More likely	Less likely
Graft contraction	More contraction	Less contraction
Colour match	Abnormal pigmentation	Better colour match
Robustness	Less robust	More robust
Sensory recovery	Limited	Better
Donor site healing	Heals secondarily	Heals through primary intention
Size of graft	Large grafts can be harvested	Limited due to need for primary closure of donor

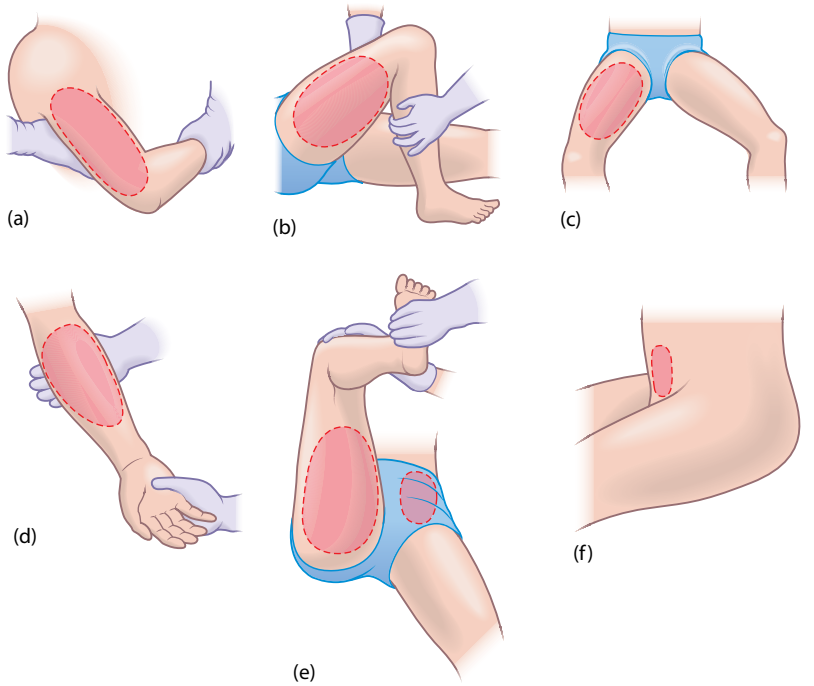

Figure 91.7 Split-thickness skin graft donor sites.

Skin graft donor sites

After an STSG is harvested, the donor site heals by re-epithelialization from adenexal structures, such as hair follicles and sweat glands, in the remaining dermis. Resurfacing occurs by the migration of keratinocytes from these structures to cover the wound. As there is no remaining epithelium in FTSG donor sites, the wound needs to be closed directly. This limits the amount of skin that can be harvested and the size of the defect that can be reconstructed using a FTSG. STSGs can be taken from anywhere on the body.[16] Commonly used areas include the thigh, trunk and buttocks as shown in **Figure 91.7**.

The graft is harvested with either an air- or battery-powered dermatome or a hand knife such as a Watson knife. The standard thickness which is preset on a dermatome is 0.3–0.4 mm or 10–12/1000 of an inch. The skin can then be either meshed or fenestrated by hand. The donor site is dressed with a non-adherent dressing[19] and left undisturbed for approximately 14 days. Most STSG donor sites are healed by 21 days with minimal scarring but they may be discoloured and susceptible to sunburn for up to 2 years afterwards.

The thickness and colour of skin varies greatly from different parts of the body and this affects the choice of FTSG donor site. Commonly used sites are pre- and post-auricular, the supraclavicular fossa, the antecubital fossa and the groin, as shown in **Figure 91.8**.

The FTSG is harvested with a scalpel and is closed directly with sutures to leave a linear scar. The amount of skin that can be taken is limited by the need to obtain a tension-free closure of the donor site. Examples of the use of a skin graft in the head are shown in **Figure 91.9**.

LOCAL FLAPS

Basic principles

A flap, unlike a skin graft, has its own blood supply. Flaps are useful in reconstructing defects with poor vascularity, exposed vital structures and where skin grafts are inappropriate or would lead to poor cosmesis. Flaps are also useful in reconstructing defects where post-operative radiotherapy is planned as they are less susceptible than skin grafts to the ill effects of radiotherapy.

Flaps can be classified according to their circulation, composition, contiguity or contour. The circulation of flaps may be random, which means that the blood supply is from a non-named vessel in the base of the flap, or axial, which means that they are based on an anatomically recognized artery.[17] Flaps can be composed of different tissue types, such as skin, fascia and skin (fasciocutaneous), muscle or muscle and the overlying skin paddle (myocutaneous). The contiguity of a flap relates to the distance between its source and the defect to be reconstructed. This can be local, regional, distant or free. A local flap is composed of tissue adjacent to the defect. A regional flap is from the same anatomical region as the defect (e.g. forehead flap for nasal reconstruction). A distant flap is from a different part of the body away from the region of the defect (e.g. pectoralis major flap in head and neck reconstruction). A free flap is completely detached from the body and anastomosed to recipient vessels close to the defect. The contour of the flap relates to the method in which it is transferred into the defect. It can either be advanced or moved about a pivot point.

A flap is inset into a primary defect. The secondary defect is the site from which the flap is raised. This is

usually closed directly but can be grafted or closed by another flap. When designing a local flap in the head and neck, the two most important considerations are appreciation of the relaxed skin tension lines (see **Figure 91.2**) and the cosmetic units (see **Figure 91.4**). It is preferable to reconstruct an entire cosmetic unit with a single flap to optimize cosmesis and, in some cases, it may be necessary to excise the remaining tissue beyond the boundary of the original defect to facilitate this. This is particularly important if more than 50% of the cosmetic unit is involved. If the defect involves two cosmetic units, then two flaps (one for each unit) may be preferred. The donor area from the flap should be from the same cosmetic unit or one adjacent if possible and should not transgress multiple units. Ideally, the scar from a direct closure of a secondary defect should be in a relaxed skin tension line as it will be under the most tension of any part of the flap.

Flap planning is crucial to the success of the reconstructive procedure. When planning a random flap, the breadth of the base should be no more than the length of the flap to prevent necrosis of the flap (a ratio of 1 : 1). In the head and neck region, the blood supply is good so this can be extended to a ratio of base breadth to flap length of 1 : 1.5. For axial flaps, the length to breadth ratio is much greater but it is important to delineate and protect the named blood supply to the flap. Reverse planning is an important principle in flap design. This is a technique where a template of the primary defect is reflected from the defect to be reconstructed onto the flap donor area from a fixed point, usually the pivot point of the flap, to help assess where the flap needs to be raised from to provide sufficient defect coverage as well as minimal donor site morbidity.

Advancement flaps

Advancement flaps are moved forward into a defect without any rotation or lateral movement. They may be simple or modified. A simple advancement flap relies on the skin's elasticity to cover the primary defect. There are a number of ways in which advancement flaps can be modified to aid advancement. Burow's triangles are triangles of skin that are excised at either side of the base of the flap to equalize the length between the sides of the flap and the adjacent wound margin. These help in allowing the flap to advance, as demonstrated by a Rintala flap[18] being used to cover a defect of the nasal tip (**Figure 91.10**). A V–Y flap is another modified advancement flap. The flap itself is raised as a triangular (or 'V'-shaped) flap. When is it advanced, the secondary defect is closed directly, leaving a 'Y'-shaped scar. An example of one such flap is the nasolabial V–Y advancement flap shown, which is an axial flap based on either the superior labial artery or the angular artery (**Figures 91.11**).

Bipedicled flaps

A bipedicled flap receives a blood supply from both ends as it has two bases. It is less prone to necrosis than flaps of similar dimensions which are attached at only one end. An example of this is the Tripier flap[19] for lower eyelid reconstruction (**Figure 91.12**). Skin from the upper lid based on both a medial and a lateral attachment is swung down, like a bucket handle, to provide cover for a defect in the lower lid. To increase the viability of this flap, a strip of the orbicularis oculi muscle can be included, making it a musculocutaneous flap.

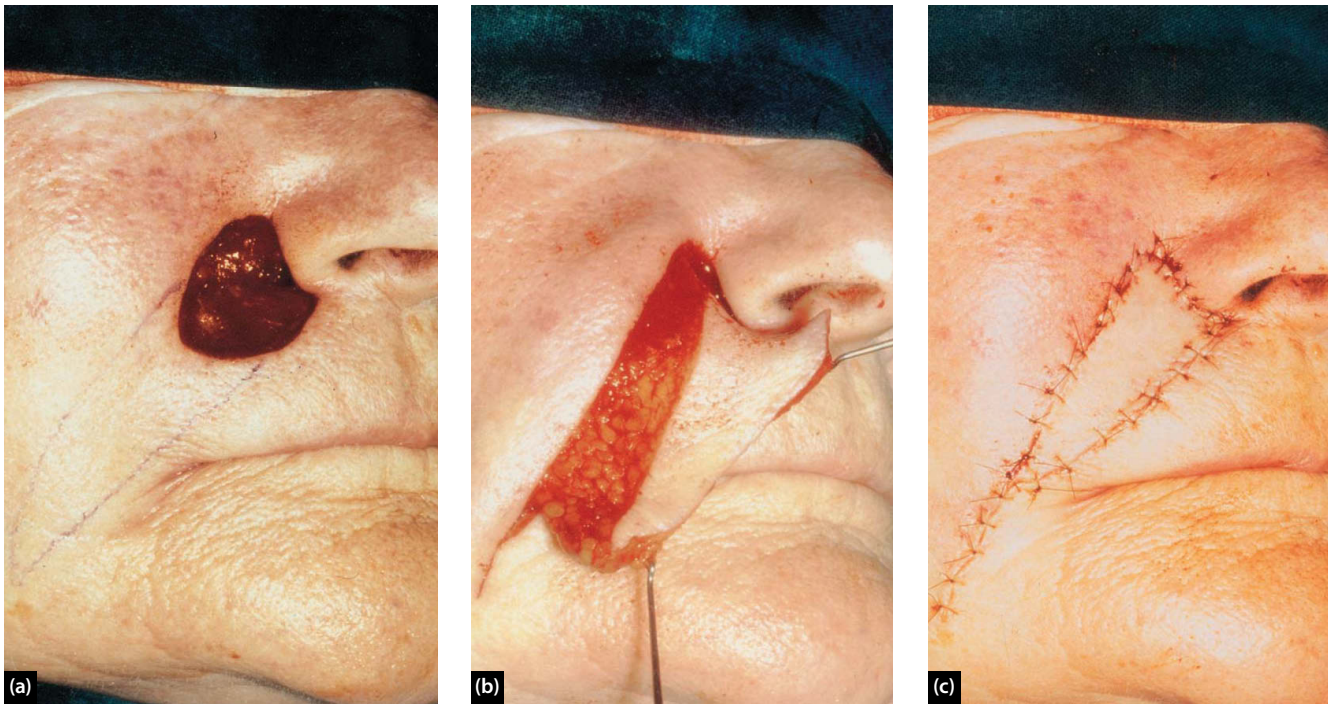

Figure 91.11 (a) Defect in right alar/nasolabial region with design of nasolabial V–Y advancement flap. **(b)** Flap raised. **(c)** Flap inset.

Pivot flaps

All pivot flaps move about a fixed pivot point and an arc which is the line of greatest tension of the flap. A pivot flap can be either a transposition flap, where the flap is moved into an adjacent defect by pivoting around the pivot point, or a rotation flap, where the flap is rotated around the pivot point into the defect (**Figure 91.13**). When a flap is transposed to cover the primary defect, the secondary donor defect is usually closed directly if possible, skin grafted, or reconstructed with a second flap. An example of this is the bilobed flap, where a second flap is raised to close the donor defect (**Figure 91.14**).

TRANSPOSITION FLAPS

A transposition flap is a flap that is moved into an adjacent defect by pivoting around its fixed point. Various types of transposition flaps have been described including the rhomboid flap, the flag or banner flap, and the bilobed flap.

Rhomboid flaps

A rhomboid flap is a type of transposition flap where the donor defect is closed directly.[20] The defect is firstly designed as a rhomboid. Each of the limbs of the defect and the flap being raised need to be of equal length and the angles of the rhomboid need to be 120 degrees and 60 degrees, respectively. The flap needs to be designed so that the donor site scar lies parallel to the relaxed skin tension lines (**Figure 91.15**). A variation of the rhomboid flap is the Dufourmentel flap,[21] which has limbs of equal lengths but angles of 150 degrees and 30 degrees. Other variations of the geometry of the rhomboid flap have been described.[22] One of these is the 'square peg in the round hole' where the primary defect is circular (as is the case in most clinical situations) and the rhomboid flap is stretched to fill the defect.[23] This reduces the need to excise the extra skin required in the standard rhomboid flap, which is particularly important in cosmetically sensitive areas such as the face.

Flag or banner flaps

A number of small transposition flaps can be used around the face and generally the donor site is closed directly. These are termed flag flaps as the piece of tissue moved resembles a flag or banner. These are normally random pattern flaps but can be based on a known artery in some parts of the head or neck. A glabellar flap is an axial transposition flag flap based on the supratrochlear artery. This allows the flap length to be three times the base breadth (**Figure 91.16**). It is transposed to cover the primary defect and the donor site is closed directly.

Bilobed flaps

A bilobed flap consists of two transposition flaps.[24] The first flap is transposed into the primary defect, the second flap is transposed into the secondary defect (the original site of the first flap) and the tertiary defect (the original site of the second flap) is closed directly. The flap should be designed so that the directly closed tertiary defect is parallel to the relaxed skin tension lines (see **Figures 91.14** and **91.15**). Theoretically, the bilobed flap uses less tissue than any other method of wound closure and because of this minimizes tension at the primary defect.[25]

Figure 91.12 **(a)** Total lower eyelid defect. **(b)** Tripier flap design from upper eyelid. **(c)** Flap raised. **(d)** Tripier flap inset to lower eyelid defect.

The ideal use of a bilobed flap is where there is tissue available locally and where it is important to avoid producing tissue stretch. The bilobed flap is most commonly used to deal with defects at the tip of the nose. Although there is some spare tissue around this area, the nasal tip can become displaced if skin is imported to cover defects here as a local flap.[26]

ROTATION FLAPS

Rotation flaps are large flaps that rotate into the primary defect. The volume of tissue raised in the flap is high when compared to the defect being closed. Normally, the flap is a semicircle and the primary defect is 'triangulated' or designed as a triangle, adjacent to the flap. Geometrically, the flap circumference should be at least eight times the width of the defect to allow closure of the donor site; however, in practice, it is best to design the flap as large as possible as the direct closure of the donor site relies on tissue redistribution and tissue elasticity. Occasionally, the use of a Burow triangle or a back cut may be needed. A back cut releases a rotation flap that is too tight by decreasing the tension at the base of the flap, thus moving its pivot point towards the defect. This decreases the tension of closure at the site of the primary defect. A back cut that is taken too far, however, may significantly decrease the width of the flap, which will increase the chance of devascularizing it. These flaps are useful for dealing with defects of the scalp or cheek (see **Figure 91.13**).

RECONSTRUCTION OF SPECIFIC ANATOMICAL REGIONS OF THE HEAD AND NECK

Scalp

ANATOMY

The scalp has five distinct anatomical layers. From superficial to deep, these are the skin, subcutaneous connective tissue, muscle or aponeurosis (galea), loose areolar tissue and pericranium. The skin of the scalp is the thickest on

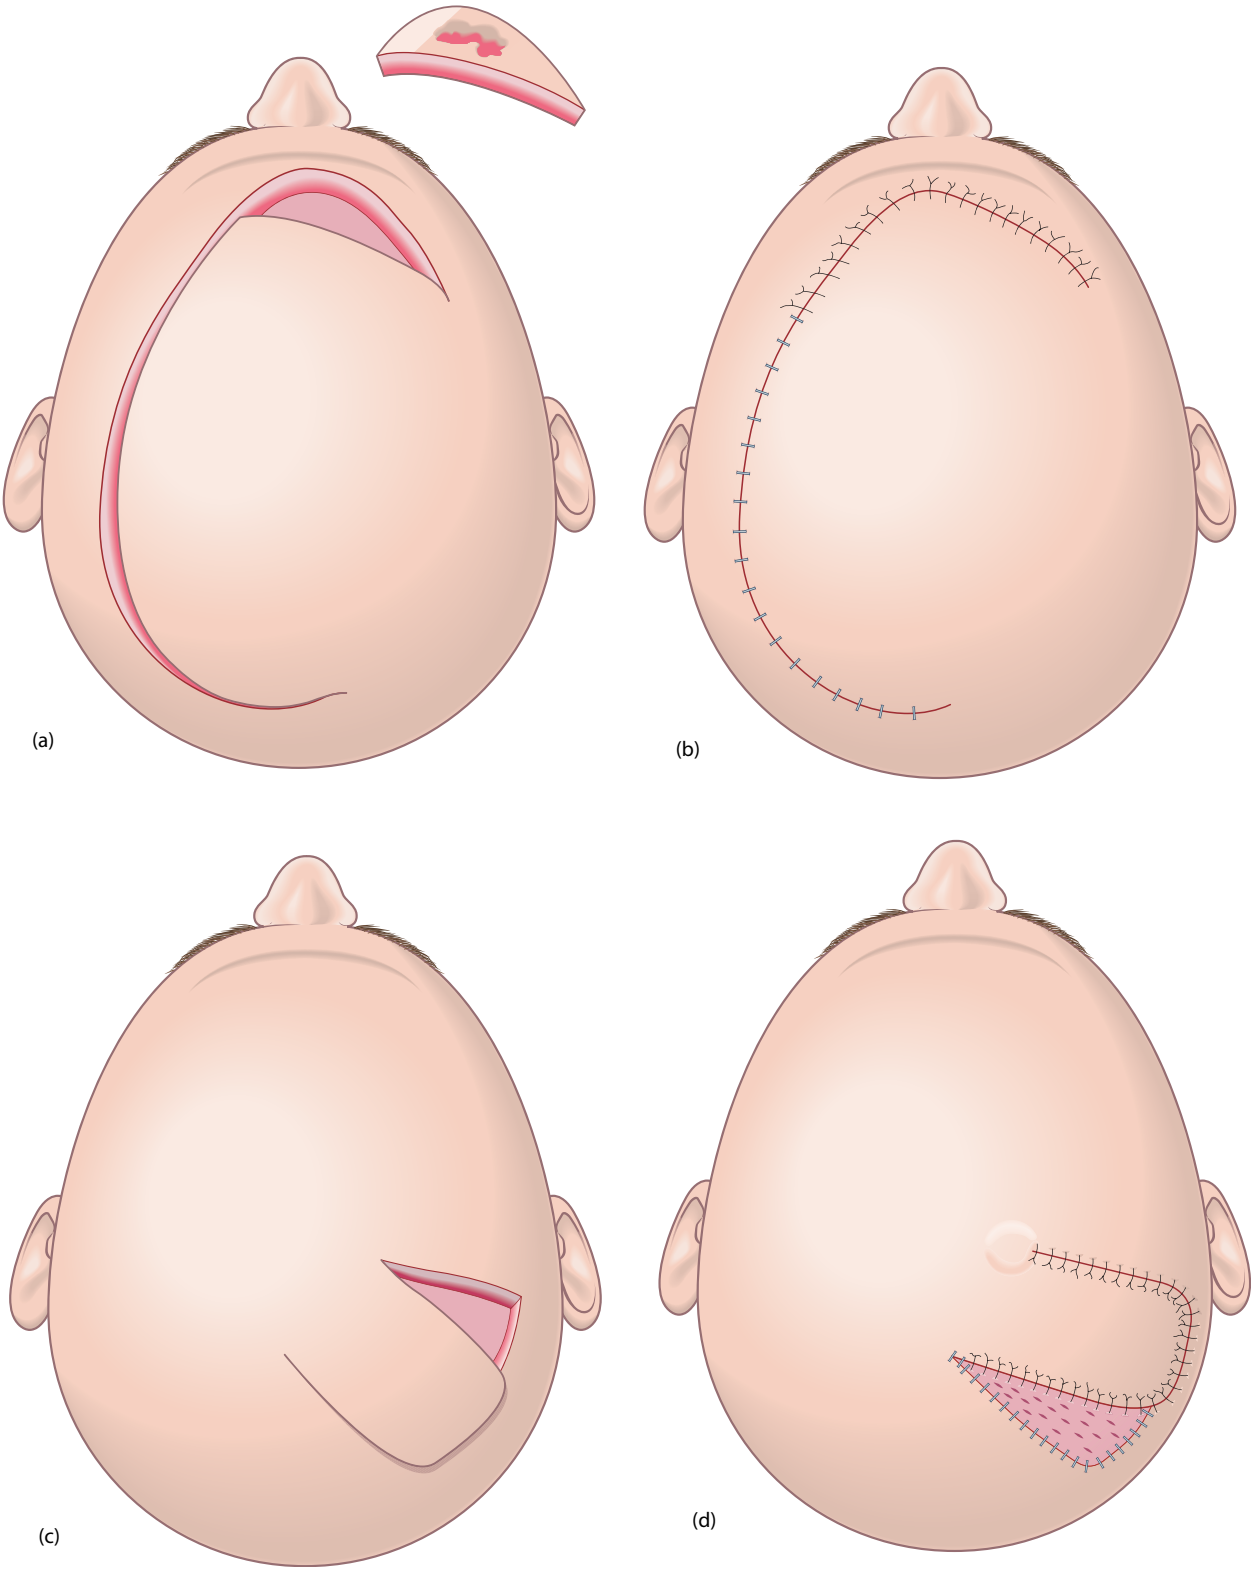

Figure 91.13 Scalp transposition and rotation flap design.

the human body, ranging from 3 mm to 8 mm. Beneath the skin, the subcutaneous tissue contains the vessels and nerves supplying the scalp. Deep to this is the musculoaponeurotic layer consisting of the frontalis muscle anteriorly and the occipitalis muscle posteriorly. These muscles are connected by an aponeurotic layer (the galea aponeurotica). Laterally, this aponeurosis is connected to the subcutaneous musculoaponeurotic system (SMAS) of the face.

Figure 91.16 (a) Glabella transposition flap design for right inner canthal defect reconstruction. **(b)** Flap raised and donor site closed. **(c)** Final result.

The layer of loose areolar tissue deep to this, also known as the inominate fascia, is an avascular plane. Owing to this, most local flaps of the scalp are raised at this level because it is easy to dissect and relatively bloodless, thus making scalp flaps fasciocutaneous rather than cutaneous. The deepest layer is the pericranium (the periosteum of the skull) which is firmly adherent to the underlying bone. However, it can be raised and turned over on itself to form a pericranial flap.[27] This is viable tissue that can cover exposed bone and is capable of taking a skin graft. Laterally, the pericranium is continuous with the deep temporal fascia overlying the temporalis muscle.

The scalp has a rich blood supply and is supplied by tributaries from the external and internal carotid arterial system. The external carotid branches supplying the scalp include the paired superficial temporal, posterior auricular and occipital arteries. On the anterior scalp, there is further supply from the paired supratrochlear and

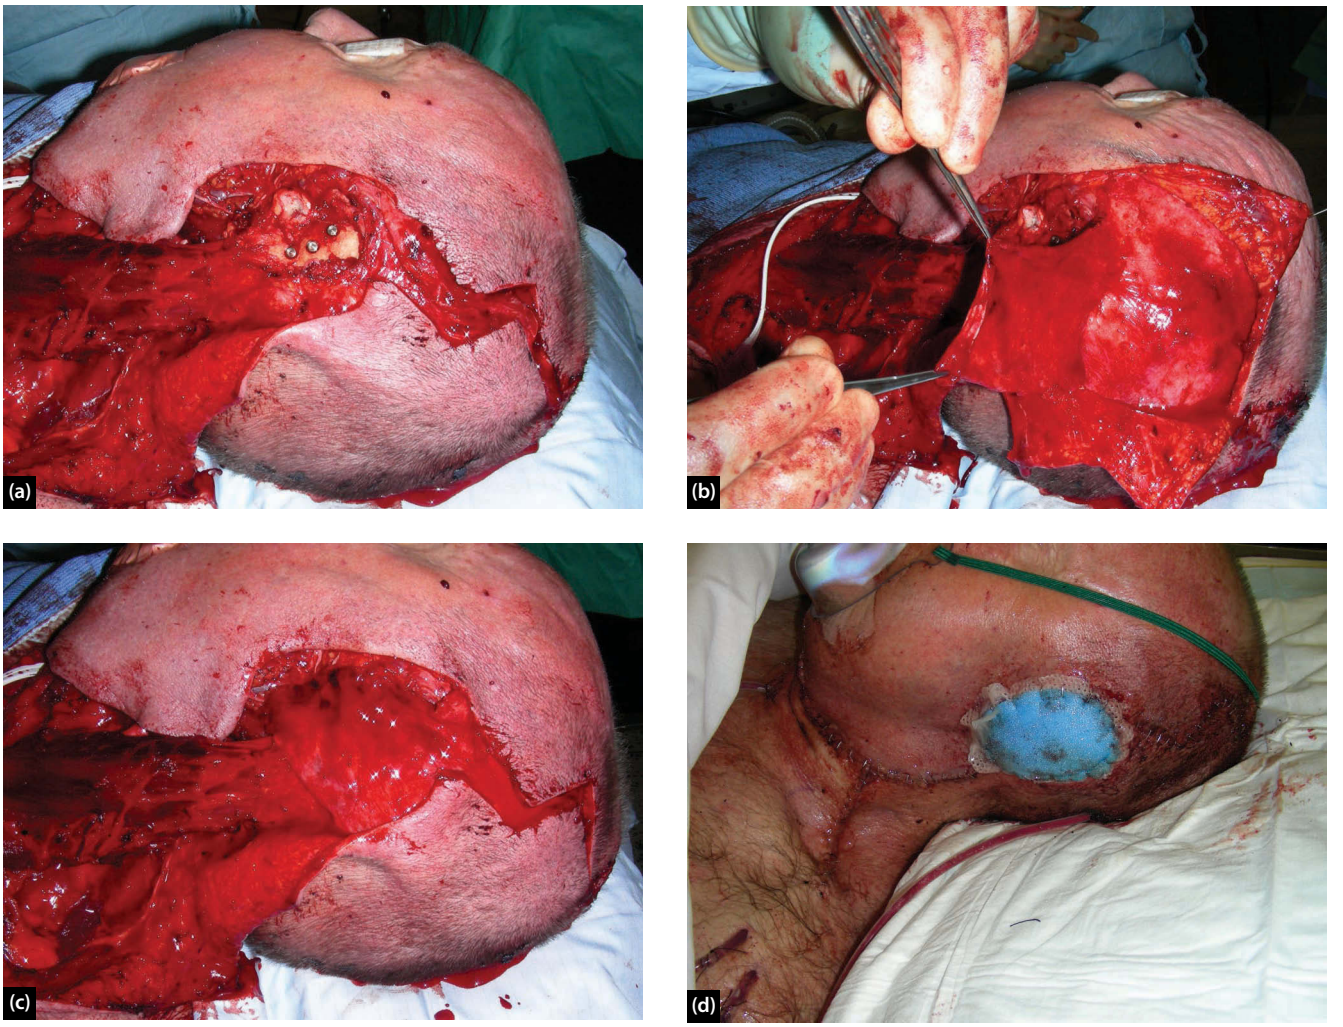

Figure 91.17 (a) Defect in left auricular area with placement of osseointegrated implants. **(b)** Temporoparietal flap raised to cover osseointegrated implants. **(c)** Flap inset. **(d)** Foam dressing covering split skin graft over temporoparietal flap with closure of neck dissection incisions.

supraorbital arteries, themselves being branches of the ophthalmic artery. There is a rich anastomosis between these arteries which allows the entire scalp to survive on any one of these vessels. For the purposes of scalp reconstruction using local flaps, however, it is often convenient to view the blood supply as arising from three separate axes: anterior axis (supratrochlear, supraorbital), lateral axis (superficial temporal, posterior auricular) and a posterior axis (occipital). To allow for reliable vascularity and survival, scalp flaps should contain at least one of these axes.

SCALP FLAPS

There is a paucity of skin and soft tissue on the scalp and therefore only small defects (<3 cm) of the scalp may be closed primarily with undermining. Larger defects require reconstruction with a skin graft, local flaps or free flaps.

Skin grafts are used often on the scalp but require a healthy vascular bed such as the pericranium in order to take. When the ablative surgery includes the pericranium and the outer table becomes exposed, a vascular bed may be achieved either by burring the outer table to expose the small diploic vessels or by covering the exposed bone with a healthy vascular bed such as with a pericranial turnover flap prior to skin grafting.[28] This technique, however, risks dural exposure in children whose cranial bones are thin.

Local scalp flaps can be either rotation or transposition flaps. In order for a rotation flap to be successful, the defect needs to be triangulated and the flap designed large enough to allow coverage of the primary defect and allow direct closure of the donor site. Back cuts or Burow triangles as well as scoring the galea on the underside of the flap can help the flap stretch adequately for closure. A transposition flap on the scalp involves raising a flap adjacent to the defect and transposing it to achieve coverage. This will expose the pericranium over the donor site requiring skin grafting (see **Figure 91.14a**). An alternative is a pericranial transposition flap to achieve a vascularized bed which can subsequently be skin grafted. In larger defects, tissue expansion is a useful adjunct to increase

the amount of tissue available for reconstruction.[29] Alternatively, multiple interdigitating flaps[30, 31] or free flaps can be used; however, this is beyond the scope of this chapter.

TEMPOROPARIETAL FASCIA FLAPS

Scalp flaps can also be useful in reconstructing defects around the head and neck. The fascia in the temporal region is a prime example. This fascia has several well-described layers. The superficial temporal fascia (temporoparietal fascia, TPF) lies immediately deep to the hair follicles and is in continuity with the galea superiorly and the SMAS inferiorly. Deep to this is an avascular layer, known as the innominate fascia, which is in continuity with the loose areolar tissue of the scalp. The deep temporal fascia (or temporalis fascia) is the deepest layer and this is in continuity with the pericranium superiorly.[32] Each of these layers may be used as a local flap to cover defects within their arc of rotation. They are particularly useful in covering exposed bone around the skull (**Figure 91.17**) where a TPF flap is used to cover the exposed temporal bone following total resection of the external ear and extended neck dissection for a $T_4N_1M_0$ cutaneous squamous cell carcinoma.

Forehead and glabella

ANATOMY

The forehead is bounded by the anterior hairline superiorly, the eyebrows inferiorly and the temporal hairline laterally. Underlying the skin is the frontalis muscle which arises as a continuation of the galea aponeurotica and inserts into the dermis of the forehead, allowing brow elevation. It is supplied by the temporal branch of the facial nerve. Sensation to the forehead and vertex of the scalp is supplied by the supratrochlear as well as the superficial and deep divisions of the supraorbital nerve. The superficial division of the supraorbital nerve and the supratrochlear nerve branches lie superficial to the frontalis muscle. The deep division of the supraorbital nerve lies between the galea aponeurotica and the periosteum, medial to and parallel with the superior temporal line of the skull. The blood supply of the forehead is rich and is provided by branches of the internal (supraorbital and supratrochlear arteries) and external (facial and superficial temporal arteries) carotid arteries.

LOCAL FLAPS

The forehead is very visible to observers and so care should be taken to place incisions horizontally or along the hairline and eyebrow. Where direct closure may cause distortion of the hairline or brow, a large full-thickness skin graft would give an adequate result. Larger defects of the forehead can be reconstructed with advancement flaps or hatchet flaps, which are random rotation flaps with a back cut. They can be single or double and heal with minimal scarring. Large defects can be closed using this technique and it is possible to preserve the supratrochlear and supraorbital nerves when dissecting the forehead to maintain sensation.[33] Other techniques for forehead reconstruction include the use of scalp rotation flaps, which can be tissue expanded to produce a larger flap.[34] These, however, are limited as they import hair-bearing skin onto the forehead and distort the hairline.

Eyelid

ANATOMY

The anatomy of the periorbital region is complex and without a good understanding of the structure and function of the eyelids periorbital excisions and reconstructions should not be undertaken. The upper and lower eyelids can be divided into the anterior and posterior lamella in cross section, with an intervening orbital septum. This septum is continuous with the periosteum and extends from the arcus marginalis or the bony margin of the orbit to the margin of the eyelid. In the upper lid, the septum inserts onto the levator aponeurosis 2–5 mm above the superior tarsus whereas, in the lower lid, it attaches to the inferior tarsus directly. The anterior lamella consists of the skin and the orbicularis oculi muscle, whereas the posterior lamella consists of the conjunctiva and the tarsal plates. The skin of the eyelid is the thinnest in the body (1 mm) and is loosely attached to the orbicularis oculi muscle. This muscle is arranged in a concentric ring around the orbit and upon contracture acts as a sphincter, closing the orbital aperture. It can be divided into three parts: an outer orbital part covering bone, and inner preseptal and pretarsal components. Medially, the orbital portion originates directly from the bony orbital rim and the medial canthal tendon. Inferiorly, the orbicularis attaches indirectly to the orbital rim through the orbital-retaining ligament. Laterally, this ligament merges into the lateral orbital thickening.[35] The tarsal plate forms the skeleton of the eyelid and is a dense sheet of fibrous tissue. The superior tarsus measures approximately 10–12 mm vertically from the lid margin; the lower tarsus measures approximately 3.7 mm vertically.[36] The deepest structure of the eyelid is its lining, the conjunctiva, which contains many eccrine and apocrine glands. There are further sebaceous glands of Zeis associated with the eyelashes.

The upper eyelid elevates due to the contraction of the levator palpabrae muscle (innervated by the oculomotor nerve). This originates from the lesser wing of the sphenoid and extends anteriorly along the superior orbit to Whitnall's ligament, which acts as a fulcrum to change its vector of pull from a horizontal to a vertical direction, before finally attaching to the superior tarsal plate. Constriction of the upper eyelid is due to contraction of the orbicularis oculi muscle (innervated by the temporal and zygomatic branches of the facial nerve). The lower lid has only limited descent from the action of the capsulopalpebral fascia, which originates as fibroelastic tissue from the interior rectus muscle and inserts into the inferior tarsal plate. The blood supply of the eyelids consists of a rich anastomosis between branches from the internal and external carotid arterial systems. The sensory supply

of the upper and lower eyelids is derived from branches of the ophthalmic and maxillary divisions of the trigeminal nerve respectively.

EYELID RECONSTRUCTION

Partial-thickness defects

Defects in the eyelid can be partial thickness, with either the anterior or posterior lamella having been excised, or full thickness. Partial-thickness defects of the anterior lamella are best either closed directly if small (up to a third of the eyelid) or resurfaced with a full-thickness skin graft. The posterior lamella can be reconstructed with a graft of buccal or hard palate mucosa[37] or a nasal chondromucosal[38] graft consisting of nasal mucosa and septal cartilage. These grafts are also useful in full-thickness defects.

Full-thickness defects

Reconstruction of full-thickness defects of the eyelids is complex and requires reconstruction of both the anterior and posterior lamella for a satisfactory result. This can be done by using either a single flap to reconstruct both layers or a flap to reconstruct the anterior lamella and a composite graft for the posterior lamella. At least one of the two layers must have its own blood supply as a graft placed on another graft will fail. The size of the defect also needs to be taken into account when planning for reconstruction. Full-thickness defects of up to one-quarter of the lid length can be closed directly and this increases to one-third in the elderly population with lax skin. It is important to note that each of the layers (i.e. conjunctiva, tarsal plate, orbicularis and skin) will need to be repaired individually.

When the size of the defect approaches 50% of the total eyelid, two additional techniques may be used to recruit adjacent lateral tissue to enable closure. The first of these is a lateral cantholysis. A horizontal incision is made from the lateral canthus to the orbital rim. The lateral canthal tendon is identified and divided. The lateral part of the lid can then be mobilized medially to close the wound. The second is by using a tenzel semicircular flap which allows lateral tissue consisting of skin and muscle to pivot on the lateral canthus and advance/rotate into the defect to allow closure.[39] The technique requires a lateral canthotomy, inferior cantholysis and suture suspension of the flap to the lateral orbital margin. This flap is useful in both upper and lower eyelid defects provided some tarsus remains to provide support.

Larger defects of the lower eyelid can be reconstructed with a cheek rotation flap[40] combined with a free composite graft to reconstruct the posterior lamella. Larger defects of the upper eyelid are difficult to reconstruct and usually require a glabellar transposition flap or recruitment of tissue from the lower eyelid in the form of a switch flap[41] or a Cutler-Beard flap.[42] Switch flaps can be based medially or laterally on medial lower eyelid tissue which is then rotated into the upper lid defect. At a second stage, the flap is divided at its base and the donor site is closed with a cheek rotation flap.

The Cutler-Beard flap is an advancement flap from the full thickness of the lower lid, preserving the lower lid margin and tarsus. At a second stage 4–6 weeks later, the flap is divided and returned to the lower border of the intact lower lid margin. The tissue that is left on the upper lid is used to fashion the upper lid margin. These techniques do not import components for the posterior lamella and this will therefore require a suitable graft for reconstruction.

Nose

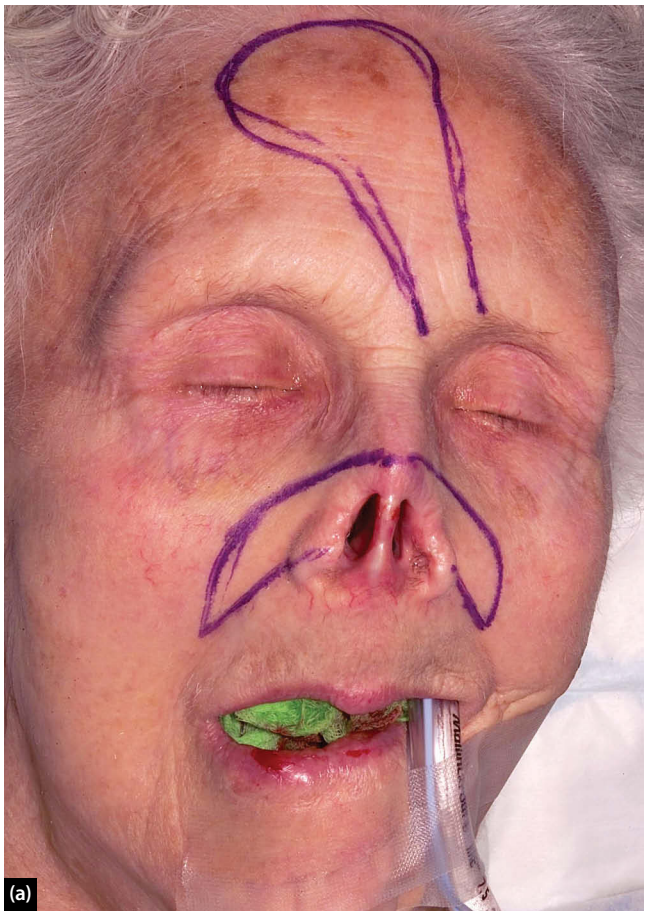
Analysis of the nasal defect to be reconstructed in terms of the component layers is essential when planning reconstruction. Primary closure is limited to small defects due to the relative lack of skin laxity. In partial-thickness defects where there is remaining subcutaneous tissue or perichondrium, the use of full-thickness skin grafts can result in very good cosmetic outcomes. Local flaps are also useful in such cases and will be discussed later. If the defect is full thickness, three distinct layers need to be considered and reconstructed: these are the nasal lining, nasal support and overlying skin. When a small nasal rim defect is being reconstructed, a composite graft taken from the ear which has all three layers is an option. This involves taking a full-thickness piece of the ear including both anterior and posterior skin.

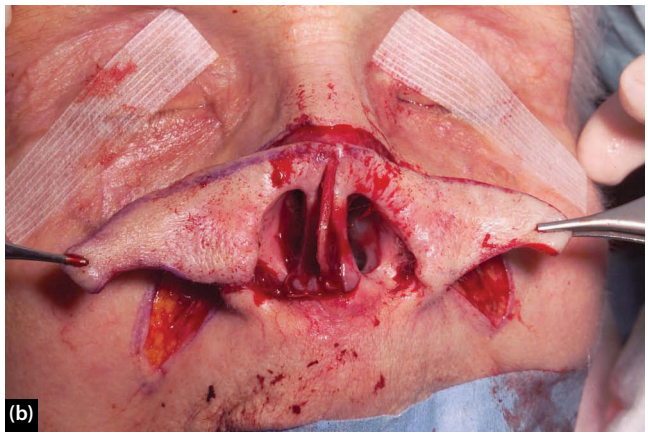
Larger full-thickness defects of the nose following partial or total rhinectomy are more difficult to manage. A local flap can be used to reconstruct both the lining and skin cover of the nose by folding the flap in two. The most commonly used flaps for this are superiorly based nasolabial flaps. Bilateral flaps can be raised to import a large volume of tissue.[43] An alternative to folding a flap is to use one flap for the lining and another for the cover. The nasolabial flap can be used for the lining as can a random hinge flap where adjacent tissue is raised and flipped over to fill the defect.[44] The flaps used as lining can then be covered with either a skin graft or another flap such as a forehead flap (**Figure 91.18**). It has to be remembered that, when dealing with a total rhinectomy defect, very good results can be obtained using a prosthesis. With the advent of osseointegration, a prosthetic nose is both cosmetically acceptable and convenient for the patient.[45] This is a viable alternative to surgical reconstruction.

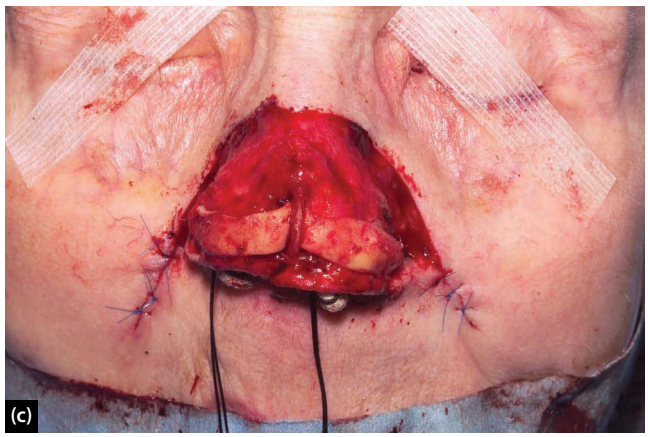
SKELETAL SUPPORT

The nose is supported by a rigid central framework and the more flexible lateral walls composed of the upper and lower lateral cartilages. When lost, it is important to reconstruct these elements to maintain projection and to allow the nasal aperture to remain open to permit airflow. Midline support can be provided by an L-strut, a hinged septal flap, a septal pivot flap or a cantilever bone graft.

An L-strut consists of a longitudinal piece of bone or cartilage that is secured on the nasal radix and extends along the dorsum of the nose to the tip where it is bent







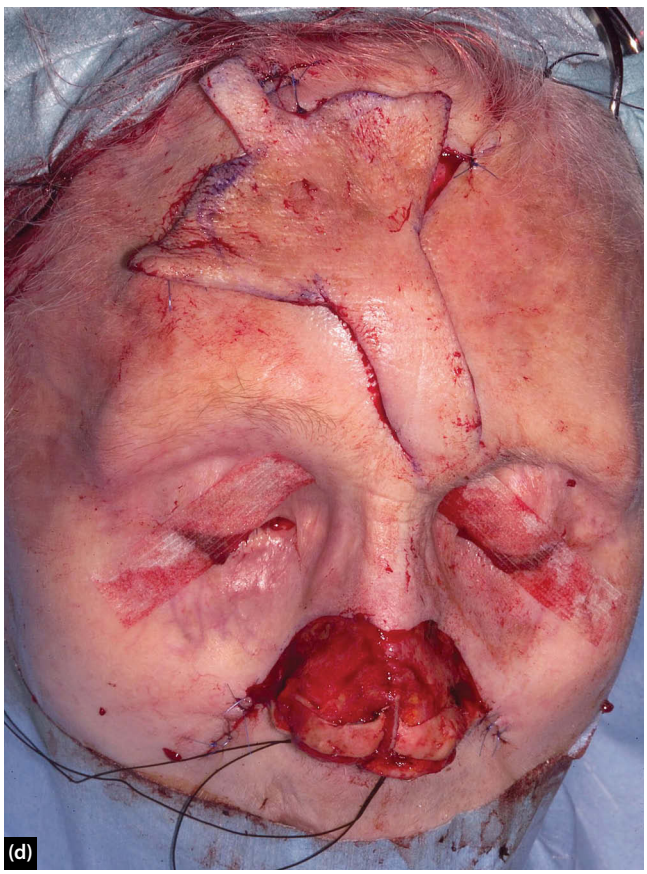


Figure 91.18 (a) Forehead and nasolabial flap design for cutaneous and lining reconstruction respectively. **(b)** Nasolabial flaps raised. **(c)** Nasolabial flaps inset with cartilage grafts to support. **(d)** Forehead flap raised. *(Continued)*

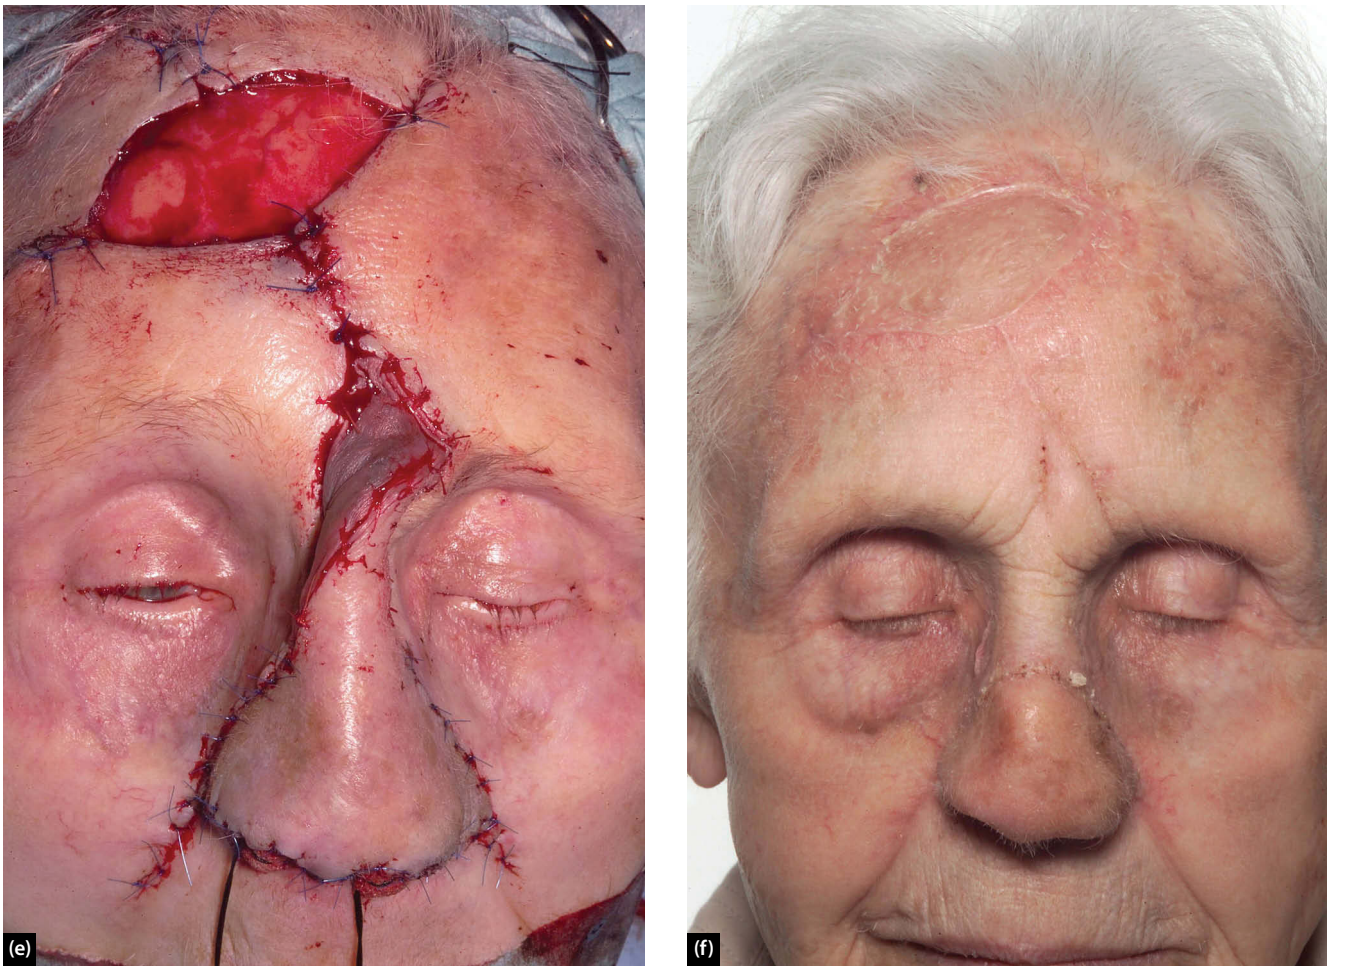

Figure 91.18 (Continued) (e) Forehead flap inset and split skin graft coverage of pedicle and donor site. **(f)** Final result.

sharply to rest on the anterior nasal spine.[46] The hinged septal flap is an L-shaped flap carved from the patient's remaining septum and hinged superiorly on the caudal end of the nasal bones.[47] The septal pivot flap is similar to the hinged septal flap except that the septum in this case brings with it simultaneous mucosa that can be used as lining. If there is insufficient local tissue, then a cantilever graft can be used which consists of a strong, longitudinal bone graft harvested from the calvarium or rib and secured to the radix with miniscrew fixation or wires.[48] The flexible lateral walls of the nose require more pliable cartilage grafts to be used.

LINING

The lining is an important component of the reconstruction as even partial necrosis may result in secondary contracture that will invariably distort the overall result. There are several methods to provide lining. The simplest method is to graft the underside of a flap that is to be used as external cover (e.g. the underside of a forehead flap prior to transfer). When support is also required, a composite graft consisting of skin and cartilage can be used. Local flaps such as the septal door flap,[47] septal mucoperichondrial flap, bipedicled mucosal advancement flap[49] and nasolabial flaps are useful for providing large amounts of tissue for lining. When there is a paucity of local tissue, free flaps such as a free radial forearm flap can be employed to provide lining.

SKIN COVER

The local flap options used to cover nasal defects are varied and choice is dependent on the size and location of the defect. Sidewall defects can be effectively reconstructed with a cheek advancement flap or rhomboid flap.[50] There are a large variety of local flaps that can be used to reconstruct dorsal defects. The glabellar flap[51] transfers tissue from the glabella and is useful in reconstructing defects of the root and upper bridge of the nose. Defects of the dorsum of the nose in the mid and lower third of less than 2 cm in diameter can effectively be reconstructed with the dorsal nasal flap[52] or one of its many variants. These flaps are based on the angular artery and require the nasal dorsum to be degloved to allow sufficient movement prior to flap inset. Advancement flaps such as the Rintala flap[53] are also useful for dorsal nasal defects (see **Figure 91.10**). Other flaps that are commonly used include transposition flaps such as a superiorly based nasolabial flap[54] (see **Figure 91.11**) or a bilobed

flap (see **Figure 91.14**).[55] In addition to these techniques, microvascular free-tissue transfer of a chondrocutaneous flap from the ear has been described.[56]

FOREHEAD FLAP

The forehead flap is a local cutaneous axial flap based on the supratrochlear artery. It is one of the oldest flaps in use and the earliest available description is from 600 BC by Susruta in India.[57] A large flap of skin from the forehead can be raised on this vessel which can then be used to cover defects around the orbit and the nose. The donor site can be the vertical height of the forehead or the flap can be planned obliquely to maximize the length and therefore the reach of the flap. An obliquely placed donor site also reduces the arc of rotation. The donor site can be closed directly if the width of the flap is kept small (less than 2.5 cm) and this leaves minimal scarring. If a wider flap is required, the defect needs to be skin-grafted; an alternative to this is to leave the defect to heal by secondary intention, which can give a very acceptable cosmetic outcome.[58] The transfer is normally carried out in two stages: the flap is raised and the tip of the flap inset into the primary defect. The remainder of the flap is then tubed to form a pedicle. After 3 weeks, the tip of the flap will have undergone some revascularization from the recipient site and the pedicle is then divided and reinset into the secondary defect (see **Figure 91.18d–f**). Alternatively, when reconstructing nasal defects, a third stage can be included.[59] The flap is raised 2 weeks after it is inset, thinned and then reinset. The pedicle is then divided after a further 2 weeks. This prevents having a bulbous nasal tip, giving an overall better cosmetic result.

Lip

The lips are complex structures involved in articulation, swallowing and facial expression. They are three-dimensional structures with an outer layer of skin and an inner layer of mucosa separated by muscle. The junction between the skin and mucosa is a specialized area as the skin blends into white roll, then vermilion and then into mucosa. A 1 mm discrepancy at this junction is noticeable at a distance of 1 metre.

The orbicularis oris muscle contained within the lips is a complex muscle containing fibres in different orientations which can close the mouth, approximate the lips to the maxilla and mandible or purse the lips. In addition, muscle fibres blend into the orbicularis oris from the levator labii superioris and other elevators of the lip superiorly, from buccinators laterally and from depressor labii inferioris and the other lip depressors inferiorly.

The options for donor tissue for lip reconstruction are the remaining lip, the adjacent cheek, the opposite lip or from distant sites. It should be remembered that the goal of lip reconstruction is to restore oral continence, i.e. the role of the mouth as a sphincter, without causing microstomia (a tight or small mouth),[60] and to ensure accurate opposition of the vermilion. The upper and lower lips should be considered separately as different techniques are needed to reconstruct similar defects in the upper or lower lip.

LOWER LIP

Defects up to one-third of the length of the lower lip can be excised as a wedge (or a pentagon) and closed directly. It is important to repair all three layers of the lip, namely the mucosa, muscle and skin, to achieve good function and approximation. Larger, superficial defects of the lip can be resurfaced with a split-thickness skin graft (the entire lower lip can be resurfaced in this way) or by a tongue flap. A flap is raised from the undersurface of the tongue and inset in the defect in the lower lip. The flap is based anteriorly and the donor site is not closed at the time the flap is raised. After 10 days, the flap is divided and inset. At this point the donor site is closed directly.

For defects of three-quarters of the lower lip the Karapandzic flap can be used.[61] This is a combined axial advancement/rotation flap based on the facial artery. A transverse incision from the base of the defect to both nasolabial folds is made and the nasolabial folds are then incised in a cephalic direction. Laterally, the vessels and nerves are identified and preserved. The flap is mobilized by spreading, not dividing, the fibres of the orbicularis oris to preserve its neurovascular supply. The bilateral flaps are then advanced and rotated and then repaired in layers. Total reconstruction of both the upper and lower lip has been described using microvascular free-tissue transfer.[62]

UPPER LIP

Defects up to one-quarter of the size of the upper lip can be closed directly. The orbicularis oris needs to be dissected free of the skin and the mucosa and repaired separately before the overlying tissues are closed. For larger defects, a reverse Karapandzic flap can be used, where the nasolabial folds are incised along with the nasal sill and the skin kept intact in the submental area.

The Abbe flap is a full-thickness flap taken from the lower lip and inset into the upper lip. The layers of mucosa, muscle and skin need to be accurately inset. The flap is then left attached to the lower lip for 1 week before division of the pedicle from the lower lip.[63] The Abbe flap should be taken from the lower lip to reconstruct the upper lip and not from the upper lip to the lower lip. A variation of the Abbe flap is the Abbe-Estlander flap, which is used to reconstruct defects of the oral commisure. It can be taken from either the upper or the lower lip and is a single-stage operation as the pedicle of the flap becomes the new commissure.

Cheek

The cheeks are the largest region of the face. They consist of skin that covers muscle groups which are either attached to the underlying maxilla and mandible or are lined on their inner surface by buccal mucosa. Various important structures transverse the cheeks, including the parotid duct and the branches of the facial nerves. The cheek has

been subdivided into three separate overlapping zones – a suborbital, a preauricular and a buccomandibular area – and reconstruction should follow these regional aesthetic units where possible (see **Figure 91.4**).[64] Consideration also needs to be paid to the 3D structure of the cheek with its natural contours, shadows and hair lines.

TECHNIQUES FOR RECONSTRUCTION

The majority of defects of the cheek will be following ablative surgery for cutaneous malignancies. These normally present in the elderly population and even quite large defects can be closed directly, due to pre-existing skin laxity in this age group. As well as the relaxed skin tension lines, there are other noticeable lines in the cheek in which scars can be hidden. These are the nasolabial fold, infraorbital rim, alar crease, hairline and jawline. Split-thickness skin grafts on the cheek are very noticeable as they tend to transgress the different regions of the cheek and alter the contour and colour, giving a poor cosmetic result. When used in close proximity to the lower eyelid, they may also result in ectropion. For situations where a skin graft is necessary, full-thickness grafts are best to limit contracture and improve colour match. For small defects not amenable to direct closure, local flaps are appropriate. Due to the large surface area of the cheek, a full range of flaps can be utilized, including rhomboid transposition flaps, small cheek rotation–advancement flaps (**Figure 91.19**) or V–Y advancement flaps. Defects that are not amenable to small local flaps may require reconstruction with a cervicofacial flap (**Figure 91.20**).[65] These flaps import tissue from the neck and lower jawline, giving excellent colour, texture and contour match.

In even more extensive defects of the cheek, it may be necessary to import tissue from the chest wall with a cervicopectoral flap.[66] Tissue expansion techniques have also been described and offer excellent colour and texture match[67] but they require at least two stages, multiple visits for expansion and a period of time when the patient will have to tolerate the appearance of the expander.

Figure 91.20 (a) Basal cell carcinoma on left cheek marked for excision with cervicofacial flap designed for reconstruction. **(b)** Post-operative appearance following cervicofacial flap reconstruction.

Ear

ANATOMY

The ear consists of skin covering an auricular cartilage framework. The framework comprises the conchal complex, the antihelix–antitragus complex and the helix–lobule complex. The musculature consists of intrinsic (helicis major and minor, tragicus, antitragicus) and extrinsic (anterior, superior and posterior auricularis). Vascular supply is derived from the posterior auricular and superficial temporal arteries with extensive interconnections between the two networks. Sensation is supplied by the great auricular nerve, the auriculotemporal nerve, the lesser occipital nerve and the auricular branch of the vagus nerve.

TECHNIQUES FOR RECONSTRUCTION

The ear is one of the commonest sites for cutaneous malignancies, particularly squamous cell carcinomas, and resection of these tumours may result in partial- or full-thickness defects. Successful reconstruction requires accurate analysis of the defect and a systematic approach to reconstruction. If the defect is small enough, direct closure can be undertaken. Lesions on the upper or middle third of the ear requiring a larger margin for clearance can be closed with a wedge excision. There are various patterns of excision that have been described to decrease tension at the suture line.[68] This technique results in a smaller ear and patients must be warned, but it is well tolerated and usually results in an acceptable cosmetic appearance. Full-thickness skin grafts are useful if the perichondrium is intact or if excision involves either the anterior or posterior skin along with its underlying cartilage. This technique gives a good colour match particularly if the graft is harvested from the head and neck region. If the defect is small but involves the full thickness of the ear, a composite graft from the opposite ear is an option but its survival can be tenuous.

There are also various local flaps that can be employed. An Antia–Buch chondrocutaneous advancement flap is useful for small to moderate sized defects of the upper and middle ear.[69] This involves freeing the helix from the scapha through an incision in the helical sulcus extending through the anterior skin and cartilage. The posteromedial skin superficial to the perichondrium is undermined, and the superior and inferior chondrocutaneous components are advanced for closure.

Another reconstructive option for the upper ear is a conchal rotation flap, which involves the rotation of the full thickness of the concha on the external edge of the ear to form the new superior ear.[70] The Converse tunnel technique involves the insertion of a cartilage graft shaped to the size of the defect beneath the mastoid skin, which is then sutured to the edges of the defect. At a second stage, the auricle is separated from the mastoid area with the graft attached and the donor site is skin-grafted.[71]

For large defects of the middle ear, reconstruction can be undertaken as described by Dieffenbach.[72] This involves a postauricular advancement flap which is approximated into the defect. A cartilage graft can be used as support beneath the flap. At a second stage, the flap is divided at its base and folded around the posteromedial aspect of the ear to complete the reconstruction. A skin graft is applied to close the donor defect. Techniques for reconstructing defects of the lower third of the ear are limited. A double-lobed postauricular flap may be used to reconstruct the earlobe. It is raised and folded onto itself, then sutured onto itself and remaining auricle to form the new earlobe.[73]

KEY POINTS

- Make use of the reconstructive ladder.
- Understand the process of wound and graft healing.
- Replace like with like.
- Reconstruct individual cosmetic units where possible.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: pedicled flap, head and neck, temporoparietal flap, FAMM flap, submental flap, nasolabial flap, pectoralis major flap, latissimus dorsi flap, trapezius flap.

INTRODUCTION

Defects following head and neck surgery can often be closed by direct suture. This applies to both the skin and mucous membranes. This technique is used when the defect is small, and where local conditions allow adequate amounts of mobile tissue. However, for larger defects or in situations when direct suture is not applicable, surgical defects may be filled by free grafts, local skin flaps, with pedicled flaps that may be either axial cutaneous or musculocutaneous, or with free tissue transfer. This chapter outlines the use of pedicled flaps in head and neck surgery.

GILLIES' PRINCIPLES OF RECONSTRUCTIVE SURGERY

There are some simple rules to head and neck reconstruction. These are well summarized by some of the commandments of Sir Harold Gillies[1] that relate to reconstruction in general:

- Losses must be replaced in kind.
- Treat the primary defect first.
- Thou shalt provide thyself with a lifeboat.
- Thou shalt not throw away a living thing.
- Replace things into their normal position by recreation of the defect.

Reconstructive techniques can be used effectively as building blocks, either singly or in combination, to reconstruct the defect. However, before they are described in detail, it is important to understand in general terms how they work. The many and varied clinical situations in which they may be used are discussed in those chapters that relate to the resection of the specific tumour in question (i.e. Chapter 12, Oral cavity tumours including the lip and Chapter 13, Oropharyngeal tumours).

TYPES OF FLAP

There are a number of different types of flap that maybe used in head and neck reconstruction. These are:

- local flaps:
  - random
  - axial pattern
- distant axial:
  - deltopectoral
  - cervical
  - occipitomastoid
- myocutaneous:
  - pectoralis major/latissimus dorsi
- free tissue transfer.

Distant axial and myocutaneous pedicled flaps are used less and less in head and neck reconstruction following the introduction of free tissue transfer. However, they do have a number of uses in certain situations for soft tissue

TABLE 92.1 Advantages and disadvantages of pedicled flap transfer

Advantages	Disadvantages
• Relatively straightforward to raise • Reliable • Adequate blood supply • Can be used as 'life boats' for salvage surgery • Useful in the presence of infection	• Bulky • Cannot be tubed • May be associated with significant donor site morbidity • May represent a compromise balancing the ideal reconstruction and the surgeon's skill set

reconstruction and their advantages and disadvantages are shown in **Table 92.1**.

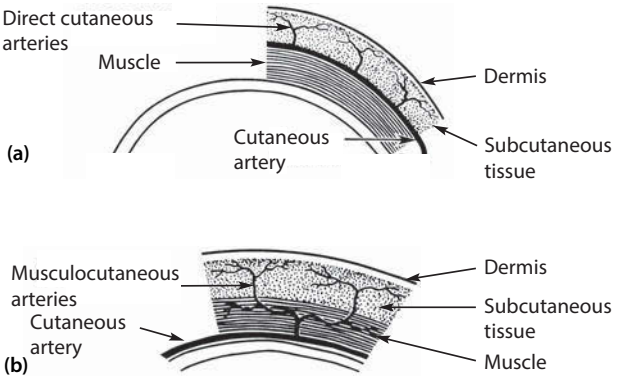

Figure 92.1 Blood supply of axial and random flaps. (a) Note that the axial flap is based on an arteriovenous pedicle that runs within the skin superficial to the underlying muscle layout and parallel to the overlying skin. **(b)** This differs from a random flap.

AXIAL FLAPS

An axial flap is based on a named arteriovenous pedicle that runs within the skin superficial to the underlying muscle layer, parallel to the overlying skin (**Figure 92.1**). Axial flaps have an extremely good blood supply that is determined not only by their length and breadth ratio but also by the vascular territory of the vessels that supply them. Because of this, they can generally be raised to a much greater length than random flaps and can therefore be used to move skin over a greater distance. The use of these flaps in the 1960s was the first major step in head and neck reconstruction. Their routine use has largely been superseded by musculocutaneous and free tissue transfer, but the deltopectoral flap still has a role in head and neck surgery.

Forehead flaps

The forehead flap is an axial flap that provides large areas of skin and subcutaneous tissue that may be used to reconstruct defects below the level of the eyes. In its original form (as described by McGregor and McGregor),[2] the axial forehead flap based on the anterior branch of the temporal artery was one of the first flaps used in intraoral reconstruction. It is rarely used today as it leaves a disfiguring donor site and there are better alternatives. It does represent a potential lifeboat for a failed myocutaneous or free tissue transfer in oral or oropharyngeal reconstruction. When used for oral cavity reconstruction, it is passed into the oral cavity medial to the zygomatic arch. The temporalis muscle tendon must be divided from the coronoid process to facilitate access.

The most commonly raised forehead flap is the cutaneous axial median forehead flap, based on the supratrochlear artery. It can be raised and transposed to reconstruct areas in the upper medial cheek region and any defect of the external nose (**Figure 92.2**). The donor site will often close primarily and the cosmetic result is excellent. Where larger areas of tissue are required, for example in complete nasal resurfacing, larger forehead flaps may be designed (e.g. Millard flying seagull flap), which may be facilitated by prior tissue expansion to ease donor site closure. Controversy exists regarding the use of tissue expansion to achieve primary closure. Some authors believe that the expanded forehead flap contracts excessively when used for nasal reconstruction, compromising the ultimate reconstructive result. Additionally the defect on the scalp when left to close with secondary intention often produces an excellent aesthetic result with normal contour and skin colour. These techniques are best suited in patients with high foreheads with some lax tissue to facilitate primary closure.

Nasolabial flaps

The nasolabial flap was first documented in the Indian Sushruta of 600 BCE and has been a workhorse for reconstruction of defects around the face and the anterior oral cavity. The artery is based on distal branches of the facial artery and its venae commitantes. The flap is usually designed with an inferior base, but can be based superiorly with a more random vascular supply. The design usually places the most medial limit of the flap in the nasolabial fold with the superior limit approximating the medial canthus of the eye. The medial to lateral dimension of the flap is determined by the defect to be reconstructed and the ability to primarily close the donor site. Flap elevation is usually initiated distally with a retrograde dissection above the plane of the facial musculature. In the intraoral application a tunnel is placed traversing the facial muscles and buccinators, allowing the inferiorly based flap to enter the oral cavity (**Figure 92.3**).

This flap is extremely reliable when based inferiorly, with a relatively inconspicuous donor site, particularly when bilateral flaps are used. Its greatest application intraorally is for the anterior floor of mouth and gingiva, where its use is both simple and effective. The donor site for this flap is best tolerated in elderly patients with rhytids that mask the donor site.

Submental island flaps

This flap, first described by Martin in 1983,[3] has great utility as an axial pattern flap or a free flap for reconstruction of the facial skin or intraoral lining. The flap is supplied by a branch or branches of the facial artery that pass

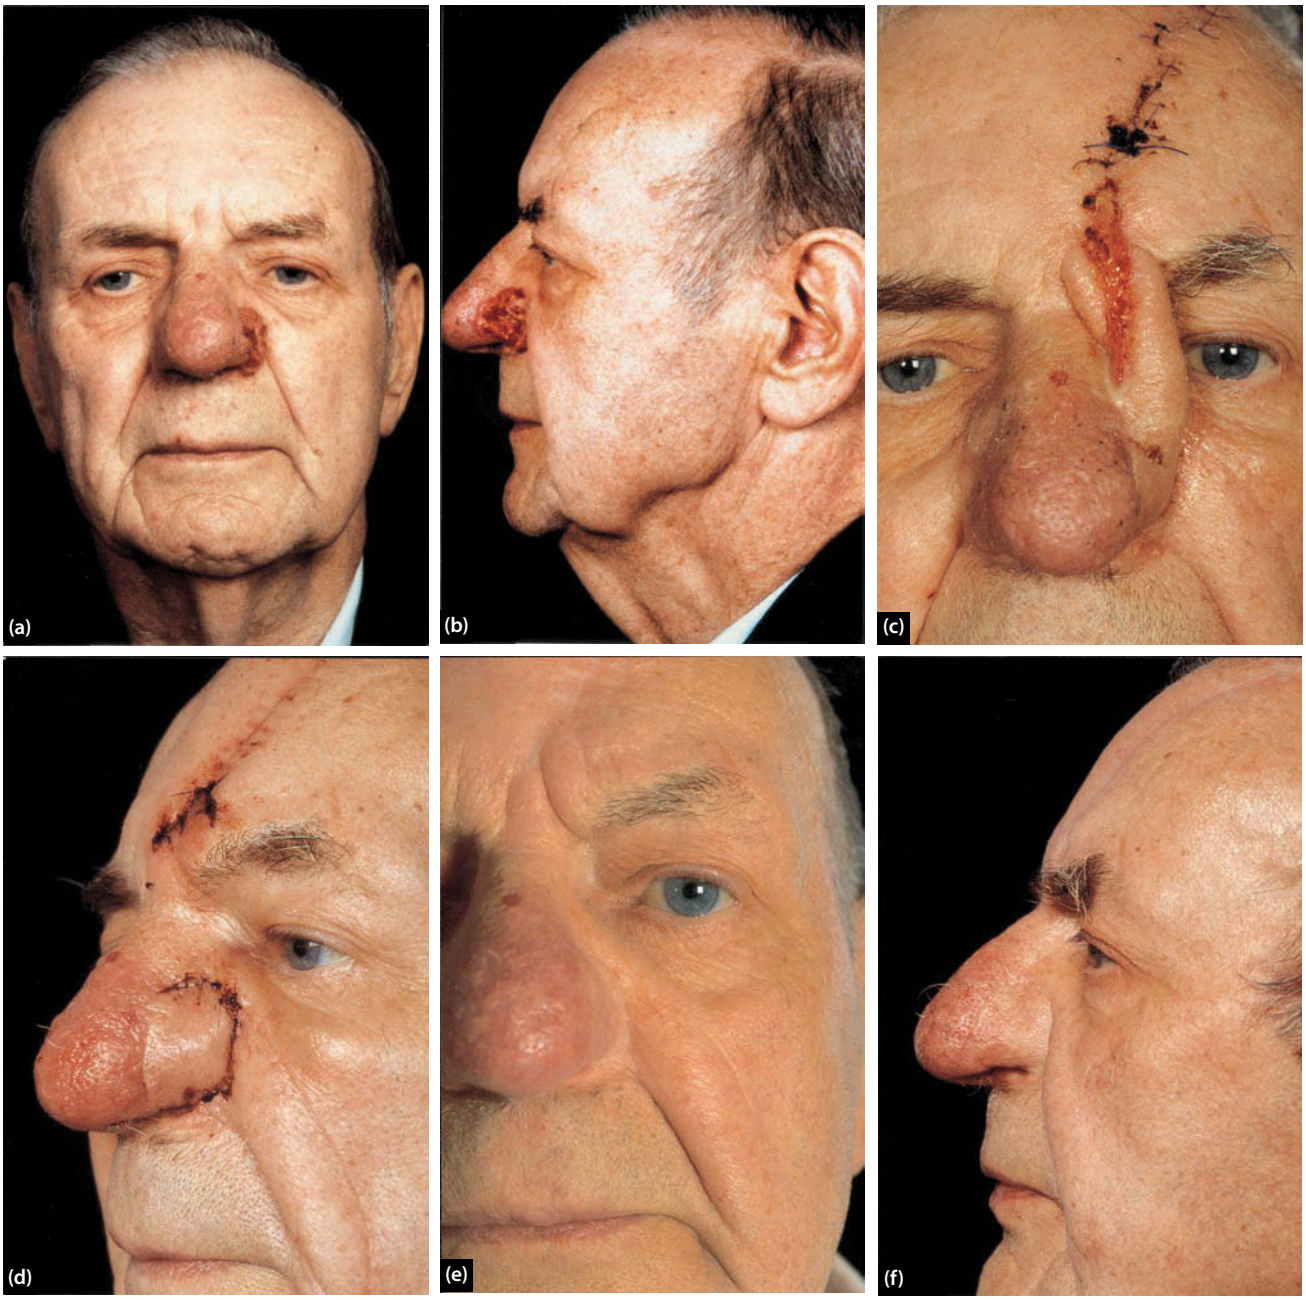

Figure 92.2 Use of a midline forehead flap to repair a defect in the lower left aspect of the nose and cheek. (a, b) A patient with a T4 basal cell carcinoma of the lower aspect of the nose and medial part of the cheek. **(c)** Wide excision was achieved, repair of the lateral side of the nose was with an infolded delayed forehead flap and the cheek was repaired using V to Y advancement. **(d)** The forehead flap was divided 3 weeks later. **(e, f)** The final result.

either over or through the submandibular gland, traversing medially on the mylohyoid muscle and then deep to the anterior belly of the digastric muscle to provide a perforator-based arterial supply and venous drainage to the submental skin.[4] The flap has a variable venous drainage via the facial vein. There can be occasional problems with venous congestion, particularly in the reverse flow design, because of valves in the facial vein. The flap is usually designed in the midline, just below the margin of the mandible, with the superior/inferior dimension determined by the ability to close the submental skin (**Figure 92.4**). Dissection is usually initiated on the contralateral side to the planned vessel pedicle. Skin and subcutaneous tissues are incised down to the level of the investing fascia of the digastric muscle, with the plane of dissection carried in the submental triangle at the level of the mylohyoid muscle. The ipsilateral anterior belly is usually divided distally and proximally to preserve the blood supply to the flap and the dissection proceeds in a retrograde fashion to the facial artery and vein. The flap can be tunnelled under the mandible and through the submandibular and submental space for oral reconstruction, or can be rotated or transposed onto the face for soft tissue coverage. The unique advantage of this flap is its colour match with

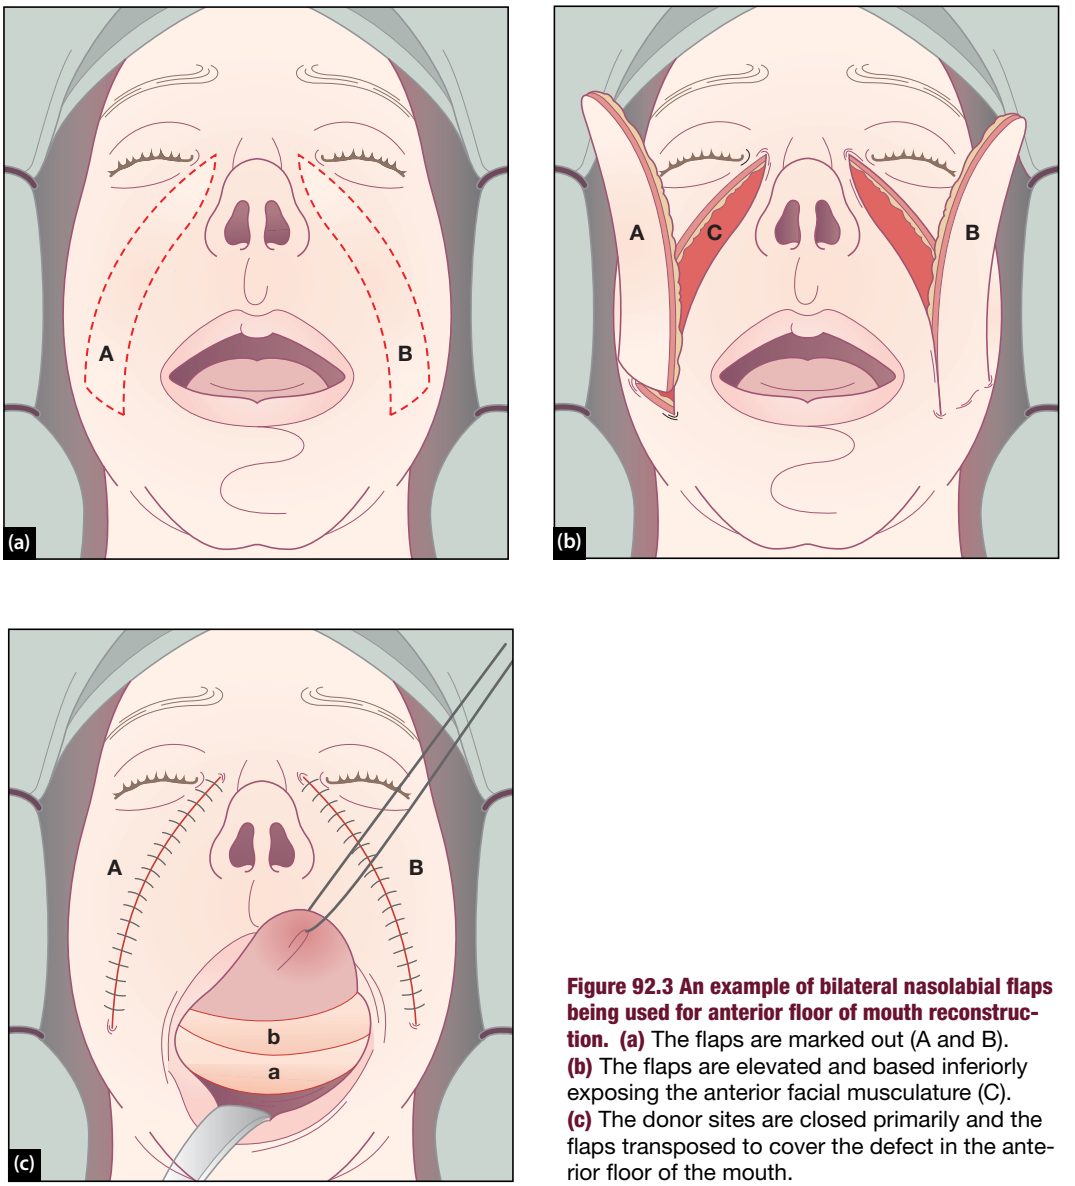

Figure 92.3 An example of bilateral nasolabial flaps being used for anterior floor of mouth reconstruction. **(a)** The flaps are marked out (A and B). **(b)** The flaps are elevated and based inferiorly exposing the anterior facial musculature (C). **(c)** The donor sites are closed primarily and the flaps transposed to cover the defect in the anterior floor of the mouth.

facial skin and the relative inconspicuous nature of the donor site scar. There have been reports of problems with venous congestion, particularly when tunnelled through the submandibular space.

Facial artery myomucosal flaps

The facial artery myomucosal flap (FAMM) was first described by Pribaz et al. in 1992.[5, 6] This flap is composed of oral mucosal and buccinator muscle and is based on branches of the facial artery. The anatomy of this flap is based on the buccinator muscle and its relationship to the facial artery. The buccinator is covered medially by the submucosa and mucosa and laterally by the external lamina of the muscles of facial expression, the masseter, the buccal fat pad, and the facial artery and vein.

The facial artery, a branch of the external carotid artery, enters the face by curving around the lower border of the mandible at the anterior edge of the masseter muscle. It then follows a tortuous course, passing superiorly and anteriorly to a position just lateral to the commissure of the mouth. At this point it lies deep to the risorius, zygomaticus major muscle and the superficial lamina of the orbicularis oris muscle. It lies superficial to the buccinator muscle and the lateral edge of the deep lamina of the orbicularis oris muscle. At this point in its course it gives off multiple perforating vessels to the cheek and the superior labial artery. It continues superiorly to the angular artery, which reaches the medial canthus. It has communicating branches with the buccal and infraorbital branches.

The FAMM flap is an axial pattern flap based on the facial artery. The flap may be harvested as an inferiorly based flap based on antegrade flow or a superiorly based flap with retrograde flow. The basic harvest technique is to Doppler out the facial artery through the buccal mucosa and map the course of the vessel. For the inferiorly based flap, dissection begins anterosuperiorly to identify the arterial supply to the upper lip with division of the facial

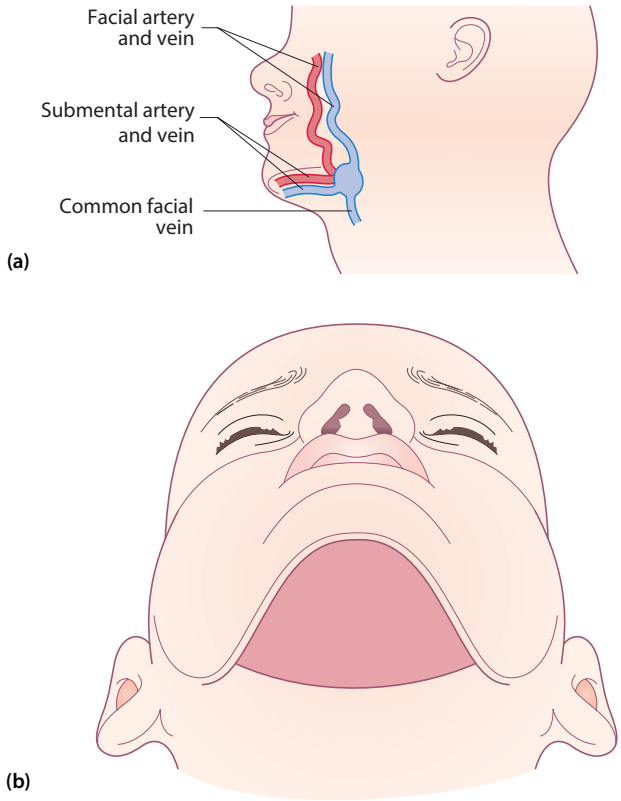

Figure 92.4 **(a)** The submental island flap is pedicled on branches of the submental artery and vein; **(b)** the size of flap available.

artery at this point and then retrograde dissection, which includes the mucosa, buccinator, facial artery and the tissue and venous plexus that lies between the artery and the muscle. In the superiorly based flap, the dissection begins inferiorly with visualization and ligation of the facial artery and then a retrograde dissection of the tissues including the buccinator muscle. A flap of 7–8 cm can be harvested with a thickness of 8–10 mm.

The FAMM flap is ideally suited for reconstruction of small mucosal defects in the oral cavity and in particular the mucosa of the lip. The flap can also be rotated across the alveolus to close small defects of the floor of mouth or tongue, as well as the palate.

Temporoparietal fascial flaps

The temporoparietal flap is a versatile local rotation or free fascial flap for reconstruction of the head and neck or extremities. The flap was first described by Golovine in the 19th century for orbit reconstruction. More recently it has been popularized by Brent and Byrd,[7] and others, for microtia repair and auricular reconstruction. Its unique characteristics are a remarkably robust vascular supply with a very thin and pliable flap with minimal donor site morbidity.

The arterial supply of the temporoparietal flap is the superficial temporal artery, a terminal branch of the external carotid artery. The vessel classically has a number of branches above the zygoma, with most patients

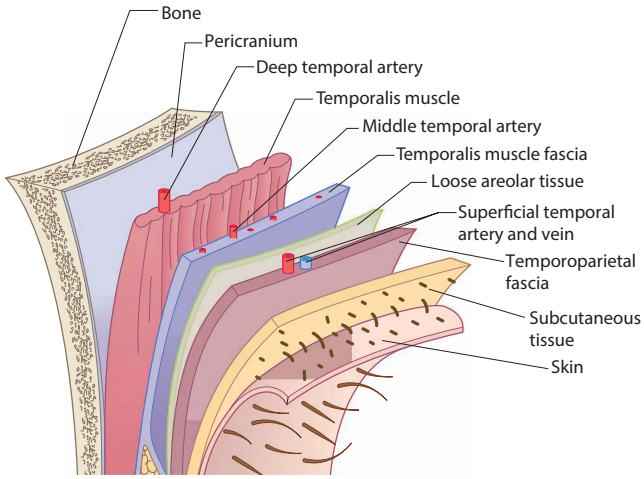

Figure 92.5 The different layers of the scalp, with particular reference to the position of the temporoparietal fascia.

having a prominent frontal branch and dominant branch that ascends towards the vertex of the skull. The venous drainage is via the superficial temporal vein running with the artery. There is some variation in venous anatomy, with a small percentage of patients having venous drainage through the post-auricular vein or occipital veins. The temporoparietal fascia (TPF) lies just under the subcutaneous tissue of the lateral scalp (**Figure 92.5**). The fascia has an inner and an outer layer, with the artery and vein entering between the inner and outer layers and then coursing vertically in the outer layer of the fascia. The outer layer of the TPF extends as the superficial muscular aponeurotic system (SMAS) below the zygoma. A thin muscular layer (the superficial auricular muscle) separates two parts of the outer layer of the fascia below the temporal line. The inner layer of the TPF contains a dense vascular network, which originates from the outer layer. Two nerves have an anatomic relation to the flap: the auriculotemporal nerve, a branch of V3, lies within the superficial layer of the TPF and theoretically could provide for a sensate flap; and the frontal branch of the facial nerve traverses over the zygoma in the same plane as the frontal branch of the superficial temporal artery and can be injured if the dissection is carried too far forward in the plane of this vessel.

For flap harvest the patient is usually positioned in the supine position, with the drape line along the vertex of the scalp leaving the post-auricular area exposed.

The important landmarks for this flap are the arch of the zygoma, the pinna and the usual landmarks of the facial nerve. The artery usually lies just in front of the pinna and is easily palpated or detected with the Doppler in the this location. The artery ascends vertically to the apex with a frontal branch coming off 1–3 cm above the zygomatic arch. The flap is harvested as an elliptical or teardrop shape, above the level of the zygoma. The incision is placed just posterior to the position of the vertical branch and can be either a straight or curvilinear incision into the scalp or 'Y' shaped for larger teardrop-shaped flaps. The inferior limit of the incision is usually the tragus but inferior extensions can be used for extended rotations or if the surgeon

wishes to visualize the facial nerve. The initial incision is started just above the zygoma, extending into the scalp. The surgeon harvesting this flap for the first time must take great care not to incise too deeply as the pedicle can easily be divided during the incision. The plane of dissection is initiated by defining the level of the superficial temporal fascia just below the subcutaneous fat layer in the scalp. A good landmark is to look for the hair follicles; if they are being transected, the surgeon is elevating the flap too superficially. Once fully mobilized from the overlying skin, the flap is incised around its periphery and elevated in the plane just above the temporal fascia. Dissection is carried down to about 2 cm below the arch of the zygoma to ensure an appropriate arc of rotation (**Figure 92.6**). Clinical applications for this flap include: orbital reconstruction, including the extenteration cavity; upper and lower eyelids and the eyebrow as a fascio-cutaneous hair bearing flap; auricular reconstruction, including microtia and traumatic or oncologic deformities; palate reconstruction; and buccal mucosal reconstruction.

DISTANT AXIAL FLAPS

Deltopectoral flaps

This flap was described by Bakamjian and Littlewood in 1964[8] and is an axial pattern flap designed on the anterior chest wall between the line of the clavicle and the level of the anterior axillary fold. Its vascular supply arises from the upper three or four perforating branches of the internal mammary artery that emerge through the medial end of the intercostal spaces (**Figure 92.7**). Its boundaries are the clavicle superiorly, the acromium laterally and a line running through the anterior axillary fold to above the nipple inferiorly. The flap will extend to any site in the neck and occasionally up to the level of the zygoma. This flexibility is explained first by the fact that it retracts from side to side after it has been elevated, and not from end to end, so that it may elongate slightly over time, particularly in patients over 60 years of age. Second, its flexibility is due to an anomalous pivot point (see 'Planning the transfer' below).

The territory of the perforator vascular system has been shown to extend as far as the groove separating the deltoid from the pectoralis major (deltopectoral groove). Any extension of the flap beyond this should not be regarded as an axial pattern flap. One must be aware that any extension of the flap beyond this area may result in failure of the tip of the flap.

The flap is marked out using the landmarks described above and then elevation begins laterally. The pectoral

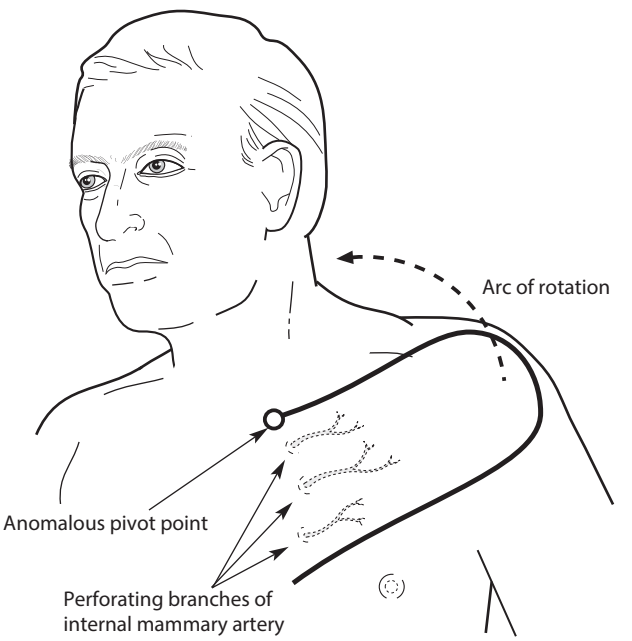

Figure 92.7 Design and planning of the deltopectoral flap. Note the position of the anomolous pivot point at the upper medial end of the flap.

fascia is left on the flap, leaving the muscle fibres below absolutely bare. Any branches of the acromiothoracic axis that are encountered should be ligated. Monopolar diathermy is used judiciously on the flap and the muscle, as this could damage the flap and any diathermy marks on the muscle may compromise the subsequent take of any skin graft. When raising the flap, retraction is upwards by an assistant using skin hooks; it must not be doubled back on itself as this could lead to buttonholing.

PLANNING THE TRANSFER

The deltopectoral flap has an anomalous pivot point. There is considerable laxity of the skin on the anterior axillary fold when the arm is abducted. This means that the lower border of the flap is considerably longer than the upper part. The pivot point on the flap is thus at the medial end of the upper limb and not the lower limb. This needs to be taken into account when planning the flap. The donor site is usually covered with a split skin graft. The uses of a deltopectoral flap are:

- to allow a one-stage reconstruction of the anterior neck skin
- to reconstruct a defect by passing as a bridge over normal; once take has occurred over a period of 3 weeks, the pedicle is divided and the remaining part of the flap may be returned to the donor site or discarded
- to reconstruct large defects on the lower face and upper neck. The pedicle may be inserted into part of the defect to facilitate take and then the pedicle is divided inferiorly and the flap inserted into the rest of the lower defect. This is analogous to 'waltzing'. The deltopectoral flap may also be used in the repair of a pharyngeal fistula but usually muscle bulk is required with the skin, and therefore other flaps are preferable.

Supraclavicular artery island flaps

The supraclavicular artery island flap (SAI) is a local fasciocutaneous flap harvested from the skin on the shoulder and supraclavicular area. This flap was first described in 1979 by Lamberty,[9] who described a supraclavicular artery flap based on a branch of the tranverse cervical artery in the majority of cases with occasional supply from the suprascapular vessels. Pallua et al.[10] expanded the anatomic knowledge of this flap, demonstrating that the flap in all cases was supplied by a branch of the transverse cervical artery with venous drainage via paired venae commitantes joining either the external jugular vein or the transverse cervical vein. They described the take-off of the artery within a triangle bounded anteriorly by the posterior border of the sternocleidomastoid muscle, posteriorly by the external jugular vein and inferiorly by the clavicle (**Figure 92.8**). Pallua demonstrated that flaps up 30 cm in length and 12 cm in width could be harvested and rotated into head and neck defects. Chiu et al.[11] in 2009 reported an initial experience with this flap in oncologic defects of the head and neck and since that time numerous authors have reported experiences with this flap.

FLAP HARVEST

The supraclavicular artery is identified using a hand-held Doppler, usually originating in a triangle bounded anteriorly by the posterior border of the sternocleidomastoid muscle, posteriorly by the external jugular vein and inferiorly by the clavicle. The vessel is followed out over the clavicle to identify the axis and design of the flap. The flap is usually designed with a width of 6–7 cm and a length of 20–25 cm from the rotation point. Dissection starts distally and is carried subfascially over the deltoid until one reaches the anterior border of the trapezius. The spinal accessory nerve is identified and dissection continues in a subfascial plane. The dissection then turns to elevation of the infraclavicular portion of the flap in the subfascial plane; this dissection in the subfascial plane is maintained until over the clavicle. Once the acromion is reached the dissection is continued with careful dissection, with branch ligation with either bipolar cautery or surgical clips. Skeletonization of pedicle is not usually necessary, unless wider arcs of rotation are required. The distal extension of the transverse cervical artery may restrict rotation and

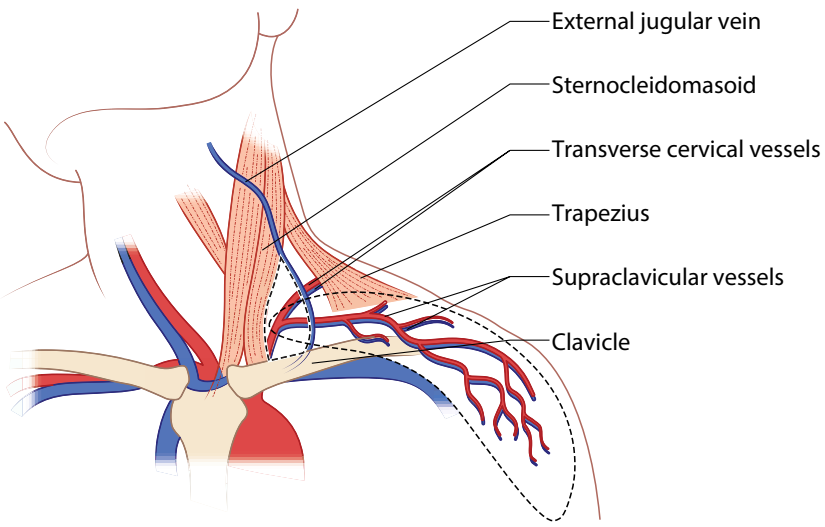

Figure 92.8 Supraclavicular artery island flap.

can be ligated if necessary. The proximal portion of the flap is usually de-epithelialized to allow tunnelling into a facial or intraoral defect.

CLINICAL APPLICATIONS

The SAI flap has broad application for external skin defects extending from the base of the neck to the parotid. In addition, numerous authors have described its use for oral and oropharyngeal defects. The advantages of the flap are the ease of elevation and a neck donor site. Rates of venous congestion and flap failure vary in the literature, but are likely much higher than those experienced with classic free tissue transfer.

OTHER DISTAL AXIAL CUTANEOUS FLAPS

These include other cervical skin flaps and occipitomastoid-based flaps.

Cervical-facial skin flaps of varying shape, size, site and direction may be designed to make good use of lax neck skin for reconstructive purposes. In general, they make use of the side of the neck. They are most frequently used as a primary or salvage procedure for external skin defects of the lower face and cheek. This flap has the unique advantage of providing excellent if not identical colour match for external defects. The nape of neck (Mütter) or posterior scalp flap is a random pattern skin flap that exploits the neck skin over the trapezius muscle and can be raised on the occipital vessels and extended downwards to the spine of the scapula. It may be swung on its upper pedicle to reconstruct areas in the lower face and submandibular region.

Myocutaneous and muscle-only axial distant flaps

One of the most important discoveries in the last 30 years is that the skin over most parts of the body receives its blood supply from small musculocutaneous arteries (perforating vessels) that enter it from the underlying muscle (**Figure 92.9**). It subsequently became apparent that an obvious way to move a large area of skin for reconstructive purposes was to transpose the skin with its underlying muscle vascularized by its dominant blood supply:

- pectoralis major
- latissimus dorsi
- sternomastoid
- trapezius
- platysma.

The pectoralis major and the latissimus dorsi flaps represent the workhorses for many head and neck reconstructive surgeons and a detailed understanding of the anatomy and harvest techniques will be a significant asset to the head and neck surgeon.

The muscles are supplied ultimately by segmental vessels that have similar perfusion pressures to the aorta. They run deep within the muscle and give off perforators that enter the muscles and provide communication between the segmental vessels and the musculocutaneous vessels in the skin. There may be several arterial pedicles. The artery is usually accompanied by two venae commitantes that unite after leaving the muscle to drain into a major regional vein. Five types of muscular arterial supply have been described (**Table 92.2**).

The blood supply to the muscles may also be random or axial in pattern. Most of the round muscles, for example the sternomastoid, have a random supply: perforators penetrate the belly at one end and immediately break up into small branches. The flatter muscles such as pectoralis major and latissimus dorsi have an axial supply: the major arterial supply runs the whole length of the deep surface of the muscle, giving off perforators as it goes.

Essential surgical points are:

- With the axial muscular flaps, although the blood supply to the muscle is axial, the blood supply of the skin upon the muscle is random.
- There is a minimum size of skin paddle that should be taken to ensure that one incorporates enough perforators

TABLE 92.2 Patterns of vascular anatomy

Vascular pedicle		Examples used in head and neck surgery
I	One pedicle	None
II	Dominant pedicle and minor pedicles	Sternocleidomastoid Trapezius Platysma
III	Two dominant pedicles	Temporals

V	One dominant pedicle plus secondary segmental pedicles	Pectoralis major Latissimus dorsi

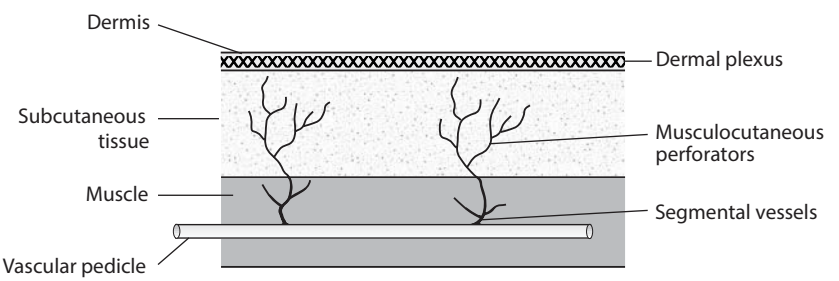

Figure 92.9 Blood supply to a myocutaneous flap.

to supply the skin flap. For pectoralis major and latissimus dorsi flaps, this usually means a skin paddle measuring 5×3 cm (the size of the palm of an adult's hand).
- Smaller skin paddles may not survive.

Pectoralis major flaps

This flap was first described by Ariyan in the late 1970s.[12, 13] The muscle's origins are the clavicle, the sternum and slips from the upper seven ribs. There is also a variable origin from the aponeurosis of the external oblique, which is variable in size. It is inserted into the bicipital groove of the humerus. The muscle has three major segmental sub units: clavicular; sternocostal; and an external segment (the most lateral part of the muscle), which originates from the ribs.

The main arterial supply, which provides the vascular basis for this flap, comes from the pectoral branch of the acromiothoracic artery that arises from the first part of the axillary artery (**Figure 92.10**). The pectoral branch of the acromiothoracic axis emerges from the clavipectoral fascia, along with the lateral pectoral nerve, medial to the insertion of pectoralis minor on the coracoid process, a bony prominence that can be felt below the clavicle near the junction of its middle and outer thirds. The point, 2–3 cm medial to the coracoid process, represents the surface marking of the vascular hilum of the muscle. The vessels do not enter the muscle belly immediately but run on its deep surface in a downward and medial direction giving off its branches. The acromiothoracic artery gives off a superior (clavicular) branch to the clavicular segment of the muscle and a main pectoral branch, which then gives off an inferior thoracoacromial branch to the sternal segment and a lateral thoracic trunk to the external segment.

In approximately 50% of cases, the external segment of the muscle may be supplied exclusively by the lateral thoracic vessels that arise from the second part of the axillary artery and descend along the lateral border of the pectoralis minor. In one-third of cases, this external segment receives a dual supply from both the lateral thoracic and the thoracoacromial vessels. The sternocostal segment also receives a supply immediately from a perforating branch of the internal mammary artery, which may account for significant bleeding during the raising of the flap. The pectoralis major flap has a Type V vascular pedicle.

The major advantages of this flap are that it has a large skin territory (the whole of the skin overlying the muscle may be raised), it has a rich vascular supply and it can be transferred without prior delay. It has a large arc of rotation and can be transferred up to the upper aspect of the ear to the level of the zygomatic arch. It can be harvested in the supine position, and can be transferred either as a muscle-only, skin and muscle paddle, or as two epithelial surfaces for inner and outer lining with a de-epithelialized segment between them. Primary donor site closure is easily achieved. However, it is a large bulky muscle that is relatively immobile and, therefore, is suited best to providing well-vascularized tissue to fill large defects where mobility is not of paramount importance, as in the repair of fistulae. It violates the breast in the female and, in this situation, the latissimus dorsi flap provides an appropriate alternative.

TECHNIQUE

The whole of the skin overlying the pectoralis major muscle may be raised if required. However, this will leave a large defect that will require coverage with a skin graft and so the flap is usually designed to facilitate primary closure.

With the patient in the supine position, the surface markings of the acromiothoracic artery are outlined. A dotted line is marked from the acromium to the xiphoid process and a further dotted line is dropped to join this line in a perpendicular direction from the sternal notch. The point at which the line bisects the first line represents the location where the vascular pedicle meets the first line (**Figure 92.11**). The pedicle then runs in the direction of the first line from the acromium towards the xiphisternum. The clavipectoral fascia is then marked by a point two-thirds of the distance along the clavicle from the sternal

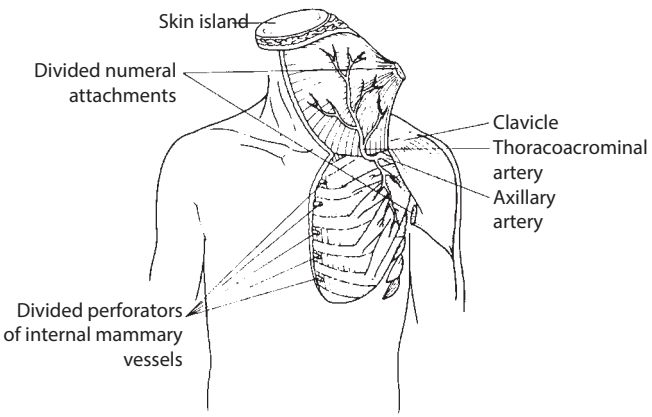

Figure 92.10 Blood supply to the pectoralis major myocutaneous flap.

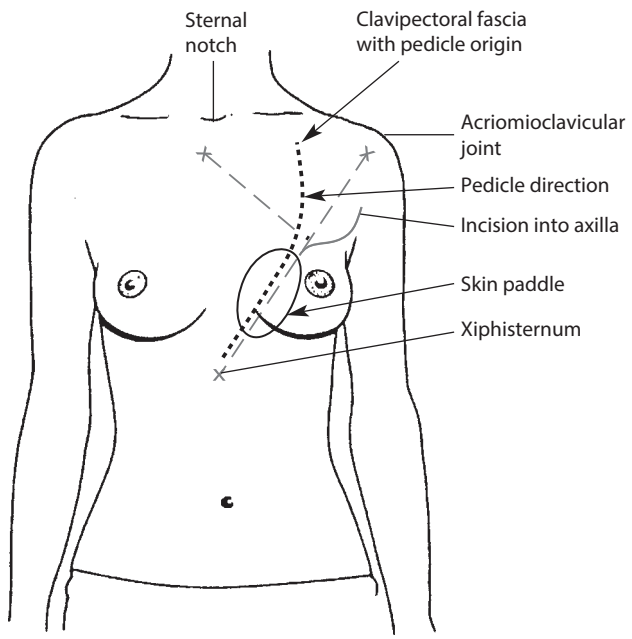

Figure 92.11 Landmarks for raising the pectoralis major myocutaneous flap.

notch to the coracoid process. The vascular pedicle runs in a curved direction downwards to meet the bisection point already described. A skin island of the appropriate size and shape may be drawn over the distal part of the artery, to facilitate a suitable arc of rotation. The borders of the skin paddle should lie between the lateral edge of the sternum medially and the nipple laterally. The incision for access should be extended into the axilla. The technique described by McGregor and McGregor[2] (i.e. designing the skin incision to allow a secondary deltopectoral flap from the same side) should be considered in both males and females. This technique allows for an easier wound closure and provides a salvage flap for neck resurfacing.

Unless the arc of rotation needs to be increased, it is advisable not to extend the lower part of the skin paddle beyond the inferior edge of the muscle. This part of the flap is random and, although the survival of this segment can be increased by taking part of the rectus sheath, this is not wholly reliable and should not be done unless absolutely necessary. Remember that the flap will retract by 10% in all directions when the skin is cut and this should be allowed for in planning, although some expansion will occur when the muscle is sewn in under tension.

The steps for elevation of the pectoralis major flap are as follows:

1. Start the dissection inferiorly.
2. Incise the skin down to the underlying muscle.
3. Define the inferior and lateral borders of the pectoralis major muscle.
4. Incise and mobilize the inferior attachments of the muscle to gain access to the subpectoral plane, which is relatively avascular.
5. Divide the inferior muscle attachments from the ribs or rectus sheath.
6. Mobilize in an upward direction.
7. At this point the pectoralis minor muscle will be visualized.
8. If the skin paddle is thick or excessively mobile, place sutures from the dermis of the skin island to the muscle surface to prevent shearing and flap loss.
9. Combine mobilization in an upward direction, first laterally and then medially.
10. Identify the lateral border of the external segment of the muscle.
11. Identify and ligate the major branch of the lateral thoracic artery to increase the arc of rotation.
12. Continue the dissection upwards.
13. Divide the sternal insertion of the muscle at the level of the anterior axillary line and remember to continue in a vertical direction.
14. Do not curve the scissors medially at this point or you may cut the pedicle – the ultimate disaster.
15. The muscle will now be rotated and the vascular pedicle will be clearly identified.

Once the origin of the sternal portion of the muscle has been divided, the flap may be easily elevated by blunt dissection in the subpectoral fascial space between pectoralis major and minor. The vascular pedicle is now clearly seen and the sternal edge of the muscle may be divided up to the level of the clavicle with the pedicle in clear view. Haemostasis is maintained throughout the elevation of the flap by carefully cauterizing the intercostal perforators, as well as the perforators supplying the medial portion of the muscle from the internal mammary vessels. If there is any lateral muscle mass attachment this is divided at this point, bearing in mind that the axillary vein is extremely close. The flap is now fully raised and mobile and if further mobility and arc of rotation are required, it may be islanded on the vessels by dividing the remaining muscular pedicle.

As a teaching aid, it is prudent to observe the neurovascular pedicle of the pectoralis minor muscle at this point, which is now visible and easily accessible. This muscle may be raised on its own as a free flap and used in facial reanimation techniques (see Chapter 95, Facial reanimation surgery).

Whilst the flap is being sewn in at the recipient site, the donor site can usually be closed. Haemostasis must be carefully achieved. Two large drains are inserted and the defect is closed, primarily using a two-layer closure. If closure is anticipated to be difficult, a one-layer blanket nylon or Ethilon stitch is an elegant technique of closing the wound as it takes up the tension gradually in the same way as a mastectomy wound is closed. Large defects may require a skin graft.

Modifications of the flap include harvesting of muscle alone when, for example, closing large lower neck wounds that require bulk with no skin paddle. A subsequent skin graft can be applied to the raw muscle surface. Access is achieved along the lateral border of the muscle and primary closure easily achieved. The incorporation of vascularized bone has been described where part of either the fifth rib or the sternum can be transferred with the flap to provide composite soft tissue and bony reconstruction. The vascular supply to these bony segments is at best precarious and in the majority of instances non-existent. Newer and more effective techniques for composite soft-tissue and bony reconstruction are available, obviating the need for the myo-osseous pectoralis major flap. Double skin paddles may be used with de-epithelialized islands in between them to provide oral lining and cutaneous cover but, again, in this situation, the muscle is very bulky and newer techniques such as double-paddled radial forearm flaps are probably better. Where the excessive bulk of the pectoralis major is a problem, harvesting over the thinner, parasternal area has been described (e.g. to tube the flap for reconstruction in the hypopharynx). Although this sounds attractive, practical experience has shown that it is virtually impossible to tube a pectoralis major myocutaneous flap. This should be considered as a salvage technique only, as better free tissue transfer techniques are available

When the above guidelines are followed, there are very few potential pitfalls with this flap. It is highly reliable and even when the skin paddle fails, the underlying muscle will usually survive and can be allowed to granulate and heal by secondary intention, or covered subsequently with a skin graft. It is always worth checking for congenital

absence of the pectoralis major, although it is extremely rare, with an incidence of 1 : 11 000. Congenital absence of the sternocostal head is part of Poland syndrome.

When a conventional flap is used, the skin paddle is designed medial to the nipple, at about the level of the sixth rib. In this area, the skin overlying the muscle is usually relatively thin in males. To achieve similar thickness in females, a design placing the skin island in the inframammary fold oriented transversely or slightly angled superiorly in its medial extent allows for the thinnest flaps. Where greater flap length is required, the flap design may be extended inferiorly beyond the lower border of the muscle. The extension should not extend beyond 3–4 cm and the rectus abdominus aponeurosis together with the rectus sheath should be raised with the flap. In this situation, the survival of the lower part of the flap is unpredictable. The breadth of the flap may be extended by including the nipple/areolar complex. The design of the incisions for this flap is particularly critical in females, where vertical scars result in significant secondary deformities of the breast. The surgeon considering this flap in females should consider the inframmary incision as the preferred approach.

Latissimus dorsi flaps

This flap represents the first myocutaneous flap described in the medical literature (by Tanzini). It was repopularized by Olivari in 1976[14] for the repair of local defects. Further work by Quillen et al. in 1978[15] described its use for head and neck reconstruction, and it remains a reliable and versatile fundamental component of the surgeon's repertoire.

The muscle is large and triangular in shape and arises from the sacrum and lumbar vertebrae, thoracolumbar fascia, the posterior iliac crest and the lower six thoracic vertebrae. In addition, some slips arise from the lower three ribs and the muscle converges to have a narrow insertion into the intertubercular groove of the humerus. Hence, it forms the posterior wall of the axilla. It is a type V muscle, which receives a significant but smaller blood supply from the perforating vessels through the lumbosacral fascia, and a pedicled flap can be based on this to repair defects in the buttock region.

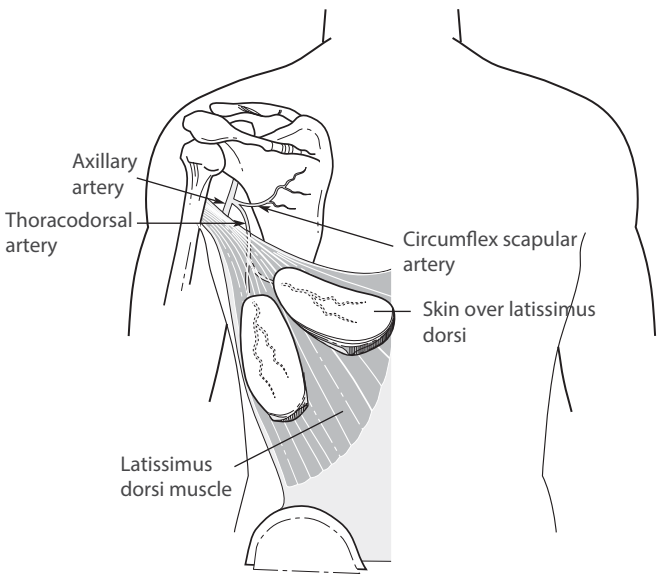

Figure 92.12 Blood supply to the latissimus dorsi flap. The thoracodorsal artery is a continuation of the subscapular artery, which comes directly off the axillary artery.

Its major vascular supply arises from the thoracodorsal vessels, which have their origin in the subscapular artery (**Figure 92.12**). This latter artery arises from the axillary artery, gives rise to the circumflex scapular artery about 4 cm from its origin (**Figures 92.13** and **92.14**) and then continues as a thoracodorsal artery to enter the latissimus dorsi about 10 cm from its humeral insertion. Just before its insertion, it gives off a branch that accompanies branches from the lateral thoracic artery (which also arises from the subscapular artery) and carries on to supply the serratus anterior. Within the latissimus dorsi muscle, the thoracodorsal vessels divide into superior and lateral branches that allow the muscle to be split into two. Either two flaps can then be taken or just one flap, thereby leaving some muscle behind.

Venous drainage is by the venae commitantes, which accompany the thoracodorsal artery and drain into the axillary vein. The nerve supply is via the thoracodorsal nerve, which is a branch of the posterior cord of the brachial plexus.

Large amounts of tissue are made available using this flap. Flaps measuring 10×8 cm are easily harvested and subsequent primary closure is easily achieved. Even larger amounts of tissue may be taken as a musculocutaneous flap measuring 40×20 cm but this requires skin grafting of the donor defect and may lead to problems with healing on the back.

A latissimus dorsi flap may not only be raised as a myocutaneous pedicled flap but also used for free tissue transfer. It is reliable, with a long pedicle of greater than 10 cm which can be further lengthened by dividing the circumflex scapular artery. The diameter of the subscapular artery at this point is at least 3 mm and the veins are of similar size.

By designing the flap low down on the back, the arc of rotation allows transfer into the head and neck region up to the zygomatic arch and flaps can be made to reach the top of the head (particularly if only muscle is used). The other advantages of this flap are that it does not violate the breast and because it is a large flat muscle, it is possible in extreme circumstances to tube it for total pharyngeal reconstruction. In addition, the subscapular artery offers a variety of flaps which may be used either singularly or in combination. Therefore, a scapular flap along with a latissimus dorsi flap and serratus anterior flap may all be raised on the same pedicle.

The advantages of the latissimus dorsi flap are:

- large amounts of tissue can be transferred
- pedicled or free tissue transfer
- it has a cosmetic advantage, especially for females
- it is versatile; may be tubed/multiple/osseous components
- when pedicled, it can reach the upper face and scalp.

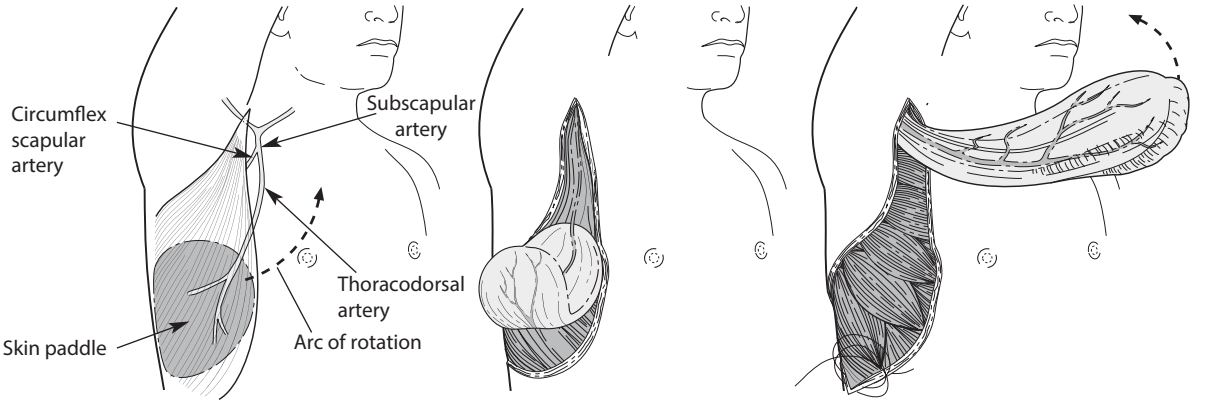

Figure 92.13 Technique of raising the latissimus dorsi flap. When designing for pedicled transfer, an oblique incision is used to allow maximal length to the flap. The dissection begins low down and then the pedicle is identified more proximally as the dissection approaches the axilla.

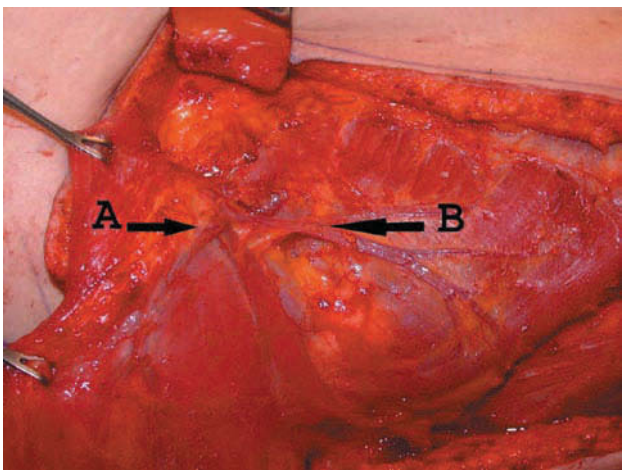

Figure 92.14 Lateral view latissimus dorsi pedicle. (a) Thoracodorsal branch to latissimus dorsi; **(b)** thoracodorsal branch to serratus anterior.

Despite these advantages, it still remains a musculocutaneous flap with thick skin and is therefore more bulky than, for example, a radial free forearm flap. Its use tends to be in resurfacing large defects of the external neck skin and for secondary repair of wound complications such as salivary fistula. It has an excellent application in reconstructing the total glossectomy defect as the volume of the flap makes it ideal for filling the mucosal defect and the dead space below the resection site. Serious donor site problems are rare but dehiscence and late wound seroma can be a problem. Congenital absence of the muscle should be checked for prior to surgery, and in athletes and those who do manual work the flap should be raised from the non-dominant side.

Raising the flap usually involves a variable amount of turning of the patient. Some authors advocate the lateral decubitis position, which often requires a repositioning manoeuvre following the ablative procedure. Most surgeons who are experienced with this flap will harvest it with the patient turned 15–30 degrees, which obviates the need for the repositioning manoeuvre and allows two team procedures.

The disadvantages of the latissimus dorsi flap are:

- it is very bulky
- there is occasional donor site dehiscence
- reduction in upper limb power
- it may require moving of the patient to harvest.

RAISING THE FLAP

Small flaps may be raised with the patient supine, but larger flaps require the patient in a rotated position with the arm freely draped so that it may be moved during the flap harvest.

Skin may be raised over the whole area of the muscle, although the vascular supply from the thoracodorsal artery decreases as one approaches the lumbosacral fascia. The posterior axillary fold is marked out and this represents the anterior edge of the muscle. The posterior iliac crest is also marked, together with the tip of the scapula. The skin flap is designed to the appropriate size and shape, with particular reference to the length of pedicle. If an arc of rotation is required to facilitate transfer to the head and neck via a pedicled myocutaneous flap, it will usually mean an oblique or vertical design; but if a free flap is required, the flap may be harvested in a horizontal direction, which gives a more acceptable scar in young women since it can be hidden behind the bra strap.

The steps for elevation of the latissimus dorsi are:

1. Outline the flap.
2. The initial incision exposes the anterior edge of the latissimus dorsi muscle.
3. Dissect round inferiorly, cutting through the muscle.
4. Identify the serratus anterior.
5. Do not go deep to serratus anterior here: this places the pedicle in jeopardy.
6. Recognize serratus anterior, as its fibres run at right angles to those of the latissimus dorsi.
7. Divide latissimus dorsi inferiorly.
8. The muscle flap may be extended beyond the skin island in a lateral to medial and superoinferior direction to

provide additional muscle to resurface external defects or provide additional volume to fill defects. Remember at this point that if one is low and on top of the latissimus dorsi, the pedicle is not in jeopardy.
9. Elevate the flap in the submuscular plane.
10. Identify the pedicle running down the muscle, usually in its central portion. The key to easy identification and protection of the pedicle to latissimus dorsi is to identify the branches to the serratus and follow them superiorly to the take-off from the thoracodorsal. Occassionally, patients will have a separate pedicle to serratus but this is very infrequent. Once the thoracodorsal pedicle is identified, divide the vessels to serratus anterior and continue dissecting superiorly.
11. Continue the dissection up towards the tip of the scapula.
12. The junction of the thoracodorsal vessels with the circumflex scapular vessels to form the subscapular artery can be clearly seen at the upper anterior end of the muscle in the axilla.
13. If a longer pedicle is required (as is usual), ligate the circumflex scapular vessels.
14. Follow the subscapular vessels into the axilla.

At this point, it is usual to island the flap if a free transfer is required. This also can provide a longer pedicle for the myocutaneous rotation flap. The surgeon may insert a pair of scissors under the latissimus dorsi tendon above the vessels and then cut the muscle to complete the islanding. When using the flap as a myocutaneous rotation flap, consideration should be given to not dividing the insertion of the muscle. When the muscle is left intact, the insertion prevents twisting of the vascular pedicle and reduces the risk of kinking and venous congestion. If an extended pedicle is required than the tendon must be divided to get additional length.

There are two steps in the delivery of the latissimus dorsi flap:

1. Ligate the circumflex scapular artery and vein.
2. Follow the subscapular vessels into the axilla.

If a pedicled transfer is to be completed, the flap must be tunnelled into the neck. There are essentially two options, sub- or suprapectoral, with the subpectoral route being the favoured approach. The border of the pectoralis major is identified and dissection deep to the muscle establishes the space between pectoralis major and pectoralis minor. A tunnel may be developed with blunt or sharp dissection, making sure that the pedicle to the pectoralis major is kept medially. The surgeon then develops the superior dissection, if it has not already been performed, by exposing the clavicle and the clavipectoral fascia. A tunnel is then developed by splitting the pectoralis major. The tunnel needs to be wide enough to allow the passage of the muscle without compression, usually the breadth of one's hand:

1. Use blunt finger dissection going on top of the pedicle.
2. Remember to go 'over pectoralis minor – under pectoralis major'.
3. Dissect from above through the clavipectoral fascia, dividing some of the lateral fibres of pectoralis major.
4. Open and widen the tunnel.
5. Deliver the flap without twisting or rotating the muscle.

The donor site is closed primarily in two layers using two large drains, one of which should be left for up to a week to avoid a seroma, which can occur following such a large dissection. This can be avoided by suturing the muscle remnants to the chest wall prior to closure. With a pedicled flap, the muscle should be denervated by dividing the nerve. If a free flap is being used, the thoracodorsal nerve may be preserved and used for reinnervation procedures such as anastomosis to a cross facial nerve graft for facial reanimation, or following total glossectomy where the maintenance of muscle bulk has been noted following anastomosis to the hypoglossal nerve.

Sternomastoid flaps

The sternocleidomastoid muscle, unlike the previously described muscles, does not have a localized vascular hilum. It is supplied segmentally by vessels that enter the muscle at intervals along its length. There are two principal vessels in its upper half, which consist of two branches of the occipital artery, and in its lower half, a branch from the superior thyroid artery. Further minor arterial branches enter in between. Its use has been described as: a myocutaneous flap raised as a composite skin muscle flap; a myocutaneous skin island flap taking a skin island based over the lower aspect of the muscle (**Figure 92.15**); or a composite muscle–bone flap used for mandibular reconstruction taking a segment of clavicle. Its routine use is not recommended as it has a number of distinct disadvantages:

- The upper sternomastoid composite skin muscle flap is poorly vascularized and not reliable.
- The blood supply to the skin paddle based over the lower third of the muscle is similarly unreliable.
- The upper and lower ends of the muscle are areas of oncological significance.
- The inclusion of clavicle for mandibular reconstruction is usually no longer required as superior reconstructive options are available.

The sternomastoid flap is therefore rarely used but it may still have a role to play in two situations: first, it can be particularly useful as a muscle-only flap pedicled superiorly to fill small defects in the pharynx and oral cavity; and second, when split along its length and rotated anteriorly, it may be used to cover vessels in the compromised neck.

Trapezius flaps

Three basic myocutaneous flaps have been described that make use of trapezius: the upper trapezius, the lateral trapezius and the lower trapezius flaps.[16] These may be pedicled into the head and neck area and, in addition, descriptions of the upper and lateral trapezius flaps to include transfer

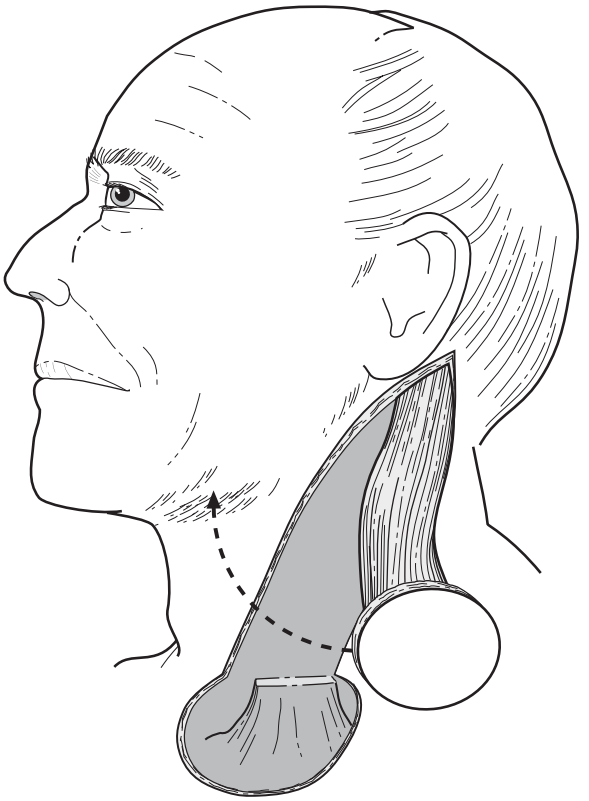

Figure 92.15 Sternomastoid flap.

of the spine of the scapula have been described for mandibular reconstruction. The vascular supply of these flaps is complex and varied depending on the design.

The superiorly based trapezius flap incorporates the upper third of the trapezius muscle and the overlying skin. The flap is supplied predominantly by the occipital artery and its venae commitantes. This flap has a limited used but can be applied for defects of the temporal bone, lateral face or upper neck. The flap is harvested by designing a skin island over the pars descendens of the trapezius muscle with dissection carried out in a retrograde direction along the deep surface of the muscle.

The pars horizontalis (middle) and a pars ascendens (lower) of the trapezius muscle form the basis of the lateral and lower trapezius flaps (**Figure 92.16**). The middle parts of the muscle are supplied mainly by the superficial cervical artery (superficial branch of the transverse cervical artery) and the lower part is supplied by the dorsal scapular artery (deep branch of the transverse scapular artery) and segmental intercostals perforators. The origins of the arteries supplying the trapezius muscle are highly variable and the aforementioned vessels may arise from different trunks.

An anatomic study[17] published in 2004 has demonstrated that the superficial cervical artery always runs lateral to the levator scapulae and rhomboid muscles, dividing into a short superior branch and long inferior branch that courses inferiorly with the accessory nerve to the level of the scapular spine. The dorsal scapular artery – the dominant supply to the lower third of the muscle – runs deep to the levator scapulae and minor rhomboid muscles.

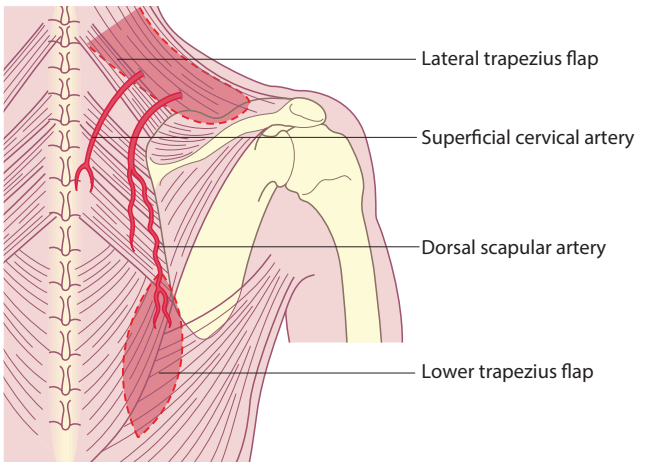

Figure 92.16 The trapezius group of flaps.

The flap with the most utility for head and neck reconstruction is the pedicled lower trapezius myocutaneous flap. This version of the flap has an arc of rotation appropriate for resurfacing of the neck and face and has great utility as a salvage option when a free tissue transfer has failed or there are no recipient vessels available for anastomosis of a free tissue transfer. The patient is positioned in the lateral decubitus position with the arm draped freely for repositioning of the scapula during dissection. The muscle margins, the medial border of the scapula and the thoracic spines down to the 12th vertebra are marked. The skin island is usually designed with the majority of the flap overlying the lower trapezius. Dissection begins medially, identifying the superior and lateral borders of the latissimus dorsi muscle and the lateral border of the trapezius. Dissection continues under the trapezius muscle where the dorsal scapular artery is identified. Retrograde dissection continues, following the vascular pedicle of the flap. The descending branch of the dorsal scapular artery (running deep to the rhomboids) must be divided to allow rotation and complete elevation of the flap. Dissection can be carried up to the levator scapulae with occasional division of the minor rhomboids to improve the arc of rotation. The flap can then be tunnelled subcutaneously into the neck.

Although these flaps are reasonably reliable and may play a role, particularly in the repair of the posterior aspect of the head and neck, such areas are easily reached with a pedicled latissimus dorsi flap. The patient positioning issues and anatomic variability related to the trapezius flap mean that it has a limited role to play in current head and neck reconstructive practice. Its role is principally to salvage (e.g. as a lifeboat when other flaps have been exhausted).

Platysma flaps

The platysma flap was first described in 1978. It is really one half of the myocutaneous apron flap and the skin transferred can either be at the level of the hyoid or in the supraclavicular region, after which the donor site is closed primarily. The blood supply to the upper part of the flap

comes from the submental branch of the facial artery and to the lower part from a branch of the transverse cervical artery. Although initially attractive as a simple way of providing a method of intraoral reconstruction, this flap has a number of distinct disadvantages and is rarely used today:

- Blood supply can be unreliable.
- There may have been previous surgery that has violated the neck and therefore precludes its use.
- When based on the submental branch of the facial artery, this requires preservation of muscularity in an area of oncological significance that may have to be addressed in the resection.
- By and large, the neck should be avoided as a source of reconstruction for the oral cavity.
- Removal of the platysma interferes with the blood supply to the overlying skin, which can have disastrous results.

CONCLUSION

While there has been a dramatic increase in the use of free tissue transfer in head and neck reconstruction, pedicled local or regional flaps have a major role to play in head and neck reconstruction. A clear understanding of the principles of use of local flaps and a comprehensive understanding of the anatomy of these flaps provides the head and neck surgeon with a plethora of local and regional options for primary and secondary reconstruction.

BEST CLINICAL PRACTICE

✓ With the axial muscular flaps, although the blood supply to the muscle is axial, the blood supply of the skin upon the muscle is random.
✓ There is a minimum size of skin paddle that should be taken to ensure that one incorporates sufficient perforators to supply the skin flap. For pectoralis major and latissimus dorsi flaps, this usually means a skin paddle measuring 5×3 cm (the size of the palm of an adult's hand).
✓ Smaller skin paddles may not survive.

FUTURE RESEARCH

➤ Numerous techniques have described using local and myocutaneous flaps in head and neck surgery. Unfortunately, very little data exists evaluating the outcomes in terms of the functional and aesthetic results.
➤ The field of local and myocutaneous flaps is additionally challenged by the advent of free tissue transfer that has dramatically reduced the need for complex local reconstructions except in reconstruction of the external skin.
➤ Future research in all areas of head and neck reconstruction should be focused on functional outcomes: speech, swallowing, aesthetics and patient quality of life.

KEY POINTS

- Pedicled flaps are usually straightforward to both use and harvest.
- Pedicled flaps are generally reliable, but may be bulky and poorly pliable.
- Pedicled flaps can be useful for salvage, particularly in the presence of infection.
- Pedicled flaps may be associated with significant donor site problems.
- Pedicled flaps should be in the surgical repertoire of every head and neck surgeon.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: angiosome, perforator flap, free tissue transfer, fluid management, prophylaxis, deep vein thrombosis (DVT), Doppler, medicinal leech, free flap salvage, fibrinolysis, forearm flap, lateral arm flap, scapular flap, facial recontouring, scalp reconstruction, rectus abdominus, deep circumflex iliac artery (DCIA), anterolateral thigh flap, fibular flap, mandibular reconstruction, pharyngeal reconstruction, jejunal transfer and gastro-omental flap.

INTRODUCTION

Over the past 30 years, the introduction of reconstructive techniques incorporating microvascular free tissue transfer has transformed the quality of life of patients undergoing head and neck surgery. The microsurgeon's ability to transfer autologous tissues comprised of bone, functioning muscle, skin or composites has dramatically improved functional outcomes for all head and neck reconstructive procedures, whether oncologic, congenital or traumatic.

The revolution in the understanding of the blood supply to the various anatomic regions of the body[1,2] has dramatically increased the number and variety of reconstructive options. The wide variety of flaps and the breadth of anatomic knowledge required to offer patients the full panel of flaps available has demanded that most microvascular surgeons acquire specialized training. This evolution has also led to the development of specialized units offering the highest quality reconstruction and outcomes based on the effect of high surgical volumes and the inherent development of advanced technical expertise that comes with extensive surgical experience.

CLASSIFICATION OF FREE FLAPS

A variety of classification systems has been advocated for the description of the various types of free flaps available for reconstruction. A simple classification would divide flaps into cutaneous flaps, including fascia, subcutaneous fat and skin; myocutaneous flaps, including muscle with cutaneous elements; osseocutaneous flaps, including bone and cutaneous elements; and myo-osseous flaps combining muscle and bone.

Most recently a great deal of interest and terminology has evolved around the concept of perforator flaps (**Figure 93.1**).[3] A perforator flap consists of skin and/or subcutaneous tissues supplied by a perforating vessel that passes through or between the deep tissues, usually muscle. A muscle perforator is a vessel that traverses through muscle to supply the overlying skin. A septal perforator is a vessel passing only through an intermuscular septum to supply the overlying skin. A flap vascularized by a muscle perforator is called a muscle perforator flap and a flap vascularized by a septal perforating vessel is called a septal perforator flap. Based on this nomenclature, flaps may be described based on the anatomy of their supplying

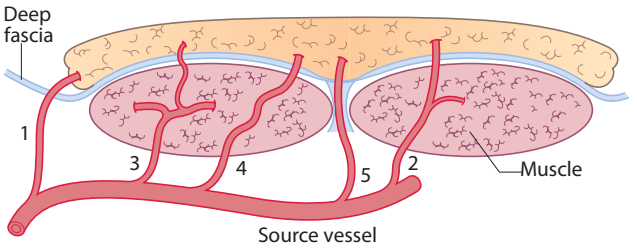

Figure 93.1 Schematic drawing of the different types of direct and indirect perforator vessels with regard to their surgical importance. 1, Direct perforators perforate the deep fascia only; 2, indirect muscle perforators predominantly supply the subcutaneous tissues; 3, indirect muscle perforators predominantly supply the muscle but have secondary branches to the subcutaneous tissues; 4, indirect perimysial perforators travel within the perimyssium between muscle fibres before piercing the deep fascia; 5, indirect septal perforators travel through the intermuscular septum before piercing the deep fascia. Redrawn from Ref. 3, with permission.

vessels. For example, the perforator based skin flap arising on the deep inferior epigastric artery that traverses the rectus abdominus muscle is called the deep inferior epigastric perforator flap and is a muscle perforator flap.

GENERAL CONSIDERATIONS IN FREE TISSUE TRANSFER

Peri-operative management

Considerable literature exists regarding the peri-operative management of patients undergoing free tissue transfers. In general, it is probably fair to state that there exists very little level I evidence regarding best practice. Numerous authors have advocated and continue to advocate for pre- or peri-operative use of volume expansion, particularly with synthetic plasma expanders.[4, 5] Many authors have advocated for higher than normal volume replacement during surgery in order to reduce the risk of arterial or venous occlusion. The evidence would suggest that none of these measures affect flap outcome. Paradoxically, some evidence suggests that excessive volume replacement results in higher rates of flap loss because of the resultant peri-operative complications of congestive heart failure and its sequelae.

The surgeon engaged in free tissue transfer must anticipate a long operative procedure and the following issues must be addressed. The patient must be protected from pressure sores, as procedures in excess of 8 hours often result in pressure sores on the sacrum, heels and back. Long periods of immobility require the use of deep vein thrombosis prophylaxis. Depending on jurisdiction and local practice, this includes heparin prophylaxis and intra-operative and peri-operative use of compression stockings.[6, 7]

Post-operative management

Patients undergoing free tissue transfer are best managed in monitored units where appropriate flap checks and appropriate invasive and non-invasive monitoring is available. In many jurisdictions this is provided in an intensive care facility or its equivalent. In centres with large volumes of free tissue transfers, specialized peri-operative units have been developed staffed with nurses specially trained in the management of free tissue transfers. Monitoring techniques vary from simple observation to implantable flow probes. A number of devices have been developed to detect venous or arterial occlusion. These techniques include percutaneous Doppler of donor vessels, cutaneous laser-Doppler flow probes and implantable flow probes.[8, 9] Little evidence suggests that any modality other than specialized nursing care and frequent observation represents best practice, with most major centres using percutaneous flow probes and specialized nursing units.[10, 11]

Recipient vessels

The head and neck represent a rich supply of vessels for vascular anastomosis. In the era of radical neck dissection, venous recipient vessels were often a problem as most ablative surgeons sacrificed the jugular vein. In the past 30 years, with the move to more selective neck dissections except in advanced disease, venous recipient vessels have not been a problem. Most experienced surgeons rely heavily on the facial artery, superior thyroid artery and transverse cervical artery for recipient arterial supply. These vessels often have a long mobile segment and are ideally positioned for most head and neck defects. Most microvascular surgeons advocate end-to-side venous anastomosis, and the internal jugular vein is often used. Secondary options include the external jugular vein, or the group of veins associated with the transverse cervical artery. The key to optimal vessel selection is careful peri-operative planning and communication between the reconstructive and ablative team with regard to vessel options and preservation during ablative procedures. New technologies are available for vascular anastomosis, with many centres advocating the use of mechanical anastomotic devices to expedite venous repair and reduce the rates of peri-operative occlusion.[12, 13]

Management of flap failure

The use of a free flap for head and neck reconstruction represents a major investment both for the patient and the reconstructive team. In the majority of head and neck procedures, flap failure represents a major peri-operative complication and a potential catastrophe. The majority of flap failures require major revision procedures and can result in significant prolongation of hospital stays and a delay in the delivery of post-operative radiotherapy or chemoradiotherapy. The functional and esthetic sequelae of flap loss can be devastating for oncologic patients.

The rationale for intensive peri-operative observation is to detect venous or arterial occlusion early with an emergent return to the operative theatre to attempt to salvage the flap. Most series report salvage rates between 50% and 80% dependant on the timeliness of detection of venous or arterial occlusion and the speed with which

the problem can be corrected.[14] The majority of occlusions are venous based largely on low flow and likely the greater technical difficulty in suturing a venous anastomosis. Two adjunctive techniques are widely used for venous occlusion. Many authors advocate the use of localized perfusion of the occluded flap with fibrinolytic agents.[15, 16] These agents, when perfused locally (but not systemically), seem to improve the rates of flap salvage. The other technique that is used widely for venous failure is the application of medicinal leeches. A detailed description of leech use is beyond the scope of this text, but they can be extremely effective at salvaging venous occlusions.[17]

FREE FLAPS IN HEAD AND NECK RECONSTRUCTION

The forearm flaps

The free forearm flap was first described for head and neck reconstruction by Yang[18] in 1983 when he used this flap to reconstruct a neck defect secondary to a burn scar contracture. The forearm flap was popularized for head and neck reconstruction by Soutar et al.[19] in 1983. Soutar described the first large series of forearm flaps for oral reconstruction, as well as the osseocutaneous forearm flap that incorporated the radius for mandibular reconstruction.[20] Numerous authors have published series of forearm flaps demonstrating its utility and versatility in head and neck reconstruction.

ANATOMY

The cutaneous forearm flap is based on the radial artery with venous drainage provided by the venae comitantes or branches extending from the skin to the cephalic vein of the forearm (**Figure 93.2**). The artery and venae have a remarkably consistent anatomy with rare anatomic variations. The vessel generally lies between the tendons of the brachioradialis and the flexor carpi radialis in the distal third of the arm and lies deep to the brachioradialis in the proximal forearm. The vascular supply to the skin is provided by perforating vessels that extend vertically through the overlying fascia to supply the subcutaneous fat and skin. The osseocutaneous version of the flap requires the incorporation of perforating vessels that cross over the velar and lateral surface of the radius to supply the periostemon of the distal radius. The flap can incorporate a sensory nerve – the lateral ante brachial cutaneous nerve of the forearm, which can provide a sensate flap for oral reconstruction.

The skin island can be as large as the entire velar surface of the arm. The bone available is from the pronator teres insertion to the distal radius with a maximum length of 10–12 cm available.

ADVANTAGES

The forearm flap has a number of unique advantages for head and neck reconstruction. Its surgical anatomy is remarkably consistent, making it a relatively easy flap for surgeons to learn and harvest reliably. The skin on the distal third of the arm is extremely thin, making it an ideal flap for interiorly reconstruction of the lateral tongue and floor of mouth. The flap can be harvested as a sensate flap, providing the most robust sensation available of all the cutaneous flaps available for head and neck reconstruction.[22] Because of the positioning of the arm during surgery the flap can be harvested simultaneously with an ablative head and neck procedure.

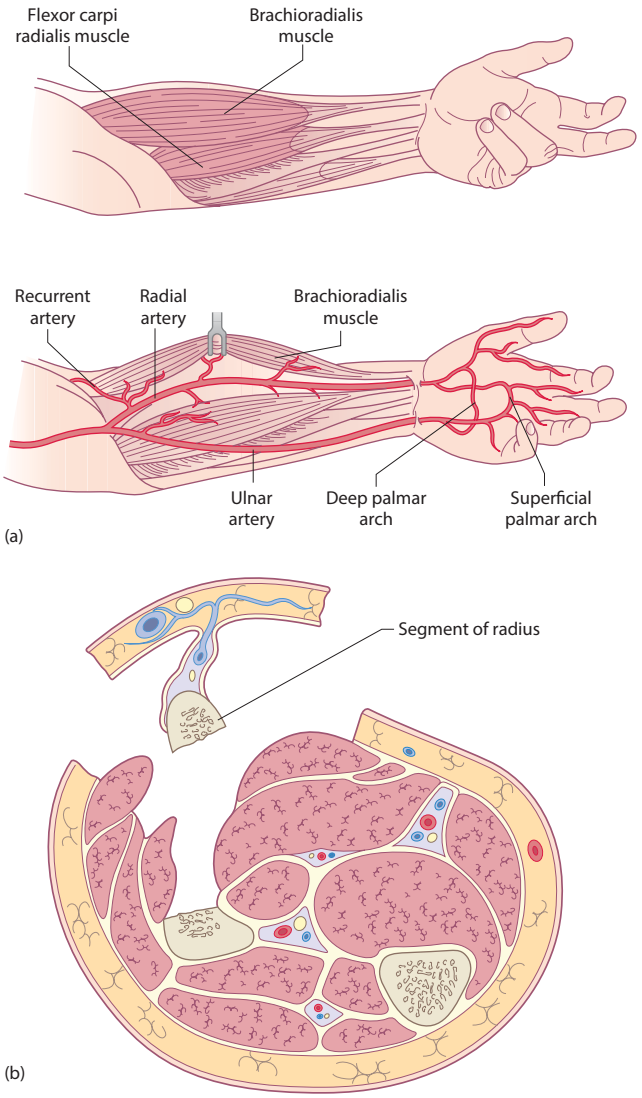

Figure 93.2 Detailed anatomy of the forearm flap: (a) muscular and vascular anatomy; **(b)** coronal section of the forearm illustrating the osteocutaneous version of the forearm flap, note the perforators extending from the radial artery to the overlying skin as well as the lateral and descending perforators to the radius. Redrawn from Ref. 21, with permission.

DISADVANTAGES

The forearm flap has few disadvantages. In terms of match to recipient defects, its only liability is the volume of tissue for some defects that incorporate large mucosal or cutaneous defects with a considerable amount of dead space.

The skin colour match to external skin is probably the poorest of the cutaneous flaps, except in patients of South Asian or African American origin, for whom the flap can have an excellent colour match. The donor site is not popular with patients as it usually requires a skin graft, leaving a relatively unsightly scar on the velar forearm. Bardsley et al. have described a so-called hatchet flap variation utilizing a volar ulnar artery based flap for primary closure of the forearm defect (**Figure 93.3**).[23] Other potential problems include wrist stiffness, cold sensitivity and, on occasion, tendon exposure, which often require long periods of wrist splinting to ultimately achieve skin closure.

TECHNICAL NUANCES

This flap is usually harvested under tourniquet control offering a blood free dissection. It is critical to be certain prior to harvest and tourniquet inflation that the patient has a patent lunar artery. In most patients the lunar artery is the dominant blood supply to the deep palmer arch that supplies the hand and digits. A simple Allen's test to evaluate collateral flow through the lunar artery is a mandatory pre-surgical procedure. During the harvest it is important to avoid injury to the cutaneous branch of the radial nerve. To avoid problems with tendon exposure following harvest, the paratenon overlying the flexor carpi radialis must be preserved to well-vascularized surface for a skin graft. Most surgeons use a relatively thick split thickness skin graft for the donor site. Some series have reported success with the use of full thickness grafts. In terms of the bone harvest in the osseocutaneous version of the flap, the major complication associated with this flap is fracture of the distal radius at the site of the bone harvest. The distal radius proximal to the radial styloid is relatively narrow and too vigorous a bone harvest can result in radial fracture. Most authors advocate taking no more than one-third of the width of the radius, and also suggest curving the osteotomy, avoiding perpendicular bone cuts, which can produce stress risers and potential fracture sites.[24] Some authors advocate prophylactic plating of the distal radius if a bone harvest is performed.[25] Most experienced microvascular surgeons would avoid this osseocutaneous flap in elderly osteoporotic females.

APPLICATIONS

Oral cavity and oropharynx

The forearm flap was popularized by Soutar for oral reconstruction and is the most important application for this flap in head and neck reconstruction. The function of a reconstruction of the oral tongue is to retain the mobility of the tongue remnant. One can easily appreciate that the forearm is ideally suited to the task (**Figure 93.4**). This flap's thin subcutaneous layer, pliability and potential sensation makes it unique among the variety of cutaneous flaps available for oral reconstruction. In defects including a segmental mandibular defect, authors have advocated the use of the osseocutaneous forearm flap. The radius is a less than ideal reconstruction for even short mandibular defects. It has a short vertical height, making secondary prosthetic reconstruction of the dental arch difficult or impossible, particularly if osseointegrated implants are indicated. In addition, the short length of available bone is problematic for extended defects. The radius is not easily osteotomized for defects including the symphysis or angle. Its only application in mandibular reconstruction is likely as a secondary option when the other bone flaps are not available or for short defects of the symphysis or body of the mandible. The osseocutaneous flap has been used for central maxillary defects, where a soft pliable cutaneous flap containing bone, associated with a long vascular pedicle, represents an ideal reconstruction (**Figure 93.5**).

The forearm is likely the best flap available for buccal mucosal reconstruction as it is the only cutaneous flap with the appropriate thickness for buccal defects.

This flap has been widely used for palate reconstruction, particularly small defects of the central palate and alveolus. Its unique strengths in this application are the thinness of the flap and its long vascular pedicle, which will readily reach neck recipient vessels.

Many reconstructive surgeons use this flap for defects of the oropharynx, particularly the tonsil–tongue base soft palate defect where the flexibility of the flap allows it to contour into these complex three-dimensional defects and provides excellent functional reconstruction of the soft palate.

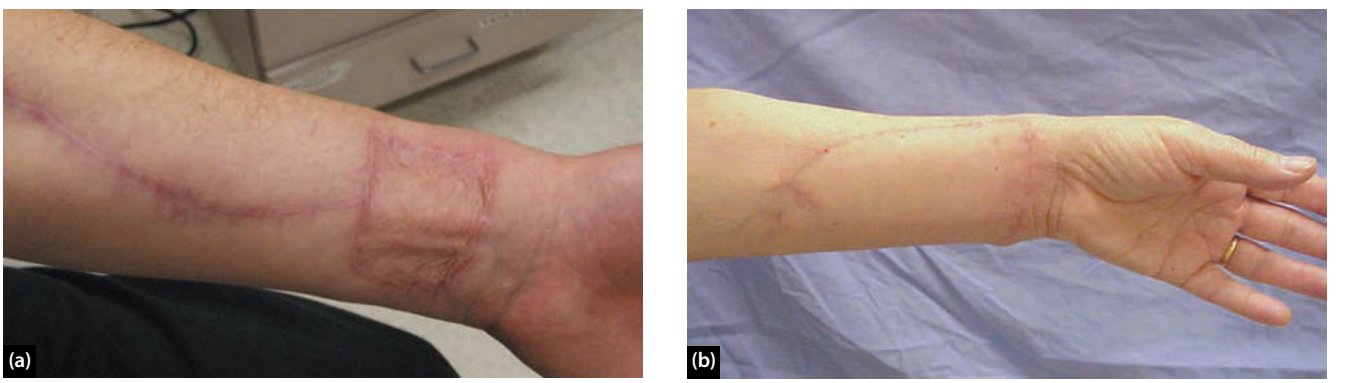

Figure 93.3 **(a)** Skin grafted donor site; **(b)** primary closure with hatchet flap.

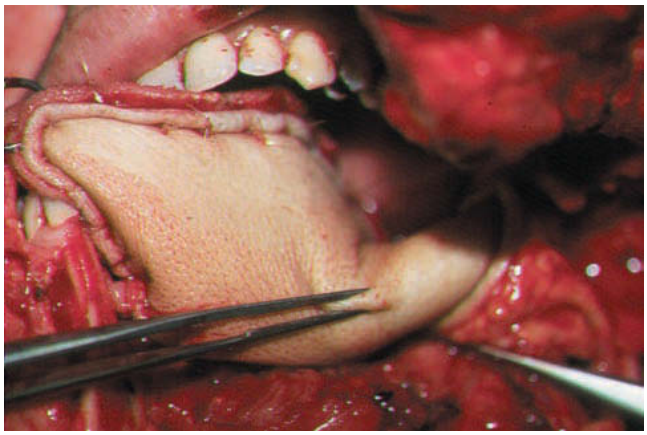

Figure 93.4 Oral tongue reconstruction with forearm flap.

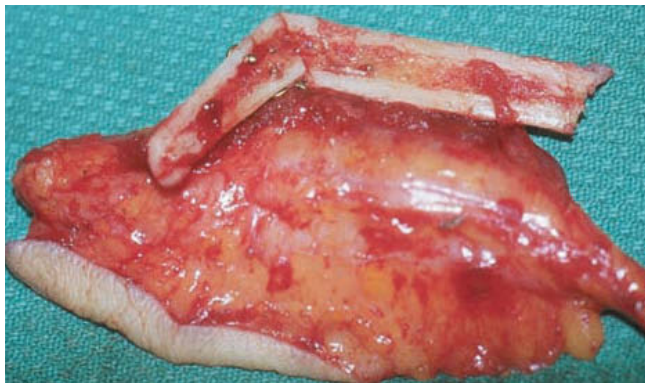

Figure 93.5 Osseocutaneous radius for midface reconstruction.

External skin

The forearm flap has been widely used for cutaneous defects of the head and neck. Because of the limited amount of skin available the applications for external defects are limited to small defects where the unique features of the flap are an advantage. One of the disadvantages of this flap in Caucasians is a relatively poor colour match to facial skin.[26]

The forearm flap's greatest applications in external skin reconstructions are the total upper or lower lip defect and total nasal reconstruction. In total lip reconstruction the ability to replace the entire aesthetic unit of the upper or lower lip along with a tendon sling (incorporating the palmaris longus or flexor carpi radialis tendon with the flap) makes this an excellent functional reconstruction for this formidable defect.[27] In total nasal reconstruction, a number of authors have described the use of this flap to create the lining and infrastructure for the nose, using a multistage procedure incorporating a forehead flap for external cover.

The lateral arm flap

The lateral arm flap described by Song et al.[28] in 1982 has been widely used in head and neck reconstruction. This flap has application in oral cavity reconstruction and in reconstruction of soft tissue and cutaneous defects of the face and neck. This flap has a relatively large cutaneous flap available up to 14 × 20 cm; however, donor sites wider than 6 cm cannot be closed primarily.

ANATOMY

This flap's blood supply is based on the radial collateral artery of the arm (**Figure 93.6**). The radial collateral artery arises from the deep brachial artery and runs with the radial nerve on the lateral aspect of the upper arm. Once the radial collateral appears on the anterolateral aspect of the trapezius it divides into a posterior and anterior branch. The anterior branch continues inferiorly to accompany the radial nerve deeply between brachialis and brachioradialis. The posterior branch enters the lateral intermuscular septum between brachialis and triceps and then runs toward the lateral epicondyle. In its course along the lower lateral arm the posterior branch gives off a number of fasciocutaneous perforators to supply the skin in this area. The skin of the lateral arm flap is innervated via the lower lateral cutaneous nerve of the arm a branch of the radial nerve. The innervation provided is relatively dense but not as sensate as the forearm flap.

ADVANTAGES

The major advantage of the lateral arm flap is its location on the arm. The donor site for this flap is relatively inconspicuous and can be closed primarily in most patients. The colour match to facial skin is excellent, even in Caucasians. The flap can be harvested as a sensate flap and does provide functional sensation.

DISADVANTAGES

The major disadvantages of the lateral arm flap relate to the available width of the skin flap and the pedicle size. Extremely wide flaps will require a skin graft for closure. The fat in the lateral arm may provide too much volume for oral reconstruction in obese patients. The pedicle associated is of small calibre with a maximum diameter of 1.5 mm with potential very small venae comitantes. Microsurgical anastomosis is therefore technically difficult and less reliable than other flaps. The vascular pedicle is short, 4–8 cm, making this flap less than ideal when recipient vessels are at a distance from the defect site.

TECHNICAL NUANCES

The flap design is critical to ensure that the posterior branch of the radial collateral artery is included in the flap. The axis of the flap and area to be harvested are planned by drawing a line from the deltoid insertion to the lateral epicondyle. Dissection begins on the posterior aspect of the flap with harvest of the deep fascia overlying the trapezius. Dissection continues superiorly until the lateral intermuscular septum is encountered. The posterior branch is visualized and then dissection begins on the anterior aspect of the flap again in the subfascial plane until the intermuscular septum is isolated on both sides. The flap is then dissected in a retrograde fashion with great care taken to avoid injury to the radial nerve.

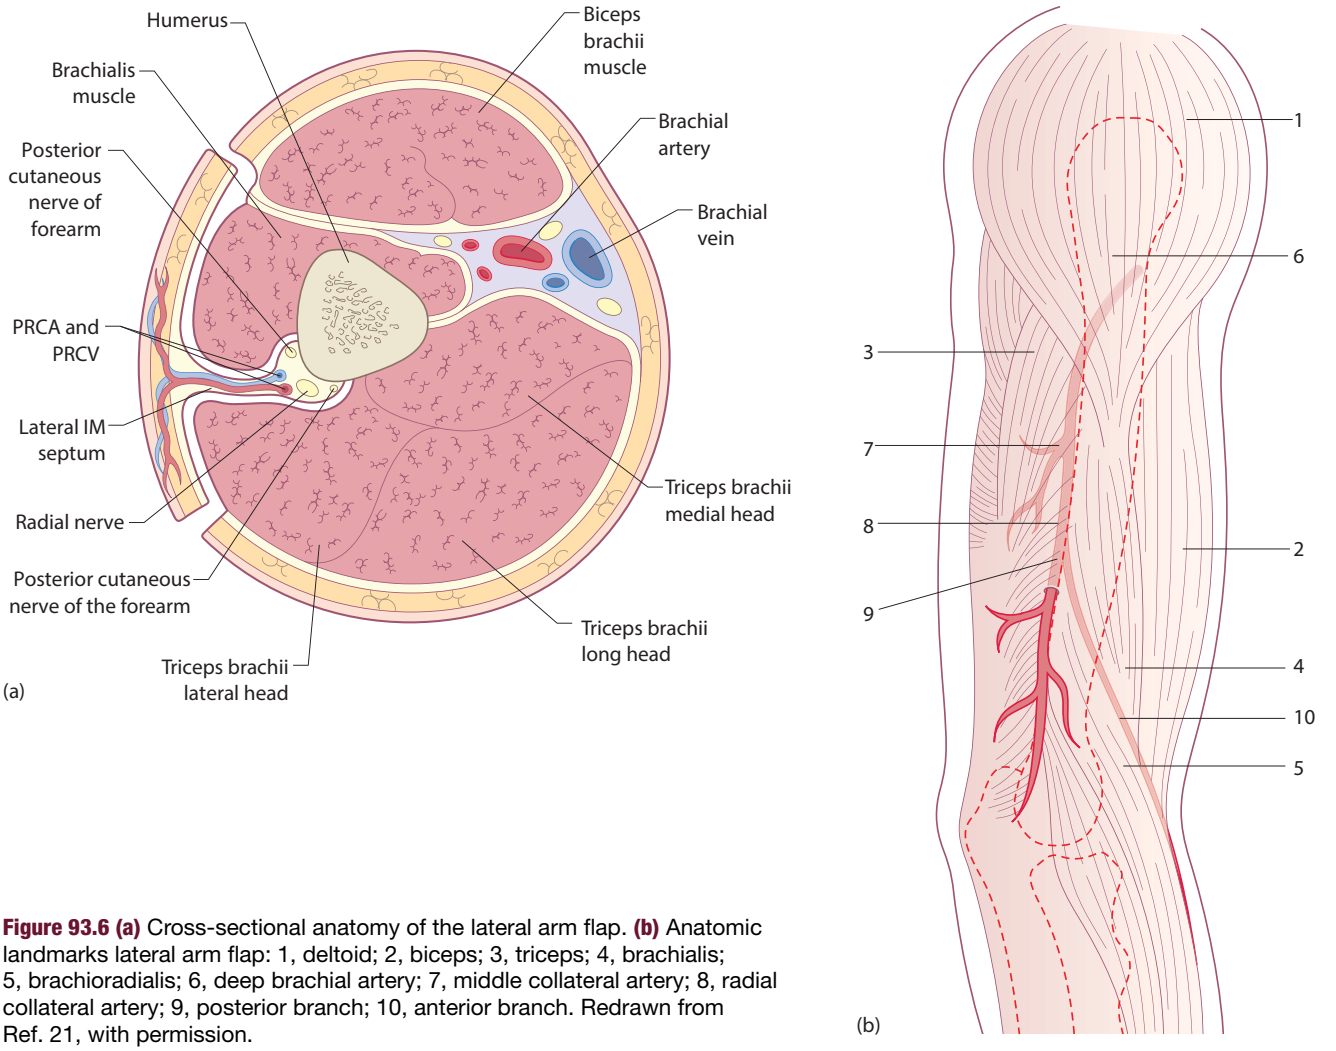

Figure 93.6 (a) Cross-sectional anatomy of the lateral arm flap. **(b)** Anatomic landmarks lateral arm flap: 1, deltoid; 2, biceps; 3, triceps; 4, brachialis; 5, brachioradialis; 6, deep brachial artery; 7, middle collateral artery; 8, radial collateral artery; 9, posterior branch; 10, anterior branch. Redrawn from Ref. 21, with permission.

CLINICAL APPLICATIONS

The major disadvantage of this flap is its pedicle length. It should not be considered when recipient vessels are at a distance from the defect site. The major applications for this flap are in reconstruction of the floor of mouth and lateral tongue. The excellent colour match to the lateral aspect of the face and neck make it ideal for recontouring radical parotidectomy defects or replacements for narrow defects of the lateral face or neck.[29]

SCAPULAR SYSTEM OF FLAPS INCLUDING THE LATISSIMUS DORSI FLAP

Cutaneous or osseocutaneous scapular or parascapular flap

The scapular system of flaps were popularized for head and neck reconstruction by Swartz et al.[30] and dos Santos.[31] A number of head and neck surgeons have described their experience with this flap in complex oromandibular reconstruction.[32]

The scapular system of flaps is unique in the area of head and neck reconstruction as no single area provides such a variety of options for reconstructive tissues. Flaps harvested from this group of flaps can provide skin, skin and muscle, skin and bone or skin, muscle and bone with two or three muscle flaps available based on a single vascular pedicle.

ANATOMY

In order to take full advantage of this group of flaps a detailed understanding of the vascular anatomy of this area is critical (**Figure 93.7**). The axillary artery gives rise to the subscapular artery, which descends in the posterior axilla to give rise to the circumflex scapular artery and the thoracodorsal artery. The circumflex scapular artery provides nutrient and periosteal supply to the lateral border of the scapula, then divides into two perforating branches that supply the skin overlying the scapula. The circumflex scapular artery lies in the space bordered inferiorly by the teres major muscle, superiorly by the teres minor muscle and laterally by the long head of the triceps. Once through this space the artery divides into the two aforementioned branches, giving rise to a parascapular perforator and a

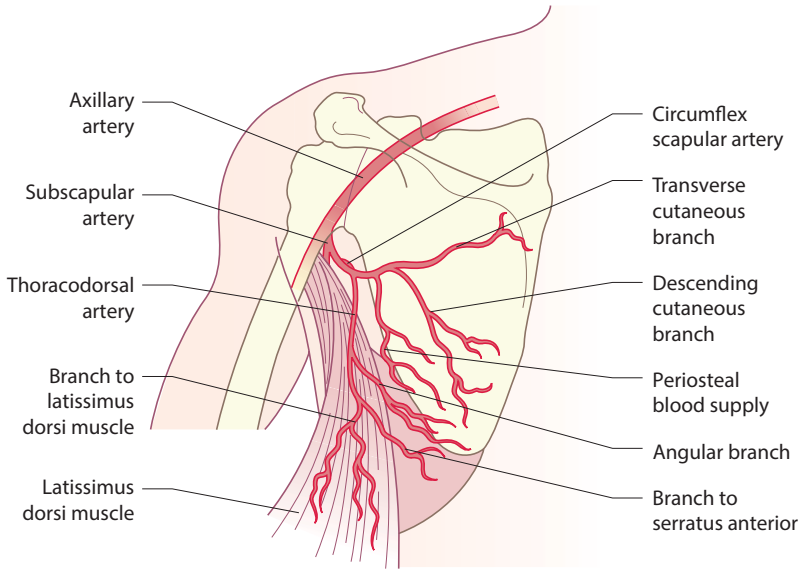

Figure 93.7 Anatomy of the scapular system of flaps. Redrawn from Ref. 21, with permission.

transverse scapular perforator. The thoracodorsal artery descends inferiorly, providing branches to the serratus anterior and the latissimus dorsi, as well as providing the angular artery, a branch that supplies the distal one-third of the scapula and its overlying musculature. The venous drainage is via paired venae comitantes, which usually join the axillary vein close to the origin of the subscapular artery. It can easily be appreciated from this vast array of vessels that any combination of flaps may be harvested depending on the requirements for the reconstructive defect. The cutaneous flaps available include a transverse scapular flap, a parascapular flap and a thoracodorsal artery perforator flap. The myocutaneous flaps available include the latissimus dorsi flap; the myogenous flaps available include serratus anterior, the latissimus dorsi and the teres major muscles. The osseous flaps include the scapular bone flap based on the nutrient vessels from the circumflex scapular artery or the scapular tip via the angular artery.

ADVANTAGES

The scapular systems of flaps have some particular advantages. The available skin, either via the parascapular or scapular perforators, can be as large as 18 × 10–12 cm with primary closure of the donor site. The latissimus dorsi perforator flap or the latissimus dorsi myocutaneous flap can provide even larger skin islands with primary closure of the donor defect. In composite reconstructions (bone and skin) the skin island may be rotated or positioned relatively independently of the bone flap, allowing considerable flexibility in positioning of the skin island relative to the bone segment. The vascular anatomy other than the blood supply to the tip of the scapula is remarkably consistent, and dissection based on anatomic landmarks makes the flap harvest relatively simple. The donor site when designed along the posterior axillary line is relatively well hidden. The skin colour of the scapular region generally is a good colour match to the face and neck, even in Caucasian patients. The donor site has very limited morbidity. However, when scapular bone is harvested most patients have some restriction of shoulder motion and require aggressive shoulder rehabilitation. It is the experience of a number of authors that this flap is extremely well tolerated in the elderly and vessels to the scapular system of flaps seem to be relatively spared in patients with extremity peripheral vascular disease, making it an excellent option in this group of patients.

DISADVANTAGES

This flap, while offering a plethora of reconstructive options, does have some disadvantages. In the original description of the harvesting of this flap the patient is positioned in the lateral decubitus position. For most ablative oncologic procedures, that would mean that the patient required repositioning for flap harvest and then a return to the original position for flap inset. Most experienced surgeons position the patient in the supine position with the body rotated 15–20 degrees. This positioning allows the ablative procedure and flap harvest without repositioning. Two teams or simultaneous harvest is next to impossible given the proximity of this donor site to the head and neck. The bone of the lateral scapula is technically difficult to harvest, given the array of muscular origins on the scapula, making a surgeon's early experiences with this flap relatively difficult. If the teres major and subscapularis are not properly repaired, patients may have considerable problems with shoulder strength and range of motion post-operatively. The pedicle of the scapular flap, particularly when a bone segment based on the nutrient artery is harvested, can be relatively short as the bone branch from the circumflex scapular artery is relatively close to its origin. The available bone is relatively short – 10–12 cm in an adult male – making it less than ideal for hemimandibular or extended resections of the mandible. The skin of the back, while ideal in terms of colour, has a relatively thick dermis and dense subcutaneous fat, making it an inflexible

reconstruction for defects requiring contour changes such as floor of mouth, tongue and palate reconstruction.

TECHNICAL NUANCES

The most important technical nuance for the harvesting of this flap is appropriate patient positioning. One approach is to position the patient on a 'bean-bag', essentially a polyethylene bag filled with beads. When the air is removed from the bag the beads form a firm structure that maintains the patient in the appropriate position. The patient is usually turned 20–30 degrees from the supine position so that the medial border of the scapula is visible and palpable.

Harvesting of the flap requires a detailed understanding of the muscular anatomy of the region. The location of the pedicle within the triangle bordered by teres major, teres minor and the long head of triceps is an important concept to understand. Identifying these structures during the harvest allows easy visualization of the perforators to the skin island. Perhaps one of the more difficult aspects of this flap is the bone harvest and position of the osteotomies. The key is to identify the bone nutrient artery just below the inferior tip of the glenoid. Make a transverse osteotomy between the inferior lip of glenoid and the entry of the nutrient artery into the lateral border of the scapula. The lateral border is then detached by making a vertical cut along the long axis of the scapula medial to the crest or the point of insertion of the teres major, teres minor and the subscapularis. We routinely drill holes in the remaining lateral border of the scapula and carefully reattach the teres major and subscapularis muscles, to maximize recovery of shoulder function.

CLINICAL APPLICATIONS

Cutaneous flap

The cutaneous scapular or parascapular flap has a wide variety of applications in head and neck reconstruction. Because of its colour match, it is ideal for defects of the lateral face, neck and temporal bone. The flap can be de-epithelialized for recontouring of facial defects and a number of authors have described its use for facial recontouring for conditions such as Romberg's disease[33] or secondary deformities of the lateral face. The latissimus dorsi myocutaneous flap has a similar range of reconstruction and is ideally suited for extensive defects of the lateral neck, and has been widely used as a muscle-only flap for scalp reconstruction.[34] The flap has been widely used for oral cavity reconstruction, particularly for composite defects, but the thickness of the dermis and the fat density of the flap make it a less than ideal reconstruction for this defect.

Osseocutaneous flap

The osseocutaneous versions of this flap have a variety of applications in head and neck reconstruction. The bone length available of 10–12 cm limits the use of this flap in extensive mandibular defects, but is adequate for the majority of ablative defects encountered (**Figure 93.8**). The bone is relatively easy to osteotomize, usually with osteotomies of one cortex and then 'green-sticking' the scapula to contour it to the appropriate shape. One of the unique aspects and applications of this flap are in defects including oral lining and external skin cover. The flexibility of the flap allows at least two separate skin islands that can rotate independently of the bone segment. Numerous authors have described the use of the scapular flap in midface and maxillary reconstruction. Two bone flaps are available for this application; the classic scapular bone flap based on the nutrient artery arising from the circumflex scapular artery and the tip of scapular flap based on the angular artery. The former has the limitation of a relatively short vascular pedicle, making its application in midface reconstruction relatively problematic. The tip of scapula based on the angular artery has the advantage of an extremely long vascular pedicle, making it ideally suited for maxillary and midface reconstruction.

FLAPS FROM THE ABDOMINAL WALL AND PELVIS

Rectus abdominus and deep inferior epigastric artery perforator flaps

The rectus abdominus flap has been a 'workhorse flap' for head and neck reconstruction over the past 30 years. Originally popularized for breast reconstruction as a local myocutaneous flap based on the superior epigastric vessels, it has remarkable utility for head and neck reconstruction. The flap can be harvested as a myocutaneous or perforator-based flap, offering a wide variety of cutaneous or myocutaneous options.[35, 36]

ANATOMY

The rectus abdominus flap is based on the deep inferior epigastric artery and its venae comitantes (**Figure 93.9**). The deep inferior epigastric artery arises from the external iliac artery immediately above the inguinal ligament. It ascends in a lateral to medial direction penetrating the transversalis fascia below the arcuate line, then travelling superiorly between the rectus muscle and the posterior rectus sheath. The artery generally divides into a number of large branches just below the umbilicus, providing numerous perforating branches to the rectus abdominus muscle and the overlying skin. Pedicle lengths from origin to insertion into the muscle range from 8 cm to 14 cm with average vessel diameters of 2.0–3.0 mm. The flap has its sensory and motor supply from the lower six or seven spinal thoracic nerves, making its innervation segmental and less than ideal for functional reconstruction or restoration of sensation.

ADVANTAGES

The rectus abdominus myocutaneous flap or deep inferior epigastric perforator (DIEP) flap has a number of advantages for head and neck reconstruction. The vascular anatomy of the flap is extremely consistent, making it a relatively simple flap to harvest. The ability to transfer a skin/muscle flap, a perforator-based skin flap or a myogenous flap speak to its versatility. Large areas of skin are available, with the majority of defects amenable to primary closure. The donor site is not problematic for males or females and in some patients may offer the aesthetic benefit of an abdominal lipectomy. In most situations the selection of this flap for reconstruction offers the opportunity for a two-team procedure with flap harvest occurring simultaneously with tumour ablation.

DISADVANTAGES

The major disadvantages of this flap relate to donor site issues and the nature of the subcutaneous fat associated with this flap. The most frequent complication associated with this flap is central abdominal hernias, particularly when portions of the anterior rectus sheath are harvested below the arcuate line. The move to the use of more perforator based rectus flaps, which spare the rectus muscle and the majority of the anterior sheath, have certainly reduced the rates of donor site complications. The body habitus of

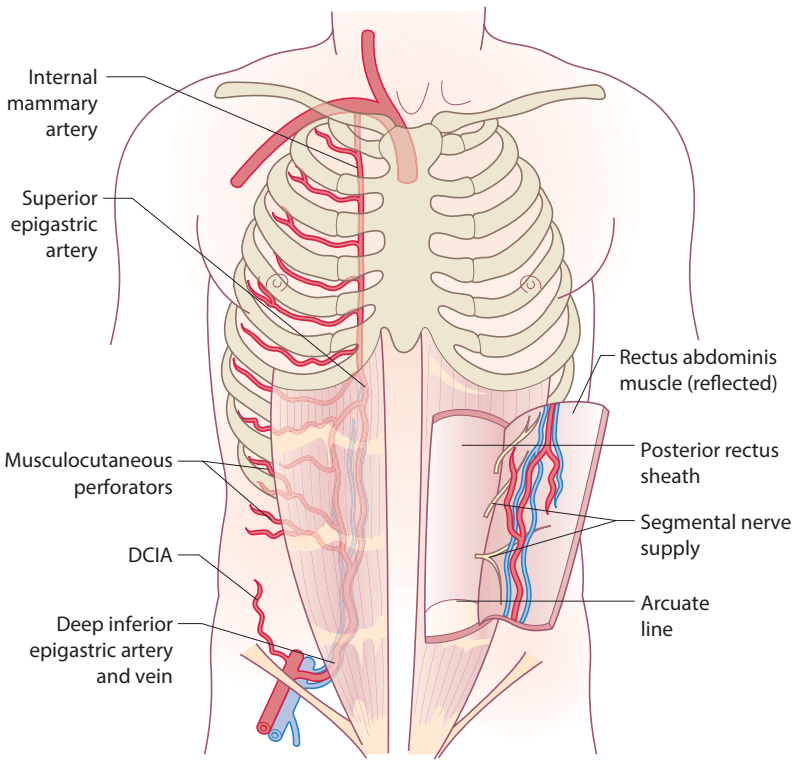

Figure 93.9 Anatomy of the rectus abdominus flap. Redrawn from Ref. 21, with permission.

the patient will determine the tissue match to defects of the head and neck. In obese patients the volume of subcutaneous fat may be inappropriate for defects of the lateral face and neck. In addition, as patients gain weight peri-operatively, the subcutaneous fat will gain volume in proportion to its usual location. These patients may require secondary procedures to reduce the volume of fat in the reconstruction. The colour match to the face and neck is relatively poor with the rectus flap, particularly in Caucasian patients.

TECHNICAL NUANCES

The technical nuances with this flap are largely about reducing donor site complications. The key to minimizing donor site problems is to take as small a piece of the anterior rectus sheath as possible and in particular attempt to avoid taking the anterior sheath below the arcuate line (as there is no posterior sheath). The perforators to the skin of the anterior abdominal wall exit the anterior rectus sheath in an arc around the umbilicus. Most flaps are designed with the base just below the umbilicus where the density of perforators is the greatest. In order to have a viable flap the only fascia that needs to be removed is that which immediately surrounds the perforators themselves. A small narrow strip of anterior fascia is all that should be taken, preserving the remainder for closure. The dissection for the myocutaneous flap begins laterally over the rectus sheath with dissection medially until one identifies the major perforators in the periumbilical region. The anterior sheath is then incised at this point, with a small island of fascia overlying the rectus abdominus muscle with the incorporated skin perforators. The entire rectus muscle is then harvested in a retrograde fashion with the pedicle identified on the deep lateral surface of the muscle, with dissection carried down to the vascular origin. In the DIEP harvest, the surgeon selects a major perforator then follows it through the muscle to the deep inferior epigastric artery (**Figure 93.10**). The lateral aspect of the muscle is identified and lifted medially to facilitate the dissection of the pedicle. The flap is harvested by delivering the vascular pedicle through the muscle, preserving the majority of the rectus abdominus muscle and the anterior rectus sheath.[37, 38] Careful and precise closure of the donor site is critical to avoid abdominal hernia. Where the anterior sheath cannot be closed primarily, reconstructive mesh should be used to avoid hernia formation.

CLINICAL APPLICATIONS

The rectus abdominus myocutaneous flap has been widely used in head and neck reconstruction. Its major applications have been in large volume reconstructions of the oral cavity or oropharynx and lateral skull base. The volume of tissue and the combination of muscle and skin offer the reconstructive surgeon the ability to fill surgical dead space and protect critical structures such as the carotid sheath or dural repairs. The flap is particularly useful for the total glossectomy defect where the volume of tissue can fill the space under the mandible, reducing the risk of perioperative fistula and infectious complications. The perforator-based DIEP flap extends the use of this flap, as the ability to harvest a large cutaneous flap, without the associated muscle, makes it useful for total glossectomy and extensive tongue defects. The DIEP flap can also be used to cover extensive facial and neck defects and may be used to recontour soft tissue defects of the lateral face.

Deep circumflex iliac artery osseomyocutaneous and the myo-osseous flap

The deep circumflex Iliac artery osseomyocutaneous, myo-osseous or osseous flap has the been a 'workhorse' flap for composite defect reconstruction of the oral cavity and mandible since its description by Taylor in 1982.[39]

ANATOMY

The iliac crest transfer is based on the deep circumflex iliac artery and its venae comitantes (**Figure 93.11**). The deep circumflex iliac artery (DCIA) arises from the lateral aspect of the external iliac artery, just above the

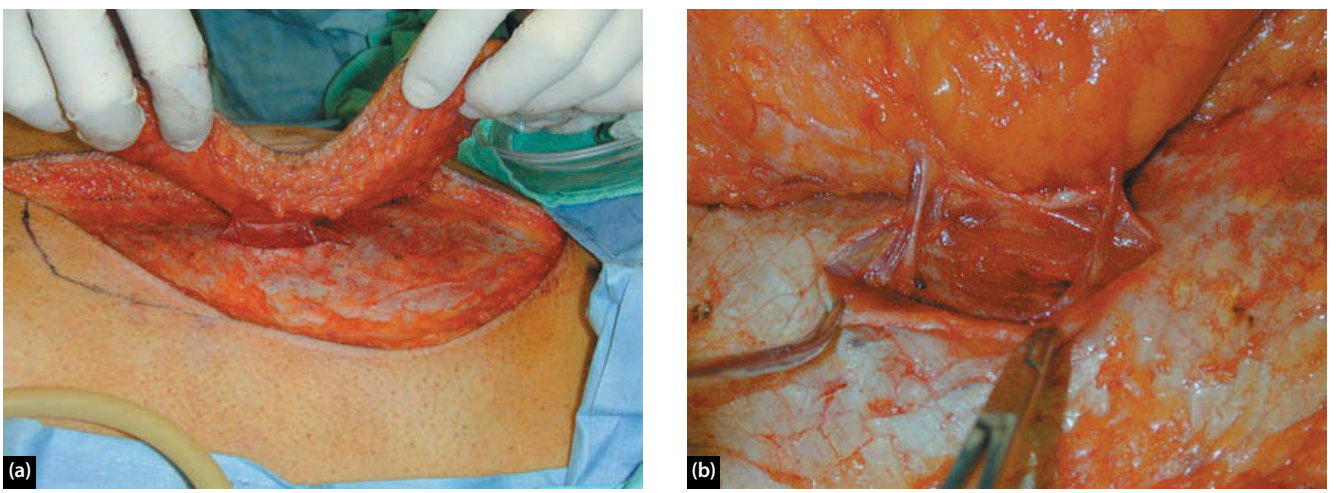

Figure 93.10 (a) DIEP perforator flap; note two dominant perforators and small fascial incision; **(b)** magnified view.

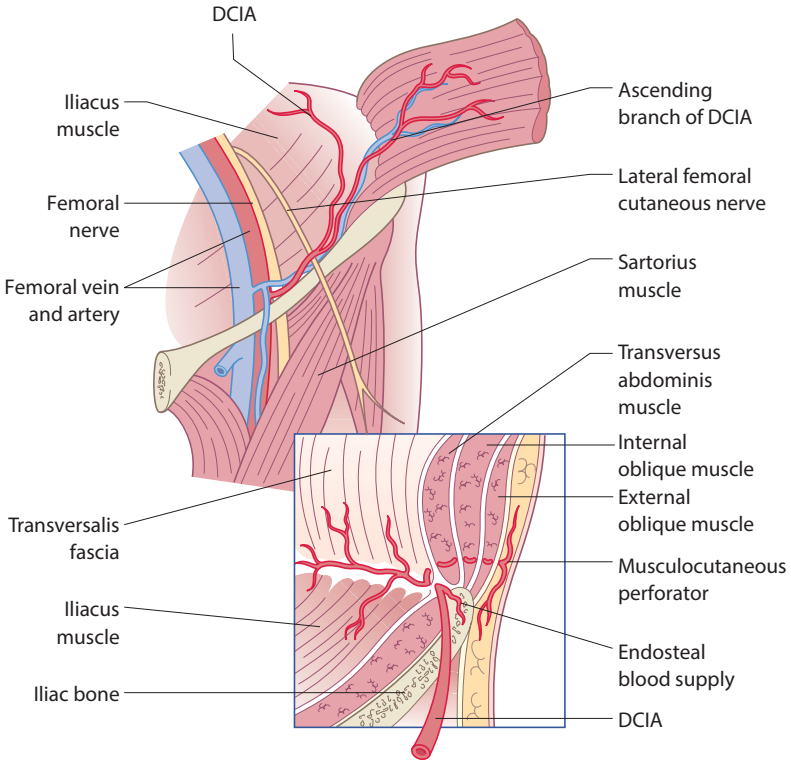

Figure 93.11 Anatomy of the DCIA flap. Redrawn from Ref. 21, with permission.

inguinal ligament. It runs a course parallel to the inguinal ligament, and 1 cm medial to the anterior superior iliac spine it gives off a large ascending branch that pierces the transverses abdominus muscle to lie on the deep surface of the internal oblique. The deep circumflex iliac artery (DCIA) then penetrates the transervsalis fascia and lies along the inner aspect of the crest, about 2 cm below the surface of the crest in the line of fusion of the iliacus and transveralis fascia. The artery extends posteriorly along the crest and about the midpoint of the crest, where it re-enters the transversus abdominus to anastomose with iliolumbar and superior gluteus arteries. Along its course it provides perforating branches that traverse all layers of the musculature of the abdominal wall just above the crest and supply the overlying skin. The venous drainage of the flap is the deep circumflex iliac vein (DCIV) which runs as a venae comitantes but often courses superiorly prior to its drainage into the internal iliac vein. There is some variability in vascular anatomy. The anterior branch may arise from a separate independent pedicle, originating just below the DCIA. The vascular pedicle is 6–8 cm in greatest length, with the artery and vein usually being of large calibre (2–3 mm).

ADVANTAGES

The DCIA-based iliac crest is an ideal flap for reconstruction of the mandible. It can be shaped to recreate both the mandibular body and the vertical ramus. The bone stock is excellent, in terms of both its corticocancellous proportions and the vertical height and breadth of the available bone. The physical properties of the crest make it ideally suited for primary or secondary osseointegration. This flap, when transferred with the internal oblique, provides an excellent vascularized reconstruction for patients with osteoradionecrosis.

DISADVANTAGES

The major disadvantages of the flap relate to the reliability of the skin paddle, the character of the skin paddle and secondary problems with the donor site. The skin paddle associated with the flap needs to be based on the line of the crest. While this makes an ideal skin closure in terms of scar location, in order to harvest a reliable skin island, a cuff of muscle that includes all three muscular layers of the abdominal wall must be retained in order to preserve the perforating vessels. This results in a relatively thick and inflexible reconstruction, making this version of the flap less than ideal for most head and neck applications. The skin flap is notoriously unreliable based on the fragility and unpredictability of the perforator supply. The donor site is problematic, as a significant number of patients will have either frank hernia formation or chronic laxity of the lower abdominal wall. While the lateral cutaneous nerve of the thigh can be preserved in the majority of dissections, in some situations it must be sacrificed, leaving an area of numbness on the lateral thigh. The donor site is painful, particularly when the entire crest is harvested, and peri-operative mobilization can be an issue, particularly in elderly patients. The pedicle length can be problematic when the flap is used for maxillary reconstruction, and vein grafting may be required.

TECHNICAL NUANCES

The DCIA flap is one of the more technically difficult flaps to harvest. Patient positioning is quite important in order

to allow visualization of the medial aspect of the crest. In most iliac crest bone graft harvests, a bag is placed under the hip to rotate it away from the surgeon. In the DCIA flap the surgeon must be able to visualize the medial crest and therefore the reverse position is most appropriate. One approach is to place a soft roll under the sacrum to elevate the pelvis and then rotate the operating table towards the surgical side to maximize visualization. Most experienced microsurgeons try to avoid the osseocutaneous version of the flap because of the unreliability of the flap. Likely the most commonly harvested version of the flap incorporates the internal oblique as a myosseous flap. The pedicle in this harvest is most easily identified by finding the anterior branch of the DCIA on the deep side of the internal oblique and then dissecting in a retrograde fashion to the DCIA. One option to reduce donor site complications is to harvest only the inner table, splitting the crest by making an oblique cut through the top of crest extending just below transversalis reflection. This technique provides adequate bone for mandibular reconstruction and preserves the lateral crest and anterior iliac spine. If one harvests the internal oblique, most surgeons routinely repair the defect with a surgical mesh to avoid abdominal wall laxity.

CLINICAL APPLICATIONS

The DCIA flap is largely used for bone only or composite defects of the mandible or maxilla. Taylor described the DCIA for hemimandibular reconstruction, and numerous series have demonstrated its efficacy for this application.[40, 41] Bone length to be harvested ranges from 8 cm to 12–14 cm, making it useful for the majority of defects encountered. Currently, most authors use this flap as a myo-osseous flap, using the internal oblique to close the oral defect with and either skin grafting of the muscle or allowing it to mucosalize secondarily (**Figure 93.12**).[42]

Most recently, Brown[43] has described the use of the iliac crest transfer for maxillary defects. The flap can be used for premaxillary and infrastructure by turning it horizontally to replace the hard palate. The mucosal defect is not reconstructed but rather the surface of the bone is allowed to granulate and secondarily mucosalize. In classic maxillary defect, the crest is inverted with the vascular pedicle oriented towards the maxillary tuberosity. The muscle is then rotated into the defect and allowed to mucosalize secondarily to recreate the hard palate (**Figure 93.13**). These two flap orientations both allow secondary osseointegration for dental restoration with a thin mucosalized reconstruction of the hard palate.

The anterolateral thigh flap

The anterolateral thigh flap is a fasciocutaneous flap based on the musculocutaneous and septocutaneous perforators of the descending branch of the lateral circumflex femoral artery and its venae comitantes. This flap's surgical anatomy and clinical use were first reported by Song et al.[44] in 1984. In 1989 Koshima et al.[45] described its use in the Japanese population, and numerous subsequent reports have described its successful use in head and neck reconstruction in the Asian population. It has gained popularity in oral cavity reconstruction, particularly in the Asian population, whose body habitus is ideally suited to the use of this flap.[46]

ANATOMY

The anterolateral thigh flap is supplied by perforating vessels arising from the descending branch of the lateral circumflex femoral artery. The descending branch runs downward in the intramuscular space between the rectus femoris and the vastus lateralis, terminating in the vastus lateralis just above the knee (**Figure 93.14**). In the midportion of the lateral thigh, the descending branch provides a number of perforators to the skin of the lateral thigh. These perforators can either run between the rectus femoris and vastus lateralis muscle then traverse the fascia lata as septocutaneous perforators to supply the skin of the lateral thigh or they can traverse the vastus lateralis muscle and the deep fascia as musculocutaneous perforators to supply the skin. The length of the pedicle ranges from 8 cm 16 cm.

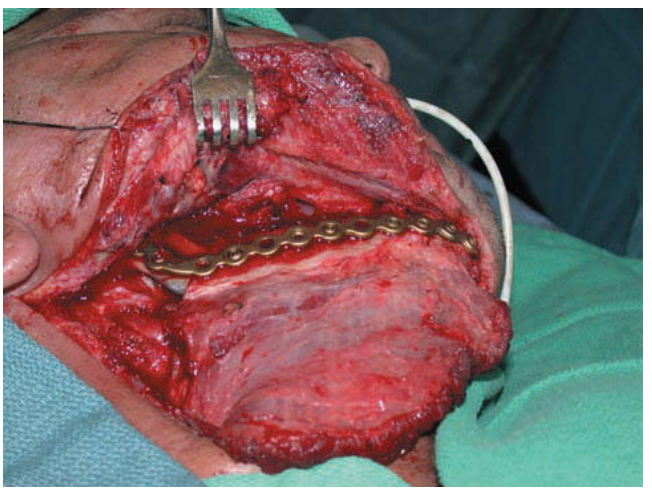

Figure 93.12 DCIA myo-osseous flap; note available muscle for intraoral closure.

Figure 93.13 Split DCIA for maxillary and orbit reconstruction.

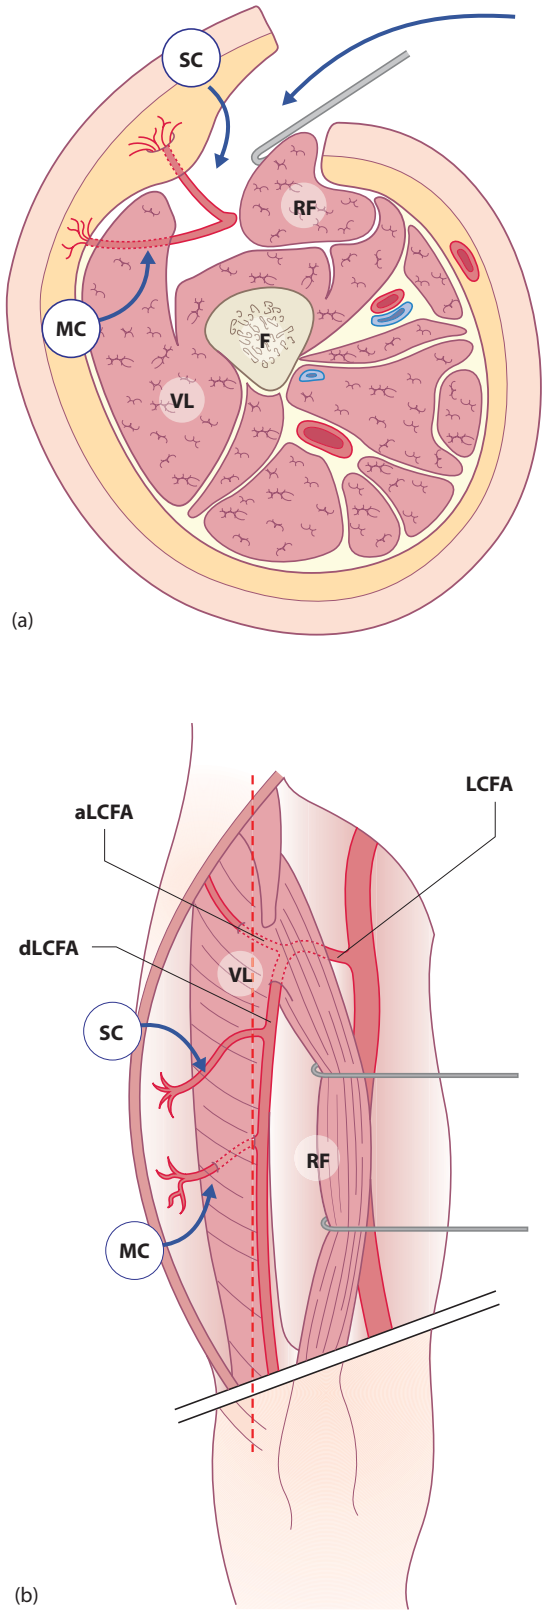

Figure 93.14 Anatomy of anterolateral thigh flap: (a) axial view; and **(b)** coronal view. aLCFA, ascending lateral circumflex femoral artery; dLCFA, descending lateral circumflex femoral artery; LCFA, lateral circumflex femoral artery; MC, myocutaneous perforator; RF, rectus femoris; SC, septocutaneous perforator; VL,vastus laterialis. Redrawn from Ref. 48, with permission.

ADVANTAGES

The anterolateral thigh has a number of advantages for head and neck reconstruction. The flap has a distant site from the head and neck, allowing a two-team harvest. The donor site has limited morbidity and in most patients can be closed primary, in a vertical line. Provided the nerve to vastus lateralis is preserved, little functional disability is associated with this flap. Large skin islands measuring 15–20 cm × 10 cm may be harvested and closed primarily. The flap may be harvested as a perforator flap with or without the fascia lata and can incorporate the vastus lateralis if a muscle component is required. In patients with the appropriate body habitus this flap is thin and pliable and provides an excellent reconstruction for the oral tongue and floor of mouth.

DISADVANTAGES

The anterolateral thigh flap has some disadvantages. The skin colour match to facial and neck skin is poor, especially in Caucasian patients. The anatomy of the flap is variable and somewhat unpredictable so; the surgeon contemplating the use of this flap needs to understand the basic anatomic variations and be prepared for them. Since the cutaneous version of this flap is usually supplied by a single perforating vessel, proximal venous occlusions are usually difficult to salvage because of the small calibre of the perforating vessels. In addition, because of the small size of the perforating vessels, the flap pedicle may be easily compromised by external compression. This makes it a poor choice for reconstructions requiring tunnelling of the pedicle. In some ethnic populations the thickness of fat in the lateral thigh makes this a poor donor site as the volume and bulk of the flap will produce an unreliable flap and a poor functional result.

TECHNICAL NUANCES

The skin perforators of the lateral thigh are mapped with Doppler, using the midpoint of a line drawn between the anterior superior iliac spine and the lateral aspect of the patella as a landmark. The first skin incision is placed on the medial aspect of the flap design. If a suprafascial technique is to be used for a thin flap, the dissection is carried laterally until the major perforators to the skin are identified. If a fasciocutaneous harvest is planned, the incision is carried through the deep fascia with the flap site mobilized laterally until the perforating vessels are visualized traversing the deep fascia. Once the perforators are identified, the skin incisions are completed. The pedicle is dissected in a retrograde fashion, either to the descending branch for septocutaneous flaps or through the vastus lateralis in patients with myocutaneous perforators. In myocutaneous perforators, a small cuff of muscle is left around the pedicle to protect the small perforating branches. Great care should be used to maintain haemostasis in this portion of the elevation because the vessels frequently will go into spasm and the muscle may bleed excessively after revascularization.

CLINICAL APPLICATIONS

The anterolateral thigh flap in appropriately selected patients is ideally suited to a variety of defects in the head and neck. It matches the reconstructive capabilities of the forearm flap, particularly if the thigh is thin and pliable. It can be tubed to reconstruct a tubed conduit for total pharyngeal reconstruction and can be used for external defects anywhere in the head and neck.[47] The donor site is much more attractive than the forearm flap and hence the reasons for this flap replacing the forearm as the standard reconstruction for the oral cavity in Asian countries.

The free osseocutaneous fibular flap

The free osseocutaneous or osseous fibular flap was first described by Taylor[48] for the reconstruction of tibial pseudarthrosis. This flap was popularized by Hidalgo and Rekow[49] for mandibular reconstruction and currently represents the benchmark for composite defects of the mandible and oral cavity.

ANATOMY

The osseocutaneous fibular flap is based on the peroneal artery and vein (**Figure 93.15**). The peroneal artery is a branch of the tibioperoneal trunk. The artery passes distally with paired venae comitantes lying on the medial aspect of the fibular between the tibial posterior and the flexor hillocks longus. The peroneal artery provides perforating branches to the surrounding musculature and nutrient artery and periosteal supply to the fibula. In the distal half of the leg it gives off perforating branches that run laterally through the flexor hallucis longus, usually passing within or deep to the intermuscular septum separating the peroneus longus and soleus muscles (**Figure 93.16**). The skin available includes the majority of the surface of the lateral aspect of the lower leg, with flaps measuring 12–16 cm × 8–10 cm available. The length of bone available is usually 18–24 cm depending on the length of the leg. Pedicle length depends on the amount of bone required (longer bone lengths = shorter pedicle) The usual vessel diameter is 3–4 mm for the artery and 4–5 mm for the vein.

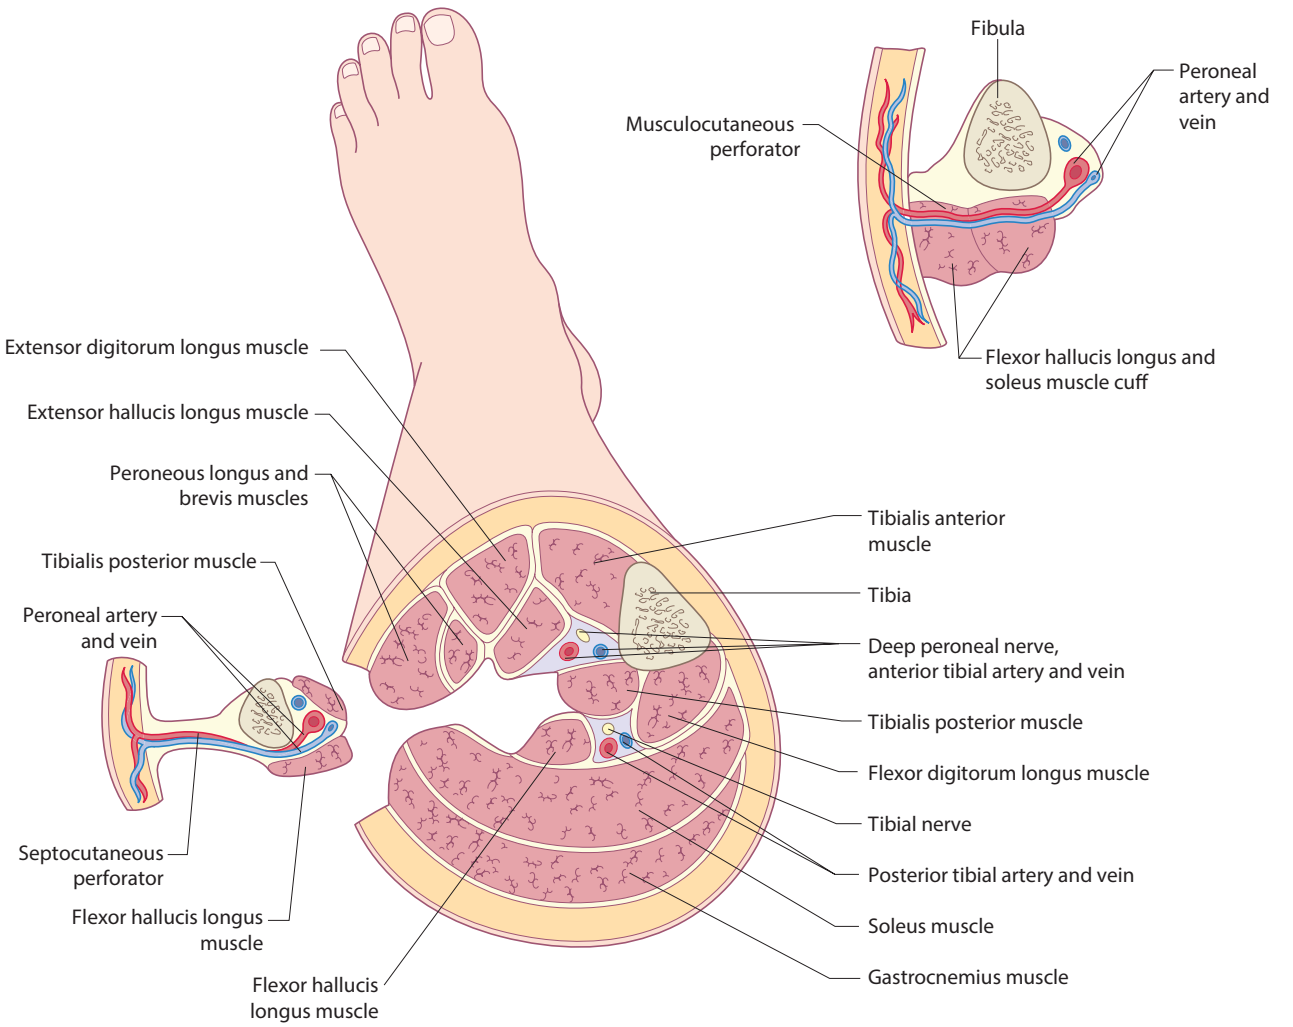

Figure 93.15 Anatomy of the free fibular transfer. Redrawn from Ref. 21, with permission.

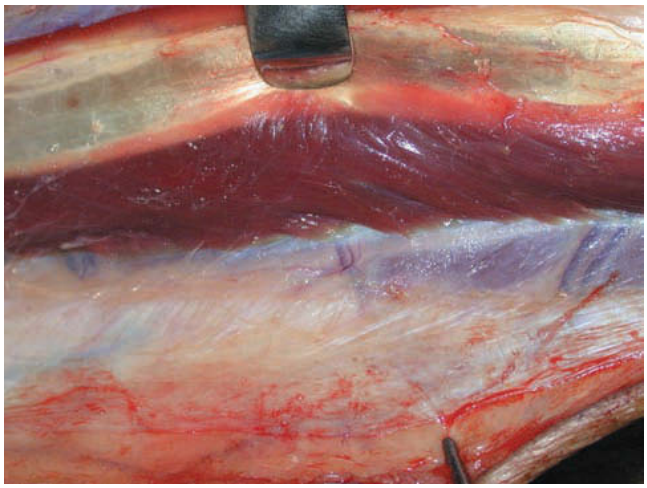

Figure 93.16 Lateral view of perforators to fibular skin paddle; note peroneous longus anteriorly and three septocutaneous perforators running to the skin island.

Figure 93.17 Osteotomized fibula, for mandibular reconstruction; note the use of a low profile reconstruction plate.

ADVANTAGES

The fibula is an ideal transfer for the majority defects of the oral cavity and mandible. The bone length available will almost reconstruct the entire mandible. The skin island is of an appropriate thickness for most oral cavity and oropharyngeal reconstructions.

DISADVANTAGES

The fibula has some established liabilities. It is not a good option in individuals with established peripheral vascular disease as harvesting a single vessel in an arterially comprised leg could be catastrophic. Some authors have reported relatively high failure rates with the skin island. These can be reduced with particular attention to harvest technique as outlined below.[50] The donor site can be problematic in patients with venous insufficiency in the lower extremity, with delayed healing of skin graft sites. Some patients have reported long periods of ankle and leg stiffness and occasional instability of the ankle. If a large cuff of flexor hallucis is harvested with the flap, some patients will acquire a flexion deformity of the great toe.

TECHNICAL NUANCES

As in all free tissue transfers, surgical planning is paramount to avoid complications. Most authors routinely advocate some type of non-invasive imaging of the vascular anatomy of the leg and tibioperoneal trunk. Options include colour Doppler, magnetic resonance angiography (MRA) and computed tomographic angiography (CTA). Experienced surgeons routinely Doppler the perforating branches to the skin to ensure that the skin island is appropriately placed on the leg. The flap is usually harvested under tourniquet control to provide a dry surgical field. Current harvest technique is usually via the lateral approach. After incising the skin island the peroneous longus and brevis are reflected anteriorly off the fibula. The anterior compartment is entered and opened over the length of the fibula, avoiding the anterior tibial artery. The posterior interosseous membrane is divided, visualizing the tibialis posterior. The fibula is divided distally and proximally, leaving at least 6 cm of fibula at the ankle and knee to avoid instability of the ankle and prevent injury to the common peroneal nerve. The distal peroneal artery is divided; the tibialis posterior is divided, visualizing the full course of the peroneal artery. To avoid injury to the perforators to the skin and assure appropriate venous drainage of the skin flap most authors advocate harvesting a cuff of flexor hallucis longus and soleus. Pedicle length is established by detaching the peroneal artery from the fibula. Closure is achieved either primary or with a skin graft. Most authors splint the leg for 5–7 days to maximize skin graft take.

The fibula may be osteotomized into multiple segments to recreate the shape of the mandible. Most authors currently use a single reconstruction plate lagging the bone segments to the plate while others prefer using multiple small plates to recreate the mandible. It is our preference to generally harvest the fibula from the leg contra lateral to the mandibular defect, as this positions the pedicle in the appropriate location for recipient vessel access and keeps the skin island in the right orientation for insetting into the oral defect. If the skin island has to be rotated around the fibula to get into the oral cavity the perforating vessels to the skin may be compromised, resulting in loss of the skin flap.

CLINICAL APPLICATIONS

The fibular flap is widely used for oromandibular reconstruction and is ideally suited for this defect (**Figure 93.17**). The bone flap is relatively short in vertical height, often leaving a disparity between the natural bone height of the mandible and the reconstructed segments. Some authors have advocated 'double-barreling' – placing one segment on top of the other to maximize vertical height for secondary osseointegration.[51] This flap has been used for maxillary reconstruction and is ideal for reconstructing the premaxilla in central maxillary defects. The other advantage of this flap for maxillary reconstruction is the

potential length of the vascular pedicle, a major asset in midface reconstruction.

ENTERIC RECONSTRUCTIONS

The free jejunal transfer

The free jejunal transfer, described by Seidenberg and Hurwitt[52] in 1958, has been widely used for conduit reconstruction of pharynx over the past 30 years. Numerous large series report success, in terms of both reliability and functional outcomes.[53, 54]

ANATOMY

The jejunum comprises approximately two-fifths of the 7-metre length of small bowel extending from the duodenum to the ileocecal valve. The blood supply of the jejunum arises from approximately five branches arising from the superior mesenteric artery with a total of 12 to 15 branches to the jejunum and ileum. The vessels run parallel to each other between the mesenteric layers. Each vessel divides into two, forming a series of arcades. From the terminal arcade, numerous vasa recta pass to the mesenteric border of the jejunum. Jejunum of 10–20 cm may be harvested with pedicle lengths of up to 8–10 cm. The artery is usually 1.5–2.5 mm in diameter with a matching venae comitantes. The vein can be extremely thin and technically difficult to sew.

ADVANTAGES

The jejunum is a mucosal lined conduit that makes its own secretions, making it theoretically an ideal reconstruction for a total pharyngectomy defect. The length of jejunum available for harvest is adequate for any head and neck defect. The jejunum has a peristaltic wave, which is unidirectional and can assist in swallowing

DISADVANTAGES

The jejunum has some problematic disadvantages. The flap does not tolerate long periods of ischemia and like other intestinal conduits does not tolerate long periods of venous congestion. The flap must be oriented in the appropriate direction or patients may be unable to swallow. The swallowing characteristics of this flap are highly variable. Some patients find that the flap easily goes into spasm with ingestion of hot or cold liquids and most patients describe swallowing as adequate but slow. One of the major drawbacks of the jejunum for pharyngeal reconstruction is that secondary tracheo-oesophageal puncture (TEP) speech is patulous and wet, with the majority of patients preferring not to use a TEP. The swallowing and speech results seem to be improved in patients who have received post-operative radiotherapy reducing the contractility and inherent secretions of the jejunum. Because the flap is enteric in origin it does not develop collateral circulation from the surrounding tissues. The pedicle of this flap can never be divided without risk of conduit necrosis, even after being in place for many years.

TECHNICAL NUANCES

The flap is usually harvested with a mini-laparotomy or endoscopically. The jejunal segment is delivered up onto the abdominal wall and the arcades visualized with back lighting. Usually the second intestinal branch is harvested with the segment of jejunum it supplies. Most surgeons harvest more length than needed so that a segment of the mesentery is available to place through the skin incision as an external monitor. Insetting of this flap is critical. It must be placed in an isoperistaltic position to allow swallowing. Most authors advocate marking the distal or proximal ends with a suture to avoid confusion about the direction of inset. The jejunum must be stretched to fit the defect as much as possible as, once it is revascularized, its length will increase, producing a tortuous conduit that functions poorly for swallowing.

CLINICAL APPLICATIONS

The most common application for jejunum is the total laryngopharyngectomy defect (**Figure 93.18**). Some authors have used it as a mucosalized and self-lubricating flap for oropharyngeal reconstruction, particularly in the radiation failure patient where xerostomia may be a problem. This technique can be problematic as the jejunal secretions are often tenacious and foul smelling.

The free gastro-omental flap

The free gastro-omental flap was described by Baudet et al.[55] in 1978. This flap has seen limited use over the past 30 years, with limited reports of use for oral cavity and conduit reconstruction of the total laryngopharyngectomy defect.[56]

ANATOMY

The greater curve of the stomach and the omentum are supplied by the right and left gastroepiploic arteries, terminal branches of the gastroduodenal and splenic arteries, respectively. They course along the greater curvature of the stomach and anastomose with each other, forming the gastroepiploic arterial arch. From the gastroepiploic arch,

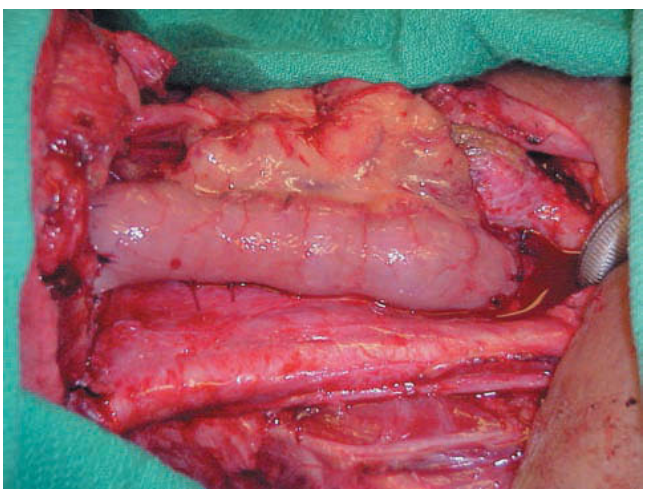

Figure 93.18 Free jejunal transfer for pharyngeal reconstruction.

numerous small branches extend to the greater curvature and three major omental arteries, the right, middle and left, supply the greater omentum. The right gastroepiploic artery is the dominant supply (**Figure 93.19**).

ADVANTAGES

The free gastro-omental flap as a tubed conduit represents a near ideal reconstruction for the laryngopharyngectomy defect, particularly in an era of organ preservation approaches incorporating chemotherapy and radiation. The flap can be customized to tube size, is self-lubricated and not motile. The major benefit of the flap is that it is harvested with a large segment of the greater omentum, providing valuable well-vascularized tissues to cover the carotid sheath and prevent wound complications. The limited reports of its use in total pharyngectomy reconstruction have indicated that the TEP speech is better than with the jejunal transfer.

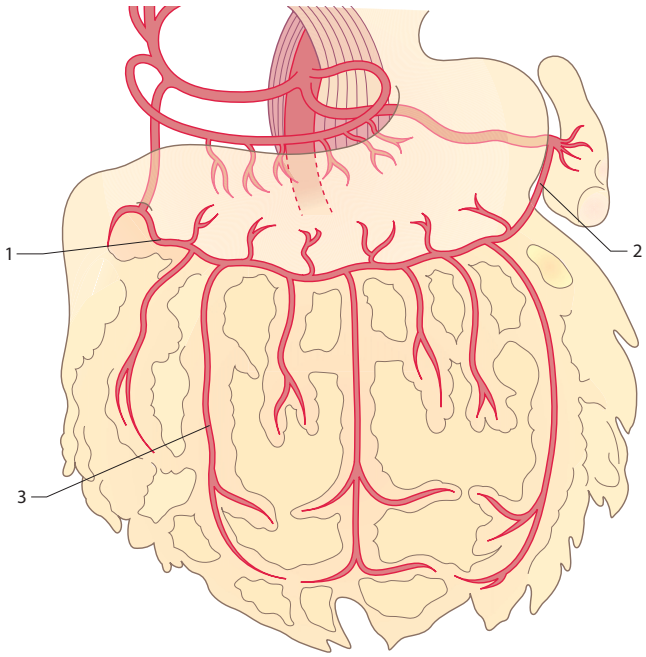

Figure 93.19 Surgical anatomy of the gastroepiploic flap. 1, Right gastroepiploic artery; 2, left gastroepiploic artery; 3, blood supply to the greater omentum.

DISADVANTAGES

The gastro-omental flap has few disadvantages. It does require a laparotomy, which can be a problem in patients with significant comorbidity or poor performance status. The flap is relatively easy to harvest, with a few caveats as discussed below.

TECHNICAL NUANCES

The flap is harvested through a mini-laparotomy incision. The stomach is delivered and the greater omentum visualized. The lesser sac must be entered to visualize the greater curve completely. A large segment of greater omentum is harvested, which can be reduced in volume after insetting. The stomach tube is created by placing a gastrotomy at least 2–3 cm proximal to the pylorus and an appropriate proximal gastrotomy for the length of stomach required. The gastric tube is formed by placing a 35-gauge chest tube through the gastrotomies and then using a GIA stapler to create the conduit. It is critical that the stomach be stretched out to length before stapling to ensure that enough functional stomach remains. A jejunal feeding tube is placed for patients undergoing laryngopharyngeal reconstruction.

CLINICAL APPLICATIONS

The gastro-omental flap is largely used for conduit reconstruction following laryngopharyngetomy. Its unique advantage is the large segment of greater omentum, which will dramatically reduce the risk of peri-operative complications in chemoradiation failure patients (**Figure 93.20**).

DEFECT-BASED OPTIONS

Oral tongue and floor of mouth

ISSUES

Reconstruction of the oral cavity continues to represent one of the major challenges in head and neck reconstruction. Numerous authors have reviewed functional outcomes following oral cavity reconstruction and have all come to similar conclusions.[57, 58] It would appear that the key element in producing high quality oral function is the amount of sensate tongue remaining in the oral cavity. Any reconstruction used in the oral cavity should have the goal of replacing the volume resected but must maintain and not limit the mobility of the tongue remnant. Highly sensate flaps such as the free forearm flap have been widely used in oral cavity reconstruction, clearly providing two-point, touch and temperature sensation for the reconstructed oral cavity. Intuitively it would seem that sensation would be beneficial but there is little evidence that sensate flaps make a major difference in oral function following ablative procedures. In posteriorly placed defects in the oropharynx, specifically the tongue base and palate, two additional issues are of importance. In tongue base resection, appropriate but not excessive volume replacement appears to improve swallowing results. In soft palate reconstruction, recreating appropriate palate closure is particularly important to avoid nasal regurgitation.

OPTIONS

The current options for oral reconstruction are outlined in **Table 93.1**. The forearm flap has a number of unique advantages. It is thin and pliable, and certainly functions well at maintaining the mobility of the residual tongue. This flap is likely the best sensate flap available and if one believes sensation is important this would be the preferred flap. The anterolateral thigh flap in patients with the appropriate body habitus is likely very close to the forearm in producing high quality functional results. The other flaps available all suffer from providing too much bulk and potentially can limit the residual movement of the oral and oropharyngeal structures.

PROBLEMS

The problems still needing to be addressed in the oral cavity are the production of functional sensation and correcting problems with xerostomia following radiation treatment. The use of the submandibular gland transfer, moving the gland out of the field of radiation, is likely a technique that will be more widely used in the future.[59]

Pharynx

ISSUES

Reconstruction of the total pharyngectomy defect continues to represent one of the major challenges in head and neck reconstruction. The ideal pharyngeal reconstruction would provide a mucosalized conduit that has appropriate motility and functions with a TEP. The reconstruction would be of low morbidity in terms of its donor site, and relatively easy to harvest and revascularize.

OPTIONS

The current options for reconstruction of this defect are the enteric reconstructions; the jejunum or gastro-omental flap or tubed skin flaps. There is extensive experience worldwide with the jejunal flap and it has proven efficacy in the reconstruction of this defect. Swallowing and speech results with the jejunum are less than perfect, which has led some centres to consider the free gastro-omental flap. The gastro-omental flap appears to produce improved swallowing and voice results with the benefit of a large segment of greater omentum.

There have been numerous reports of cutaneous skin tubes for oral reconstruction, in particular the free forearm flap and anterolateral thigh flap. Both these reconstructions have excellent swallowing and voice results, with low donor site morbidity, but have been problematic in the development of distal anastomotic strictures. A number of authors now advocate the use of silastic stents with the cutaneous flaps, an approach that appears to have dramatically reduced the rate of distal anastomotic stricture.

PROBLEMS

The current options in pharyngeal reconstruction appear to be a choice between the improved functional results with enteric reconstructions (particularly the gastro-omental flap) as compared to cutaneous flaps, balanced against the inherent morbidity of the enteric flaps, which

TABLE 93.1 Options in oral cavity reconstruction

Flap	Anatomy	Pedicle length	Sensation	Donor site morbidity	Skin quality
Forearm	+++	+++	+++	++	+++
Lateral arm	++	+	++	+++	++
ALT	+	+++	+	+++	++
DIEP	+++	+++	+	++	++
Scapula	+++	++	+	++	++

+++, best; ++, intermediate; +, poor. ALT, anterolateral thigh; DIEP, deep inferior epigastric perforator.

require a laparotomy. Prospective studies evaluating the long-term functional outcomes of these various reconstructions will help elucidate the best approach for this complex group of patients.

Composite mandibular defects

ISSUES

Reconstruction of composite defects including oral lining and the mandible continue to challenge reconstructive surgeons. In mandibular reconstruction the key issue is the length of bone required, whether the transferred bone is amenable to secondary osseointegration and the morbidity associated with the donor site of the bone flap.

Secondary issues are the correction of disparities in bone height between the native mandible and condylar reconstruction. The mandibular resection that extends to include the condylar head continues to be a problem in terms of recreating a functional joint that will allow an appropriate range of movement for mouth opening and mastication.

OPTIONS

The current options for mandibular reconstruction are illustrated in **Table 93.2**. Currently the flap of choice in most centres is the free fibular transfer based on the quality of the available skin island and the length of available bone with limited donor site morbidity. The scapular bone flap is likely an excellent option where the fibula is not an option because of peripheral vascular disease and is particularly useful in the elderly. The DCIA flap has great utility in limited defects in younger patients. The osseocutaneous radius transfer has a limited bone stock and significant potential donor site problems, making it a poor choice for mandibular reconstruction. A new option for improving functional outcome in mandibular reconstruction has been the developments in computerized assisted design with three-dimensional planning of defect creation and reconstruction. In the most advanced form of this technology, surgeons are supplied with a pre-bent reconstruction plate and a cutting guide for both the fibula or scapula and the ablative defect. This technology while currently expensive, offers the opportunity for improved aesthetic and functional outcome, particularly when comprehensive dental reconstruction with osseointegrated implants is an option.

PROBLEMS

The available options for mandible reconstruction largely achieve the goals of reconstruction of this defect. Re-creation of a functional non-prosthetic condyle continues to be a problem and simple surgical techniques to augment the vertical height of the existing mandibular reconstructions would be helpful.

Cutaneous defects

ISSUES

The major issues in selecting a reconstruction of the external skin of the face or neck are the colour match of flap, donor site morbidity and the ability of the defect to match the volume of the defect. There is a wide variation in skin colour based on anatomic regions of the body, with areas close to the head and neck providing the best colour match. In addition there are remarkable variations in the colour of the various skin flaps based on the race and genetic background of the patient.

OPTIONS

There is a wide variety of options for replacement of facial and neck skin. When balancing donor site morbidity with skin colour, amount of available skin and the ability to adjust the volume of the reconstruction, the scapular system of flaps and the anterolateral thigh appear to offer the greatest potential

CONCLUSIONS

Developments in free tissue transfer over the past 30 years have dramatically affected the outcomes for patients with head and neck deformity. As experience develops with the aforementioned reconstructions, the indications and efficacy of the various techniques will be further delineated. The developments over the next decade in tissue engineering and in the management of the immune response to allogeneic transplants will certainly offer further opportunities for better and more functional reconstructions for head and neck patients.

TABLE 93.2 Osseocutaneous flaps for mandibular reconstruction

Flap	Bone length (cm)	Pedicle length (cm)	Donor complications	Osseointegration	Skin reliability
Fibula	16–20	6–8	+++	++	++
Scapula	8–12	4–8	++	++	+++
Iliac crest	10–14	6–8	+	+++	+
Radius	8–12	8–10	+	+	+++

+++, best; ++, intermediate; +, poor.

BEST CLINICAL PRACTICE

- ✓ Free tissue transfers are best performed in centres with high clinical and surgical volumes with specialized nursing units for post-operative management and monitoring.
- ✓ For reconstruction of oral cavity mucosal defects the best options are:
  - ✓ free forearm flap
  - ✓ anterolateral thigh flap
  - ✓ lateral arm flap
  - ✓ DIEP flap.
- ✓ Options in the reconstruction of mandibular defects need to be tailored to the specific defect, bone length, mucosal defect and rehabilitation plan. Current options are:
  - ✓ fibular transfer
  - ✓ iliac crest
  - ✓ scapula
  - ✓ radius.
- ✓ Reconstruction of the total pharyngectomy defect is a balance between ultimate functional requirements and donor site morbidity. Current options include:
  - ✓ cutaneous tubed flaps – forearm flap and anterolateral thigh flap
  - ✓ enteric flaps – free jejunal transfer and free gastro-omental transfer.
- ✓ Reconstruction of large cutaneous defects of the head and neck is a balance between skin colour match, defect size and donor site morbidity. Current options include:
  - ✓ scapular system of flaps including latissimus dorsi
  - ✓ rectus abdominus and DIEP flaps
  - ✓ anterolateral thigh flap
  - ✓ lateral arm flap
  - ✓ forearm flap.

FUTURE RESEARCH

- ➤ Oral cavity mucosal reconstruction, the value of sensation and the options for recreating sensation in the oral cavity. Prospective outcome studies evaluating the efficacy of the various reconstructive techniques in terms of speech and swallowing. Research and creative opportunities in prefabrication of reconstruction and evaluating the utility of allotransplantation.
- ➤ Mandibular reconstruction, deficiencies in prospective evaluations of functional outcomes (swallowing and deglutition). Further definition of the role of osseointegration technology in oral rehabilitation. Prefabrication of mandibular components and evaluating the utility of allotransplantation.
- ➤ Maxillary reconstruction, deficiencies in prospective studies evaluating outcome and quality of life in patients treated with reconstructive procedures or maxillofacial prosthedontics. Further developments in reconstructive options are required.

KEY POINTS

- It is necessary to understand the blood supply of the skin, the angiosome concept.
- There has been recent interest in the terminology and concept of perforator flaps.
- The special considerations for patients undergoing free tissue transfer include:
  - perioperative fluid management
  - deep vein thrombosis prophylaxis.
- There is a need for specialized nursing units for monitoring free tissue transfer to facilitate rapid return to the operating theatre for vessel occlusion. Two techniques used are:
  - fibrinolytics
  - medicinal leeches.
- The forearm flap is the ‘workhorse’ for oral cavity and oropharyngeal defects. Its advantages are ease of harvest, long pedicle length and potential for sensation.
- The lateral arm flap offers limited donor site morbidity with the disadvantage of a short vascular pedicle and small donor vessels.
- The scapular system of flaps includes the latissimus dorsi flap and provides the following options:
  - variety of skin, muscle, bone or combinations of tissues available
  - skin paddle can be rotated independent of the bone flap
  - great utility for extensive head and neck defects.
- The rectus abdominus flap has consistent anatomy and is excellent for large cutaneous, oral or skull base defects. The perforator-based DIEP flap reduces donor site morbidity and broadens the range of use of this flap.
- The DCIA is the ideal bone for mandibular reconstruction. Its disadvantages relate to donor site morbidity and a short pedicle. Recently, a new application in maxillary reconstruction has been described.
- The anterolateral thigh flap is a recently popularized flap, particularly in patients with thin thighs. Advantages are minimal donor site morbidity and long vascular pedicle. It has a wide variety of applications in head and neck reconstruction.
- The fibular flap is the current standard of care for extensive mandibular defects. Care needs to be taken in using this flap in patients with peripheral vascular disease.
- The free jejunal flap has been widely used for total pharyngeal reconstruction. The swallowing results are good but not excellent, and speech rehabilitation with this flap is problematic.
- The gastro-omental flap has seen limited use for pharyngeal reconstruction over the past 30 years. It has become more popular based on the opportunity to transfer large segments of omentum, which may be an advantage in the chemoradiation failure patient.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed and Cochrane library search using the keywords: skin cancer, basal cell carcinoma, squamous cell carcinoma, non-melanoma skin cancer, actinic keratosis, Bowen's disease, melanoma, excision margins, incomplete excision, diagnosis, management, guidelines, recurrence, head and neck.

INTRODUCTION

Skin cancer is on the rise. According to the World Health Organisation (WHO), between 2 to 3 million non-melanoma skin cancers (NMSC) and 132 000 melanomas are diagnosed every year,[1] with one in every three cancers being a skin cancer. NMSC incidence is difficult to assess, as these cancers do not need to be reported to most cancer registers. However, it has been estimated that in the US the increase over the last two decades has been threefold, with an 8% yearly increase.[2] In Scotland, between 1990 and 2011, basal cell carcinomas (BCCs) have increased by 260% and squamous cell carcinomas (SCCs) by 334%. In England, the incidence of BCCs was calculated at 76.2/100 000 and SCCs 22.65/100 000.[3] The incidence of melanoma has also risen continuously since the 1950s. In 2012, the incidence was estimated by the WHO at 111 481, accounting for 1.7% of all cancers (excluding NMSC).[4] The incidence is estimated to have been rising by 3–7% yearly for fair skinned Caucasian populations.[5] At the same time, the mortality (reported in the same study at 24 069) seems to be decreasing.[6]

PREMALIGNANT SKIN LESIONS

Premalignant epithelial lesions are associated to an increased risk of transformation into skin cancer and are confined above the dermo-epidermal junction. Almost all of them are induced by excessive, chronic sun exposure.

Actinic keratosis

Actinic keratoses (AKs) or solar keratoses are the commonest premalignant lesions of the skin (**Figure 94.1**). They are intra-epithelial neoplasms formed by proliferation of atypical keratinocytes and have the potential to grow into invasive SCC. They usually appear after 50 years of age. Sun-seeking behaviour, outdoor occupations, chronic use of sun beds, fair skin, high ultraviolet index of the environment, immunosuppression and genetic syndromes such as albinism and xeroderma pigmentosum are important predisposing factors. Ionizing radiation and ultraviolet light phototherapy can also result in the formation of these lesions.

EPIDEMIOLOGY

AKs are frequently found on skin chronically exposed to ultraviolet radiation, with 80% or more presenting on the face, scalp, neck and dorsal hands.[7] Patients with Fitzpatrick skin phototypes I to III (i.e. those with light coloured skin and a tendency to burn) are at higher risk, and those living near the Equator or at higher altitudes have a greater predisposition. Men are more commonly affected than women. The reported prevalence is variable, with 40–50% of the Australian population aged 40 years and over and 11–25% in the US thought to be affected.[8] The risk of transformation to SCC is low for individual lesions but in patients with a large number of AKs the risk is higher than for the general population.

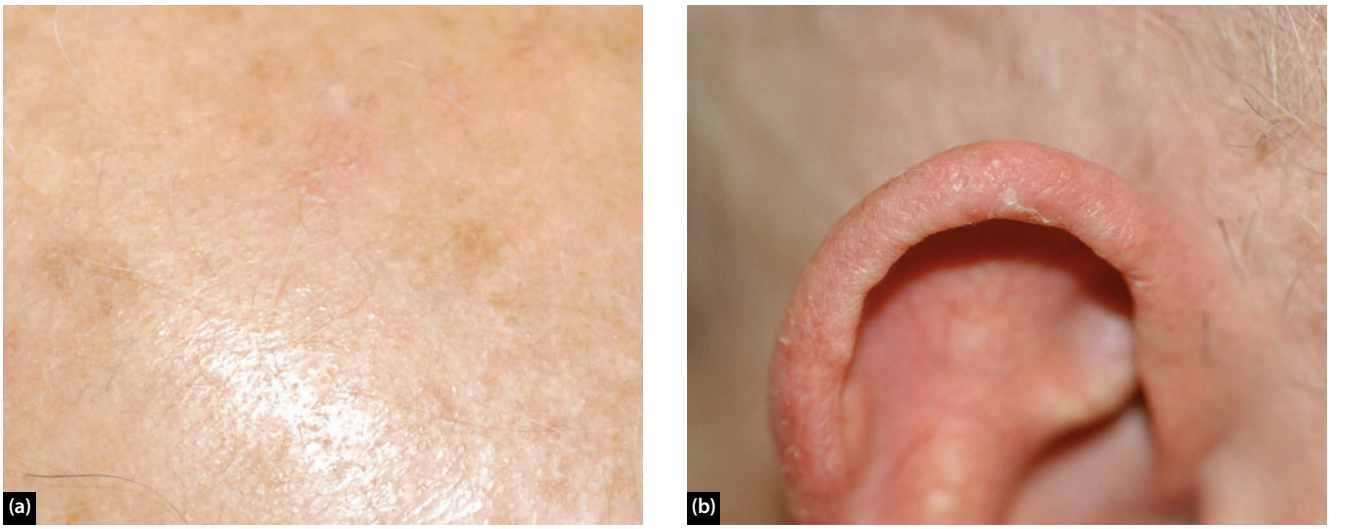

Figure 94.1 Actinic keratosis.

CLINICAL FEATURES

AKs are usually asymptomatic but are noticed because of their rough texture. They appear as dry and erythematous lesions on sun-exposed skin (**Figure 94.1**). Thin lesions are more easily palpable than visible. They are usually covered with an adherent scale. Lesions may be pigmented or telangiectatic and may be numerous. Thicker lesions may have significant hyperkeratosis that can form a cutaneous horn. The surrounding skin often shows evidence of chronic sun damage in the form of wrinkled and atrophic skin, scarring, pigmentation, telangiectasia or changes of solar elastosis characterized by thickened, yellow and wrinkled skin.

DIAGNOSIS

The diagnosis can be made clinically but where there is uncertainty a skin biopsy may be indicated. Features that should raise suspicion of SCC include induration, rapid proliferation, ulceration, bleeding and the presence of a cutaneous horn. Histologically atypical cells confined to the epidermis are seen with increased mitoses, nuclear polymorphism, hyperchromasia and loss of polarization.

The differential diagnosis includes other malignant lesions, such as superficial BCC, Bowen's disease (BD), SCC, amelanotic melanoma and benign lesions such as seborrheic keratosis, viral warts and discoid lupus.

MANAGEMENT

Spontaneous resolution of these lesions has been reported to occur in 21% of cases[9] and for thin and small lesions no treatment may be necessary. In such cases a moisturizer or a keratolytic agent containing salicylic acid may be sufficient to soften the skin. Cryotherapy can be effective for thicker lesions but it is painful and leaves a scar. Topical 5-fluorouracil cream administered once or twice daily for up to 6 weeks can result in clearance with superior cosmetic results but soreness and inflammation during treatment are common. Similar results are achieved with the topical immune response modifier imiquimod used three times a week for 4 weeks with a side-effects profile very similar to that of 5-fluorouracil. Ingenol mebutate has a similar side-effect profile, but has the advantage of needing only two daily applications to treat head and neck AKs. Photodynamic therapy (PDT) with a photosensitizer such as methyl aminolevulinic acid and red light source can be a highly effective treatment, with good overall tolerance and patient satisfaction.[10] Surgery in the form of curettage or excision may be performed when other treatments fail or if there is diagnostic uncertainty.

Prevention is an important aspect of management and advice regarding avoidance of sunlight and tanning beds, protective clothing and regular use of sun blocks should be given. Use of regular sunscreen is the only intervention that can reduce the formation of AKs.[11] Patients should also be taught how to recognize skin cancer and should be prompted to seek medical attention for non-healing and enlarging skin lesions.

Bowen's disease

Squamous cell carcinoma *in situ* or BD was first described by John Bowen in 1912. It is an intra-epidermal carcinoma that involves the full thickness of the epidermis without invading the basal membrane. It persists for many years and can grow, but the risk of progression to invasive SCC is small (3–5%).[12] As with AKs, chronic sun exposure plays an important role in the pathogenesis and immunosuppression predisposes to these lesions. Mucosal BD also occurs[13, 14] and is associated with human papillomavirus (HPV).

EPIDEMIOLOGY

BD is seen more commonly in women than in men. It is usually diagnosed in patients from 60 years of age. Most lesions present on the head and neck[15, 16] but in the UK the distribution is significantly different with only 13% on the head and neck and 67% on the lower limbs.[17] Lesions of

BD are usually solitary but can be multiple. The risk of progression to invasive SCC has been estimated to be around 5%.

CLINICAL FEATURES

Patients present with a long-standing and slowly growing skin lesion, which is usually asymptomatic. It appears as a well-defined, sharply demarcated and scaly erythematous plaque on chronically sun-exposed skin.

DIAGNOSIS

The diagnosis can be suspected clinically but a skin biopsy is recommended to exclude differentials and rule out invasive SCC. Histologically the full thickness of the epidermis shows dysplastic cells with disordered architecture, abnormal mitoses and hyperkeratosis. The abnormal cells do not invade the basal membrane but can sometimes extend along the hair follicle epithelium.

The clinical differential diagnosis of BD includes lichen simplex, eczema, psoriasis, fungal infection and superficial BCC.

MANAGEMENT

Most lesions of BD can be treated by non-surgical methods. As with AKs the use of 5-fluorouracil cream can be a highly effective treatment. Imiquimod cream can achieve similar results and is particularly useful in cases associated with HPV. Cryotherapy using liquid nitrogen with one or two freeze-thaw cycles can be effective but the usefulness of the procedure is limited by pain and slow healing rates and it is often impractical for larger lesions. PDT can achieve cure rates of around 90%.

Surgery may be performed when conservative measures fail or there is suspicion of invasive disease. Curettage and cautery can be a simple and effective treatment with less pain, rapid healing and low recurrence rates. The procedure allows histological evaluation of the specimen but invasive SCC cannot always be excluded. Therefore, it is recommended that clinically suspicious lesions should be fully excised with a small diagnostic margin (2 mm).

KEY POINTS

- Most premalignant lesions are induced by ultraviolet light.
- They can transform to skin cancer, mainly SCC.
- The only intervention that will reduce the formation of AKs is photoprotection.
- It is important to teach patients how to detect skin cancer.

NON-MELANOMA SKIN CANCERS

BCC and SCC are the two most important types of NMSC. BCC is the commonest cancer worldwide and constitutes nearly 75% of all NMSCs, followed by SCCs. These cancers commonly affect white skinned individuals and are very rare in darker and Afro-Caribbean skin.

Risk factors

Several host, environmental and genetic factors are implicated in the pathogenesis of NMSCs. Middle- or old-aged, fair skinned individuals with Fitzpatrick skin type I or II are at increased risk. The frequency of these cancers increases significantly with immunosuppression. Chronic exposure to sunlight, especially since childhood, is associated with an increased risk for SCCs while intermittent and intense exposures are thought to be more relevant for the development of BCCs. The risk is also potentiated by therapeutic use of artificial ultraviolet (UV) light, ionizing radiation and excessive use of recreational tanning beds. SCCs have been known to sometimes develop in non-healing wounds or from chronic irritation. Certain genetic syndromes, such as xeroderma pigmentosum, albinism and epidermolysis bullosa, predispose to all types of NMSCs, and Gorlin's syndrome is a hereditary disorder characterized by multiple BCCs throughout life.

Staging

In the new AJCC 8th edition classification, the entity of non-melanoma skin cancer (cutaneous squamous cell carcinomas and other cutaneous carcinomas) has been eliminated and amalgamated with cutaneous squamous cell carcinoma of the head and neck (**Table 94.1**).[18]

Prevention of NMSCs

The most effective measure for prevention of skin cancers is avoidance of sun exposure. Patients should be advised to avoid deliberate suntanning or using artificial sunbeds. Sunlight should be avoiding during peak daylight hours by wearing appropriate clothing in the form of long-sleeved shirts, wide-brimmed hats and sunglasses.[19] Sunblock with broad spectrum UVA and UVB protection can offer further protection. Those who have precursor lesions (i.e. actinic keratoses and BD) should be educated about the recognition of skin cancer and advised to seek medical attention early.

Basal cell carcinoma

Basal cell cancer (BCC) is the commonest type of skin cancer and arises from the basal keratinocytes. It is locally invasive and distant metastases are exceedingly rare.

CLINICAL FEATURES

BCCs are slow growing tumours and develop for months or years. They are commonly found on the head and neck and may grow to a large size. They may invade deeper structures such as cartilage, muscle or bone. There are several types of BCC that have different clinical appearances. The commonest form is the nodular BCC; it appears as a raised lesion with a rolled edge, telangiectasia and central ulceration – constituting the features of the classical 'rodent ulcer' (**Figure 94.2**). Another variant

Figure 94.2 Basal cell carcinoma.

is the superficial BCC, which presents as a macule or thin plaque and can be difficult to distinguish from AKs or BD. The morphoeic or infiltrative varietes presents as a poorly demarcated, atrophic and scar-like lesion that, on microscopic examination, shows extensive invasion beyond its perceived boundaries. Cystic, micronodular and pigmented types of BCCs also exist.

DIAGNOSIS

The differential diagnosis includes a range of benign conditions such as seborrhoeic keratosis, sebaceous hyperplasia, trichoepithelioma, lichenoid keratosis, BD or intradermal naevus, but also malignancies such as SCC, sebaceous carcinoma (SC) or melanoma. The diagnosis is confirmed on histological examination. Due to their slow growing nature, it is acceptable to perform a small punch biopsy for confirmation before fully excising the lesion. Histology shows islands of basaloid cells in the dermis with peripheral palisading, and clefting or retraction artefact surrounding the tumour. Perineural invasion, if present, signifies higher chances of recurrence following surgery. Imaging techniques such as computerized tomography or magnetic resonance imaging may be employed to assess invasion of bone, nerves, orbit or parotid gland.

MANAGEMENT

There are several guidelines for the management of BCCs.[20, 21] They all discuss the treatments outlined below.

Non-surgical treatments

Superficial BCC (sBCC) can be treated without surgery using imiquimod cream, PDT or cryotherapy. Imiquimod can achieve cure rates of more than 80% with a regimen consisting of once daily treatment five times a week for 6 weeks.[22] A local inflammatory reaction consisting of erythema, erosion and scabbing is expected and the severity correlates with higher success rates. PDT can also

achieve high rates of clearance and can vary depending on the photosensitizer from 75% to 95%.[23,24]

Surgical treatment

Nodular and morphoeic BCCs are best treated with surgical excision. Small, well-defined lesions may be excised with peripheral margins of 4–5 mm and deep margins down to fat. This method has a clearance rate of approximately 95%. The adequacy of excision is judged by histological clearance of at least 1 mm at both the peripheral and deep margins. Infiltrative, morpheic or large BCCs will need wider margins to achieve the same success rate.

High-risk lesions are defined as those that are poorly defined, larger than 2 cm, located on the central face or histologically shown to be morphoeic or infiltrative. High-risk lesions should be considered for Mohs micrographic surgery, a highly effective and cost-effective technique that allows the assessment of 100% of the margin under frozen sections (**Figure 94.3**). Once adequate clearance of the tumour is achieved the defect is closed using reconstructive surgery. This technique offers very high cure rates reported to be between 98% and 100%.[25,26]

Radiotherapy

BCCs are highly radiosensitive, with cure rates ranging from 79% to 100%.[27] Radiotherapy can be offered as a stand-alone alternative to surgery or as adjuvant treatment for incompletely excised tumours. It is contraindicated for recurrent tumours in previously irradiated areas. It is usually reserved for elderly patients. The treatment is offered in fractions requiring several hospital visits but in the very elderly a single fraction may suffice. The use of weekly dosing for this age group has also been reported.[28]

Treatment for advanced disease

For locally advanced BCCs not suitable for the above approaches, electrochemotherapy can be used.[29] Vismodegib, a hedgehog inhibitor, can also be used[30] for locally advanced or metastatic disease.

FOLLOW-UP

Completely excised BCCs do not require regular follow-up. For marginally excised lesions a decision to review over a 12-month period may be made to look for recurrence.

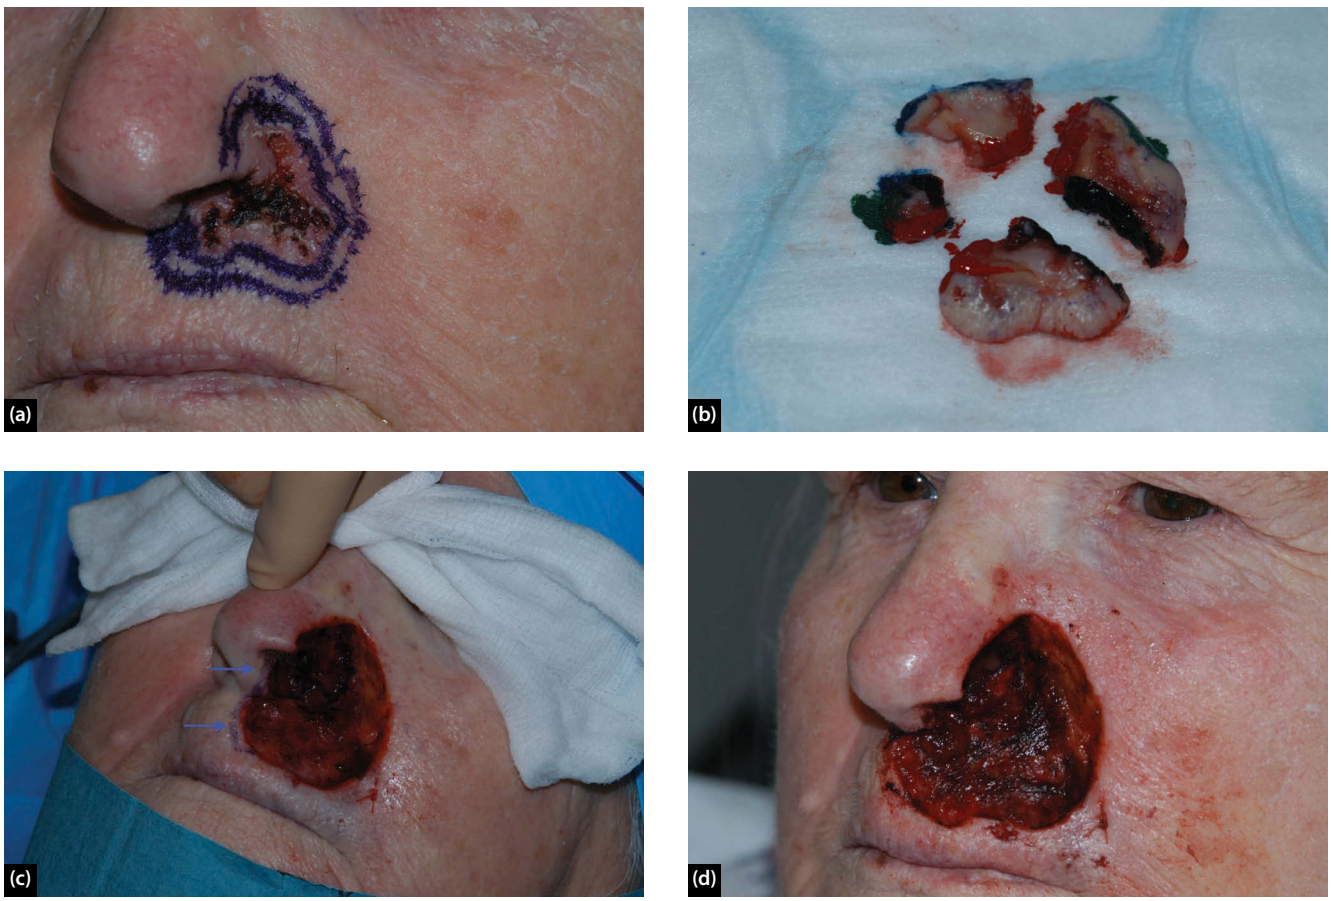

Figure 94.3 Mohs micrographic surgery. **(a)** BCC affecting lip, nose and cheek, marked for surgery. **(b)** After initial debulking, the lesion is removed, separated in blocks and color coded ready for processing in the cryostat. **(c)** After identifying an incompletely excised area in the lip and columnella, a second stage is marked (blue arrows). **(d)** Surgical defect after the second stage. This was clear and is now ready for reconstruction.

KEY POINTS

- BCC is the most common cancer in the world.
- Its incidence is continuing to rise.
- Topical treatments may be sufficient for low-risk BCC.
- For high-risk BCC, the gold standard is Mohs micrographic surgery.
- For advanced disease, radiotherapy, electrochemotherapy and vismodegib can be used.

Squamous cell carcinoma

SCC is the second most common NMSC. It is a malignant neoplasm of the keratinocytes that may arise *de novo* or from precursor lesions (i.e. AKs and BD). SCCs have the potential to metastasize. This risk is generally low (< 5%), but when it happens, the 5-year survival rates are 25–40%.[31] There is a group of SCCs that have a higher risk of developing metastasis. This includes locally advanced disease, poorly differentiated or undifferentiated histology, high-risk areas and immunosupression.

CLINICAL FEATURES

SCCs are found on sun-exposed areas of skin, commonly arising on the face, scalp, ears, lip, hands and forearms but may arise from mucous membranes. The surrounding skin usually shows evidence of chronic actinic damage. They usually grow quickly over weeks or months. Lesions may appear as enlarging plaques, papules or nodules that may be smooth and soft or rough and hardened (**Figure 94.4**). The edges are usually irregular and the base is indurated. With progression they can ulcerate and bleed and may become painful. On the mucosal surfaces they may present as thickened white plaques (leukoplakia) or moist erythematous plaques.

Figure 94.4 Squamous cell carcinoma.

Occasionally SCCs appear as non-healing ulcers with no evidence of keratinization. When they metastasize it is usually to the regional lymph nodes. If distant metastatic disease happens, the most common site is the lungs.

DIAGNOSIS

The differential diagnosis includes other malignant lesions (amelanotic melanoma, BCC, SC) or benign lesions (hypertrophic BD or AK, viral warts, pyogenic granuloma, keratoacanthoma). Histological confirmation is essential for diagnosis. When clinical uncertainty exists, a punch or incisional biopsy may be obtained before excision of the lesion. When doing a biopsy it is important to bear in mind the risk of sampling error, more so when assessing lesions that arise from a very photodamaged skin. In those cases, diagnosic excision may be necessary. The microscopic features include proliferation of atypical keratinocytes, nuclear pleomorphism, keratin whorls and mitotic figures. The degree of these changes may vary. The depth of invasion, histological grade and extension around nerves correlate well with prognosis. When lymph node metastasis is suspected a fine-needle aspiration (FNA) may be performed for cytological analysis. If FNA is inconclusive a radiologically guided core biopsy may be obtained.

MANAGEMENT[32–34]

Surgical treatment

The treatment of choice for most SCCs is surgical excision. It allows examination of the tumour in its entirety and assessment of adequacy of treatment. Well-defined T1 lesions should be excised with a peripheral margin of at least 4 mm and down to the subcutaneous fascia. T2 should be excised with a margin of 6 mm or more.

SCCs with high-risk features may be excised using Mohs micrographic surgery, which has been reported to provide high cure rates.[35] This technique is particularly useful for areas where wider margins of excision may be technically difficult or cause significant visual and functional impairment or if there is nerve involvement.

Radiotherapy

Radiotherapy can be used as a primary treatment for selected patients or adjunct when there is incomplete surgical excision or perineural invasion. The main disadvantages are lack of histological control, secondary skin cancer and atrophy and telangiectasia in the long run. Sites that respond well to radiotherapy include lower eyelid, inner canthus, tip of nose and lip. Radiotherapy should be avoided in tumours that invade bone or cartilage due to the risk of radionecrosis.

KEY POINTS

- SCC is the second most common cancer.
- It has a low but real risk of metastasis.
- No imaging is required in Stage I disease.
- Surgery should be carried out with 4 mm margins for low risk and 6 mm for high risk.
- Radiotherapy is a very effective treatment modality.

MELANOMA

Melanoma is a malignant neoplasm of melanocytes. It accounts for 5% of all skin cancers but 75% of all skin cancer-related deaths, due to its metastatic potential.

Epidemiology

Melanoma can occur in any ethnic group but is much more common in white skinned populations. The highest incidence rates are reported in Australia and New Zealand with 40–60 per 100 000 individuals affected each year.[36] In the US it is estimated to affect 18 per 100 000 and in Europe 10 to 15 patients per 100 000 yearly. These figures appear to be rising worldwide. It can affect any age but the median age at diagnosis is 59 years. Melanoma affects males and females equally.

Risk factors

SKIN TYPE

Fair skinned people are at greater risk of developing melanoma. Having a tendency to burn easily and tan poorly, blonde hair and freckles doubles an individual's risk.[37] Melanoma rarely presents in non-white people, who are 10–20 times less likely to develop this skin cancer.

SUN AND ULTRAVIOLET LIGHT EXPOSURE

Intermittent and intense exposure to sunlight can increase the chances of developing melanoma. Sunburn during childhood is thought to be a risk factor. Studies also support the association of sunbed use with melanoma, especially in those who start to use them before 35 years of age.[38] However, this malignancy can be seen on sites not routinely exposed to sunlight, such as the sole of the foot, genitalia and mucosal surfaces.

FAMILY HISTORY

Patients with an affected first-degree relative are twice as likely to develop melanoma.[39] Germline mutations in the *CDKN2A* gene are found in some families. Inherited photosensitivity disorders such as xeroderma pigmentosum are associated with a high incidence of melanoma and NMSC.

MULTIPLE NAEVI

The risk of melanoma is increased in individuals with a large number of moles. According to a meta-analysis, those with >100 naevi are seven times more likely to develop melanoma compared to mole counts of <15.[40] The presence of multiple clinically atypical naevi also increases the risk significantly. Studies indicate a sixfold increase in people with more than five atypical naevi compared to those with none.

Clinical features

Malignant melanocytic cells can initially appear in the epidermis. This is termed melanoma *in situ*. As it is only in the epidermis, it is not considered to have metastatic potential (**Figure 94.5**).

The four main clinical and pathological subtypes of invasive melanoma are superficial spreading melanoma (SSM), nodular melanoma (NM), lentigo maligna melanoma (LMM) and acral lentiginous melanoma (ALM). Rarer types include mucosal and desmoplastic melanoma and occasionally metastatic melanoma is diagnosed with no known primary.

SUPERFICIAL SPREADING MELANOMA

SSM is the commonest type of melanoma. It presents initially as a flat lesion that undergoes change in size, shape or colour (**Figure 94.6**). Histologically a radial or horizontal growth phase is apparent in the early stages but over time nodular areas with vertical growth may appear.

NODULAR MELANOMA

NM presents as a raised, firm lesion, which may erode or bleed. This type is commonly found on the head and neck and presents more often in older individuals. Lesions may be uniformly coloured or even non-pigmented. Histologically there is a prominent vertical growth phase without radial growth.

Figure 94.5 Lentigo maligna / melanoma *in situ*.

M: Distant metastasis	
M0	No distant metastasis
M1	Distant metastasis

LENTIGO MALIGNA MELANOMA

LMM arises from a precursor lesion called lentigo maligna, which is a slowly growing dark patch on sun-exposed skin. It has a strong predilection for the head and neck of elderly patients. Histologically LMM is characterized by lentiginous proliferation of atypical melanocytes at the dermo-epidermal junction and background changes of chronic sun damage.

ACRAL LENTIGINOUS MELANOMA

ALM arises on the palms and soles or in the nail bed. The incidence is equal in fair and dark-skinned individuals and may not be related to ultraviolet light exposure. It appears as a flat lesion, which may be light coloured or pink. Histology in the early phase may show horizontal or intraepidermal growth but later nodular growth with invasion is seen.

OTHER TYPES OF MELANOMA

Primary melanoma arising from mucosal surfaces is rare. It may present in the oral cavity, nose or sinuses and may metastasize to lymph nodes or distant sites. The prognosis of mucosal melanoma is poor, with 5-year survival rates reported to be 38% according to a recent study.[41] Because of this, the AJCC in its 8th ed is current separated head and neck mucosal melanoma from cutaneous melanoma (**Table 94.2**).

Desmoplastic melanoma is another uncommon type typically found on the head and neck. Affected individuals are older and have chronically sun-damaged skin. The appearance of the lesion may be non-specific and it may look similar to a keloid scar or a benign lesion called dermatofibroma. Histologically an abundance of collagen is found and there may be prominent neural involvement. The 5-year survival rate is around 85%.[42]

Although most melanomas present as cutaneous lesions, occasionally metastatic deposits are found without any signs of a primary tumour. The original lesion may be hidden or may have undergone complete regression due to lymphocyte activation by the immune system. In such cases a careful search for a hidden primary should be performed by doing a full skin examination. They should also have an eye examination (looking for ocular melanoma), ENT and colonoscopy. In some cases, full PET-scanning is used.

Prognostic factors

The most important prognostic factor for patients with melanoma is the clinical stage. For localized melanoma the following characteristics of the tumour are considered to be the key determinants of outcome:

- **Breslow thickness:** this is the microscopic measurement of vertical depth of the tumour and is expressed in millimetres. It has shown to be one of the most important predictors of risk in a large study of 17 600 patients.[43]
- **Ulceration:** the histological presence of ulceration is another important factor that affects the prognosis of melanoma. The survival rate for ulcerated melanomas has been shown to be equivalent to that of non-ulcerated melanomas of the next greatest thickness category.
- **Mitotic rate:** high mitotic activity in the tumour is an independent risk factor that denotes biological aggressiveness of a melanoma.[44, 45]

Other factors that have been reported but are thought to be less relevant are anatomic location, patient age, gender,

level of tissue invasion (Clarke level), histological regression, lymphocytic infiltration and vascular invasion.

Staging

The American Joint Committee on Cancer published a revised staging system of melanoma in 2016, which is widely accepted as standard. In this classification, melanoma has been split into head and neck mucosal melanoma (**Table 94.2**), cutaneous melanoma (**Table 94.3**), conjunctival melanoma and uveal melanoma. When stratified by stage, the 5-year survival curves of melanoma goes from 97% for stage IA to 15% for stage IV (**Table 94.4**).

Management

ROLE OF SKIN SPECIALIST MULTIDISCIPLNARY TEAM

Melanomas above a certain Breslow thickness should be managed in the context of a multidisciplinary team (MDT). The team should ideally include histopathologists, radiologists, oncologists, dermatologists, plastic surgeons and other surgical specialties such as ENT or maxillo-facial surgeons. It is important to recognize the role of specialist cancer nurses in these meetings as they commonly have a very good knowledge of the patient's psychosocial needs. This MDT should consider on an individual basis the appropriate treatment, the role of sentinel lymph node biopsy (SLNB), adjuvant radiotherapy and inclusion in clinical trials.

SURGERY

Treatment of primary melanoma is surgical removal. Initially all suspected melanomas should be excised down to fat with a 2 mm margin to establish the Breslow thickness. Partial thickness, punch or incisional biopsies should not be performed as they may lead to diagnostic uncertainty. Once the thickness is established, a wider and deeper excision is performed. Margin recommendation varies slightly in different countries (**Table 94.5**).[46–50] The National Institute for Health and Care Excellence (NICE) recommends at least 5 mm margins for stage 0 melanomas, at least 10 mm for stage 1 and at least 20 mm for stage 2.[51]

Mohs micrographic surgery can be used to treat lentigo maligna (*in situ* melanoma), invasive lesions with indistinct margins such as desmoplastic melanoma or for surgery close to important anatomical areas such as eyes or ears. Clinical data for this technique in the management of melanoma are limited,[52] however, and should only be used under the auspices of an MDT.

INVESTIGATIONS

Investigations for stage I and IIA and B melanoma are not required. Patients with stage IIC or above should have a CT scan of the head, chest, abdomen and pelvis. For those with stage IV disease, serum lactate dehydrogenase (LDH) should also be measured. Full body PET-CT can also be used. However, due to the rapid development of new, more effective treatments, this recommendation is likely to change in the future.

Stage IV:	15–20	10–15

LYMPH NODE DISEASE

For patients with no apparent lymph node involvement, a SLNB may be performed at the time of wider excision. The sentinel lymph node is the first node where the skin involved with melanoma drains to and is detected by injecting a blue dye that is visually traced and by detecting the path of a radioactive tracer. SLNB is offered for stage 1B disease or above. The procedure has prognostic significance[53] but to date there has been no proven impact in melanoma-specific survival.[54]

For clinically enlarged nodes a FNAC sample should be obtained. If negative or equivocal this may be repeated, or an image-guided core biopsy or open biopsy should be performed.

If a lymph node is involved, then completion lymphadenectomy should be performed. For head and neck, it should include levels 1–5. Superficial parotidectomy can be performed if the disease is in that area. Radical parotidectomy is usually saved for cases of parotid involvement.

Adjuvant radiotherapy can be used to a lymph node basin. There is evidence that in high-risk patients, it reduces local recurrence, without an improvement in overall survival.[55]

LOCOREGIONAL METASTASES

Metastatic disease confined to the skin between the scar of the primary lesion and regional lymph node basins may be treated palliatively by surgical excision or ablative techniques such as CO2 laser or electro cautery. Radiotherapy may be used if these fail. Electrochemotherapy using intravenous bleomycin is an emerging palliative modality for locoregional metastatic melanoma.[56] Interleukin-2 is licensed in the United States, but there is limited data. Interferon alpha may have a benefit in high-risk melanomas (stage II–III) in disease-free survival and, perhaps, in overall survival, although trials are still ongoing.[57]

DISTANT METASTASES

Patients with stage IV disease should be referred to an oncologist. Palliative surgery or radiotherapy may be offered for oligometastaic disease. Historically chemotherapeutic options have been limited to dacarbazine, which has limited benefit with response rates ranging from 5% to 28%. In recent years, due to the discovery of signalling pathways and mutations in those pathways, new targeted therapies have emerged. For BRAF mutations, vemurafenib and dabrafenib are available, often used along MEK inhibitors such as trametinib. Of special interest in head and neck is a mutation in KIT that is present in 39% of cases, and for which imatinib is available (but unlicensed for this indication). There is also the developing of immunotherapies such as ipilimumab (anti-CTLA-4); pembrolizumab

TABLE 94.5 Melanoma surgical margins recommended by different guidelines

Thickness (mm)	UK (cm)	German (cm)	European (cm)	American (cm)	Australia / New Zealand (cm)
In situ	0.5	0.5	0.5	0.5	0.5
<1	1	1	1	1	1
1–2	1-2	1	1	1–2	1–2
2–4	2–3	2	2	2	1–2
>4	3	2	2	2	2

TABLE 94.6 Melanoma follow-up (taken from the British Association of Dermatologists melanoma guidelines)

Stage IA	3 to 6 monthly for 12 months
Stage IB to IIIA	3 monthly for 3 years, then
	6 monthly to 5 years
Stage IIIB and IIIC	3 monthly for 3 years, then
	6 monthly to 5 years, then
	Annually to 10 years
Stage IV	See according to need

and nivolumab (anti-PD1). With multiple molecules being developed currently, the next few years are likely to completely rewrite the way we approach and treat melanoma.

Follow-up

Patients with *in-situ* melanoma do not require follow-up. Patients with stage I and above disease require monitoring on a regular basis for assessment of recurrence or metastatic spread. Guidelines on the timings vary but the schedule based on the British Association of Dermatologists recommendations can be used as a guide (**Table 94.6**).

KEY POINTS

- Melanoma accounts for 75% of all skin cancer deaths.
- Its incidence is rising worldwide.
- Mucosal melanoma of the head and neck has a worse prognosis and its own TNM classification..
- The only treatment for primary melanoma is surgery with adequate margins.
- Surgery is the treatment of choice for lymph node metastasis. Levels 1–5 should all be removed.
- Radiotherapy has a role as adjuvant therapy.
- For metastatic disease, it is essential to know the mutation status (BRAF) in order to tailor treatment.

RARE SKIN CANCERS

Merkel cell carcinoma

Merkel cell carcinoma (MCC) is an uncommon malignancy of neuro-endocrine origin and it is though to be associated to a poliomavirus (MCPyV) in 80% of the cases.[58] However, its incidence has increased fourfold since 1986.[59] It is usually seen in elderly, white-skinned individuals but may arise in younger adults, particularly those who are immunosuppressed. The incidence is highest on the head and neck (40–60%).[60] The morphology of skin lesions is variable and it may mimic a number of benign or malignant tumours. A common presentation is an enlarging solid nodule and rapid growth is characteristic (**Figure 94.7**). Due to its increasing incidence and aggressive nature, it has a separate TNM staging in the AJCC classification.

The survival rate depends on the stage at diagnosis (**Table 94.7**).[61]

Figure 94.7 Merkel cell carcinoma.

TABLE 94.7 5-year survival rates for Merkel cell carcinoma. Adapted from AJCC Cancer Staging Manual 8th Edition. MB Amin ed. Springer 2017[18]

AJCC clinical staging	
I	55.8%
IIA	41.1%
IIB	31.8%
III	35.4%
IV	13.5%

Traditionally MCC has been treated with surgery with wide margins (up to 3 cm). However, MCC is radiosensitive and radiotherapy can be used as first line or as adjuvant to surgery. Current trials are trying to ascertain the efficacy of these treatment modalities.

Dermatofibrosarcoma protuberans

Dermatofibrosarcoma protuberans (DFSP) is the commonest sarcoma of the skin with 14% of DFSPs arising in the head and neck.[62] These tumours exhibit slow growth and are locally infiltrative. They often recur locally following treatment but lymphatic or distant spread is uncommon. They can arise in any age group but the highest incidence is seen in 20–40-year-olds. Lesions appear as plaques or nodules that are fixed to the dermis and the overlying skin may be atrophic or telangiectatic. The treatment is surgical excision with wide margins. Mohs micrographic surgery can offer greater chances of complete removal and is advocated by many as the treatment of choice.[63,64] Other treatment options include radiotherapy and imatinib; these are usually employed for unresectable or metastatic disease. Although with total margin control surgery recurrences are very rare, due to the historical high rates of local recurrences follow-up is normally suggested (6–12 monthly).

Atypical fibroxanthoma

Atypical fibroxanthoma (AFX) is an uncommon spindle cell tumour. Most tumours affect the head and neck and are usually seen in elderly individuals with chronically

sun-damaged skin. The usual clinical presentation is a rapidly growing ulcerated nodule but the appearance may be non-specific and lesions are often confused with BCCs or SCCs. The incidence of metastases is low and most AFXs follow a benign clinical course. The treatment of choice is complete micrographic surgical excision.[65]

Angiosarcoma

Cutaneous angiosarcoma is a rare vascular neoplasm that is most commonly seen in patients over 50 years of age. Up to 60% of these cancers arise in the head and neck. The initial appearance is often a bruise-like plaque that progresses to larger nodules but they can look non-specific, presenting with oedema or ulceration (**Figure 94.8**). They carry a high risk of local recurrence and distant metastases to lymph nodes, lung and liver. The 5-year survival has been estimated in 15%,[66] with size (5 cm cut off) being the main prognostic factor. The ideal treatment has not been established but combined surgery and local radiotherapy appear to have better results than either treatment done alone.[67] Chemotherapeutic agents such as paclitaxel appear to have some benefit and are being evaluated.[68]

Figure 94.8 Angiosarcoma.

Sebaceous carcinoma

Sebaceous carcinoma (SC) arises from the sebaceous glands. They most commonly affect the head and neck, with the eyelids reported as being the most common site. It is more common in older patients. It has been associated with Muir-Torres syndrome and Lynch syndrome so all patients with SC should be assessed for this.

Its appearance can vary widely, often mimicking other benign and malignant cutaneous lesions. Classically they have a firm yellowish appearance.

The treatment of SC is surgical. With conventional excision with 5–6 mm margins, the recurrence rate is 32%.[69] Because of the high local recurrence rate, Mohs surgery is favoured over conventional excision, with recurrences reported from 0%[70] to 11%.[71] SC has the potential to spread, with a 5-year survival rate of 91%, a 10-year survival rate of 79%[72] and a mortality rate of 5–10%.

Skin cancer in immunosuppressed patients

Immunosuppression from any cause, such as HIV-AIDS, malignancy, chemotherapy and drugs, increases the likelihood of developing skin cancer. Most skin cancers in immunosuppressed patients are SCCs[73] but the incidence of other skin cancers such as BCCs, melanoma, MCC and Kaposi sarcoma is increased several-fold compared to immunocompetent individuals. These patients may develop multiple cutaneous neoplasms over their lifetime and regular surveillance of their skin is recommended.

BENIGN LESIONS

Melanocytic lesions

LENTIGINES

Lentigines (singular lentigo) are benign lesions that appear as small, pigmented flat spots surrounded by normal skin. There are several types and the commonest form is a simple lentigo that is not caused by solar radiation or systemic disease. Solar lentigines are common in fair skinned individuals and the incidence increases with age. They may also result from tanning beds, therapeutic ultraviolet light treatment and radiation. A large number of lentigines are seen in patients with xeroderma pigmentosum. Lentigines can appear on the lips, gums or oral mucosae and may be associated with organ abnormalities such as in Peutz-Jeghers syndrome.

MUCOSAL MELANOCYTIC LESIONS

Diffuse oral mucosal melanosis is often physiological in dark skinned individuals but may arise as a result of smoking, medication or following inflammation. The differential diagnosis of focal melanotic lesions includes benign melanotic macules, melano-acanthoma, melanocytic naevi and melanoma. Benign melanotic macules are synonymous with lentigines and are described above. A melano-acanthoma is a benign lesion that often rapidly increases in size and usually resolves without treatment or following biopsy. Melanocytic naevi in the oral cavity are usually acquired rather than congenital and have a smooth surface. They do not transform to melanoma but a biopsy should be performed for new lesions. Mucosal melanoma is rare and can arise in the nose, sinuses or mouth. Within the mouth the palate is the commonest site of involvement and thus all pigmented lesions in this area should be regarded with suspicion.

Figure 94.9 Junctional naevus.

Figure 94.10 Intradermal naevus.

MELANOCYTIC NAEVI

These are benign proliferations of melanocytes that may be congenital or acquired. They may be seen on any part of the skin and are often found on the scalp in children and adults. The incidence of new acquired naevi (**Figure 94.9**) decreases with age. There are three histological subtypes, which can be differentiated clinically. Junctional naevi consist of melanocytic nests at the basement membrane and appear flat macroscopically. When these nests are in the dermis the lesion appears above the surface giving intradermal naevi a papular appearance. Compound naevi have junctional and intradermal components and thus have flat and raised areas on gross examination (**Figure 94.10**). Melanocytic naevi are usually asymptomatic and often come to attention when they become inflamed or irritated, resulting in itching or pain.

ATYPICAL/DYSPLASTIC NAEVI

Atypical nevi are acquired moles with unusual features that may mimic melanoma. Clinically they are often larger than 5 mm in diameter, have irregular borders and may display several shades of pigment. Histology shows foci of atypical melanocytes but no invasion. Several dysplastic naevi may be seen in the same individual and, when accompanied by large number of benign naevi and a family history of melanoma, form the familial atypical mole and melanoma syndrome.[74] These patients are at high risk of developing melanoma. UV light can promote the development of dysplastic naevi and their transformation to melanoma but these lesions can appear in non-exposed sites. Atypical moles should be referred to dermatologists for assessment with dermoscopy, full skin examination and photographic records, especially if there are multiple unusual lesions. Excision with a 2 mm margin is recommended if the lesions change in appearance or when there is diagnostic uncertainty.

Seborrhoeic keratosis

These are benign epithelial tumours and are extremely common. They may be located anywhere on the skin except mucous membranes, palms and soles. The frequency of these lesions increases with age and elderly patients often have numerous seborrheic keratoses. The lesion is usually well defined and appears stuck on the skin (**Figure 94.11**). The surface is rough, corrugated and warty and the colour may range from that of normal skin to dark brown or black. Early lesions may be flat and can cause diagnostic confusion with melanocytic lesions. Dermoscopy shows horn pseudocysts and pseudofollicular openings.[75] Histological confirmation may be required for lesions lacking typical features. Treatment is not essential but can be carried out for cosmetic or symptomatic reasons as the lesions often become irritated or inflamed. Cryotherapy, shave excision and curettage are some of the commonly used surgical techniques.

Figure 94.11 Seborrhoeic keratosis (Blue arrow) next to a basal cell carcinoma (red arrow).

Keratoacanthoma

Keratoacanthomas are low-grade squamoproliferative tumours that arise from the pilosebaceous follicles. They grow rapidly and appear as nodules with a central keratin-filled crater and can be difficult to distinguish from SCC clinically. They commonly arise on the head and neck, and intra-oral lesions have also been reported. If untreated the lesions would involute over several months but lesions should be excised for diagnosis and exclusion of SCC.[76]

Cysts

A number of benign cysts can arise on the head and neck. Dermoid cysts are developmental inclusion cysts that appear at birth or in childhood and are commonly seen on the face. They contain mature skin with hair follicles, sweat glands and sebaceous glands. Epidermoid cysts form from proliferation of squamous epithelium in the dermis, which can follow trauma or a blocked pore. They are commonly seen on the face, neck and scalp. Pilar or trichilemmal cysts arise from stratified squamous epithelium similar to that found in hair follicles. Most pilar cysts occur on the scalp but may also form on the face or neck. Cysts may cause problems with cosmesis or symptoms following inflammation, and surgical excision can be offered for these reasons.

Pilomatricoma

A pilomatricoma is a benign tumour that arises from hair matrix cells. It commonly affects children in the form of a solitary, angulated, hard nodule on the cheek, eyelid, scalp or neck. The lesions tend to grow slowly and are usually asymptomatic. Transformation to pilomatrix carcinoma is possible but extremely rare. Multiple lesions may be seen in patients with myotonic dystrophy. These lesions should be excised, as they never regress spontaneously. Recurrence can occur if they are not removed completely.

Sebaceous adenoma

Sebaceous adenomas are benign adnexal neoplasm resulting from the proliferation of sebaceous gland-like structures. They appear as a small, slow growing, smooth, pink or yellow papules with central umbilication on the face or scalp. Lesions may be single or multiple. They may be mistaken for BCCs and histological confirmation is essential. These are rare neoplasms and often linked to Muir-Torre syndrome, which is a hereditary cancer syndrome characterized by visceral malignancies. Sebaceous adenomas should prompt a careful evaluation of the patient with attention to their family history for internal organ cancers.

Sebaceous hyperplasia

This is a common finding in the elderly or those who are receiving long-term immunosuppression. They appear as multiple, skin coloured or yellow papules on the forehead, nose or cheeks that are a few millimetres in diameter. Lesions are often umbilicated and may be confused with BCCs. These lesions have no malignant potential and treatment is not essential but a biopsy may help when the diagnosis is doubtful.

Syringoma

Syringoma is a benign sweat duct tumour. They usually appear in clusters on and around the eyelids or cheeks. Individual lesions are skin coloured papules, 1–3 mm in diameter. Treatment is often sought for cosmetic reasons and options include electrocautery, laser, cryotherapy and trichloracetic acid.

KEY POINTS

- Skin cancers are the most common cancers in the world.
- The incidence of skin cancer is increasing.
- Appropriate management with adequate surgical margins to prevent recurrences is vital.
- Mohs micrographic surgery can offer complete margin control for many skin cancers.
- Rare skin cancers are also on the rise. It is important to recognize them early so that appropriate multidisciplinary approach can be taken.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: facial paralysis, Bell's palsy and facial nerve.

THE CLINICAL PROBLEM

Facial paralysis causes a highly visible deformity with profound consequences from both a functional and psychosocial standpoint.

The absence or dysfunction of facial musculature (**Table 95.1**) can lead to an inability to control the eye and mouth, leading to corneal exposure and chronic irritation of the eye as well as oral incompetence, producing a disfiguring asymmetry and difficulty in eating and drinking.

From a psychosocial viewpoint, the lack of mimetic facial expression produces difficulties in communication and can affect self-confidence, professional advancement and social interaction and produce depression.

Brow ptosis is more commonly a problem in the older patient. The weight of the forehead pushes the eyebrow down, producing eyebrow asymmetry and obstructing upward gaze. This may be complicated by overactivity of the unaffected contralateral frontalis muscle, elevating the contralateral brow, worsening the asymmetry.

The orbicularis oculi muscle is crucial to the protection of the globe, providing closure of the eyelids during blinking, maintaining tone of the lower eyelid and providing the pumping mechanism for the lacrimal drainage apparatus. Paralysis of this muscle prevents eye closure, risking corneal exposure, ulceration and blindness. During normal eye closure, the majority of movement occurs in the upper eyelid – the lower eyelid elevates by approximately 2 mm during forced closure. The absence of Bell's phenomenon (upward rotation of the globe on forced eye closure) is a significant risk factor for the development of corneal exposure and must be assessed.

The normal orbicularis is responsible for the lacrimal pump apparatus. Paralysis of this active pumping mechanism reduces movement of tears down the lacrimal duct into the nasal cavity. Weakness of orbicularis may produce a paralytic ectropion, allowing the lacrimal punctum to fall away from the globe, worsening tear drainage.

The lateral canthus lies 2 mm cranial to the medial canthus; thus, tears naturally flow medially to the punctum and are carried away through the lacrimal apparatus, and are thence actively pumped away by the contractions of orbicularis oculi muscle. Laxity of the lower lid disrupts this smooth gradient, forming a paralytic ectropion, producing a bowing of the lower lid, producing a sump that allows tears to pool, overflow, and then run down the cheek.

As a result, patients with facial paralysis are frequently troubled by dryness of the eye coupled with a watering eye. This is exacerbated during cold and windy weather.

Weakness of the facial muscles may lead to cosmetic and functional problems with the nose. Overactivity of the muscles on the normal side of the face may pull midline structures over to the normal side. The nasal tip is drawn across the midline, along with the philtrum. There may be collapse of the internal and external nasal valves due to paralysis of the dilator nares and levator labii alequae nasi muscles.

TABLE 95.1 Aetiology of facial nerve dysfunction by anatomical level

Intracranial	Intratemporal	Extratemporal

• Vascular abnormalities
• CNS degenerative disease
• Intracranial cavity tumour
• Brain tumour
• Congenital abnormalities and agenesis
	• Bacterial and viral infection
	• Cholesteatoma
	• Trauma:
	  ○ temporal bone fracture
	  ○ gunshot wounds
	• Tumours invading middle ear, mastoid, FN
	• Iatrogenic cause
		• Malignant tumour of parotid
		• Trauma: lacerations, gunshot wounds
		• Iatrogenic
		• Primary tumour of FN
		• Malignant tumour of ascending ramus of mandible, pterygoid and skin

The other major concern for patients is inability to move the mouth. This affects the ability to speak clearly, drink fluids and eat. A common complaint is biting the inside of the mouth when eating. Speech is affected – many facial paralysis patients have difficulty with plosives ('b' and 'p' sounds).

ANATOMY

Facial muscles

There are 17 paired muscles of facial expression and one unpaired sphincter muscle, the orbicularis oris. The major muscles affecting the forehead and eyelids are the frontalis, corrugator and orbicularis oculi. There are two groups of muscles controlling the movement of the lips. The lip retractors include the levator labii superioris, levator anguli oris, zygomaticus major and minor for the upper lip, and depressor labii inferioris and depressor anguli oris for the lower lip. The antagonist to these muscles is the orbicularis oris, which is responsible for oral continence and is also involved in expressive movement of the lips. The detailed anatomy of the facial musculature has been well described in many standard surgical and anatomical textbooks.

Physiology of nerve repair

To understand the strategies employed in the management of facial nerve injury it is important to have an understanding of the principles of nerve repair.

SEDDON'S CLASSIFICATION

Seddon[1] described the following types of neuronal injury:

- **Neuropraxia**. This is temporary cessation of conduction of the nerve with no loss of axon continuity. Neuropraxia is a transient phenomenon with complete recovery once the causative factor is removed.
- **Axonotmesis**. Damage is sustained to the axon resulting in Wallerian degeneration. Regeneration occurs at a rate of 1–4 mm a day and recovery is usually satisfactory.
- **Neurotmesis**. The nerve fibre is severed and the endoneurium disrupted. Recovery is unlikely.[1, 2]

SUNDERLAND'S CLASSIFICATION

Sunderland's classification[3] discusses the extent of nerve injury allowing predictions to be made regarding prognosis:

- **First degree** injury is a conduction delay with no evidence of discontinuity of the neuronal anatomy.
- **Second degree** injury demonstrates disruption to the axon, resulting in Wallerian degeneration of the distal component. The proximal segment of the nerve becomes a passage for proteosynthetic substances to allow axonal regeneration. The endoneurium is intact so the axonal sprout can grow (usually at a rate of 1 mm a day) within the endoneurium, ensuring the motor end plate, and therefore muscles, receive the same nerve supply as prior to the injury. Factors that may affect recovery include site and type of injury, nutritional status and age.[4]
- **Third degree** injury also affects the endoneurium; therefore, in addition to the features seen in type two injury, the neuronal regrowth is less organized as regenerating axons may enter any endoneurial tubules. This means that the subsequent reinnervation may not supply the same muscles as previously, resulting in synkinesis or mass movement.
- **Fourth degree** injury affects the perineurium and **fifth degree** injury affects both perineurium and epineurium. This in turn results in a decreased number of axons regenerating as efficiently as in the less severe injuries, manifesting itself as weaker muscle function and also synkinesis.

The time from axonal degeneration to irretrievable muscle atrophy is accepted to be approximately 18 months but there have been reports of successful reinnervation up to 20 years later.[2]

ASSESSMENT OF THE PATIENT

A detailed clinical assessment is important in the diagnosis of facial paralysis. Attention should be paid to the duration and progression of symptoms, associated history ear problems, trauma, recent vaccinations, travel history, family history of facial weakness and medical history.

A diagnosis of idiopathic Bell's palsy should only be made with a classical history – any atypical clinical features should prompt further investigation to exclude another cause.

Examination should include careful assessment of each branch of the facial nerve and, where possible, the House–Brackmann[5] (**Table 95.2**) and Sunnybrook grading scales[6] should be used to document the severity of facial weakness. The Sunnybrook Facial Grading in particular will allow assessment for recovery or progression (**Table 95.3**). In younger children, where it may not be possible to use the House–Brackmann grading scale, it is important to document what spontaneous facial movements are noted (particularly when the child is crying) and what movement the parents feel may have altered. Forehead sparing in a patient presenting with facial weakness represents a supranuclear lesion due to cross-innervation. A thorough history and examination will reveal the presence of a complete or partial VIIth nerve paralysis and the extent and severity of weakness. The history should explore the physical problems from the patient's perspectives as a guide to treatment. The patient's concerns and expectation should be sought and evaluated: for some, functional considerations will predominate; for others, simply looking symmetrical in photos is all they seek; others will want restoration of dynamic spontaneous facial movement. The level of nerve lesion can be assessed clinically. Injury within the bony canal is suggested by hyperacusis, loss of taste to the ipsilateral tongue and facial weakness. Injury near the geniculate ganglion will result in decreased secretory function of the nose, mouth and lacrimal gland.

TABLE 95.2 The House–Brackman grading scale[5]

Grade	Characteristics
I. Normal	Normal facial function in all areas
II. Mild dysfunction	Gross: • slight weakness noticeable on close inspection • may have slight synkinesis • at rest, normal symmetry and tone Motion: • forehead – moderate-to-good function • eye – complete closure with minimal effort • mouth – slight asymmetry
III. Moderate dysfunction	Gross: • obvious but not disfiguring difference between the two sides • noticeable but not severe synkinesis, contracture, or hemifacial spasm • at rest, normal symmetry and tone Motion: • forehead – slight-to-moderate movement • eye – complete closure with effort • mouth – slightly weak with maximum effort
IV. Moderately severe dysfunction	Gross: • obvious weakness and/or disfiguring asymmetry • at rest, normal symmetry and tone Motion: • forehead – none • eye – incomplete closure • mouth – asymmetric with maximum effort
V. Severe dysfunction	Gross: • only barely perceptible motion • at rest, asymmetry Motion: • forehead – none • eye – incomplete closure • mouth – slight movement
VI. Total paralysis	• No movement

Examination should also include otoscopy, examination of the head and neck for signs of trauma and masses, particularly in the region of the parotid, as well as assessment of the remaining cranial nerves.[3]

Examination of the face begins with the brow. The position of the brow and degree of forehead rhytids must be assessed and brow movement should be measured. The palpebral aperture should then be measured. Visual acuity and the presence of Bell's phenomenon should be tested. Lower lid laxity can be assessed by the snap test, gently pulling the lower lid away from the globe and releasing – adequate tone is demonstrated by a slightly audible snap as the lid is snaps back into position. This fails to occur if lid laxity is present. Alternatively, distraction greater than 6 mm from the globe on gentle downward traction of the lower lid suggests lid laxity is present. The position of the inferior canalicular punctum should be noted and the presence of medial canthal tendon laxity assessed.

The nose is examined for deviation to the unaffected side. Forced inspiration may produce collapse of the internal nasal valves on inspiration due to loss of tone in the dilator nares muscle.

Static asymmetry of the face should be assessed, including midline shift of the philtrum, the depth of the nasolabial folds, jowling and the presence of platysmal bands (often present on the paralyzed side). Static asymmetry of the oral commissures is noted and the presence of hypertonicity on the each side of the face is assessed. Active movements are then assessed: excursion of the oral commissures is measured and the degree of synkinesis. The lower teeth are examined with regard to how much they show during smiling; the smile is classified using the Rubin Smile Classification.[7]

INVESTIGATIONS

Imaging of the facial nerve may be useful in delineating the site of neural injury. Indications include recurrent, progressive or persistent paralysis, trauma and suspected nerve involvement in systemic diseases.

Magnetic resonance imaging (MRI) is the only modality that demonstrates the facial nerve comprehensively from the pons to the parotid gland; with gadolinium enhancement it is capable of showing inflammatory changes. High resolution CT of temporal bone makes it possible to see

bony detail and is ideal when facial nerve involvement is in the middle ear cleft.

Electrophysiological tests allow objective assessment of function, even in children.[8] Typically testing is delayed until 72 hours post onset of paralysis (to allow for Wallerian degeneration). This can be repeated every 3–5 days up to 21 days until a trend or confirmation can be obtained. The most clinically helpful use of this test is objectively to assess facial nerve function, once spontaneous motion is lost in acquired paralysis or if it had never been seen in congenital paralysis. The authors maintain that the test is not an absolute predictor for return of function but that the added data, when used with clinical information, make assessment of prognosis more rational.

TIMING OF REPAIR

For reinnervation procedures to be considered the ipsilateral facial nucleus must have an adequate number of functioning cell bodies, the proximal nerve segment must be in continuity with the facial nucleus and be able to support axial regeneration, and the distal nerve segment must be in contact with functioning muscle units and be capable of accepting regenerating neurons.[9]

Immediate or early repair of nerve injuries should always be repaired if at all possible. Primary repair of the facial nerve should be performed using an operating miscroscope if possible. Epineural repair using 9/0 nylon is as successful as fascicular repair.[10] Fibrin glue may also be used.[11]

Interposition graft

Interposition grafts are used when there is an insufficient length of nerve to allow a tension free anastomosis. The length of a graft should exceed the gap by 3–5 mm on each side.[12] The commonest donor nerves are the greater auricular nerve and the sural nerve. The greater auricular nerve usually lies within the surgical field; however, only about 5 cm graft length is available. The sural nerve has the advantage of providing a long segment of nerve and has a reliable course, allowing ease of location. Disadvantages include a potentially larger diameter and higher neural to connective tissue ratio.[4] In one series 95% of patients had some return of function following interposition graft and success has also been described in patients who have had postoperative radiotherapy.[13]

Atrophy of muscle and degeneration of motor end plates begins to occur following denervation of facial muscles. There is little prospect of successful reinnervation after

2 years.[14, 15] As it may take 6–9 months for nerve regeneration to occur following nerve transfer, this must be taken into account when evaluating the likelihood of success of a nerve transfer.

TREATMENT PLANNING

Treatment should be individualized. However, aims of treatment are:

- the protection of the eye
- to provide symmetry at rest
- correction of synkinesis
- to provide oral continence
- to provide dynamic facial movement
- to improve speech
- to improve nasal deviation and airway patency.

NON-SURGICAL MANAGEMENT

Non-surgical management of the eye

Non-surgical strategies to protect the eye are used whilst waiting for a damaged facial nerve to recover or sometimes, in a well-motivated patient, as a permanent solution for the eye as an alternative to surgery. The aim is to prevent exposure dermatitis of the corneal leading to ulceration and blindness. Adequate provision of ocular lubricants during the day is essential and the patient must be taught how to tape the lids closed at night to prevent desiccation. Eye irritation mandates ophthalmology review.

Non-surgical treatment of the face

The cornerstone of management of facial paralysis is facial therapy.

Neuromuscular retraining by an experienced therapist can improve aberrant activity on the unaffected side, and the treatment of synkinesis and hypertonicity (if present) on the affected side. A variety of treatment modalities are used, including biofeedback, electromyography and self-directed mirror exercises.[16]

Strong consensus exists as to the importance of facial therapy in the multidisciplinary management of facial palsy. Some evidence exists that tailored facial exercises can help to improve facial function, mainly for people with moderate paralysis and chronic cases, and reduces recovery time and negative sequelae in acute cases.[17]

SURGICAL MANAGEMENT

Brow

In the young, paralysis of one side of the forehead causes relatively minimal problems. They have no forehead crease lines, so the difference between each side of the face is only noticed on animation. The eyebrow does not descend since there is still some elasticity in the tissues. In a 20-year-old man, the animation of one side of the forehead may be considered an embarrassment as it draws attention to the overall asymmetry of the face. Botulinum toxin injections to contralateral frontalis may be employed after careful discussion with, and thorough understanding by, the patient.

In later life, with loss of skin elasticity, the eyebrow sometimes descends, taking part of the eyelid skin with it, so that vision may be partially obstructed. A direct brow lift provides long-lasting correction. Other brow-lifting techniques, used in cosmetic surgery, include endoscopic brow-lifts and transblepharoplasty brow-pexy techniques using implants. These may be useful in correcting small ptoses in partial facial weakness but have limited application in profound facial palsy, particularly in the elderly.[18] More sophisticated transfers of muscle groups, for example from the contralateral frontalis muscle, do not seem to be particularly reliable, which probably relates to devascularization of the muscle fibres.

Upper eyelid

In congenital unilateral facial palsy, even if the young patient does not close their eye perfectly they seem to have minimal problems with exposure keratitis. The child passes through a phase before the age of 3 when excess epiphora may cause them to rub their eye and develop pseudo-conjunctivitis. Eventually they learn to avoid this and by the age of 4 seem to have no further problems. Upper lid weighting is not required and indeed is actively disliked by the child as it may narrow the palpebral fissure and sometimes interfere with their visual field compared to the normal contralateral side.

As the patient with congenital unilateral facial palsy reaches their mid-20s, the lower eyelid descends and scleral show may be apparent. A McLaughlin's lateral tarsorrhaphy is an effective and aesthetic means to elevate the lower eyelid, slightly narrow the palpebral fissure and restore symmetry.

However, a unilateral facial palsy developing in adulthood is a different matter and avoidance of exposure keratitis is mandatory. Even if recovery is expected, the eye must be protected by creams at night, tape closure or surgery. There are numerous methods available to protect the cornea. The principle is to either allow the upper eyelid to drop, elevate the lower, or both. On blinking, the levator palpebrae relaxes and, if the upper eyelid is either loaded or sprung, the eyelid can be persuaded to close. Specially made gold weights, smoothly rounded and capable of fixation to the tarsal plate, are easy to insert and largely reliable. Fixation to the tarsal plate is essential as it significantly reduces extrusion and migration. It is desirable to use as light a weight as will effectively close the eye, and rarely is more than 1 g required (1.5 g gold weights are heavy and eventually the levator is apt to weaken, producing ptosis). Closure sufficient to cover the cornea is reported in 78% of cases with resolution of keratitis in 62–100% of cases.[9, 19–21]

Other methods of treating lagopthalmos include: lengthening the levator by division or inserting a strip of temporalis fascia; insertion of magnets in upper and lower lids;[22] and the Morel-Fatio palpebral spring.[22, 23]

The classic Gillies procedure – the transfer of slips of temporalis muscle and deep temporal fascia to upper and lower eyelids – has been used extensively in the past. It has now fallen out of favour due to unpredictability of result compared with the simpler and more predictable lid loading techniques described above.

Lower eyelid

Elevation of the lower eyelid may be required where there is a scleral show beneath the limbus of the eye, and to correct epiphora. Many methods are available to achieve this, but a McLaughlin's lateral tarsorrhaphy is aesthetic and effective for minor degrees; however, large procedures narrow the palpebral fissure and are extremely unaesthetic. If this is unsuccessful or the depression is more severe, then a palmaris tendon sling between the medial canthal ligament and the supraorbital margin laterally can provide good elevation. Conchal cartilage grafts may be used to support the lower eyelid, set between the infraorbital margin and the lower edge of the tarsal plate.[24]

The treatment of epiphora remains challenging. The massaging action of the orbicularis on the tear flow and its siphoning effect on the lachrymal sac is important, as is the position of the lower lateral canaliculus in respect of the orbit. However, a perfectly positioned lachrymal canaliculus does not mitigate against a watering eye. Overproduction of tears by reducing the inhibition on the secretor motor fibres to the lachrymal sac via the greater superficial petrosal nerve may be an unwanted factor.

The Gillies procedure, involving transferring the temporalis muscle and extending it by using the temporalis fascia passed through the upper and lower eyelids, is less popular these days, although, if perfectly tensioned, satisfactory results can be achieved using this technique. It is probably less reliable than the methods mentioned previously.

Nasal airway

Paralysis of the nasalis, dilator nares and levator labii aleque nasi muscles may lead to collapse of the external and internal nasal valves. This may be exacerbated if the nose is pulled towards the unaffected side by the unopposed action of the contralateral facial muscles. The airway is narrowed with reduction in airflow. If the patient is symptomatic, elevation of the nasal base by tendon slings fixed to the maxillary periosteum is effective. Septal deviations, if present, should be corrected. Insertion of supportive cartilage grafts to the alar rim have also been used.

Upper lip and cheek (smile reconstruction)

The majority of patients presenting with refractory facial paralysis do so for correction of facial asymmetry and/or the restoration of dynamic facial movement. For those patients who simply want to look symmetrical in photographs and/or are either not a candidate for more complex procedures or for whom a prolonged recovery and period of facial rehabilitation is not attractive, then static facial slings can restore a surprising degree of resting facial symmetry.

STATIC TECHNIQUES

Facia lata, harvested from the lateral thigh, is commonly used in this application, although some proponents prefer tendon grafts of plantaris or palmaris longus as they are said to stretch less over time. The grafts are inserted into the corner of the mouth at the nasolabial fold and anchored either to the deep temporal fossa or zygomatic periosteum using either permanent sutures or Mitek® Bone Anchors. Using the contralateral normal side as a guide to assess the vector required, the grafts are inserted with sufficient tension to just overcorrect the asymmetry to allow for post-operative relaxation.

DYNAMIC TECHNIQUES

Regional muscle transfers

Dynamic muscle transfers have traditionally involved the transfer of muscle of mastication to the mouth to replace the lost activity of levator anguli oris and zygomaticus major and minor muscles. Regional muscle transfers have the advantage of immediate results as no reinnervation is required; however, the transfer of a regional muscle produces a voluntary smile rather than a natural spontaneous smile, and abnormal movements can be produced during chewing. Transfer of the masseter muscle produces little in the way of movement of the mouth and an unsightly bulge in the cheek. Temporalis transfer, popularized by Gillies, involved the turnover of strips of temporalis muscle and deep temporal fascia over the zygoma and inset into the corner of the mouth and/or the eyelids. This may produce an unsightly bulge over the zygoma. More recently a prograde temporalis transfer, described by Labbé and Huault, has become popular.[25]

In recent years the use of regional muscle transfers has largely been superceded by free muscle transfers.

Free muscle transfers

Microsurgical functioning muscle transfer has become the mainstay of facial reanimation in the developed world over the past three decades. Pre-operative planning is essential – assessment of the vector and magnitude of the smile on the normal side must be made to plan. A variety of muscles have been described for facial reanimation but the most popular remain the gracilis muscle and the pectoralis minor muscle. To produce a voluntary smile requires the use of the VIIth nerve, most commonly by way of a cross-facial nerve graft.

Single stage muscle flaps with innervation from the contralateral facial nerve have been reported. This technique requires the use of a muscle flap with a long nerve segment, such as latissimus dorsi or rectus abdominis.[26]

A comprehensive exploration of the branches of the contralateral facial nerve is performed at a first stage. Usually a redundant buccal branch is selected as the donor nerve, using bipolar nerve stimulation. A sural nerve graft, harvested from the leg, is placed onto a redundant buccal branch and tunnelled across the midline to the paralyzed side of the face. Growth of the facial nerve is followed clinically by way of Tinel's sign and, following successful regeneration, a free functioning muscle transfer is performed 6–9 months later at a second stage. The muscle is inset into the nasolabial fold and commissure of the mouth and revascularized using either the facial vessels or the superficial temporal vessels.

The use of the masseteric branch of the Vth cranial nerve to power muscle transplants in a single operative stage has recently become used. Advocates of the masseteric nerve cite benefits of a single-stage procedure, a greater axonal load that can be delivered to the muscle resulting in a stronger contraction of the transplanted muscle – a more normal excursion of the mouth and preservation of the contralateral facial nerve.[27] These combine to allow a more normal reconstructed smile. The disadvantage is the need to relearn to smile by biting.

The use of cross-facial nerve grafts and other donor nerves to power the transplant or reinnervate intact facial musculature depends on the goals of treatment and patient factors. Although initially thought that only a cross-facial nerve graft could produce spontaneous facial activity, spontaneous activity has been observed in a significant proportion of transplants innervated by the nerve to masseter.[28, 29] This has been ascribed to the phenomenon of cortical plasticity; however, activity of the normal masseteric nerve during smiling has been observed on EMG studies, and this may offer an alternative explanation.

Lower lip

Transfer of the anterior belly of digastric muscle[30] and platysmal muscle[31] have been described for dynamic reanimation of the lower lip. The results of these are variable. A simpler and more predictable result can be achieved by the selective weakening of the contralateral depressor labii inferioris muscle. This can be achieved temporarily by the use of Botox or more permanently by direct excision of the muscle through an intra-oral approach.[32, 33]

ADJUNCTS

Other cosmetic interventions may be performed as required, including facelifts, midface lifts, rhinoplasty and correction of platysmal bands.

KEY POINTS

- A diagnosis of idiopathic Bell's palsy should only be made with a classical history – any atypical clinical features should prompt further investigation to exclude another cause.
- Facial paralysis should be managed in a multidisciplinary fashion.
- Reinnervation can only be successful for approximately 18 months following onset of facial paralysis.
- Early intervention to protect the eye may be required.
- Facial reanimation can be vey effective but a completely normal appearance is rarely achieved.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: partial and total ear reconstruction, and total and partial auricular reconstruction. It is focused on a narrow range of common partial ear reconstruction techniques and the basic principles guiding total ear reconstruction.

INTRODUCTION

The external ear is a convoluted 3D structure with a vestigial function to gather sound waves towards the external auditory meatus (EAM). This delicate structure with a complex contour has become a subject of beauty over the ages. There has been increasing awareness that individuals desire the appearance of a pair of symmetric, aesthetically pleasing ears. In a representative proportion of the UK general population, the awareness of perceived differences in the appearance of their ears has led to self-consciousness or increased sensitivity to these differences.[1] Reconstructive surgeons should have comprehensive knowledge of normal ear anatomy in order to perform accurate and aesthetic auricular reconstruction.

ANATOMY

Surface anatomy

Auricular surface anatomy is characterized by a series of ridges and depressions (**Figure 96.1**).[2] The outer border of the upper two-thirds of the ear is framed by the elevated helix. Darwin's tubercle is a prominence that sits on the posterior upper helix. The crus or root of the helix slopes downwards and curves posteriorly from the anterior upper third of the ear, over the superior aspect of the EAM. This ridge separates the conchal depression into the upper cymba concha and lower cavum concha. A complex elevation – the antihelix, separates the wide and deep concha from the narrow and shallow scaphal depression. The upper part of the antihelix follows the curve of the outer helix before dividing to form 'V-shaped' delicate ridges called the superior and inferior crura. These crura border a depression called the triangular fossa. The antihelical elevation extends towards the ear lobule to meet a short semicircular ridge – the antitragus – which is separated from the tragus by the more inferiorly placed intertragic notch or incisura. The tragus is a prominent quadrangular ridge which points posteriorly and lies over the anterior aspect of the EAM. The flat ear lobule sits inferior to the tail of the helix at the lower quarter of the ear, below the antitragus and the incisura. On the medial (cranial) surface of the auricle, the scaphal and conchal eminences are convexities that correspond to the scaphal and conchal depressions on the lateral surface described previously. The conchal eminence meets with the mastoid process to form the postauricular sulcus.

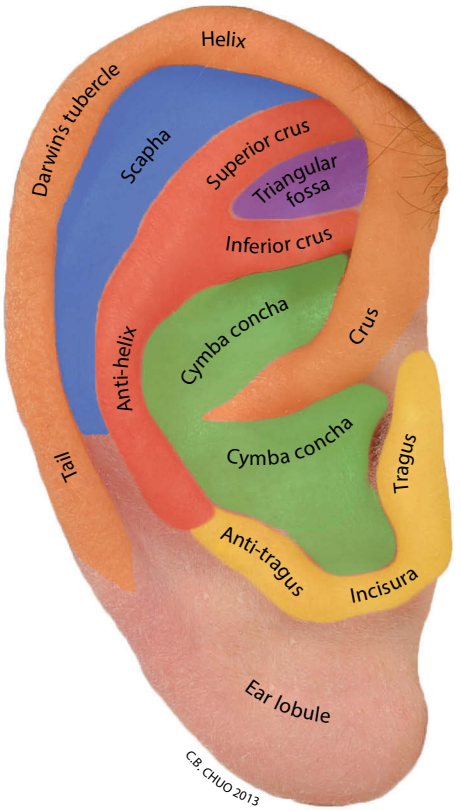

Figure 96.1 Lateral surface of the external ear. The locations and proportions of the key structures including the ear lobule are shown. Important ridges are the helix, antihelix, tragus and antitragal complex. Important depressions are the scapha, concha and triangular fossa.

Posture and position

The posture and position of the ear are shown in **Figure 96.2**.[3–7] The longitudinal axis of the ear is considered by Tolleth as the 'line of balance' that extends from the fullest point on the upper helical border to the most dependent point on the lower border of the ear lobule. It lies posteriorly rotated from the vertical axis of the head by 15–30 degrees. The axis of the ear may sometimes lie parallel to the dorsum of the nose, but more frequently lies 12–15 degrees more vertical than the nasal dorsum.

The ear is sited approximately the length of an ear, measured along its longitudinal axis, posterior to the lateral orbital margin. In 85% of individuals, the upper border of the ear is level with the most lateral point of the eyebrow.

The lateral surface of the ear is turned anteriorly with a conchomastoid angle of 30 degrees and a concho scaphoid angle of 90 ± 15 degrees. The most prominent point of the ear sits 17–20 mm lateral to the side of the head in the horizontal plane.

Three key measurements are required in order to site the reconstructed ear in an aesthetic and symmetric position: an appropriate angle of rotation for the longitudinal axis, the vertical level for the upper border of the ear and the horizontal distance of the ear from the lateral orbital margin.

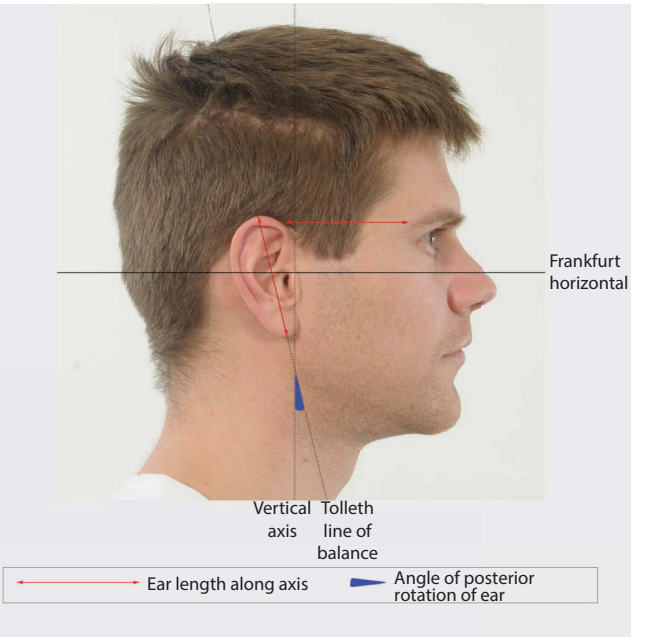

Figure 96.2 Lateral aspect of the head. This illustrates the ideal position of the upper external auditory meatus in line with the Frankfurt horizontal and the anterior border of the helix positioned one ear length posterior to the lateral orbital margin. The longitudinal axis of the ear is posteriorly rotated relative to the vertical axis of the head.

Proportions

The normal adult ear measured along its longitudinal axis is 63–65mm and the width of the ear is 50–65% (mean 55%) of its length (**Figure 96.3**).[3, 5, 8]

The triangular conchal depression has a width two-thirds of its length. The average length of the ear lobule as measured from the lowermost incisura to the most dependent point on the lower border of the ear lobule is 18 mm, and the ratio of lobule length to full ear length is 0.28–0.30.

Structure

Mechanical strength to maintain the structure of the external ear is provided by fibrocartilage which extends from the helix to the incisura.[2, 9–11] At the anterior aspect of the concha, a cartilaginous cylinder continues from the EAM medially to form the outer third of the external auditory canal. The auricular cartilage is attached to the temporal bone by two ligaments. The anterior ligament holds the tragus and anterior helical crus to the root of the zygomatic arch. A posterior ligament holds the medial conchal eminence to the lateral mastoid process.

Six vestigial intrinsic and three extrinsic muscles attach to the perichondrium of the ear. The extrinsic muscles auricularis anterior and superior attach to the galeal aponeurosis, and the auricularis posterior attaches to the periosteum at the base of the mastoid.

The skin on the lateral surface of the ear is thin and binds tightly to the underlying perichondrium encasing

the fibrocartilage. This allows the details of the complex convolutions of the cartilage to be easily seen.

Skin on the medial surface of the ear is mobile, with a thickness of 0.4–0.8 mm. There is minimal subcutaneous adipose tissue and extensive fatty infiltration of the dermis, beginning at the level of the sebaceous glands, and increasing in density with depth. A loose areolar fascial plane lies between the perichondrium and subcutaneous fat. This well-vascularized layer is a continuation of the intrinsic muscles of the ear, and contributes to the mobility of the postauricular skin.

The ear lobule is a soft fibro-fatty cutaneous flap that is suspended from the lower border of the auricular cartilage.

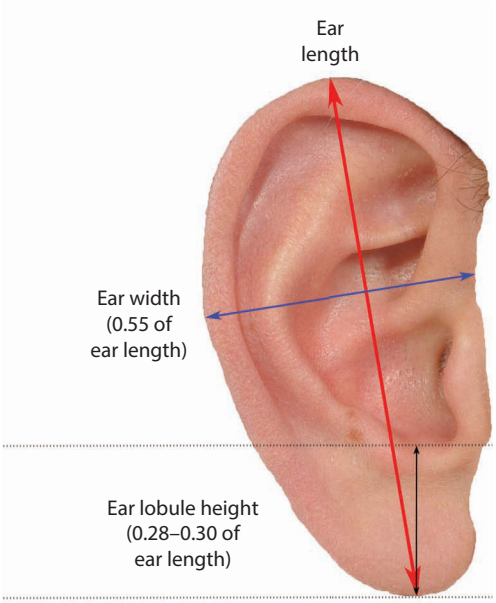

Figure 96.3 Lateral surface of the external ear in its natural orientation. Note the width-to-length ratio of the ear and the height of the ear lobule relative to total ear length.

Blood supply

The ear is supplied by the superficial temporal artery (STA) and the posterior auricular artery (PAA).[2, 9, 11–15] The STA ascends in the preauricular area through the parotid gland and gives rise to one to three branches to the ear. The lower branch supplies the lower margin of the ear lobule, the middle branch the tragus, and the upper branch the ascending helix and the triangular fossa–scapha arterial network. After supplying the ear, the STA ascends to form two terminal branches about 3 cm above the zygomatic arch – the anterior (frontal) and posterior (parietal) branch. These branches supply a fascial layer – the temporoparietal fascia (also called the superficial temporal fascia). This lies superficial to the deep temporal fascia layer, which is supplied by the middle temporal artery – a branch of the STA that arises 1–3 cm below the upper border of the zygomatic arch. See **Figure 96.4**.

The PAA travels towards the scalp in the groove between the mastoid and the cartilage of the posterior EAM, and then continues onto the conchal eminence.

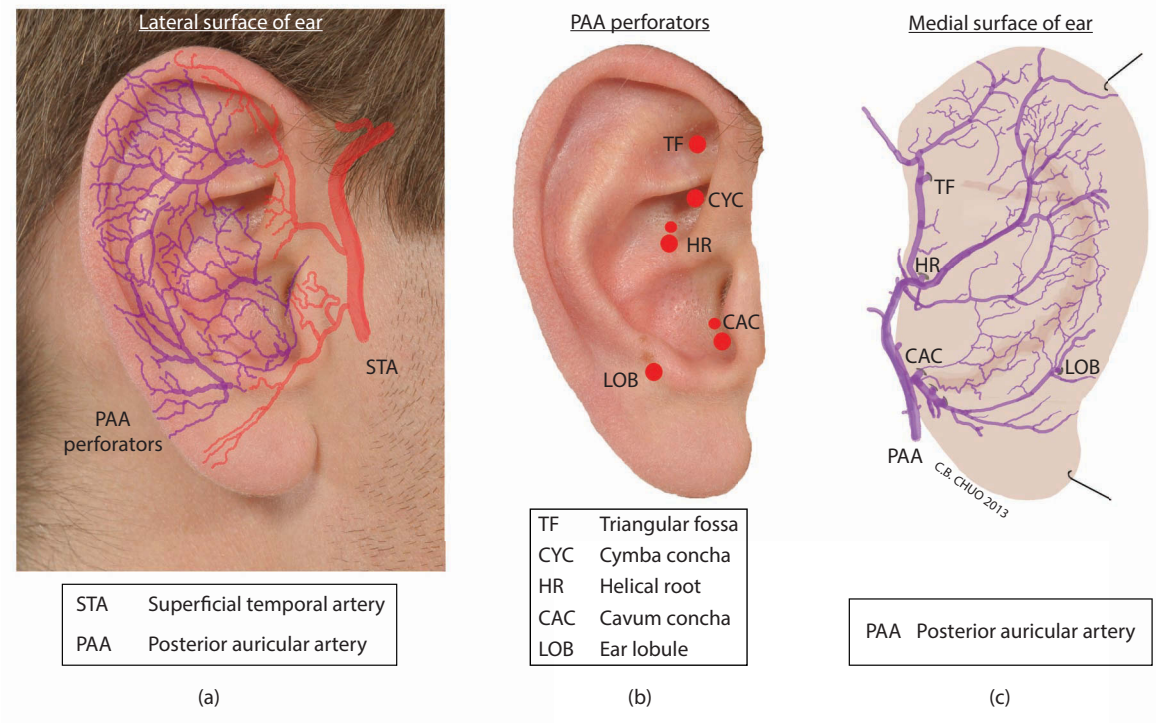

Figure 96.4 The pattern of distribution of the two key arterial networks that supply the skin of the external ear. The superficial temporal artery (STA) provides input to limited areas of the anterior and inferior aspect of the lateral surface, and the remaining ear is supplied by the posterior auricular artery (PAA). Vessels from the PAA perforating the ear cartilage provide a means of communication between the two arterial networks on the lateral and medial surfaces of the ear.

The lower division supplies the posterior surface of the ear lobule, minor posterior branches supply the mastoid fascia and the middle and upper divisions supply the middle and upper thirds of the medial surface of the ear. Perforating branches of the PAA form during its course over the medial surface of the concha. These traverse the cartilage and supply the lateral surface of the ear at key areas: the outer border of the antitragus, cavum concha, helical crus, cymba concha and triangular fossa.

Two main arterial networks formed by communicating branches from the STA and PAA are present on the lateral surface of the ear. The triangular fossa–scapha network is primarily formed from the STA and the conchal network is dominated by perforating branches of the PAA. The upper branch of the STA also communicates with the upper division of the PAA on the superior medial surface of the ear. These networks supply the skin via well-developed subpapillary (intradermal) and the subdermal plexus.

The venous drainage of the ear via the superficial temporal system is variable, whereas the drainage to the posterior auricular system is predictable via the venae comitantes accompanying the PAA.

EAR RECONSTRUCTION

A number of factors need to be considered to determine the most appropriate technique of reconstruction in patients who have congenital and acquired ear deformities and defects. The reconstructive surgeon needs to understand the aetiology of the defects and whether cartilage and/or skin are involved in partial ear defects. Account needs to be taken of whether ear deformities are unilateral or bilateral, the condition of the soft tissues local to the site of the intended reconstruction, the degree of function of the middle and inner ear, the age of the patient, the availability of costal cartilage for framework construction and the patient's preferences for reconstruction.

Indications for ear reconstruction

Patients with complex congenital ear deformities, including those with microtia and anotia, are candidates for total ear reconstruction. Partial ear reconstruction may be indicated in congenital (e.g. lop ear deformity) and acquired deformities involving up to two-thirds of the ear. Trauma (e.g. bite injuries, avulsions and burns) and cancer are common causes of acquired partial or total ear loss requiring ear reconstruction.

Multidisciplinary care

Ear reconstruction is best managed within the setting of a multidisciplinary team comprising plastic surgeons, maxillofacial prosthetists, otolaryngologists, audiologists, radiologists, clinical psychologists and speech and language therapists. This allows the patient and their family to be provided with all possible avenues for reconstruction including prosthetic and autologous ear reconstruction. Imaging of the ear and options for optimizing hearing in patients with hearing loss can also be offered. Clinical psychologists are able to counsel patients with pre-existing psychiatric conditions and assist with the management of patient expectations for future reconstruction.

Surgical goals of ear reconstruction

The aim of total ear reconstruction is to create a contoured replacement structure, with natural proportions, located and orientated in an ideal position on the side of the head. This should appear symmetrical in appearance and location to the opposite normal ear if the reconstruction is unilateral. It is particularly important to replicate key features of the surface anatomy of the lateral ear. The reconstructed ear should also be elevated posteriorly away from the side of the head, to produce symmetrical ear projection and to re-create a post-auricular sulcus.

In practice, the individual aesthetic preference of the patient, the desire for and acceptance of a longer recovery time required for autologous reconstruction influence the agreed plan for correction of the ear deficit or deformity. Furthermore, any autologous reconstruction that is offered is tempered by the need for and available options for structural replacement and soft tissue cover.

Clinical assessment

As part of their clinical assessment[16] the multidisciplinary team should note the patient's general medical health and medications. Medical history of cardiorespiratory disease, diabetes, hypertension and immunodeficiency need to be considered in terms of fitness for surgery and the risk of complications afterwards. Use of aspirin, steroids, warfarin, immunosuppressive agents, tobacco and recreational drugs are documented. Previous procedures on the ears and chest, including operations for ear reconstruction, are noted. A history of hypertrophic or keloid scarring is sought. Previous or current psychiatric history may influence the patient's perception of his or her condition and must be documented.

Specific assessment for ear reconstruction is made in these key areas:

- size, nature and location of the ear defect or deformity
- whether defects or deformities are unilateral or bilateral
- symmetry of the size, shape, appearance of the lateral surface of the ear, angle of reclination (rotation from the vertical) and elevation or projection of the ear
- availability and condition of local and regional vascularized tissues for soft-tissue reconstruction
- availability and condition of donor conchal and costal cartilage for structural reconstruction
- audiology assessment
- assessment by a prosthetist
- patient expectations and preferences
- age of the child in congenital deformities.

Clinical photographs of both ears in close-up and in standard frontal, oblique and lateral facial views are taken to document the condition. The size of any partial defect is

measured and the site described in relation to the upper, middle and lower thirds of the ear, and a note is made of key aesthetic contours which are affected. In unilateral deficits, key aspects of the normal ear are measured – ear height, width, angle of reclination and horizontal distance from the lateral canthus. Any deficiency of cartilage structural support or overlying skin is identified. The presence of scars and the quality of the skin over and adjacent to the site of intended reconstruction influence the options available for reconstruction. The STA is palpated along its course to the frontal and parietal branches. Primary sources of cartilage graft for replacement of structural support and framework construction are conchal and costal cartilage. The chest is examined for the presence of scars and the contour of the costal margin. Contralateral ears are examined for the availability of conchal cartilage for unilateral partial reconstruction.

An assessment by the maxillofacial prosthetist is carried out to present the patient with the available prosthetic options for the individual defect or deformity. This may range from osseointegrated implant-based to adhesive-based silastic devices. The required care and maintenance regimen for these prosthetics is described. If autologous ear reconstruction is desired, moulds of the affected and unaffected ears are taken to produce 3D silicone models for planning surgical reconstruction.

The reconstructive preference of the patient is sought, and his or her expectation of the outcome of surgery is evaluated against the achievable result. Unrealistic expectations of the outcome of reconstructive surgery are a relative contraindication to proceed. Caution against surgery is also advised in patients who exhibit symptoms of body dysmorphic disorder (BDD) and untreated psychiatric conditions.[16]

Special investigations and planning

A chest radiograph is helpful for reviewing the configuration of the ribs in conjunction with the clinical assessment of the costal margin, especially if the patient has had previous chest trauma or thoracic surgery. Patients with extensive local scarring may require a temporoparietal fascial flap as vascularized soft-tissue cover for ear reconstruction. Angiography of the external carotid artery or Doppler ultrasonography is important for assessing the continuity and calibre of the STA.

Two-dimensional templates and 3D models are important for the planning of partial and total ear reconstruction. Templates are typically made from radiographic or acetate film. These may be customized by tracing the outer border, antihelix, superior and inferior crus, tragus and antitragus of the contralateral normal ear (**Figure 96.5**).[17, 18] These images are then reversed to create a basis on which to plan reconstruction. Nagata has designed a series of standardized templates for cartilage framework construction based on key height and width measurements, and Tolleth's described proportions of the ideal ear.[19] An appropriate standardized template for an individual patient is chosen based on the height of the contralateral normal ear (**Figure 96.6**).

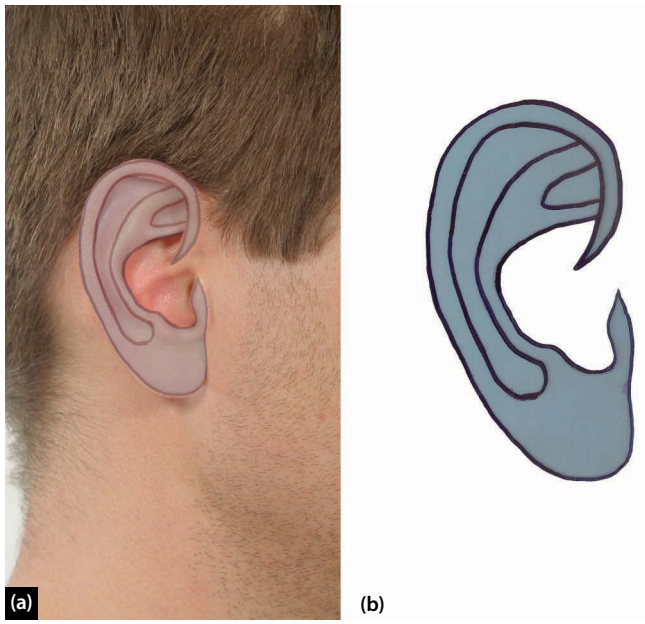

Figure 96.5 **(a)** Customized 2D template, drawn on a semi-transparent film, that highlights the key structures of the ear described in Figure 96.1. **(b)** Overlay of the template on the ear to show that the template provides an accurate depiction of the size and proportions of the ear. The customized template taken from the remaining normal ear and reversed is useful in patients where unilateral reconstruction is required.

Customized templates are helpful in assessing partial ear defects and for unilateral total ear reconstruction. Standardized templates are less sympathetic to the individual features of the contralateral normal ear but support the fabrication of frameworks that can be replicated time and again, and they are helpful in providing a basis for bilateral total ear reconstruction.

Three-dimensional silicone models are made by taking an impression of and replicating the contralateral normal ear, and then creating a mirror image of this model. These models not only recreate the complex depressions and ridges on the lateral surface of the ear but also provide additional information on the degree of projection of the ear. Both templates and models can be sterilized for use intra-operatively as a guide for cartilage framework fabrication and surgical incision design for the creation of soft-tissue cover over the framework.

Principles of ear reconstruction surgery

Partial ear reconstruction may require the replacement of one or both components of cartilage and skin cover. Cartilage support is more important in defects affecting areas that provide length or width stability for the ear framework, such as the helix and antihelix. In addition, cartilage replacement in highly contoured areas on the lateral surface of the ear improves the aesthetic appearance of the reconstruction. Isolated cartilage loss in the concha causes minimal framework instability, hence conchal cartilage is often a preferred source of grafts for reconstruction of small defects.

Figure 96.6 **(a)** Standardized 2D template, with the position and proportions of key structures as described for the ideal ear according to Tolleth.[3] **(b)** Silastic 3D model produced from the remaining normal ear in a patient with unilateral deformity. This may be reversed to act as an intra-operative model during reconstruction. **(c)** Overlay of the template on the ear model to show that the standardized template, although well-proportioned, may not accurately reflect the appearance of the contralateral normal ear.

Costal cartilage is available in larger volume and provides much higher structural rigidity than conchal cartilage. It is thus ideal for framework fabrication in total and subtotal partial ear reconstruction as it is able to withstand the deformational forces generated by scar contracture of the skin and soft tissue used for draping the framework.

Alloplastic materials such as shaped silastic and high-density porous polyethylene implants are also able to provide good mechanical strength when used as support in ear reconstruction. However, the use of silastic ear implants is associated with a significant risk of implant exposure and infection and is therefore not recommended.[20, 21] Porous polyethylene (Medpor®) is a biocompatible material that allows host tissue ingrowth for better tissue integration, but it has also been shown to have a high exposure rate of 44% unless fully enveloped by a large well-vascularized temporoparietal fascial flap, decreasing the rate of exposure to 7%.[22] These implants are also prone to fracture which may be difficult to detect.

Defects of skin only on the medial (cephalic) surface of the ear can usually be repaired by direct advancement of the mobile skin in this area of the ear (see 'Structure' above). A consequence of significant skin advancement in this area is a decrease in projection of the ear, loss of the postauricular sulcus and ear asymmetry. Skin on the lateral surface of the ear is adherent to the underlying perichondrium, thus traumatic lacerations and cancer excisions in this area tend to cause cartilage exposure. Skin defects in this area may be reconstructed by converting it to a full-thickness defect that is closed directly (e.g. a wedge excision if the defect is sited at the helical rim). Alternatively, the underlying cartilage may be excised (e.g. if the defect is sited at the scapha or concha) to produce a vascular bed suitable for a full-thickness skin graft. Skin grafts are ideally harvested from the head and neck area for a better colour match. Caution should be paid to cartilage excision in this way, as there is a high risk of causing a secondary ear deformity if medium to large sections of cartilage are removed which compromise the structural support of the ear.

Skin-cartilage defects and full-thickness defects of the ear may be reconstructed with local, random-pattern cutaneous or chondrocutaneous flaps, which may be used in combination with a structural framework. For example, a large, full-thickness middle-third defect involving the helix and antihelix requires the replacement of contoured cartilage support and flap cover for more than twice the surface area of the skin deficiency. This provides skin cover for the medial surface of the framework, as well as taking into account the increased area required for draping over the ridges and depressions of the lateral surface.

Patients undergoing subtotal and total ear reconstruction require skin or fascial flaps over the ear framework which provides vascularized soft-tissue cover. The amount of cover needed depends on the height, width and depth (thickness) of the framework constructed. A more complex and detailed framework exhibits more anatomically accurate features and may include a conchal bowl, which increases the thickness of the frame and hence the surface area of the soft-tissue cover required. The local hairless mastoid skin at the site of intended reconstruction is the workhorse for frame cover. When this is not available (e.g. in burns) or limited (e.g. in patients with low hairline), then the temporoparietal fascial flap with an overlying skin graft is used to cover the lateral surface of the framework. Usually, there is insufficient vascularized soft tissue to envelope both the lateral and medial surfaces of the framework adequately in a single procedure. Ear reconstruction is therefore often staged and provision of soft-tissue cover for the less visible medial surface is left for a later procedure.

It is essential for skin or fascial flap cover to be well-vascularized, as autologous cartilage frameworks are large avascular grafts containing chondrocytes that rely on the surrounding soft tissues for nutrient and oxygen delivery. Secondary vascularization from these soft tissues also improves framework stability through fibrous scar formation and aids long-term frame retention.

Timing of ear reconstruction

The majority of paediatric ear reconstruction is indicated for congenital deformity and is a primary subtotal or total reconstructive procedure. By 5 years of age the ear of the child achieves 87% of the adult size, and by 12–13 years 98% of adult ear size is reached.[23] The complex nature of the Nagata costal cartilage framework requires a large volume of costal cartilage to fabricate the frame. He proposes that children are offered a two-stage ear reconstruction after the age of 10 years and when they achieve a horizontal chest circumference of ≥60 cm at the level of the xiphoid.[24] Brent believes that the timing of reconstruction should take into account the psychological effect of childhood teasing which starts at 7–10 years of age and the physical growth of the child until a substantial amount of costal cartilage is available.[25] He produces a simpler framework for his three- or four-stage ear reconstruction, and 40% of his patients undergo their first operation at 5–6 years and another 40% at 6–10 years of age. The ability of the child to cooperate with post-operative care is also a key factor in the choice of timing to proceed with reconstruction.

The timing of adult partial ear reconstruction depends on the size and cause of the ear defect, and on patient preference. Reconstruction after cancer excision is dependent on the clearance margins and the need for adjuvant radiotherapy. If primary autologous reconstruction is carried out immediately after tumour excision, adjuvant radiotherapy is deferred for at least 4 weeks to allow time for wound healing and vascularization of the cartilage framework. Delaying ear reconstruction for 12–24 months after cancer removal provides time for regular evaluation for locoregional recurrence in patients with high-risk tumours or narrow excision margins. Traumatic lesions after bite injuries are ideally closed or skin grafted initially due to an increased risk of wound infection. Small defects after traumatic or wide-margin cancer excision benefit from early reconstruction. If delayed reconstruction is planned, a period of 3–6 months will allow time for soft-tissue induration to subside and scarring to mature.

PARTIAL EAR RECONSTRUCTION

It is useful to classify partial defects of the lateral surface into those that affect the upper third, middle third and concha, and the lower third of the ear. Upper-third defects are easily visible and may involve the helix, superior and inferior crus, and superior antihelix, which are features that provide structural support. Priority is given to preservation of the junction of the anterior helix with the scalp, which is important for spectacle retention. Small skin-only defects in the upper third may be closed directly with minimal deformity. Medium-sized lesions may be reconstructed with local skin flaps or converted to a full-thickness triangular excision and a closing chondrocutaneous wedge performed (**Figure 96.7**). The apex of the wedge ideally extends into a depressed area of the lateral ear contour and the cartilage in this area requires debulking as part of a dog-ear reduction. Wedge excision reduces the height and changes the shape of the ear. It also tends to cause a 'cupped' appearance of the auricle, which is corrected by the use of accessory triangles at the apex. In order to minimize altering the shape and prominence of the ear, the Antia-Buch technique is used for helical lesions and advances chondrocutaneous flaps from the crus and tail of the helix into the defect (**Figure 96.8**).[26] The flap encompassing the helical crus is only mobilized using V–Y advancement if the defect is large. Large defects causing substantial loss of ear height and defects associated with the loss or deformity of the helix at the junction of the anterior helix with the temporal scalp will benefit from reconstruction with the use of a cartilage graft for support and appropriate soft-tissue cover. This complex reconstruction can be performed in one or two stages.

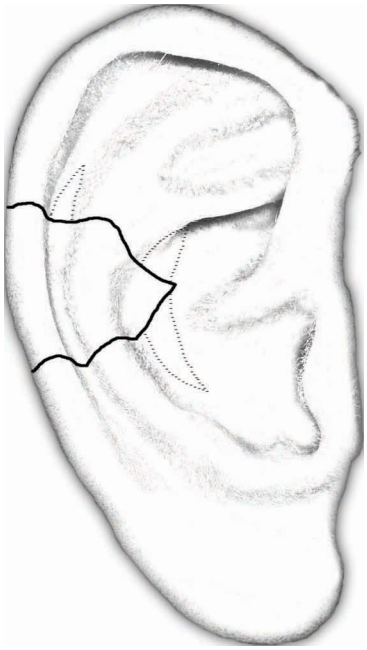

Figure 96.7 Wedge excision with refinements. The apex of the wedge ideally extends into a depressed area of the lateral ear contour and the cartilage in this area requires debulking as part of a dog-ear reduction. Wedge excision reduces the height and changes the shape of the ear. It also tends to cause a 'cupped' appearance of the auricle, which is corrected by the use of accessory triangles at the apex of the wedge.

Defects of the peripheral middle third of the ear involving the helix and antihelix, which provide structural support, are therefore treated differently from isolated defects involving the concha only. Additional cartilage support is not required if either the helical or antihelical ridges remain intact. Options for managing peripheral middle-third defects include:

- direct closure
- wedge excision and closure
- local or regional skin flaps, e.g. bipedicled tubed flap for helical defects, retroauricular (mastoid) flap of Dieffenbach[27]
- helical and conchal chondrocutaneous advancement flaps, e.g. Antia-Buch flap (**Figure 96.8**)

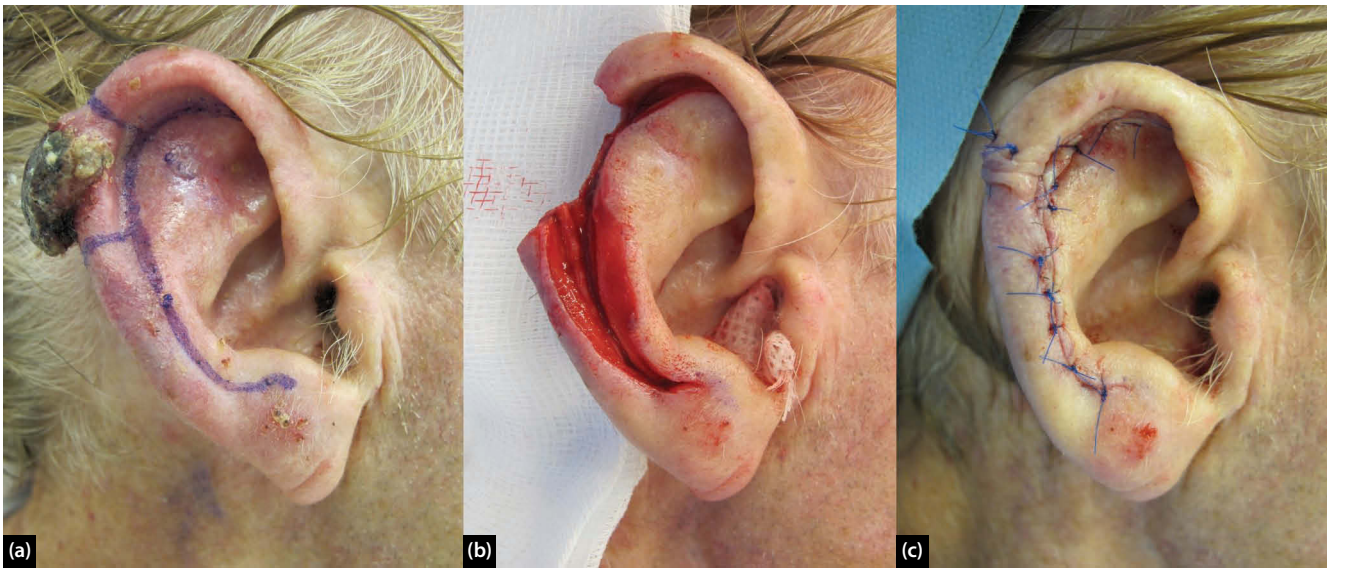

Figure 96.8 Antia-Buch helical chondrocutaneous advancement flap. This composite flap reconstruction is ideal for defects on the outer margin of the upper third of the external ear, and involves local transposition of the crus and anterior helix. Larger defects may require the additional local transposition of the tail and posterior helix, as shown.

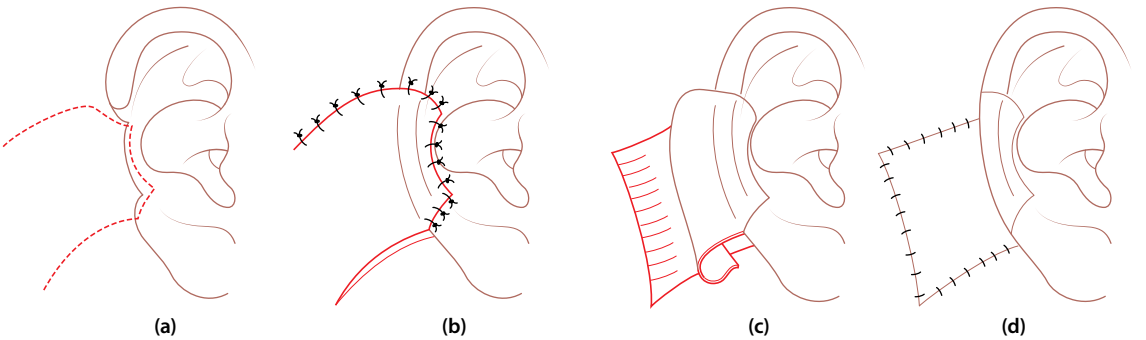

Figure 96.9 Dieffenbach postauricular flap with costal cartilage graft.

- cartilage graft in combination with a local or regional flap, e.g. Dieffenbach flap (**Figure 96.9**).

Skin-only conchal defects can be skin grafted if the perichondrium is intact. Exposed conchal cartilage may be excised to facilitate a vascular bed suitable to receive a skin graft. Due to the depressed contour of the concha, a soft bolster over the inlaid skin graft can be used to ensure adequate contact of the skin graft with the underlying soft-tissue bed. Alternatively, skin and cartilage defects of the concha may be reconstructed with a postauricular revolving-door flap.[28] It is not essential to replace the cartilage in these defects.

Lower-third ear defects include those that affect the earlobe and the antitragus. The antitragus is not a cosmetically sensitive area and isolated lesions here are uncommon. They can usually be managed by cartilage excision and direct closure or local transposition flap. The earlobe contributes significantly to the overall aesthetic appearance of the ear and defects or deformities in this area are often noticed by the patient and surrounding observers. A number of different one- and two-stage techniques utilizing local flaps have been described for earlobe reconstruction. Applying skin graft to lateral defects of the earlobe is less aesthetic and may be associated with graft contracture resulting in a persistent deformity. In order to avoid this, a cartilage batten graft sized and shaped to that of the ideal earlobe is inserted in a subcutaneous pocket deep to the flaps. Grafts used in this way are sourced from the concha, costal cartilage and nasal septum.

AUTOLOGOUS TOTAL EAR RECONSTRUCTION

The key steps for carrying out autologous total ear reconstruction are:

1. Identifying and marking the ideal site for the new ear
2. Making a 2D template and/or a 3D model for cartilage framework fabrication
3. Planning of soft-tissue cover, including skin incisions and flaps at the ideal site for the new ear
4. Costal cartilage harvest

5. Removal of remnant fibrocartilage in microtia or deformed cartilage
6. Dissection and preparation of skin and/or fascial flaps to receive cartilage framework
7. Formation of costal cartilage framework
8. Insertion of framework and inset of overlying soft tissues
9. One or more further stages of ear reconstruction, including framework elevation.

Patients are marked using the upper border of the EAM and inferior orbital margin to determine the Frankfurt horizontal as a line of reference. The upper border of the new ear is marked one ear length posterior to the most lateral point of the eyebrow on a line parallel to the Frankfurt horizontal. The lower border of the new ear should be located at the level of the upper lip, with the ear reclined posteriorly by 20 degrees along its axis.[29]

Costal cartilage for framework fabrication is harvested from the costal margin. The amount of cartilage required is estimated from the features of the template or model. Typically, three or four costal cartilages are used, including an area of synchondrosis from the 6th and 7th costal cartilages. When harvested without perichondrium, the form of the costal margin may be restored by returning diced unused cartilage into the perichondrial sleeves.[30]

Different techniques for autologous ear reconstruction are in use around the world. The most popular current techniques for microtia are those of Brent, Firmin and Nagata, and modifications of these.

The four stages of the **Brent ear reconstruction** technique are shown in **Table 96.1**.[25]

The **Nagata ear reconstruction** technique condenses the steps of the Brent technique into two stages by the utilization of local transposition flaps, with the preservation of a subcutaneous pedicle for the skin flap overlying the cavum concha of the new ear. Nagata also advocates the construction of a detailed and complex costal cartilage framework.[31] Stages of this technique are detailed in **Table 96.2** (see **Figure 96.10**).

Firmin ear reconstruction is a two-stage reconstruction technique adapted from Nagata, but which differs from Nagata in the approach to soft-tissue cover. She describes four types of skin approach for the placement of a cartilage framework in total or subtotal ear reconstruction (**Table 96.3**) and does not utilize any subcutaneous pedicles for the skin flap overlying the framework.[32] Firmin further classifies the costal cartilage framework fabricated according to the structural features that require reconstruction (**Table 96.4**).[32] Two projection pieces are added to the framework to increase the depth of the framework and accentuate the contours of the lateral surface of the new ear. 'P1' links the tragus and helical crus and provides stability to the anterior frame. 'P2' is placed under the base plate deep to the antihelix.

A comparison of the three types of costal cartilage framework is shown in **Figure 96.11**. Costal cartilage frameworks are typically carved with sculpture knives in component parts according to the templates or models and then assembled. These components, such as the helical piece, are held rigidly in place with the use of monofilament 38-gauge stainless steel wires which have high tensile strength and modulus of elasticity. This prevents displacement of the component pieces of the framework and facilitates framework vascularization and fibrous healing. The frames are made smaller than the intended size of ear reconstruction to take into account the thickness of the soft-tissue layer that is draped over it.

The cartilage framework is elevated to create ear projection and a postauricular sulcus as a separate surgical procedure 3–6 months after the frame is inserted. The ear projection produced is better maintained using a costal cartilage strut between the mastoid area and the framework in the postauricular sulcus. Vascularized soft tissue such as the temporoparietal fascial flap with an overlying split-thickness skin graft is used to sustain this cartilage strut. Alternatively, full- or split-thickness skin grafts, with or without mastoid fascial flaps, are used to reconstruct the medial (cranial) surface of the cartilage framework and postauricular sulcus. The latter technique is associated with a higher incidence of retraction of the sulcus so formed, resulting in a loss of ear projection.

TABLE 96.1 The four stages of the Brent ear reconstruction technique

Surgical stage	Description of surgical procedure
1	Carving and insertion of simple two-piece costal cartilage framework at the ideal site for the new ear
2	Ear lobule transposition and insertion of inferior framework into bivalved lobule
3	Framework elevation and full-thickness skin graft to medial surface of the new ear
4	Formation of tragus with contralateral composite conchal cartilage graft and full-thickness skin graft to concha

TABLE 96.2 The two stages of the Nagata ear reconstruction technique

Surgical stage	Description of surgical procedure
1	W-shaped skin incision with central subcutaneous pedicle for creation of neoexternal auditory meatus and local flap for the lateral surface of the earlobe
	Carving and insertion of seven-piece costal cartilage framework at the ideal site for the new ear – includes one tragal piece and two conchal pieces
2	Framework elevation supported in place with two- to four-piece costal cartilage strut
	Posteromedial surface of the new ear and cartilage strut covered with temporoparietal fascial flap and thick split-thickness skin graft

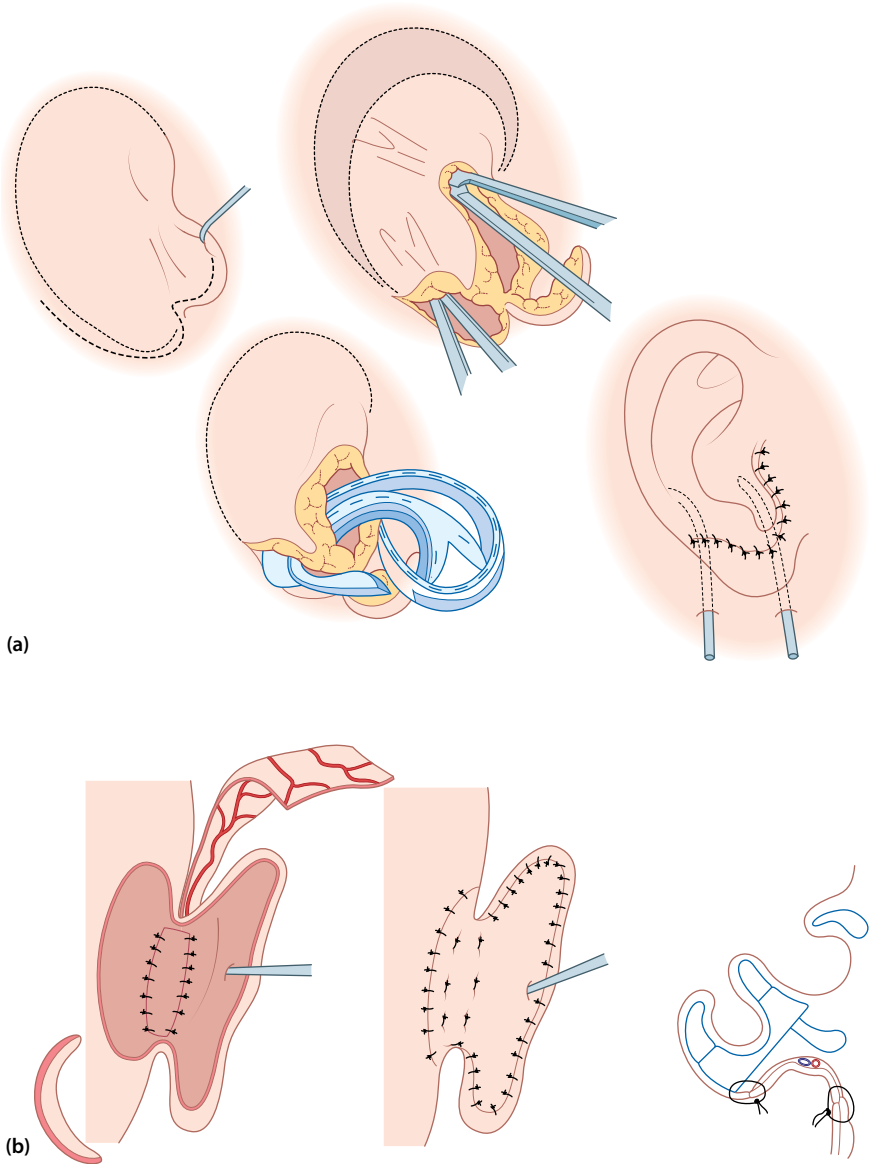

Figure 96.10 Schematic drawing of Nagata two-stage ear reconstruction procedure. (a) First stage, **(b)** second stage.

TABLE 96.3 Classification of the four types of skin approach for the placement of a cartilage framework after Firmin

Type of skin approach	Description of skin incision
1	Z-plasty skin flaps modified from Nagata
2	Transfixion skin flap, where the microtia skin envelope is released superiorly then transposed inferiorly and bivalved to accept the caudal portion of the cartilage framework
3a	Skin incision at the upper scapha of a deformed ear, where there is adequate skin cover for one-stage cover of the lateral and medial surfaces of the ear reconstruction
3b	Skin incision is placed at the anterior border of the microtia skin envelope or the mastoid hairline, where the microtia remnants are absent or not in a position to facilitate transposition or transfixion flaps

TABLE 96.4 Classification of the types of costal cartilage framework after Firmin

Type of cartilage framework	Description of framework
1	Complete framework with antitragus and tragus
2	Framework without tragus
3	Framework without antitragus and tragus

COMPLICATIONS OF EAR RECONSTRUCTION

Soft-tissue necrosis secondary to ischaemia of the covering skin and fascial flaps may occur. As a consequence, exposure of the cartilage framework may ensue that requires timely coverage with available local flaps. Infection of the cartilage framework may result from exposure and

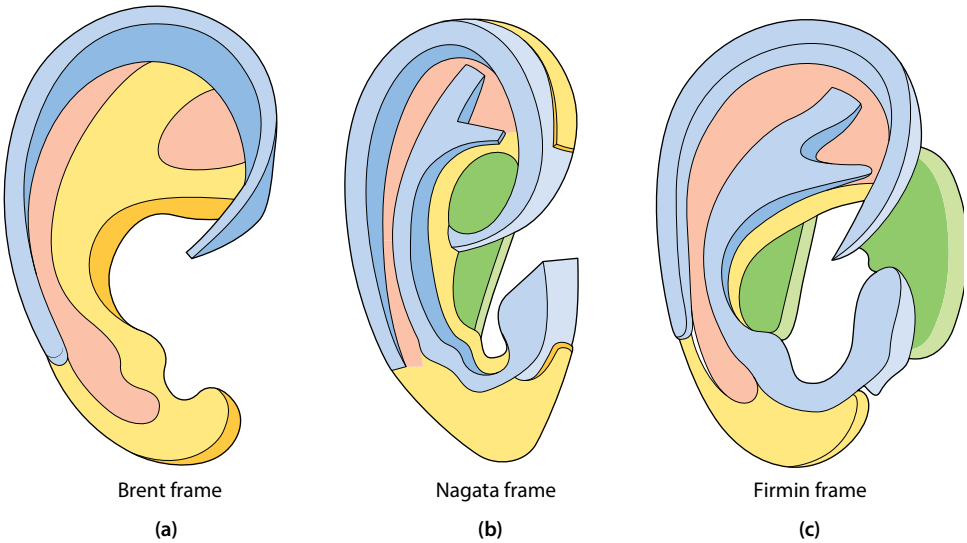

Figure 96.11 Comparison of the Brent, Nagata and Firmin costal cartilage frameworks. **(a)** The Brent framework consists of two layers of carved costal cartilage: a base plate (yellow) from which the antihelix is carved, and a separately carved helical piece (blue) which is then secured to the base plate. Note the concavity of the scapha and triangular fossa (orange) which is used to accentuate the prominence of the antihelix. **(b)** The Nagata framework is more complex and builds upon a carved base plate (yellow) with separately carved helix, antihelix (blue) and tragal (blue) structures which are secured onto the base plate with stainless steel wires. In addition, the root of the helix is anchored deep to the base plate to create depth in the concha and additional carved pieces for the cymba concha and cavum concha (green) are anchored to the underside of the base plate to enhance the 3D features of the reconstructed ear. **(c)** Firmin also uses separately carved pieces of costal cartilage to recreate the helix, antihelix and tragus (blue) on top of a base plate (yellow). However, the tragus produced is of less depth and the root of the helix is less prominent. Two other pieces of cartilage (green) are secured to the underside of the base plate and are used to create depth in the concha (P1) and anchor the positions of the helix and tragus (P2).

is a devastating complication that may require removal of the framework. Wire extrusion from the framework and alopecia along scalp incision scars may also occur. Harvest of costal cartilage grafts is associated with a small risk of pneumothorax which must be checked with a Valsalva manoeuvre before closure of the chest incision.

SUMMARY

- Successful reconstruction of a partial ear defect demands meticulous analysis of the deficit and knowledge of key structural features which would benefit from cartilage replacement.
- Aesthetically pleasing partial ear reconstruction is based upon a sound understanding of the donor sources for cartilage replacement and the available options (based on vascular anatomy) for local skin and fascial flaps.
- Surgeons intending to perform subtotal or total ear reconstruction need to be attentive to details throughout the planning process, including the intended proportions of the new ear.
- Careful consideration should be paid to the formation of an anatomically accurate framework and the design of surgical incisions for local flaps used to protect and sustain it.
- In order to ensure familiarity and competence with the equipment required for autologous ear reconstruction (e.g. stainless steel wires and sculpture knives) and with the handling of the costal cartilage graft used, it is recommended that a period of training is undertaken.

BEST CLINICAL PRACTICE

- ✓ Acquire the appropriate training and expertise.
- ✓ Ideally, work within a multidisciplinary team able to offer the option of prosthetic reconstruction and psychological support.
- ✓ Audit your results.

FUTURE RESEARCH

There is poor quality of evidence available for partial and total ear reconstruction techniques. This is because of the myriad different techniques which have been published, often to address the variable types of partial defects and congenital ear anomalies presenting to the ear reconstruction surgeon. In addition, international standardized outcome measures for surgery are absent, making it difficult to run surgical trials. Further research should involve the development of and consensus for international outcome measures. Subsequent case series using a consistent technique and reporting these outcomes will allow comparison between techniques and centres of excellence.

KEY POINTS

- Intimate knowledge of the anatomy, features and location of the ear is essential for the ear reconstruction surgeon.
- Ear reconstruction is best performed with the support of a multidisciplinary team.
- Partial ear reconstruction should take into account the aesthetic significance of the area to be reconstructed and whether structural support is required for reconstruction.
- Surgery for autologous total ear reconstruction is technically demanding and usually performed in stages.
- An anatomically accurate costal cartilage framework providing structural support and overlying vascularized soft-tissue cover is essential for autologous total ear reconstruction.

ACKNOWLEDGEMENTS

The author would like to thank Mr Lok Huei Yap, Consultant Plastic Surgeon at Prince's Court Medical Centre, Malaysia, for his advice on the structure of the chapter; Southampton General Hospital Medical Photography Department, for assistance with photography of the male model; and Royal Victoria Infirmary, Newcastle-upon-Tyne Medical Photography Department, for their assistance with photography of the 3D ear model.

SEARCH STRATEGY

The references in this chapter are supported by a Medline search and a manual search of maxillofacial technical journals using the key words/phrases facial prostheses, maxillofacial prosthetics, rehabilitation, facial defect, prosthesis and implants and extra-oral implants.

INTRODUCTION

In our increasingly body-conscious society, there is a stigma attached to disfigurement. Acquired facial defects, especially after radical surgical operations, very often result in huge functional, cosmetic and psychological deformity in patients.[1] Complex prosthetic rehabilitation, such as the midface, is necessary as alternative treatment when facial defects cannot be surgically fulfilled.

A team consisting of maxillofacial surgeons, plastic surgeons and restorative dentists play an important part for the success of the final outcomes. Surgical reconstruction of these defects is frequently limited due to unfavourable conditions, such as vascularity following radiotherapy and insufficient residual soft and hard tissues.

Facial prosthesis using dental implants and bars or magnets are the preferred choice of retention methods in the replacement of missing hard and soft facial tissues. Nose, eye and ear form, colouration and texture must be as unnoticeable from the surrounding natural tissues as possible. Rehabilitation efforts can be successful only when patients can appear in public without fear of attracting unwanted attention.

The quality of life of patients with severe deformity or even head and neck cancer patients prior to maxillofacial prosthetic rehabilitation can be low, but little or no evidence is currently available to assess the impact facial prosthetics can have following surgery.

HISTORY

The use of prosthetics has been well documented throughout history. The use of facial prostheses was first reported in ancient Egypt. Evidence documented historically comes from the 16th century,[2] when a French surgeon Ambroise Paré described the first nose prostheses from gold, silver and 'papier mâché', which were held to the face by a string tied around the back of the head.[2]

It was not until the beginning of the 19th century that successful nasal reconstruction was reported in India[3] and only at the end of the 19th century did plastic surgery begin to provide an alternative to facial prosthetics.

In the 20th century, while the quality of realistic craniofacial prostheses was considerably improved with the introduction of silicone materials and greater expectations from patients, the problem of their retention, which is important for aesthetics, function and comfort, was not entirely solved.[4]

Prostheses were used for defects which could not be surgically reconstructed or for patients whose treatment was delayed. Teams of surgeons, working together with dentists,

helped develop new techniques that radically improved the outcome for patients – an early example of multidisciplinary teams, which are now more common in modern-day practice – hence the importance of being treated in a regional centre with specialized surgeons, whether it be for craniofacial, oncological or traumatic rehabilitation.[3]

PATIENT SELECTION

Defects in the craniofacial region can improve the final outcome for patients with facial disfigurement. Careful planning of surgical resections and careful handling of the traumatic defects can influence long-term rehabilitation. The decision to provide a patient with a facial prosthesis should always be carefully evaluated and there are many factors to consider.

Prosthetics should be used to complement reconstructive surgery. The decision to use prostheses rather than autologous materials should be made only after considering all available options. The aetiology of defects is important in deciding the type of treatment and timing of any reconstructive procedures.

The following factors should be considered when planning treatment with facial prosthetics:

- **medical factors** – the patient's physiological status and general health
- **patient factors** – age, dexterity, hygiene, motivation, compliance
- **defect considerations** – use of autogenous tissue, soft-tissue cover, skin condition, defect shape to allow optimum prostheses positioning, availability of bone for implant placement, support for prostheses, facial movement during function, previous radiotherapy.

USE OF IMPLANTS IN PROSTHETICS

Facial

It was Brånemark who first placed a modified extraoral implant for a bone-anchored hearing aid (BAHA) in 1977 and for a bone-anchored auricular prosthesis in 1979.[5]

The benefits of implant-retained prostheses have been recognized for many years and have changed the concepts of maxillofacial prosthetic rehabilitation. Osseointegrated implants are widely used for the retention of orbital, auricular and nasal prostheses. Extraoral implants (3 mm or 4 mm) should generally be used in auricular defects, as the bone in that area is fairly thin, and dental implants used for orbital and nasal defects due to the length of the implant.

Their use reduces the need for adhesives and any related problems such as discolouration and deterioration of the prosthetic material. Osseointegration has allowed predictable retention of prostheses. However, it is not suitable or desirable for all patients and on its own will not guarantee an acceptable aesthetic result. All prosthetic and surgical options need to be evaluated by the team, including the patient, to achieve optimum results.

Osseointegrated implants have various advantages over either adhesive or spectacle-retained prostheses for the reconstruction of facial defects. They provide better retention, so that the prosthesis is properly positioned and the patient can wear it more confidently. There is no skin irritation from adhesive and the prosthesis does not need to have adhesive cleaned off each time it is used, which increases the deterioration of the materials used. The edges of the prosthesis can be made thinner and feathered, blending better into the skin, which offers the patient enhanced aesthetics.

A pre-operative planning meeting with the patient and multidisciplinary team provides the opportunity not only to consider different prosthetic options but also for the patient to ask the prosthetist questions about aftercare, such as cleaning of the abutments and prosthesis. Development and application of osseointegrated implants to facial defects has, in part, changed patient perceptions of facial prosthetics. Implants allow convenient and secure positioning of the prosthesis, leading to greater patient acceptance. Patients like the security, comfort and convenience of implant-retained prostheses, benefits that are not attainable with earlier methods of retention. Surgeons have come to appreciate the reduced need for numerous complex surgical reconstructive procedures in many of these patients.

For large defects, a multidisciplinary approach is recommended, combining flap reconstruction and implant-retained prosthetic rehabilitation to achieve optimal results.

Although implants are the 'gold standard' for rehabilitation, earlier reports have shown that implants are not uniformly successful and the failure rates in some patients/sites are quite high.[4] The failures and complications appear to be site-specific and radiation- and time-dependent, although implants have been used successfully in patients who have had vascularized and non-vascularized bone and soft-tissue grafts to the jaws and facial skeleton.

It has been suggested that careful selection of patients and pre-surgical planning are necessary to achieve predictable outcomes when using primary placement, and close teamwork between oncological surgeons and the maxillofacial prosthetics department is vital.[6]

Midfacial

Midface defects can be divided into two major categories:

- **midface defects**, which include the nose and/or the upper lip
- **lateral defects**, which include the cheek and the orbital contents.

The choice between surgical reconstruction and prosthetic rehabilitation of large facial defects remains a difficult one and depends on the size and aetiology of the defect, as well as on the wishes of the patient. The aims of surgical and prosthetic rehabilitation are for the replacement of missing soft and hard facial structures while giving patients

TABLE 97.1 Comparison of surgical and prosthetic rehabilitation

Rehabilitation	Advantages	Disadvantages
Surgical	Uses patient's own tissue Reconstruction at same time as resection may be possible More acceptable to patient Does not require prosthetic maintenance/ replacements	No visual access for inspection of defect site (for tumour patients) May require multiple procedures Variable aesthetic result: depends on quality of host site Separate donor site often required
Prosthetic	Immediate temporary reconstruction Inspection of defect (tumour patients) Predictable results Easily modifiable Does not preclude future surgical reconstruction Immediate temporary reconstruction	Non-mobile tissue Requires skilled prosthetist Long-term follow-up required Replacement prosthesis required

a better quality of life along with social acceptance. **Table 97.1** summarizes the advantages and disadvantages of surgical and prosthetic rehabilitation.

The use of osseointegration in the midface region can dramatically improve anchorage and enable complex and movable connections to be accommodated within the prostheses.[7]

Placing fixtures at the time of ablative surgery gives great advantages. It significantly reduces the time before prosthetic rehabilitation can commence. Fixtures are placed in bone prior to any radiotherapy, in so doing increasing implant osseointegration and survival rate. Implants are best placed in areas where bone quality has not been compromised and still has a good thickness available. It is often necessary to trim back thin bone to allow placement into thicker denser bone. Intraoral fixtures should always be used to take advantage of as much depth of bone in the premaxilla as possible. It can be advantageous to utilize zygomatic implants which use good quality bone at distant sites.[8] Patients will also generally see the prosthetist as early as possible so that impressions can be taken of the facial structures prior to ablative surgery. This enables a template to be constructed for use as a starting point in reconstructive planning of the lost tissues.

AETIOLOGY OF FACIAL DEFECTS

The diagnoses which are indicated for surgical treatment are divided into three main categories:

- congenital
- trauma
- disease

} acquired

Congenital defects

Congenital defects include the absence of:

- the ear (microtia)
- the nose (arhina)
- the eye and orbits (anoptholima).

In patients with congenital defects, treatment is an elected decision which can only be made by the patient when provided with all the relevant information and the ability to meet and talk to patients previously treated. This gives a balanced, informed view of potential treatment options. It is, of course, possible that the patient may accept the defect, or is unwilling to undergo any possible treatment.

Acquired defects

Acquired traumatic defects include those caused by:

- road traffic accidents
- thermal injuries
- ballistic injuries
- accidental injury
- physical assault.

Acquired surgical defects can be created by removal of benign and malignant tumours. Patients with acquired defects have to come to terms with a sudden change of appearance. Cancer patients will also have the psychological worry of dealing with potential life-threatening conditions, for which the treatment can involve the loss of vital structures and create potential impairment of function, such as sight, hearing, swallowing, speech, taste and smell. Every effort should be made to use the patient's own tissue and, if necessary, surgical procedures are undertaken in stages until the optimum result is obtained. If surgery is not possible (or will involve multiple procedures with an unpredictable result), prosthetics can be considered.

For patients with tumours, the defect size is determined by the amount of tissue that has to be removed during ablative resection. How the defect is left is of paramount importance if a prosthetic is to be used as it will determine the final aesthetic result. Ideally, thin skin cover is always preferable as this allows for an optimum interface between defect and prosthesis. Bulky flaps are to be avoided as they restrict contouring and positioning of prostheses and will not allow mirror imaging of existing structures.

Defect reconstruction

The reconstruction of hard and soft tissues is a combination of medicine and art. Major defects in the craniofacial region have challenged the skills of the reconstructive surgeon. The use of microvascular free-flap transfers of

hard and soft tissue in the mandible, maxilla, cranial and midface regions has greatly improved the outcome for patients. Surgical techniques have advanced using autogenous tissues to replace aesthetically difficult areas, such as the nose and pinna.

There may also be the case where a decision not to reconstruct is made. This allows the clinician to look for evidence of any recurrent disease at the defect site, prior to any secondary reconstruction. Alternatively, the defect may be obliterated with a large, bulky flap to close a large surgical cavity. This can have the advantage of creating an oral–nasal seal to allow patients to talk and eat/swallow without problems but a disadvantage is that it has limited or unacceptable aesthetics.

Craniofacial defects should be reconstructed as soon as the patient's condition allows. This is an important factor for all patients, including those with poor prognosis. With the high standard of autogenous and prosthetic techniques available, it is not acceptable for patients with facial deformity to be precluded from as normal a life as possible.

Small soft-tissue defects are reconstructed by covering with skin grafts, deeper defects by the use of local flaps, with larger defects which usually requiring coverage by free flaps. Bony defects are mainly reconstructed by non-vascularized bone graft, provided there is sufficient soft-tissue coverage in non-irradiated tissue. For defects of both hard and soft tissue, a composite flap containing bone and skin is often used. Skeletal fixation is obtained by use of plates and screws. Sites of composite free flaps include iliac crest, fibula, scapula and radius. Radial forearm flaps have a large surface area of skin to volume; this makes them thin and suitable for both intra- and extraoral mucosal or skin defects. The use of bulky flaps can compromise aesthetics and make prosthetic options impracticable. Smaller, thinner flaps and skin grafting may give coverage without compromising prosthetic possibilities.

TREATMENT USING DIGITAL APPLICATIONS

There have been many developments in materials used for the production of prostheses. The advent of percutaneous osseointegrated implants has dramatically improved the potential for retention of a prosthesis. However, many of the construction methods and mould-making have changed, becoming highly skilled and time-consuming. Each prosthesis is individual and the use of high technology has been difficult to adapt or is not cost-effective in some individual cases.

With advances in software applications (manipulation and design) using computed tomography (CT) data, there are programs available which allow 3D simulation of facial reconstructive methods including osteotomy and distraction procedures. Data from medical scanners (CT, magnetic resonance imaging (MRI)) can be used to reproduce physical models of human anatomy via additive layer manufacture (ALM) or rapid prototyping (RP).

Several techniques exist, the most common being stereolithography. The basic principle of creating a 3D structure is to build an object in layers using the CT data and an optical scanning system that deposits a polymeric resin material to mirror the object on screen one layer at a time onto the 'build bed' until the desired object is completed. Each layer of resin is cured using a high-intensity UV light, ensuring the strength of the model.

It is possible to have individual implant templates for either soft tissue or direct bone contact to allow exact implant placement. Precise anatomical models (3D) made by ALM/RP enable surgeons to view and evaluate their treatment plans. On this physical model, osteotomy lines or drilling holes can be indicated and trial surgery can be undertaken. These models are also used for reconstructive procedures. 3D models act as visual aids for the surgical team, indicating the resection lines and allowing the prosthetics team to pre-bend the reconstruction plates. This allows accurate positioning and fixation of the bony flap in the planned location. The applications of these models can be advantageous in facial reconstruction, the production of obturator prostheses for maxillary defects and designing and planning cranioplasties for skull defects.

Improvements in surgical techniques and the advent of specialization have enabled more accurate and aesthetic reconstructions to be performed. While prosthetic materials continue to be improved and refined, these surgical improvements may render a prosthesis necessary in a more limited format. The necessity of treating tumours by ablative surgery in the future may be reduced by other treatment regimes and therefore the necessity to surgically or prosthetically reconstruct these defects could be reduced.

The use of high-technology and digital imaging in processing complex shapes and patterns is now achievable and readily available. In certain circumstances it can produce moulds and patterns that are difficult to duplicate by conventional methods. It remains to be seen whether the use of advanced technology is cost-effective in individual cases or is just another method of obtaining the same result. As with most new techniques, there is a tendency for overuse, and careful evaluation of each individual case should be balanced to obtain the optimum result and cost-effectiveness of the process. However, it is now an essential and welcome addition to the practice of reconstructive surgical and prosthetic techniques.

TREATMENT PROTOCOL

The treatment of a patient with facial or oral cancer or after disfiguring trauma is a collaborative team effort. Free-tissue transfers are habitually used to reconstruct both the soft tissue and bone defect instantly following the ablative surgery. A selected proportion of patients receive radiation 4–6 weeks post-operatively. The type of radiation therapy prescribed by a radiation oncologist depends on many factors, including:

- type of cancer
- size of the cancer
- location of the cancer

- pathological status, i.e. margins, nodal involvement
- how close the cancer is to normal tissues that are sensitive to radiation
- how far into the body the radiation needs to travel
- the patient's general health and medical history
- whether the patient will have other types of cancer treatment
- other factors, e.g. the patient's age and other medical conditions.

The total radiation dose to the tumour bed depends on the presence or absence of microscopic disease at the surgical margin. Radiation positioners are used extensively, and radiation fields are configured to minimize exposure of the major salivary glands to high doses of irradiation. Radiation dose to bone can often be minimized in areas of proposed implant sites.

As a generalization, 6 weeks after ablative surgery patients would receive radiation therapy for 5–7 weeks. Prostheses are generally made as soon as the healing from reconstructive surgery and radiotherapy permit. Whether implants are inserted at the primary stage of surgery may depend on the need for post-operative radiation therapy. At least three intraoral implants of 7–15 mm in length and 3.75 mm in diameter (orbits and nasal defects) would give adequate retention. Ideal placement of the implants depends upon the skill of the surgeon and, where possible, the prosthetist would advise to achieve the best prosthetic outcome.

DEFECT SITES

Nasal

Nasal defects are predominately as a result of tumour surgery or traumatic loss; congenital absence is an extremely rare condition. The goal of reconstruction is to construct an aesthetically pleasing and 'functional' nose. Autogenous reconstruction must address the underlying cartilaginous support, cutaneous coverage and reconstruction of nasal lining.

Acquired defects produce a variety of midface deformities dependent on the extent of traumatic injury or ablative resection. Smaller defects are easier to reconstruct using autogenous methods. The cosmetic anatomy of the nose is classified in five aesthetic units: dorsum, lateral tip, tip, alar lobule and soft-tissue triangle, as described by Burget and Menick.[9]

The majority of acquired defects are confined to skin. Skin grafts from the postauricular or preauricular area are ideal because of colour and texture match in the proximal two-thirds of the nose. The distal tip requires 'thicker' coverage and is usually best reconstructed with a composite flap.

The decision to reconstruct is dependent on the health of the patient, the quality and availability of donor tissue, the presence of any residual disease and patient choice. The defect may also involve orbital and maxillectomy components, and this should be considered in treatment planning.

If the lip is to be sacrificed, it is essential to reconstruct the competent boundaries if possible. This can be achieved by using nasolabial or free flaps.[10] Prosthetic reconstruction is difficult in these cases because of the mobility of surrounding tissue and the functional seal required for lip competence. Large prostheses can be difficult to stabilize and retain.

Orbital or ocular

Any defect that is confined to the globe is treated with an 'indwelling prosthesis', which sits behind the lids. These prostheses, which are self-retaining, have historically been referred to as 'glass eyes', although in the UK they are now always made in acrylic. Defects including the loss of orbital contents and the lids are more extensive and an orbital prosthesis will often be the treatment of choice.

The loss or absence of an eye may be caused by a congenital defect, irreparable trauma, tumour, a painful blind eye, sympathetic ophthalmia, or the need for histological confirmation of a suspected diagnosis. Orbital diseases are relatively rare but, considering the anatomy of surrounding structures, they present a very serious disorder. Depending on the severity of the situation, the surgical management may include one of three approaches: evisceration, enucleation or exenteration. The majority of patients requiring orbital prostheses have acquired defects as a result of tumour surgery. These can also include defects into the maxilla and or nasal area. There are three types of surgery for which prosthetics are required (**Table 97.2**):

- **Evisceration** is a surgical procedure wherein the intraocular contents of the globe are removed, leaving the sclera, Tenon's capsule, conjunctiva, extraocular muscles and optic nerve undisturbed; the cornea may be retained or excised.
- **Enucleation** is the surgical removal of the globe and a portion of the optic nerve from the orbit.
- **Orbital exenteration** is the removal of the entire orbit, usually involving partial or total removal of the eyelids, and is primarily performed in order to eradicate a malignant orbital tumour.

Specific diagnostics is provided by an ocularist; otorhinolaryngologist and dentist examinations are also suitable. Auxiliary imaging methods are also an indispensable part of the diagnostic procedure. These include X-ray images of the skull in dorsoventral, semiaxial and lateral projection. Ultrasonography, CT and nuclear MRI are also frequently employed. According to the specific diagnosis it is possible

TABLE 97.2 Orbital surgery requiring prostheses

Term	Tissue lost	Solution
Evisceration	Cornea	Hepatic/cosmetic shell
Enucleation	Eye	Artificial eye
Exenteration	Eye and orbital contents	Orbital prostheses

to establish precisely the extent of the damage to the eye and surrounding structures in the orbital area and to determine a medical treatment. In the treatment of solid tumours, radical surgery is usually the first step despite the risk of possible functional and aesthetic defects.

The disfigurement associated with the loss of an eye can cause significant physical and emotional problems. Replacement of the lost eye as soon as possible after healing is necessary to promote physical and psychological healing for the patient and to improve social acceptance.

Prosthetic rehabilitation that restores these facial disfigurements may improve the level of function and self-esteem for patients. However, difficulties with facial prostheses arise due to movable tissue beds, quality of prosthesis retention and associated skin reactions to adhesives. The use of osseointegrated implants in the craniofacial region reduces prosthesis limitations associated with medical-grade adhesives and is a treatment option with high long-term success rates.

Facial prosthesis with three dental implants is a method of choice in the replacement of missing hard and soft orofacial tissues. Prosthesis form, colouration and texture must be as indiscernible from the surrounding natural tissues as possible. Rehabilitation efforts can only be successful when patients can appear in public without fear of attracting unwanted attention. Dental implant support gives the patient confidence in society. An important requirement for successful treatment of such handicapped patients is high-quality osseous tissue of defect margins.

Auricular

The indications for an autogenous auricular versus prosthetic auricular reconstruction with osseointegrated implant-retained prostheses were outlined in literature. The choice between the two techniques depends more on the surgeon's training and tradition than on an analysis of which procedure is preferable in a given clinical situation. For example, most children with microtia in the USA are treated with autogenous techniques. In contrast, the same deformities in the UK are more commonly treated with prosthetics. Patients with post-traumatic or post-ablative auricular defects are more often adults and their defects differ from those of children with congenital deformities in several ways. First, the skin loss and scarring resulting from trauma or previous surgery may make standard autogenous reconstruction difficult. Second, the tragus is frequently preserved in the trauma/ablative patient, making the aesthetics of prosthetic reconstruction much more favourable. The presence of a tragus allows the anterior border of the prosthesis to be hidden, which is a major aesthetic benefit.

The incidence of malformation of the external ear is around 1 : 10 000 live births.[11] Auricular defects frequently appear in combination with those of the external auditory canal and middle ear. Unilateral microtia may be associated with facial malformations involving the first and second branchial arch. Unilateral or bilateral microtia can be part of a bilateral condition, such as mandibular facial disostosis (Treacher Collins syndrome).

Children born with congenital defects can invoke feelings of anxiety and guilt, causing the parents to seek an immediate solution. This should be resisted and reassurance should be given to parents with an explanation of potential treatments available. Delay in treatment will allow sufficient growth to occur for an optimum aesthetic result to be achieved and for the child to understand and be involved in the process.[5]

The introduction of parents to other parents of children with the same condition is very useful in allaying fears that their child was the only one with this condition. Patients are best assessed by a multidisciplinary team, which should include specialists in ENT, maxillofacial, prosthetics and plastic surgery. Depending on the severity of the condition, a variety of treatment options may need to be considered.

The importance of hearing to development should never be overlooked or considered less important than aesthetics. It should be treated as a priority and, if necessary, a BAHA should precede ear reconstruction.

A realistic age for successful prosthetics in children is upward of 10–12 years. Our experience is that, before this age, children are not sufficiently developed physically or psychologically to commit to a long-term treatment regime.

Many patients referred for prosthetics have had disappointing autogenous reconstructions. This should not be used as a reason to prevent this option to be explored further, as cooperation between prosthetics and autogenous reconstruction is vital to achieve a balanced and appropriate treatment for the varied range of patients with auricular defects.[12] There have been great improvements in autogenous reconstructive techniques with major contributions by Brent and Nagata.[13, 14] With improved techniques, more consistent aesthetic results can be achieved, but specialization is as important as technique to achieve these standards. The decision to go for the prosthetic option is easier when an autogenous reconstruction is totally impractical, such as the presence of compromised skin or following tumour resection.

Indications for auricular prostheses include:

- lack of autogenous tissue
- irradiated area
- failed autogenous reconstruction
- cancer resection
- absence of the lower half of the pinna
- microtia
- patient preference
- craniofacial anomaly
- traumatic defect.

Microtia cases can predictably be reconstructed with a prosthesis, but they have the disadvantage of long-term follow-up, and treatment can compromise any future autogenous reconstruction by removal of ear remnants or compromise available soft tissue. The amount of ear left (particularly the lower third) or the position and shape of remnants can make autogenous reconstruction a more viable option. There is a role for both options

in auricular reconstruction and the combination of both autogenous and prosthetic options working to complement each other can only benefit patient treatment regimes.

Once treatment is decided upon, careful planning is required to determine the stages and timing of treatment. The prosthetist should be involved in all stages of treatment if prosthetics is the chosen option.

The auricular region was found to be the most dependable implant site. Patients having implants placed for this defect will possibly benefit from having CT scans. This allows for evaluation of the proposed bone sites in an attempt to maximize implant length. The mastoid air cells frequently pose logistical problems at the most inferior auricular implant sites, and occasionally implant position has to be recalculated. Exposure of the air cells at the time of implant placement does not appear to cause any detrimental effects. If there is adequate bone to provide stability, the implant may be left in position; otherwise, a new site will have to be found. The use of two implants in the auricular region reduces the amount of cantilevering and prevents any rotation of the prosthesis, conferring mechanical advantage. All implants are connected with a gold bar which sits above the skin, and retention is achieved with gold clips. Alternative methods can be used, including magnets and/or adhesives.

Oral cavity

Intraoral prosthetics are well documented in technical and dental literature. This section will only cover prosthetics in relation to ablative surgery.

The management of oral cancer requires understanding and skills in assessment, access and ablative and reconstructive surgery. Prosthetic input may be required in dealing with complex and difficult defects. Removal of soft and hard tissue has a dramatic effect on function; small defects can be closed by local flaps, with free-tissue transfer available for larger defects. While surgical reconstruction has improved and is the treatment of choice, there are occasions when prosthetics is a suitable option or if a surgical reconstruction has failed.

The objective of prosthetic rehabilitation in patients with defects of the orofacial region is the restoration of form, function and appearance. In patients with orofacial cancer, a decision should be made as to whether immediate or staged surgical reconstruction is advocated. If possible, a one-stage procedure should be used. Surgery involving the oral cavity will require pre-operative dental checks and any necessary treatment should be undertaken prior to surgery. When a maxillary resection requires an intermediate obturator, impressions are required pre-operatively to enable design and construction of the plate.

The design needs to consider how the plate is to be retained, the approximate extent of the resection and whether any teeth are to be lost or utilized for retention. The type of dressing/pack is important as the type of pack can affect the design of the plate.

In the maxilla, the bony margins and alveolus should be trimmed parallel. The hard palate pterygoid plates and nasal septum should be examined and cut back to provide a smooth, non-sharp surface and, where possible, covered with local mucosa.

Following a maxillectomy, it is important to remove the coronoid process of the mandible as it can dislodge and break the seal of a definite prosthesis.

The surgical plate is essential to immediately restore speech and mastication and to provide support for soft tissue. It must be possible to modify any prostheses at the time of surgery to accommodate any surgical variations that may be necessary.

The obturator is retained by using skeletal wiring or bone screws through the acrylic plate or by clasping to existing teeth. It is possible to use pourable, expandable silastic foam both as a dressing medium and to provide retention by a mechanical attachment to the plate.[5] This technique requires the dental plate to be held in place and the foam is poured or syringed into the defect from above the plate. The foam will expand to fill the defect and connect with the retentive posts that are incorporated into the underside of the plate. The foam can easily be trimmed with scissors to give a flexible and very accurate fitting 'bung' which obturates the defect and provides support and retention to the plate. It is useful to pour a duplicate foam which can be used in the maxillofacial laboratory to replicate further foams which can be used during the healing phase. With practice and help, the patient can quickly learn to remove the plate and separate the foam component for cleaning. This can be performed until the healing is complete and a definitive prosthesis can be provided. The foam is particularly useful during any radiotherapy treatment as its flexibility makes it easy to fit and it is well tolerated by sensitive tissue.

STAGES IN PROSTHETIC CONSTRUCTION

Various technical stages are involved in the fabrication of prostheses (**Figure 97.1**):

- impression
- pattern
- mould
- processing
- fitting.

These include taking an impression of the defect to create a master cast on which a wax pattern is sculpted. This can be adjusted and aligned on the patient to achieve the desired contour and orientation.

When completed, a two- or three-part mould is constructed and, using the lost wax technique, a void is created which is then replaced by the prosthetic material. The materials of choice are silicone elastomers, which are individually coloured to match patient skin shades.

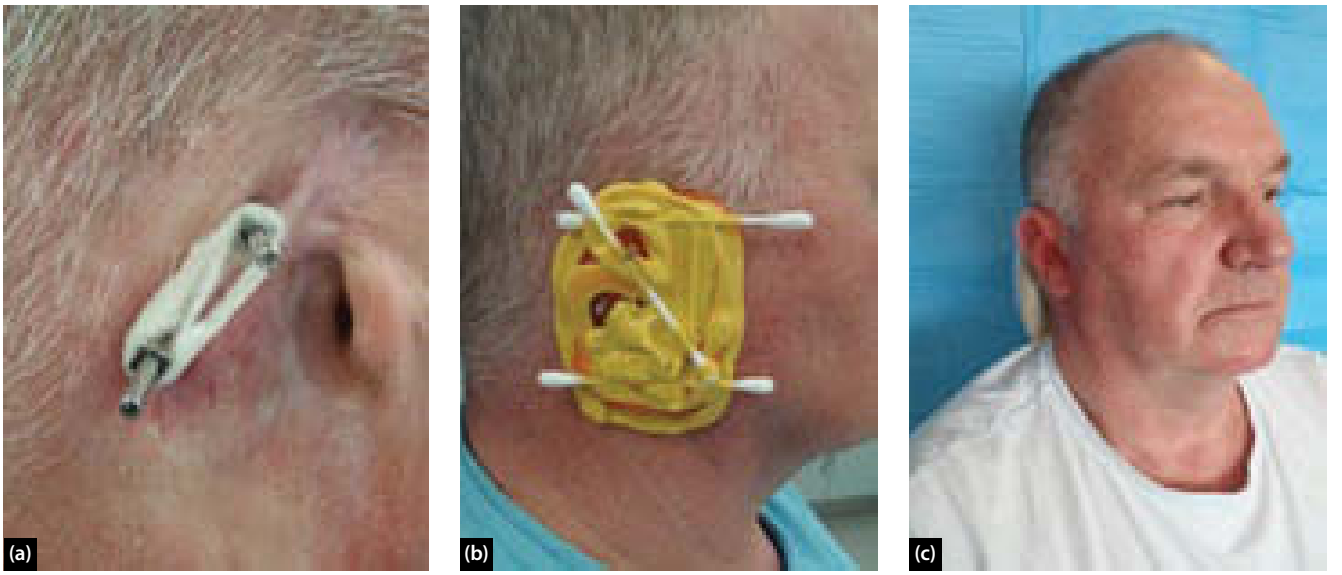

Figure 97.1 Prosthesis construction. (a,b) Impression stage for the fabrication for an ear prosthesis. **(b)** Cotton buds are used to determine the highest and lowest point of the ear to match the opposing side. **(c)** Wax trial of the ear to determine the final position and fit.

FACIAL PROSTHESIS RETENTION METHODS

The success of facial prostheses depends not just on aesthetics but on the retentive qualities. It must be comfortable and give confidence to the wearer. Methods of retention are:

- adhesive
- mechanical/anatomical
- implant.

With some prosthetic devices, retention can be retained by virtue of its anatomical location, for example an artificial eye held in place by the eyelids. This also disguises any margins.

Adhesive

Until the advent of implants, adhesives were often the method of choice for extraoral prostheses, providing good aesthetics if used carefully by a compliant patient. The adhesives used are waterproof and, if correctly applied, the prostheses will remain in position for many hours. Most problems are encountered by the continual fitting and removal of the prostheses. This can have a detrimental effect, particularly on the fine edges of the prostheses. Patients will need a certain amount of dexterity to be able to locate and position the prostheses. The type and quality of the skin can influence the choice of adhesive and the suitability of this technique. Patients with broken or compromised skin are best treated with other retentive methods.

Mechanical/anatomical

Using mechanical retention of facial prostheses is the oldest form of retention. Early retention included spring bands and straps. Current facial prosthetic mechanical methods are generally limited to the use of spectacle frames. Mechanical retention can be incorporated into interlocking intra- and extraoral prosthetic combinations, such as an obturator linked to an orbital prosthesis. Spectacle-retained prostheses are still useful in cases where simplicity and ease of location are of paramount importance. They have a particular application in the elderly and patients who have dexterity problems. The prosthesis is attached to the spectacle frame, which means that the patient is not able to remove their glasses without revealing the defect.

The adjustment of the glasses is important as it will have a direct bearing on the location and fit of the prostheses. Anatomical retention is possible in patients who have favourable undercut tissue areas; soft silicone flanges may be incorporated within a prosthesis to engage these areas.

Obtaining the correct amount of retentive pressure is difficult and care must be exercised not to ulcerate the tissue. This technique is more suited to intraoral defects as obturator-retention extraoral prostheses are more likely to be affected by facial movements, which can cause the loss of margin integrity.

Implant retained

The use of implants provides a stable and secure method of retention which allows very thin prosthesis margins for maximum aesthetics. Used first extraorally in Sweden in 1977, it is an established technique that provides predictable results for patients with various craniofacial defects.[15, 16] Implants allow prostheses to be extremely stable and secure. The prosthesis is generally retained in place by a rigid bar with clips or by magnets incorporated in the prosthesis connecting to magnetic caps on the implant.[17]

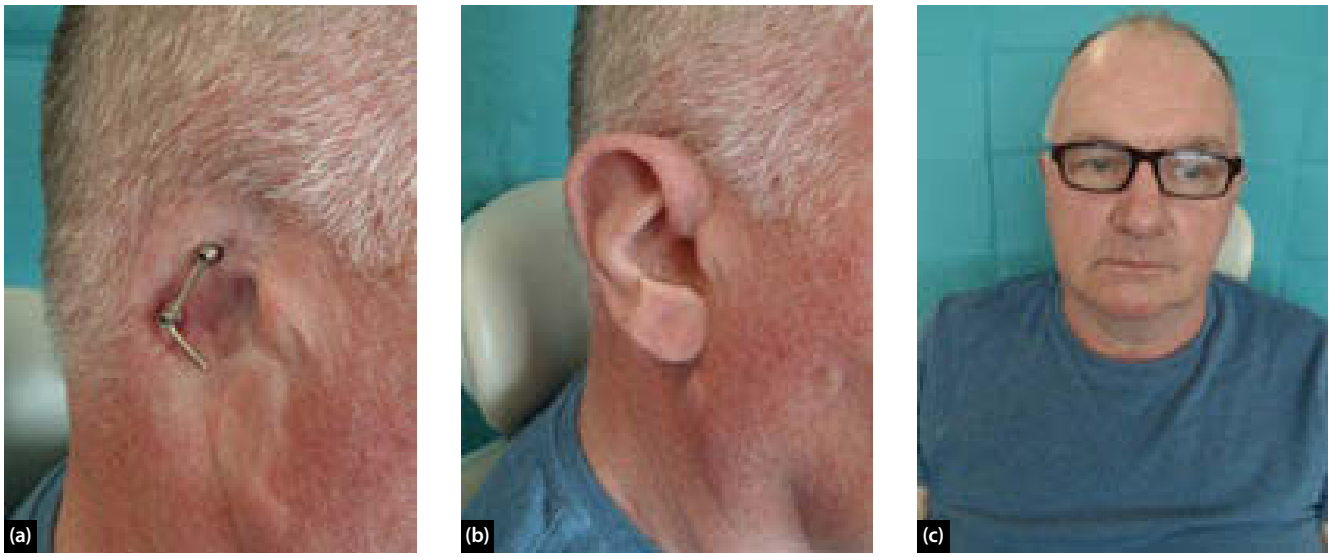

Figure 97.2 Prosthesis retention. (a) Bar design for retention using the bar and clip method. **(b,c)** Finished results.

The number of implants required for retention of the prosthesis is determined by the size and shape of the defect. Auricular defects that involve only the pinna will usually require two implants for adequate retention. This is achieved by a bar splint and clip arrangement (**Figure 97.2**). In cases where bone quality is poor or when tissue is irradiated, it is advisable to place further fixtures as 'sleepers' in case of future failures.

Following fixture placement, the skin-penetrating abutment height and type are determined by the thickness of the tissue and the aesthetic requirements. It can be advisable to place healing abutments initially and then the prosthetist can select the optimum abutment type and size following the healing phase. The abutments are fitted with the appropriate prosthetic components, depending on the retention elements selected for prosthesis attachment. If necessary, angled abutments can be used to aid prosthesis location. In certain cases, prosthetic components can be connected directly to the fixture.

The bar and clip arrangement has the advantage that the clips are adjustable and the bar design can be modified to keep retention components low within the prosthesis. The bar is connected by gold screws into the abutments (**Figure 97.2a**).

Magnets have a role with some patients in auricular cases and retention can be further enhanced by using lip magnets, which have increased resistance to lateral dislodgement. Magnets are particularly useful in orbital and midface cases where bar construction is difficult or complex and location of the prosthesis could be difficult for the patient.

AFTERCARE/PATIENT MANAGEMENT

The choice of prosthetic reconstruction is an ongoing commitment by the prosthetic team and the patient. The patient has to maintain hygiene of the area, particularly if there are skin-penetrating abutments. They have to exercise care in positioning and cleaning the prosthesis and attend for long-term follow-up.

The success of the prosthesis depends on the ability of the prosthetist to design a functional and well-fitting prosthesis. The prosthetist should give instructions on how to position, apply and remove prostheses with any necessary details regarding wearing. It is important that the prosthesis does not restrict the patient's activities and lifestyle. Implant-borne prostheses give the most predictable results but should not be considered the only option.

Dealing with patients with facial disfigurement is very demanding and requires an understanding of patient expectations as well as of what is practical or possible.[18] Patient reactions to facial disfigurement vary greatly. Time spent with patients in consultation is important in building a relationship to enable sensible and practical options to be considered.

Quality-of-life outcomes are now a welcome and vital issue to be considered in patient management.[19] Patients will require lifelong follow-up for maintenance and adjustment of the prostheses, the skin fitting area and implant and abutments in osseointegration cases.[20] The commitment to long-term management must be discussed with the patient.

CASE STUDIES

We would like to thank Mr Nicholas White, Consultant Plastic and Craniofacial Surgeon, University Hospital Birmingham NHS Foundation Trust, for the use of his patients as case studies.

Case study 1

PRESENTATION

In 2011 a 58-year-old female presented with large cylindromas to the scalp, face and ears which had invaded underlying structures (**Figure 97.3**).

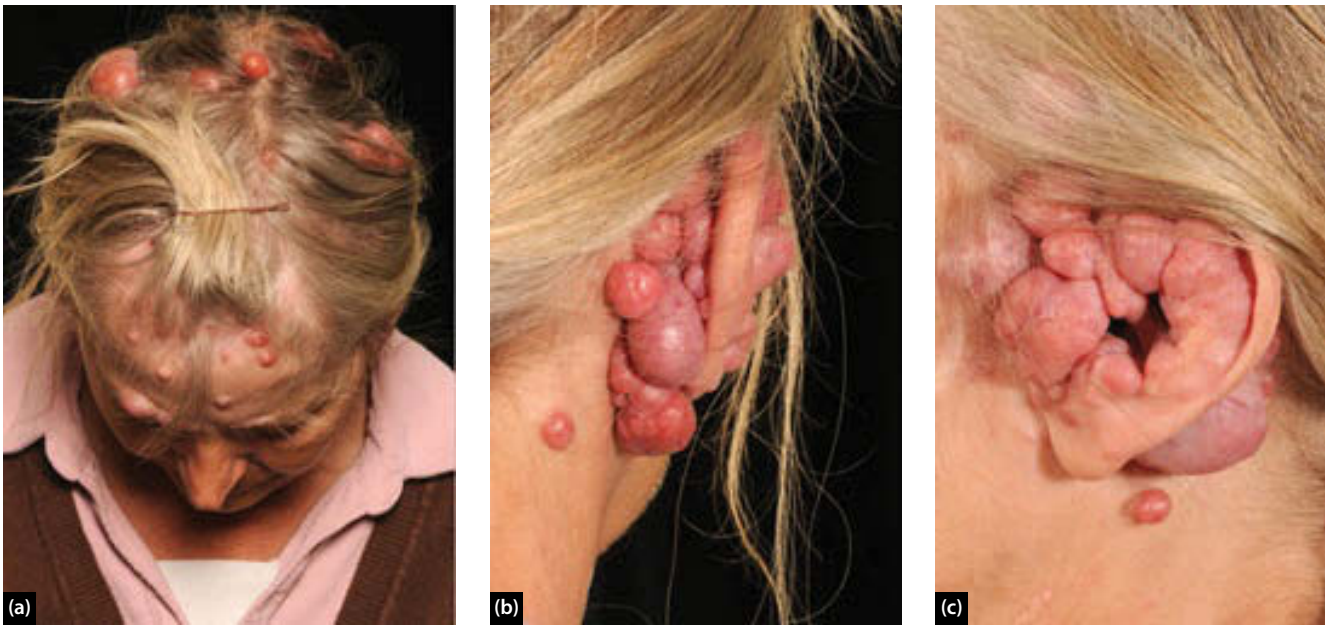

Figure 97.3 Case study 1. The presented cylindroma growth to the scalp and ears.

Figure 97.4 Case study 1. The extent of the lesions pre-operatively.

MEDICAL AND SOCIAL HISTORY

She did not smoke or drink and had no other medical complications. Her manual dexterity was adequate, she had family and was very independent.

IMAGING REPORTS

Imaging reports (CT) showed tumours eroding through the vertex of her skull with a lesion of 12 mm × 12 mm attached to the skull. As a result of the complex nature of this case, multidisciplinary input was required.

Figure 97.5 Case study 1. (a) Post-operative results of the scalp, **(b)** pinnectomy with first-stage implants and **(c)** second-stage implants with healing caps *in situ*.

Figure 97.6 Case study 1. (a–c) Final prosthetic results of the right side. **(d–f)** Final result of the left side. Note the implant position varies due to the bone quality at the time of surgery.

Excision of the lesion on the skull and scalp resulted in a substantial defect requiring soft-tissue reconstruction. A free latissimus dorsi flap was used as the multiple cylindromas had precluded the use of her common soft-tissue flap sites and an anterolateral thigh (ALT) flap was too bulky to be used.

The following surgical risks were explained to the patient:

- a 5% risk of flap failure
- deep vein thrombosis (DVT)
- scarring
- infection
- bleeding.

Her ears were virtually destroyed by the coalescing syringomas and required total pinnectomies of both the left and right ears (bilateral), Again, risks were explained.

PATIENT CONCERNS

The patient had aesthetic concerns about the ears and so a prosthetic consultation was required prior to surgery at which the patient and clinician could discuss the treatment options available and consider the best one for her. At this time it was decided that extraoral implants would be inserted at primary surgery as the quality of bone was good, allowing the final prosthesis to be retained using gold bar and clip. It is important the patient has a full understanding of what is achievable and a realistic time frame from start to finish. As the patient's ears were too distorted in this case, a pre-operative impression was not possible.

With further surgical discussions with the surgeon it was decided that the external auditory meatus was to be left intact. As we know, the implant positioning for prosthetic treatment is vital and so the meatus was used to determine the 'ideal' implant placement.

SURGERY

In 2011 the patient had surgical intervention for the lesions on her scalp (**Figure 97.4**) and a staged pinnectomy of the left ear. The ear was removed and two 4 mm implants (first stage) were inserted into the bone. Early in 2012 a pinnectomy on the right side was performed and two 4 mm implants were inserted on that side.

Once the patient had healed, the second stage of the implants was performed. Here a small 4 mm biopsy punch was used to expose the first-stage implants and a healing abutment was placed. This allowed the prosthetist to assess the skin thickness and replace the healing abutment with definitive abutments. On both the left and right sides a 7 mm abutment was used for the upper implant and a 5.5 mm abutment for the lower implant.

PROSTHETIC RESULT

The patient's prosthetic treatment started in August 2012 and the final prostheses were fitted in October 2012 (**Figure 97.6**).

Case study 2

PRESENTATION

A 75-year-old male presented with local crusting to the left alar in 2008 (**Figure 97.7a**).

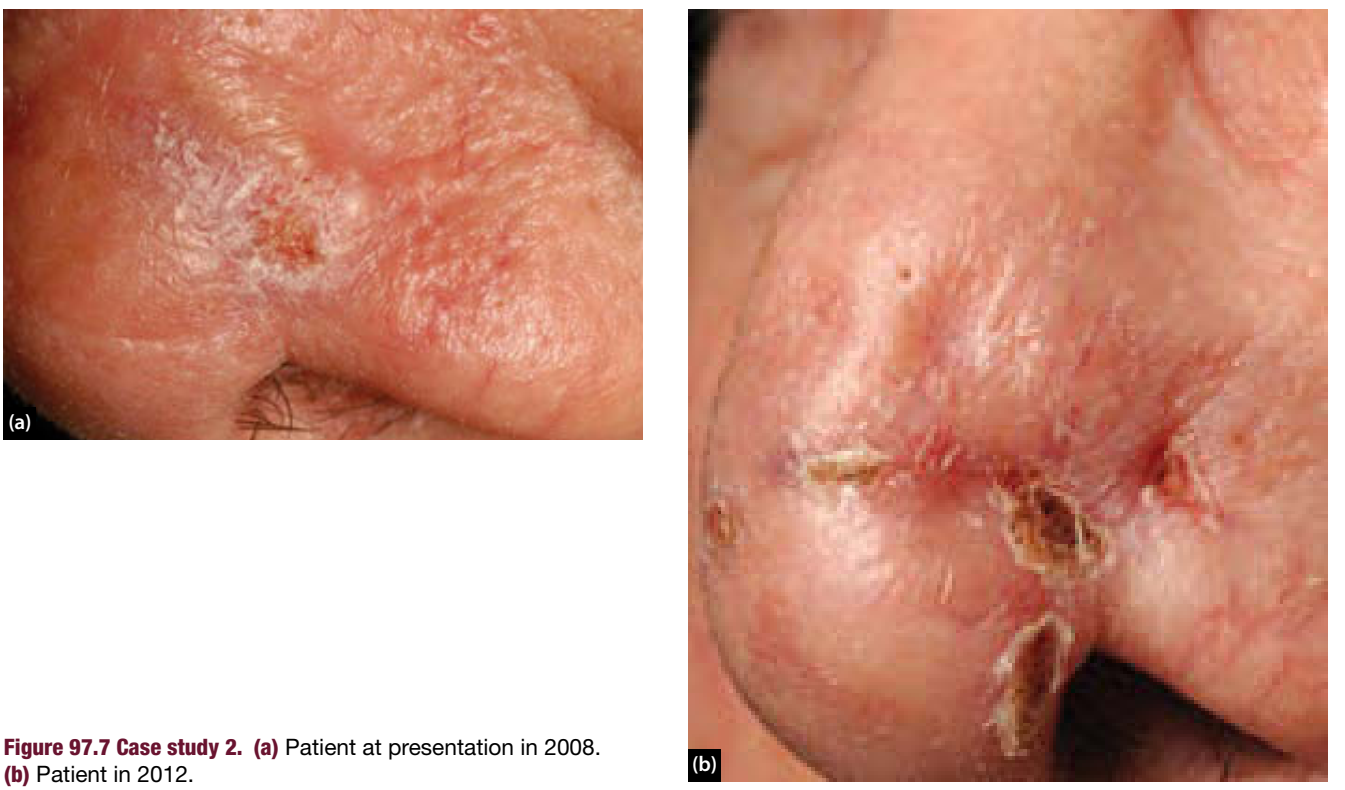

Figure 97.7 Case study 2. (a) Patient at presentation in 2008. **(b)** Patient in 2012.

Figure 97.8 Case study 2. Implants fully integrated with a 10 mm abutment on the left and 7 mm abutment on the right. Both abutments can be seen with multiunit magnacaps attached.

MEDICAL AND SOCIAL HISTORY

The patient was a regular smoker who consumed alcohol in excessive amounts on a daily basis. He also had an abnormal growth in the left lung.

DIAGNOSIS

Recurrent squamous cell carcinoma (SCC) involving the entire dorsum and the tip of the nose was diagnosed.

TREATMENT

Although surgical intervention was discussed and achievable with a combination of flaps, the outcome would be inferior to that of prosthetics treatment. It was concluded that the best possible treatment for this patient was to have a total rhinectomy (total removal of the nose) with the insertion of osseointegrated implants followed with prosthetic rehabilitation.

SURGERY

During the procedure two 7 mm Brånemark (intraoral) implants were inserted in the piriform aperture. The reason

Figure 97.9 Case study 2. (a–c) Final result from prosthetic rehabilitation. Profile left, front and right side respectively. **(d)** The prosthesis allows the patient to wear his glasses, which can be advantageous to help hide the edges of a prosthesis.

was dependent on the bone and space available, ensuring there was no interference with the roots of the teeth. In almost all cases, conventional implants such as those used for intraoral reconstruction are suitable. There are clear advantages to using longer implants in terms of long-term survival and load-carrying ability.

Following his surgery the patient was looked after by a clinical nurse specialist who managed his dressing and helped his healing while the implants integrated. Four months after his surgery, in October 2012, the healing abutments were removed and definitive abutments replaced. The height of the abutments should allow clearance from the cavity wall yet allow space for the magnacaps to be attached to the definitive abutments (**Figure 97.8**).

An impression of the defect was taken, recording the accurate positions of the implants using impression magnets. A nasal profile was waxed up using pictures of the patient before he had the rhinectomy. This was then tried and modified according to the patient's requirements. A colour match of the patient's skin was also taken.

PROSTHETIC RESULT

Figure 97.9 shows the final result from prosthetic rehabilitation.

Case study 3

HISTORY

A 64-year-old female had an ongoing symptom of drooping to the right eye. Her optician recorded further drooping to the right eye 3 years after the initial observation. Aged 67 she also had a neuroendocrine tumour in the pancreas, which was picked up after she developed jaundice. As a result, she had a biliary stent inserted early in 2012.

IMAGING REPORT

MRI demonstrated a growth behind the eye, which was excised as a benign tumour in 2012. The biopsy report identified the growth as a lipoma with atypical feature. Following the excision, the patient developed slow progressive proptosis.

DIAGNOSIS

In October 2012 the patient had a further decrease in her vision and developed diplopia. She had another MRI scan, which showed tumour growth above the eye, and a CT scan was carried out to determine bone involvement. A biopsy of the mass showed a myxoid liposarcoma. After further investigations and further discussion it was

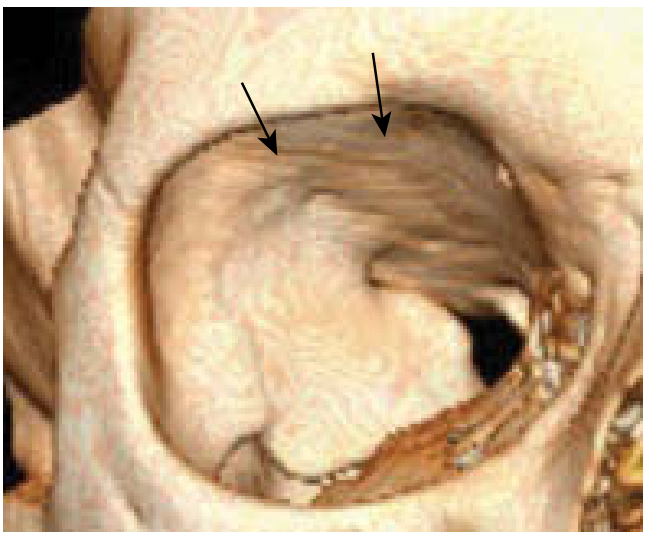

Figure 97.10 Case study 3. Location of the implants.

Figure 97.11 Case study 3. (a,b) The right-sided prosthesis *in situ*. **(c)** The use of glasses helps to draw attention away from the prosthesis.

decided that the best treatment was an orbital exenteration with orbital implants followed by prosthetics.

TREATMENT

In April 2013 the patient had the orbital exenteration and two 7 mm dental implants were inserted into the roof of the orbit and left to integrate.

The second stage of the implants was performed at 2 months post-operatively by placing a 2 mm and a 5 mm abutment to the existing implants.

OUTCOME

The final result is shown in **Figure 97.11**.

FUTURE RESEARCH

- There have been many developments in materials used for the production of prosthesis.
- The advent of percutaneous osseointegrated implants has dramatically improved the potential for retention of prosthesis. However, many of the construction methods and mould making have changed little and are highly skilled and time-consuming. Each prosthesis is individual and the use of high technology has been difficult to adapt or is not cost-effective in some individual cases.
- With advances in computer software using CT data, there are programs available that allow 3D simulation of facial reconstructive methods including osteotomy and distraction procedures. Data from medical scanners (CT, MRI) can be used to reproduce physical models of human anatomy via additive layer manufacture (ALM).
- Several ALM techniques exist, the most common is stereolithography. The basic principle of creating a 3D structure is by building layers using the CT data and an optical scanning system that draws a shape one layer at a time onto the surface of the liquid photosensitive resin until the desired model is completed.
- Over the last few years improvements in surgical techniques with the involvement of in-house surgical guide design and enhanced surgical simulation and planning have enabled more accurate and aesthetic reconstructions to be performed. While prosthetic materials continue to be improved and refined, these surgical improvements may render prosthesis to be necessary in a more limited format. The necessity of treating tumours by ablative surgery in the future may be reduced by other treatment regimes and therefore the necessity to surgically or prosthetically reconstruct these defects could be reduced.
- As 3D printing has evolved to build bony structures we still endeavour to find materials and technology to print in silicone materials with the ability to reproduce patient skin texture and colour which may enhance the prosthetic outcome with a view to giving patients a more realistic understanding of the outcome.

KEY POINTS

- Assess patient psychological status.
- Understand patient expectations.
- Build relationships/rapport with patients.
- Keep prosthesis simple for patients to cope with.
- Understand the reconstruction pathway and patient support.
- Understand the importance of facial aesthetic.
