The most effective, optimal and least toxic sequential chemotherapy regimen is still debated and more recent publications have been less encouraging. The TREMPLIN study by Lefebvre et al[14] used induction chemotherapy followed by chemoradiotherapy or by cetuximab plus radiotherapy. There was no difference in outcome with regard to larynx preservation. The PARADIGM trial,[15] which compared sequential chemotherapy versus concomitant chemotherapy alone, showed no overall survival difference in locally advanced head and neck cancer. The DeCIDE trial[16] also found no overall survival difference in patients with nodal stages N2/N3 disease, where induction chemotherapy was added to concomitant chemo-radiotherapy compared with concomitant chemotherapy alone.

These disappointing induction trials are reviewed by Garden[17] in an editorial suggesting that the evidence to date does not suggest that induction chemotherapy is beneficial in head and neck cancer.

CONCURRENT OR CONCOMITANT CHEMOTHERAPY

Concurrent or concomitant chemotherapy given with radiotherapy is more frequently used than induction or sequential chemotherapy. It is given for its direct cell-killing effect and for its effect in sensitizing cancer cells to the effects of radiotherapy. It probably has less effect in suppressing micro-metastatic distant spread than induction chemotherapy. Its main advantage is that when used with radiotherapy, without induction chemotherapy, there is less chance of patients having to stop treatment because of toxicity, and have breaks in radiotherapy, which can be detrimental to treatment outcome.

In the meta-analysis of chemotherapy on head and neck cancer (MACH-NC),[7–9] the overview looked at concurrent chemotherapy in 16 000 patients and showed that it gave a survival benefit when added to radiotherapy alone, giving a 6.5% decrease in mortality at 5 years, in absolute terms. This benefit was not seen in patients over 70 years of age, but patients over 70, formed a very small number of the total patients reviewed.

The most commonly use concurrent chemotherapy regimens are cisplatin 100 mg/m² at days 1, 22 and 43 of radiotherapy, either alone or with 5-FU, 1 g per day on days 1 to 4. Although this regimen is commonly used, there are few direct comparisons with other concomitant chemotherapies within randomized controlled trials.

Increased toxicity produced by adding platinum chemotherapy to radiotherapy can be considerable with more marked mucositis, dysphagia, nephrotoxicity, ototoxicity, myelodysplasia and neutropenia. A significant proportion of patients do not receive all three cycles of chemotherapy because of toxicity, but one study has shown no survival difference in patients receiving two cycles of cisplatin rather than three cycles; however, the radiotherapy delivered was not identical within the arms of this study.[18] Chemotherapy toxicity can also interfere detrimentally with radiotherapy delivery causing breaks and treatment which are associated with poorer outcomes.

While high-dose cisplatin, 100 mg/m², 3-weekly may be optimal for younger patients with good performance status and fewer comorbidities, many head and neck patients are not in this category and other dose regimens may be better tolerated. Cisplatin, 40 mg/m², capped at a total of 70 mg given weekly, may allow for more flexibility with the ability to reduce or omit a weekly dose in response to changes in the patient's tolerability and individual toxicity. Daily cisplatin at a dose of 6 mg/m² is also an occasionally used regimen. Weekly and daily regimens may be easier to administer in an outpatient or day ward setting. High-dose cisplatin at 100 mg/m² may require inpatient admission for prehydration and monitoring.

If cisplatin is contraindicated because of renal function status, the presence of neuropathy, tinnitus or deafness, or where there is a danger of fluid overload with the necessary pre-hydration used in cisplatin administration, carboplatin can be considered as it causes less nephrotoxicity, ototoxicity and peripheral neuropathy but is more myelosuppressive. It is not thought to be as tumouricidal as cisplatin and for this reason it has now been largely overtaken by the epidermal growth factor receptor (EGFR) inhibitor, cetuximab in clinical practice when cisplatin is contraindicated.

CONCURRENT RADIOSENSITIZERS

It is known that tumour cell hypoxia induces radioresistance, and there has been renewed interest in giving hypoxic cell radio-sensitizing drugs during radiotherapy. The two most common in use are the anti-helminthic drug nimorazole, which is extensively used in some parts of Europe, and tirapazamine, an anticoagulant that is activated in hypoxic environments. Although established in some parts of the world, trials are ongoing with these agents to establish efficacy and with nimorazole, patient tolerability.

TARGETED BIOLOGICAL AGENTS

Targeted therapy in head and neck cancer developed with the recognition that EGFR is overexpressed in most head and neck cancers, up to 90% in some studies, and is associated with a poorer prognosis. When a growth factor attaches to its receptor on the cell surface, cells are stimulated to divide and consequently tumours grow. If the receptor is abnormal because of a mutation the stimulation to divide may even occur without growth factors interacting with the receptor. Cetuximab is a

mouse–human chimeric monoclonal antibody that binds to the extracellular portion of EGFR and turns this signalling system off.

In the initial innovative cetuximab trial by Bonner et al,[19] patients with advanced cancers of the oropharynx, larynx or hypopharynx were randomized to receive radical radiotherapy with or without cetuximab. At 3 years, survival was better in the patient group who had received cetuximab, 55% vs 45%; and local control was also better, 50% compared to 41%.[20] Subset analysis, with its inherent limitations, suggested that cetuximab may have more effect in younger patients under 65 years, in those with oropharyngeal cancer and in those with better performance status, broadly reflecting the response with non-targeted standard chemotherapy regimens.

While these initial results with cetuximab were encouraging, a major drawback to the study was that, since it had started, radiotherapy alone as used in this study has been overtaken as a standard of care by chemoradiotherapy for advanced head and neck tumours. Thus, comparing radiation alone versus radiation plus cetuximab is much less relevant in the context of contemporary standard practice.

Despite initial hopes that cetuximab would give less toxicity than standard chemotherapy, and could therefore be given to older patients and those with a poorer performance status, it has been shown to have a different, although not necessarily more gentle toxicity profile. It does show less morbidity with nephrotoxicity, ototoxicity and peripheral neuropathy but it gives patients a more intense grade 3 and grade 4 radiation dermatitis.

Patients may also develop an acne-like rash predominantly over the face, neck and trunk with a more eczema-like condition at the fingertips and elbows, and paronychia may develop. In a minority of patients this reaction can be so severe that cetuximab may need to be stopped but these side effects can usually be managed by increasing the treatment interval and supportive care with topical medications. There is some suggestion that patients who develop this rash also have a better tumour response with improved overall survival.[21]

While receiving cetuximab, infusion-related side effects are not uncommon with headache, flushing, pyrexia, urticaria, swelling of the lips and tongue or bronchospasm. Patients, therefore, usually receive steroids 24 hours before starting a cetuximab infusion. Cetuximab may have a role to play in the treatment of metastatic disease (see below), as shown in the EXTREME trial, but that role is still to be fully defined.

Other targeted EGFR monoclonal antibodies are under investigation, such as panitumumab[22] or zalutumumab,[23] but to date with less encouraging results, showing no improvement in overall survival. Another target further down this biological pathway, offering a different mechanism of action is used by erlotinib, a small molecule inhibitor of EGFR tyrosine kinase. In one phase II trial of erlotinib given alone or combined with cisplatin, unfortunately it did not show any benefit in outcome for the combination. Despite this, other targets in the EGFR pathway are being investigated.[24]

This emerging modality and immuno-oncology are discussed in greater detail in Chapter 30, Biologically targeted agents in head and neck cancers.

CHEMOTHERAPY FOR RECURRENT OR METASTATIC HEAD AND NECK CANCER

Chemotherapy or targeted biological agents may be indicated for patients with recurrent and/or metastatic disease but patients with metastatic disease have a median survival of approximately 6–12 months in most studies.

Appropriateness of chemotherapy depends on several factors, such as: extent and burden of disease; whether symptoms are present or not; and whether failure of control has taken place at the primary site only, there is metastatic disease only, or both. Often, the most important consideration is the fitness and performance status of the patient and whether they could tolerate the proposed chemotherapy, and how much it would reduce their pre-treatment quality of life, for whatever limited survival they have.

LOCOREGIONAL FAILURE

This has been reported in up to 50% of patients with head and neck cancer. Prognosis in this patient group is typically poor and salvage treatments can be limited by the extent of the recurrent disease, the time interval since original treatment and the type of primary treatment.[25]

In this group of patients, if other salvage surgery or re-treatment with radiotherapy and chemoradiotherapy is being considered, it is important to assess the presence of distant metastatic disease, and also to confirm that the locoregional recurrence disease is not a second primary. Discovering that metastatic disease is also present is not an absolute contraindication to salvage treatments at the primary site, as locoregional failure and metastatic disease can be considered as two separate problems in the patient's management plan. If good palliation at the primary site or local regional control can be achieved relatively easily by a salvage procedure, the presence of metastatic disease, especially small volume metastatic disease, should not necessarily stop treatment to the primary or locoregional site. The patients who do better with salvage treatment are those with smaller volumes of recurrence, a longer disease-free interval and fewer comorbidities. Some head and neck subsites, such as the larynx, also have better outcomes than other subsites.[26]

DISTANT METASTASES

Chemotherapy is often indicated here as part of a best supportive care package but has not been shown to significantly extend survival. The presence or absence of symptoms will influence when they receive chemotherapy. The therapeutic window for giving chemotherapy in this

situation would be when the patient still has an appropriate performance status to receive and benefit from chemotherapy, with the trade-off being an improved symptom state for the inevitable morbidity caused by the chemotherapy. Giving chemotherapy to the patient with no symptoms to palliate and little hope of extending survival, while giving some treatment side effects and increased hospital attendances, may well decrease the patient's quality of life by a factor greater than any symptoms alleviated by the chemotherapy. A shared decision-making approach where the patient and his family are given as complete information as possible on the potential benefits and morbidities of having chemotherapy with its likely effect on symptoms, positive or negative effects and prognosis and treatment morbidity may let the patient make a more fully informed decision.

If chemotherapy is to be given for distant metastatic disease, the most appropriate regimen depends on several factors including the performance status, comorbidities present, renal function and the physiological reserve of the patient. Additionally, the regimens the patient has had before and the length of the interval since last chemotherapy was given, may be important.

The most common regimens used are cisplatin or carboplatin with 5-FU. These give an expected response rate of approximately 40%.[27] Carboplatin is used more often in this palliative metastatic setting than with induction or concurrent regimens, because although deemed slightly less effective than cisplatin, it is less toxic and is considered to be more appropriate in the palliative setting.

Elderly patients do appear to respond to platinum-based chemotherapy in the metastatic setting,[28] in contrast to a lack of benefit in the elderly when used in primary chemoradiotherapy regimens. There does, however, appear to be more toxicity using chemotherapy in an elderly patient population than the standard patient population.

Other more toxic chemotherapy regimens have also been investigated using platinum and a taxane (docetaxel or paclitaxel) in combination. These have not been shown to improve survival compared to the standard of care combination of cisplatin and 5-FU, although some studies have found a high response rate but with the cost of higher toxicity.

Cetuximab with cisplatin and 5-FU, which has become a more commonly used regimen, can increase both response rate and improve short-term survival slightly, as shown in the EXTREME trial,[29] but a 5-year follow-up published recently in abstract form shows very low survival for patients in both arms of the study. The EXTREME study did not allow crossover between regimens so similar results might be achieved by the use of cisplatin and 5-FU followed by cetuximab used sequentially. In patients who have become refractory to cisplatin and 5-FU, cetuximab as a single agent does have a low response rate of approximately 10–15%.[30–32]

KEY POINTS

- Concurrent chemoradiotherapy is at present the standard of care for treatment of locally advanced head and neck cancer with a confirmed absolute survival benefit of 6.5% at 5 years.
- Single agent cisplatin, which in the past has been shown to be as effective as multiple drug regimes, is now being challenged by the introduction of the use of taxanes.
- Targeted biological agents, such as cetuximab, have a role to play in both advanced head and neck cancer and recurrent or metastatic disease but those roles are still being established.
- At present HPV status does not alter management regimens, although there are multiple studies underway, examining if less intense treatment, both with radiotherapy and chemotherapy, could be given to achieve the same outcome but with less toxicity.
- The potential benefit of neoadjuvant or induction chemotherapy is being re-examined.
- Elderly patients benefit least in terms of survival advantage with the use of concurrent chemotherapy.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: odontogenic cyst, jaw cysts, non-odontogenic cysts, and jaw neoplasms.

INTRODUCTION

The maxilla and mandible – the upper and lower jaws, respectively – form an important part of the bony facial skeleton and are unique in that they consist, in part, of the alveolar process which has the sole purpose of supporting the teeth. The teeth develop within the deeper part of the jaws and erupt up through the alveolar process, coming to lie within the tooth socket, suspended by the periodontal ligament which lies between the bony tooth socket and the cementum of the tooth root. The crown of the erupted tooth is cuffed at the neck by gingival mucoperiosteum and this junction of hard and soft tissues is a potential source of infection and inflammation. The inflammation can stimulate odontogenic epithelial remnants left after tooth development leading to the inflammatory radicular cyst, the most common type of cyst affecting the jaws. In addition, other types of odontogenic epithelial residues may give rise to developmental odontogenic cysts. The odontogenic cysts, being unique to the jaws, form a major part of this chapter. Also covered are the non-odontogenic cysts which arise from embryonic epithelial residues found within canals running through the facial bones or entrapped at lines of bone fusion. The non-odontogenic cysts are less common but important in the differential diagnosis of cystic lesions. Non-epithelialized bone cysts are also covered since, although they are rare within the jaws compared to the long bones, they are important in the differential diagnosis of cysts of the facial skeleton.

The second part of the chapter focuses on fibro-osseous lesions, a diverse group of bone conditions that can cause 'tumour' or swelling of the bones, drifting of teeth and radiological appearances that mimic cysts and neoplasms. Some are unique to the jaws and their diagnosis requires detailed clinicopathological correlation. The third part of the chapter deals with 'tumours' ranging from developmental anomalies to true neoplasms beginning with an overview of lesions arising from bone cells. Emphasis is given to the clinical and radiological presentation and any ways in which jaw/facial lesions differ from lesions elsewhere in the skeleton. The odontogenic tumours are covered in detail since they are unique to the jaws and both the diagnosis and management can be challenging. Finally, intraosseous salivary gland tumours, miscellaneous lesions and metastatic tumours are briefly considered.

CYSTS

A simple definition of a cyst is 'a cavity, generally lined by epithelium, filled with fluid or semi solid contents but not formed by the accumulation of pus'. As outlined above and summarized in **Table 25.1**, cysts of the jaws and bony facial skeleton arise from several types of epithelial residues. These residues probably exist within the jaws and covering alveolar/gingival mucoperiosteum in all individuals but the factors which lead to cyst formation are poorly understood.

TABLE 25.1 Classification of cysts of the bony facial skeleton

Lining of cyst lumen	Category of cyst	Subcategory	Source of epithelial lining
Epithelialized	Odontogenic	Developmental and inflammatory (see Table 25.2)	Residues of the tooth-forming organ
Epithelialized	Non-odontogenic	Nasopalatine duct cyst and variants	Remnants of nasopalatine duct (Jacobson's organ)
		Intraosseous dermoid and epidermoid	Entrapped epithelium at lines of embryonic closure
Non-epithelialized	Solitary bone cyst		
	Aneurysmal bone cyst		
	Staphne's idiopathic bone cavity		
	Focal marrow-containing jaw cavity		

TABLE 25.2 Odontogenic epithelial remnants, their origin and associated cyst(s)

Odontogenic epithelial residue	Source of odontogenic epithelial residue	Associated odontogenic cyst(s)
Reduced enamel epithelium	Fusion of inner and outer enamel epithelia of enamel organ	Dentigerous (follicular) and eruption cysts
		Paradental cyst
Rests of Malassez	Root sheath of Hertwig	Radicular (apical and lateral) and residual cysts
Rests (glands) of Serres	Dental lamina	Dental lamina cysts of the newborn (Bohn's nodules)
		Lateral periodontal, botryoid odontogenic cysts and gingival cyst of adults
		Keratocystic odontogenic tumour (formerly, odontogenic keratocyst)

Epithelialized cysts

ODONTOGENIC CYSTS

The odontogenic cysts arise from remnants of the tooth-forming apparatus.[1] There are three distinct types of epithelium which persist once odontogenesis is complete (**Table 25.2**). First, the dental lamina, which, in the developing embryo, is the downgrowth of surface oral epithelium that extends into the underlying developing mesenchymal tissue and gives rise to the enamel organ (**Figure 25.1**). Once tooth formation is complete, this structure fragments, but its persistence as small, rounded islands of epithelium within the bone and alveolar soft tissues, the rests (glands) of Serres, is well recognized (**Figures 25.2–25.4**). These dental lamina residues give rise to the developmental lateral periodontal and gingival cysts (and the keratocystic odontogenic tumour, formerly the odontogenic keratocyst). Second, once enamel formation is complete, prior to eruption, the tooth is covered by a layer of reduced enamel epithelium, formed by fusion of the two layers of inner and outer enamel epithelia. This is the source of epithelium for dentigerous (follicular), eruption and inflammatory paradental cysts. The third epithelial residue is the rests of Malassez within the periodontal ligament between the tooth root and the bony tooth socket which results from the fragmentation of Hertwig's root sheath on the completion of root formation, and gives rise to the inflammatory radicular cysts. The classification of odontogenic cysts used in this chapter (**Table 25.3**) is based on that recommended by the World Health Organisation.[2]

Figure 25.1 Photomicrograph depicting developing tooth germ arising from down growth of oral cavity lining surface epithelium, the dental lamina.

Developmental odontogenic cysts

DENTIGEROUS (FOLLICULAR) AND ERUPTION CYSTS

These account for around 15–18% of jaw cysts. Dentigerous cysts, formed by expansion of the dental follicle, the soft tissue covering the crown of an unerupted tooth, are attached to the cemento-enamel junction. Teeth most commonly affected are those more likely to remain

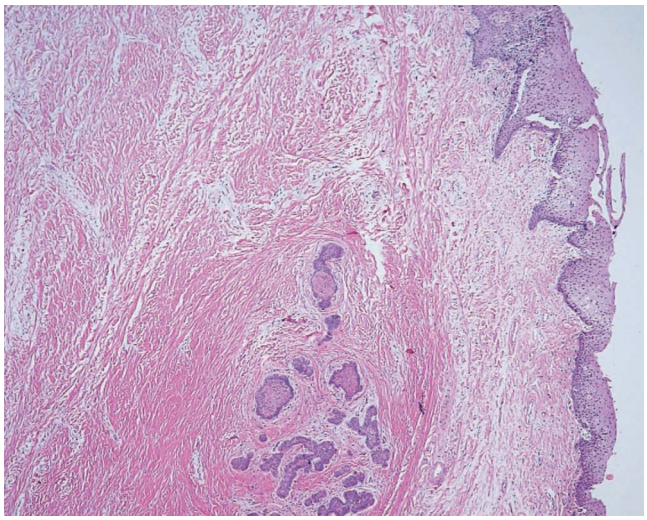

Figure 25.2 Photomicrograph showing remnants of fragmented dental lamina, odontogenic epithelial rests, in an adult within alveolar connective tissues.

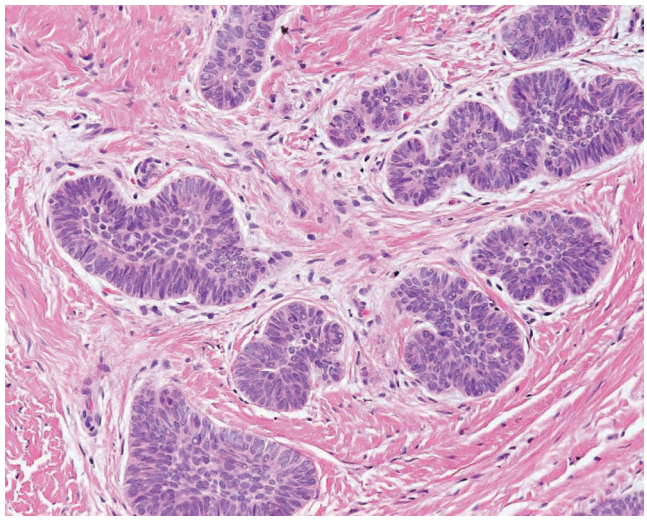

Figure 25.3 Photomicrograph showing remnants of fragmented dental lamina, odontogenic epithelial rests, in an adult within alveolar connective tissues.

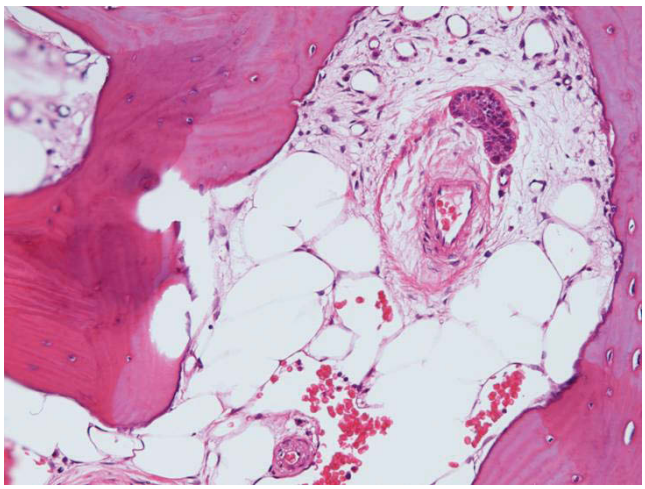

Figure 25.4 Odontogenic epithelial remnants within bone.

unerupted, typically, in order of decreasing frequency, mandibular third molars ('wisdom' teeth), maxillary canines, mandibular second premolars and maxillary third molars. Peak age of presentation is second to third decades but they can be diagnosed later in adulthood. Some present with swelling, displacement of teeth and symptoms resulting from secondary infection but many are found on radiological assessment of a missing tooth. Dentigerous cysts can reach up to 5 cm in radiographic diameter, and the clinical differential diagnosis of larger lesions includes keratocystic odontogenic tumour and unicystic ameloblastoma, two more aggressive lesions that can present in a dentigerous relationship (see below).

Radiographically, dentigerous cysts typically present as unilocular radiolucencies connected to the cemento-enamel junction (**Figures 25.5** and **25.6**). They have a greater tendency than other non-neoplastic cysts to cause root resorption in adjacent teeth[3] possibly because resorption of the deciduous predecessor is a normal function of the follicle.

Histological diagnosis is generally straightforward especially when accurate clinical and radiographic information are provided on the request form. The epithelial lining is thin, either simple cuboidal, columnar or non-keratinized stratified squamous, although metaplasia may result in focal keratinization and scattered mucus and ciliated cells.

TABLE 25.3 Classification of the odontogenic cysts

Pathogenetic category	Cyst type	Subtype	Dental relationship
Developmental	Dentigerous (follicular)	Eruption	Cover the crown of an unerupted tooth; attached to cement-enamel junction
	Lateral periodontal	Gingival cyst of adults	Lateral to root of vital tooth
		Botryoid odontogenic	
	Sialo-odontogenic (glandular odontogenic)		
Inflammatory	Radicular (dental)	Apical	Root apex of non-vital tooth
		Lateral	Lateral root canal of non-vital tooth
		Residual	Within jaw after removal of associated causative tooth
	Paradental		Lateral aspect of partially erupted tooth

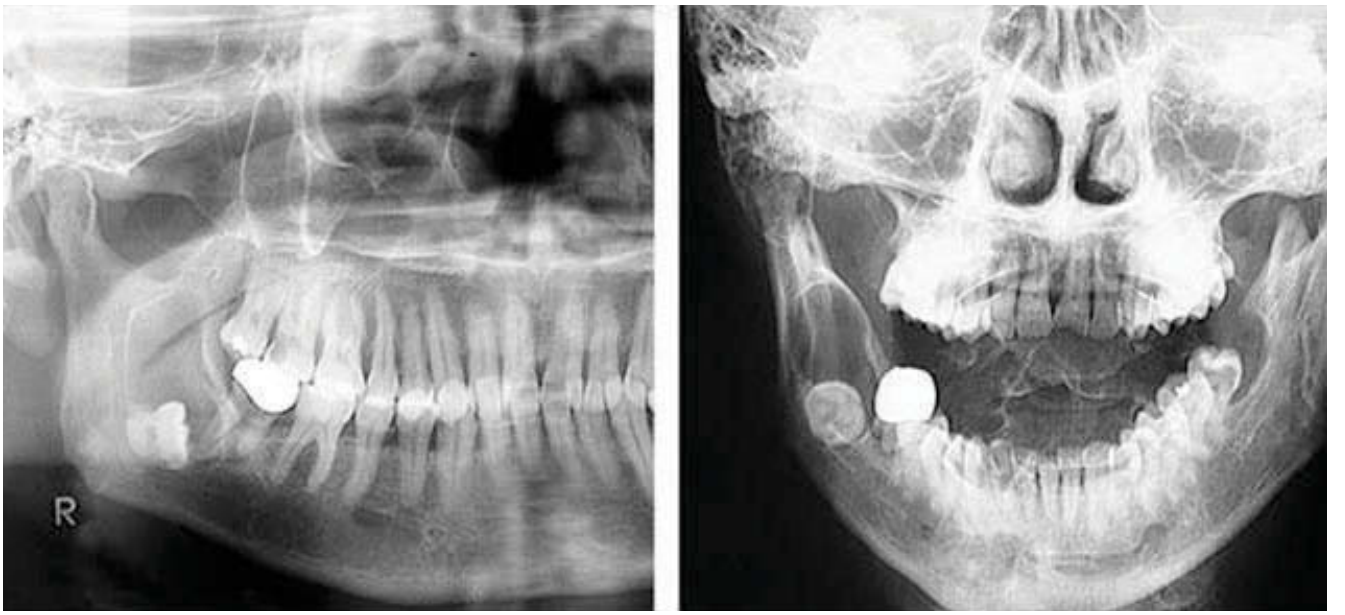

Figure 25.5 Bilateral dentigerous cysts seen radiologically.

Figure 25.6 Macroscopic image of dentigerous cyst and associated lower premolar (impacted) noting relationship to cemento-enamel junction.

Numerous pathogenetic theories have been proposed but why only a minority of patients with unerupted teeth develop dentigerous cysts remains poorly understood. In one study, 29.6% of maxillary third molars were impacted but the frequency of cyst formation was only 5.4%;[4] and other studies have estimated the ratio of cyst:unerupted tooth to be 1 in 150 and 1.44 in 100, respectively.[5, 6]

The eruption cyst[10] is a superficially located dentigerous cyst, presenting as a bluish swelling of the gum overlying an erupting tooth. They are most commonly seen in children, typically affecting the mandibular first molar and maxillary incisor teeth. Cyclosporin therapy is a recognized predisposing factor.[7, 8]

Depending on the type and position of the associated tooth, many dentigerous and gingival cysts can be treated by marsupialization which generally results in full eruption of the tooth.

LATERAL PERIODONTAL AND BOTRYOID ODONTOGENIC CYSTS

Developmental lateral periodontal cysts are rare (accounting for only 0.7% of jaw cysts). They typically present in older adults and mainly affect mandibular premolars, presenting in a lateral position but not related to pulpal or periodontal inflammation.[9] They are generally asymptomatic and detected incidentally on routine radiological examination. Removal for histological diagnosis is usual. The histological features are distinct: thin, non-keratinized epithelium with focal plaque-like thickenings. The debate on the epithelial source of the lateral periodontal cyst is ongoing. Enucleation is the treatment of choice and recurrence is rare. In contrast, the botyroid odontogenic cyst, the multilocular / multicystic variant, has a propensity to recur and complete surgical removal is the preferred treatment.[10]

GLANDULAR ODONTOGENIC CYST (SIALO-ODONTOGENIC CYST)

Accounting for less than 1% of jaw cysts, the glandular odontogenic cyst is of interest to both clinician and diagnostic pathologist due to its propensity to recur and potentially puzzling histological features. With a peak presentation in elderly males, most cases arise in the anterior mandible, presenting as a slow-growing, painless swelling, and on radiology, a unilocular or multilocular radiolucency. Histologically, the cyst is lined by cuboidal or columnar epithelium with scattered goblet cells and characteristic intra-epithelial gland-like crypts. Important differential diagnoses include botryoid odontogenic cyst, intra-osseous mucoepidermoid carcinoma and metaplasia within a dentigerous cyst. The glandular odontogenic cyst shows more aggressive behaviour than other odontogenic cysts and multilocular lesions have a particular propensity to recur and should be treated by complete excision.[11, 12]

Inflammatory odontogenic cysts

RADICULAR (DENTAL) CYSTS: APICAL, LATERAL, RESIDUAL

These are by far the most common jaw cysts, accounting for 65–70%[13] and ones for which there is a clearly defined etiological agent. They occur in both sexes and over a wide age range. Inflammation at the root apex of a tooth, either as a result of extension of pulpal inflammation and/or necrosis due to deep dental caries, or triggered by loss of tooth vitality following trauma, can lead to proliferation of the epithelial rests of Malassez within the periodontal ligament. Radicular cysts may arise in association with any damaged tooth but there is a tendency for the maxillary incisor teeth to be involved more frequently than other sites.[13]

Many factors are involved in cyst initiation and progression. Cytokines and growth factors released by the inflammatory cells cause epithelial proliferation and also lead to soft-tissue destruction and osteoclast-mediated bone resorption, thus allowing space for an established cyst to grow by expansion. Bacterial endotoxins may also stimulate epithelial proliferation. Within the mass of proliferating epithelium, intercellular oedema and degeneration of the more centrally located cells leads to cavitation. The presence of abundant proteinaceous debris within the resulting lumen leads to increased osmolarity and drawing in of fluid leading to further expansion of the established cyst.

A radicular cyst may present with acute symptoms of pain and swelling but many are asymptomatic and seen as a radiolucency at the root apex on routine dental radiological examination (**Figure 25.7**). The associated tooth is, by definition, non-vital. Some teeth have additional communications between the root pulp canal and the periodontal ligament – one or more lateral canals – and these are the origin of lateral radicular (lateral dental) cysts.

The main differential diagnosis of a radiolucency at, or close to, the apex of an obviously carious or damaged tooth is that of granulation tissue without cyst formation, commonly referred to a periapical granuloma. The size of the radiolucency can be used as a diagnostic guide since radiolucencies greater than 20 mm are highly likely to be cysts and ones below 5 mm are likely to be granulomas.[14]

Theoretically, adequate endodontic treatment with elimination of necrotic, infected and inflammatory debris within the pulp canal should lead to resolution of the cyst but many persist and require surgical removal via apicectomy or tooth extraction. Cysts that persist after removal of the associated tooth are referred to as residual cysts (**Figure 25.8**).

Pathological diagnosis is usually straightforward. Characteristically, the fibrous wall is thick with active acute and chronic inflammation, and the epithelial lining is non-keratinized stratified squamous with areas of hyperplasia and focal ulceration. There are, however, some potential pitfalls. First, it is not unusual to find areas of epithelial metaplasia, with mucous-secreting and ciliated cells leading to a resemblance to respiratory-type epithelium and misdiagnosis as antral mucosa or a sialo-odontogenic cyst; or keratin-forming cells and misdiagnosis as a keratocystic odontogenic tumour. Second, a developmental cyst or even a cystic odontogenic neoplasm may become secondarily inflamed and lose its characteristic appearances and acquire features that can be indistinguishable from a radicular cyst, especially if only a small

Figure 25.7 Radiological image of radicular cyst upper lateral incisor with typical location.

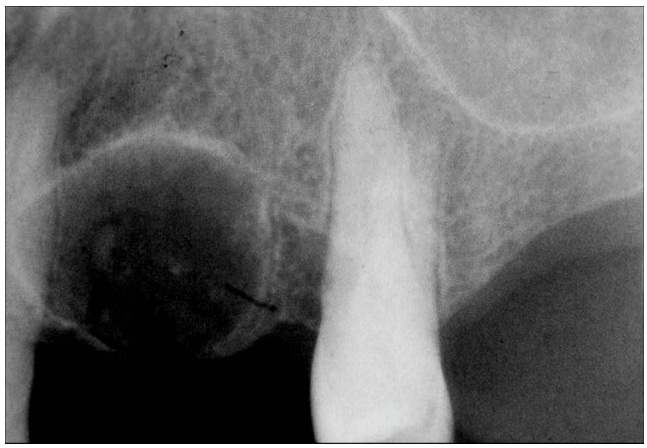

Figure 25.8 Residual cyst; unilocular radiolucency, several years post extraction of a tooth with apical pathology.

portion of the lesion is submitted for histological examination. Submission of any cystic lesion of the jaws should always be accompanied by a brief description of its location in relation to the roots and crown of adjacent teeth; the status of the teeth; and the size, shape, margins and radiodensity of the lesion. A further potential diagnostic pitfall concerns periapical granulomas and radicular cysts following successful endodontic treatment when the inflammation has largely resolved, and there is little, if any, active inflammation. Such lesions should be diagnosed as periapical scar tissue and generally are found as a symptomless radiolucency and probably arise due to a lack of bony infilling following successful endodontic treatment.

PARADENTAL CYST

This inflammatory cyst arises in association with a vital tooth, usually on the lateral aspect, and results from inflammation within a periodontal pocket. The commonest site of occurrence is following pericoronitis around a partially erupted mandibular third molar. Hence, the peak age of presentation is young adults (18–25 years) and males are affected more than females. Paradental cysts account for around 3–5% of jaw cysts. The epithelial origin may be the reduced enamel epithelium or the epithelial cell rests of Malassez in the periodontal ligament.[15] The histological features are similar to the radicular cyst and the correct diagnosis depends on accurate clinical and radiological information. Enucleation is curative.

Non-odontogenic epithelial-lined

NASOPALATINE DUCT (INCISIVE CANAL), MEDIAN PALATINE, MEDIAN ALVEOLAR AND PALATINE PAPILLA CYSTS

The nasopalatine duct cyst and its variants are the most common non-odontogenic cysts accounting for 5–10% of jaw cysts.[16] They arise from epithelial remnants of the vestigial Jacobson's organ (part of the olfactory system in some mammals) within the nasopalatine canal which runs from the nasal septum to the palate in the anterior maxilla immediately behind the maxillary central incisor teeth. The nasopalatine duct cyst presents in the midline of the anterior maxilla. The median palatine and median alveolar cysts are posteriorly and anteriorly located variants, and the palatine papilla cyst is superficially located within the soft tissue of the incisive papilla.

The nasopalatine duct cyst and its variants are seen over a broad age range, peaking in middle-aged adult males. They may present with swelling and pain and may be associated with a salty taste. Many are asymptomatic and identified on routine radiography. The radiolucency is typically symmetrical and heart-shaped with a sclerotic border but may resemble periapical pathology of the incisor teeth. Testing the vitality of the incisor teeth is an important diagnostic step, but in the presence of diseased/non-vital teeth, pathological examination may be necessary for definitive diagnosis. A small nasopalatine duct cyst can be difficult to distinguish from the anterior palatine fossa and asymptomatic lesions less than 10 mm should be observed rather than removed.

The typical histological appearance of the nasopalatine duct cyst is a thick-walled sac, with a lumen lined by both squamous and respiratory type epithelia and often sizeable neurovascular bundles (branches of the long sphenopalatine nerve and vessels) within the collagenous wall. Secondary infection and ulceration may mask the characteristic features making accurate clinical and radiographic information essential. When symptomatic or large, the cysts can be managed by simple enucleation and recurrence is rare.

INTRAOSSEOUS DERMOID AND EPIDERMOID CYSTS

Dermoid and epidermoid cysts[17, 18] generally arise within the soft tissues from entrapped epithelium at lines of embryonic fusion. Rarely, they arise within the bone – in the midline mandible or lateral to the orbit being the most common sites. They generally present in children and young adults, as asymptomatic, well-defined radiolucencies. Histologically, they contain laminated keratin and are lined by orthokeratinized epithelium. Dermal appendages characterize the dermoid cyst and often hairs are found within the lumen. Enucleation is curative.

Non-epithelialized primary bone cysts

SOLITARY (SIMPLE, TRAUMATIC, HAEMORRHAGIC) BONE CYST

Although this is the most frequent of the non-epithelialized bone 'cysts', it occurs mainly in long bones and is uncommon in the jaws. It occurs almost exclusively in the mandible, mainly the molar/premolar regions. Peak incidence is in the second decade.[19] Most are asymptomatic and discovered on routine radiography. Typically, the well-defined radiolucency is scalloped around the roots of the teeth.[20] Around 25% result in bony expansion. Lip paraesthesia is exceptional.[19] Surgical exploration may be necessary for confirmation and reveals an empty intrabony cavity with no obvious soft tissue lining. Curettings consist of delicate loose, vascular fibrous tissue containing scattered osteoclasts and haemosiderin pigment. The favoured pathogenetic theory proposes traumatic intramedullary haemorrhage is followed by failure of organization and subsequent lysis of the blood clot. The interval between trauma and discovery ranges from months to years and the apparent relationship may be spurious. Careful curettage, avoiding damage to tooth roots and neurovascular structures, results in fresh intramedullary haemorrhage, organization of the clot and bony in-filling. Some lesions may resolve spontaneously.

ANEURYSMAL BONE CYST

This rarely affects the jaws with only 60–70 reported cases, mainly in teens/young adults with a slight female predilection.[21] Most arise in the mandibular posterior molar/angle and present as a firm, expansile swelling with

Figure 25.9 Multilocular radiolucency body of mandible: differential includes keratocystic odontogenic tumour, ameloblastoma, odontogenic myxoma, giant cell lesion and haemangioma.

facial deformity and often, pain. Radiographs reveal a uni- or multilocular, balloon or soap-bubble-like radiolucency (similar to ameloblastoma and odontogenic myxoma, **Figure 25.9**). Surgical exploration leads to the characteristic welling-up of blood. The curetted tissue consists of numerous blood-filled spaces without obvious endothelial lining. Multinucleated giant cells and haemosiderin are frequent within the fibrous septae. The pathogenesis is uncertain. In some, a translocation involving chromosome 17 and the oncogene USP6 can be demonstrated suggesting they are neoplastic.[22] Other cases may be associated with an intramedullary haemodynamic disturbance and 20–30% appear to complicate central giant cell granulomas or other fibro-osseous lesions.[23] Curettage is generally curative.

STAFNE'S IDIOPATHIC BONE CAVITY

This uncommon mandibular developmental anomaly may be mistaken as a jaw cyst on radiography[24] when a symptomless round/oval, well-demarcated radiolucency of the premolar-angle region is discovered (**Figure 25.10**). It is located beneath the inferior dental canal and may be bilateral. The appearance is due to a saucer-like concavity of the lingual plate occupied by submandibular salivary gland tissue. Anterior lesions related to the sublingual gland are rare. Sialography is helpful in confirming the diagnosis and can prevent unnecessary surgical exploration.

Figure 25.10 Radiology of Stafne's bone cavity; well-defined radiolucency below the level of the ID canal.

FOCAL MARROW-CONTAINING JAW CAVITY (FOCAL OSTEOPOROTIC BONE MARROW DEFECT)

Haemopoietic marrow, typically in the maxillary tuberosity and mandibular ramus/condylar neck, may be mistaken for a cyst radiographically.[25] Histological assessment of curetted tissue is diagnostic.

FIBRO-OSSEOUS LESIONS

These form a diverse group of conditions with differing aetiologies but similar histology (**Figure 25.11**). Normal bone is replaced by variably cellular fibroblastic stroma within which pathological ossification and/or calcification gradually occurs.[26] Diagnosis requires clinical and radiological correlation as well as good knowledge of subtle histological differences. The fibro-osseous spectrum[27–29] includes lesions with a clear developmental aetiology and known genetic mutations, inflammatory/infectious conditions and benign neoplasms. A helpful classification, proposed by Eversole et al,[30] is shown in modified form in **Table 25.4**.

Bone dysplasias

FIBROUS DYSPLASIA

In most cases, fibrous dysplasia (FD) is monostotic and maxillary cases are more frequent than mandibular.[30–33] Maxillary lesions that involve contiguous areas of the zygoma and sphenoid (craniofacial FD) are restricted to a defined anatomical region and generally regarded as variants of monostotic rather than polyostotic FD.[27]

Monostotic FD usually presents in children and young adults or on reactivation of quiescent lesions in adults (for example, during pregnancy) as a painless, slow-growing facial asymmetry or swelling. The smooth, fusiform enlargement is more marked buccally than palatally.[32] Teeth may be displaced or fail to erupt. Involvement of the maxillary sinus and zygomatic process results in exophthalmos and proptosis. Radiographically, the ill-defined

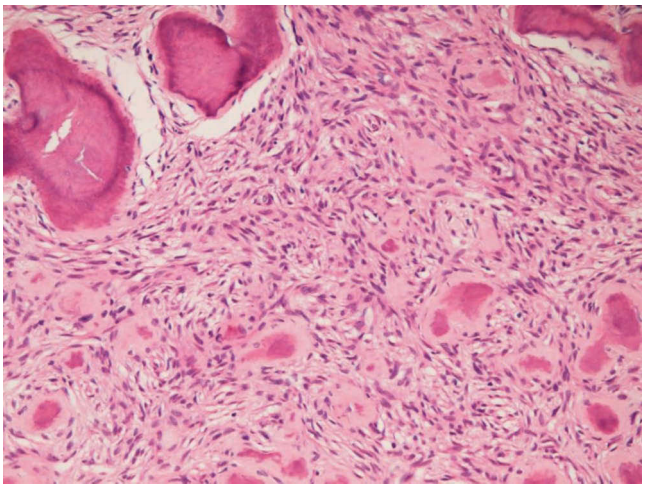

Figure 25.11 Pathological image of a fibro-osseous lesion. This could be an ossifying fibroma or one of the cemento-osseous dysplasias and distinction would require close clinical and radiological correlation.

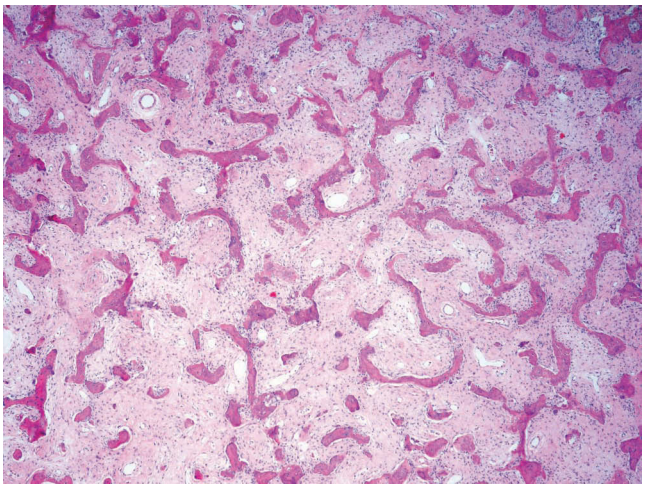

Figure 25.12 Histological picture of typical fibrous dysplasia; cellular fibrous stroma in which so called 'Chinese' character-like trabeculae of bone are deposited.

TABLE 25. 4 A modification of the classification of fibro-osseous lesions of the craniofacial complex proposed by Eversole et al[30]

Pathological process	Disease / condition	Sub-type
Bone dysplasias	Fibrous dysplasia	Monostostic (including craniofacial variant)
		Polyostotic
		Polyostotic with endocrinopathy (McCune–Albright syndrome)
	Osteitis deforms (Paget's disease)	
Cemento-osseous dysplasias	Focal cemento-osseous dysplasia	
	Florid cemento-osseous dysplasia	
Inflammatory / reactive processes	Focal sclerosing osteomyelitis	
	Diffuse sclerosing osteomyelitis	
	Proliferative periostitis	
Metabolic bone disease	Hyperparathyroidism	
Genetic	Cherubism	
Neoplastic	Ossifying fibroma	Ossifying fibroma NOS
		Juvenile ossifiying fibroma (trabecular and psammonatoid types)
		Gigantiform cementoma

lesions merge with normal bone. Early radiolucent lesions pass through mottled and ground-glass/orange-peel stages becoming opaque as bony trabeculae increase in number and size, extending to and distorting, but not crossing, suture lines.

Polyostotic FD mainly affects females (M:F ratio, 1:3), often affecting one side of the body. Most cases present in childhood with bony deformities and pathological fractures, occasionally with skin pigmentation and precocious puberty in females (McCune–Albright syndrome).[32]

Histology depends on the developmental stage of the lesion. Classically, the delicate trabeculae of newly-formed, woven bone resemble Chinese characters and are gradually remodelled to lamellar bone as the lesion ages (**Figure 25.12**).[32] The margin merges with surrounding normal bone, an important distinction from ossifying fibroma (see later).

FD is a sporadic (non-inherited) developmental disorder caused by mutation of somatic cells in fetal (polyostotic FD) or postnatal (monostotic FD) life resulting in alterations in osteoblast growth/differentiation due to faulty expression/signalling of the *GNAS1* gene which encodes for a stimulatory protein.[32] Lesions tend to become quiescent and management is mainly aesthetic reduction of deformity. Lesions are not radiosensitive. Radiotherapy is contraindicated and may increase the risk of transformation to fibro-/osteosarcoma.

OSTEITIS DEFORMANS (PAGET'S DISEASE OF BONE)

This occurs mainly in older adults and many cases are subclinical.[30, 34] Skull involvement is common and often associated with jaw lesions (mainly maxillary). Presentation includes bone pain and deformity, spacing

of teeth, difficulty with dentures, and motor/sensory deficit due to cranial nerve compression. In early lesions, increased bone vascularity results in post-extraction haemorrhage. Hypercementosis and ankylosis, common in later stages, make for traumatic extractions, thus exacerbating poor healing due to late-stage ischaemia. Radiographically, lesions are ill-defined, initially osteoporotic, gradually becoming osteosclerotic ('cotton-wool patches'). Histologically,[34] osteoclastic activity dominates early lesions. Resorbed bone is replaced by vascular, cellular fibrous tissue. Gradually, trabeculae of new bone are deposited and remodelled with prominent resting and reversal lines (mosaic bone). Serum alkaline phosphatase is raised in active disease and useful in monitoring treatment.[34]

Osteitis deformans results from osteoclast dysfunction.[34] Aetiology is unclear, possibly involving paramyxovirus infection and genetic predisposition (on chromosome 18q). Treatment is with calcitonin and/or bisphosphonates. Osteosarcoma is a rare complication mainly affecting cases with widespread lesions.

Cemento-osseous dysplasias

These non-neoplastic proliferations are subdivided into focal and florid based on differences in location and number of lesions (**Figure 25.13**).[34–37] COD is more prevalent in females than males (M:F ratio, 1:10), and in Blacks with most cases presenting after 30 years. Focal COD[36] is more common, and seen as multiple periapical lesions of mandibular incisors which are asymptomatic being discovered on routine radiographs. Early lesions are rounded radiolucencies, which become increasingly radiopaque (maintaining a narrow radiolucent rim) as bone/calcified acellular cementum-like tissue is deposited.[38] Related teeth are vital (in contrast to periapical granulomas/radicular cysts). Florid COF[36] affects all four quadrants and may cause jaw expansion or symptoms related to ulceration/infection. Gigantiform cementoma[37, 38] is a rare familial variant sometimes categorized as neoplastic. Histologically, in CODs, new bone and rounded cementum-like globules are increasing deposited within the fibrocellular stroma eventually leading to a solid, bone-like mass. COD is self-limiting and treatment (for cosmesis or infection) is rarely needed.

Inflammatory/reactive processes

SCLEROSING OSTEOMYELITIS (SO)

This is a form of non-suppurative chronic osteomyelitis[33, 34] and is usually a localized reaction to low-grade periapical inflammation or infection although bacteria are not readily cultivable. Focal lesions affect mainly the mandibular premolar/molar region in children and young adults and present as a localized, uniform radiodensity

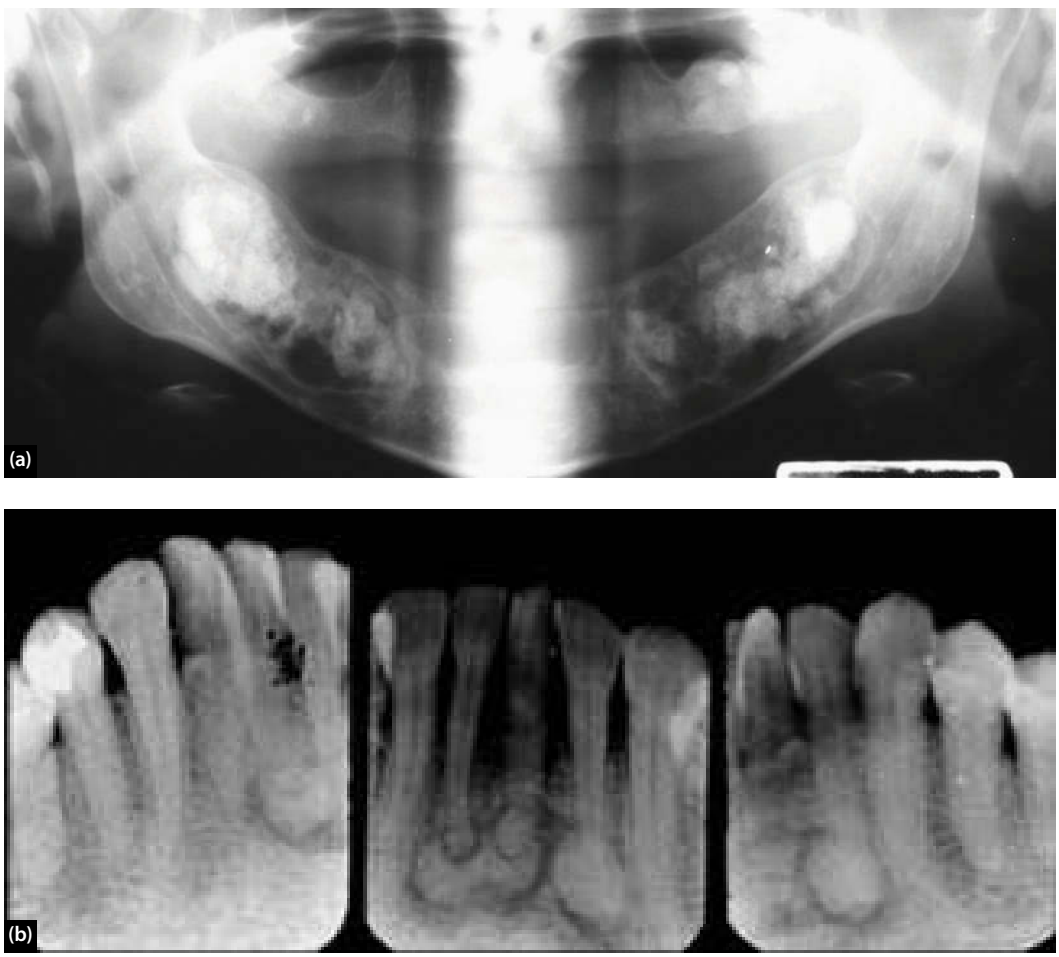

Figure 25.13
(a) Radiological appearances of florid cemento-osseous dysplasia and **(b)** periapical cemento-osseous dysplasia **(b)**.

related to the tooth root apex without jaw expansion. Histologically, dense sclerotic bone with scant fibrous connective tissue or inflammatory cells is seen. The diffuse form of SO affects adults[33, 34] and resembles florid COD radiographically. Treatment of SO is elimination of the source of inflammation by extraction or endodontic therapy. Sclerotic areas may remain radiographically.

PROLIFERATIVE PERIOSTITIS (GARRE'S OSTEOMYELITIS)

Mainly affecting adolescents, this form of chronic osteomyelitis results in onion-skin thickening and swelling of the mandibular lower border due to periosteal reaction to periapical inflammation.[30, 34] Histologically, highly cellular, woven bone is arranged in parallel layers. The bone gradually remodels 6–12 months following elimination of infection.

Metabolic bone disease: Hyperparathyroidism

The jaws may be affected as part of the multifocal replacement of bone by brown tumours, collections of osteoclasts within a vascular, haemosiderin-rich stroma.[30, 33, 34] Primary hyperparathyroidism (HP) due to parathyroid hyperplasia or adenoma mainly affects post-menopausal females. Radiolucent cyst-like lesions may be seen together with loss of lamina dura around tooth roots. Blood biochemistry is essential in interpreting the histological features which are indistinguishable from a giant-cell granuloma. Bone lesions due to the secondary HP associated with chronic renal failure are more common. The bone lesions of HP reverse on treatment of primary HP and respond to oral vitamin D in secondary HP.

Genetic: Cherubism

This is inherited as an autosomal trait (mapping to chromosome 4p16.3), but due to weaker penetrance in females, the phenotype is more common in males.[30, 33, 34] Onset usually occurs before the age of 7 years, presenting with swelling of the mandibular angles and in severe cases, the posterior maxillae, resulting in chubby face, interference with speech and swallowing, displacement/loosening of teeth and cervical lymphadenopathy (due to reactive hyperplasia). Maxillary involvement results in the eyes appearing to turn upwards. Radiography reveals multilocular radiolucencies with fine bony septae. Histologically, early lesions resemble giant cell granulomas with focal collections of multinucleated giant cells within cellular and vascular fibrous tissue. Vessels may show a hyaline cuff. Older lesions show increasing bony repair. Initial rapid growth slows on puberty and lesions gradually regress. Treatment by curettage or paring down is rarely needed.

Neoplastic: Ossifying fibroma and cemento-ossifying fibroma

Although neoplastic, traditionally ossifying fibroma (OF) and cemento-ossifying fibroma (COF)[30, 33] have been categorized with the fibro-osseous jaw lesions, and are considered part of a spectrum rather than two separate lesions. They present slowly as an expansile, well-circumscribed, painless swelling mainly affecting the mandibular premolar or molar regions. Females are more commonly affected than males with a peak incidence between 20 and 40 years of age. Radiographically, lesions are well-defined, initially radiolucent but with increasing calcifications centrally and eventually becoming mainly radiopaque with a narrow radiolucent rim. Roots of related teeth may be displaced. Histological appearances match the radiographic appearances being initially fibrous and cellular, later developing trabeculae of woven bone with peripheral osteoblasts, dystrophic calcifications and rounded cementicles.[38] The calcifications fuse with maturation eventually forming a dense calcified mass with a peripheral fibrous zone which allows the lesion to shell out from the adjacent bone during surgical enucleation.

Juvenile active (aggressive) OF affects the maxilla in children and adolescents[39] and histologically[40] the stroma is often highly cellular and the calcification pattern either trabecular (mainly osteoid with plump osteoblasts) or psammomatoid (compact, rounded calcifications). Some lesions are locally aggressive with a tendency to recur, but most respond to conservative surgery.

TUMOURS (NEOPLASMS)

Tumours arising from bone cells

OSTEOMAS

Osteoma, a benign neoplasm of bone, is subclassified into 'compact' (cortical) and 'cancellous'.[34] They can be situated on the surface of the bone and present as hard swellings (exostosis) or alternatively, can exist purely within the substance of the bone (enostosis, dense bone island) and in the latter location would likely be an incidental radiological finding. Some probably represent developmental anomalies or reactive hyperplasias rather than true neoplasms, common examples being mandibular tori (bilateral exostoses on the lingual aspect of the mandible in the premolar region) and palatine torus (a mushroom-like swelling in the midline of the palate). The most common site for a true osteoma is in the paranasal sinuses. Generally, tori present in childhood and grow slowly, and can be removed for cosmetic reasons or before fitting a denture. Multiple osteomas may be the presenting features of Gardner syndrome (**Figure 25.14**),[41] often leading to the diagnosis (and management by prophylactic colectomy) before adenocarcinomatous transformation of the familial colonic polyps.

OSTEOID OSTEOMA, OSTEOBLASTOMA

These are benign neoplasms of bone with 80% involving long bones and only 1% involving the jaws.[34] Most present in young adult males with severe pain which is relieved by aspirin. Osteoid osteomas are typically <2 cm in size while osteoblastomas are larger and more likely to present with swelling.[34] Radiography reveals a radiolucency

Figure 25.14 Gardner syndrome patient: multiple osteomas seen as radiodensities along with unerupted and supernumerary teeth.

with sclerotic rim and intralesional speckled calcification. Surgical exploration reveals a gritty lesion with well-defined boundaries, which shells out easily.

Histologically, a loose fibrovascular stroma containing abundant trabeculae of osteoid rimmed by plump osteoblasts and mineralized trabeculae is evident. Diagnosis of bony lesions should only be made when clinical and radiographic details are known since the plump osteoblasts could lead to an erroneous diagnosis of osteosarcoma especially when only curettings are available.

OSTEOCHONDROMA

This cartilage-capped exostosis is rare in the jaws, occurring mainly in the mandiblular condyle and coronoid process.[34] Differentiation from condylar hyperplasia can be difficult. Peak presentation is in females in the 4th–5th decade.[42] The slow-growing swellings cause progressive deformity. Histologically, both the overgrowth of bone and its cartilage cap are entirely benign. Any cellular atypia, especially within the cartilage, may indicate development of a secondary chondrosarcoma, a rare but well-documented occurrence.[33]

OSTEOSARCOMA

This is a malignant bone-producing tumour,[34] with only 6–10% of cases involving the jaws.[43–47] The average age at presentation of jaw lesions is 30–40 years, a decade more than for lesions at other sites. Most develop sporadically with no obvious aetiological factors. 'Secondary' osteosarcomas arise following radiotherapy or in Paget's disease of bone, FD, and in association with hereditary retinoblastoma, Ollier disease and Li-Fraumeni syndrome.

Swelling, pain, paraesthesia, ulceration and loose teeth are common presenting features.[46, 47] The radiographic appearance depends on the proportion of radiolucent soft tissue to radiopaque malignant bone matrix. The classical 'sunray' appearance results from the perpendicular spicules of periosteal new bone. Widening of periodontal ligament spaces and the inferior alveolar canal are other classical changes. Histological diagnosis requires the demonstration of osteoid and bone by overtly malignant cells. The architecture of the malignant bone is abnormal ('lace-like'). A high proportion of jaw lesions also contain malignant cartilage (chondroblastic osteosarcoma) while bone is scanty in some (fibroblastic osteosarcoma).

Osteosarcomas arising on the bone surface present specific characteristics and behaviours.[34, 46, 47] The parosteal osteosarcoma is a low-grade neoplasm which can mimic osteochondroma if a cartilage cap is present and also end-stage FD, highlighting the need for close radiological correlation and submission of reasonable quantities of lesional tissue for pathological diagnosis. The malignant cells are generally bland but some focal atypia should be demonstrable. Periosteal osteosarcomas are exceptionally rare and although generally clinically indolent, display more overt malignant cytological features and often abundant cartilage admixed with the malignant bone.

Surgery is the mainstay of treatment with the aim of achieving clear margins.[59] The 10-year survival is 59% in one series[45] with local recurrences more frequent than distant metastasis (31% versus 21%). Pre-surgical or adjuvant chemo- and radiotherapy may offer some benefits. The rarity of jaw osteosarcoma makes it difficult to assess the effectiveness of the well-defined protocols that exist for long-bone osteosarcoma. Overall, it is considered that the prognosis of osteosarcoma of jaws is better than long bones with 40% 5-year survival for jaw lesions compared with 20% at other sites.[43, 44]

CHONDROMA, CHONDROSARCOMA

These are rare in the jaws; the most common sites being the anterior maxilla and mandibular condyle, presenting mainly in middle age with pain, swelling and loosening of teeth.[34, 48, 49] Histologically, the chondroma is a cytologically benign tumour forming mature cartilage. A high degree of cellularity, multiple chondrocytes occupying a single lacuna and plump/binucleate cells are suspicious of well-differentiated chondrosarcoma.[34, 48] Demonstration of invasion is also important. Less well-differentiated chondrosarcomas exhibit more obvious cytological features of malignancy. Calcification and endochondral ossification may occur in both benign and malignant lesions and accounts for the variable radiographic appearances. The outline may be well- or ill-defined or multilocular. Signal characteristics typical of cartilage matrix can best be seen on CT scanning. As in osteosarcoma, the rarity means evidence-based treatment protocols are not yet established. Surgery is the mainstay of treatment with 60% 5-year survival.[49] Mandibular compared to maxillary lesions, small tumour size and high degree of differentiation are favourable prognostic features, the first two presumably reflecting the importance of achieving surgical clearance.

Odontogenic tumours

Odontogenic tumours, a spectrum of lesions unique to the jaws, are derived from tooth-forming apparatus.[50] They range from hamartoma-like dental malformations (odontomas) through to benign neoplasms, locally invasive growths, malignant neoplasms with metastatic potential

TABLE 25.5 Classification of odontogenic tumours (a modification of WHO classification[50])

Benign odontogenic tumours	
Arising from odontogenic epithelium only	Ameloblastoma
	Squamous odontogenic tumour
	Calcifying epithelial odontogenic tumour
	Keratocystic odontogenic tumour (formerly, odontogenic keratocyst)
Including odontogenic epithelium as well as ectomesenchyme with or without hard tissue formation	Ameloblastic fibroma
	Ameloblastic fibro-dentinoma and fibro-odontoma
	Complex and compound odontoma
	Calcifying cystic odontogenic tumour
	Dentinogenic ghost cell tumour
Arising from odontogenic ectomesenchyme only	Odontogenic fibroma
	Odontogenic myxoma
	Cementoblastoma
Malignant odontogenic tumours	
Odontogenic carcinomas	Metastasizing (malignant) ameloblastoma
	Ameloblastic carcinoma • Primary type • Secondary type (dedifferentiated)
	Primary intraosseous carcinoma • Solid type • Arising from keratocystic odontogenic tumour • Arising from other odontogenic cysts
	Clear cell odontogenic carcinoma
	Ghost cell odontogenic carcinoma
Odontogenic sarcomas	Ameloblastic fibrosarcoma
	Ameloblastic fibro-dentino-sarcoma and fibro-odontosarcoma

to primary intraosseous carcinomas with few, if any, odontogenic features. An abbreviated form of the WHO classification,[50] based on behaviour and pathogenesis, is shown in **Table 25.5**. Odontomas account for around one-third. Of the true neoplasms, excluding the keratocystic odontogenic tumour, recently redesignated as an odontogenic tumour, the ameloblastoma is as common as all other types combined. Diagnosis depends on clinical and radiological features as well as the precise histology, hence, accurate information on location, relationship to teeth, circumscription and radiodensity should be submitted to the reporting pathologist.[51] Odontogenic tumours tend to reflect morphological features and inductive interactions of normal tooth germs and histological distinction between some tumours relies on subtle features. The rarity of many lesions, and hybrid forms, add to the diagnostic challenge.

BENIGN ODONTOGENIC TUMOURS

Ameloblastoma

Although the most common odontogenic neoplasm,[52] ameloblastoma only accounts for around 1% of oral biopsies.[53] Based on clinical, radiographic, histological, behavioural and prognostic features, four subtypes[52] can be distinguished (**Table 25.6**). In addition, two malignant forms and a benign variant in which dental hard tissues develop are recognized (**Table 25.6** and see later).

Solid / Multicystic (Conventional) Ameloblastoma

Solid/multicystic (conventional) ameloblastoma (SMA), the most common type of ameloblastoma, displays benign but locally invasive growth with a high recurrence rate if not removed adequately.[52, 54] It is derived from rests of the dental lamina but trigger factors are unknown. The most common site is mandibular molar-ramus and the mandibular: maxillary ratio is around 5:1. All age groups are affected (mean, 37 years) with a M:F ratio of 1.2:1. SMA is centrally located within the jaw and hence, there are few clinical signs in early stages. Later, there may be increasing facial deformity, loosening of teeth, eggshell crackling, bone perforation and spontaneous jaw fracture. Radiographically, multilocular destruction of bone creates a soap-bubble (honeycomb) appearance (**Figure 25.9**). The scalloped margin may incorporate tooth roots typically showing resorption. Some SMA occurs in a dentigerous relationship with an unerupted tooth. At operation, the tumour appears as a greyish-white mass replacing bone. The cut surface is variously solid and cystic. Histologically,[52] the lesion consists of odontogenic epithelium within a fibrous stroma. The odontogenic epithelium shows two

TABLE 25.6 Classification of ameloblastomas and related odontogenic tumours

Benign odontogenic neoplasm	Subtype	Histological variants / key features
Ameloblastoma	Classic solid/multicystic (SMA)	Follicular
		Plexiform
	Unicystic (UA)	Luminal type
		Intraluminal type
		Intramural type
	Peripheral (extra-osseous) ameloblastoma (PA)	
	Desmoplastic ameloblastoma (DA)	
Odontoameloblastoma		Growth features are similar to SMA but contains dysplastic dentine and enamel
Malignant odontogenic neoplasms		
Metastasizing ameloblastoma		A retrospective diagnosis: typical histology but distant metastases occur
Ameloblastic carcinoma		Cellular atypia present

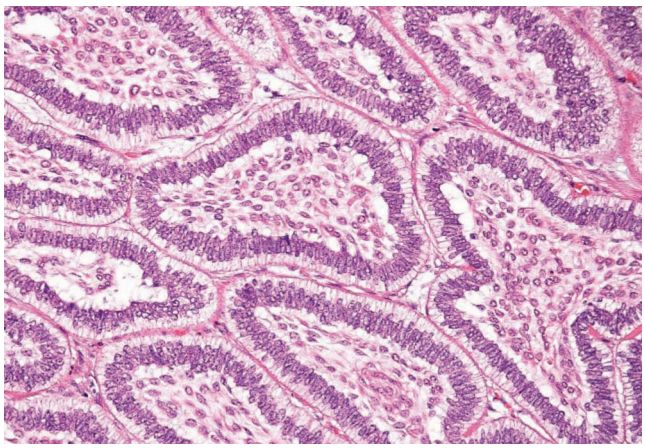

Figure 25.15 Histological image of follicular ameloblastoma. Tumour islands exhibit typical peripheral palisading, reverse polarity and there are central more loosely cohesive stellate reticulum like cells.

main patterns, follicular and plexiform, but many lesions comprise both. Each follicle/strand consists of outer, columnar ameloblast-like cells and inner stellate reticulum-like cells (**Figure 25.15**). Cysts may develop within the stellate cells (especially in the follicular pattern) or within the stroma (especially in the plexiform pattern). The stellate reticulum-like cells are more obvious in the follicular pattern and may display features of the spindle cell, basal cell, granular cell, acanthomatous (squamous), ghost cell or other, less common, histological variants.[52] The tumour infiltrates within the cancellous bone leading to poorly defined margins. The preferred treatment is *en bloc* resection since cancellous infiltration may extend 5mm or more beyond the radiological limits. A conservative approach (enucleation, curettage and burring the bone cavity followed by close review of healing) may be considered for small mandibular lesions. All maxillary lesions should be treated radically since the consequences of recurrence involving the skull base are severe with a mortality of up to 60%.[52, 54]

Unicystic Ameloblastoma

Unicystic ameloblastomas (UAs)[52] account for 5–15% of all ameloblastomas.[55] The term should be reserved for well-defined, monocystic lesions with a lining focally composed of ameloblastomatous epithelium (type I, luminal UA). The inner surface of the cyst lumen may show one or more polypoid, pedunculated masses (type II, intraluminal UA) or intramural nodular growths (type III, intramural UA). Types I and II tend to be in a dentigerous relationship although on removal, the involved tooth is displaced by the cyst rather than projecting into the lumen. Pathogenesis is controversial, theories including an origin from a pre-existing odontogenic cyst, ameloblastic transformation of reduced enamel epithelium, and cystic degeneration and subsequent fusion of microcysts within a SMA. The posterior mandible is the most common site (maxilla: mandible ratio, 1:5). Teens and young adults are mainly affected without an obvious gender distribution. Usual presentation is a painless swelling. Radiographically, UA may be unilocular or multilocular. Root resorption is common. Diagnosis requires assessment of the complete cyst and categorization based on findings in both the epithelial cyst lining and fibrous cyst wall. Types I and II are usually treated conservatively by enucleation and curettage. Type III shows a greater tendency to recur and is generally managed as SMA.

Peripheral (extra-osseous) ameloblastoma (PA)

These comprise 2–10% of all ameloblastomas and are thought to arise from extra-osseous residues of dental lamina (glands of Serres) or the basal layer of the oral mucosa.[52, 56] Around 70% affect the mandible, mainly premolar region. All ages are affected (mean, 52 years) with a M:F ratio of 1.9:1. PA presents as a painless, sessile, firm, 1 cm gingival/alveolar growth. The surface may be smooth, granular or warty. Colour varies from normal to deep red. Masticatory trauma may result in ulceration or frictional keratosis. In most cases, there is

no radiological evidence of bone involvement but large lesions may cause superficial saucerisation. Many PA are removed as suspected fibrous or inflammatory epulides. Histological features resemble SMA. PA are rare and the histological differential diagnosis includes peripheral odontogenic fibroma, squamous odontogenic tumour and odontogenic gingival epithelial hamartoma. PA does not invade bone and recurrence is rare after conservative supraperiosteal surgical excision with adequate (disease-free) margins.

Desmoplastic Ameloblastoma (DA)

This variant[52, 57] of SMA (accounting for 4–13%) exhibits locally infiltrative growth. In contrast to the other ameloblastoma categories, maxillary lesions are as common as mandibular. Lesions present over a wide age range. Males and females are equally affected. Initial usual clinical complaint is a painless swelling, 1–8 cm in size. Radiographically, the borders are ill defined (in contrast to other ameloblastomas) and around 50% are mixed radiolucent/radiopaque potentially leading to a pre-operative diagnosis of fibro-osseous lesion. Resorption of tooth roots is common. The tumour appears as a solid, white infiltrative growth. Histologically,[58] the irregularly shaped islands and cords of odontogenic epithelium are embedded in a densely fibrous stroma often with osseous metaplasia. Focal peripheral pallisading is seen but central areas are hypercellular, whorled spindle or acanthomatous cells rather than stellate reticulum-like. Radical resection is favoured and recurrence rates resemble those for SMA.

Squamous odontogenic tumour (SOT)

This rare benign, locally infiltrative tumour[59, 60] develops from the rests of Malassez within periodontal ligament of vital, erupted teeth and mainly affects the mandible. A wide age range, slight male predominance, and occasional multicentric lesions are reported. Tooth mobility, local pain, gingival swelling/erythema and bony expansion are typical presenting features. Radiographically, a unilocular (or in larger lesions, multilocular) rounded or triangular radiolucency between the roots of adjacent teeth is usual. Histologically, rounded islands of well-differentiated squamoid epithelial cells are embedded in a fibrous stroma. The differential diagnosis includes ameloblastoma, intra-osseous squamous cell carcinoma and 'squamous odontogenic tumour-like islands arising within the walls of odontogenic cysts'. Recurrence is rare after complete, conservative surgical treatment.

Calcifying epithelial odontogenic tumour (CEOT, Pindborg tumour)

CEOT,[61, 62] a locally invasive epithelial neoplasm, accounts for around 3% of odontogenic tumours. The mandibular: maxillary ratio is 2:1. Peak age of presentation is 40 years with most cases presenting between 20 and 60 years. There is no gender predilection. Usual presentation is asymptomatic, slow-growing expansile jaw mass. Radiographically, the unilocular/multilocular, mixed radiolucency-radiopacity may be associated with an unerupted tooth, most often a mandibular third molar. The tumour is solid and histologically consists of islands and sheets of polyhedral cells with conspicuous intercellular bridges embedded within a fibrous stroma. Important diagnostic features include the marked nuclear pleomorphism including giant/monster forms but lack of mitotic figures (unless the tumour has undergone malignant change); and the eosinophilic hyaline material within or around the tumour cells which is positive with stains for amyloid and frequently shows concentric rings of calcification. Differential diagnosis includes intraosseous squamous cell carcinoma, metastatic carcinoma, and, if clear cells are evident, a salivary gland neoplasm. Attention to cellular details such as the lack of mitotic figures and the amyloid globules should prevent a misdiagnosis. CEOT is locally invasive and local resection is needed except for small lesions where enucleation may be sufficient. The overall recurrence rate is around 15% but is higher after enucleation, in larger tumours and in the clear cell variant.

Adenomatoid odontogenic tumour (AOT)

This slowly progressive odontogenic epithelial lesion[63, 64] accounts for around 3% of odontogenic tumours and may be harmatomatous rather than neoplastic. It predominantly affects the maxilla (maxilla:mandible ratio, 2.1:1), females (M:F ratio, 1:1.9), and younger ages (90% < 30yrs). Most cases arise in association with the follicle of an unerupted canine presenting as a painless palpable bony-hard swelling and radiographically as a well-defined unilocular 'dentigerous' radiolucency often with discrete radiopaque foci. Intraosseous periapical and interdental, and peripheral (gingival) variants are less common. Histologically, the tumour is well circumscribed and encapsulated, consisting of variably sized nodules of cuboidal and columnar odontogenic epithelium, some with a characteristic glandular formation, embedded within a sparse fibrous stroma with droplets of eosinophilic amorphous material. Enucleation or curettage is curative. Recurrence is rare.

Keratocystic odontogenic tumour (KCOT), formerly odontogenic keratocyst

Formerly called 'odontogenic keratocyst', the KCOT[65] was renamed at the WHO Consensus Conference, 2003,[50] to reflect its neoplastic nature.[66–68] It is now designated a benign, uni-/multicystic odontogenic tumour with potential aggressive, infiltrative behaviour.[69] It is one of the most common odontogenic tumours, peaking in the 2nd and 3rd decades, with a M:F ratio of 1.6:1. Around 75% occur in the mandible, mainly in the molar-angle-ramus region. Many cases are asymptomatic presenting radiographically as a radiolucency, either small and round-ovoid, or larger with scalloped border (**Figure 25.16**). Large lesions may present with pain, swelling, discharge, pathological fracture and if cortical bone is penetrated, soft tissue involvement.

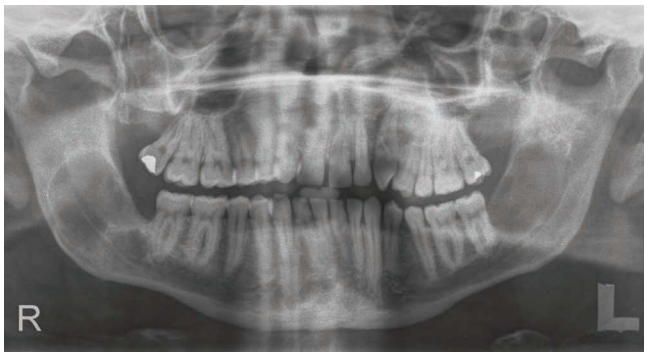

Figure 25.16 OPG of patient with Gorlin Golltz syndrome demonstrating three distinct radiolucencies: LLQ, LRQ and ULQ.

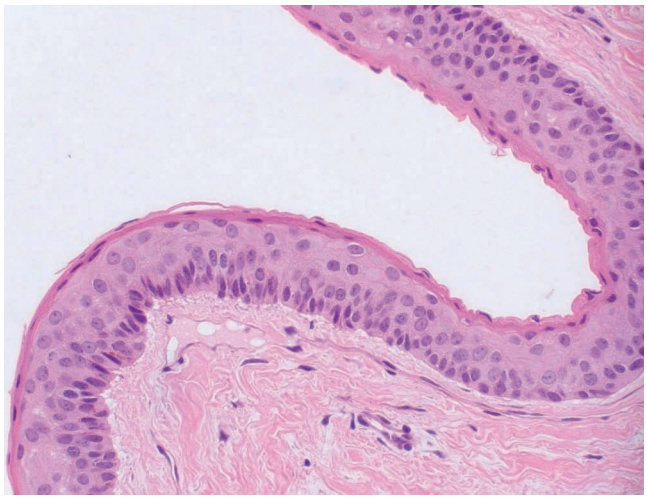

Figure 25.17 Parakeratinized epithelium characteristic of keratocystic odontogenic tumour.

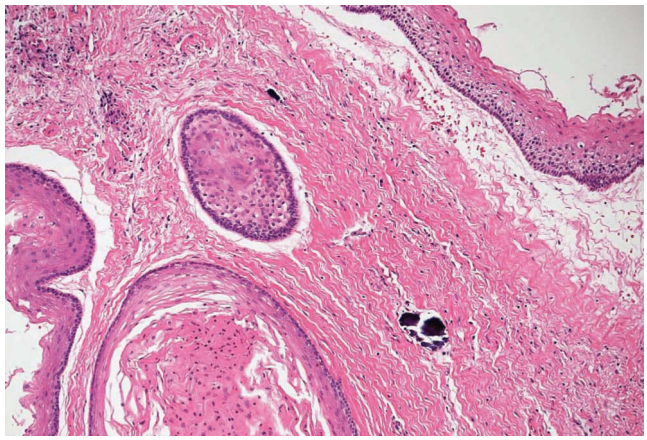

Figure 25.18 Daughter or satellite cysts in keratocystic odontogenic tumour from syndromic patient.

TABLE 25.7 The most common features of naevoid basal cell carcinoma syndrome

Features of naevoid basal cell carcinoma syndrome
Multiple keratocystic odontogenic tumours – either simultaneous or sequential
Basal cell carcinomata - multiple, often in non-sun-exposed skin sites
Frontal and temporoparietal bossing, hypertelorism, mandibular prognathism
Calcification of the falx cerebri
Bifid or deformed ribs
Medulloblastoma, abdominal neoplasms

Adjacent teeth may be displaced but root resorption is rare. The cyst lumen is full of creamy material – keratin squames – and the cyst wall is thin and lined by a thin, parakeratinized epithelium (**Figure 25.17**).

Odontogenic epithelial residues are frequent in the cyst wall and may give rise to satellite cysts (**Figure 25.18**). Budding of the cyst lining is less common but can give rise to daughter cysts. Mitotic figures may be present within suprabasal layers of the epithelial lining and other dysplastic features are occasionally seen and may herald malignant transformation.

Multiple KCOT (either simultaneous or sequential) are an important part of the inherited naevoid basal cell carcinoma syndrome (NBCCS, Gorlin Syndrome, Gorlin and Goltz Syndrome).[1, 70] **Table 25.7** shows the more common clinical features of the syndrome, and notable differences between non-syndrome sporadic and syndrome KCOT are shown in **Table 25.8**.

TABLE 25.8 A summary of clinical and histological features of keratocystic odontogenic tumours in non-syndrome and naevoid basal cell carcinoma syndrome patients

Non-syndrome KCOT	NBCCS KCOT
Single	Multiple – either simultaneous or sequential
Maxilla:mandible ratio, 1:3	Maxilla:mandible ratio, 1:1
Peak age, 20–40 years	Peak age, 15–30 years
Radiographically, generally small round-ovoid and unilocular	Radiographically, frequently large and multilocular
Few proliferating odontogenic epithelial residues and satellite cysts	Proliferating epithelial residues (some 'ameloblastomatous') and frequent satellite cysts
Rarely budding of main cyst lining or presence of daughter cysts	Occasional budding of main cyst lining and presence of daughter cysts
Recurrence rare after complete removal	Recurrence and further new cysts expected

The source of odontogenic epithelium giving rise to the KCOT is uncertain. The dental lamina and its remnants are favoured but there is some evidence for extensions of basal cells from overlying oral epithelium – the original source of the dental lamina in the embryo/infant.[1, 76] The genetic basis of KCOT[1] lies in the NBBCCS or PCTH gene, a tumour suppressor gene on chromosome 9q22.3-q31 which may suffer allelic loss leading to over-expression of bcl-1 and TP53. Over-expression and amplification of genes located in 12p may also be involved.

KCOT has a tendency to recur and the rate depends on the original treatment (overall recurrence rate, 20–25%). Local resection and enucleation with peripheral ostectomy and Carnoy's solution are curative while enucleation with peripheral ostectomy, enucleation alone, marsupialization and enucleation with Carnoy's solution are associated with increasing risk of recurrence (18%, 26%, 40% and 50% respectively in a recent systematic review).[71]

Ameloblastic fibroma, ameloblastic fibro-dentinoma, ameloblastic fibro-odontoma (AF, AFD, AFO)

AF is a rare, benign neoplasm of both odontogenic epithelium and ectomesenchyme.[72, 73] The presence of dentine or other dental tissues leads to the designation ameloblastic fibro-dentinoma[73] (AFD) and ameloblastic fibro-odontoma (AFO),[73, 74] respectively.

Most AF are found in the posterior mandible, presenting as painless swelling or on investigation of disturbed tooth eruption. The peak age is 15 years and there is no sex predilection. Radiographically, a well-demarcated, uni- or multilocular radiolucency with a sclerotic rim is typical. Histologically, strands and islands of odontogenic epithelium forming knots with peripheral palisading (each knot resembles a normal developing tooth germ) are embedded in a cell-rich ectomesenchyme resembling dental papilla. Differential diagnosis includes ameloblastoma (in which the stroma is mature and fibrous rather than immature, cell rich and myxoid); enlarged/hyperplastic dental follicle (scanty epithelium; typical location overlying unerupted tooth); and when hard tissues are evident, the AFD and AFO. Enucleation and curettage is generally curative. Recurrence may follow incomplete removal and rarely, progression to malignancy (ameloblastic fibrosarcoma) is reported.[72]

Odontomes

Odontomes[75–77] are dental hamartomas rather than neoplasms, and range from malformed teeth at one end of the spectrum through to masses of haphazardly arranged enamel, dentine and cementum (composite odontomes). A malformed tooth may replace one of the normal series in either the deciduous or permanent dentition and well-recognized forms include the dens-in-dente (dilated gestant), geminated, and taurodont. The diagnosis of a mature malformed tooth is obvious on radiography but immature forms are radiolucent with variable focal radiopacities (increasing as maturity is reached). Treatment depends on symptoms, location and dental factors and most cases require surgical removal.

The **compound odontome**[75, 76, 78] consists of a varying number of miniature teeth (denticles/odontoids) within a fibrous sac. The anterior maxilla is the usual site but they are found in any tooth-bearing area of both jaws. They are diagnosed mainly in children and adolescents, show no sex predilection, and are one of the most common odontogenic hamartomas/tumours. Once fully mature, growth ceases (generally at 1–2 cm in diameter) and jaw swelling is unusual. Most cases are diagnosed when they impede eruption of a nearby tooth or cause displacement of an erupted tooth. Multiple compound odontomes may be sporadic or part of Gardner syndrome.[34, 79] Radiologically, the denticles and surrounding fibrous sac (radiolucent peripheral zone) are usually obvious. Macroscopic assessment of the specimen may be sufficient to make a definitive diagnosis. Demineralized sections show the denticles, and depending on maturity, immature enamel, dentinoid, cementoid and variable amounts of odontogenic epithelium, dental papilla and reduced enamel epithelium. Enucleation is curative and recurrence does not occur.

The **complex odontome**[80] is also common in children and adolescents of both sexes. The most frequently affected tooth bearing site is posterior mandible. They tend to grow to 3–6 cm in diameter and generally present as slowly increasing, painless swelling, often associated with impairment of eruption or displacement of adjacent teeth. The typical radiographic appearance of a maturing lesion is a spherical/ovoid radiopacity with a radiating periphery and surrounding radiolucent zone. Local enucleation is generally curative but recurrence may follow incomplete removal of an immature lesion. Histological assessment of mature complex odontomes shows variable amounts of enamel, dentine and cement, haphazardly arranged and surrounded and supported by a collagenous capsule containing strands and islands of odontogenic epithelium. Developing lesions show more unmineralized dental tissues and cellular areas of soft tissue. The distinction from the compound odontome is not clear cut.[81] Immature forms may contain AF-like areas leading to uncertainty about the true nature of the AF and its variants which some workers consider represent immature odontomes.[72, 73]

Odontoameloblastoma

This extremely rare tumour[82] is similar to an SMA but contains hard dental tissues. Most lesions present in the posterior mandible, in teens and young adults. The M:F ratio is 2:1. Radiographically, a well-defined uni-/multilocular radiolucency containing variable amounts of radiopaque material (either denticles or a central, solid mass) is seen. Growth characteristics, management and prognosis are similar to SMA.

Calcifying cystic odontogenic tumour (CCOT, keratinizing and calcifying odontogenic cyst, calcifying odontogenic cyst, Gorlin cyst)

This is a rare cystic benign neoplasm,[81, 83] occurring mainly in the anterior region of either jaw, over a wide age range and without sex predilection. Most cases are asymptomatic and present radiographically as a well-circumscribed unilocular radiolucency containing variably-sized calcified bodies. Adjacent erupted teeth frequently show root resorption or divergence and unerupted teeth may be displaced. Histologically, the cyst shows similarities with UA but the stellate-reticulum-like cells are transformed to eosinophilic ghost cells. Ghost cells frequently calcify and dentinoid-like material may be deposited within the fibrous cyst wall. Enucleation is usually curative and recurrence is rare.

Dentinogenic ghost cell tumour (calcifying ghost cell odontogenic tumour, odontogenic ghost cell tumour) (DGCT)

This tumour[81, 84] used to be considered a solid variant of the calcifying odontogenic cyst but is now classified as a locally invasive neoplasm with features resembling ameloblastoma but characterized by keratinization, ghost cells and dentinoid.[50] The tumour occurs in any tooth-bearing area of either jaw (but mainly premolar), affecting a wide age range with males more frequently affected than females. Small lesions are generally asymptomatic but larger lesions cause bony expansion or perforation, and tooth displacement and mobility. Radiographically, the lesion is generally well demarcated, radiolucent or mixed radiolucent/radiopaque. Histologically, an infiltrative margin is seen and the presence of ghost cells and dentinoid are critical in distinguishing the lesion from an ameloblastoma. Distinction from a CCOT can be difficult. The presence of mitoses is suspicious of transformation to odontogenic ghost cell carcinoma. The infiltrative nature of DGCT dictates wide local excision as the treatment of choice.

Odontogenic fibroma

Controversy exists over the concept and definition of this rare tumour.[85, 86] Currently, odontogenic fibroma (OF) is applied to two histological types:[50] epithelium-poor (formerly known as simple type) and possibly derived from dental follicle, and epithelium-rich (formerly known as complex or WHO type) and possibly derived from periodontal ligament. The intraosseous lesion, most common in the premolar region of the mandible, is mainly epithelial-rich and affects adults with a M:F ratio of 1:3. The usual presentation is a slow-growing, painless jaw swelling with cortical expansion. Radiographically, most cases present as a unilocular radiolucency with a well-defined sclerotic border. Larger lesions may have a scalloped margin and sometimes, spotted radiopacities are evident. Histologically, the epithelial-rich type is composed of cellular, fibroblastic connective tissue containing islands and strands of inactive-looking odontogenic epithelium and foci of calcified material (metaplastic cementum/osteoid/dentine). Differential diagnosis includes hyperplastic/enlarged dental follicle and fibromyxoma. OF is well circumscribed and simple enucleation is curative.

Odontogenic myxoma (OM), odontogenic fibromyxoma (OFM)

This benign, locally infiltrative tumour[87, 88] accounts for 3% of odontogenic neoplasms. Pathogenesis is uncertain and the name was originally based on location, resemblance to dental papilla/follicle, and sporadic presence of odontogenic epithelium. Ultrastructural and immunohistochemical studies have not confirmed an origin from ectomesenchyme of the developing tooth and suggest a non-odontogenic origin from myofibroblasts and/or histiocytes. The tumour is more common in females, typically 15–35 years, and two-thirds occur in the mandible (mainly posterior). Typical presentation is a slowly increasing, painless swelling or asymmetry of the affected jaw but growth may be rapid and associated with tooth mobility, root resorption, and in maxillary lesions, nasal obstruction and exophthalmus. Radiographically, a multilocular, soap-bubble (honeycomb) appearance is seen (as in ameloblastoma, KCOT and haemangioma). Macroscopically, the cut surface is white, mucoid and sticky. Histologically, tumour infiltrates bone marrow spaces and consists of cytologically bland rounded, spindle-shaped or angular cells evenly spaced within abundant mucinous matrix. The matrix is finely fibrillar and may contain scattered small islands of odontogenic epithelium, sometimes with a hyaline cuff. More collagenous examples are designated fibromyxoma. The differential diagnosis includes enlarged (hyperplastic) dental follicle, and myxomatous degeneration in fast growing neoplasms such as chondrosarcoma and liposarcoma. Recurrence ranges from 10% to 33% and is more common after conservative surgery. Currettage with frozen-section assessment of margins is generally adequate for smaller lesions but radical resection may be necessary for large, diffuse lesions. Metastases do not occur.

Benign cementoblastoma

This is a benign neoplasm[89, 90] arises from cementoblasts and is fused to a tooth root. The mandibular first molar in young adults (peak, 20 years of age) is most frequently affected. There is no sex predilection. Most present with painful swelling of the buccal and lingual alveolar ridge over a vital tooth. Radiographically, a well-defined, rounded, radiopaque or mixed-density lesion, replacing the apical third of the root, is surrounded by a narrow radiolucent zone (**Figure 25.19**). Histologically, dense

Figure 25.19 Periapical radiograph of benign cementoblastoma, typical relationship to root of molar tooth, radiodense with lucent rim.

masses of acellular cementum (similar to Pagetoid bone) are supported by a fibrovascular stroma often with scattered multinucleated cells. A zone of unmineralized cementoid is seen peripherally. The dental origin is key to distinguishing it from an osteoblastoma and osteosarcoma. Extraction of the associated tooth and complete enucleation are recommended. Recurrence is common after incomplete removal.

MALIGNANT ODONTOGENIC TUMOURS

These are rare.[50] Some appear to be the malignant counterparts of benign odontogenic tumours. Others arise by malignant transformation of epithelial residues or the lining of odontogenic cysts. Aetiology is unknown. Odontogenic carcinomas[91] are more frequent in the elderly while odontogenic sarcomas affect younger age groups. Clinical features include swelling, pain, bleeding, mucosal ulceration, tooth mobility, paraesthesia, and pathological fracture. Radiographically, extensive jaw destruction with ill-defined borders, sometimes with patchy radiopacities, is typical. In carcinomas, metastasis to local lymph nodes and distant sites may occur early and prognosis is generally poor even after resection with tumour-free margins.

Metastasizing (malignant) ameloblastoma

This is a diagnosis made retrospectively when a histologically typical ameloblastoma gives rise to metastases (mainly lung).[92]

Ameloblastic carcinoma (primary type)

This rare tumour, an ameloblastoma with atypia,[92] presents mainly in the posterior mandible and shows no obvious sex predilection. Differential diagnosis includes ameloblastomas with occasional mitotic figures (and no other cellular/architectural atypia), other odontogenic carcinomas and metastatic carcinoma. Pulmonary metastases are present at initial diagnosis in around one-third of maxillary lesions but mainly follow local recurrence in mandibular lesions.

Ameloblastic carcinoma, secondary type (de-differentiated)

This very rare lesion arises within a pre-existing, and often long standing/recurrent, benign ameloblastoma.[92] Cellular atypia and nerve invasion are characteristic changes. Size and proximity to skull base and other vital structures dictate the adequacy of surgical resection and survival.

Primary intra-osseous squamous cell carcinoma (primary intra-osseous epidermoid carcinoma)

This is a central jaw carcinoma derived from odontogenic epithelial residues.[93] Once the tumour destroys the cortex, it may merge with the surface mucosa and be difficult to distinguish from squamous cell carcinoma (SCC) of mucosal (and antral) origin.

Primary intra-osseous squamous cell carcinoma (PIOSCC), **solid type,**[94] invades marrow spaces and induces osseous resorption. The aetiology is unknown. It is derived from odontogenic epithelial residues such as the periradicular rests of Malassez within the periodontal ligament and the reduced enamel epithelium surrounding impacted unerupted teeth. Dedifferentiation from a benign ameloblastoma is a further (rare) possibility. Most arise in later adult life with a M:F ratio of 2:1). Most are located in the body and posterior mandible. Maxillary cases tend to involve the anterior region. The lesion is often discovered as an incidental irregular, non-corticated radiolucency following routine jaw radiography. Large lesions may cause facial swelling and paraesthesia. Histologically, PIOSCC, solid type, is generally moderately differentiated and without specific features. Metastatic SCC must be excluded by clinical and radiological examination. Surgical resection is frequently followed by local recurrence, regional and distant metastases and prognosis is poor.

The other rare subtypes of **PIOSCC**, derived from **KCOT**,[94, 95] and **PIOSS**, derived from **odontogenic cysts**,[94] show SCC in association with a KCOT or odontogenic cyst and generally affect older adults, with a M:F ratio of 2:1. The mandible is much more affected than the maxilla. The SCC may be discovered on histological assessment of a suspected benign tumour/cyst or may present with pain, swelling, loose teeth, non-healing tooth socket, paraesthesia and regional lymphadenopathy. Radiographic appearances range from a typical cyst to an ill-defined radiolucency to gross cortical destruction and soft-tissue extension. Histologically, well differentiated SCC is seen merging with KCOT or the lining of the odontogenic cyst which may show dysplasia or features of verrucous hyperplasia/carcinoma. Differential diagnosis[93] can include keratoameloblastoma, SOT, central mucoepidermoid carcinoma and metastatic tumour. Based on small numbers,

the prognosis is thought to be more favourable than PIOSCC, solid type.

Clear cell odontogenic carcinoma

The rare clear cell odontogenic carcinoma (CCOC)[95–97] predominantly affects the mandible of older females, presenting as jaw swelling with loosening of teeth and radiographically, as an ill-defined radiolucency with root resorption. Histologically, a biphasic pattern of sheets of clear cells and irregular cords of basaloid cells supported by fibrous septae is typical. Many of the tumour cells contain diastase-degradable PAS-positive granules. Differential diagnosis includes salivary gland neoplasms, clear cell variant of CEOT, metastatic renal cell carcinoma and malignant melanoma. Surgical resection may be followed by local recurrence, regional and distant (lungs, bone) metastases and prognosis is poor for large lesions. Post-operative radiotherapy should be considered especially if there is cortical erosion/perforation.

Ghost cell odontogenic carcinoma

This rare neoplasm[81, 98] shows features of CCOT and/or GCOT and mainly affects the maxilla in adult males. Clinical symptoms include swelling and paraesthesia. Radiographically, a poorly demarcated radiolucency with patchy radiopacity and root displacement or resorption is typical. Histologically, the malignant component consists of rounded, mitotically active, epithelial islands in a fibrous stroma and lies adjacent to, or admixed with, typical benign GCOT. Prognosis is unpredictable. Some recur locally and metastasize.

Ameloblastic fibrosarcoma, fibro-dentinosarcoma and fibro-odontosarcoma

Ameloblastic fibrosarcoma (AFS) is the initial diagnosis in around two-thirds of cases while the remainder develop within a pre-existing AF.[99] AFS[100] has a mean age of 28 years (compared to 15 years for AF) and M:F ratio of 1.6:1. Posterior mandible is the most common site. Histologically, benign epithelial nests and cords are present in a highly cellular, cytologically malignant ectomesenchyme. Scattered areas of dentine and enamel, dentine and cementum are present in the ameloblastic fibro-dentinosarcoma (AFDS) and fibro-odontosarcoma (AOFS),[100] respectively. Surgical resection is treatment of choice and the tumours are generally low grade, and with few metastases and a better survival than other jaw sarcomata.

INTRA-OSSEOUS SALIVARY GLAND TUMOURS

Salivary-type carcinomas may occur in the jaws as primary central tumours,[101] but this is very rare compared to the more common jaw involvement by direct spread from an extra-osseous site (mainly, parotid or retromolar). Mandible is affected more often than maxilla and mucoepidermoid and adenoid cystic carcinoma are the most common histological types. Intra-osseous salivary tissue may result from entrapment during embryonic development, surgical manipulation, or metaplastic odontogenic epithelium.[100] Central intra-osseus salivary adenocarcinoma with non-specific/not otherwise specified histology, is very rare and imaging and monitoring clinical progress are important adjuncts to immunohistochemistry in reaching the correct diagnosis. Intra-osseous salivary gland tumours (IOSGT) are usually managed by radical surgical excision, often supplemented by radiotherapy.

MISCELLANEOUS NEOPLASMS

Ewing sarcoma

This is rare in the jaws, mainly affecting the mandibular body in children and young adults.[102] Progressive bone swelling, followed by pain, loosening of teeth and mucosal ulceration is usual. Systemic symptoms of fever, leucocytosis, raised ESR and anaemia indicate a poor prognosis. Histologically, the neuroectodermal Ewing sarcoma cells resemble enlarged lymphocytes and form sheets separated by fibrous septae. Wide excision, followed by radiotherapy and combination chemotherapy, is the usual treatment but may be unsuccessful due to distant spread to the lungs, other bones and lymph nodes.

Haemangioma of bone

Haemangioma of the jaws is uncommon.[34, 79, 103] Solitary lesions mainly affect the mandible, and females, but involvement of the maxilla is an important part of Sturge–Weber syndrome (together with facial port-wine stain and epilepsy). Progressive, painless swelling is the usual presentation. Pulsation indicating resorption of the overlying bone, and loosening teeth with gingival bleeding may be seen with larger lesions. Radiographically, the honeycomb locularity can be difficult to distinguish from ameloblastoma, KCOT and OM. Fresh blood on attempted aspiration is an important diagnostic clue. Histologically, most intra-osseous haemangiomas are of cavernous type. Wide surgical resection may be the only practical treatment but selective arterial embolization may be useful if there are well-defined feeder vessels.

Melanotic neuroectodermal tumour of infancy (Progonoma)

This is a rare tumour of neural crest origin that involves the anterior maxilla either congenitally or in the first few months after birth.[76, 79, 104] It presents as a painless, bluish swelling which occasionally grows rapidly. Radiographically, there is ragged bone destruction and displacement of developing teeth. Histology shows the characteristic clusters and strands of melanin-pigmented and non-pigmented epithelial cells supported by a fibrous stroma. The tumour is benign but non-encapsulated.

Curettage or conservative surgery is curative and recurrence is rare.

Multiple myeloma (myelomatosis), solitary plasmacytoma

Multiple myeloma, a monoclonal immunoglobulin-producing neoplasm of plasma cells, may present with multiple 'punched-out' radiolucencies (typically of the skull vault and areas of red-marrow) on routine radiography or with bone pain/tenderness or signs of bone marrow replacement (anaemia, infections and thrombocytopenia).[34, 79, 105] Peak incidence is 50–70 years of age. Histologically, sheets of neoplastic plasma cells may be well or poorly differentiated with bi- and multi-nucleated forms. Immunohistochemistry for kappa and lambda chains and Ig class shows the monoclonal nature and monoclonal 'M' band seen on serum electrophoresis is confirmatory. Healing may follow combination chemotherapy but relapse is common and 5-year survival is only 20%. The solitary plasmacytoma[106] is managed by radiotherapy and has a good 5-year prognosis but the majority of patients succumb to multifocal disease after 10 or more years.

Langerhans cell histiocytosis (histiocytosis X), eosinophilic granuloma

Langerhans cells, the antigen-presenting histiocytes of epithelia, occasionally give rise to bone tumours. Langerhans cell histiocytosis (histiocytosis X) (LCH) of bone may present as a single 'eosinophilic granuloma'; or multifocally within bone and other organs, or with generalized disseminated multiorgan disease.[34, 79, 107] Multifocal involvement of the craniofacial bones, orbit and posterior pituitary presents with skull defects, exophthalmus and diabetes insipidus (Hand-Schuller-Christian syndrome). The most severe form, disseminated Letterer–Siwe disease, occurs mainly in infants and has a high mortality. Unifocal and multifocal eosinophilic granuloma typically occur in older children/young adults with a 2:1 M:F ratio. The cranium and jaws, in particular the mandible, are common sites. Radiographically, the lesions are osteolytic, rounded and indistinct. Multiple jaw lesions result in the classic 'teeth floating in air' appearance. Loosening and exfoliation of teeth is a common presentation. Involvement of the temporal bone can present as otitis media mastoiditis. Histologically, collections of histiocytes admixed with eosinophils are seen. Immunohistochemical demonstration of the Langerhans cells surface antigen, CD1a, and S-100 protein is diagnostic and has largely replaced the electron microscopical detection of Birbeck granules. Generally, eosinophilic granuloma heals after curettage and some regress spontaneously. More disseminated disease is unpredictable. Genetic studies have shown LCH represents a clonal proliferation and the neoplasm may progress despite irradiation and/or chemotherapy.[107]

METASTATIC TUMOURS

Metastatic carcinoma to the jaws may be from a known or as yet undiagnosed primary carcinoma.[48, 106, 142] Elderly men and women are mainly affected and haemopoietic marrow within the posterior mandible is the most commonly involved site. It is not known whether healing extraction sockets and/or subclinical chronic inflammation which result in foci of increased vascularity encourage deposition of metastatic tumour at other sites within the jaws. Clinical presentation varies from asymptomatic to mobile/drifting teeth, pain, swelling and pathological fracture. Radiography typically reveals an ill-defined or mottled radiolucency. For men, the most common origins of the primary carcinoma are lung, prostate and adrenal glands; and for women, breast, adrenal glands, colon and rectum, genital tract and thyroid.

Details of the immunohistological profiles for the cytokeratins and transcription factors that are useful in the histological diagnosis of the source of the metastatic carcinoma, and the limitations, are discussed by Woolgar et al[102] A logical approach to identify an undifferentiated/poorly differentiated neoplasm begins with a basic screening panel including markers for epithelial, mesenchymal and haemopoietic lineages, and malignant melanoma. This is then followed by staining for cytokeratin profiles and specific antigens or transcription factors (useful in poorly differentiated neoplasms) and in suspected adenocarcinomas, mucosubstance histochemistry. Limited confirmatory staining only is necessary if the existence of a primary tumour is already known and declared on the pathology request form. Management is palliative and depends on factors related to the primary tumour, number and site of metastatic deposits and general patient factors. Even when the prognosis and life expectancy are poor, localized radiotherapy can help control symptoms such as jaw pain particularly when referred to the ear.

KEY POINTS

- The bones of the facial skeleton, by virtue of their association with dentition, can be the origin of a unique group of bone cysts and tumours.
- Owing to the complex embryologic origin, significant epithelial remnants can be trapped within the jaw bones, leading to the high prevalence of cysts in the human body.
- Additionally, other osseous benign and malignant pathology seen elsewhere in the body, can also arise in the jaw bones.
- While clinical presentation and radiologic findings may indicate the nature of the pathology, histologic examination is almost always required to make the diagnosis owing to the wide array of pathologic processes.
- Specialist pathologic expertise is needed as some of the entities are rare and the classification of these lesions is constantly evolving.
- Malignant and systemic diseases affecting the jaw bones will need the input of a multidisciplinary team.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: head and neck, biopsy, pathology, cytology, histopathology, histochemistry, immunohistochemistry, *in situ* hybridization, tumour, neoplasia, salivary gland tumour, squamous cell carcinoma, nasopharyngeal carcinoma, lymphoma and neuroectodermal tumour.

INTRODUCTION

The head and neck comprises a complex anatomical region composed of diverse tissues. Consequently many of the diseases that occur are challenging to diagnose and require careful clinico-pathological correlation. Some of the diseases are unique to the site and specialist knowledge is required to derive a differential diagnosis and pursue the appropriate investigations leading to a definitive diagnosis and effective management. Furthermore, some of the diseases are rare and require evaluation by specialist pathologists with the requisite experience to render an accurate diagnosis.

For neoplastic disease, the pathologist has a significant role in assessing whether the tumour has been completely eradicated. For malignant disease, parameters such as tumour grade and stage are important prognostic indicators and determine adjuvant treatment. Furthermore, the evolution of molecular pathology in recent years has led to the emergence of tests that can be used to tailor treatment for individual patients. Biological treatments, such as trastuzumab for breast cancer, require 'companion diagnostic tests' to select the right patients. This strategy ensures that patients have access to the most effective treatment and the best chance of cure. Whilst targeted treatments for head and neck disease remain elusive, this is likely to change over the next decade.

PATHOLOGICAL EVALUATION

There are a number of techniques available to obtain a biopsy specimen for pathological evaluation. The choice of technique mainly depends on the size and location of the lesion (**Table 26.1**).

Fine-needle aspiration biopsy

Fine-needle aspiration biopsy (FNAB) is the first-line investigation for patients presenting with cervical lymphadenopathy or with a lesion in the major salivary glands or thyroid gland.[1] FNAB is highly accurate, especially when the evaluation is restricted to determining non-neoplastic vs. neoplastic and benign vs. malignant.[2] Furthermore, the procedure is acceptable to patients and there is minimal morbidity. The technique is simple to perform and relatively inexpensive. FNAB can be performed 'free-hand' by palpation; however, the use of ultrasound guidance increases the yield of relevant material. It may be possible to get support from a cytologist to determine the adequacy of the specimen in the clinic. Some units provide a 'one-stop' head and neck lump clinic with immediate cytological diagnosis.[3] It is important to emphasize that a negative result on FNAB does not exclude disease and that 'triple assessment' (clinical, imaging and cytolopathology) is essential to arrive at the correct diagnosis.

Fixed smears should be immersed in fixative, usually alcohol-based, without delay and are typically stained with the Papanicolau (Pap) method or sometimes haematoxylin and eosin (H&E). Air-dried smears are best subjected to assisted air flow and are usually stained with a Romanowsky-type stain, commonly May-Grünwald-Giemsa (MGG) or Diff-Quik variants (**Figure 26.1**). Needles and syringe

TABLE 26.1 The advantages and disadvantages of commonly used tissue sampling techniques

Type of sample	Advantages	Disadvantages
Fine-needle aspiration biopsy (FNAB)	• Simple technique • Inexpensive • Can be undertaken in clinic • Relatively risk free • Does not usually compromise future management • Highly accurate, especially when the evaluation is restricted to determining non-neoplastic vs. neoplastic and benign vs. malignant	• Primary cytological diagnosis by FNAB must be confirmed by histology prior to radical treatment for head and neck cancer • Diagnostic yield is both lesion-sensitive and operator-dependent and there can be a high non-diagnostic rate, but this may be improved with the use of ultrasound guidance • Requires an expert cytopathologist • Clinicians must be aware of inherent limitations including a risk of false positives and false negatives • FNAB is of limited help in the diagnosis of lymphoma. Flow cytometry may be helpful in excluding a diagnosis of lymphoma
Core biopsy	• Simple technique • Inexpensive • Can be undertaken in clinic • The diagnostic yield is higher than for FNAB and the sample undergoes histopathological analysis, and therefore specific cytopathological expertise is not required • The complications of the procedure are relatively minor, the most common being haematoma formation • By contrast to FNAB, a core biopsy sample permits a greater chance of sub-classification of a lymphoma and may obviate the need for an open biopsy	• Appropriate precautions are required for patients taking anticoagulation therapy to prevent bleeding and haematoma formation • There is a theoretical risk of tumour seeding associated with the larger needles used in obtaining a core biopsy, but published case series have rarely encountered this complication
Incision biopsy	• Can provide definitive histological diagnosis	• Can affect definitive management of the tumour • Can require admission as a day case • May require a general anaesthetic • Higher complication rate than FNAB or core biopsy • Costlier than FNAB or core biopsy
Excision biopsy	• Can provide definitive histological diagnosis • Can be definitive treatment of the tumour	• Higher risk of complication compared to other biopsy techniques • Can require admission • May require a general anaesthetic • Costliest method of obtaining a biopsy

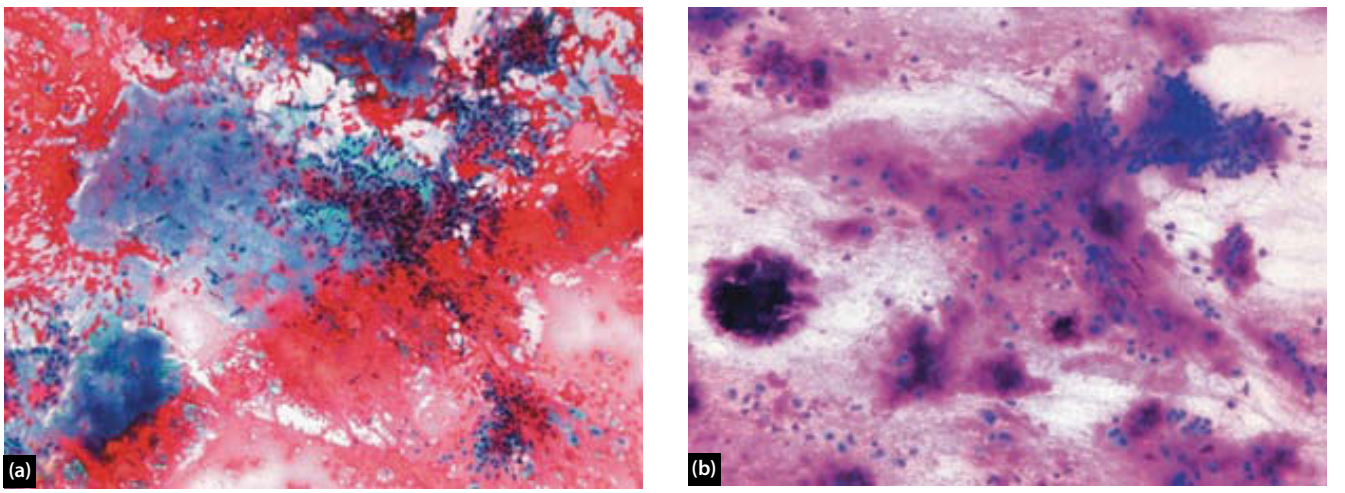

Figure 26.1 Fine-needle aspiration biopsy (FNAB) preparations from a pleomorphic salivary adenoma. (a) This alcohol-fixed slide shows weakly stained, feathery stroma admixed with loosely cohesive, isomorphic epithelioid and spindle cells (Pap stain, medium magnification). **(b)** This air-dried slide from the same tumour at the same magnification highlights the intensely stained myxoid ground substance, which obscures cytological detail in areas (May-Grünwald-Giemsa (MGG) stain, medium magnification).

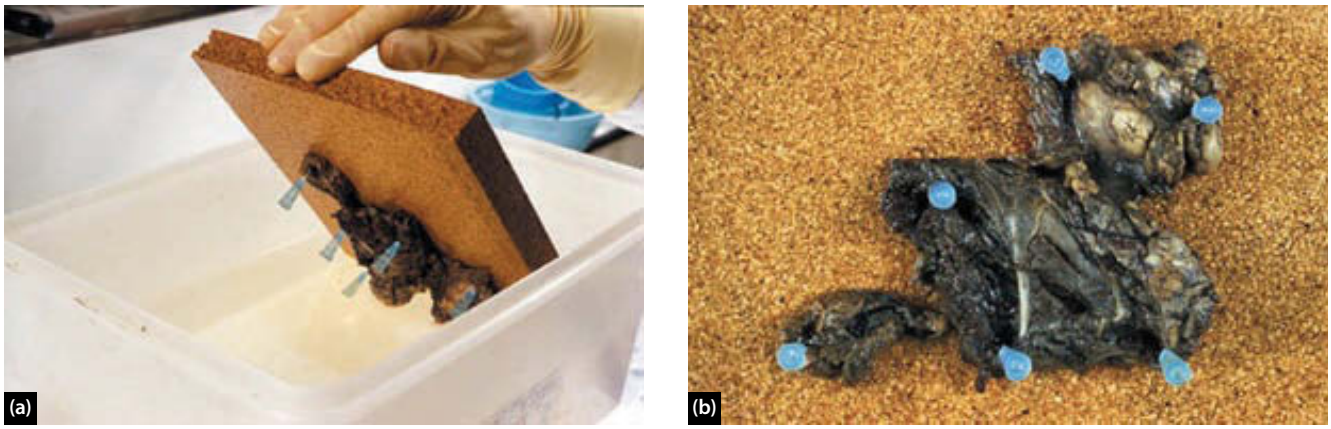

Figure 26.2 Resection specimen orientation utilizing a corkboard. **(a)** Radical neck dissection specimen pinned to cork block, inverted and immersed to float in formalin. **(b)** The fixed specimen as received in the laboratory, ready for trimming and block selection. This was accompanied by separate annotation by the surgeon. Alternatively, the surgeon may prefer to separate the levels in theatre and place them individually in labelled pots.

hubs may be rinsed in transport medium or proprietary liquid-based cytology fluid (e.g. SurePath, BD or, ThinPrep, Hologic) in an attempt to maximize the cell yield. The resultant 'needle washings' may be handled in the laboratory, by a variety of cell concentration techniques, such as filtration or centrifugation dependent upon local preferences and the reliance upon liquid-based cytology. Any clot material is best processed using conventional histology, because free-floating cells tend to be sequestered in such clots and valuable material may otherwise be discarded.

Core biopsy

A core biopsy is performed using a specific large calibre needle (e.g. Tru-Cut, BD) and will yield a cylinder of tissue that can undergo histological analysis. The clinical utility of a core biopsy is limited by the requirement for local anaesthesia, patient discomfort and the risk of damage to local structures.[4] The use of ultrasound guidance reduces the risk of inadvertent damage to a large calibre blood vessel.[5] The amount of tissue harvested and the preserved tissue architecture increases the diagnostic utility and there is also the possibility of yielding sufficient material for immunohistochemical analysis. It is particularly useful for metastatic disease, where the primary tumour location is unknown. In these circumstances, immunohistochemical tests can be used to indicate the most likely anatomic site of the primary tumour.

Incision biopsy

Incision biopsy involves taking a representative sample or wedge of a lesion for histological analysis. This is a suitable technique for obtaining a diagnosis in accessible tumours affecting the oral cavity, pharynx, larynx or hypopharynx. However, in lesions affecting the major salivary glands or in cervical lymphadenopathy, incision biopsy may compromise further treatment so is used as a last resort.

A sufficient sample of tissue must be obtained to allow histopathological analysis. Thermal artefact and mechanical disruption, either crushing or stretching, during handling or processing of the specimen can make analysis difficult and occasionally impossible. Certain tissues (e.g. lymphoid tissue) and tumours (e.g. neuroendocrine carcinoma) are more susceptible to this than others. It must be noted that a thick biopsy does not necessarily equate to a deep biopsy; it is often the interface between the lesion and the underlying connective tissue that is critical when seeking evidence of invasion and a thick sample from an exophytic epithelial proliferation may still be too superficial to adequately assess this feature.

Excision biopsy

Excision biopsy involves complete removal of the lesion and provides a definitive histological diagnosis. This can range from the removal of a small vocal cord polyp to a major *en bloc* resection. Where appropriate, the specimen should be orientated by the surgeon using sutures or marker clips in appropriate positions. Annotated diagrams or digital photographs aid communication. Specimens can be pinned or clipped on to a cork board or a foam sheet (**Figure 26.2**). Dehydrated cucumber slices are a suitable medium for laryngeal biopsies, which are held in place with tissue adhesive (**Figure 26.3**).[6] Resection planes or other structures of particular clinical concern ought to be brought to the pathologist's attention, especially if these may not be immediately obvious following inevitable distortion induced by fixation. It should always be borne in mind that there will be a reduction in measured specimen margins when a fixed, processed, stained and mounted tissue section is compared to the intra-operative state due to shrinkage inherent in tissue preparation for microscopic examination.

Sentinel lymph node biopsy

This technique is recommended for patients with clinically T1/T2 N0 oral cavity squamous cell carcinoma.[7]

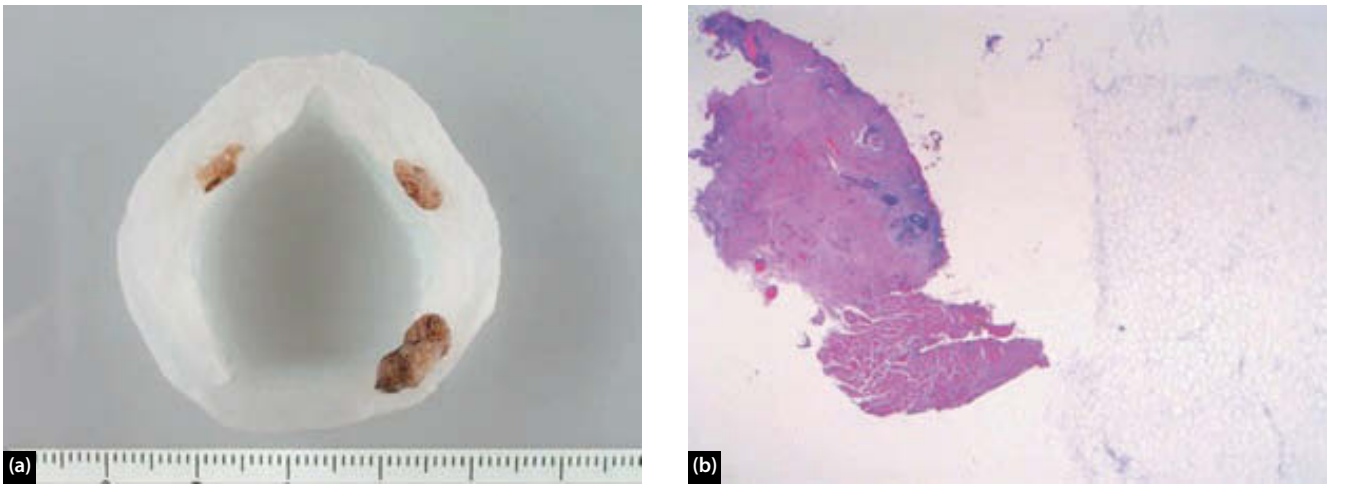

Figure 26.3 Biopsy orientation using a biomount. **(a)** Three laryngoscopic biopsies glued to a dehydrated cucumber biomount in order to maintain correct orientation in the laboratory. An accompanying endoscopic digital photograph further assists handling of such small biopsies. These may be further inked and/or sliced prior to processing. **(b)** A correctly embedded, though heavily thermalized, laryngeal biopsy on the left with anucleate cucumber biomount to the right (H&E stain, ultralow magnification).

Prior to surgery, four sites around the oral carcinoma are injected with a radioactive-labelled colloid tracer. The tracer enters the lymphatic system and drains to the first echelon lymph nodes. The radioactive lymph nodes can then be mapped by imaging. The surgeon uses a gamma radiation detection system to confirm the location of the sentinel lymph nodes and harvests them using a small incision in the neck. Up to four sentinel nodes may be found. Each 'hot node' is then processed in the pathology laboratory using a protocol that samples the entire lymph node at 125 µm intervals. Immunohistochemical staining for cytokeratins (pan-cytokeratin cocktail, AE1/AE3) is used to increase the sensitivity of the test. A negative sentinel lymph node biopsy has a high negative predictive value (95%) and the neck can be monitored, avoiding elective neck dissection. A positive lymph node requires a completion neck dissection, which is performed at a second operation.

Request form

When requesting pathological analysis of a specimen, it is vital that the pathologist is provided with all relevant information to enable a full assessment of the specimen. Ideally the information should include:

- patient identification and demographics
- clinician responsible
- relevant details of lesion (duration, symptoms, etc.)
- clinical photographs of the lesion can also help
- differential diagnoses
- relevant medical history and medications
- history of tobacco, alcohol and drug use
- previous treatment surgery and/or radiotherapy
- type of biopsy (FNAB, core biopsy, incision biopsy or excision biopsy)
- site of biopsy (if biopsies are taken from multiple sites, each site should be clearly labelled and allocated a separate specimen pot).

If the specimen has been orientated, then an annotated diagram or photograph should be included with the request.

Tissue preparation

Tissue specimens are ideally fixed immediately in theatre by immersion in 10% neutral buffered formalin (NBF), which is the routine fixative of choice. This effectively stops metabolism and arrests autolysis and putrefaction, thereby preserving the tissue structure. The apocryphal maxim is that the minimum ratio by volume of NBF to specimen should be 10 to 1, although this is somewhat arbitrary and if this was ever evidence-based, it is likely to be influenced by intangible factors, such as type of tissue, temperature, agitation and so on – as a rule, more liberal volumes of fixative are preferable. On rare occasions, alternative fixatives, such as glutaraldehyde or alcohol, may be employed if specialized studies (e.g electron microscopy) are required. Fresh unfixed material intended for intra-operative frozen section examination, direct immunofluorescence, molecular studies or microbiology must be despatched without delay to the laboratory, cognizant that it constitutes a biohazard.

Upon receipt in the laboratory, the specimen identity is corroborated and a unique accession number is allocated. Following an appropriate period of fixation (24–48 hours), either the pathologist or senior biomedical scientist staff will describe the specimen macroscopically, and dissect and submit representative tissue slices for examination. These slices are inserted into proprietary sealable cassettes appropriately labelled.

After a further period of fixation, the tissue slices undergo cycles of dehydration, clearing, infiltration and embedding in preparation for microtomy (section cutting). During dehydration, alcohol replaces the aqueous fixative within the tissue. Clearing replaces the alcohol with an antemedium, such as xylene. Molten paraffin wax then replaces the clearing agent and infiltrates the tissue. The tissue is

subsequently embedded by encapsulation in paraffin wax in a mould to provide a rigid support for microtomy. The additional step of decalcification may be instituted in mineralized tissue, which might otherwise hinder sectioning. Automatic tissue processors enhanced by pressure, vacuum, heat and microwave facilities in a self-contained, microprocessor-controlled, programmable unit are used in many modern laboratories, tailored to local conditions.

The pre-chilled, hardened paraffin wax-embedded tissue block is then sliced, typically at 3–5 µm thick on a microtome. The thin sections are then floated on a warm water bath prior to transfer on to a glass slide. The sections are then dried on a hotplate.

The sections may now be stained, typically with H&E and mounted under a glass or self-adhesive plastic film coverslip to form a permanent preparation. Haematoxylin stains nuclei dark blue and tissue glycoproteins light blue. Eosin stains the cytoplasm and collagen pink. The H&E stained slides are then made available to the pathologist for examination. A wide repertoire of additional histochemical and/or immunohistochemical stains may be required, on additional sections, to render a diagnosis. The majority of biopsies are reported within 7 days; however, it is possible to reduce the 'turn-around time' for urgent specimens to 24 hours. Large resection specimens that include bone require a decalcification step, which extends the processing time to around 2 weeks.

Histochemistry

Histochemistry is used to highlight a variety of biological substances in the tissue. Sometimes referred to as 'special stains', there are numerous methods based on chemical reactions that can be visualized by a specific colour change in the tissue sections. For example, Periodic acid-Schiff (PAS) stain can be used to highlight carbohydrates, which stain deep purple; pre-treatment of the tissue section with the enzyme diastase removes simple carbohydrate moieties leaving mucins, which are found in glandular secretions and fungal hyphae. Elastic van Gieson stain is used to appreciate tissue architecture, especially blood vessels; elastin fibres stain black and collagen red. Ziehl Neelsen stain is used to detect bacteria and identify acid-fast bacilli in tuberculosis.

Immunohistochemistry

The principle underpinning immunohistochemistry (IHC) is the demonstration of an epitope or antigen via its binding to a specific antibody, which in turn is conjugated to a label that can be visualized by microscopy. A variety of reporter and linkage systems to produce a visual signal have been developed based on fluorescent molecules and enzyme-generated chromogenic substrates.

In general, monoclonal antibodies are more specific than their polyclonal counterparts. Importantly, no antibody is 100% sensitive and specific – immunophenotyping is best performed using a panel of expected positive and negative antibodies. Expected staining can be checked by examining 'internal controls' (tissue elements that are positive for the antibody) and 'external controls' ('on slide' analyte control material such as cell lines or tissue/tumours with known protein expression patterns). It is important to be mindful of aberrant cross-reactivity, spurious co-expression, false positives, false negatives and vagaries of technical quality. Correlation with conventional morphology is imperative.

Among the broad categories of commercially available diagnostic markers are antibodies directed against intermediate filaments (e.g. cytokeratins, desmin, neurofilament, vimentin), epithelial markers (e.g. Ber EP4, epithelial membrane antigen), structural proteins (e.g. calponin), storage granules/products (e.g. calcitonin, chromogranin, synaptophysin, thyroglobulin), hormone receptors (e.g. oestrogen, progesterone), nuclear epitopes (e.g. p16, thyroid transcription factor-1), lympho-reticular epitopes (e.g. CD3, CD20, CD79a), cell proliferation (e.g. Ki67), apoptosis molecules (e.g. bcl-2, p53) and infectious agents (e.g. cytomegalovirus, herpes simplex virus 1/2, human herpes virus 8, varicella zoster, LMP-1 for Epstein–Barr virus (EBV)).

In-situ hybridization

In-situ hybridization (ISH) is similar to IHC, but instead of using antibodies to detect a protein, a DNA probe is designed to hybridize (stick) to either a complementary sequence of RNA or DNA. RNA ISH is used to detect EBV and kappa and lambda light chains in B lymphocytes. DNA ISH can be used to identify low-risk and high-risk human papillomavirus infection. Chromosomal abnormalities, such as amplifications, translocations and deletions, can be identified by fluorescence ISH.

Molecular tests

More recently, molecular biology techniques have been used to generate high resolution genetic profiling of tumours, by either DNA sequencing and/or gene expression arrays. Such molecular information is currently used in the management of breast cancer (e.g. Oncotype DX breast cancer test). It is likely that these types of test will become available for head and neck cancers in the not too distant future. Projects like the US Cancer Genome Atlas (TCGA) aim to accelerate the understanding of the molecular basis of cancer and facilitate molecular diagnosis.[8] One of the aims of the 100 000 genomes project (Genomics England) is to create a new genomic medicine service for the National Health Service for the benefit of patients.[9]

Multidisciplinary diagnosis

The cytological and histopathological analysis is a complex process. It cannot be overemphasized that reaching a final conclusion depends on many factors, including detailed site-specific knowledge coupled with experience of normality, familiarity with the manifold appearances of many disease processes at various stages in their natural history, awareness of mimics and artefacts plus cognizance of the limitations of the technique, in conjunction with patient-specific details and the clinical context.

Without consideration of these and appropriate correlation with clinical, radiological and other relevant background information, a pathological slide is in danger of becoming a two-dimensional, brightly stained artefact, which may be as misleading as it can be potentially helpful.

Subsites of the head and neck

The head and neck region is divided into a number of subsites as outlined in **Table 26.2**.

TUMOURS OF THE HEAD AND NECK

Tumour typing

There is a multitude of benign and malignant tumours that affect the head and neck region. Benign and malignant tumours can be classified according to the proposed tumour cell origin (histogenesis) and/or its differentiation pathway (**Table 26.3**). This section is not intended to be an exhaustive account of the pathology of benign and malignant tumours affecting the head and neck region, which can be found in any head and neck pathology text.[10–12] We will cover those benign and malignant tumours that are more commonly encountered in clinical practice, and are exemplars of their type.

BENIGN TUMOURS

Benign epithelial tumours

SQUAMOUS CELL PAPILLOMAS

Squamous cell papillomas are benign epithelial lesions that can affect the oral cavity, larynx, sinonasal tract and nasopharynx. They are typically polypoidal or verrucoid lesions arising from the epithelial surface and can be solitary or multiple lesions depending on site and subtype.

TABLE 26.2 Head and neck cancer sites and subsites

Head and neck site	Subsite
Oral cavity (from lips to anterior tonsil fauces)	• Lips • Anterior tongue • Buccal mucosa • Retromolar trigone • Floor of mouth
Oropharynx (from level of hard palate to hyoid bone)	• Tongue base • Tonsils • Lateral and posterior pharyngeal wall
Hypopharynx	• Pyriform fossa/sinus • Post-cricoid region • Posterior pharyngeal wall
Larynx (from epiglottis to lower border of cricoid cartilage)	• Supraglottis: epiglottis to false cords • Glottis: false cords to 5–10 mm below true cords • Subglottis: 10 mm below true cord to lower border of cricoid cartilage
Nasal cavity and paranasal sinuses	• Nasal cavity • Maxillary sinus • Frontal sinus • Ethmoid sinus • Sphenoid sinus
Nasopharynx	
Ear	• External auditory canal • Middle ear • Inner ear
Salivary gland	• Parotid gland • Submandibular gland • Sublingual gland • Minor glands
Thyroid gland	
Parathyroid glands	
Neck	• Level I, submandibular IB and submental IA nodes • Level II, upper jugular nodes divided by spinal accessory nerve into IIA and IIB • Level III, middle jugular nodes • Level IV, lower jugular nodes • Level V, posterior triangle nodes divided by spinal accessory nerve into VA and VB • Level VI, anterior compartment
Skin	

TABLE 26.3 Classification of tumours

Cell type		Examples	
		Benign	**Malignant**
Epithelial		• Squamous cell papilloma • Pleomorphic adenoma • Warthin's tumour	• Squamous cell carcinoma • Mucoepidermoid carcinoma • Acinic cell carcinoma • Adenocarcinoma • Adenoid cystic carcinoma
Mesenchymal	• Nerve • Vascular • Smooth muscle • Skeletal muscle • Fibrous • Adipose tissue • Bone • Cartilage • Immune system	• Schwannoma, neurofibroma • Angioma • Leiomyoma • Rhabdomyoma • Fibroma • Lipoma • Osteoma • Chondroma	• Malignant peripheral nerve sheath tumour • Angiosarcoma • Leiomyosarcoma • Rhabdomyosarcoma • Fibrosarcoma • Liposarcoma • Osteosarcoma • Chondrosarcoma • Lymphoma
Neuroectodermal			• Malignant melanoma • Olfactory neuroblastoma • Neuroendocrine carcinoma

TABLE 26.4 Pathological features of oral squamous cell papillomas[12]

Subtype	Squamous cell papilloma or verruca vulgaris	Condyloma acuminatum	Multifocal epithelial hyperplasia (Heck's disease)
HPV status	• Approximately half are associated with HPV infection • Squamous cell papilloma HPV6 and 11 • Verruca vulgaris HPV2, 4, 40 and 57	• Associated with HPV6 and 11 • Transmission is venereal or autoinoculation and there is an association with genital condyloma	• HPV13 and 32. • Disease of children, adolescents and young adults
Macroscopic appearance	Wart-like exophytic lesion	Dome-shaped exophytic nodules, which are usually larger than squamous cell papillomas	Multiple clusters or patches of soft, plaque-like lesions

Oral cavity and oropharynx

The pathological features of oral cavity and oropharynx papillomata are outlined in **Table 26.4**.

Larynx

Squamous cell papilloma (and recurrent respiratory papillomatosis) is the most common benign epithelial neoplasm affecting the larynx. It has a bimodal distribution with a peak before the age of 5 and a second between 20 and 40 years of age. There is convincing evidence that recurrent respiratory papillomatosis is due to human papillomavirus (HPV) infection, with HPV6 and 11 as the dominant subtypes.[13] Macroscopically, the lesions are exophytic or sessile with a fine lobular surface that can be prone to bleeding when subjected to even minor trauma. Microscopically, the lesions have a typical papilloma appearance with hyperplastic squamous epithelium covering fibrovascular cores. Branching papillae covered by thin squamous epithelium may be seen, associated with a basal and parabasal cell proliferation. Koilocytes are often focally present in the upper and superficial zones and contain perinuclear halos. IHC and other studies can be used to confirm evidence of HPV infection, but are not required for diagnosis, treatment or to predict clinical behaviour.

Sinonasal tract

Unlike the oral cavity and the larynx, papilloma of the sinonasal tract is relatively uncommon. Sinonasal papillomas arise from the ectodermally-derived ciliated epithelium of the nasal cavity, termed the 'Schneiderian membrane'. There are three morphologically distinct types of papilloma:[14]

- *Exophytic sinonasal papilloma* typically arises on the septum around the nasal vestibule. It closely resembles verruca vulgaris and is associated with HPV6 and HPV11 infection. Malignant transformation is uncommon (**Figure 26.4a**).
- *Inverted sinonasal papilloma* may present anywhere within the nose and paranasal sinuses, occasionally elsewhere within the upper aerodigestive tract (e.g. larynx, lacrimal apparatus). It shows a complex, arborescent exo-endophytic growth pattern with primary, secondary and tertiary ramifications into underlying stroma. Numerous intra-epithelial microabscesses are characteristic and stain for macrophage

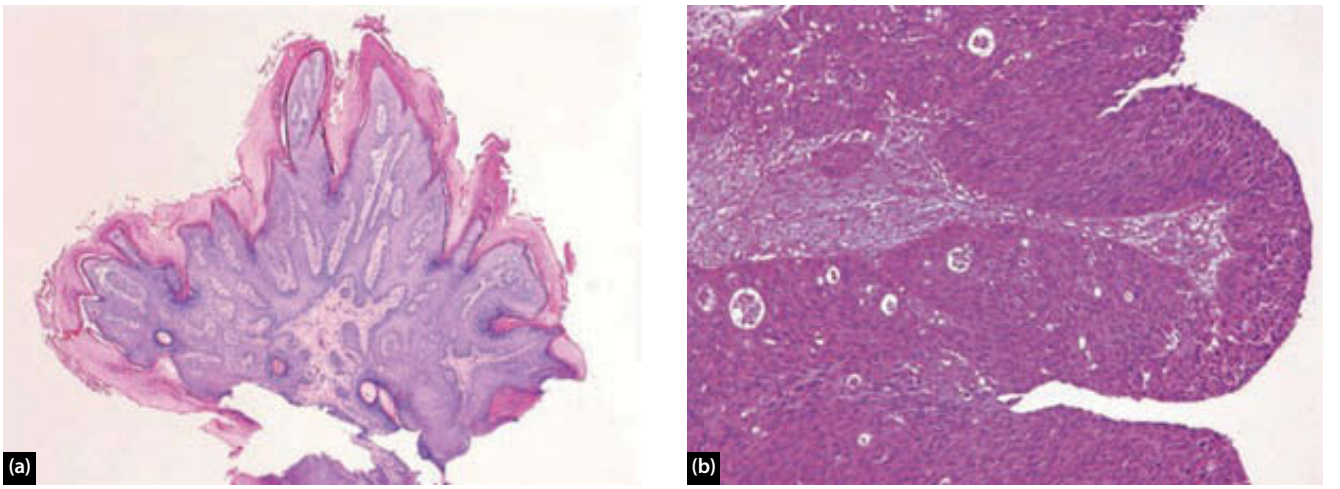

Figure 26.4 Sinonasal papilloma. (a) Exophytic sinonasal papilloma characterized by its radially symmetrical, hyperkeratotic outline (H&E stain, ultralow magnification). **(b)** Inverted sinonasal papilloma illustrating a papillary surface. The tumour is composed of non-keratinizing squamous and transitional epithelium with scattered intra-epithelial microabscesses (H&E stain, medium magnification).

markers (CD68). The epithelium may be squamous (usually non-keratinizing), respiratory, glandular, transitional cell-like or a mixture in any combination or permutation. Varying rates of HPV infection are reported, around a third are considered to be HPV-positive, usually with HPV6 and HPV11. The tumours may be synchronously or metachronously multicentric and because it is difficult to achieve adequate surgical clearance, there is a risk of persistence/recurrence. With each recrudescence, the likelihood of malignant transformation increases (**Figure 26.4b**).

- *Oncocytic sinonasal papilloma* (cylindrical cell papilloma) is not associated with HPV infection. It comprises exophytic fronds of bi-layered, well polarized, oncocytic epithelium supported by a fibrovascular stroma. Microabscesses confined to the epithelium are invariable. There is a predilection for persistence/recurrence if incompletely excised. A small proportion (3–17%) of oncocytic sinonasal papillomas harbour a carcinoma, consequently judicious sampling of the biopsy material is essential.

Benign salivary gland tumours

Benign salivary gland tumours are classified according to WHO and are listed in **Table 26.5**.

PLEOMORPHIC SALIVARY ADENOMA

Pleomorphic salivary adenoma (PSA; benign mixed tumour) is the most common tumour affecting the salivary glands. The annual incidence is reported as 2.4–3.05/100 000. It comprises approximately 50% of all salivary gland tumours, 65% of parotid tumours and 40% of intra-oral minor salivary gland tumours.[15]

Macroscopic appearance

PSA tends to be well demarcated, round or ovoid with broad-based surface bosselations. There may be areas of cystic change and also calcification. They are variably encapsulated and, where present, the capsule may be thick and fibrotic or attenuated and incomplete. The cut surface may either be homogeneous or variegated, dependent upon the precise histological pattern (**Figure 26.5**). Protuberant peri-capsular nodules may be seen, sometimes attached to the main body of the tumour by a slender pedicle. Simple enucleation of the body of a pleomorphic adenoma risks detaching these nodules, which remain behind forming a nidus for recurrence. Predominantly myxoid examples may be semi-fluid and fluctuant – peri-operative capsular rupture and spillage may seed tumour throughout the operative field, increasing the risk of recurrence. Such recurrences are typically multifocal (**Figure 26.6**).

Microscopic appearance

The basic components of a PSA are ductal elements and myoepithelial cells embedded in a chondromyxoid matrix. The appearances vary widely both between PSAs and within the same tumour. A panoply of other changes may be superimposed or even predominate, for example, metaplastic changes (squamous, lipomatous, osseous, neuroid, angiomatoid), degeneration (cystic change, infarction, mineralization, hyalinization, elastosis), specific growth

TABLE 26.5 WHO classification of benign epithelial salivary gland tumours[12]

Benign epithelial salivary gland tumours
• Pleomorphic adenoma • Myoepithelioma • Basal cell adenoma • Warthin's tumour • Oncocytoma • Lymphadenoma • Cystadenoma • Sialadenoma papilliferum • Ductal papillomas • Sebaceous adenoma • Canalicular adenoma

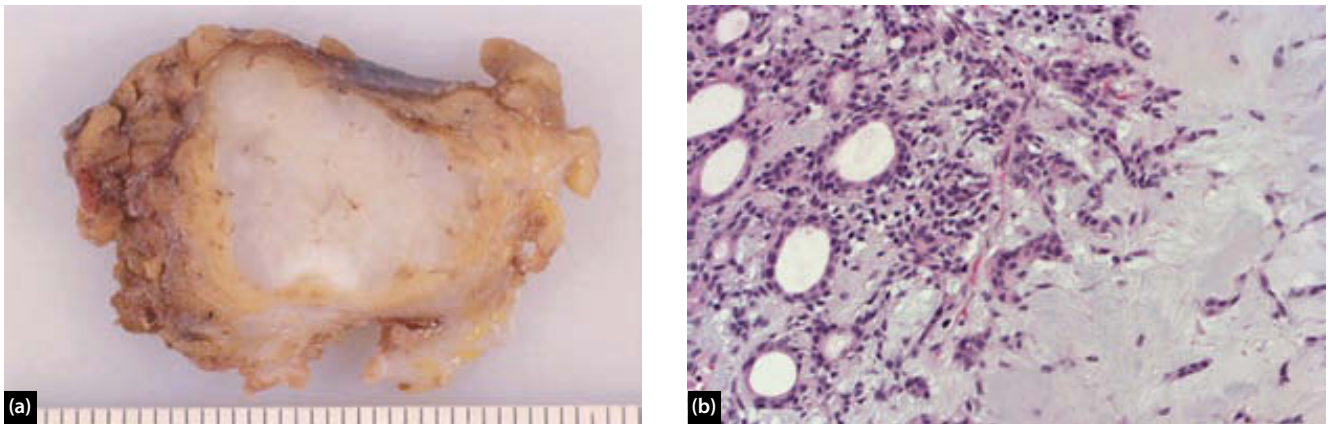

Figure 26.5 Pleomorphic salivary adenoma. **(a)** Cut surface of the tumour displaying a solid blue/grey hue characteristic of chondromyxoid matrix. **(b)** Histology showing double layered ducts and strands of myoepithelial cells invested by a myxoid matrix (H&E stain, medium magnification).

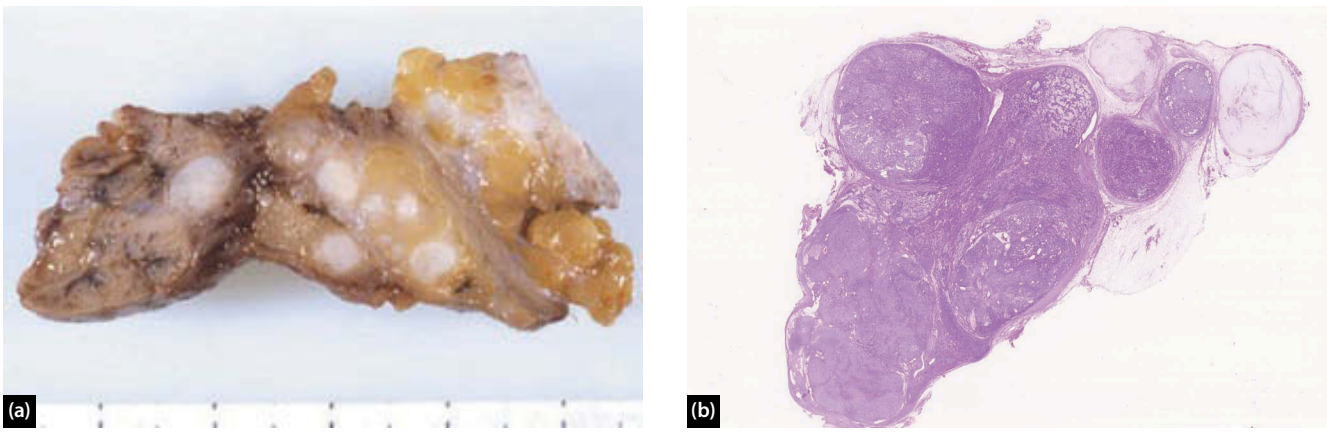

Figure 26.6 Recurrent pleomorphic salivary adenoma. **(a)** Excision of multi-focal recurrence of pleomorphic salivary adenoma encompassing the original surgical field. **(b)** Whole mount section of another local recurrence showing secondary seeding of fat, residual salivary gland and fibrous tissue. The nodules are clearly of differing composition despite having arisen from the same parent lesion [H&E stain, ultralow magnification].

patterns (e.g. adenoid cystic carcinoma-like, clear cell, epithelial-myoepithelial carcinoma-like, basaloid, giant cell, spindle cell, acinar, plasmacytoid, oncocytoid) and crystal deposition. This heterogeneity can occasionally make diagnosis difficult, especially from limited samples derived from FNAB or core biopsies.

Risk of malignant transformation

PSA has a risk of malignant change, around 6%. Clinical features that are associated with an malignant transformation include:[12, 15, 16]

- older patient age
- male patient
- long duration of tumour
- multiple recurrences
- deep lobe parotid location.

WARTHIN'S TUMOUR

Warthin's tumour (adenolymphoma, papillary cystadenoma lymphomatosum) is the second most common tumour of the salivary glands.[17] It is exclusive to the parotid gland and para-parotid lymph nodes and can be multicentric and/or bilateral in 4–10% of cases. It comprises between 3.5% and 30% of primary epithelial salivary gland tumours with geographical variation. It occurs in Caucasians and Asians with a lower incidence in African-Americans and Black Africans. It can occur over a wide age range, but is common in the sixth decade for women and seventh decade for men. It is more common in males but the male:female ratio has reduced over the last few decades. There is a link between Warthin's tumour and cigarette smoking.[18]

Macroscopic appearance

The tumour is a circumscribed, often thinly encapsulated soft mass that contains multiple cystic and solid/papillary areas, which is white to brown in colour. There may be coagulated tan exudate in the cystic spaces (**Figure 26.7a**).

Microscopic appearance

Warthin's tumour is composed of ciliated, bi-layered oncocytic epithelium supported by reactive lymphoid

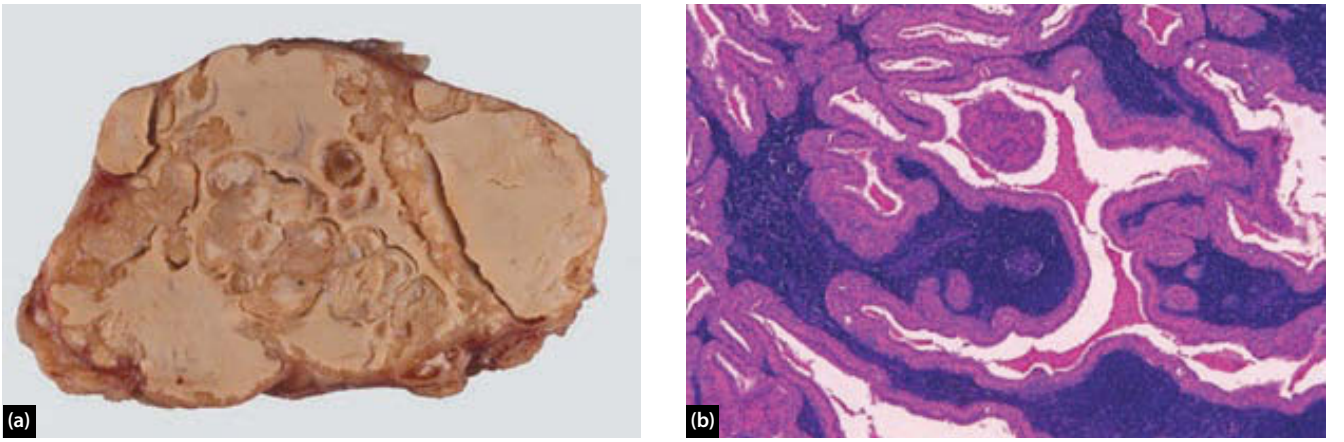

Figure 26.7 Warthin's tumour. (a) The characteristic papillary-cystic cut surface appearance of Warthin's tumour. Oncocytic epithelium is typically mid-brown. The light tan micronodules correspond to reactive lymphoid follicles. **(b)** Papillary-cystic tumour composed of fronds of oncocytic epithelium supported by hyperplastic lymphoid stroma (H&E stain, low magnification).

stroma (**Figure 26.7b**). The cystic areas contain amorphous debris. Warthin's tumour can undergo infarction or degeneration and metaplastic change either spontaneously or secondary to manipulation (e.g. FNAB, core biopsy). Benign oncocytic epithelial inclusions are commonly seen in intraparotid and para-parotid lymph nodes. These inclusions probably account for Warthin's tumour's propensity for multicentricity and bilaterality. Malignant transformation, either carcinomatous or lymphomatous, is rare.

Benign mesenchymal tumours

SCHWANNOMA

Schwannomas (neurilemmomas) are benign encapsulated tumours that originate from the Schwann cells of the peripheral nerve sheath. Schwannoma in the head and neck may arise from the cranial nerves including Vth and VIIth–XIIth, sympathetic chain, cervical or brachial plexus. It is the most common neoplasm affecting the temporal bone, vestibular Schwannoma, and a common site of occurrence is the neck, but it is rare in the oral cavity.[19] The NF2 gene is inactivated in 67% of Schwannomas.[20,21] Approximately 2% are due to neurofibromatosis 2, which is an uncommon autosomal dominant condition characterized by the presence of bilateral vestibular Schwannomas and an increased incidence of extra- and intracranial meningiomas.

Macroscopic appearance

Schwannomas are typically encapsulated, but those affecting the temporal bone tend to be non-encapsulated (**Figure 26.8**). The tumour is usually attached to an identifiable nerve and is firm and rubbery with a tan-white to yellow colour. At operation, it may be mistaken for a lymph node and excised without seeking to preserve or repair the nerve, thereby sustaining unexpected neurological damage.

Microscopic appearance

The tumour consists of a mixture of Antoni A and Antoni B areas. Antoni A areas are formed by short fascicles of closely packed monomorphous spindle cells with fibrillar cytoplasm. The cells sometimes form a palisaded arrangement around acellular, collagenized foci known as Verocay bodies. Antoni B areas are composed of the spindle cells haphazardly arranged within a loose myxoid stroma. Secondary areas of vascular wall hyalinization, microcystic degeneration, haemorrhage, foam cell infiltration and calcification may be seen. Focal bizarre, hyperchromatic and multinucleate giant cell transformation is sometimes encountered. In the absence of increased numbers of mitoses, abnormal mitotic spindles, necrosis or other atypical features, this is designated ancient change, probably a degenerative phenomenon, which is of no known clinical relevance. On IHC, Schwannomas are strongly S100-positive; neurofibromas tend to be weakly positive and also contain neurofilament positive fibres. However, occasionally distinction between Schwannoma and neurofibroma is problematic, invoking the rubric 'benign peripheral nerve sheath tumour'.

MALIGNANT TUMOURS

Malignant disease of the head and neck is the sixth most common form of cancer worldwide with around 300 000 new cases per annum. In the UK there were 11 449 cases of head and neck cancer in 2014 and 3225 deaths, equating to an incidence of 25 per 100 000 (7918 cases) in males and 11 per 100 000 (3531 cases) in females.[22] The majority (90%) of head and neck malignancies are squamous cell carcinomas arising from the epithelial-lining of the upper aero-digestive tract.

Tumour staging

Cancer of the head and neck, due to the diversity of pathology and the variation in progression at different anatomical subsites, cannot be meaningfully staged by a single, generic schema. The tumour, node, metastasis (TNM) staging system, developed and maintained by both the American Joint Committee for Cancer (AJCC) and the International Union Against Cancer (UICC), is the most

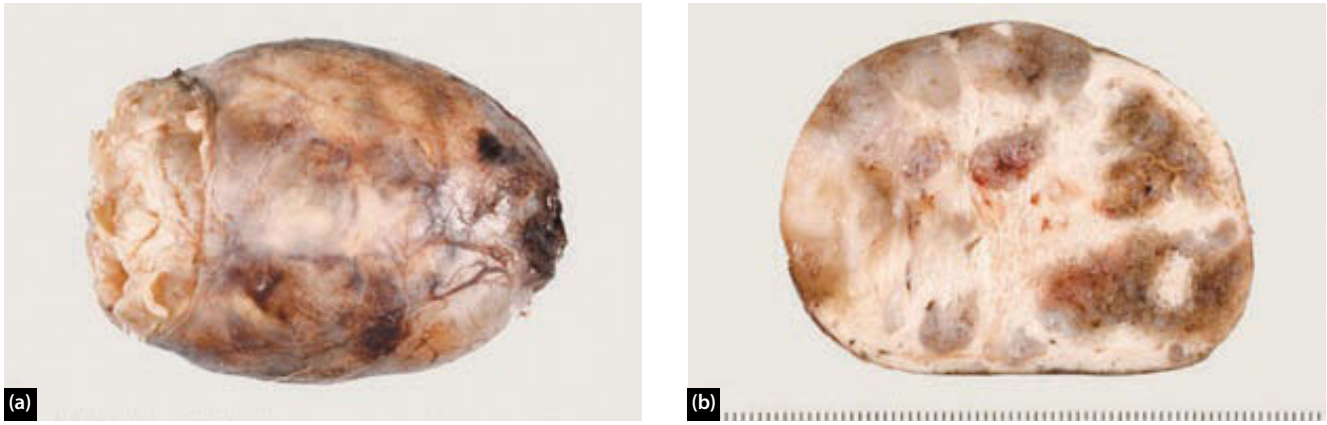

Figure 26.8 Schwannoma. **(a)** Encapsulated Schwannoma from the parapharyngeal space giving a smooth surfaced nodal appearance, although the capsule is deficient at one pole. **(b)** The cut surface displays a variegated texture.

widely used method for staging.[23, 24] There are international expert committees that keep the system under review and the 8th edition was published by both the AJCC and UICC in 2017.[24] There have been major changes in TNM staging of the head and neck cancer, when compared to the 7th edition published in 2010,[23] and it remains to be seen how widely this will be adopted and implemented by the head and neck oncology community.

The basic principles of the TNM staging system are:

- *Clinical*. cTNM or TNM is based on clinical findings (physical examination and imaging) and assigned prior to starting first definitive treatment.
- *Pathological*. pTNM is based on the cTNM modified by further information obtained from surgery and subsequent pathological examination.
- *Autopsy*. aTNM is used when the cancer is only classified from the results of post-mortem examination and no evidence of cancer was evident prior to death.

Other descriptors of TNM may occasionally be used and include:

- the 'm' suffix, which is used when there is more than one primary at a single site, pT(m)NM
- the 'y' prefix, which is used when classification is performed during or after initial multimodality therapy, ycTNM or ypTNM.

Tumour differentiation refers to how well developed or mature the malignant cells are. Well-differentiated cells resemble normal cells and tend to grow and spread at a slower rate. There is often morphological heterogeneity, however, both between different tumours of the same type and within the same tumour. Conventionally, tumours are histologically subtyped according to their differentiated components. They are graded with reference to their worst differentiated elements on the premise that it is these that will behave most aggressively, and thereby be the major determinant of prognosis:

- Gx – grade cannot be assessed
- G1 – well-differentiated
- G2 – moderately differentiated
- G3 – poorly differentiated.

The presence or absence of residual tumour is classified as:

- Rx – the presence of residual tumour cannot be assessed
- R0 – no residual tumour is present
- R1 – microscopic residual disease
- R2 – macroscopic residual tumour.

The UICC or AJCC TNM atlas provides detailed descriptions of T-, N- and M-categories for each anatomical sub-site. TNM provides an indication of the amount and spread of the disease. The TNM categories are then used to assign a stage grouping, which relates to prognosis.[23, 24]

Carcinomas

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma (SCC) and its variants represent by far the most common malignant tumour affecting the head and neck region, accounting for approximately 95% of all primary tumours of the oral cavity, oropharynx, hypopharynx, larynx and sinonasal tract. By contrast, SCC is uncommon in the major salivary glands and thyroid, although these may be affected by direct contiguous invasion from neighbouring structures or metastatic spread. Head and neck squamous cell carcinoma (HNSCC) may also arise from skin. Typically, HNSCC spreads by direct invasion or via regional lymphatics, although haematogenous spread, especially to the lungs, is possible.

Squamous epithelial dysplasia

SCC of the oral cavity and larynx is well known to arise from epithelial precursor lesions, which may be localized or represent wider areas of 'field cancerization'. The precursor lesions harbour varying degrees of epithelial dysplasia, defined by the accumulation of architectural and cytological abnormalities. By convention, epithelial dysplasia is graded and numerous systems have been suggested.

The most recent WHO classification recommends that laryngeal dysplasias are assigned low and high grade categories, whereas oral dysplasia are assigned mild, moderate and severe dysplasia (though there is an option to use a high and low grade categories as well).[12] Grading is known to be subjective and prone to inter-observer variation; nevertheless it is still used to guide management. The more severe the dysplasia, the greater the risk of transformation into malignant disease. A meta-analysis of oral dysplastic lesions indicates a malignant transformation rate of 12% and a mean time to transformation of 4.3 years.[25] Similar transformation rates are quoted for laryngeal precursor lesions.[12] It is clear from these data that progression to invasive malignancy is not inevitable, which implies that such lesions may remain stable over time or possess the capacity to regress – indeed most lesions do not proceed to invasive carcinoma within the time period of the studies conducted. Clinically, these lesions are irregular, circumscribed lesions with a white (leukoplakia), red (erthyroplakia) or variegated appearance (erythroleukoplakia). In reality, dysplasia is a dynamic process manifest as a continuous morphological spectrum. Therefore, the rigorous application of discrete categories, whatever their arbitrary histological basis, is destined to be problematical. IHC, molecular and other biomarkers are presently of limited assistance in resolving this issue.

Aetiology

The main risk factors for HNSCC are tobacco and alcohol abuse, which either alone or combined, are implicated in 75% of all HNSCC.[26] Tobacco alone increases the risk of cancer occurrence two- to three-fold, but acts synergistically with alcohol leading to a multiplicative rather than additive increase. Increased duration of exposure to tobacco and/or alcohol increases the risk of developing HNSCC. Tobacco contains a number of known carcinogens (e.g. polynuclear aromatic hydrocarbons), which cause DNA damage leading to gene mutations. Alcohol causes DNA damage and gene mutation by a number of mechanisms. These include the effect of acting as a solvent for other carcinogens, nutritional deficiencies, acetaldehyde (a by-product of alcohol metabolism) and the direct effect of ethanol. Increasingly, it is recognized that HPV, especially HPV16, is an important cause of oropharyngeal SCC.[27] HPV-positive tumours typically affect non-smokers, non-drinkers and younger patients. Patients with HPV-related oropharyngeal SCC have a better overall survival than those with HPV-negative disease.[28] HPV infection at other subsites is less frequent (< 5%) and consequently the data around survival are less convincing. SCC of the lip is associated with sun exposure and pipe smoking. Sinonasal SCC is linked to nickel and chromate exposure and woodworking. Dietary deficiencies have also been linked to the development of HNSCC, especially vitamins (A, C and E), foods (fruit, vegetables and dairy) and elements (e.g. iron especially when associated with iron-deficiency anaemia of Plummer–Vinson (Paterson–Brown–Kelly) syndrome, which is associated with hypopharyngeal SCC). Oral cavity SCC is particularly common in India where a third of all cancers originate in the head and neck. The widespread chewing of betel nut and paan, which causes both oral submucous fibrosis, a recognized oral potentially malignant disorder, and oral cavity SCC has been implicated. HNSCCs are typically sporadic, but a familial inheritance has been noted in some cases. The risk of HNSCC is also increased in patients with any syndrome associated with an increased risk of cancer. Patients with Fanconi's anaemia have a 700-fold increased risk and the cancer is usually diagnosed in the third decade.

Pathogenesis

HNSCC is a heterogeneous disease, but a hypothetical progression model has been proposed.[26] Histological progression from normal epithelium to hyperplasia, dysplasia and finally invasive carcinoma is related to a number of factors, including genetic changes causing genetic instability leading to cellular change.[29] Genetic changes include the sequential inactivation of tumour suppressor genes and activation of proto-oncogenes. Carcinogens produced by tobacco, which include nitrosamines and benz-(a)-pyrene, produce mutations in p53 associated with HNSCC. The molecular changes are due to a number of genetic alterations, which include loss of heterozygosity (LOH) of 9p21, seen in 70–80% of HNSCC. Other abnormalities include LOH 3p, 17p, 11q and 13q. In HPV16 infection the E6 and E7 viral oncoproteins cause inactivation of tumour suppressor molecules, pRb and p53. Loss of pRb causes uncontrolled cell proliferation. Loss of p53-mediated response to DNA damage leads to genomic stability. There is also reactivation of telomerase driving cell immortality.[27, 29]

Macroscopic appearance

HNSCC appearance varies depending on subsite, but can be an exophytic or ulcerative lesion. On the skin, it typically looks like a non-healing scab or ulcer, which can intermittently bleed. On mucosal surfaces, lesions typically start as whitish or reddish plaque-like lesions (leukoplakia or erthyroplakia), which then progress to ulcerated or fungating masses with irregular indurated borders (**Figure 26.9**).

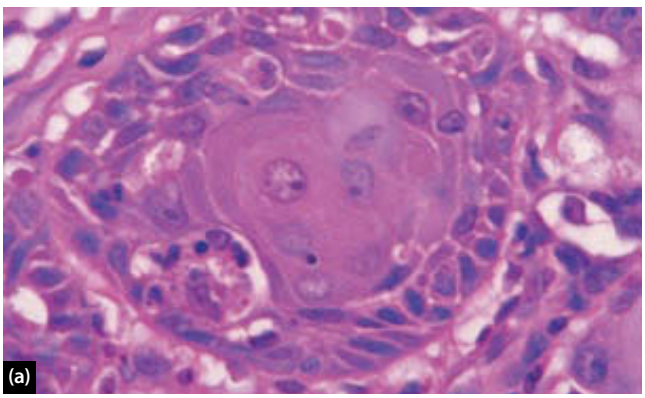
Microscopic appearance

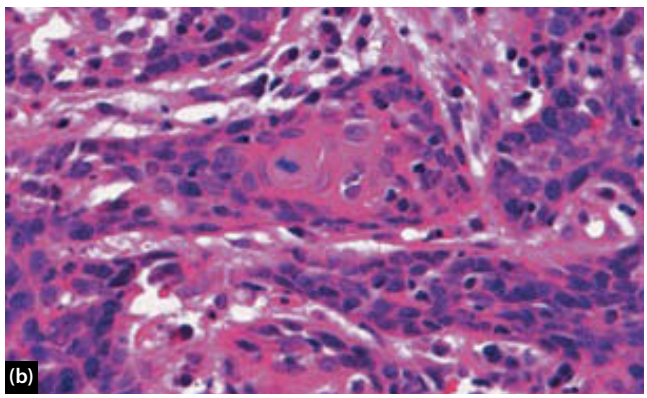
The histological appearance of SCC is very similar across all sites in the head and neck. Well-differentiated and moderately differentiated SCC characteristically shows evidence of keratinization and intercellular prickles (desmosomes) (**Figure 26.10a**). Poorly differentiated SCC lacks evidence of keratinisation and immunohistochemical analysis may be required to support the diagnosis (**Figure 26.10b**).

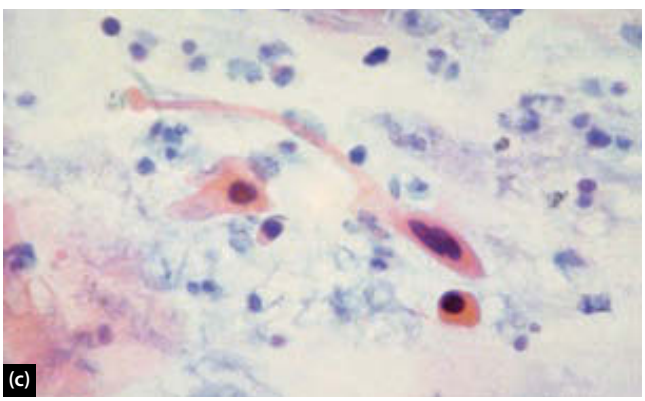
Malignant squamous cells display some or all of the following features:

- irregular shape and orientation
- increased and abnormal mitoses

Figure 26.9 Laryngeal squamous cell carcinoma. **(a)** Total laryngectomy specimen opened in the posterior sagittal plane to show advanced, fungating carcinoma effacing much of the supraglottic larynx with local extension on to the left true vocal cord. **(b)** Transverse section through the specimen confirms bilateral midline tumour herniating through the anterior commissural ligament into anterior strap musculature.







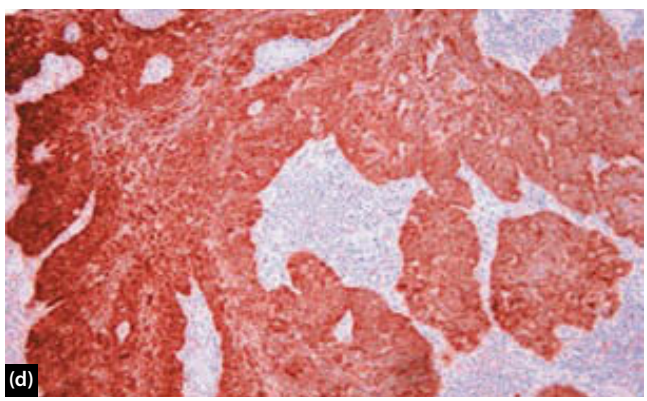


Figure 26.10 Squamous cell carcinoma. **(a)** Moderately differentiated SCC illustrating a focus of keratinization. Note the disordered cell polarity, nuclear pleomorphism (variation in size, shape and intensity of nuclear staining), coarse chromatin and prominent nucleoli (H&E stain, high magnification). **(b)** Poorly differentiated SCC lacking keratinization (H&E stain, medium magnification). **(c)** Cytology preparation from an SCC showing several atypical squamous cells amidst a necrolytic background. Note the large, binucleate caudate ('tadpole') cell, intermediate-sized obovate ('comet') cell and the smaller hyperkeratinizing orangeophilic ('carrot') cell. Other forms commonly seen include fibre ('snake') cells, acanthocytes ('spider') cells and bizarre giant ('monster') cells. Anucleate squames, dissociated keratotic debris, parakeratotic scale ('sprigs') and keratin whorls ('pearls') may accompany these (Pap stain, high magnification). **(d)** Immunohistochemistry showing strong and diffuse nuclear and cytoplasmic p16 expression in an HPV-associated SCC (p16 IHC, medium magnification).

- nuclear hyperchromatism
- coarse and clumped chromatin
- nuclear pleomorphism
- increased nucleus–cytoplasmic ratio
- prominent nucleoli
- premature keratinization (dyskeratosis)
- loss of keratin production
- disordered cell polarity
- disorganized growth.

Cytologically, SCC may be so well differentiated that it is impossible to reliably discriminate it from non-neoplastic squamous epithelium; for example, an FNAB from an inflamed branchial cyst may mimic a cystic metastasis and vice versa. Obviously, the context is all-important and, in experienced hands, FNAB from a cervical lymph node containing abnormal squamous cells against a background of proven SCC may be reasonably taken as presumptive evidence of a secondary deposit until otherwise proven (**Figure 26.10c**). For these reasons, only under exceptional circumstances should radical cancer treatment be undertaken on the basis of a primary diagnosis reached by FNAB without more definitive tissue diagnosis and even then rigorous clinico-radiological correlation must be exercised.

The defining feature of SCC is breach of the subepithelial basement membrane allowing malignant cells to infiltrate into the normal underlying connective tissue, thereby gaining access to lymphatics, blood vessels and nerves. Typically, areas of dysplasia will surround invasive SCC, although this is by no means invariable. The phenomenon of 'field cancerization' reflects the long-term exposure of head and neck mucosa to carcinogens causing genetic alterations, which enable multifocal tumours to arise due to independent genetic events.[29]

The microscopic description of an SCC includes:

- histological subtype
- histological grade (well-, moderate-, poorly-differentiated)
- invasive front (cohesive or non-cohesive)
- vascular invasion
- neural invasion.

The terms 'superficial invasion', 'minimally invasive carcinoma' and 'micro-invasive carcinoma' are sometimes used to denote SCC with limited infiltration. However, these presently have no agreed, validated definition and are, therefore, potentially confusing. It is more helpful to measure tumour depth and/or thickness and overall dimensions, and place this within the recognized TNM schema with any relevant subjective descriptive comments. It is also important to assess for the presence of malignant cells within lymphovascular channels and also neurotropism, signifying vascular or neural invasion respectively, both of which are associated with an unfavourable prognosis.

Immunohistochemistry

For poorly differentiated tumours, IHC is required to render an accurate diagnosis. The initial panel of IHC is directed at identifying broad groups of tumours: carcinoma, melanoma, lymphoma and sarcoma. A pan-cytokeratin cocktail is used to demonstrate cytokeratin intermediate filaments, which is positive in virtually all carcinomas. S100, MelanA, HMB45 and Sox10 can be used to identify melanoma. CD45 (leucocyte common antigen), CD79a (B cell marker) and CD3 (T cell marker) are used to identify lymphoma. Sarcomas are more variable and panels are formulated based on morphological clues. Antibodies for desmin and vimentin are often used to start the process of investigation.

For poorly differentiated carcinomas, cytokeratins 5, 6, 14, and staining with the nuclear proteins p40 and p63, are used to support a diagnosis of poorly differentiated SCC. The results of these panels of IHC are usually described in the pathology report.

For oropharyngeal SCC, HPV testing is recommended.[30] Tests are carried out for prognostication and for entry into clinical trials. Typically, testing is carried out using a combination of p16 IHC and high-risk HPV DNA ISH (**Figure 26.10d**).[31] Other HPV specific tests, such as polymerase chain reaction (PCR)-based tests have also been validated. Tumours that harbour oncogenic HPV show increased p16 expression. There is strong and diffuse, nuclear and cytoplasmic staining in more than 70% of malignant cells. p16 is a recognized surrogate marker of oncogenic HPV infection; the test is highly sensitive but lacks specificity. By contrast, high-risk HPV DNA ISH is highly specific but lacks sensitivity. The combination of both tests provides a satisfactory classification for the majority of oropharyngeal SCC (95%). The significance of p16-positive, HPV-negative SCC is controversial; in some studies p16 is an independent marker of good prognosis, whereas in other studies p16 positivity alone does not confer a favourable prognosis.[32, 33]

For the clinical scenario of an enlarged cervical lymph node that turns out to be metastatic SCC, HPV and EBV tests (see below) are useful in locating the putative primary site. HPV-positive SCCs are usually located in the oropharynx, whereas EBV-positive SCCs are typically discovered in the nasopharynx. A similar strategy can be used to link a distant metastases to an index primary tumour in the head and neck region.

HNSCC variants

A number of morphological variants of SCC are recognized, which include: verrucous carcinoma (VC); spindle cell carcinoma (sarcomatoid carcinoma); papillary SCC; adenosquamous carcinoma; and basaloid SCC.

- VC is a controversial manifestation of well-differentiated SCC, typically occurring in the oral cavity but rarely said to occur in the larynx (1–3% of all laryngeal malignancies), hypopharynx, sinonasal tract and nasopharynx, plus other sites outside the head and neck. Clinically, VC is a warty, exophytic lesion that arises from a broad base. It has a superficial spreading growth, but can be deeply destructive extending

into muscle, cartilage or bone. Histologically, VC lacks significant cellular atypia and is characterized by blunt incursions and an expansile advancing margin sometimes eliciting brisk lymphocytic response. If adequately sampled, approximately 20% of VCs contain areas of conventional SCC, although often very localized, and it is these elements that determine overall prognosis. Incision biopsy diagnosis of VC is problematic as its predominant bland morphology may be indistinguishable from benign squamoproliferative lesions on superficial or limited volume material. Typically, three or four biopsies are required, or even excision biopsy, before the overall architecture is appreciated and the diagnosis is seriously considered. A high index of pathological suspicion and clinical persistence are thus prerequisites.

- Spindle cell carcinoma (sarcomatoid carcinoma) (**Figure 26.11**) occurs in the upper respiratory tract or, less commonly, in the oral cavity. Patients are typically elderly males and a significant number will have had previous radiation. Spindle cell carcinoma usually has a polypoidal, exophytic configuration with either a broad base or narrow pedicle that can occasionally auto-amputate and be expectorated by the patient. The surface tends to be ulcerated. It is usually a bi-phasic lesion with areas of SCC, and/or high-grade dysplasia, associated with bizarre spindle cell and/or giant cell proliferation of sarcomatoid appearance. The squamous component can be difficult to identify due to the ulceration and the sarcoma-like component predominates. IHC may be helpful, although the spindle cells are often negative for epithelial markers and a significant minority paradoxically co-express aberrant positivity for mesenchymal markers.
- Papillary SCC is an uncommon variant.[34] It may affect most anatomical subsites of the head and neck, including the larynx and hypopharynx. Macroscopically, the tumour is similar to VC, but lacks the typical surface keratinization. Microscopically, the lesion is composed of obviously atypical squamous cells overlying fibrovascular papillary stromal cores. The tumour behaves in a similar manner to conventional SCC and management is therefore similar.
- Adenosquamous carcinoma is an uncommon variant of HNSCC, which is considered aggressive and associated with a poor prognosis.[35] It predominantly affects males in the sixth or seventh decade. The larynx, and occasionally the hypopharynx, is the most commonly affected site. Macroscopically, the tumour resembles a typical HNSCC. Microscopically, the tumour is characterized by the presence of conventional SCC admixed with a variable proportion of true glanduloductal elements indicative of divergent differentiation. Mucin histochemistry and keratin immunoprofiling may aid distinction from acantholytic SCC with pseudoglandular growth and also from mucoepidermoid carcinoma.
- Basaloid SCC is a high-grade aggressive variant of SCC typically found in middle-aged male patients, affecting the oropharynx, larynx and hypopharynx.[36] Macroscopically, these are firm to hard tumours with central necrosis and superficial ulceration. Microscopically, the tumour is infiltrating and deeply invasive and presents a typical basaloid appearance consisting of pleomorphic cells arranged in a lobular configuration with palisading. Cystic degeneration with central comedonecrosis is often a feature. There may be minimal objective evidence of squamous cell differentiation.

Other variants include acantholytic, small cell, clear cell, giant cell and lymphoepithelial carcinoma. In practice, many SCCs are heterogeneous in pattern at least focally.

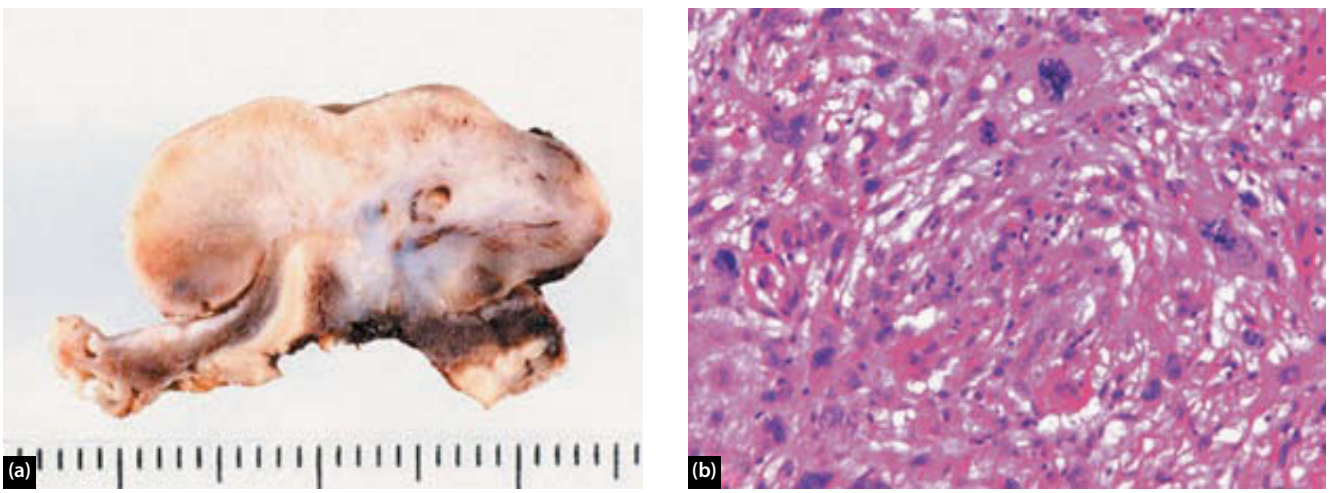

Figure 26.11 Spindle cell carcinoma of larynx. (a) Cross-section of epiglottic resection specimen. This is ulcerated and polypoidal, but also infiltrates deeper, penetrating into and through epiglottic cartilage. **(b)** Representative field beneath the tumour surface exhibiting highly pleomorphic spindle and bizarre giant cells with abnormal mitoses reminiscent of undifferentiated pleomorphic sarcoma (H&E stain, high magnification).

NASOPHARYNGEAL CARCINOMA

Nasopharyngeal carcinoma (NPC) is a distinct type of SCC arising in the nasopharynx.[37] Worldwide, NPC is an uncommon disease with an incidence of less than 1 per 100 000, but has a very distinct geographical distribution. In China, 18% of all adult cancers are NPC and it is especially common in northern provinces, Kwantung and Taiwan, but is uncommon in children (2%). By contrast, 10–20% of all paediatric cancers in northern and central Africa are NPC. Ethnic groups with intermediate risk include Greenland Inuit and the Maghrebis of Northwest Africa, but Caucasian populations have the lowest risk. Other factors implicated in the development of NPC include EBV and dietary factors, especially a high intake of salted fish and preserved vegetable products. Clinically, the tumour can be a bulging, exophytic and lobulated, or ulcerative mass. Occasionally, there may be no visible tumour, necessitating blind biopsy of the nasopharynx.

Microscopically, NPC is classified according to the WHO system, which is dependent on the presence or absence of keratinization. Around a quarter of tumours contain more than one type and are then classified according to the dominant type:

- Keratinizing NPC represents approximately 25% of all NPC in North America, but only 2% of Chinese patients.[37] This type is rarely found in patients under 40 years of age. Like HNSCC in other sites, this type of NPC can be classified as well, moderately or poorly differentiated. The cells grow in well-defined nests with easily demonstrable intercellular bridges and keratin pearl formation. The stroma undergoes a desmoplastic response to invasive growth.
- Non-keratinizing NPC, which is associated with EBV, can be divided into differentiated or undifferentiated, but is of no clinical or prognostic significance:
  - Differentiated non-keratinizing NPC is the least common subtype, accounting for 12% worldwide (2% in China).[37] As the name suggests, there is little or no evidence of keratinization, vague intercellular bridges and it may undergo cyst formation. There is no desmoplastic response to invasive growth.
  - Undifferentiated non-keratinizing NPC is the most common subtype, accounting for approximately 63% of cases, rising to 95% in China,[37] and is the most common type to affect children. The cells possess round nuclei, prominent eosinophilic nucleoli, and/or dispersed or microvacuolated chromatin with scant cytoplasm. There is generally a prominent non-neoplastic intra-tumoral and peri-tumoral lymphoid cell infiltrate. When there is a diffuse, non-cohesive growth pattern, such malignant cells are easily overlooked on cursory inspection. Other recognized growth patterns include cohesive or nested cells. There is no desmoplastic response to invasive growth.

EBV infection can be reliably detected in biopsy specimens using ISH for EBV encoded early RNA (EBER) (**Figure 26.12**). The majority (90%) of Asian NPCs are EBV-positive. There is emerging evidence that some of NPCs are HPV-positive, typically those that occur in Caucasian patients.[38]

MALIGNANT SALIVARY GLAND TUMOURS

Malignant salivary gland tumours are very uncommon and represent approximately 0.5% of all malignancies,

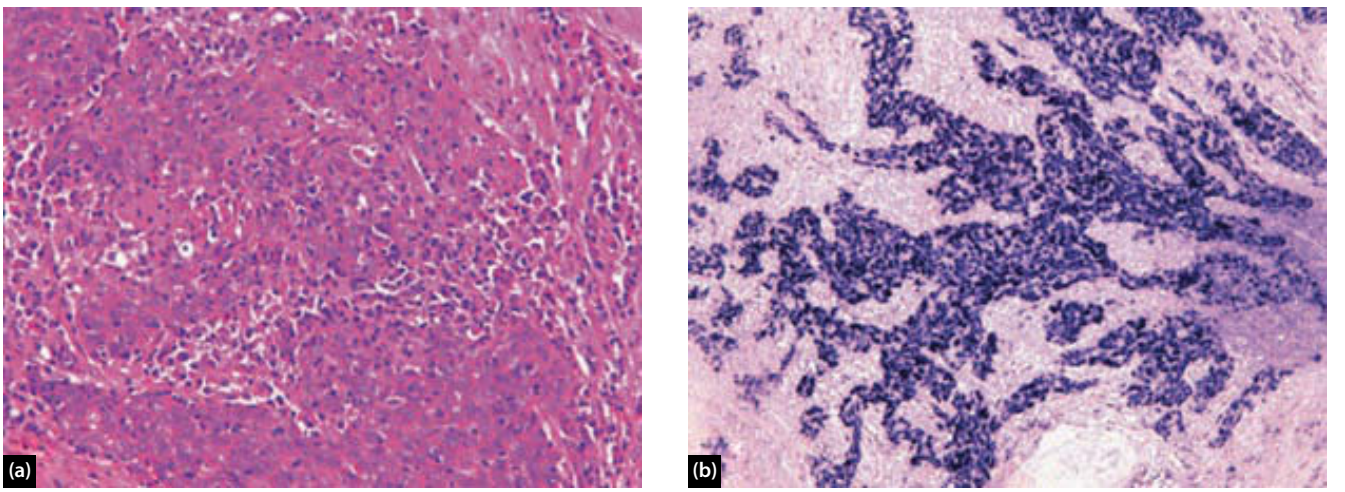

Figure 26.12 Epstein–Barr virus (EBV)-associated undifferentiated carcinoma of nasopharyngeal type. (a) Sheets of poorly differentiated, non-keratinizing malignant cells with ill-defined cytoplasmic borders imparting a syncitial appearance. The nuclei are variously vacuolated or nucleolated. Small lymphocytes are present within and surrounding the tumour cells (H&E stain, medium magnification). **(b)** *In situ* hybridization (ISH) for EBER confirms a diffusely positive signal indicating EBV infection (EBER ISH, medium magnification).

TABLE 26.6 WHO classification of malignant epithelial salivary gland tumours[12]

Malignant epithelial salivary gland tumours
• Mucoepidermoid carcinoma
• Acinic cell carcinoma
• Adenoid cystic carcinoma
• Adenocarcinoma NOS
• Carcinoma ex-pleomorphic adenoma
• Polymorphous adenocarcinoma
• Clear cell carcinoma
• Basal cell adenocarcinoma
• Intraductal carcinoma
• Salivary duct carcinoma
• Myoepithelial carcinoma
• Epithelial/myoepithelial carcinoma
• Secretory carcinoma
• Sebaceous adenocarcinoma
• Carcinosarcoma
• Poorly differentiated carcinoma
• Undifferentiated carcinoma
• Small cell neuroendocrine carcinoma
• Large cell neuroendocrine carcinoma
• Lymphoepithelial carcinoma
• Squamous cell carcinoma
• Oncocytic carcinoma
• Sialoblastoma

5% of all head and neck cancers and an incidence in the Western world of 2.5–3/100 000/year.[13] Despite the low incidence, over 20 named malignant salivary gland neoplasms are recognized (**Table 26.6**). This section will describe the pathological characteristics of the more common malignant neoplasms and the authors recommend reference to a specific head and neck pathology atlas for information regarding less common tumours.[11, 12]

MUCOEPIDERMOID CARCINOMA

Mucoepidermoid carcinoma typically affects the parotid gland, but may also occur in the minor salivary glands. The tumour is triphasic comprising goblet cell mucocytes, epidermoid cells (usually with no keratinization) and non-descript cells of intermediate size and shape.

Epidemiology

Mucoepidermoid carcinoma is the most common malignant salivary gland neoplasm (12–29% of all salivary gland malignancies).[11, 12] It is found more frequently in female patients and can present at any time between the first and ninth decade, but peaks in the fifth decade. The major risk factor for development is previous therapeutic radiation exposure with a latent period of 7–32 years.[11, 12]

Macroscopic appearance

The tumour has a variety of appearances. It can be circumscribed or infiltrative. Tumours are predominantly solid, tan-white to pink masses, often cystic filled with a viscous brown fluid. Areas of scarring can also be present and may occasionally prevail.

Microscopic appearance

The tumour consists of varying proportions of admixed mucinous, epidermoid and intermediate cells (**Figure 26.13**). Low-grade tumours are macrocystic and microcystic with plentiful mucocytes, fewer epidermoid cells and infrequent intermediate cells. Extravasated, dissecting mucin pools may be seen. There may be a sclerosing/fibrosing component. Reactive tumour-associated lymphoproliferation is characteristic. High-grade tumours are more solid and contain fewer mucinous elements with a preponderance of atypical epidermoid cells. High-grade tumours are easily mistaken for SCC and recourse to exhaustive sampling augmented by a panel of mucin histochemistry may be diagnostic. This diversity makes FNAB interpretation challenging. The behaviour of mucoepidermoid carcinoma is very varied and various systems have been proposed to attempt to grade tumours and hence predict outcome. A commonly used system is outlined in **Table 26.7**.[39]

ACINIC CELL CARCINOMA

Epidemiology

Acinic cell carcinoma accounts for 7–17.5% of all malignant salivary gland neoplasms. Approximately 80% arise from the parotid gland, with the remaining 20% arising mainly from the minor salivary glands or submandibular glands, and only 1% from the sublingual gland. There is a male preponderance and they usually present in the third decade of life.[11, 12]

Macroscopic appearance

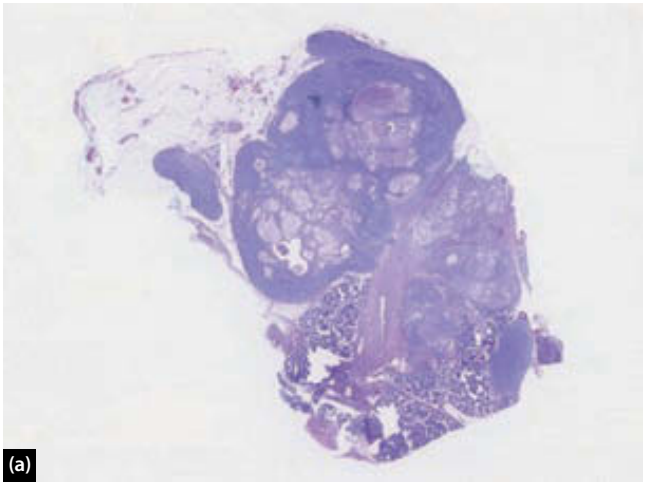
Macroscopically, the tumours are of a firm to rubbery consistency and range in colour from a tan-grey to yellow or pink mass. They are usually rounded, well circumscribed and can be encapsulated. They can contain areas of haemorrhage or cystic change. Recurrent tumours tend to be less well demarcated and can appear multinodular.

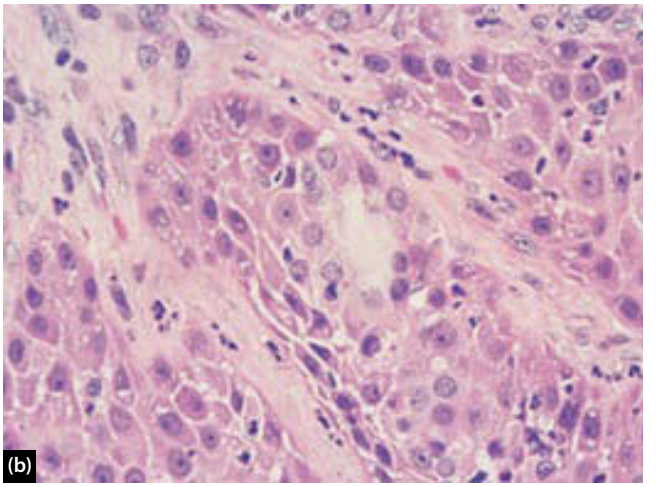
Microscopic appearance

Acinic cell carcinomas recapitulate the serous acinar cell of normal salivary gland tissue. There are a number of recognized growth patterns, which can coexist in a single tumour (**Table 26.8**). Histochemical stains are used to demonstrate zymogen granules in serous acinar cells; in some tumours these cells are sparse, making diagnosis challenging (**Figure 26.14**). Reactive lymphoid tissue is characteristic of acinic cell carcinoma and may mimic lymph node involvement.[40]

ADENOCARCINOMA NOT OTHERWISE SPECIFIC

Adenocarcinoma not otherwise specified (NOS) refers to malignant tumours with glandular or ductal differentiation that do not have specific histologically defining features to enable further sub-classification as a recognized subtype.





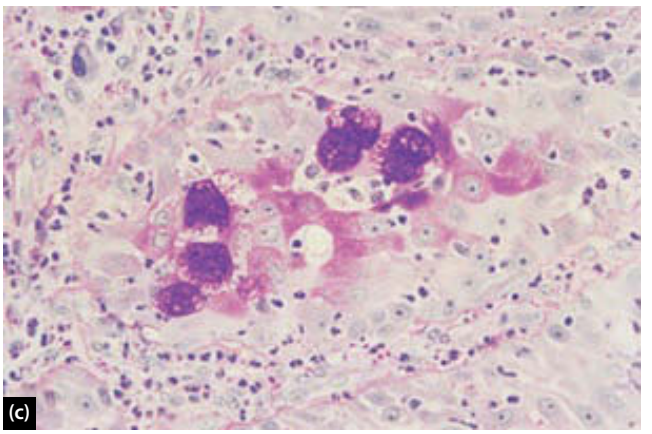


Figure 26.13 Mucoepidermoid carcinoma. **(a)** Whole mount slide of a low-grade mucoepidermoid carcinoma illustrating an expansile multilobulated architecture, substantial macrocystic and microcystic growth plus peripheral lymphoid tissue response (H&E stain, ultralow magnification). **(b)** Intermediate-grade tumour depicting epidermoid cells surrounding a rudimentary tubuloductal lumen lined by goblet cell mucocytes, characterized by abundant microvacuolated cytoplasm (H&E stain, high magnification). **(c)** The same tumour stained for neutral mucosubstances demonstrates mucocytes (dPAS stain, high magnification).

TABLE 26.7 Grading system for mucoepidermoid carcinoma[39]

Parameter	Point value	
Intracystic component <20%	2	
Neural invasion	2	
Necrosis	3	
Mitoses (>4 per 10 HPF)	3	
Anaplasia	4	
Grade	**Total score**	**Overall survival (10 years)**
Low	0–4	90%
Intermediate	5–6	70%
High	7–14	25%

HPF, high power fields.

Epidemiology

Adenocarcinoma NOS is the third most common malignant salivary gland neoplasm. It is more common in women and frequently seen in the fifth to eighth decade with a mean age of diagnosis of 58 years, and it is rarely seen in adolescents or children. Sixty per cent occur in the major salivary glands, usually the parotid, and 40% occur in the minor salivary glands.[11–13]

TABLE 26.8 Growth patterns of acinic cell carcinoma[11, 12]

Growth pattern	Features
Solid	Cells aggregate into sheets forming lobules or nodules
Microcystic	The tumour has a sieve-like appearance due to the presence of microcysts
Papillary–cystic	The tumour contains prominent cysts with intraluminal papillary projections
Follicular	Contain multiple variable-sized cysts loosely resembling thyroid parenchyma

Macroscopic appearance

Macroscopically, tumours appear as a firm tan-white mass, which can be circumscribed to poorly demarcated with an irregular periphery and potentially infiltrative appearance. There may be areas of haemorrhage, cystic change or necrosis.

Microscopic appearance

Adenocarcinoma NOS is a diagnosis of exclusion and therefore tumours that fall within this category can display a variety of features. Common to all tumours in this group is the presence of glandular or ductal features, an invasive

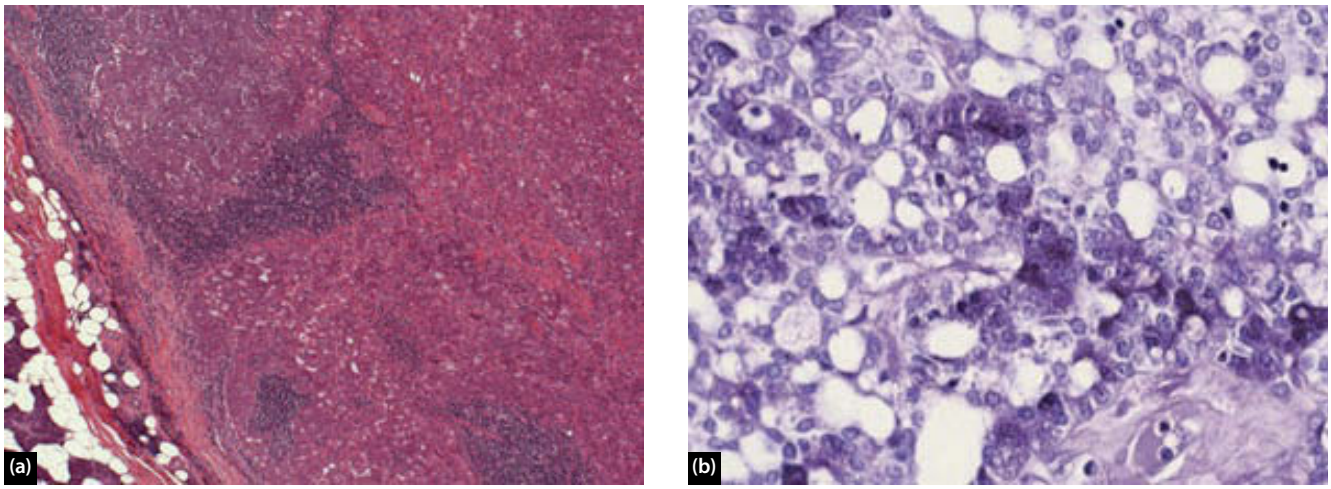

Figure 26.14 Acinic cell carcinoma. **(a)** Sheets of serous acinar cells arranged in a lobular pattern, note the lymphoid stroma (H&E stain, low magnification). **(b)** Microcystic pattern acinic cell carcinoma, there are a few serous acinar secretory cells containing purple zymogen granules (dPAS stain, high magnification).

growth pattern and the lack of histological characteristics of other salivary adenocarcinomas. The malignant epithelium can display various architectural features including glandular, ductal, papillary, solid and nest-like. There may be clear cell change and/or mucinous differentiation. The tumours can also be graded into low, intermediate and high, based on the degree of gland formation, cellular pleomorphism and mitotic count:

- Low-grade tumours have easily identifiable gland and duct-like structures. There is usually a single cell type with small nucleoli, abundant cytoplasm, distinct cell borders and little nuclear pleomorphism with few mitoses. This can occasionally lead to a benign diagnosis if the invasive growth is not identified.
- Intermediate-grade tumours also have easily identified gland and duct-like structures. Unlike low-grade tumours, there is greater nuclear pleomorphism with more mitoses.
- High-grade tumours tend to be solid, with areas of haemorrhage and necrosis. Unlike low- and intermediate-grade tumours, the gland and duct-like structures are much sparser. The cells are much more abnormal and varied. Cellular features include frequent atypical mitoses and enlarged, hyperchromatic, pleomorphic nuclei.

ADENOID CYSTIC CARCINOMA

Epidemiology

Adenoid cystic carcinoma (ACC) accounts for approximately 10–12% of all malignant salivary gland tumours and is the most common malignant tumour of the submandibular gland. It represents approximately 5% of parotid neoplasms and 30–50% of minor salivary gland neoplasms. There is no sex predilection and it is usually seen in patients in their 40s to 60s, rarely in patients under 20 years old. [11–13]

Macroscopic appearance

The tumour is usually a poorly circumscribed solid white tumour. ACC infiltrates into surrounding soft tissue, muscle and bone, sometimes directly through lymph node capsules.

Microscopic appearance

There are often two recognizable malignant cell subpopulations representing epithelial and myoepithelial components. Three growth patterns have been described but many tumours are mixed.

Tubular pattern represents the most differentiated form of ACC.[41] Small nests of cells form few true glandular or tubule-ductal spaces and occasional cords.

Cribriform pattern is the most common pattern and most tumours will contain areas displaying this pattern even if not the predominant type. In addition to true gland lumina containing secretions, cells group to form multiple pseudocysts (pseudolumina) containing mucoid basement membrane material. The overall pattern resembles 'Swiss cheese' (**Figure 26.15**). This architecture represents an intermediate level of cellular proliferation and biological aggressiveness.[41]

Solid pattern is the least common type and unlike the other two types there are few glandular spaces. Cells in the solid type tend to be larger and more pleomorphic with mitoses, interspersed with areas of necrosis. A biphasic cell population may not be apparent and without at least some better-differentiated fields, it may be impossible to arrive at the diagnosis.

ACC may be graded according to the predominant growth pattern:[11–13]

- Grade I, mostly tubular with some cribriform elements
- Grade II, either entirely cribriform or cribriform/tubular with less than 30% solid component
- Grade III, any tumour with more than 30% solid growth.

Low-grade ACC pursues a pernicious course typified by relentless, troublesome local recurrence, ultimately presaging

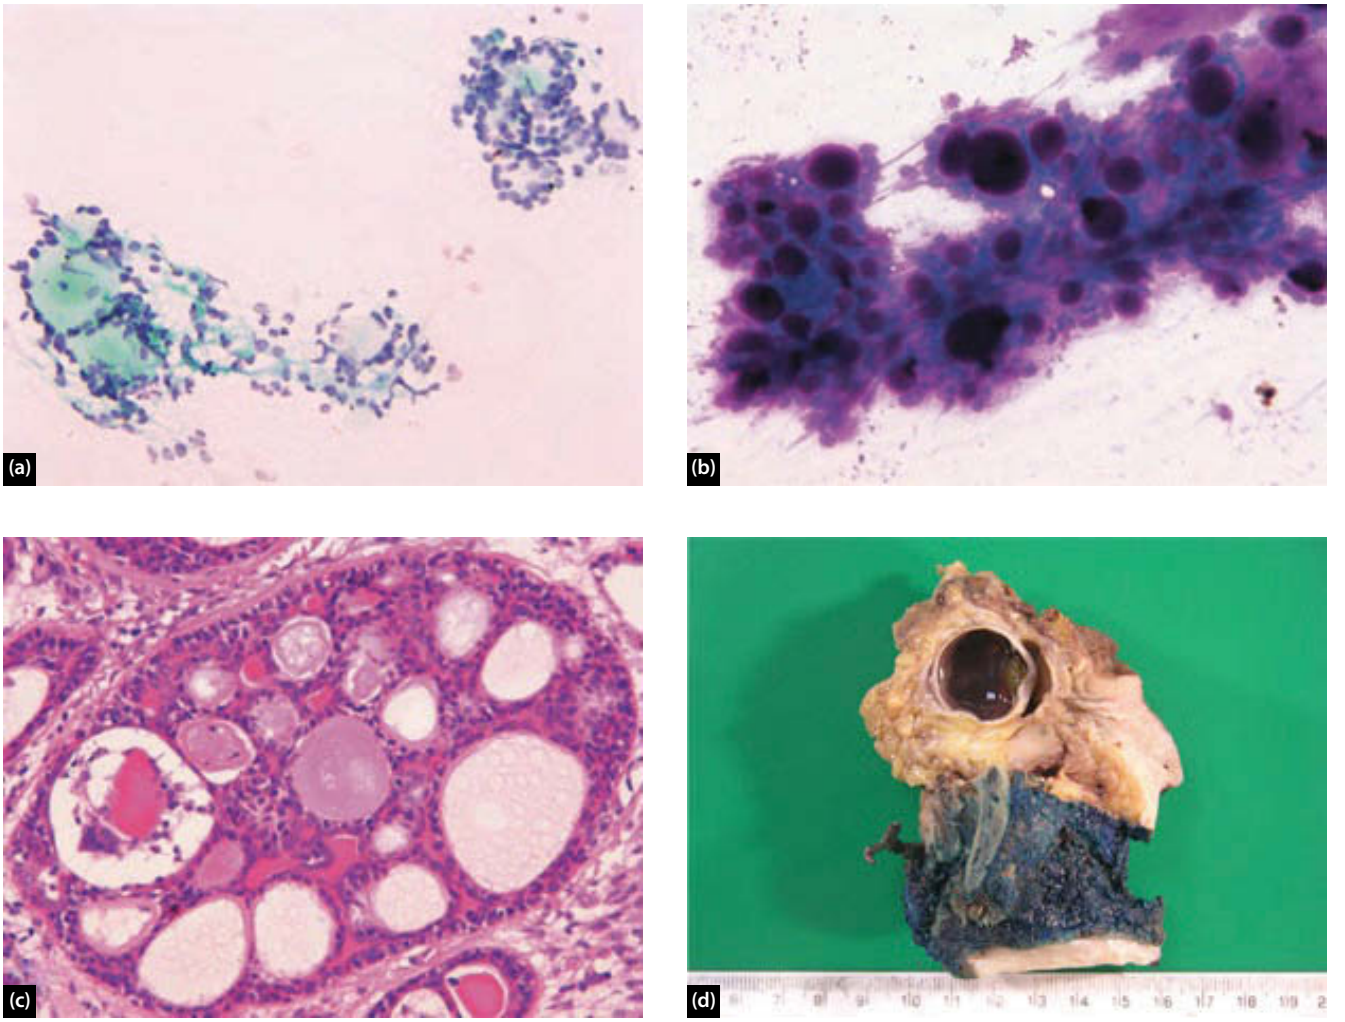

Figure 26.15 Adenoid cystic carcinoma (ACC). **(a)** FNAB illustrating cribriform microbiopsies. The characteristic hyaline basement membrane globules are pale in this preparation (Pap stain, medium magnification). **(b)** Cytology showing similar features albeit with striking intense staining of the hyaline globules (May–Grunwald-Giemsa (MGG) stain, medium magnification). **(c)** Classical cribriform ACC demonstrating pseudolumina filled with variably dense basement membrane type droplets, together with true gland lumina, either empty or containing sparse secretions (H&E stain, high magnification). **(d)** Right maxillectomy and orbital exenteration, for recurrent ACC.

wider dissemination after a prolonged interval of years or even decades. Many malignant salivary gland tumours show a propensity for perineural growth, though this is characteristic for ACC, the latter commonly visualized microscopically some considerable distance beyond what would be regarded as adequate surgical clearance. This neurotropism may radiate in a tentacular fashion well beyond the main body of the tumour. Positive surgical resection planes are, therefore, sometimes an unexpected and unwelcome feature of pathology reports, as this signifies inevitable local recurrence. Obversely, the histological suggestion of surgical clearance is not particularly reassuring. High-grade (solid) ACC is an aggressive, destructive malignancy.

CARCINOMA EX PLEOMORPHIC SALIVARY ADENOMA

Carcinoma ex-pleomorphic adenoma arises from within a pre-existing PSA or at the site of a previous pleomorphic adenoma.

Epidemiology

Carcinoma ex-pleomorphic adenoma is not uncommon and accounts for approximately 12% of all salivary gland malignancies and 6.2% of all pleomorphic adenomas.[42] Risk factors for malignant transformation of a pleomorphic adenoma include older age of patient (mean, 61 years), male sex, prolonged duration of tumour and multiple recurrences.[12, 43] It commonly affects the parotid gland and, rarely, the sublingual gland.

Macroscopic appearance

Carcinoma ex-pleomorphic adenoma tends to be larger than its benign counterpart. Tumours tend to be poorly circumscribed, firm, tan-white and extensively infiltrative masses. They can occasionally be well circumscribed and appear encapsulated. The 'ghost' of a pre-existing adenoma is often identified, sometimes alluded to by a dense, occasionally mineralized, scar. The malignant component tends to radiate centrifugally from this nidus, if present (**Figure 26.16**).

Figure 26.16 Carcinoma ex-pleomorphic salivary adenoma. Cut surface of a longstanding adenoma seen centrally forming a discrete, cream, elastotic scar with focal calcification. This is part-circumferentially surrounded by peripheral lobules of tan carcinoma ex-adenoma.

Microscopic appearance

The malignant element of a carcinoma ex-pleomorphic adenoma typically comprises high-grade adenocarcinoma or salivary duct carcinoma often with squamoid differentiation, but other specific subtypes of salivary carcinoma are seen and these may on occasion be monotypic rather than mixed. The benign pleomorphic adenoma component can be difficult to identify, may require extensive sampling and in some cases it may never be identified. The association of pleomorphic adenoma, carcinoma and sarcoma (carcinosarcoma, true malignant mixed tumour) is very rare. Invasion of tumour through the original lesion's capsule carries prognostic significance and has been classified as:[11–13]

1. Intracapsular carcinoma
2. Minimally invasive carcinoma (less than 4–6 mm invasion)
3. Widely invasive carcinoma.

In principle, (1) and (2) have a favourable prognosis compared to (3), although the precise cut-off point to define a category of invasion with minimal metastatic potential is controversial. Ordinarily, pleomorphic adenomas may show peripheral permeative growth, lymphatic tumour embolus, necrosis and focal internal cytonuclear atypia without signifying malignant transformation. Caution should be exercised in the interpretation of such features if prior FNAB has been attempted. Such tumours are sometimes termed 'atypical pleomorphic adenoma' and generally behave no differently from their more typical counterparts.

MOLECULAR PATHOLOGY OF SALIVARY GLAND TUMOURS

In recent years, a number of genetic alterations have been associated with salivary gland neoplasms.[12] Specifically, the presence of chromosomal translocations and their gene fusions have been used to aid diagnosis (**Table 26.9**).

TABLE 26.9 Chromosomal translocations in salivary gland tumours[12]

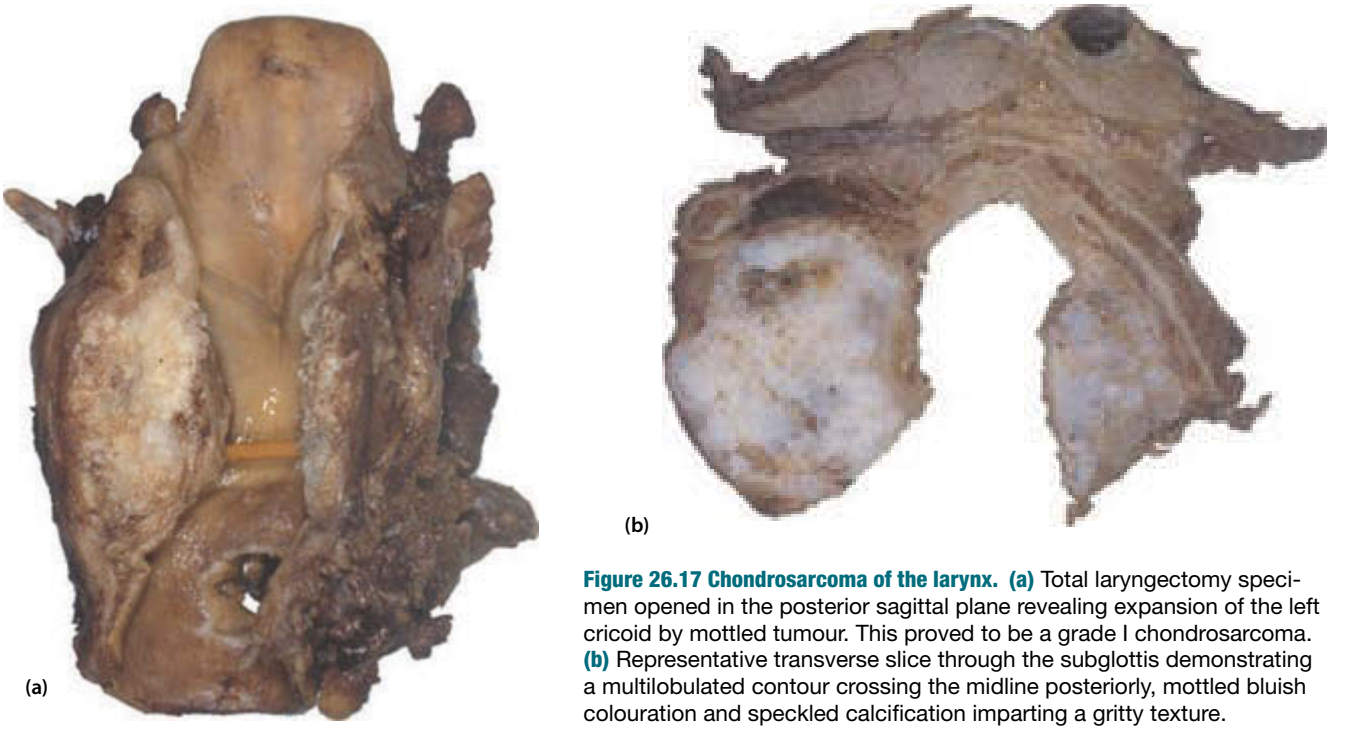
Salivary tumour	Fusion oncogene	Diagnostic utility
Pleomorphic adenoma	PLAG-1 fused to CTNNB1, TCEA1 or others	*PLAG-1* abnormality in 30% of tumours
Mucoepidermoid carcinoma	CRTC1-MAML2 (>80%) CRTC3-MAML2 (<10%)	Present in low and intermediate grade tumours
Adenoid cystic carcinoma	MYB-NFIB MYBL1-NFIB	Present 80–90% of tumours
Secretory carcinoma	ETV6-NTRK3	Defines the entity

These molecular alterations can be detected by fluorescence *in situ* hybridization (FISH), PCR or DNA sequencing. Recently, secretory carcinoma, a low grade salivary gland carcinoma, has been described and is defined by a translocation (12;15)(p13;q25) leading to formation of an ETV6-NTRK3 fusion oncogene. In the past, these cases were likely diagnosed as acinic cell carcinomas. It is hoped that such molecular information will facilitate accurate diagnosis and produce new insights into the management of these interesting and rare tumours.

Lymphomas

Lymphoma is the second most common primary malignancy occurring in the head and neck region. Approximately 25% of all extra-nodal lymphomas occur in the head and neck. Thus, although in the UK the overwhelming majority of haematolymphoid tumours, predominantly lymphomas and leukaemias, are managed by specialist haemato-oncology multidisciplinary teams, head and neck surgeons are frequently involved in the initial diagnosis of lymphoma. It is, therefore, important that the head and neck pathologist possesses a sound working knowledge of lymphoproliferative conditions and their differential diagnosis.

It is beyond the scope of this chapter to delve into the complexities of lymphoma diagnosis and the interested reader is referred to the comprehensive World Health Organisation (WHO) classification of tumours of haematopoietic and lymphoid tissues (4th edition, 2008), which is internationally recognized, periodically reviewed and updated.[44,45] This takes a multiparameter approach to classification incorporating clinical, morphological and immunophenotypical features plus genetic studies into account with the expectation that the schema will continually evolve and be refined over time. Lymphomas are broadly divided into Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL). HL is characterized by Reed–Sternberg cells and is subdivided into classical HL (incorporating nodular sclerosing, mixed cellularity, lymphocyte-rich and lymphocyte-depleted subtypes) and nodular lymphocyte predominant HL, according to site of involvement, clinical features, growth pattern, presence of fibrosis, composition of cellular background, number and/or degree of atypia



(a) (b)

Figure 26.17 Chondrosarcoma of the larynx. (a) Total laryngectomy specimen opened in the posterior sagittal plane revealing expansion of the left cricoid by mottled tumour. This proved to be a grade I chondrosarcoma. **(b)** Representative transverse slice through the subglottis demonstrating a multilobulated contour crossing the midline posteriorly, mottled bluish colouration and speckled calcification imparting a gritty texture.

of the tumour cells and frequency of EBV infection. The immunophenotype of the neoplastic cells in these classical HL subtypes is identical. Around 85% of NHLs are B-cell lymphomas, which include chronic lymphocytic leukaemia/small lymphocytic lymphoma, follicular lymphoma, marginal zone lymphoma, the latter often extranodal involving the mucosa-associated lymphoid tissue of Waldeyer's ring. Diffuse large B-cell lymphoma is the most common aggressive NHL. Mantle cell lymphoma and Burkitt lymphoma are aggressive NHLs sometimes seen in the head and neck region. Plasma cell neoplasms, most commonly plasma cell myeloma and extramedullary plasmacytoma, are occasionally encountered in the head and neck region. Cutaneous T-cell NHLs (e.g. mycosis fungoides) may affect head and neck skin, but are rarely seen at mucosal sites. Extra-nodal NK/T-cell lymphoma is strongly associated with EBV infection and shows a predilection for the upper aero-digestive tract, typically the nasal cavity. Its angiocentric and angio-destructive nature may mimic the histological features of granulomatosis with polyangitis.

Malignant mesenchymal tumours

Malignant mesenchymal tumours (sarcomas) are uncommon in the head and neck region, but include:

- fibrosarcoma
- malignant fibrous histiocytoma
- leiomyosarcoma
- rhabdomyosarcoma
- liposarcoma
- angiosarcoma
- Kaposi sarcoma
- malignant peripheral nerve sheath tumour
- synovial sarcoma
- chondrosarcoma (**Figure 26.17**)
- mesenchymal chondrosarcoma
- osteosarcoma
- chordoma.

Neuroectodermal tumours

MUCOSAL MALIGNANT MELANOMA

Mucosal malignant melanoma is a rare tumour that originates from neuroectodermal-derived melanocytes.[46] Between 15% and 20% of malignant melanomas arise in the head and neck region, but the vast majority, over 80%, are of cutaneous or upper aerodigestive tract origin. Mucosal malignant melanoma represents merely 0.5–3% of malignant melanomas from all sites.[10] Common sites for mucosal malignant melanoma include the sinonasal tract and the oral cavity, particularly the palate. It is more common in men, but this finding is not consistent, and the tumour affects a wide age range (20–80 years).

Macroscopic appearance

Mucosal melanomas are usually pigmented and colour ranges from a light tan to black depending on the amount of melanin production, though amelanotic examples do occur.

TABLE 26.10 Hyams' grading classification of olfactory neuroblastoma[14]

Histological feature	Grade I	Grade II	Grade III	Grade IV
Architecture	Lobular	Lobular	May be lobular	May be lobular
Mitoses	Absent	Present	Prominent	Marked
Nuclear pleomorphism	Absent	Present	Prominent	Marked
Neurofibrillary matrix	Prominent	Present	May be present	Absent
Rosettes	Homer–Wright rosettes	Homer–Wright rosettes	Flexner–Wintersteiner rosettes	Flexner–Wintersteiner rosettes
Necrosis	Absent	Absent	Present	Prominent

Microscopic appearance

They typically comprise epithelioid and/or spindle cells. Plasmacytoid, rhabdoid, small cell, giant cell, balloon cell, neurotropic and desmoplastic variants are recognized. The cells are markedly pleomorphic and may contain pigment. Nucleoli are conspicuous and intra-nuclear inclusions are typical. An adjacent inflammatory infiltrate and necrosis can also be present. Melanocytic atypia or melanoma *in situ* may be observed in the background mucosa.

With few exceptions, the cells show nuclear and cytoplasmic immunoreactivity for S100 protein. MelanA, HMB-45 and SOX10 are usually positive. Epithelial markers are negative, although up to 10% of melanomas may show focal cytokeratin reactivity. The desmoplastic variant of melanoma may be negative for all these markers. Mucosal melanomas usually do not harbour BRAF v600E mutations and consequently are unlikely to benefit from vemurafenib targeted treatment.[12]

OLFACTORY NEUROBLASTOMA

These are uncommon malignant tumours of the upper nasal cavity affecting specialized olfactory mucosa and arising from the superior turbinate, cribriform plate and superior one third of the nasal septum. The reported incidence is four cases per million with a bi-modal distribution in the second and sixth decade, and no sex or racial predeliction.[12]

Macroscopic appearance

Macroscopically, olfactory neuroblastoma appears as a soft, polypoidal, highly vascular mucosa-covered mass.

Microscopic appearance

The malignant cells are uniform, with small round nuclei, scant cytoplasm and possess finely stippled (salt and pepper) chromatin. Hyams' classification system divides olfactory neuroblastoma into four types (**Table 26.10**).[14] The better-differentiated (grade I and II) examples are sometimes termed 'aesthesioneuroblastoma'. Homer–Wright pseudorosettes are formed by cells mantling

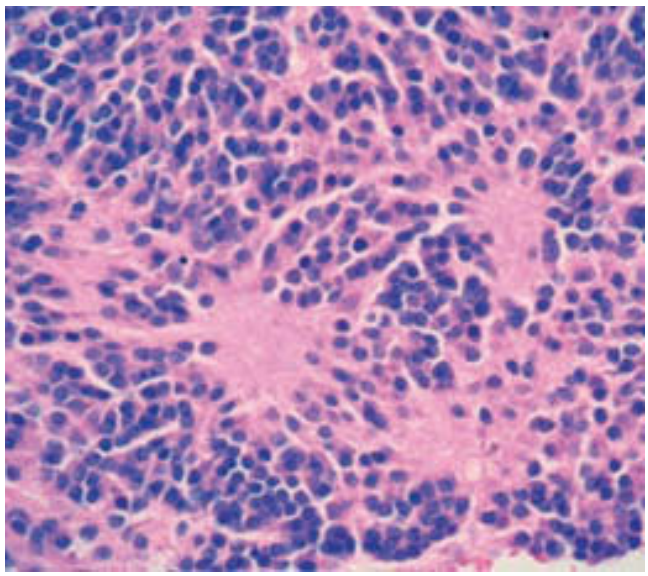


Figure 26.18 Grade I/II olfactory neuroblastoma. Loosely cohesive, uniform, small cells including two Homer–Wright pseudorosettes centred on fibrillary neuropil material. Mitoses are inconspicuous. There is no necrosis (H&E stain, high magnification).

solid, fibrillary neuropil stroma (**Figure 26.18**). Flexner–Wintersteiner rosettes consist of cells surrounding an empty pseudolumen. Other tumours may form perivascular rosettes encircling blood vessel lumina. IHC may aid discrimination between this and other primitive neoplasms (so-called round blue cell tumours), such as lymphoma, Ewing's tumour, melanoma, Merkel cell tumour, rhabdomyosarcoma, nephroblastoma, retinoblastoma and primitive neuroectodermal tumour (PNET).[47] There is, however, no single specific positive marker.

Metastases to the head and neck region

Uncommonly, a primary tumour at another body site may metastasize to the head and neck region. The most commonly encountered are carcinomas of the lung, colon, breast, prostate and kidney (**Figure 26.19**).[11]

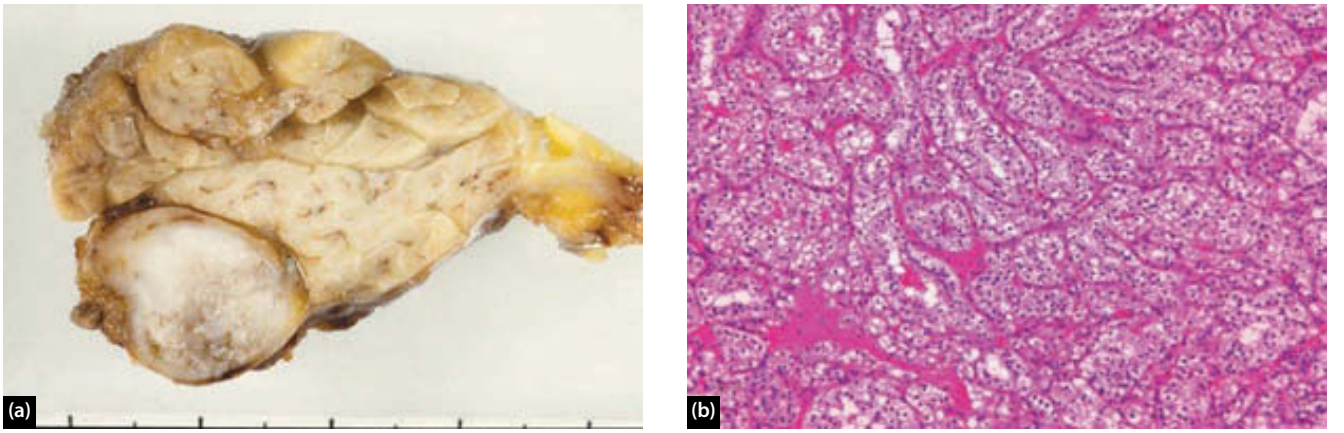

Figure 26.19 Metastatic disease in the head and neck. **(a)** Cut surface of a metastatic deposit effacing a para-parotid lymph node. **(b)** Metastatic clear cell carcinoma from an occult renal primary tumour (H&E stain, medium magnification).

KEY POINTS

- Meticulous and judicious pathological evaluation of head and neck biopsies is essential for effective clinical management.
- Morphological assessment by light microscopy constitutes the cornerstone of cytological and histological diagnosis, supplemented by immunohistochemical and molecular tests, where relevant.
- Fine-needle aspiration biopsy (FNAB) is a comparatively low-risk, cost-effective preliminary investigation in the management of head and neck lumps.
- The histocytopathological diagnostic process is historically heuristic in nature, correlating clinical, pathological, radiological and treatment outcome observations using population and individual case study evidence.
- The head and neck pathologist must be an accomplished practitioner familiar with perhaps the widest range of organ/tissue-specific diseases out of all the anatomically defined site-specific specialities.
- Tumour site, type, grade and stage are major determinants of survival in head and neck cancer, which is influenced to a lesser degree by a variety of other patient-specific and tumour-specific factors. These are accommodated in the UICC/AJCC TNM classification.
- Squamous cell carcinoma in its numerous manifestations accounts for upwards of 90% of all malignant head and neck tumours with lymphoma as the second most common malignancy.
- Fine-needle aspiration biopsy (FNAB) is an established first-line investigation for suspected head and neck cancer. It is rapid, comparatively atraumatic, requires minimal specialized equipment and in experienced hands offers good clinical efficiency, as long as awareness of its inherent limitations and pitfalls is maintained by all concerned.
- The application of immunohistochemistry and molecular markers with deeper understanding of their genetic basis continues to yield insight into the pathogenesis of many head and neck tumours. Their routine use in diagnosis, treatment and prognostication is likely to become more widespread in the future.

SEARCH STRATEGY

Data in this chapter may be updated by a searching using the following keywords: laryngeal squamous cell carcinoma, conservation laryngeal surgery, laryngeal preservation and functional outcome.

INTRODUCTION

Cancer of the larynx is a debilitating disease associated with significant functional morbidity (breathing, speech, swallowing) and mortality. The preferred treatment choice for laryngeal cancer patients provides the optimal balance between disease control prospects and likelihood of treatment-related functional, aesthetic and psychological side effects.[1] Total laryngectomy (TL) with or without post-operative radiation treatment (PORT) offers the best chances for cure across all types and stages of laryngeal cancer.[2] However, TL is associated with severe functional sequela (**Table 27.1**), significant reduction in quality of life (QOL) and low patient acceptance. As such, it is now mostly applied to clinical scenarios in which TL is the sole viable treatment option, such as advanced (T4a) tumour stage, or in cases of locally recurrent disease after radiation treatment. The majority of laryngeal cancers can be treated with more conservative treatment alternatives that provide an improved risk-benefit ratio compared to TL.[3]

Primary radiation therapy can be applied for definitive treatment of early (T-stage 1/2) laryngeal cancers, yielding local control and larynx preservation rates of 85–95%, acceptable voice outcomes, and the possibility for surgical salvage in cases of failure.[4] However, in advanced stage III/IV laryngeal cancer, its efficacy is considered too low (40% local control), even in the setting of intensified radiotherapy protocols (accelerated, hyperfractionated, or intensity-modulated RTx).[5] The efficacy of radiation therapy for advanced laryngeal cancer can be improved significantly with the addition of cisplatin-based chemotherapy.[5] Evidence from several randomized controlled trials suggests that chemoradiation treatment of advanced laryngeal cancer provides control rates that approximate those of TL, while larynx preservation can be achieved in 66–84% of these patients.[5,6] Although the introduction of primary (chemo) radiation has revolutionized the treatment of laryngeal cancer, increasing follow-up data demonstrate a progressive accumulation of significant treatment sequela over time.[7,8] These include laryngeal oedema, fibrosis,

TABLE 27.1 Sequela of total laryngectomy

Communication	• Loss of normal speech quality and quantity
Airway closure	• Loss of airway protection • Loss of effective cough • Loss of ability to strain
Nasal airflow	• Loss of nasal air conditioning • Loss of smell and taste • Loss of normal nasal homestasis and immunity
Swallowing	• Loss of normal constrictor muscle anatomy • Loss of normal sensory and motor innervation • Fibrosis of constrictor muscles • Loss of upper esophageal sphincter
Psychological	• Body image issues with stoma

TABLE 27.2 Comparison open partial laryngectomy (OPL) and transoral laser microscopic laryngectomy (TLM) and (chemo)radiotherapy (C)RTx for laryngeal cancer

	OPL	TLM	(C)RTx
Oncologic results	Equivocal	Equivocal	Equivocal
Speech quality	Poor	Good	Good
Swallowing	Normal	Normal	Impaired
Complications	Respiratory	Rare	GI ,respiratory, systemic
Feeding tube	Temporary – 1 month	No	5–10%
Tracheostomy	Temporary – 1 month	No	Occasional
Treatment duration	1 day	1 day	7 weeks
Costs	Medium cost	Low cost	Expensive
Repeated treatment	No. Only salvage TL or RT	Yes. Repeated laser possible	No. Only salvage TL

laryngeal neuropathy, dysphagia, vocal cord (VC) dysfunction and airway insufficiency. Surgical salvage is required in a significant number of cases with these complications.

Conservation partial laryngeal surgery may provide the best balance between cure and complications for a significant proportion of laryngeal cancer cases.[2, 9] Traditional partial laryngeal surgery is performed through an open transcervical approach, but recent technical developments (refinement of medical laser applications, introduction of endoscopes, microscopes and image guidance systems) have led to the development of less invasive transoral laser microsurgery (TLM) (**Table 27.2**). In early laryngeal cancers, partial laryngectomy provides local control and laryngeal preservation (LP) rates that are at least equivalent to primary radiation therapy, and acceptable functional outcome.[9] In advanced laryngeal carcinomas, open partial laryngectomy can be applied in selected cases and the role of TLM is increasing, both showing oncologic and functional efficacy that may outperform chemoradiation.[9] With appropriate patient selection, partial laryngectomy can be applied in approximately 30–50% of radiorecurrent laryngeal cancers as well, providing surgical salvage and avoiding TL in these patients.[10] Although transoral laser surgery has now largely replaced open partial laryngectomy, several indications for open partial laryngectomy remain, and mandate comprehension and inclusion into the armamentarium of the head and neck surgeon. This chapter will focus on the open conservation surgical approaches for laryngeal cancer, while transoral laser partial laryngectomy will be discussed in Chapter 23, Anatomy as applied to transoral surgery.

SURGICAL GOALS OF OPEN PARTIAL LARYNGECTOMY

The goal of open partial laryngectomy is complete tumour removal, while preserving the functional integrity and separation of larynx and pharynx. This delicate balance requires a detailed understanding of anatomical relationships, a high level of surgical finesse and familiarity with different conservational surgical options, as well as experience on the part of the surgeon.

Complete tumour removal is defined by acquisition of microscopically negative margins of resection upon pathological examination. Chances of local control are decreased significantly in the absence of pathologically negative margins after conservation laryngeal surgery. Survival may be compromised in this setting as well, as the altered post-surgical anatomy and tissue plane boundaries both facilitate unconventional tumour spread, and hamper early detection of tumour recurrence, making salvage treatment more complicated. In recurrent laryngeal cancers after (chemo)radiation, microscopic complete tumour removal is clearly critical, as adjuvant treatment options are limited. In radiation-naive laryngeal cancers amenable to conservation laryngeal surgery, the treatment plan is generally geared towards avoidance of alternative larynx preservation strategies including primary (chemo) radiation treatment and its sequelae, and this focus can only be maintained upon confirmed negative margins. For these reasons, conservation laryngeal surgery should only be attempted when acquisition of negative margins can be anticipated with confidence.

Successful functional outcome after conservation laryngeal surgery is dependent on three factors that need to be addressed during surgery: (i) establishment of an adequate airway with functional (neo)glottic valve; (ii) recreation of adequate post-operative pharyngeal anatomy for optimal swallowing; and (iii) maintenance of an optimal laryngopharyngeal coordination between motor input and sensory feedback to guarantee airway protection and adequate swallowing.[12] Airway patency after conservation laryngeal surgery may be reduced due to post-operative oedema, fibrosis, redundant mucosa and poorly positioned laryngopharyngeal anatomical constituents, all of which may lead to delayed decannulation, upper and lower airway complications, and need for reoperation. All of these potential issues need to be carefully addressed during surgery and in the post-operative period. Moreover, preservation of a competent (neo)glottic valve is critical for

successful conservation surgery, as it decreases aspiration, improves subglottic pressures and coughing ability, and optimizes speech.

The cricoarytenoid unit is the basic functional unit of the larynx. The cricoarytenoid unit consists of an arytenoid cartilage, the cricoid cartilage, the associated musculature and the nerve supply from the superior and RLNs for that unit. It is the cricoarytenoid unit, not the vocal folds, that allows for physiologic speech and swallowing without the need for a tracheostoma. Preservation of at least one functional unit allows organ preservation laryngeal surgery.[11] Careful preservation of the RLN, which can be placed at risk during dissection in the area of the cricothyroid joint, is one critical aspect of an intact cricoarytenoid unit. Scarring in and around the cricoarytenoid joint should be prevented, as it increases chances for arytenoid fixation. Also, scarring of key intrinsic laryngeal muscles such as the lateral cricoarytenoid muscle should be prevented. In some cases, arytenoid resuspension may be necessary to optimize its anatomical position.

Optimal pharyngeal anatomy is critical for successful swallowing after partial laryngectomy, and although this is in part dependent on wound healing, it can be influenced intra-operatively. Important aspects of this goal are optimal resuspension of the larynx to the tongue base, in a fashion that takes into account the delicate balance between airway protection by a posteriorly 'overhanging' tongue base and airway obstruction by the same. In addition, the shape and position of the pyriform sinuses are vital to unobstructed food passage and reduction of aspiration risk. The normal configuration of the pyrifom sinuses is disrupted by partial laryngectomy and often, resuspension of the pyriform sinuses is needed. This recreates the anatomic funnel shape of the hypopharyngeal inlet and decreases the chance for obstruction by redundant mucosa after the procedure. Cricopharyngeal myotomy can further help facilitate unobstructed food passage and can be considered in case the constrictor lumen feels narrow on finger dilatation.

Proper neurological coordination is also vital for adequate swallowing, not only in terms of intact motor function of swallowing muscles but also in terms of intact sensory feedback of the passing food bolus. Therefore, a detailed knowledge of the neurological anatomy is critical for surgical success. The bulk of laryngopharyngeal sensation above the VCs is provided by the inner branches of the SLNs. These enter the laryngopharynx through the thyrohyoid membrane and, once inside, run in the pharyngoepiglottic fold from lateral to medial direction. Next, they give off two major branches on each side of the larynx, which run in the laryngopharyngeal submucosa in an inferior direction towards the pyriform sinuses and VCs and form an anastomosing bilateral network. Although many laryngeal extensions of the SLN will be sacrificed during partial laryngectomy, great care should be taken to leave the main trunk of the nerve, and the pharyngeal extensions intact. During partial laryngectomy, there are several procedural steps at which the SLN may be at risk. These include: (i) separating infrahyoid muscles from hyoid, in which too much lateral dissection will damage the nerve; (ii) trans-vallecular pharyngotomy, in which too much lateral dissection will damage the nerve; (iii) freeing the superior horn of the thyroid cartilage where the SLN lies just superolateral to the tip of the thyroid horn; and (iv) releasing inferior constrictor and pyriform sinus mucosa from the paraglottic space. Experience and careful surgical technique contribute significantly to optimized functional outcome after partial laryngectomy.[12]

TYPES OF OPEN PARTIAL LARYNGECTOMY

Open partial laryngectomy was first performed by Theodor Billroth in 1874, and several different modifications have since been developed. These procedures can be applied to both glottic and supraglottic disease, and they include vertical and horizontal oriented procedures. Procedures that can be applied to glottic disease include several vertical hemilaryngectomy modifications and horizontal supracricoid laryngectomy with cricohyodoepiglottopexy (CHEP). For supraglottic disease, supraglottic laryngectomy and supracricoid laryngectomy with cricohyoidopexy (CHP) have been developed, both of which are horizontally oriented procedures.

Vertical partial laryngectomy

This procedure may be an anterolateral, frontolateral or anterior vertical partial laryngectomy.

ANTEROLATERAL HEMILARYNGECTOMY

Anterolateral hemilaryngectomy has been developed for glottic tumours that do not involve the anterior commissure. This procedure involves exposure of the thyroid cartilage below the strap muscles, and the ipsilateral perichondrium overlying the thyroid cartilage is lifted in order to preserve it. Next, vertical cuts through the laryngeal cartilage in a midline laryngofissure fashion are performed (**Figure 27.1**). The majority of the ipsilateral thyroid cartilage, true VC, portions of the subglottic mucosa and false cord are removed. The extent of resection depends on the pre-operative and intra-operative assessment of tumour extent. The strap muscles are closed over the residual perichondrium to form a pseudocord. A tracheostomy and feeding tube are generally required for 3–7 days.

If the anterior commissure is involved, a frontolateral or anterior partial laryngectomy can be done.

FRONTOLATERAL HEMILARYNGECTOMY

In frontolateral vertical laryngectomy (**Figure 27.2**), the vertical cartilage cut in the thyroid is performed 1 cm paramedian from the anterior midline on the contralateral thyroid ala. This procedure is preferred if the tumour involves the VC on the ipsilateral side, the anterior commissure and up to one-third of the contralateral VC.

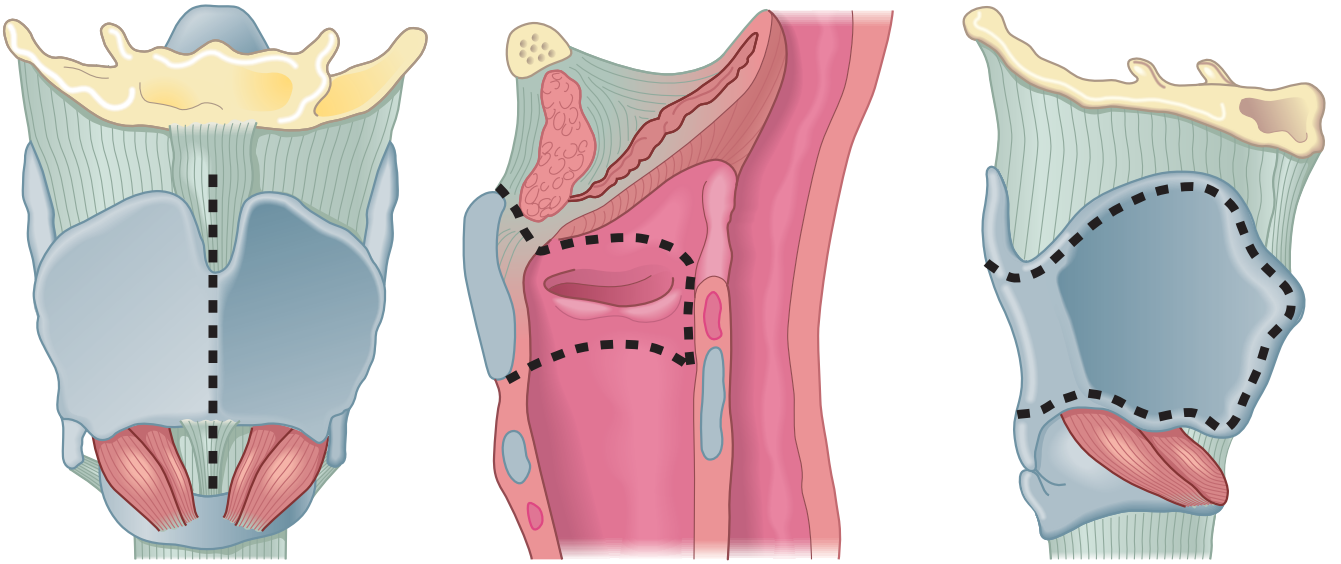

Figure 27.1 Anterolateral midline hemilaryngectomy.

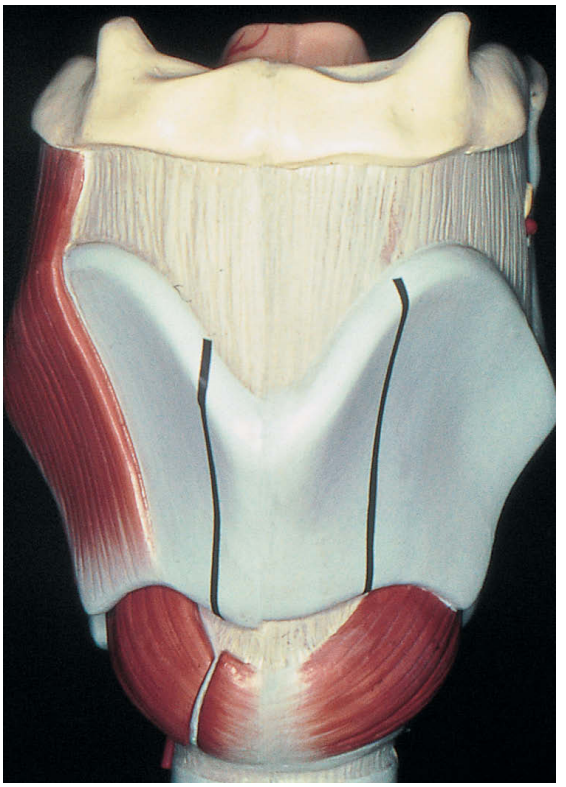

Figure 27.2 Frontolateral and anterior hemilaryngectomy.

Figure 27.3 Silastic keel.

ANTERIOR VERTICAL LARYNGECTOMY

Anterior vertical laryngectomy makes use of two paramedian thyroid cartilage incisions, each positioned approximately 1 cm paramedian from the anterior midline. This procedure may be preferred for an anterior commissure tumour that involves no more than the anterior third of one or both VCs. After tumour removal, the remnant posterior VCs are reattached to the anterior aspects of the remnant thyroid ala that are approximated in the midline. Formation of anterior laryngeal web is avoided with the use of a silastic keel, positioned at the anterior commissure between the VCs (**Figure 27.3**), which is removed endoscopically after 4 weeks.

Supracricoid partial laryngectomy (SCPL) with cricohyoidoepiglottopexy (CHEP)

Glottic tumours that extend across the midline through the anterior commissure are not suitable for vertical hemilaryngectomy if they involve more than the anterior third

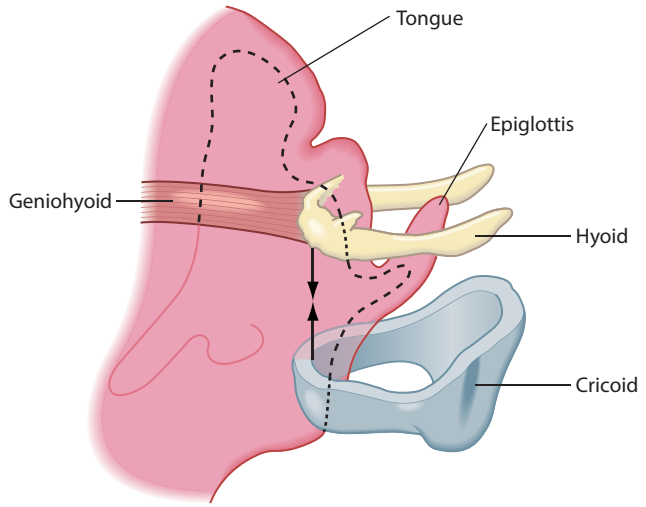

Figure 27.4 Supracricoid laryngectomy.

of the opposite VC. Supracricoid partial laryngectomy offers the possibility for resection of both true cords, both false cords, the entire thyroid cartilage, paraglottic spaces bilaterally, and a maximum of one arytenoid (**Figure 27.4**). Essential goals of this operation include careful preservation of the bilateral superior laryngeal nerves (SLNS) for optimal sensation during swallowing, functional preservation of at least one recurrent laryngeal nerve (RLN) for airway closure during attempted speech and swallowing, and adequate recreation of a functional neoglottic valve.[12, 13] The best functional results are achieved when both arytenoids are functionally and anatomically preserved. However, functional separation of the airway and the alimentary tract is possible provided at least one arytenoid is preserved.[14] Reconstruction is achieved by approximation of the hyoid bone to the cricoid with three absorbable sutures: one in the midline and two sutures placed 1 cm paramedian (to avoid suturing the lingual arteries, hypoglossal and SLN nerves). Also, the suprahyoid epiglottis is preserved and reapproximated to the cricohyoidopexia. Essential in the understanding of the post-operative functional status, is the fact that the orientation of the airway has undergone a 90% turn in the horizontal plane, from its anatomic slit-like antero-posterior orientation to a transverse or T-shaped orientation of the neoglottic valve. The latter can be closed sufficiently by the mobile arytenoid(s). A temporary tracheostomy is required, and most patients can be decannulated early. A nasogastric feeding tube is used in most patients, and can be removed in 4–6 weeks in most patients, provided that stringent swallowing therapy is in place. A PEG tube is advocated in older patients, patients with a single preserved arytenoid, patients with a history of radiation, or hypoglossal, SLN or RLN dysfunction. Quiet aspiration is present in most patients, and stringent oral hygiene is a prerequisite for pulmonary health.

Supracricoid partial laryngectomy (SCPL) with cricohyoidopexy (CHP) for supraglottic cancer

This operation is suitable for supraglottic carcinomas not amenable to horizontal supraglottic laryngectomy due to: (i) glottic level involvement through the anterior commissure or ventricle; (ii) pre-epiglottic space invasion; (iii) decreased cord mobility; (iv) limited thyroid cartilage invasion; or for glottic carcinomas with epiglottic or pre-epiglottic extension. The operation is essentially the same as described above, but an essential difference is the absence of the epiglottic remnant for reconstruction. Naturally, post-operative swallowing is delayed, and the rate and intensity of long-term aspiration is increased.

Horizontal supraglottic partial laryngectomy (HSPL)

In this procedure, the epiglottis, (part of the) hyoid bone, pre-epiglottic space, thyrohyoid membrane, upper half of the thyroid cartilage, aryepiglottic fold and part of the false cords are removed (**Figure 27.5**). The vallecula

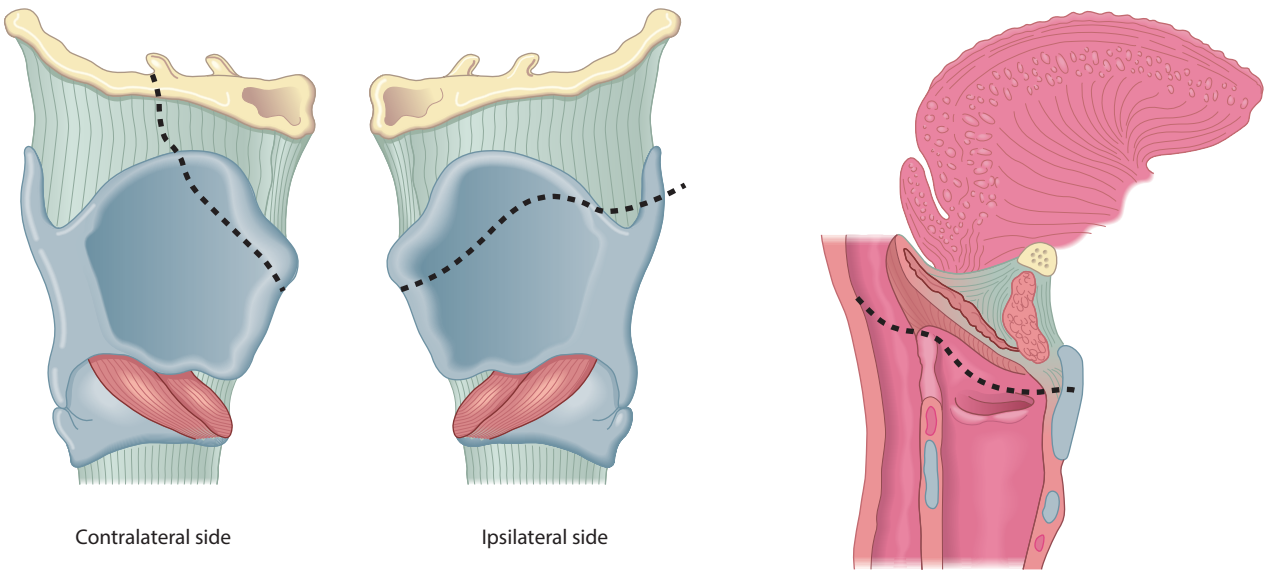

Figure 27.5 Horizontal supraglottic laryngectomy.

is transected superiorly, the ventricles inferiorly and the aryepiglottic folds laterally. Closure is by approximating the base of tongue to the lower half of the thyroid cartilage and closing the posterior false cord mucosa to the medial pyriform sinus mucosa. A temporary tracheostomy is required. Bilateral selective neck dissection is carried out at the same time, for the high rate of (contra) lateral neck metastasis from supraglottic cancers. In this procedure it is important to identify and preserve the internal and external branches of the superior laryngeal nerve. The tongue base sutures are placed in the midline and 1 cm off the midline to avoid damage to the hypoglossal nerves and lingual arteries.

Extended vertical hemilaryngectomy and reconstruction with a neovascularized tracheal autograft

Delaere et al.[15] described this two-stage technique for extended hemilaryngectomy defects involving up to half of the cricoid cartilage. Stage 1 involves tumour resection, following which reconstruction is performed using the cranial 4 cm of the cervical trachea, which is wrapped with the fascial part of a free vascularized fasciocutaneous flap from the forearm. After 4–8 weeks, the enveloped tracheal segment acquires sufficient vascular connections between the fascial soft tissue flap and trachea to allow interruption of the intrinsic blood supply, and thus grafting of the isolated segment of the trachea to the hemilaryngeal defect. Outside of select centres,[16, 17] this technique has not found widespread use; however, favourable oncologic outcomes have been reported. Significant refinements of the procedure have been presented since its original description.

Supratracheal laryngectomy

Laccourreye et al.[18] described a modification of conventional SCPL for tumours with anterior subglottic extension by removing the cricoid ring for anterior glottic tumours, which paved the way for 'functional' supratracheal partial laryngectomies (STPL), whose current version was described in 2006 by Rizzotto et al.[19]

This is aimed at laryngeal cancers with subglottic extension: this procedure involves resection of the entire glottic and subglottic sites along with the thyroid cartilage sparing both or at least one functioning cricoarytenoid unit (i.e. half of the posterior cricoid plate, with the corresponding arytenoid and the intact inferior laryngeal nerve on the same side). Inferiorly, the limit of resection encompasses the cricoid reaching the first tracheal ring. The resultant operation can be a tracheohyoidopexy – subtotal removal of the larynx maintaining one or two cricoarytenoid units and subsequent 'pexy' of the hyoid to the first tracheal ring or tracheohyoidoepiglottopexy – resection with preservation of the suprahyoid epiglottis and maintaining one or two cricoarytenoid units, followed by suspension of the tracheal ring to the epiglottis and hyoid bone.

Succo et al.[20] have detailed the indications and technique in detail; 5-year outcomes for 142 patients are as follows: overall survival from 71% to 85% and disease-specific survival from 86% to 95% based on tumour stage. Experience with this procedure has not been forthcoming from other centres.

INDICATIONS FOR OPEN PARTIAL LARYNGECTOMY

Since most laryngeal tumours are amenable to multiple different treatment options that are equally effective, the choice of therapy is determined by patient- tumour- and physician-related factors, as summarized in **Table 27.3**. In the case of untreated early laryngeal cancers, the treatment choice is typically made between primary radiation and conservation laryngectomy. Although no randomized trials have been completed, retrospective data suggest that surgical therapy may be superior with regard to local control, larynx preservation and disease-specific survival.[8, 9] When surgical treatment of early laryngeal cancers is preferred, TLM has now largely replaced open partial laryngectomy due to its lower morbidity, better voice quality, better swallowing and lower cost. Specifically, retrospective data indicate that the improved voice outcomes after TLM are similar or superior to that after primary radiation therapy.[9] Open partial laryngectomy for untreated early laryngeal cancer is indicated in select patients in whom a strong surgical preference exists, patients that fit the criteria for open partial laryngectomy (see 'Patient factors' below) but cannot be operated by TLM due to transoral inaccessibility or lack of expertise with transoral resections. In the case of advanced laryngeal cancer, a choice exists between upfront TL, (chemo) radiation and conservation laryngectomy. Although no randomized controlled trials of primary surgery vs

TABLE 27.3 Factors impacting upon choice of treatment in laryngeal cancer

Tumour factors	• Anatomic location • Extent • Volume • N-stage • M-stage
Patient factors	• Age • Comorbidity • Pulmonary reserve • Alcohol/tobacco exposure • Other cancers • Occupation • Expectations • Social support system • Motivation • Intellect • Preference • Travel distance
Physician factors	• Availability of resources • Availability of physician • Experience/skill • Comfortability • Preferences/beliefs

chemoradiation treatment have been completed, observational data and incomplete trial data indicate that TL is superior to chemoradiation in terms of oncological outcomes, whereas functional outcome data are immature at this time.[2, 6, 7, 21, 22] In well-selected patients, oncological outcomes of partial laryngectomy in this setting are similar to that of TL, and functional outcomes are better.[9, 23–25] As the experience with TLM for advanced laryngeal cancer is relatively immature, and performed routinely only in a few expert centres around the world, a choice for conservation laryngeal surgery in these patients would entail open partial laryngectomy in most instances. In advanced laryngeal cancers, open partial laryngectomy would thus be indicated in patients that fit the criteria for open partial laryngectomy, reject TL, and are unfit for or reject chemoradiation. In the setting of radiorecurrent laryngeal cancers, TL is the standard of care used by most centres. However, retrospective evidence indicates that 30–50% of patients could be safely managed by open partial laryngectomy, using stringent selection criteria.[10, 26–28] The experience with TLM in the radiorecurrent setting is immature, as retrospective evidence suggests local control rates are significantly inferior to those obtained using open partial laryngectomy.[29] Specific criteria that guide the consideration of open partial laryngectomy are described below. Careful consideration of these factors is important to minimalize the incidence of positive surgical margins, conversion to TL, and poor functional or medical outcome after surgery.

Patient factors

Stringent patient selection is critical for successful open partial laryngectomy. Patients undergoing partial laryngectomy are at increased risk of (clinically significant) post-operative aspiration, and resultant (life-threatening) pneumonias.[11, 30] This risk is exacerbated by poor wound healing, local infection and fistula formation. Although the risk and severity of aspiration varies between different types of open partial laryngectomy, patients with poor pulmonary function such as severe COPD, asthma or restrictive lung disease are poor candidates for partial laryngectomy.[12] Pre-operative assessment of lung function is mandatory in all patients considered for open partial laryngectomy but, as a general rule of thumb, the risk of pulmonary complications is well predicted by a patient's (in)ability to walk two flights of stairs.[12] Patients suffering from chronic microvascular or immunologic diseases that may impair wound healing (e.g. transplantation patients or diabetes mellitus) are also poor candidates for open partial laryngectomy for reasons described above. In patients with previous definitive radiation therapy to the cervical region, anticipation of significantly delayed wound healing should be incorporated as a factor into the treatment consideration. However, carefully selected patients may benefit from conservation surgery provided that post-operative support is stringent. The extent of the radiation portals and the total dose received are vital pieces of information that may help predict the extent of post-operative wound healing issues. For example, patients with locally recurrent T1/T2 laryngeal SCC that have been treated with standard 70 Gy IMRT-based radiation therapy and a limited glottic radiation therapy portal are expected to be better candidates for partial laryngectomy than patients treated with accelerated radiation therapy, chemoradiation, and patients with extensive base of tongue and supraglottic laryngeal carcinomas whose radiation plans have included skull base-to-clavicle type of portals. Finally, patient non-compliance is a major contraindication for partial laryngeal surgery. Successful outcome of partial laryngectomy is influenced by adequate pre-operative counselling, management of patient/family expectations, and early involvement of the speech and swallowing pathology department. Patients must be able to understand the complexities of conservation laryngeal surgery, and must be able to understand the implications of and give consent for intra-operative conversion to TL. The post-operative course after conservation laryngectomy is long and intense, and the patient (and family) should be willing and able to play an active role in speech and swallowing rehabilitation, and be available for frequent oncologic follow-up.

Tumour factors

Tumour factors that influence the choice for partial laryngectomy are primarily related to tumour location and extent within the laryngopharyngeal complex. Histological factors do not influence the choice for partial laryngeal surgery much, and most histological subtypes of laryngeal cancer can be managed successfully by this procedure. The anatomical boundaries of successful partial laryngectomy vary per type of laryngectomy, as listed in **Table 27.4.** These criteria are general guidelines, but they are not absolute and the extent of and the indications for the operation expand as the experience of the surgeon increases.

Application of vertical hemilaryngectomy is generally limited to tumours on one side of the glottic larynx, or at least not extending beyond the anterior third of the contralateral VC. The lesion should preferably not involve more than the vocal process or antero-superior part of the ipsilateral arytenoid in order to gain sufficient margin. Subglottic extension should not be more than 5 mm posteriorly, and 10 mm anteriorly (because of sufficient margin at the cricoid cartilage), whereas cranial extension should not exceed beyond the upper limit of the lateral extension of the sinus of Morgagni. Involvement of the epiglottis is a contraindication because it increases risk for pre-epiglottic space invasion. Selected patients with fixed VCs due to paraglottic extension or arytenoid fixation may benefit from hemilaryngectomy, but involvement of the RLN as a cause of cord fixation is a contraindication for hemilaryngectomy. Cartilage invasion is a contraindication to hemilaryngectomy, although microscopic erosion may not be. Hemilaryngectomy can also be applied to highly selected hypopharyngeal tumours that originate from the medial or lateral walls of the piriform sinus with secondary laryngeal extension, provided that the piriform sinus apex is free.

TABLE 27.4 Anatomic boundaries impacting on selection of open partial laryngectomy approach

	Vertical partial laryngectomy	Supracricoid laryngectomy	Supraglottic laryngectomy
Anterior	AC or anterior one-third opposite cord	Pre-epiglottic space	5 mm margin from AC
Posterior	Ipsilateral vocal process	Inter-arythenoid region	Inter-arythenoid and post-cricoid region free
Cranial	Upper limit of sinus of Morgagni	Base of tongue	Base of tongue
Caudal	Subglottic extension < 5 mm (posterior)/ < 10 mm (anterior)	Subglottic extension < 5 mm (posterior)/ < 10 mm (anterior)	Entrance sinus of Morgagni
Medial	Tumour does not cross midline (except anterior)	NA	NA
Lateral	Ipsilateral thyroid ala	Thyroid cartilage	Thyroid cartilage
General (relative) contraindications	• Epiglottic involvement • RLN involvement • Cartilage invasion • Piriform sinus apex involvement	• Extension to pharyngeal wall, vallecula, or base of tongue • Cartilage invasion • Bilateral arythenoid involvement • Bulky pre-epiglottic space involvement	• Bilateral arythenoid involvement • Cord impairment • Cartilage invasion • Tumour > 3 cm • Piriform sinus apex involvement • Impaired tongue mobility

The basis for successful supracricoid laryngectomy is that the tumour can be removed with sufficient margin, while preservation of the cricoid cartilage and at least one functioning arytenoid will provide the basis for rehabilitation. In practice, supracricoid laryngectomy results are improved significantly when both arytenoids can be preserved and sacrifice of one arytenoid should only be attempted in highly selected patients. Limitations of supracricoid laryngectomy success include gross thyroid cartilage destruction, gross pre-epiglottic space involvement, interarytenoid, bilateral arytenoid involvement, one fixed arytenoid (indicating cricoarytenoid joint invasion), subglottic extension exceeding 5 mm posterior or 10 mm anterior, and extension to pharyngeal wall, vallecula or base of tongue.

HSPL is indicated for supraglottic tumours, within the confines of parameters described in **Table 27.4**. Contraindications include less than 5 mm margin from the anterior commissure, impaired VC mobility, interarytenoid or bilateral arytenoid involvement, cartilage invasion, impaired tongue mobility, pyriform sinus apex involvement, or lesion size greater than 3 cm. HSPL may also be applied to the treatment of highly selected patients with primary tumours of the base of the tongue, medial wall of pyriform sinus and pharyngeal wall tumours, that exhibit secondary extension to the supraglottic larynx.

In patients with tumour recurrence after radiation therapy, careful assessment of tumour dimensions is even more critical, as most radiorecurrent laryngeal tumours recur with higher T-stage disease compared to the original tumour.[9] The majority of such patients require salvage TL to circumvent tumour dimensions. But salvage partial laryngectomy is possible in approximately 30–50% of patients with radiorecurrent glottic carcinomas who do not progress on therapy or who recur within the original tumour confines.[10, 26, 27] Such patients require careful endoscopic and radiologic assessment with CT scan to exclude tumour progression beyond the original tumour confines. Zbaren et al. provided a pathologic basis for this paradigm.[31] These authors showed that recurrent tumours in pathologic salvage laryngectomy specimens often exhibited dispersion of microscopic tumour deposits far beyond the original tumour confines. This observation emphasizes the underestimation of recurrent tumour dimensions on clinical and radiological examination and explains the local failure after removal of radiorecurrent tumours despite reported negative margins. Based on these findings, we recommend intra-operative frozen section analysis to help delineate the boundaries of the recurrent tumour and the need for intra-operative conversion to TL should margins be positive. Salvage supracricoid laryngectomy with CH(E)P is an alternative for larger lesions, which can give local control rates of 83.3%.[28, 32]

Of those with supraglottic carcinoma treated with radiotherapy who fail, only 30% may still be suitable for salvage conservation surgery.[9, 10, 27, 33] For supraglottic cancers, salvage partial laryngectomy by horizontal supraglottic partial laryngectomy or supracricoid partial laryngectomy and CHP is possible if the tumour has not extended beyond the original site as assessed endoscopically and by CT imaging. However, in contrast to glottic carcinomas, supraglottic tumours after RT have usually received a significant radiation dose to the base of tongue, pharyngeal constrictors and neck. This increases poor healing and fistula complications as well as post-operative swallowing problems due to fibrosis. An exaggeration of this situation is provided by (chemo)radio-recurrent base of tongue tumours with supraglottic extension (or supraglottic tumours with base of tongue extension), in which removal of the base of tongue in conjunction with HSPL in the setting of significant post-radiation fibrosis and wound healing issues increases the risk of post-operative swallowing and aspiration problems to unacceptable levels. Poor oncologic results have also been observed in supraglottic carcinomas, especially after salvage HSPL.[9, 10, 27, 33] As a result of these factors, salvage surgery for supraglottic cancer often requires a TL.

ONCOLOGICAL OUTCOMES OF OPEN PARTIAL LARYNGECTOMY

Most laryngeal carcinomas amenable to conservation laryngeal surgery can be treated with TLM or (chemo)radiation therapy with equal efficacy. Randomized controlled trials comparing different treatment modalities have not been completed. Recently, a British and an Australian trial were closed early due to accrual issues, suggesting that randomized data to answer the question will not be available within the near future.[9] Data on the outcome of partial laryngeal surgery are available from several large retrospective studies, and can be compared to that of patients treated with (chemo)radiation or TLM. Local control and LP are the primary aim of the different treatment modalities, as disease-specific death from early laryngeal cancer is approximately 1–3%. Therefore, they are primary clinical endpoints of interest in scientific analyses of oncologic results.

A systematic review of 53 articles[33] including 5061 patients treated with open partial laryngectomy reveals that pooled local control rate at 24 months was 89.8% (95% CI: 88.3–91.2%). The pooled larynx preservation rate (assessed in 3171 patients) was 90.9% (95% CI: 8.8–92.7%). These overall data compare favourably with (chemo)radiation results and suggest that partial laryngeal surgery should be offered as an alternative treatment option to patients who qualify for organ preservation treatment.[9, 33] However, the outcome of laryngeal treatment is heavily influenced by disease stage, and anatomic location within the larynx and should therefore be analyzed within the context of these factors.

Glottic carcinomas

Treatment with open partial laryngectomy gives local control and LP rates in T1 SCC between 92% and 100%.[9] In T2 tumours, local control is between 69% and 93%, but LP after salvage surgery still reaches 93%.[9] TLM in T1 tumours achieves 85–95% local control rates and 95–99% LP after 5 years, whereas in T2 tumours, 65–85% local control rates and 83–96% LP after 5 years can be obtained.[9] Retrospective data suggest that the oncologic efficacy of primary radiation treatment may be similar to surgery, with local control between 85% and 93% and LP 89–96% for T1 tumours, and local control 57–80% and LP 73–82% for T2 laryngeal SCC.[9] Adversaries of radiation treatment further argue that the RT efficacy for early laryngeal cancers may be significantly overestimated, due to the fact that up to 30% of patients that qualify for and are included in primary RT treatment protocols, may have been cured by their pre-RT biopsy already.[9]

Factors that influence outcome in the early laryngeal cancer setting include anterior commissure (AC) involvement and VC mobility impairment.[9] Although tumours with AC involvement are unlikely to harbour a more aggressive clinical course, AC involvement does complicate surgery, which may account for decreased survival rates.[9] Steiner et al. suggested that local control may be 10–15% worse when AC is involved, and LP may be 5% worse overall.[34, 35] Their results were confirmed in a follow-up study of 444 patients.[34, 35] Laccourreye et al. reported 23% local failure after vertical partial laryngectomy in 416 cases of AC involvement.[36] When SCPL-CHEP was applied, local failure was improved to 98%, but most patients had also received an induction chemotherapy regimen in their series.[37, 38] No differences were found when open vs TLM approaches were compared in cases with AC involvement.[9] On the other hand, Peretti did not find differences in local control with or without AC involvement.[39] A literature review by Herranz suggests that all three treatment options have similar results when involvement of the AC is present.[9, 40]

Impairment of VC mobility is also an adverse predictor of outcome in early laryngeal SCC. T2 tumours with impaired VC mobility exhibit reduced local control and LP that is more akin to that of T3 carcinomas with VC fixation.[9] Local control rates in cases with true vocal cord (TVC) impairment or fixation treated with open partial hemilaryngectomy ranges between 52% and 76%.[9] However, local control and LP can be improved to 95% in this patient population with the application of supracricoid laryngectomy as per French data, but the majority of these patients received induction chemotherapy and many received post-operative RTx.[9] Studies using TLM have shown that local control was 74% in T2b, and 68% for T3 tumours, whereas LP was 85% in both groups.[9] Ultimately, 5-year local control was 87%, and disease specific survival (DSS) was 62% in both groups. Three large case series with more than 100 patients each of T2N0 disease, with organ preservation rates of 84–96%, are observed for T2N0 tumours.[41–43]

Limited literature data exist on TLM for more advanced laryngeal carcinomas. Recently, Steiner et al. published on 226 cases of T3 SCC showing a local control and LP rate of 71.4% and 87% respectively.[23] Radiation therapy reaches local control in TVC impairment between 60% and 76%, and LP is 70–80%.[9] The collective data suggest that the oncologic efficacy of open partial laryngectomy is similar to that of TLM, but superior to primary RTx.

Supraglottic carcinomas

In the case of supraglottic carcinomas, high local control rates are obtained for selected early tumours treated with open partial laryngectomy.[44] HSPL has local control of 90–100% for T1 tumours, and 80–97% for T2 tumours.[9] For T3 SCC, local control rates are 71–94%.[9] In T4 lesions, local failure is approximately 67%.[9] Therefore, HSPL should be considered with extreme caution in T3 and T4 lesions. Literature data suggest that application of supracricoid laryngectomy with CHP may improve these figures slightly,[9] where local control can be as high as 96% of patients, at the expense of significant aspiration. The reason for these favourable results is the *en bloc* resection of bilateral paraglottic spaces, pre-epiglottic space and thyroid cartilage. However, it should be noted that a majority of patients in these studies received induction chemotherapy before supracricoid laryngectomy, which may influence the data. Several small studies describe the results of TLM for supraglottic tumours showing similar results to the open approach.[9] Radiotherapy results show that T1 supraglottic tumours have local control of 75–100%, and

T2 have local control of 62–83%.[9] T3 supraglottic carcinomas are rarely treated with RT alone, following the demonstration of improved local control with the addition of concurrent chemotherapy in the 91–11 trial.[5] Comparable to the data on glottic tumours, these retrospective data suggest that open partial laryngectomy as primary treatment for supraglottic cancers achieves equal success rates compared to TLM, but is superior to primary RT.

Radiorecurrent carcinomas

Radiorecurrent tumours treated with partial laryngectomy are virtually all T1 and T2 tumours, as more advanced lesions typically require TL. A recent meta-analysis of the English language literature reported a pooled local control rate of 86.9% (95% CI: 84–89.5%), identified from 26 articles including 560 patients undergoing open partial laryngectomy for radiorecurrent disease.[10] The pooled mean larynx preservation rate derived from analysis of 502 patients was 83.9% (95% CI: 80.7–87%). When excluding patients with supraglottic tumours, the pooled salvage laryngectomy rate was 9.2% (95% CI: 7.4–11.1%) in 253 patients, and the pooled laryngectomy rate for aspiration was 4.4% (95% CI: 2.2–7.4%) in 224 patients. For 159 T1 ($n=124$) and T2 ($n=35$) tumours treated with vertical hemilaryngectomy the pooled local control rate was 84.4% (95% CI: 84.4–84.4%), and the mean LP rate was 85%. Virtually all total laryngectomies were performed for oncologic salvage. One hundred and forty-nine patients treated with supracricoid laryngectomy had pooled local control 93.9% (95% CI: 91.8–95.8%), and mean LP rate was 83.1%; 2.6% of patients required a TL for aspiration. Disease-free survival was similar between these treatments, approximately 80–85%. Few studies have analyzed the efficacy of supraglottic laryngectomy for radio-recurrent laryngeal SCC. These studies suggest that the local control rates are significantly lower than observed for the other procedures.[10, 27, 32] The experience with TLM for radiorecurrent disease has thus far been small, and insufficient for adequate comparison. Altogether, the literature suggests that approximately 30–50% of patients with radiorecurrent SCC may benefit from salvage open partial laryngectomy, with control rates equal to TL in these patients.

COMPLICATIONS AND FUNCTIONAL OUTCOMES OF OPEN PARTIAL LARYNGECTOMY

Post-operative complications

Complications after conservation laryngeal surgery can be categorized into local (wound infection, dehiscence, fistula, chyle leak), swallowing (dysphagia, stricture), airway (aspiration pneumonia, laryngeal stenosis, laryngeal oedema, granuloma formation, surgical emphysema, perichondritis, CH(E)P breakdown) and systemic (cardiac, pulmonary, renal, infectious, metabolic). The rate of overall complications after partial laryngectomy is approximately 20%.[11, 29, 45, 46] Of these, local complications are most common, and occur between 8% and 11%. The fistula rate after partial laryngectomy is between 2.5 and 4%. Prior RT is the most important predictor of local complications including fistula formation. Local complications after salvage partial laryngectomy have been described to occur in 24% of patients, and fistula formation after salvage partial laryngectomy occurs in approximately 14% of cases. Ganly et al. found that prior RT was associated with a 13-fold increase in local complications and fistula formation after partial laryngectomy, an increase that was statistically significant.[45] Several authors have suggested that the type of partial laryngeal surgery is a predictor of complications, with more extensive laryngeal surgery such as supracricoid laryngectomy associated with increased complication rates in univariate statistical analysis.[11, 29, 45, 46] It is currently unclear whether type and extent of open partial laryngeal surgery is an independent predictor of the complication rate in multivariate analysis, but it is clear that partial laryngeal surgery using TLM is associated with significantly lower rate of complications due to less extensive dissection, and absence of need for tracheostomy and percutaneous feeding tube in most patients.[9]

Functional outcomes

Functional outcome of partial laryngeal surgery is influenced by pre-operative factors (patient age, comorbidity, pulmonary status, tumour stage and pre-operative radiation), intra-operative factors (location and extent of resection) and post-operative factors (patency of airway, patency and mobility neoglottic valve, patency and mobility of (oro) pharynx, laryngopharyngeal sensation and the position of the laryngeal remnant in relation to the base of the tongue). Although functional recovery after partial laryngectomy can be qualified in several ways, decannulation rate, time to permanent decannulation, permanent gastrostomy rate, and need for TL for intractable aspiration (functional laryngectomy) are some of the more objective parameters to describe it.[22] Also, these parameters are unequivocal, objective, and allow for reliable comparison with other treatment modalities. Parameters to objectify voice outcomes are less well defined, although this is obviously also a critical outcome parameter after partial laryngectomy.

A recent meta-analysis of primary open partial laryngectomy outcomes[33] found that the pooled decannulation rate among 3955 patients derived from analysis of 42 studies was 96.3% (95% CI: 94.9–97.6%). The permanent gastrostomy rate among 2000 patients derived from 20 studies was 2% (95% CI: 0.9–3.6%). The functional laryngectomy rate was 1.7%. Although the authors excluded salvage partial laryngectomy patients, they did not stratify their data by type of partial laryngectomy. Functional outcome data from individual series demonstrate that tracheostomy and nasogastric feeding tubes can generally be removed within 1–2 weeks from vertical partial laryngectomy, and (temporary) gastrostomy tubes are generally not necessary after this type of procedure.[38, 45, 47, 48] Voice outcome data after VPL have not been reliably assessed. In the case of HSPL and SCPL, post-operative aspiration and airway issues are

generally more severe, and temporary but clinically significant aspiration (Pearson grade 2–3) has been described in 10–20% of patients, while aspiration pneumonia has been reported in 10% of patients after SCPL.[11, 29, 46, 49, 50] Time to decannulation and nasogastric feeding tube removal approaches 1–2 months in most patients, but most patients will require 6–12 months to approach their normal eating habits. Prophylactic gastrostomy tube placement is recommended in a proportion of high-risk patients after SCPL and HSPL. Predictors of clinically significant aspiration include arytenoid sacrifice, advanced age, radiation therapy and CHP reconstruction. However, the rates of permanent gastrostomy, tracheotomy and functional laryngectomy are below 5% in experienced hands and well-selected patient populations. SCPL causes an inevitable change in voice quality, which can adversely affect the QOL, especially in female patients.[51, 52] The functional outcome after salvage partial laryngectomy has been described in a recent meta-analysis.[10] The pooled mean decannulation rate among 315 patients was 95.1% (95% CI: 92.6–97.2%). Eleven studies reported a mean or median time from surgery to decannulation that ranged from 7–31 days. Other functional outcome data could not be reliably extracted from the included studies. In comparison to open partial laryngectomy, the functional outcomes of TLM partial laryngectomy are significantly better.[9] This can be attributed to avoidance of tracheotomy, preservation of hyoid bone and supra/infrahyoid muscles and pharyngeal muscles, and preservation of the extralaryngeal portions of the SLNs. Functional outcomes after RT and chemo-RT are not well described. Recently, publication of the long-term data of the RTOG 91–11 trial[7] demonstrated that 43% of patients had severe late complications, including an 18% rate of pharyngeal dysfunction (significant swallowing problems in 17–25% in concurrent CRTx group, and 13% of the induction chemotherapy and radiation alone groups), and 25% rate of laryngeal dysfunction. In addition, a 7% unexplained death rate was observed in the chemoradiation treatment arm, in addition to a high rate of complications associated with salvage TL after chemoradiation treatment. These data suggest that partial laryngeal surgery is superior to (chemo)radiation in terms of functional adequacy after treatment.

CONCLUSION

Organ preservation management for laryngeal cancer is a desirable treatment avenue. Although no phase III trials have been completed, our best available evidence suggests that conservation laryngeal surgery is a safe approach in selected patients, and is superior to primary (chemo) radiation in these patients in terms of oncologic efficacy and functional outcome. Although TLM is the preferred approach for conservation laryngectomy patients due to its less invasive nature and lower rate of complications, a specific indication for open partial laryngectomy still exists in selected patients who qualify for conservation laryngeal surgery. These include transoral inaccessibility of the tumour, salvage after radiation treatment, and lack of expertise with TLM. For these specific indications, the skill of open partial laryngectomy is important and should remain in the armamentarium of the head and neck surgeon.

KEY POINTS

- Total laryngectomy offers the best chance for cure across all laryngeal cancer types and stages but has the poorest functional outcome.
- Conservative organ-preservation laryngeal cancer treatments include (chemo)radiation and conservation surgery including transoral laser-assisted microsurgery (TLM) and open conservation laryngeal surgery.
- Conservation laryngeal surgery offers better oncologic and (long-term) functional outcomes than (chemo)radiation in properly selected patients.
- TLM offers similar oncologic outcomes but has decreased complication rates and superior functional outcomes to open conservation laryngeal surgery.
- The spectrum of open conservation laryngeal surgery encompasses several different procedures categorized by their anatomic focus (glottis or supraglottic disease), anatomic extent and surgical orientation (horizontal or vertical).
- Indications for open conservation laryngeal surgery are guided by well-defined patient, tumour and physician factors.
- Functional pulmonary reserve is the most common limiting factor for successful conservation laryngeal surgery, as most laryngeal cancer patients feature significant degrees of COPD.
- The surgical goals of open conservation include attainment of negative margins and optimization of functional outcome through preservation of (a) structurally and functionally adequate airway, alimentary tract and neuromuscular coordination.
- Oncologic and functional outcomes of open conservation laryngeal surgery support its application in properly selected (chemo)radiation-naïve and (chemo)radio-recurrent laryngeal cancers.

SEARCH STRATEGY

A search strategy, developed for PubMed, combining MeSH terms for head and neck cancer, patient reported outcomes, treatment outcomes, health-related quality of life, voice, speech and swallowing was used.

INTRODUCTION

Outcome assessment constitutes an integral part of patient management. Modern healthcare systems demand robust outcome measures, which should be disease specific and reflect the concerns of the patient. Their measurement is compounded by the fact that patients, carers and healthy 'observers' have different opinions as to what constitutes the most favourable outcome.[1]

Historically, the success of head and neck cancer (HNC) treatment and treatment in general has often been described in terms of survival rates and disease control. However, since patients seek treatment on the basis of their symptoms rather than the underlying diagnoses, one can argue that survival alone cannot be considered truly reflective of the outcomes as it omits measures of function. This can often lead to a paradox of excellent results in medical terms, but unsatisfactory/unacceptable outcomes from the patient's perspective.

Outcomes can therefore be divided into survival outcomes and functional outcomes, which ultimately determine the quality of life (QOL) of a patient. QOL, which is another important concept in the arena of outcomes is discussed at greater length in Chapter 20, Quality of life and survivorship in head and neck cancer.

SURVIVAL OUTCOMES

Undoubtedly, survival remains the cornerstone of outcome assessment for HNC. Analysis of survival has the advantage that there can only be two categories: alive or dead and this outcome cannot be misrepresented. However, this measure is insensitive in diseases with low mortality and there are many inaccuracies in recording the cause of death. Most importantly it disregards functional outcomes and QOL.

'Time-to-event' analysis

Survival analysis is based on scientific fundamentals and techniques of statistics, which analyze 'time to event' and can be used for many outcomes apart from death (**Box 28.1**).

Two key facts should be recognized in time-to-event analyses. The distribution of the data is mostly non-parametric and thus appropriate statistical techniques should be used for analyses. Some patients do not experience the event either because they are lost to follow-up or they were still alive at the end of the study. These patients represent censored events or censored observations.[2]

The Kaplan–Meier survival curve is the most common means of expressing survival and other such binary events in a study group.[3] It is used to estimate survival rates and hazards from such incomplete data assuming that those censored subjects have the same prospect of survival as uncensored subjects. The median survival time is the time at which the cumulative survival is equal to 0.5. The log rank test provides methods for comparing two or more survival curves, but is only appropriate where relative mortality does not change over time (proportional hazards assumption).

BOX 28.1 Survival analysis

PARAMETERS OF SURVIVAL

- **Overall survival (OS)** – The length of time from either the date of diagnosis or the start of treatment for a disease, such as cancer, that patients diagnosed with the disease are still alive.
- **Disease-free survival (DFS)** – The length of time after primary treatment for a cancer ends that the patient survives without any signs or symptoms of that cancer. Also called *relapse-free survival.*
- **Progression-free survival (PFS)** – the length of time that a patient lives with the cancer, but it does not get worse.
- **Disease-specific survival rate** – The percentage of people in a study or treatment group who have not died from a specific disease in a defined period of time. The time period usually begins at the time of diagnosis or at the start of treatment and ends at the time of death. Patients who died from causes other than the disease being studied are not counted in this measurement.
- **Median survival (MS)** – The length of time from either the date of diagnosis or the start of treatment for a disease, such as cancer, that half of the patients in a group of patients diagnosed with the disease are still alive. Also called *median overall survival.*

ANALYSIS OF SURVIVAL

- **Kaplan-Meier survival curve** – Most common method used to estimate survival rates and hazards assumes with incomplete data, as seen with survival, that those censored subjects have the same prospect of survival as uncensored subjects.
- **Log rank analysis** provides methods for comparing two or more survival curves, but is only appropriate where relative mortality does not change over time (proportional hazards assumption).

FUNCTIONAL OUTCOMES

Functional outcomes define anatomical and physiological impairment, disability and handicap that occur secondary to a disease process or the treatments for these and can, ultimately result in a poor QOL.[4]

Functioning, disability and health

The World Health Organisation has classified functioning, disability and health based on the ICF (International Classification of Functioning, Disability and Health). This is a classification looking at the loss/limitation of function. Disability underscores the consequences arising from this loss of function and health, reflects the disadvantages experienced by the patients as a consequence of the impaired functions and disabilities and highlights the interaction with and adaptation to their environment and in relation to their peer group and society in general.

Treatment for HNC is likely to affect some of the most basic human functions – verbal communication, social interaction, eating and breathing. It is easy to see how speech and swallowing can be affected in patients undergoing resection for large oral cavity or oropharyngeal lesions and in the most extreme case of the laryngectomy. However, with the use of concurrent chemoradiotherapy showing approximately the same long-term survival, much emphasis has been placed on organ preservation.[6] Therefore, the clinical trade-off is no longer the length of life, but functional outcome and QOL. It should be noted that anatomical preservation does not guarantee function and patients experience several debilitating side effects with organ sparing treatment paradigms, where voice quality is reduced and swallowing problems are common due to the stiffening of tissues in the pharynx and upper oesophagus. A disease-specific QOL survey covering five domains (speech, eating, aesthetics, pain/discomfort and social/role functioning) demonstrated that speech and eating had the most impact on well-being.[7] It is estimated that as high as 35–75% HNC patients suffer from speech and swallowing problems after such treatment.[8]

Which measures to choose?

Currently, there are no outcome reporting standards for clinical practice or trials in HNC. The World Health Organisation (WHO) recommended as early as 1981 that as a minimum standard, oncology clinical trials should measure tumour and metastasis response, duration of response and adverse effects.[9] Furthermore, the publication of the International Classification of Functioning, Disability and Health for head and neck cancer (ICF HNC) provided a framework for classifying health and health-related domains for measuring health and disability at both individual and population levels.[10] Whilst survival outcomes are critical, health-related QOL and functional outcomes are given less consideration and measured in a far less consistent or rigorous manner.[11] As survival rates improve, however, survivorship issues become increasingly relevant.[12–16]

In the majority of cases, clinicians and trialists make decisions about which outcomes of treatment should be measured. As a result, the data collected and measured may not reflect outcomes of importance to patients, and the lack of standardization makes comparison of outcomes difficult, if not impossible. Small numbers, tumour heterogeneity and incidence of post-treatment functional deficits provide particular challenges when choosing outcomes for patients with SCCHN. For systematic reviewers and guideline developers, disparate outcome measurement precludes the synthesis of individual trial data in

meta-analyses, and much research thus fails to contribute to the evidence base.[17]

Core Outcome Sets (COS) have been proposed by the COMET initiative to ensure that outcomes important to both patients and clinicians are measured consistently, thus facilitating the synthesis and/or comparison of outcomes.[18] A COS is a minimum outcome reporting standard for use primarily in clinical trials, but also in audit and clinical practice that is specific to a clinical condition or area of healthcare.[19] The use of a COS does not preclude the measurement of other outcomes, rather it ensures that 'core' outcomes are measured consistently, allowing for the collection of more rigorous outcomes data.[18]

A COS has been developed for clinical trials in oropharyngeal squamous cell carcinoma (OPSCC) and is in the pre-publication phase.[20]

Once the outcomes to be included in a COS have been chosen, research to establish the best instruments for measuring the outcome must be undertaken. The **C**onsensus-based **S**tandards for the selection of Health Measurement Instruments (COSMIN) initiative make recommendations about '*how*' the identified outcomes should be measured.[21] The COSMIN checklist can be used to appraise the methodological quality of studies on measurement properties and to check whether all important design aspects and statistical methods have been clearly reported.[21]

Multiple outcome measurement tools abound but there appears to be no consensus among clinicians regarding what to use and when. Choosing the most appropriate outcome measure is essential to evaluate both the effectiveness and efficacy of any treatment and rehabilitation. Outcome measurements may be subjective or objective, patient rated or clinician rated, and may take the form of questionnaire or instrument-based assessment. Ideally, specific, validated tools should be chosen.[22]

Increasingly, patient reported outcomes (PROs) are used. They measure how a patient feels or functions and are collected directly from the patient without interpretation by a clinician. They are often collected using measurement tools (PROMs) that assess the patient's view of their symptoms, functional status or QOL.[23] One could argue whether objective or subjective measures are more valuable, indeed there is poor correlation between objective and subjective measures of xerostomia in this patient population.[24]

MEASURES OF TREATMENT TOXICITY

A variety of scoring systems are used to measure toxicity, and the time points at which these are measured vary. Both acute and late toxicities are encompassed by the National Cancer Institute (NCI) Common Terminology Criteria for Adverse Effects.[22] Version 3.0 largely superseded the Late Effects of Normal Tissue (LENT SOMA) and Radiation Therapy Oncology Group- European Organisation for the Research and Treatment of Cancer (RTOG-EORTC) scales, and was updated to version 4.0, June 2010.[25] Late effects are generally accepted as those occurring 6 months beyond the end of treatment.

Xerostomia

Xerostomia is an acute and late adverse effect of radiotherapy to the head and neck, and is most often graded according to the toxicity criteria described above or as part of HR-QOL tools. Patients consider dry mouth to be a top priority after treatment for HNC. Eisbruch et al[26] implemented an 8-item self-reported xerostomia-specific questionnaire (XQ) in patients receiving parotid sparing IMRT. The XQ was found to be reliable and valid in measuring patient-reported xerostomia.

Shoulder dysfunction

Like xerostomia, shoulder dysfunction is most often measured as part of HR-QOL measures. No specific PROM exists.[26]

Voice or speech?

Voice and speech represent different ends of the same spectrum, explained by the source-filter theory. The larynx serves as the source of phonation thereby producing voice, while the vocal tract (oral cavity, oropharynx, nasopharynx, nasal cavity and paranasal sinuses) acts as a filter thereby altering the voice and shaping speech. Speech is the final outcome of voiced sound, which is characterized by resonance, nasality and articulation.[27] Cancers or treatments involving these sites will affect speech and not the voice.

MEASURES OF VOICE OUTCOMES

Voice is predominantly affected by laryngeal cancers or treatments affecting the larynx, directly or indirectly. There are numerous tools used for the evaluation of voice throughout the world (**Box 28.2**), but there exists no widely accepted voice outcome measure. Some of the commonly used tools are described in **Box 28.2.**

Questionnaire-based measures

Voice Handicap Index Voice Handicap Index (VHI)[28] is a validated, self-assessment scale that measures patient perception of the impact of dysphonia on various aspects of routine living. It is one of the most widely used voice questionnaires. It consists of 30 statements on voice-related aspects in daily life each with a scores ranging from 0 to 4. The maximum score is 120, values above 60 indicate a severe disability, those between 40 and 60 moderate disability and less than 40 mild or no disability. The questions are divided into three subscales or domains: physical, functional and emotional, with ten questions in each.

It has been used extensively as an outcome assessment tool in laryngeal cancer in both patients with a laryngeal and alaryngeal voice. VHI-based comparative voice outcomes following laryngeal cancers treated with either

BOX 28.2 Tools available for the assessment of outcome of voice

QUESTIONNAIRE BASED MEASURES

- Voice Handicap Index (VHI)[28]
- Voice Symptom Scale (VoiSS)[29]
- Voice Activity and Participation Profile (VAPP)[30]
- Voice Prosthesis Questionnaire[31]
- Vocal Handicap Index-10[32]
- Vocal Performance Questionnaire (VPQ)[33]

PERCEPTUAL MEASURES

- GRBAS rating scheme[34]
- Perceptual evaluation of alaryngeal speech

INSTRUMENT-BASED MEASURES

- Stroboscopy[35]
- Acoustic analysis of voice using inverse filtering and linear predictive coding[36]
- Electroglottographic (EGG)[37]
- Electromyographic analysis[38]

surgery or radiotherapy,[39] transoral laser excision of early laryngeal cancers,[40] endoscopic laser versus open resection,[41] supracricoid partial laryngectomy,[42, 43] alaryngeal voice[44] and chemoradiotherapy[45] and have all been published in the literature.

Voice Symptom Scale The Voice Symptom Scale (VoiSS)[29] is one of the most rigorously evaluated voice questionnaires. It contains 30-items to assess three aspects of voice: impairment, emotional and physical symptoms. The VoiSS is becoming more widely used in HNC patients to assess voice.[46, 48] In a study looking at patients with early glottic cancer treated by endoscopic resection or radiotherapy similar results were produced for the VHI, VoiSS or VPQ. The exception was the emotional subscale of the VoiSS, which gave better results for those treated with radiotherapy and in addition reflected the concurrent pharyngeal symptoms.[47]

Voice Activity and Participation Profile Voice Activity and Participation Profile (VAPP)[30] is a 28-item questionnaire validated in number of languages. It consists of five sections: self-perception of voice, effect on job, effect on daily communication, effect on social communication and effect on emotion. Each item uses a visual analogue scale 10 cm long ranging from not affected to always affected.

Voice Prosthesis Questionnaire The Voice Prosthesis Questionnaire[31] has been locally validated and looks specifically at the surgically voice-restored laryngectomee. It is a self-administered 45-point questionnaire and has sections relating to speech, leakage, valve changing, maintenance, QOL, humidification and hand-free issues.

Short-form self-assessment questionnaires

Long questionnaires can be time consuming to complete and the score may provide a degree of redundant information. They are useful research tools, but in the clinical setting concise, clinically useful self-report questionnaires are of more use. Two short-form, rigorously evaluated, voice-related scales are available, the Vocal Handicap Index-10 item questionnaire (VHI-10) and the Vocal Performance Questionnaire (VPQ).

Vocal Handicap Index-10 item questionnaire Item analysis of VHI by patients with voice disorders and controls identified the 10 most robust VHI items resulting in the creation of the Vocal Handicap Index-10 item questionnaire (VHI-10).[32] Similar to the VHI, a five-point item scale is used with scores ranging from 0 to 4, resulting in a total score of between 0 and 40.

Vocal Performance Questionnaire The VPQ[33] is a 12-item questionnaire which examines the physical symptoms and socio-economic impact of the voice disorder. The patient selects a statement that best answers each question. The statements are graded in terms of severity of vocal performance. A numerical score of 1–5 is assigned to each answer and these are summed to provide an overall score of vocal severity – maximum score 60 and minimum score 12.

These two short-form voice related scales (VPQ and VHI-10) use a single total score and correlate highly with one another.[48]

Perceptual measures

GRBAS The GRBAS rating scheme[34] is considered as a practical minimum standard for the perceptual rating of voice.[49, 50] It consists of five domains: grade (representing overall voice quality), roughness (which looks at fluctuations in F0, indicative of vocal edge abnormalities), breathiness (which assesses air escape), asthenia (a general decrease in power of or weakness of the voice) and strain (which assesses hyperfunctionality). All are assessments of laryngeal function.

Assessment is made on a recording of a voice reading an established phonetically balanced passage, such as the 'rainbow passage' or on current conversational speech. Each aspect of the GRBAS scale is given a score of 0–3, where 0 is normal, 1 shows slight deviance, 2 moderate deviance and 3 severe deviance. This scale has been shown to be reliable across all parameters except strain.[51]

The GRBAS scale has been used in the assessment of voice in the HNC population, including partial laryngeal surgery, in the comparison of radiotherapy and laser excision in the treatment of early glottic lesions. It has also been used as a tool to assess alaryngeal speech[52, 53] Interestingly little correlation has been shown between self-assessment using VHI and clinician-rated GRBAS assessment with severely dysphonic supracriciod laryngectomy patients scoring mean values of 29.9 on VHI.[42]

Perceptual evaluation of alaryngeal speech Although attempts have been made to develop a scale for perceptual evaluation of alaryngeal speech, a reliable, reproducible perceptual rating system does not seem to exist for the laryngectomee. Van As et al[54] report the use of a semantic

bipolar seven-point scale (e.g. ugly–beautiful, deviant–normal, low–high), for both untrained and trained raters. Eadie and Doyle report the use of direct magnitude estimation (continuous) and equally appearing interval scales for the auditory perceptual rating of naturalness, severity, acceptability and pleasantness of tracheoesophageal voice.[55–57] Hurren and Miller report no current evidence to support the use of acoustic instrumental measures in terms of validity. They show preliminary data support for the validity of a new tracheoesophageal voice auditory-perceptual tool the SToPS, for professional and native raters.[58]

Instrument-based measures

A number of instrument-based measurements of voice can be used to diagnose and evaluate the nature and severity of dysphonia. Only a few are useful in measuring changes in voice quality with time. Most have little use in the assessment of outcome in the HNC patient. The more common and potentially useful measures are mentioned in **Box 28.2.**

Acoustic measures of voice Acoustic analysis[36] is widely used in testing vocal function because it is objective and reproducible, as long as the same equipment is used on each occasion. A voice sample is recorded on to digital audiotape (DAT) and acoustic measurements of the voice/speech signal can be made such as maximal phonation time (MPT), frequency, fundamental frequency (the lowest tone in the harmonic), Jitter 1st (the pitch perturbation or frequency variability in percentage), Jitter 2nd (the average of the differences between successive differences in the frequencies of successive periods in percentage) and Shimmer (the amplitude perturbation or intensity variability in dB from the acoustic waveform).

The main use of acoustic measurements in HNC patients has been to compare outcomes of treatments for early glottic tumours,[59, 60] in the assessment of voice after supracricoid laryngectomy[61] and in the assessment of speech therapy following treatment for such lesions.[62] These measurements have also been assessed in the laryngectomee in which the voice is often aperiodic, and makes the assessment of these acoustic measures even more challenging.[63] A detailed treatment of acoustic measures can be found in Chapter 62, Evaluation of the voice.

MEASURES OF SPEECH OUTCOMES

Normal speech is clearly intelligible, well articulated and has adequate nasal components due to oro-nasal separation.[64] Tumours or treatments involving the vocal tract can alter speech.[65] Speech as a function is generally ignored and poorly investigated in HNC patients.[27] Measures currently in use for assessment of speech outcomes are summarized in **Box 28.3.**

Questionnaire evaluation of speech

Speech Handicap Index (SHI) The speech handicap index (SHI) was developed in 2008 by Rinkel et al[67] Recently an English version was validated.[27] It consists of 30 questions to evaluate the patient's speech and speech-related psycho-social functions. Scoring of SHI is based on a Likert five-point scale with response categories as never (0); almost never (1); sometimes (2); almost always (3) and always (4). Total SHI score is summed and higher scores indicate worse speech-related problems. In addition, there is a global question which rates the patient's overall speech quality, this has four responses: excellent; good; average and bad which are scored as 0, 30, 70 and 100. Higher scores again indicate a greater speech problem.

Perceptual evaluation of speech

This is considered gold standard for speech evaluation and involves speech rated by professionals for different speech parameters.

The London Speech Evaluation 'LSE' scale This has recently been developed and validated for use in HNC patients.[64] It evaluates five speech parameters, intelligibility, articulation, rate, nasality and asthenia and overall grade of speech impairment. Scoring of the instrument is based on a Likert four-point scale ranging from 0 to 3. Higher scores indicate greater impairment.

Assessment of Intelligibility of Dysarthric Speech The Assessment of Intelligibility of Dysarthric Speech (ASSIDS)[66] is used by speech and language therapists and contains assessment of intelligibility of speech. It requires a recording of either 50 single words or sentences of 5–15 words selected at random. Each sample is judged by a pool of scorers (one scorer can be used if improvement is being sought in an individual patient). The recording is listened to and transcribed by the scorer and an intelligibility score given as a percentage of responses that were correct. In addition to percentage intelligibility, scores can be calculated for speaking rate, rate of (un)intelligible speech and a communication efficiency ratio. These calculations are based on a healthy person speaking a 220-word paragraph at a rate of 190 words per minute.

Instrument based measures

frequency (F0) and formant frequencies. These are the natural resonance frequency of vocal tract for certain sounds and vowels in particular can be identified by their formants. There are several formants but only the first (F1), second (F2) and third (F3) formant frequencies are of use in speech evaluation of HNC. F1 and F2 are related to tongue position and F3 to size of oral cavity. Formants are extracted through linear predictive coding (LPC). Formant frequencies objectively measure approximation between various portions of the oral cavity and the oropharynx.[68] Currently, acoustic analysis of speech is still in its infancy and is predominantly used as a research tool.

MEASURES OF SWALLOWING OUTCOMES

Dysphagia assessment requires a multimodality approach (**Box 28.4**) and falls broadly into two categories: those that assess the severity of the swallowing disorder and those that try to establish its cause.

Causation generally relate to the biomechanics of the altered swallow mechanism, whether sensory or motor. The choice of examination depends largely on the clinical questions to be answered and the presentation of the patient.

Questionnaire evaluation of swallowing

Sydney Swallow Questionnaire (SSQ) This tool is for evaluation particularly of oral and-pharyngeal dysphagia;[73] it has been recently validated for use in the HNC patients.[74] It consists of 17 well-structured questions for the assessment and quantification of patient reported difficulties with swallowing.[73] It uses a visual analogue scale; the total score is calculated and ranges from 0 to 1700 with higher scores indicating a more severe swallowing impairment.

SWAL-QoL and SWAL-CARE SWAL-QoL[75] is a validated swallow-specific QOL questionnaire to assess oropharyngeal dysphagia. It consists of 44 questions grouped in several subsections to evaluate 10 different QOL domains related to swallowing, based on a 5-point scale. It remains the most comprehensive assessment of swallow performance to date. The SWAL-CARE is a 15-item tool relating to quality of care and patient satisfaction.

MD Anderson Dysphagia Inventory (MDADI) The MDADI[76] is one of the most commonly used swallowing questionnaires for HNC patients. It is a self-administered 20-item questionnaire divided into four domains (Global, Emotional, Physical and Functional). The Emotional, Physical and Functional domains consist of 6, 8 and 5 questions respectively, which are scored on a scale of 1 to 5. All (but one) questions are summed, and a mean score is then calculated. This mean score is multiplied by 20 to obtain a score, with a range of 0 (extremely low functioning) to 100 (high functioning). A higher MDADI score represents better day-to-day functioning and QOL.

The Functional Intraoral Glasgow Scale This is a self-assessment questionnaire for the assessment of speech, chewing and swallowing, validated in oral cancer patients. It consists of an ordinal five-grade scale marked for speech as: always understandable (5), needing repetition sometimes (4), needing repetition many times (3), understandable only by relatives (2), incomprehensible (1); for chewing as (5) any food, no difficulty (4) solid food, with difficulty (3) semisolid food, with no difficulty (2) semisolid food, with difficulty (1) cannot chew at all, and for swallowing as (5) any food, no difficulty (4) solid food, with difficulty, (3) semisolid food only, (2) liquids only (1) cannot swallow at all. This very simple scale showed good correlation with a conversational understandability test performed by speech and language therapists and with an objective computer-based method of speech analysis.[77]

Perceptual measures

The simplest assessments are direct bedside clinical assessments.[78] However, these are not standardized and offer poor reliability when used alone. The use of a defined volume of water – 30 ml and looking for abnormal voluntary cough, post-swallow cough or throat clear or voice has been shown to have about a 50% sensitivity and 80–92% specificity for aspiration,[69, 70, 79] and is a useful adjunct to instrumental testing.[71] In the HNC population, water swallow test (WST) using 100 ml has been found to be 67% sensitive but less specific (46%).

Instrument based assessment of swallowing

Videofluoroscopy Videofluoroscopy remains the most frequently applied assessment of complex swallow problems as it allows assessment of anatomy and co-ordination in movements of the oropharyngeal and oesophageal stages of swallowing. It is, however, a relatively expensive and time-consuming investigation involving a multiprofessional

team from radiology, SLT and ENT. There are therefore limited opportunities for repeat assessments.[72, 80, 81] Assessments of the reliability of videofluoroscopy show superior accuracy for aspiration than for determination of pathophysiology. The situation is improved with group discussion. The application of protocols and use of frame-by-frame analysis seems inconsistent.[82–84]

In the most expert of hands, semiquantitative estimates of swallow performance can be made. The most usual of these is the oropharyngeal swallow efficiency (OPSE) calculated using the formula:

> % bolus transfer to upper oesophagus/oropharyngeal transit time.

Efficiency as a measure of swallow is based on the maximum estimated percentage (proportion) of bolus left in the pharynx and can be measured on different textures.

The penetration–aspiration scale (**Box 28.5**) assesses the presence and depth of invasion of material entering the airway, and the patient response to the aspiration and the ability to eject any misdirected material.[85, 86] Traditionally, patients aspirating more than 10% of any bolus should be restricted from taking the relevant consistency orally. Manoeuvres can be tested to reduce aspiration. Ongoing aspiration is seen in 44% patients non-laryngectomy survivors of HNC at 5 years and is associated with lower scores on a number of QOL scales.[87]

DIGEST (Dynamic Imaging Grade of Swallowing Toxicity)[88] is a validated tool for SLT to grade dysphagia after radiotherapy. It combines an assessment of efficiency (E 0–4) and of safety (S 0–4), using maximum percent of pharyngeal residue and maximum penetration–aspiration scale score. A DIGEST grade is given to the dysphagia in line with the CTCAE (common terminology criteria for adverse events) scoring D 0–4.

BOX 28.5 Penetration–Aspiration Scale[89]

Score	Criteria
1	Material does not enter the airway
2	Material enters the airway, remains above the vocal folds, and is ejected from the airway
3	Material enters the airway, remains above the vocal folds and is not ejected from the airway
4	Material enters the airway, contacts the vocal folds and is ejected from the airway
5	Material enters the airway, contacts the vocal folds and is not ejected from the airway
6	Material enters the airway, passes below the vocal folds and is ejected into the larynx or out of the airway
7	Material enters the airway, passes below the vocal folds and is not ejected from the trachea despite effort
8	Material enters the airway, passes below the vocal folds and no effort is made to eject

Fibre-optic endoscopic evaluation of swallowing (FEES)

Fibre-optic endoscopic evaluation of swallowing[90] has emerged over the past two decades as not only a complement to videofluoroscopy, but as a useful investigation in its own right. This test can be performed at the bedside and is best if a digital recording is made. Different textures of foodstuffs can be given, which can be dyed with food colouring to enhance visibility. Bolus flow during swallow, laryngeal penetration and aspiration and post-swallow residue should be assessed. The main disadvantage of FEES is that swallowing dynamics are obscured by obliteration of the view as the endoscope tip opposes pharyngeal and laryngeal musculatures during hyolaryngeal excursion.

Assessment of FEES using the penetration aspiration scale developed for videofluoroscopy can achieve good agreement between raters in 97% of cases.[91] Sharing the video image with the patient offers additional therapeutic opportunities through visual biofeedback as the patient observes the impact of swallowing manoeuvres or head positions on their swallow performance. Endoscopic swallow evaluation is relatively cheap, yet only a small minority of speech and language therapists have access to the procedure.[80] FEES should be incorporated into follow-up for HNC patients, as it can be performed by the speech and language therapist and allows for assessment of recurrence and function.

Flexible endoscopic evaluation of swallowing with sensory testing (FEESST) allows more specific assessment of sensory and motor components than in a standard endoscopic evaluation. Patients with absent pharyngeal motor function combined with poor pulmonary reserve and diminished or absent laryngeal sensation are expected to aspirate. Patients with completely insensate laryngopharynx are at extremely high risk of aspiration. Moderate sensory deficits will also result in aspiration if there is a coexisting motor dysfunction.[89]

Electromyography Surface electromyography (sEMG) signals have been used to identify swallow events.[92] The full application of sEMG has yet to be established. At least in the short term, the principal value of the technique in head and neck patients probably is as an adjunct to biofeedback and rehabilitation manoeuvres.

Performance scales designed specifically for the head and neck patient population

Performance Status Scale for Head and Neck Cancer Patients

The Performance Status Scale for Head and Neck (PSSHN)[93] is a clinician-rated scale, designed specifically for the head and neck population and the unique areas of dysfunction experienced by this group of patients. It has three domains: (1) understanding of speech, (2) normalcy of diet and (3) eating in public. There is a score from 0 to 100 for each domain. A higher score correlates with better functional ability. There is strong correlation between the PSSHN and MDADI at multiple time points.[94]

BOX 28.6 Instruments to assess comorbidity

- Kaplan–Feinstein Index (KFI)[96]
- Adult Comorbidity Evaluation (ACE-27)[97]
- Charlson Comorbidity Index (CCI)[98]
- Washington University Head and Neck Co-Morbidity Index (WUHNCI)[81]
- American Society of Anesthesiologists (ASA) Risk Classification

COMORBIDITY

Comorbidity refers to disease that coexists with and is unrelated to the index disease, and has been shown to play a major role in the treatment, outcome and prognosis of a number of malignancies. While comorbidity is used to predict outcome and may play a role in decision-making for treatment, it does not strictly qualify as an outcome measure. However, it has a significant influence on oncological and functional outcomes and is thus included in this chapter.

In 1948, the first attempt to quantify the performance status of patients with advanced cancer was made by Karnofsky.[95] Since then, a variety of instruments have evolved to measure comorbidity (**Box 28.6**).

Kaplan–Feinstein index

The Kaplan–Feinstein index (KFI) was developed for assessment of comorbidity on outcome in diabetes mellitus and has been used to study the impact of comorbidity in several cancers.[96] Information is taken from notes review and specific diseases are classified and a score given of mild, moderate or severe according to severity of organ decompensation. Where multiple comorbidities are present, an overall score is assigned according to the highest ranked illness, and where there are two or more moderate outcomes the overall score is defined as severe.

Adult comorbidity evaluation

Adult comorbidity evaluation (ACE-27)[97] is a modification of the KFI, validated and especially designed for patients with cancer. An overall score of 1, 2 or 3 is assigned according to the highest ranked single condition, except where two or more grade 2 illnesses occur in different organ systems where a score of 3 is given. The National Cancer Intelligence Network in the UK recommends the collection of ACE-27 for all cancer patients.

Charlson comorbidity index

The Charlson comorbidity index (CCI)[98] is a weighted sum of the presence or absence of each of 19 conditions. Each condition is assigned a weight from 1 to 6, where a higher value indicates more severe disease. The index is the sum of all the weights.

Washington University Head and Neck Comorbidity Index

The Washington University Head and Neck Comorbidity Index (WUHNCI)[98] is a head and neck specific tool. It takes into account seven common comorbid conditions based on their relative prognostic significance in HNC patients.

Comorbidity and HNC

HNC patients have a high prevalence of comorbidity (21–35%) due to the long-term effects of smoking and alcohol, second only to lung cancer (40%). Several studies have shown the importance of comorbidity on outcome and the prognosis of HNC.[99–103] It is an independent prognostic indicator even when age and TNM stage have been controlled for.[97]

The KFI has been found to be most successful in stratification of survival analysis in HNC patients when compared with the CCI.[100] The CCI is simple to use and has been used to evaluate comorbidity in laryngeal cancer[104] and thyroid cancer,[105] and has been validated against the ACE-27 for use in HNC.[106] However, because answers evaluate the presence or absence of disease rather than severity, it has been found to be less sensitive than the ACE-27 in assessing comorbidity.[107, 108] Comorbidity assessed through the ACE-27 has been shown to have a direct impact on HNC survival especially in the early years after survival where the greatest impact is seen in the younger patient. Comorbidity is associated with an adverse influence on disease-free survival, a higher risk of more severe complications of treatment, has an adverse effect on QOL and increases the cost of treatment.[109–112]

Comorbidity data add valuable prognostic information that may influence treatment modality. Use of single sources alone may result in some misclassification of comorbidity. Enhancing data extracted from notes with a patient self-report questionnaire can improve the accuracy of comorbidity grading.[113]

PATIENT PRIORITIES FOR TREATMENT OUTCOMES

An early classic paper on the cost utility analysis of the treatment of advanced laryngeal cancer by radiotherapy and laryngectomy presented a trade-off of QOL (retention of laryngeal speech) vs quantity of life (improved survival after primary laryngectomy) to a group of healthy (non-medical) volunteers. In order to maintain natural speech, approximately 20% of those questioned would have chosen radiation instead of surgery.[114] This paper was innovative and influential in suggesting that for some people quality, not quantity, of life was more important. But in a very recent study in a population demographically matched to HNC patients, many participants indicated that larynx conservation was not their primary consideration in treatment choice. Thirty-eight per cent of participants opted for a primary laryngectomy and the functional outcome of treatment had a greater effect than treatment modality on the utility value assigned to laryngeal cancer health state outcomes.[115] In contrast, in a paper by DeSanto et al 20% of patients expressed themselves willing to accept a reduced life span in order to preserve their larynx and QOL.[116] However, 46% of the healthcare professionals questioned had felt that the patients would accept this trade off. A study published by List et al showed that both

patients and nonpatients ranked 'being cured of cancer', 'living as long as possible' and 'having no pain' most frequently in the top three of 12 statements.[117]

There are also differences in the perception of the relative importance of different categories of symptom between patients and carers. In 1992, Mohide et al[1] demonstrated that carers ranked impaired communication and self-image/self-esteem as the two most important QOL outcome domains following laryngectomy. The patients themselves ranked the physical symptoms of tracheal mucus production and interference with social activities as the two most important items. It is important to bear this lack of correlation between patient and carer priorities in mind when counselling patients about treatment options.

Blanchard et al[118] performed a systematic review of patient preferences in HNC, defined by the subsite of the primary cancer. This study showed that whilst there was homogeneity in the methods and conclusions of studies of laryngeal preservation, studies of other subsites suffered from significant heterogeneity, thus making it difficult to draw conclusions about patient priorities. However, survival consistently trumped functional outcomes, underscoring the importance of high survival rates in contemporary or experimental treatments, whatever the subsite.

HNC are heterogenous in their biological nature, and therefore tumour behaviour and response to treatment. Furthermore, the incidence and severity of adverse effects of treatments is highly variable between patients. In their analysis of RTOG 0522 Ang et al[119] support a strategy of refining study populations, for better biologically defined HNC entities. The identification, selection and reporting of disease-specific and appropriate endpoints is therefore a research priority.

BEST CLINICAL PRACTICE

- ✓ Measurement of Base line and post-treatment swallow outcomes using a combination of clinical and instrumental assessments and validated patient outcome measures such as MDADI or PSSHN and instrumental assessments such as 100 ml water swallow test and FEES.
- ✓ Measurement of voice outcomes following treatment for early laryngeal cancer using questionnaires such as VHI short-form 10 or VoiSS.
- ✓ Collection and recording of comorbidity data WHO and ACE 27 in all head and neck cancers registered (as per National Cancer Intelligence Network guidance in UK).
- ✓ Recording of early and late toxicities associated with treatments for head and neck cancer to allow for the comparison of interventions when there is equipoise for survival.

FUTURE RESEARCH

- ➤ Development of a tool to assess xerostomia following treatment in HNSCC with a view to identifying if new treatments reduce this debilitating side effect.
- ➤ Development of a PROM for evaluation of shoulder dysfunction following treatment for HNSCC.
- ➤ Standardization of outcome measurements collected to allow for useful comparison and evaluation.
- ➤ Development of a validated scale for perceptual evaluation of alaryngeal speech.

KEY POINTS

- Outcome measures are integral to the management of patients with HNC and can relate to survival or function. Choice of appropriate outcome measures is essential.
- Numerous tools exist for assessment of voice. Self-assessment questionnaires are most commonly and easily obtained. These can be combined with perceptual and acoustic measures; the latter are commonly used as research tools.
- It is important to distinguish voice from speech since these are different concepts, thus needing different measures.
- Dysphagia is perceived by patients to be one of the most important functional outcomes of HNC treatment. Assessment should be embedded in routine practice and form part of follow-up. This should include questionnaire-based tools such as MDADI or PSSHN and instrumental assessment with FEES. VF is an outcome tool in the research setting, but also valuable in managing patients with swallowing problems.
- Comorbidity assessment using ACE-27 is recommended by NCIN for all cancer patients.

SEARCH STRATEGY

Data in this chapter may be updated by a search of MedLine and PubMed using the following keywords: head and neck cancer and transoral robotic surgery.

TECHNOLOGY AND OTOLARYNGOLOGY

Surgical innovation and skillfully adapting new technology to improve patient care has been part of the fabric and culture of otolaryngology, head and neck surgery since its inception. As such, there is a long history of otolaryngologists creating and embracing new surgical technology, dating back to 1921, when Dr. Carl Nylen, a Swedish otolaryngologist, used the world's first monocular operative microscope, for the treatment of chronic otitis media.[1] The next year, Dr. Gunnar Holmgren, Dr. Nylen's chief, introduced the first binocular microscope by attaching a light source to an existing Zeiss dissecting microscope.[1] In the 1970s, Dr. Walter Messerklinger and his protégé, Dr. Heinz Stammberger in Graz Austria pioneered the technique of endoscopic sinus surgery, later popularized and refined by Dr. David Kennedy in the US.[2] These noble traditions shows that otolaryngologists, head and neck surgeons are endoscopic surgeons, pioneering new techniques to improve surgical outcomes and patient care.

Recently, the introduction of surgical robotics has transformed the practice of surgery. With robotic surgery, the surgeon and his hands are physically separate from the patient. Real surgery is performed in a virtual environment, allowing the surgeon to interact with surgical anatomy with a novel perspective, in otherwise inaccessible places and in ways that would not be possible without this innovation. In 2007, the Society of American Gastrointestinal and Endoscopic Surgeons and the Minimally Invasive Robotic Association defined 'robotic surgery' as 'a surgical procedure or technology that adds a computer technology-enhanced device to the interaction between a surgeon and a patient during a surgical operation and assumes some degree of control heretofore completely reserved for the surgeon.'[2]

Currently, the daVinci® Surgical System (Intuitive Surgical Inc., Sunnyvale, CA) is the most popular platform for robotic surgery. It consists of three parts: a 'patient-side' cart deploys surgical instruments placed by the surgeon within the patient's body including a binocular 12 mm endoscope with dual zero or thirty degree optics, and a 'surgeon's console' which is remotely placed where three-dimensional surgical anatomy is recreated and linked to instruments in a virtual environment. The surgeon's console consists of a three-dimensional display, a seat for the surgeon, foot pedals to control cautery and other instruments, and hand controls linked to instruments placed in the operative field. The three-dimensional display affords the surgeon unprecedented perspective and visualization of surgical anatomy along with the ability to operate with 540 degrees of wristed instrumentation at zero or thirty degree angles. Motion scaling increases precision by eliminating tremor and fatigue while also reducing greater hand movements. The 'vision cart' houses the video processor and screens to project the procedure, primarily used by the operating assistant and the other observers.

ROBOTIC SURGERY

Transoral robotic surgery

Melder and McLeod performed the first robotic procedure in otolaryngology at the Walter Reed Army Medical Center in 2003, removing a vallecular cyst.[3] With the first generation 'standard' DaVinci® Surgical System (Sunnyvale, CA),

Hockstein, Weinstein, and O'Malley presented a series of landmark papers beginning in 2005 defining the field of transoral robotic surgery (TORS).[4–7] Whereas Melder and McLeod placed robotic arms through a slotted laryngoscope, Hockstein et al. placed the robotic arms through the oral retractors, moving from laryngoscopes to the Feyh-Kastenbauer (FK), Crowe-Davis, McIvor, or Dingman, which provided excellent exposure for the oropharynx but even allowed access to the supraglottic larynx and occasionally the hypopharynx. Different combinations of retractors, laryngoscopes, endoscopes and microsurgical instruments were used to identify the optimal setup for robot-assisted head and neck surgery. Hockstein found that placing the robotic arms through a tubed laryngoscope, such as the Lindholm, significantly limited range of motion, but that an oral and oropharyngeal retractor, such as the McIvor, provided relatively free motion of the surgical instruments and endoscope for procedures of the oropharynx, supraglottis and hypopharynx.

The operative arms carry interchangeable 5 or 8 mm diameter instruments including atraumatic forceps, monopolar cautery, bipolar cautery, among other manipulators and dissectors. The most common cutting device is the monopolar electrocautery spatula, which doubles as a dissector. Lasers have recently been adapted to work with the robot manipulators and have been a popular addition. Fibre laser technology couples the unsurpassed visualization with a more precise cutting device with nominal thermal damage and reduced tissue necrosis when compared to the monopolar electrocautery. In addition to two operative arms, either an 8.5 or 12 mm binocular stereoendoscopy or camera provide a high-definition three-dimensional view of the anatomy of the laryngopharynx (**Figure 29.1**).

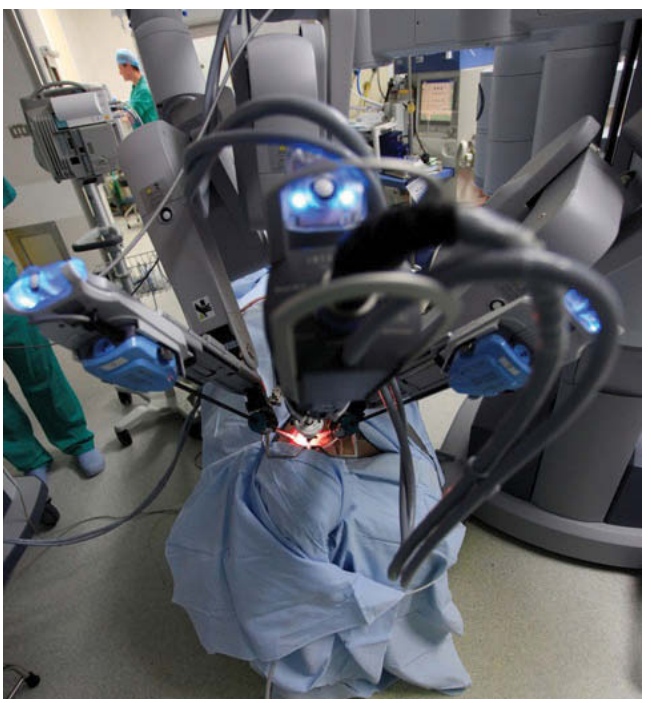

Figure 29.1 A bird's eye view of the da Vinci Si system docked in the mouth prior to TORS.

O'Malley et al. in 2006[8] demonstrated the use of TORS in cadaver and animal models. Once they had demonstrated adequate exposure with these models, they proceeded with 3 tongue base cancers on human subjects under an institution review board approved human trial. They concluded 'TORS provided excellent three-dimensional visualization and instrument access that allowed successful surgical resections from cadaver models to human patients'.[8]

Multiple studies emerged demonstrating the feasibility of transoral robotic surgery for patients with laryngopharyngeal cancer. Moore et al. reported on the feasibility of robotic surgery in a prospective case study of 45 patients with previously untreated oropharyngeal squamous cell carcinoma.[9] His case series included T1–T4a tumours with simultaneous unilateral or bilateral neck dissection. Margins were all negative, operative time improved as operative experience developed, and all 14 patients who underwent tracheostomy tube placement were decannulated. All 30 patients who had either a nasogastric or gastrostomy feeding tube placed eventually had their tubes removed. Weinstein et al.[10] in a multicentre prospective case series reported on the safety, feasibility and adequacy of surgical margins for transoral robotic resections. A total of 192 patients were initially screened and 177 were finally included, as 13 were excluded for inadequate exposure with TORS and 2 who were switched to an open approach. Most cases were oropharyngeal followed by laryngeal squamous cell carcinoma. In regard to safety, there were no intra-operative mortality or deaths in the immediate post-operative period. Blood loss averaged 83 mL and no patients required transfusions. Twenty-nine patients (16%) experienced serious adverse events requiring intervention or hospitalization. Twenty-two patients (2.3%) had a tracheostomy tube at last follow-up visit and the gastrostomy tube dependence rate was 5.0%. The positive margin rate was 4.3%. This multicentre study concluded that TORS was safe and feasible.

White et al. reported on the 1- and 2-year survival rates after transoral robotic surgery.[11] Eighty-nine patients from 2 institutions were included, mostly with oropharyngeal squamous cell carcinoma followed by laryngeal squamous cell carcinoma. T-stage ranged from T1 to T4 with most being T1 or T2 and most were overall stage III or IV. At last follow-up and after a median follow-up of 26 months, 82 had no evidence of disease, 2 died of disease, and 4 were alive with disease. The 2-year recurrence free survival rate was 86.5% and none of the patients were gastrostomy tube dependent.

Despite multiple studies and meta analyses[12] supporting the use of transoral robotic surgery, there are no randomized studies comparing surgical management of oropharyngeal carcinoma to chemoradiation. **Table 29.1** summarizes ongoing trials worldwide, aiming to identify the role of transoral surgery (with the laser or the robot) in this setting on TORS in the world, 4 of which are randomized trials. The RTOG 1221 randomized trial has been designed to compare transoral resection of p16- oropharyngeal carcinoma followed by risk-based adjuvant therapy (60 Gy IMRT with or without weekly cisplatin)

TABLE 29.1 TORS trials currently ongoing (as of January 2017)

Name of trial	Identification number	Inclusion criteria (disease specific)	Comparative arms	Primary outcome measure	Negative margin threshold
'CompARE' Phase III randomized controlled trial comparing alternative regimens for escalating treatment of intermediate and high-risk oropharyngeal cancer	ISRCTN41478539	• OPSCC in base of tongue and tonsil with MDT recommendation for treatment with definitive concurrent chemoradiotherapy • Intermediate risk [HPV +ve OPC with N2b+ disease and greater than 10 pack year history of smoking] or high risk (HPV–ve OPC) as per Ang classification	**Arm 1 (control):** Concomitant chemoradiotherapy (70 Gy in 35# and cisplatin) +/– post- treatment neck dissection **Arm 2:** Induction chemotherapy (docetaxel, cisplatin and 5-FU), followed by arm 1 **Arm 3:** Dose-escalated chemo radiotherapy (64 Gy in 25# and cisplatin) +/– post- treatment neck dissection **Arm 4:** Resection of primary and selective neck dissection plus post-operative chemoradiotherapy (T1/2 transoral surgery, T3/4 transoral or open surgery)	• Overall survival (OS) • Disease-free survival (DFS)	not specified

'PATHOS'
A phase II/III trial of risk-stratified, reduced intensity adjuvant treatment in patients undergoing transoral surgery for HPV +ve OPC
	NCT02215265	• Stage T1–T3, N0–N2b SCC of the oropharynx
		• HPV +ve
			Post-operative risk stratification
			1. Low risk: no adjuvant treatment
			2. Intermediate risk: randomized to:
			  • 50 Gy in 25#
			  • 60 Gy in 30#
			3. High risk – randomized to:
			  • 60 Gy in 30#
			  • 60 Gy in 30# with cisplatin
				• Patient-reported swallowing outcome	> 5 mm

'ADEPT' Post-operative adjuvant therapy de-intensification trial for HPV-related, p16+ oropharynx cancer	NCT01687413	• Patient must have histologically confirmed p16 positive SCC of the oropharynx (OPSCC). • Patient must have undergone transoral resection of their T1–4a oropharynx primary to a negative margin, and a neck dissection(s). • Patient's disease must be pathological N-stage positive. • Patient's disease must show ECS in their nodal metastasis verified by central pathologist's review. • Patients with synchronous primaries are included. • Patients with unknown primaries are included if the diagnosis and resection of a primary site in the oropharynx is made from an endoscopic or robotic surgical procedure(s)	Post-operative randomization **Arm 1:** 60 Gy in 30# **Arm 2:** 60 Gy in 30# and cisplatin	• Disease-free survival (DFS) • Locoregional control	not specified

(Continued)

TABLE 29.1 ***(Continued)*** TORS trials currently ongoing (as of January 2017)

Name of trial	Identification number	Inclusion criteria (disease specific)	Comparative arms	Primary outcome measure	Negative margin threshold
'ORATOR' A phase II randomized trial for early-stage SCC of the oropharynx: radiotherapy vs transoral robotic surgery	NCT01590355	• Histologically confirmed SCC primary tumour site in the oropharynx • Tumour stage: T1 or T2, with likely negative resections at surgery • Nodal stage: N0, N1, or N2, without extranodal extension on pre-randomization imaging	**Arm 1:** Radiotherapy +/– chemotherapy **Arm 2:** Transoral Robotic surgery and neck dissection +/– adjuvant radio(chemo)therapy based on pathological findings	• Quality of life	>2 mm
'ECOG 3311' Transoral surgery followed By low-dose or standard-dose radiation therapy with or without chemotherapy in treating patients with HPV Positive Stage III-IVA oropharyngeal cancer	NCT01898494	• SCC or undifferentiated carcinoma of the oropharynx; patients must have been determined to have resectable oropharyngeal and neck disease • Patients must have AJCC TNM tumour stage III, IV a, or IV b (with no evidence of distant metastases) • Nodal stage N1-N2b • p16 (HPV) positive disease	Post-operative risk stratification 1. Low risk: no adjuvant treatment 2. Intermediate risk: randomized to: • 50Gy in 25# • 60Gy in 30# 3. High risk: chemoradiotherapy	• Progression free survival rate • Accrual rate • Risk distribution • Incidence of grade 3–4 bleeding events during surgery and positive margins after surgery	>3 mm
A single-arm phase II Study of post-transoral robotic surgery (TORS) alone to the primary tumour site and SND followed by adjuvant radiation therapy (+/– chemotherapy) to the regional nodes for advanced stage, HPV positive, oropharyngeal cancer	NCT02159703	• Histologically confirmed diagnosis of SCC of the oropharynx, stage IVa, p16-positive on immunohistochemistry • Pathologic T1 or T2 disease, resected with negative margins (2 mm) • Pathologic N2a, N2b, or N2c disease		Number of adverse events	>2 mm
Robotic surgery for oropharyngeal SCC	NCT02225496	• Patients with a previously untreated, T1 or T2, N0-N2b transorally resectable (as determined by the treating surgeon), histologically proven HPV positive, SCC of the oropharynx		Time to local-regional recurrence (TTLRR)	>5 mm
Transoral robotic surgery in treating patients with benign or malignant tumours of the head and neck	NCT01473784	• Patient must present with indications for diagnostic or therapeutic approaches for benign and/or malignant diseases of the oral cavity or laryngopharynx		Determine the feasibility of the TORS in patients with oral and laryngopharyngeal benign and malignant lesions	not specified

SCC, squamous cell carcinoma; SND, selective neck dissection, HPV, human papilloma virus; ECS, extracapsular spread.

to standard chemoradiation therapy (70 Gy IMRT with weekly cisplatin); owing to reduced numbers of HPV- disease, this trial failed to meet recruitments targets, and has been closed. In the UK, the CRUK funded ComPARE trial will recruit surgically resectable intermediate and high-risk patients as per the stratification data published by Ang et al.[13] and has a surgical resection followed by platinum based RT as one of the arms.

Additionally, while HPV-associated oropharyngeal carcinoma has been clearly shown to have improved prognosis compared to HPV negative oropharyngeal carcinoma, no trials have yet been conducted on de-escalation of therapy. Accrual for ECOG 3311 is currently underway, which is a phase II randomized trial comparing low-dose radiation (50 Gy) vs standard post-operative dose of radiation (60 Gy) after transoral resection of of p16+ oropharyngeal squamous cell carcinoma with intermediate risk factors (< 3 mm margins, < 1 mm ECS, and 2–4 metastatic lymph nodes). Patients with low-risk features (T1–T2, N0-1, and negative margins) will receive no post-operative adjuvant therapy and patients with high-risk features (> 1 mm ECS, > 5 metastatic lymph nodes, or positive margins) will receive standard 66 Gy IMRT with weekly cisplatin.

In the UK, the PATHOS trial will recruit patients with low and intermediate staged HPV positive oropharyngeal cancer, managed by transoral excision followed by risk stratified radiation therapy. This trial aims to establish whether the de-intensification of adjuvant treatment in patients undergoing TLM/TORS for HPV-positive OPC, by reducing radiation dose or omitting chemotherapy, will confer improved swallowing outcomes at 1-year post-treatment whilst maintaining high cure rates. Thus, the treatment of this disease is rapidly evolving and significant changes can be expected in the next decade. A summary of these trials can be found in a recent review[14] TORS has also been shown to have a clear role in resection of supraglottic[15, 16] and hypopharyngeal cancers.[17–19] A new role has been defined for TORS in diagnosing the unknown primary, using tongue base mucosectomy, where pick-up rates of between 50% and 60% have been demonstrated,[20] even in patients who show no avidity on CT-PET imaging.[21]

Transoral robotic surgery versus transoral laser microsurgery

Transoral laser surgery has been shown to be effective in the management of tonsil tumours and is discussed at length in Chapter 22, Transoral laser microsurgery. The principles of this procedure involve resection of the tumour by following its extent, tailoring resection to each patient. Assessment of the depth of the tumour is achieved frequently by transecting the tumour until the 'normal' tissues are reached. The cutting characteristics of the laser mean this is clearly demonstrable. However, margins on the specimen are frequently reported as close and marginal biopsies are therefore used to assess status. While this approach is oncologically safe, it can present practical concerns in deciding if adjuvant therapy is needed.[22] Nevertheless, the significant amount of work in the TLM literature has paved the way to establish TORS for tonsil tumours as *bonafide* management with firm long-term oncological outcomes.

The principle of TORS surgery is *en bloc* resection with a clear margin (**Figure 29.2**). The foundations for *en bloc* resection of tonsil cancers via a transoral route had been laid back in the 1950s when P-C. Huet described this procedure.[23] This involved transoral resection of the tonsil and the superior constrictor muscle deep to the parapharyngeal space. Holsinger et al.[24] reported good outcomes for tonsil tumours with this technique. *En bloc* resections of the tonsil, although feasible with the TLM approach, are not easy due to the line of sight working and instrumentation. The advent of TORS has allowed surgeons to perform *en bloc* resections at this primary site. The superior optics and manoeuvrability combined with the ergonomics have meant that the learning curve for transoral robotic radical tonsillectomy is not as shallow as that of transoral laser microsurgery (**Figure 29.3**).

Robotic thyroidectomy

Transoral endoscopic head and neck surgeons rely on access through the mouth and axilla which provides ample opportunity for innovation and improvement in minimally invasive techniques for the treatment of laryngopharyngeal tumours. However, robotic surgery may also play a role for the management of tumours of the thyroid and parathyroid.

Advances in minimally invasive thyroid surgery date back to 1996 with the first endoscopic parathyroidectomy performed by Gagner.[25] The operative setup resembled that of laparoscopic surgery utilizing 5 mm laparoscopic instruments placed between the platysma and strap muscles with the operative space maintained with CO_2 insufflation. Subsequent advances involved minimally invasive video-assisted thyroidectomy (MIVAT) in which the thyroid gland is removed with or without gas insufflation via cervical, axillary, or anterior chest wall approaches.[26, 27] Multiple Asian studies have emerged reporting on endoscopic transaxillary thyroidectomy.[28–30] Chang et al. reported their experience with a combined endoscopic-robotic transaxillary approach for thyroidectomy.[31] Kang et al. reported on 200 patients who underwent transaxillary robotic thyroidectomy utilizing the DaVinci® Surgical System.[32] The combination of minimally invasive thyroid surgery utilizing the DaVinci® Surgical System provides many advantages for the endoscopic head and neck surgeon. The three-dimensional display employing 30-degree optics along with the 540 degrees of wristed instrumentation improve operative dexterity along with operative field exposure and visualization.

Terris et al.[33] demonstrated the use of robotic-assisted thyroidectomy via a facelift incision. In 2012, he demonstrated the feasibility of the facelift approach, comparing it favourably against transaxillary robot-assisted thyroidectomy. Specifically, in his series of 15 patients, he demonstrated decreased operative time and outpatient thyroidectomy

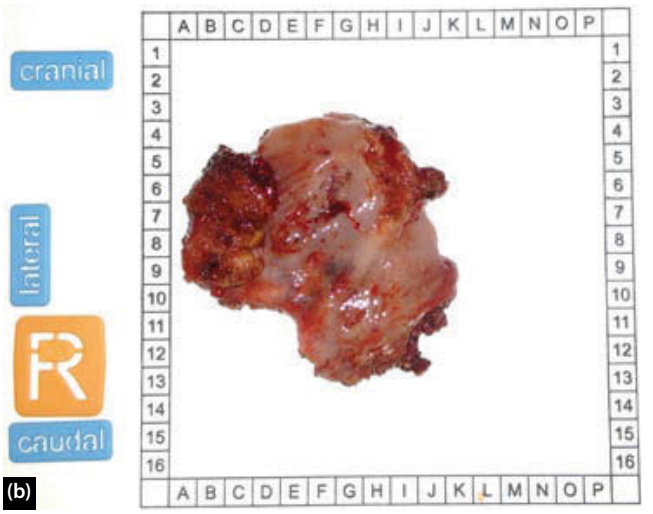

Figure 29.2 **(a)** is the view following transoral robotic *en bloc* resection of a T2 tonsil cancer. **(b)** is the specimen with the cancer in the middle and demonstrates adequate macroscopic margins. **(c)** shows a fully healed lateral oropharygectomy defect.

Figure 29.3 Photograph shows robotic surgery in progress, with dual surgical consoles. The two console surgeons share the same view and can swap control of the instruments, which facilitates training and allows rapid acquisition of skills.

without drain placement in robotic facelift thyroidectomy compared to transaxillary thyroidectomy. A recent meta-analysis of 5200 patients showed an equivalent adverse event and complication rate for robotic thyroidectomy compared to conventional approaches, generating confidence in wider adoption of the technique.[34] Many, however, remain sceptical of robotic-assisted techniques in thyroidectomy given that the time-honoured approach of conventional open thyroidectomy remains safe and effective.

Robotic neck dissection

The neck dissection has undergone significant changes from the radical neck dissections to functional and selective neck dissections without compromising oncologic principles and outcomes. This has led to a decrease in the morbidity of neck dissection. Now, authors have demonstrated minimally invasive combined endoscopic-robotic approaches to neck dissection in human cadaver models.[35] In 2004, Werner et al.[36] successfully demonstrated management of cervical lymphadenopathy using an endoscopic approach for squamous cell carcinoma in the setting of sentinel lymph node biopsy. Also, Kang et al. demonstrated the feasibility of robot-assisted neck dissection for well-differentiated thyroid carcinoma.[37] Furthermore, in 2010 Moore et al. demonstrated the use of transoral robotic surgery for retropharyngeal lymphadenectomy in papillary thyroid carcinoma.[38] Comparative studies of open and robotic neck dissections via a retroauricular/facelift route have shown equivalent functional and oncologic outcomes, with the robotic approach taking greater time, which could be ascribed to the learning curve.[39–41]

Robotic sleep apneoa surgery

Obstructive sleep apneoa (OSA) is a serious public health problem, as it is an independent risk factor for hypertension, myocardial infarction, and stroke. Sleep surgery has

a long history of improving quality of life for patients with OSA but has been limited by exposure of the posterior oropharynx as well as longevity in post-operative improvement scores. Given the success of robotic-assisted techniques in head and neck surgery, sleep medicine seemed an appropriate extension of the previously described techniques. Many surgeons were performing base of tongue resections for malignant disease with great precision and minimal complications, thus base of tongue resections for benign disease also seemed to be an appropriate use of the robot. In 2010, Vicini reported on his experience of 10 patients who underwent transoral robotic surgery for the management of OSA due to tongue base hypertrophy.[42] He resected the base of tongue in a piecemeal fashion, starting medially and subsequently resecting laterally. Vicini had confirmed in a cadaveric anatomic study that no significant neurovascular structures were present in the midline of the base of tongue, thus beginning resection there was quite safe.[43] All surgeries were successfully completely solely with TORS and there were no serious peri-operative complications. In the preliminary novel experience, Vicini routinely performed tracheostomies prior to the tongue base resections for every patient. Mean blood loss, operative time, setup time, pre-operative Epworth Sleepiness Scale, and pre-operative AHI was 25 mL, 45.5 min, 41.4 min, 12.4, and 38.3 respectively. Post-operative Epworth Sleepiness Scale and AHI were 6.9 and 20.6 respectively. There was a mean follow-up of 6 months. Vicini successfully demonstrated the feasibility of robotic-assisted sleep surgery.

In 2012, Friedman followed up on Vicini's work by performing midline posterior glossectomies for OSA without first performing a tracheostomy.[44] He included 40 patients who underwent TORS for obstructive sleep apneoa-hypopnoea syndrome and compared them to 2 cohorts: patients undergoing radiofrequency treatment or submucosal coblation. He reported that the TORS patients took longer to recover with a longer time to resume normal diet; TORS patients also took longer than the radiofrequency treated patients to resume regular activity. But that is where TORS' weakness stopped. Reduction in AHI for TORS patients averaged 60.5% while radiofrequency treated and coblated patients experienced average reductions of 32% and 37% respectively; both of these differences from TORS were statistically significant. Furthermore, only the TORS group achieved a statistically significant improvement in minimum oxygen saturation. Friedman noted no airway or bleeding complications. Once again, the feasibility of TORS for sleep surgery was confirmed.

Not satisfied with his results for in OSA outcome compared to open tongue base reduction with hyoid epiglottoplasty as described by Chabolle, Vicini wanted to apply the concept of geniohyoidpexy with transoral robotic surgery. In 2011, Vicini reported on the success of this technique in the cadaver model.[45] The hyoid bone was identified via transoral resection through the base of tongue and subsequently dissected free of its suprahyoid attachments. With minimal further dissection, the medial inferior border of the mandible is identified and two holes are drilled. One to two stitches are placed through those holes and then around the hyoid bone under slight tension, allowing for geniohyoidpexy and successfully demonstrating TOR access to the hyoid bone, which can be useful for many other applications.

Robotic skull base surgery

In 2007, Hanna et al. published on robotic-assisted anterior and central skull base surgery in a cadaver model.[46] Hanna used bilateral sublabial incisions with bilateral Caldwell-Luc antrostomies and posterior septectomy in order to gain access to the cribriform plate, fovea ethmoidalis, medial orbits, planum sphenoidale, sella turcica, suprasellar and parasellar regions, nasopharynx, pterygopalatine fossa, and clivus. The ability to perform two-handed endoscopic closure of dural defects was a major advantage of this approach. Kupferman et al.[47] described reconstruction of the skull base following robotic resection via a bilateral translabial Caldwell-Luc approach. They undertook a robotic-assisted suture based technique for reconstruction of dural defects suggesting that traditional suture techniques can be implemented after robotic resection using robotic instrumentation.

O'Malley et al.[48] developed a transoral approach to apply robotics for the treatment of tumours of the parapharyngeal space and infratemporal fossa. Beginning with pre-clinical studies on cadaver and animal models, O'Malley demonstrated the feasibility of TORS in this setting. In February 2007, the findings from this pre-clinical work led the way to perform a robotic resection of an infratemporal fossa cystic neoplasm in a live patient, as part of a prospective human trial. The robotic approach afforded adequate and safe identification of the internal carotid artery and cranial nerves. They achieved complete resection, excellent haemostasis and there were no peri-operative complications. In the prospective study, O'Malley et al. enrolled 10 patients with benign parapharyngeal space tumours without carotid encasement and found that 9 of the 10 patients were successfully completed with TORS with acceptable blood loss and no significant peri-operative complications.[48] His approach involved dissection intraorally through the pterygomandibular raphe. Seven of the patients were treated for pleomorphic adenoma, one of these required conversion to an open approach. They noted capsule disruption in 2 and pharyngeal disruption in 2. The 7 patients with pleomorphic adenomas were tumour free during the follow-up period ranging from 16 to 37 months. The other 3 patients were treated for benign cysts. Kim et al.[49] also provided support for use of TORS for benign tumours of the parapharyngeal space and infratemporal fossa in their series of 3 patients with pleomorphic adenomas. The disadvantage of this technique is adequate exposure, ensuring complete surgical resection, which is a serious consideration when considering malignant disease.

Blanco et al. also assessed the feasibility of the DaVinci® Surgical System for infratemporal fossa and anterior skull base lesions using a cadaver model.[50] They gained access to the infratemporal fossa using a maxillary window and the anterior skull base using a maxillary window and a nasal corridor. Although they deemed the robotic-assisted approach to the skull base was feasible, they felt the DaVinci

instruments need to be redesigned to be smaller and with distal articulating tips prior to clinical application.

Robotic approaches to the anterior and midline skull base via a transoral approach was assessed in a pre-clinical trial for TORS. O'Malley et al.[51] performed 10 procedures on cadaver and animal models. While they were able to access the canine skull base using a transoral approach, for the human cadaver they noted the standard transoral approach did not provide adequate access to the midline and anterior skull base. They developed a new technique deemed cervical-transoral robotic surgery (C-TORS), which successfully provided access to the anterior and midline skull base. For the C-TORS technique, standard robotic trocars are inserted at the posterior border of the submandibular gland with the robotic instruments directed cranially, parallel to the long axis of the spine. The camera was placed transorally, however, for the end effector instruments, a 3 mm cut was made through skin and platysma at the posterior border of the submandibular gland bilaterally, then standard plastic introducers and round-tip dilators were passed through those incisions and traced upward in a circular dissecting fashion until they were visualized intraorally using the camera. The introducers pierce the pharynx at the level of the lateral hypopharynx. They describe how using their technique they do not injure arteries, veins or nerves. McCool et al.[52] also described a transcervical approach along with a transoral approach for infratemporal fossa lesions using 4 cadaver models. While O'Malley described ports posterior to the submandibular gland, McCool placed a midline suprahyoid port, which pierces into the vallecula. He reported excellent visualization into the infratemporal fossa with a 30 degree scope.

Additionally, Ozer et al. described multiple approaches involving different placement of the camera and end effector instruments along with utilization of 0 degree and 30 degree scopes in order to achieve adequate visualization of the skull base.[53] They applied transoral, transnasal, transpalatal, and transcervical approaches to determine optimal visualization. Transnasal approaches required posterior septectomies while transpalatal approaches required elevation of a mucoperiosteal flap posterior to the molar teeth and resection of a portion of the hard palate and vomer. They concluded that the transoral camera and instruments with a 30 degree endoscope provide good control over the posterior and lateral nasopharynx without good control over the roof of the nasopharynx or posterior choana. The transnasal camera (0 degree) with transoral instruments provided great visualization but with cumbersome instrumentation. Overall, they felt the transpalatal approach was the best compromise of visualization and instrumentation for the nasopharynx, clivus and anterior skull base. Transcervical ports provided superior range of motion and use of instrumentation with the camera in any of the possible configurations.

Figure 29.4 TORS free flap inset in progress following resection of a recurrent oropharyngeal cancer of the tonsil and the tongue base. A medial sural artery perforator flap was used, and the pedicle fed into the neck via the oropharyngeal defect (Courtesy of Prof Vinidh Paleri, London).

Free flap inset via TORS

TORS has allowed removal of complex tumours from the oropharynx. As acceptability of the recognition of the safety and efficacy of the procedure has evolved, larger and more complex tumours are being treated. This has increased the need to reconstruct the oropharynx to provide velopharyngeal competence and reduce fistula risk. A number of algorithms have been proposed depending on the site and size of the defect. These range from allowing healing by secondary intent to velopharyngoplasties with local flaps, local flaps alone or in larger defects regional and free-flap reconstruction. Robotic assisted mobilization and inset of the flaps have been described in extending the range of options for these patients (**Figure 29.4**).[54, 55]

CONCLUSION

Robotic technology has demonstrated great promise in the field of otolaryngology. As the technology becomes refined and instrumentation is developed for the specific purpose of head and neck surgery, robotic surgery may have an even greater impact on minimally invasive surgical outcomes.

KEY POINTS

- Significant global expertise exists in transoral robotic surgery (TORS).
- TORS is primarily used for oropharyngeal and supraglottic primaries.
- Several ongoing randomized trials on transoral surgery will clarify the role of this modality in head and neck cancer treatment.
- Improvements in technology mean that transoral surgery is here to stay.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: head and neck cancer, oncogene, tumour suppressor gene, growth factor, epidermal growth factor receptor, tyrosine kinase inhibitor, monoclonal antibody, cell cycle control, DNA damage repair and immunotherapy.

INTRODUCTION

Cancer is a genetic disease that develops when the information in cellular DNA is corrupted or wrongly decoded. This leads to altered patterns of gene expression and derangement of normal protein function. Simply stated, genetic changes leading to cancer mediate two general effects: (i) overactivity of genes that stimulate cell growth, survival and spread; and (ii) underactivity of genes that repress these processes. Through these changes, cancer cells acquire properties that allow them to grow in an uncontrolled fashion, invade adjacent normal tissues, recruit their own blood supply, avoid immune detection and destruction, spread to distant sites and develop resistance to anticancer treatments. By understanding these processes, we have an opportunity to design and implement new classes of so-called targeted therapies that will exploit the fundamental biological differences between malignant and normal cells.

ONCOGENES AND TUMOUR SUPPRESSOR GENES

The functions of two classes of genes (oncogenes and tumour suppressor genes) are central to understanding cancer biology.[1] Oncogenes represent mutated versions of normal cellular genes (called proto-oncogenes) encoding proteins that control cell proliferation, survival and spread. In normal cells, the expression of proto-oncogenes is tightly regulated but, in cancer, abnormal proto-oncogene function causes uncontrolled cell division, enhanced survival (even during anticancer treatment) and dissemination. A single mutated copy of a proto-oncogene can promote cancer (so-called phenotypic dominance). Such mutations are rarely associated with inherited cancer syndromes: *ret* proto-oncogene mutations are associated with multiple endocrine neoplasia (MEN) syndromes (types 2A and 2B) and germline mutations in *H-ras* can cause Costello syndrome (high birthweight, cardiomyopathy and cancer predisposition). Oncogenes are activated in three ways to cause cancer:

- gene mutation can change the genetic code and enhance the function of the encoded protein (e.g. *RAS* mutation)
- gene amplification results in multiple additional copies of a normal gene being present in the genome (e.g. *EGFR* amplification)
- gene translocation, which is important in salivary gland cancers, involves movement of genetic material from its normal chromosomal locus to a new position which is usually on a different chromosome.

In contrast, tumour suppressor genes (TSGs) are normal cellular genes whose function inhibits cell proliferation and survival. The function of both copies of a TSG must be lost in order to promote cancer (so-called phenotypic recessiveness). Mutated TSGs are responsible for the majority of inherited cancer syndromes, although this is not a significant cause of head and neck cancers.

THE HALLMARKS AND ENABLING CHARACTERISTICS OF CANCER

Eight key changes that drive the malignant process have been described: these 'hallmarks of cancer' are: growth factor independence; evading growth suppressors; avoiding apoptosis; maintaining replicative potential; angiogenesis; invasion/metastasis; reprogrammed energy metabolism; and evading immune destruction (**Figure 30.1**).[2] In addition, two so-called enabling characteristics of cancer (genomic instability and inflammation) have been defined.[3] These processes are described briefly below.

Growth factor independence

In normal health, activation of growth factor receptors (GFRs) is very tightly controlled, as is the synthesis and release of the ligands that stimulate them. Cancer cells overactivate normal GFR signalling pathways to promote unrestrained cell division through three main strategies: (i) they make and release growth factors to stimulate their own receptors (autocrine signalling) and those on neighbouring cells (paracrine signalling); (ii) they modify the number, structure and/or function of surface GFRs to increase the rate and duration of receptor activation (even in the absence of ligand); (iii) they deregulate signalling pathways downstream of GFRs so they are permanently turned on (constitutively active).

Insensitivity to anti-growth signals

Anti-growth signals can force cells into quiescence (G0 stage of the cell cycle) or induce their terminal differentiation, which represents a state in which they will no longer multiply. Anti-growth signalling is mediated by cell surface ligand-receptor interactions, especially through transforming growth factor beta (TGF-β) binding to TGF-β receptor. Anti-growth signalling pathways mainly control cell progression and mediate their effects through retinoblastoma protein (Rb), cyclins, cyclin-dependent kinases (CDK) and their inhibitors (CDKi). Loss of normal anti-growth signalling pathways is extremely common in head and neck cancers.

Avoidance of apoptosis

Normal cells constantly audit the balance between incoming survival and death signals. They require constant 'reassurance' from their environment in order to prevent them from activating signalling pathways that would result in their committing suicide. In normal cells, DNA damage (including that induced by radiotherapy or chemotherapy) leads to a block in proliferation (cell cycle arrest) and an evaluation of the cell's capacity for repair. If the damage exceeds the repair capacity, the balance of survival and death signals swings in favour of the death signals and the cell commits to programmed cell death (apoptosis). This mechanism guards the genome against persisting DNA damage and prevents mutations being passed to the daughters of cell division. Loss of normal apoptotic pathway signalling is an extremely common event in cancer. Indeed, the best known cancer-associated gene (*p53*) is intimately involved in controlling apoptosis and is functionally inactivated in the majority of head and neck cancers.[4,5] By circumventing normal apoptotic signalling, cancer cells are better able to sustain DNA damage without its causing cell death and are more likely to be intrinsically resistant to anticancer treatments.

Sustained angiogenesis

In normal tissues, growth of new blood vessels (angiogenesis) is held very tightly in check by a balance between stimulatory (pro-angiogenic) and inhibitory (anti-angiogenic) signals, which normally favours inhibitory signalling.

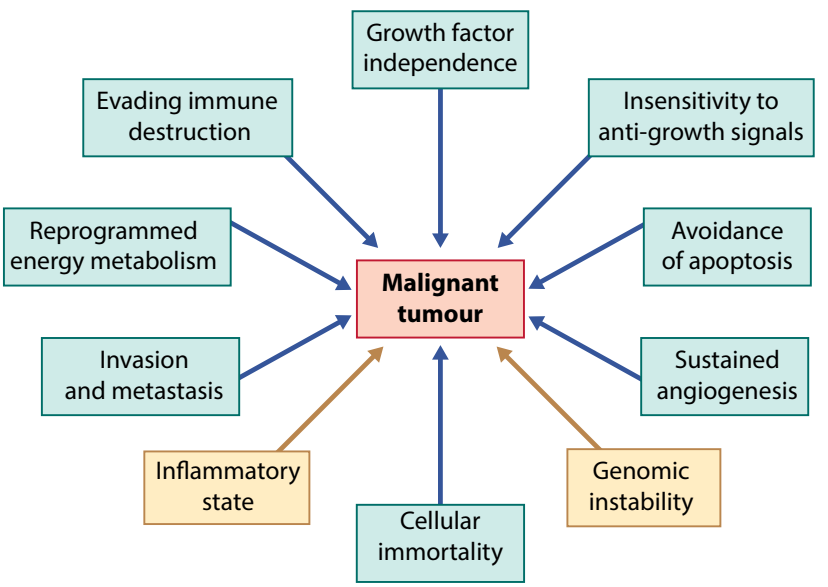

Figure 30.1 The eight hallmarks (blue boxes) and two enabling characteristics (yellow boxes) of cancer.

The growth of cancer deposits is linked to their being able to secure a dedicated blood supply. The diameter of growing cancer deposits is restricted to 60–100 μm by the diffusion limit of oxygen and nutrients from blood vessels. If a nascent tumour is to exceed this limit, it must develop its own blood supply. Cancers recalibrate the balance between pro- and anti-angiogenic factors and activate the so-called 'angiogenic switch'. To do this, they increase production of pro-angiogenic proteins, such as vascular endothelial growth factor (VEGF), and/or decrease production of anti-angiogenic proteins, such as thrombospondin-1.

Cellular immortality

Normal somatic cells can complete a finite number of cell divisions (Hayflick limit) before they permanently arrest their growth in a process of replicative senescence. This process occurs because cells cannot fully replicate the telomeric terminal portions of chromosomes at each cell division. Over time, telomeres shorten progressively, effectively behaving like molecular clocks that count down a normal cell's lifespan. In contrast, stem cells and malignant cells achieve immortality by maintaining the length of their telomeres. In most tumours, this process involves upregulation of cellular telomerase, but in 10–15% of cases a different mechanism called alternative lengthening of the telomeres (ALT) is responsible.

Invasion and metastasis

Distant metastases cause 90% of cancer deaths. A series of complex biological processes must be co-ordinated in order that metastasis can occur:[6] (i) disengagement from cellular and stromal attachments at the local site; (ii) degradation of the extracellular matrix followed by specific directional motility; (iii) invasion of blood/lymphatic vessels and tumour embolization; (iv) survival in the circulation until arrival at the metastatic site; (v) adherence to endothelium of blood vessels at the metastatic site and extravasation from the vessel; (vi) proliferation and invasion at the new location and recruitment of a new blood supply. The patterns of metastasis to specific organs are not random, but appear to be driven by expression of chemokine receptors by tumour cells that allow them to 'seek' a suitable environment in which to establish a colony.[7] Interestingly, the patterns of metastasis of human papillomavirus-positive (HPV+ve) and -negative (HPV-ve) head and neck tumours appear to be different and the underlying mechanisms of this phenomenon remain to be elucidated.

Reprogrammed energy metabolism

Chronic, uncontrolled cancer cell proliferation requires a reconfiguration of the way in which cancer cells metabolize glucose.[8] Normal cells process glucose, initially in the cytoplasm by glycolysis to yield pyruvate, and then in the mitochondria by oxidative phosphorylation to generate carbon dioxide and water. In contrast, even under oxygenated conditions, cancer cells tend to switch their metabolism to preferential use of glycolysis with generation of lactate (the so-called Warburg effect). As a consequence, they generate only two adenosine triphosphate (ATP) molecules per glucose (as opposed to a maximum of 38 via oxidative phosphorylation). As yet, the reasons for this apparently profligate use of glucose are not entirely clear but seem to provide proliferating cancer cells with a means of generating large amounts of essential metabolic precursors. This reprogramming is driven by mutations in key oncogenes and TSGs and this suggests that it is an important underlying principle of cancer biology.

Evading immune destruction

The relationship between a tumour and the immune system of the host in which it grows is immensely complex. According to the theory of immune surveillance, the immune system mounts a constant vigil against the emergence of premalignant and frankly malignant cells. The most frequently cited evidence for this comes from the observation that chronic immunosuppression (e.g. after kidney transplantation) is associated with a marked increase in specific cancers, especially those of viral origin. The immune system also appears to present a significant barrier to non-viral cancers in immunocompetent patients. However, it is clear that this function of the immune system frequently fails, as shown by the occurrence of malignant tumours. A paradigm that has been proposed to explain the interplay between an evolving tumour and the host's immune system over time is the so-called Elimination-Equilibrium-Escape model.[9] This model supposes that the immune system is frequently able to eliminate mutant precancerous/cancerous cell clones such that they never become clinically apparent. However, in some instances, the emerging tumour cells are able to suppress antitumour immune responses sufficiently to allow them to establish a state of equilibrium in which they can persist, albeit as microscopic, dormant deposits of malignant cells. Ultimately, some nascent tumour deposits will accumulate other changes (e.g. loss of tumour-associated antigens or major histocompatibility complex proteins) that will allow them to escape from immunosurveillance and emerge as clinically apparent malignancies. As part of this process, it is thought that selection of less immunogenic cancer cells (through immunoediting) and active recruitment of immunosuppressive components of the immune system (e.g. regulatory T-cells (T_{reg}) and myeloid-derived suppressor cells (MDSCs)) to some cancers allows tumours to develop and spread without becoming targets for immune clearance.

Although it is currently impossible to validate this paradigm, it provides a useful framework in which to approach the development of novel immunotherapies that may be able to target all aspects of the cancer-immune system interaction.

Enabling characteristics of cancer

The roles of genomic instability and inflammation in enabling carcinogenesis have recently been highlighted.

Genetic instability defines a state in which cancer cells lose control of the integrity of their genetic material. As such, they acquire an increasing repertoire of mutational changes that progressively alters their biology and promote the hallmarks of cancer. The second enabling characteristic describes the common situation in which premalignant and frankly malignant lesions excite an inflammatory state through the recruitment and activation of components of the immune system that promote and support tumour growth and spread.

BIOLOGICALLY TARGETED AGENTS

Huge improvements in our knowledge of the biology of cancer have opened up the possibility of developing novel targeted therapies for head and neck (and other) cancers. In this section, the review will focus on three specific themes that, at the time of writing, appear most promising. These areas are: (i) targeting growth factor independence; (ii) developing molecularly targeted drugs that enhance the response to radiotherapy (radiosensitizers); and (iii) enhancing antitumour immune responses using immunomodulatory monoclonal antibodies (MAB).

Targeting growth factor independence

Squamous cell cancers of the head and neck (SCCHN) very frequently display upregulated epidermal growth factor receptor (EGFR) signalling. EGFR is a member of the c-erbB family of transmembrane type I receptor tyrosine kinases. These receptors, comprising four members (EGFR/c-erbB-1/HER1, c-erbB-2/neu/HER-2, c-erbB-3/HER-3, c-erbB-4/HER-4),[10, 11] consist of a glycosylated extracellular ligand-binding domain, a hydrophobic trans-membrane component and an intracellular domain with tyrosine kinase activity (**Figure 30.2**). Binding of the cognate ligand to the specific ligand-binding domain on the extracellular component of EGFR leads to a cascade of intracellular secondary messengers that lead to altered patterns of gene expression, such that the binding of a protein on the cell surface is able to influence the cell's behaviour. Normally, activation of EGFR is tightly controlled, as is the synthesis and release of the ligands (transforming growth factor alpha and epidermal growth factor) that bind to it.

SCCHN achieves growth factor independence by: manufacturing and releasing growth factors that stimulate its own receptors (autocrine signalling) and those of neighbouring cells (paracrine signalling); altering the number, structure or function of the surface growth factor receptors that it displays; and by deregulating the signalling pathway downstream of the receptor. In contrast to certain tumour types where EGFR gene amplification or mutation is implicated, overexpression of the receptor, without gene amplification, is the dominant process whereby EGFR influences the pathobiology of SCCHN. A mutated form of EGFR (EGFR variant III) was reported to be present in 42% of head and neck cancers,[12] but recent reports have suggested that it does not play a major role in head and neck cancer biology.[13] The contribution of c-erbB-2 and c-erbB-3 expression to the biology of SCCHN remains unclear, but it is known that c-erbB-2:c-erbB-3 (HER2/HER3) heterodimers are potent inducers of the PI3-kinase anti-apoptotic pathway.[14]

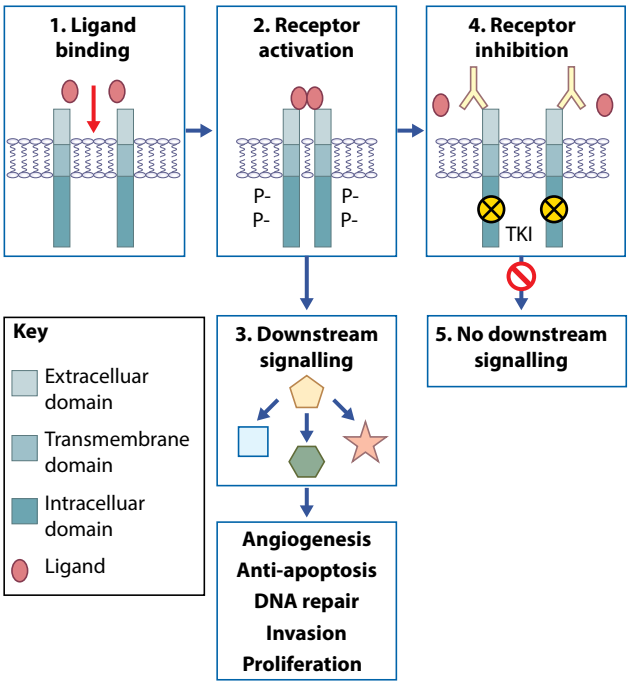

Figure 30.2 Growth factor independence can lead to sustained signalling in pathways that control essential biological functions, such as growth, apoptosis, angiogenesis, invasion and DNA damage repair. Ligand binding **(1)** leads to receptor dimerization and activation **(2)** through phosphorylation of tyrosine residues on the intracellular domain. Downstream signal transduction **(3)** activates important biological functions necessary for tumour growth, survival and spread. This process can be blocked **(4)** by monoclonal antibodies (MAB) that target the extracellular domain of the receptor or by small molecule tyrosine kinase inhibitors (TKI) that interact with enzymatic activity in the intracellular part of the receptor. These inhibitors are able to switch off downstream signalling events **(5)**.

c-erbB receptors are attractive therapeutic targets in SCCHN. Two classes of drugs, MAB and small molecule tyrosine kinase inhibitors (smTKI) have entered clinical trials. MAB are directed against the extracellular domain of the receptor, while smTKI inhibit the intracellular kinase domain of the receptor.

ANTI-EGFR MAB

Anti-EGFR MAB in the curative setting

A number of EGFR-targeted MAB have been tested in the clinic. They differ in terms of their species of origin (murine, chimeric (part human/part murine) or fully human) and the part (epitope) of the EGFR protein that they target. Cetuximab (C225, Erbitux) is a human-murine chimeric MAB. *In vitro* studies showed antitumour activity through anti-proliferative effects, direct cytotoxicity and potentiation of the effects of chemotherapy or radiotherapy.[15–18] In addition, *in vivo* experiments

demonstrated anti-angiogenic effects.[19] Early stage clinical trials confirmed the efficacy of cetuximab in combination with chemotherapy or radiotherapy.[20–24]

In a phase III study of 424 subjects with locally or regionally advanced SCCHN, locoregional control (median 24.4 vs. 14.9 months; hazard ratio: 0.68; P = 0.005) and overall survival (median 49.0 vs. 29.3 months; hazard ratio: 0.74; P = 0.03) were significantly prolonged in patients receiving radiotherapy and cetuximab compared to those treated with radiotherapy alone.[25] Cetuximab was associated with a higher incidence of rash and infusion reactions, but otherwise the grade 3 and greater toxic effects were the same in the 2 groups. Further analysis of the data showed that the occurrence of skin reaction represented a biomarker of favourable outcome in this group of patients.[26] The clinical importance of these findings, especially in an era in which concomitant chemoradiotherapy (not radiotherapy alone) is the standard-of-care, has been questioned. As a result, the Radiation Therapy Oncology Group (RTOG) conducted a follow-on study (RTOG-0522) in 940 patients with locoregionally advanced disease in which they tested radiation plus cisplatin versus radiation, cisplatin and cetuximab. Disappointingly, there were no significant differences in 2-year progression-free or overall survival rates.[27] The triple combination of bio-chemoradiotherapy was associated with significantly worse grade 3 and 4 mucosal/skin reactions. In a different approach, the phase II TREMPLIN study randomly assigned patients with locally-advanced laryngo-hypopharyngeal cancers, who had had a > 50% response to induction taxane-based triplet chemotherapy, to either concomitant cisplatin-based chemoradiotherapy or cetuximab-RT.[28] Of 153 patients who enrolled in the study, 116 were randomized after induction chemotherapy (i.e. they had a sufficiently good response to treatment). There were no differences in outcomes between the two treatment groups in terms of larynx preservation or overall survival.

Similar findings have been reported with a human MAB, zalutumumab, from the DAHANCA-19 study in which 619 patients were enrolled to receive modestly accelerated radiotherapy, the hypoxic cell sensitizer nimorazole and cisplatin (if indicated), with or without zalutumumab.[29] The majority of patients had stage III/IV disease and 70% received concomitant cisplatin. Treatment was well tolerated, but almost all (94%) patients in the zalutumumab arm reported a skin rash (grade 3–4 in 29%). No difference was seen between the study arms in terms of locoregional control at 3 years (78% in the zalutumumab arm and 79% in the control arm, (hazard ratio 0.8; 95% confidence interval 0.6–1.2). The data for disease-free and overall survival rates also failed to show a difference between the zalutumumab and control arms.

In addition, two studies with panitumumab (Vectibix), a fully human anti-EGFR monoclonal antibody have yielded negative data.[30, 31] The CONCERT-1 study randomized patients with previously untreated stage III-IVb disease to chemoradiotherapy or chemoradiotherapy plus panitumumab.[30] Of the 150 patients treated, 63 received standard chemoradiotherapy and 87 received chemoradiotherapy plus panitumumab. Locoregional control (LRC) at 2 years was non-statistically significantly better for standard chemoradiotherapy (68% vs. 61%) and the overall comparison for LRC showed a hazard ratio of 1.33 (95% confidence intervals (95% CI) 0.77–2.30). Data for progression-free and overall survival also showed no benefit from the addition of panitumumab (hazard ratios 1.15 (95% CI 0.68–1.96) and 1.63 (95% CI 0.88–3.02), respectively). The combination with panitumumab was significantly more toxic, with increased grade ≥ 3 dysphagia (40% vs. 27%), grade ≥ 3 mucosal inflammation (55% vs. 24%) and grade ≥ 3 radiodermatitis (31% vs. 13%). The CONCERT-2 study had a different design and evaluated platin-based chemoradiotherapy vs. radiation plus panitumumab (without platin chemotherapy) in patients with unresected stage III–IVb disease.[31] Of the 151 patients treated, 61 received standard chemoradiotherapy and 90 received radiation plus panitumumab. As with CONCERT-1, there was a non-statistically significant difference in LRC with radiation plus panitumumab performing worse (hazard ratio 1.61 95% CI 0.98–2.66), p = 0.06). A similar trend was also seen in terms of overall survival (hazard ratio 1.59 95% CI 0.91–2.79). Radiation plus panitumumab showed a statistically significant detriment for progression-free survival in this study (hazard ratio 1.73 (95% CI 1.07–2.81). Again, grade ≥ 3 radiation-induced toxicities were more common in the patients who received panitumumab.

Taken together, these data indicate that, in the curative setting, anti-EGFR MAB therapy should be restricted to the use of cetuximab plus radiotherapy. The precise indications for how this should be used, to replace cisplatin in patients who will not tolerate standard chemoradiotherapy or as a less toxic treatment in human papillomavirus positive oropharyngeal cancers (HPV+ OPC), remains to be defined precisely. In the latter case, a number of studies are ongoing to define the role of cetuximab plus radiotherapy combinations in HPV+ OPC [RTOG 1016 NCT01302834, UK De-Escalate HPV NCT01874171 and Trans-Tasman Oncology Group NCT01855451].

Anti-EGFR MAB in the palliative setting

Cetuximab has also been shown to improve the outcome of first-line palliative chemotherapy. In the EXTREME study, 442 eligible patients with untreated recurrent/metastatic SCCHN received cisplatin (100 mg/m^2) or carboplatin (area under the curve of 5 mg/mL/min) plus 5-fluorouracil (1 g/m^2 per day for 4 days) every 3 weeks for a maximum of 6 cycles. Cetuximab (400 mg/m^2 loading dose, then 250 mg/m^2 per week) was administered to 222 randomly selected patients. Patients in the cetuximab arm who showed stable disease were permitted to continue with maintenance cetuximab until disease progression or unacceptable toxicity. This study showed that the cetuximab/platinum/5-fluorouracil combination prolonged median overall survival from 7.4 months to 10.1 months (P = 0.04). There were also increases in the median progression-free survival time (3.3 to 5.6 months; P < 0.001) and the response rate (20% to 36%; P < 0.001).[32]

A similar trial design was employed for the SPECTRUM study, which evaluated the humanized MAB panitumumab. Patients in both groups received up to six 3-weekly cycles of intravenous cisplatin (100 mg/m^2) and 5-fluorouracil (1 g/m^2 per day for 4 days), while those in the experimental group also received intravenous panitumumab.[33] As in the EXTREME trial, patients randomized to panitumumab could continue maintenance MAB treatment. A total of 657 patients were randomized and the median overall survivals were 11·1 versus 9.0 months (hazard ratio 0·873; P = 0·1403) in the panitumumab and control groups, respectively. Despite this negative finding for overall survival, there was a statistically significant improvement in median progression-free survival in favour of panitumumab (5.8 vs. 4.6 months, hazard ratio 0·780; P = 0·0036). In sub-group analysis, the median overall survival in patients with p16-negative, but not p16-positive, tumours was prolonged in the panitumumab group (11.7 vs. 8.6 months; hazard ratio 0·73; P = 0·012). A number of toxicities, including rash and biochemical abnormalities were more common in the MAB-treated group.

Single-agent zalutumumab has been assessed in a 2:1 randomized phase III study versus best supportive care (including methotrexate) in 286 patients with platinum-resistant SCCHN.[34] The median overall survivals in the zalutumumab and control groups were 6.7 and 5.2 months (hazard ratio 0.77; P = 0.065), respectively. There was a statistically significant improvement in progression-free survival for zalutumumab (hazard ratio 0.63; P = 0.0012). As for previous studies, rash was more common in the group randomized to the anti-EGFR MAB.

Therefore, it appears that triple-agent therapy with platin/5-fluorouracil and cetuximab may be beneficial for patients as first-line therapy for relapsed/metastatic disease. In practice, many patients do not receive the triple therapy because of concerns about the additional toxicity of adding cetuximab to standard treatment. Although single-agent cetuximab is licensed for use in the USA, its use is not approved in Europe. Other single agent anti-EGFR MABs should not be used in relapsed/metastatic head and neck cancers.

SMALL MOLECULE TYROSINE KINASE INHIBITORS

Small molecule tyrosine kinase inhibitors in the curative setting

Gefitinib (ZD1839, Iressa) is a low-molecular weight smTKI that is highly specific for EGFR. By competing with ATP on the intracellular domain of EGFR it has been shown to prevent receptor autophosphorylation with resultant anti-proliferative effects observed in a variety of human xenograft models. Furthermore, combining gefitinib with cytotoxic chemotherapy increases growth inhibition and apoptotic cell death.[35–37]

It has been reported that gefitinib can be safely combined with chemoradiotherapy both with standard cisplatin-based chemoradiotherapy and with a rather unconventional split-course, twice-daily schedule with 5-fluorouracil and hydroxyurea.[38, 39] Results for erlotinib in this context have been disappointing with no improvement in treatment outcomes and increased toxicity when combined with chemoradiotherapy in a randomized phase II study.[40]

Lapatinib is an oral dual smTKI with action against both EGFR and c-erbB2/(HER-2).[41] It has demonstrated activity both *in vitro* and *in vivo*, as well as showing tolerability in phase I clinical trials.[42] A placebo-controlled randomized window-of-opportunity biomarker study has been performed with this agent in patients with advanced SCCHN. A single agent response rate of 17% was reported, with biomarker evidence of significantly reduced proliferation and receptor phosphorylation in the lapatinib treated group.[43] A phase I dose escalation study of lapatinib administered during radical chemoradiotherapy has been completed in patients with stage III and IV head and neck cancer.[44] Patients were enrolled in three cohorts of escalating lapatinib dose: 500 mg, 1000 mg and 1500 mg/day. Patients received one week of lapatinib alone followed by 6.5 to 7 weeks of the same dose of lapatinib plus radiotherapy 66–70 Gy and cisplatin 100 mg/m^2 on days 1, 22 and 43 of radiotherapy. The most common Grade 3–4 adverse events were radiation mucositis, radiation dermatitis, lymphopaenia and neutropaenia. The recommended phase II dose was defined as lapatinib 1500 mg/day with chemoradiation. Based on these findings, randomized phase II and III studies of lapatinib plus chemoradiation were initiated.

The randomized phase II study assessed the activity and safety of concurrent chemoradiotherapy and lapatinib followed by maintenance treatment in locally advanced, unresected stage III/IVA/IVB head and neck cancer.[45] Patients were randomized 1:1 to concurrent chemoradiotherapy and placebo followed by placebo or concurrent chemoradiotherapy and lapatinib followed by lapatinib. Treatment continued until disease progression or study withdrawal. Primary endpoint was complete response rate by independent review 6 months post-chemoradiotherapy. Sixty-seven patients (median age 56 years; 97% Eastern Cooperative Oncology Group performance status ≤1; 82% stage IV) were recruited. Lapatinib combined with chemoradiation was well-tolerated. Grade 3/4 toxicities during CRT were balanced between arms, with the exception of an excess of grade 3 diarrhoea (6% vs. 0%) and rash (9% vs. 3%) and two grade 4 cardiac events in the lapatinib arm. Complete response rate at 6 months post-chemoradiotherapy was 53% with lapatinib versus 36% with placebo in the intent-to-treat population. The progression-free survival and overall survival rates at 18 months were 55% vs. 41% and 68% vs. 57% for the lapatinib and placebo arms, respectively. The difference between study arms was greatest in p16-negative disease (median progression-free survival >20.4 months [lapatinib] vs. 10.9 [placebo]). These data led to the instigation of the randomized phase II TRYHARD study (NCT01711658) in patients with HPV-ve disease.

A randomized phase III study of lapatinib administered concomitantly with chemoradiotherapy and as maintenance monotherapy in patients with high-risk surgically-treated SCCHN has also been reported.[46] Patients with

resected stage II-IVA SCCHN, with a surgical margin ≤ 5 mm and/or extracapsular extension in metastatic cervical nodal disease were randomized to chemoradiotherapy (66 Gy total dose and 100 mg/m^2 cisplatin administered on days 1, 22 and 43) plus placebo or lapatinib (1500 mg/day) prior to and during chemoradiotherapy, followed by 12 months of maintenance monotherapy (either placebo or lapatinib). Six hundred and eighty-eight patients were enrolled; 346 received lapatinib and 342 received placebo. With a median follow-up of 35.3 months, the study was terminated early due to the apparent plateauing of disease-free survival events. Median disease-free survival was 53.6 months and not reached for lapatinib and placebo, respectively; hazard ratio 1.10 (95% CI 0.85–1.43). No significant differences in disease-free survival by HPV status, or overall survival, were observed between the two treatment arms. Similar numbers of patients in both treatment arms experienced adverse events, with more patients in the lapatinib arm experiencing serious events (48% vs. 40%). This study demonstrated that adding lapatinib to chemoradiotherapy and its use as long-term maintenance therapy did not offer any efficacy or safety benefits compared with placebo, in patients with surgically-treated high-risk SCCHN.

Afatinib is an irreversible inhibitor of EGFR, c-erbB2/HER2 and c-erbB4/HER4 that is being investigated in a number of settings in SCCHN. In the primary treatment setting, it is being tested in combination with chemoradiation (NCT01732640), and as adjuvant therapy after definitive chemoradiation in high-risk patients (phase III LUX2 study NCT01345669) or after surgery (GORTEC 2010-02, EudraCT 2010-023265-22). As yet, data are not available to permit a judgement of the potential role of this agent in the curative setting in patients with SCCHN.

Overall, despite significant clinical trial activity, there is no clear indication for the use of a smTKI in the treatment of newly diagnosed SCCHN. This is most clearly true in the case of combinations of smTKI with definitive chemoradiotherapy, but the existing data also suggest that there is no clear role in the adjuvant setting. Further trial data will become available in the coming years and this situation may change.

Small molecule tyrosine kinase inhibitors in the palliative setting

Gefitinib was evaluated in phase I trials that included a number of patients with head and neck cancer.[47–50] It was well-tolerated at doses from 150 to 800 mg/m^2, the most frequent grade 1 or 2 toxicities were diarrhoea (47–55%), asthenia (44%) and an acneiform follicular rash (46–64%). Antitumour activity, including both partial responses and cases of prolonged stable disease, was observed at all doses. Clinically meaningful stable disease was achieved in 50% of patients with SCCHN, and quality-of-life ratings also remained stable during treatment, except in one study where they improved significantly over time.[50]

A phase II study has evaluated oral gefitinib (500 mg/day) as first- or second-line monotherapy in 52 patients with recurrent or metastatic SCCHN most of whom had previously received combination chemotherapy or radiotherapy.[51] Forty-seven patients were evaluable for tumour response and an objective partial response rate of 10.6% (one complete response) was demonstrated. Disease control, defined as objective tumour response plus stable disease, was achieved in 53% of patients and was sustained for more than 6 months in 13% of patients. The response rates and survival times of patients who received gefitinib as first-line therapy were not significantly different to those of patients who had received prior chemotherapy. Overall, the median times to progression and death were 3.4 months and 8.1 months respectively, with an estimated 1-year survival of 29%. There was only a single case of grade 4 toxicity (hypercalcaemia), a 4–6% incidence of grade 3 toxicity (anorexia, diarrhoea, nausea and hypercalcaemia), grade 1 or 2 skin rash in 48% and grade 1 or 2 diarrhoea in 50%. A second study using single-agent gefitinib at a dose of 500 mg/day has also been reported.[52] Clinical, symptomatic and radiological response, time to progression, survival and toxicity were recorded. Forty-seven patients were treated and the observed clinical response rate was 8% with a disease control rate (complete response, partial response, stable disease) of 36%. Thirty-four percent of patients experienced a symptomatic improvement. The median time to progression and survival were 2.6 and 4.3 months, respectively. Acneiform folliculitis was the most frequent toxicity observed (76%) but the majority of cases were grade 1 or 2. Only 4 patients experienced grade 3 toxicity of any type (all cases of folliculitis). The 250 mg/day dose was also tested in phase II trial and appeared to be less active than the 500 mg/day dose.[53]

Subsequently, a randomized phase III study was conducted to compare survival in patients with recurrent or metastatic SCCHN treated with gefitinib 250 or 500 mg/day or standard-of-care single-agent methotrexate.[54] Four hundred and eighty-six patients were randomized to oral gefitinib 250 mg/day, gefitinib 500 mg/day, or intravenous methotrexate 40 mg/m^2 weekly. Neither of the gefitinib doses improved overall survival compared with methotrexate (hazard ratios 1.22 (95% CI, 0.95–1.57 and 1.12 (95% CI, 0.87–1.43), respectively. The median overall survivals were 5.6, 6.0, and 6.7 months for gefitinib 250 mg/day, gefitinib 500 mg/day, and intravenous methotrexate, respectively. Interestingly, gefitinib therapy appeared to be associated with an increased risk of haemorrhagic events. These data do not support the use of gefitinib as a palliative therapy in relapsed/metastatic SCCHN.

Afatinib has been assessed in the phase III LUX head and neck-1 study in patients receiving second-line therapy for relapsed/metastatic SCCHN.[55] A total of 583 patients were treated with afatinib (322 patients) or methotrexate (161 patients). Afatinib significantly increased median progression-free survival (2.6 vs. 1.7 months, p = 0.03) but did not improve median overall survival (6.8 vs 6.0 months) relative to methotrexate. The overall response rates of the two study arms were low – 10.2% and 5.6%, respectively. In an integrated analysis of quality of life, afatinib showed a delay in deterioration of global health status, pain and

swallowing problems (all $p \leq 0.03$). The profile of toxicities was markedly different between the two treatments, with afatinib causing more rash and diarrhoea and methotrexate causing more stomatitis and leukopenia. A randomized phase II comparison of afatinib and cetuximab has also demonstrated that afatinib has similar antitumour activity to cetuximab, as assessed by tumour shrinkage on treatment.[56] It remains to be seen if, on the basis of these data, afatinib finds a place in the treatment process for patients with relapsed/metastatic SCCHN.

Molecularly targeted radiosensitizers

Radiotherapy is an extremely effective therapy for SCCHN. Sophisticated modern 3-dimensional conformal planning techniques allow us to target tumour volumes more accurately than was the case with previous conventional methods. In addition, advanced delivery systems, such as intensity-modulated radiotherapy (IMRT) and image-guided radiotherapy (IGRT), offer the prospect of higher rates of tumour control with reduced toxicity.

In tandem with the development of advanced radiotherapy techniques, a parallel track of preclinical and clinical studies has evaluated combinations of radiotherapy with cytotoxic drugs in an attempt to enhance radiation-induced cytotoxicity in cancer cells.[57] As a result of meta-analyses of a large number of small- to medium-sized randomized trials, we now recognize radiotherapy delivered with concomitant platin monotherapy as the standard-of-care for locally advanced SCCHN.[58]

As discussed earlier, there is an increasing understanding of the molecular pathways leading to malignant transformation in normal cells. DNA damage, which is an inevitable consequence of cellular metabolism and proliferation, can also be caused by exogenous agents including ionizing and non-ionizing irradiation and environmental chemical toxins. Clinical and medical oncologists exploit these agents, in the form of radiotherapy and chemotherapy, to inflict DNA damage on cancer cells. However, cancers frequently have a deranged DNA damage response and, as discussed earlier, this leads to a state of genomic instability that can drive the evolution of more aggressive cellular clones within the tumour. Importantly, the loss of key components of the DNA damage response may also constitute a cancer-specific molecular 'Achilles' heel' that is vulnerable to therapeutic exploitation with a new generation of targeted radiosensitizing agents.[59] Development of radiosensitizers designed to target the DNA damage response (DDR) will require very careful clinical trial design, because of the potential risks of unwanted and unacceptable normal tissue toxicity arising from damage to normal cells.[57, 59]

CELL CYCLE CONTROL AND DNA DAMAGE REPAIR

Cell division is an essential component of development, growth and tissue repair. Since this process involves replicating the cell's genetic material, it is not surprising that it is tightly regulated to ensure that each daughter cell receives an accurate copy of the genome. Failure to copy the cellular DNA faithfully exposes the daughter cells to the risk of inheriting mutations. During the cell cycle, there are opportunities for the cell to slow down or pause while it assesses genomic integrity and corrects errors in the sequence of DNA. Cells can also slow down or stop in the cell cycle when they experience DNA damage, including that inflicted by radiotherapy and/or chemotherapy. Overall, there are 4 cell cycle checkpoints: at the G1/S transition, during S phase, early in G2 phase and late in G2 phase. Two of these are particularly relevant to the cellular response to radiotherapy. The G1/S checkpoint allows diploid (2n, 46 chromosomes) cells to pause before entering synthesis (S) phase, during which the entire DNA complement is duplicated to create a cell with 4n DNA content before mitosis. The TSGs *TP53* and retinoblastoma (*RB1*) play central roles in the G1/S checkpoint. *TP53* pathway mutation or inactivation is extremely common in many tumours, including head and neck cancers. In fact, smoking-induced SCCHN demonstrates almost universal loss-of-function mutations of the p53 pathway, with 84% of tumours showing *TP53* mutation in The Cancer Genome Atlas Network analysis.[4] In contrast, only 3% of HPV-positive SCCHN showed mutations of *TP53*, but these tumours inactivate the pathway through interactions between viral E6 and E7 proteins with p53 and Rb proteins, respectively.[4] As a result of this very frequent aberrant status of the G1/S checkpoint, most SCCHN have become highly reliant on a functional G2/M checkpoint.

Ionizing radiation induces a number of lesions in DNA, ranging from purine and pyrimidine lesions to single-strand (SSB) and double-strand breaks (DSB) in the DNA. DSB are potentially the most lethal DNA lesions induced by radiotherapy and therapies that can prevent their repair/resolution have the potential to be profoundly radiosensitizing. As might be expected, there are specific mechanisms to detect and repair radiation-induced abnormalities in DNA structure: DSBs are repaired by non-homologous end-joining (NHEJ) repair during G1 phase of the cell cycle and by high-fidelity homologous recombination (HR) in S and G2 phases; SSBs and base damage are repaired through the base excision repair pathway.[60]

Different types of radiation-induced DNA damage are sensed by mechanisms that activate specific DDR kinases: ataxia telangiectasia mutated (ATM) and ataxia telangiectasia and Rad3-related (ATR), which phosphorylate the checkpoint kinases, Chk1 and Chk2. In turn, these proteins transfer the signal to different effector molecules. The specific pathways involved are illustrated in **Figure 30.3**.

RADIATION-INDUCED CELL DEATH AND SYNTHETIC LETHALITY

Radiation-induced cell death requires cells to attempt to divide with unrepaired, damaged DNA. This is thought to result in cell death through mitotic catastrophe, in which a cell is unable to complete mitosis successfully and dies in the process.[61, 62] Alternatively, radiation can induce a state of replicative senescence in which the cell permanently loses

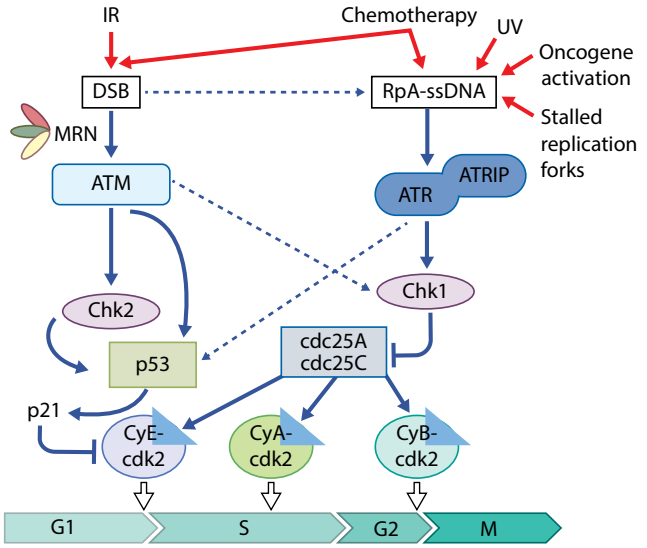

Figure 30.3 Schematic representation of the DNA damage response. The ATM pathway is activated strongly by DNA double-stranded breaks (DSB), causing activation of Chk2 and p53 with subsequent G1 cell cycle arrest. Diverse inputs converging on RpA-coated single-stranded DNA (ssDNA) activate the ATR-ATRIP complex, with downstream phosphorylation of Chk1, amongst other targets, resulting in G2/M arrest. The ATR pathway also plays an important role in S-phase progression and replication fork stabilisation. There is evidence of substantial crosstalk between these pathways (indicated by the dotted arrows).

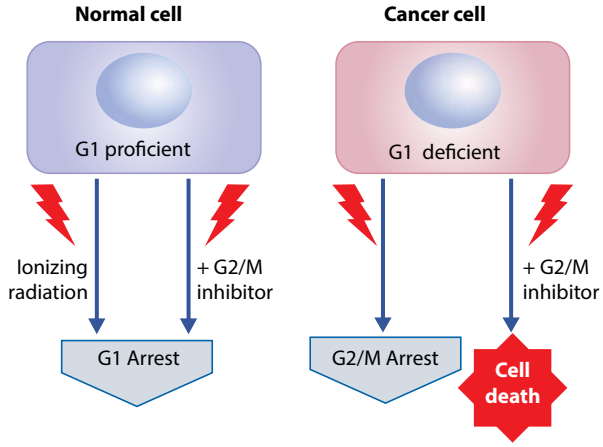

Figure 30.4 G1 checkpoint-deficient cancer cells rely heavily on radiation-induced G2/M arrest to survive after irradiation. Inhibiting the G2/M checkpoint in cancer cells will abrogate all checkpoint function in cancer cells, while intact G1 checkpoint arrest allows DNA repair in normal cells. This synthetically lethal interaction underpins interest in the G2/M checkpoint as a target for radiation-drug combination therapies.

the ability to divide and, thus, becomes non-clonogenic (and, therefore, no longer a threat to the host).[63] As discussed above, the majority of SCCHN (both HPV-ve and HPV+ve) lack a normal p53-mediated G1/S checkpoint and are highly dependent on the ATR-Chk1 pathway to mediate S and G2/M arrest to allow repair of DNA damage following irradiation. Thus, G2/M checkpoint control has been viewed as a particularly attractive target for cancer-specific radiosensitization.[59] Irradiated cancer cells that are defective in p53 pathway signalling will be unable to stop at the G1/S checkpoint and will be highly vulnerable to drugs that inhibit the G2 checkpoint.[64] Such cancer cells will proceed into mitosis before they have been able to repair their radiation-induced DNA damage and, as a result, will run a significant risk of mitotic catastrophe and cell death. This activity of G2/M checkpoint inhibitors in p53-defective tumour cells is an example of a so-called "synthetic lethal interaction" with ionizing radiation and represents a promising prospect for developing cancer-selective radiosensitizing drugs (**Figure 30.4**).

TARGETED DRUGS AS RADIOSENSITIZERS

ATR inhibitors

ATR inhibitors can radiosensitize cancer cells through disruption of the intra-S and G2 checkpoints and, perhaps, by disrupting ATR's roles in the DSB response, replication fork stabilization and the cellular response to hypoxia.[65,66] Small molecule inhibitors of ATR kinase have been tested in preclinical studies in combination with genotoxic chemotherapy or ionizing radiation. Thus far, there have been no publications on ATR inhibitors in patients with cancer, although early phase clinical trials have been initiated.

VE-821 (Vertex Pharmaceuticals, UK) is the most extensively studied ATR inhibitor to date. It caused cell death and growth inhibition in cancer cell lines and synergized with DNA-damaging agents, such as ionizing radiation.[67] The role of p53 pathway function in determining cellular sensitivity to VE-821 is, as yet, unclear.[65] A related molecule, VE-822 (Vertex Pharmaceuticals, UK) sensitized pancreatic cancer cell lines to both radiation and gemcitabine *in vitro*, without significant toxicity in normal cell lines. It also demonstrated efficacy in pancreatic tumour xenografts, with inhibition of radiation-induced Chk1 phosphorylation and a reduction in tumour growth when combined with radiation or gemcitabine-based chemoradiation in comparison to untreated or single-agent treated controls. Importantly, VE-822 did not cause any additional in-field gastrointestinal radiation-induced toxicity in animal models.[68] Specific studies in head and neck cancer models are not yet available, but it is reasonable to hypothesize that the data generated thus far should be relevant in the context of SCCHN.

AZD6738 (AstraZeneca plc) is a potent ATR inhibitor which can inhibit Chk1 pathway signalling.[69] The agent caused dose- and time-dependent induction of replication stress (measured by S-phase cell cycle accumulation by flow cytometry), increased DNA-strand breaks formation (measured by γH2AX focus formation) and growth inhibition/cell death *in vitro*. When combined with ionizing radiation *in vitro*, AZD6738 showed significant enhancement of growth inhibition activity compared to radiation or drug treatment alone in head and neck cancer (and other) cell lines. AZD6738 is currently being tested in phase I clinical trials, both as monotherapy and combined with either radiotherapy or chemotherapy [NCT02223923, NCT02264678].

Chk1 inhibitors

Chk1 is directly downstream of ATR in the DNA damage response signalling cascade and is phosphorylated by it. A number of Chk1 inhibitors have been tested preclinically,[70] but few have entered clinical trials. UCN-01 showed enhancement of radiation and genotoxic chemotherapy-induced cytotoxicity that was selective for p53-dysfunctional cells.[71] It was tested in phase I trials as monotherapy[72] and in combination with DNA-damaging agents such as platinum,[73] topoisomerase inhibitors[74] and nucleoside analogues.[75, 76] In phase II studies, UCN-01 was tested combined with DNA-damaging chemotherapy but its development was aborted due to lack of clinical efficacy.[77–79]

AZD7762 is a combined Chk1 and Chk2 inhibitor which radiosensitized tumour cells *in vitro* and *in vivo* in preclinical trials. Although it was initially suggested that this activity was p53-dependent, these data were not entirely clear-cut.[80, 81] In pancreatic cancer cell lines *in vitro* and in xenografts, AZD7762 sensitized to radiation alone and radiation in combination with gemcitabine, with abrogation of the radiation-induced G2/M checkpoint and inhibition of HR repair.[82] AZD7762 was tested in a clinical trial as a single-agent and in combination with gemcitabine (NCT00413686). Unfortunately, its development was terminated prematurely because of concerns about toxicity (especially cardiovascular effects which were manifest as significant reductions in cardiac ejection fraction).[83]

Other Chk1 inhibitors have been developed, including PF-00477736,[84, 85] MK8776 (otherwise known as SCH900776)[86] and SAR-020106.[87] The latter agent, SAR-020106, was shown to be a potent radiosensitizer both in *in vitro* and *in vivo* models. The drug inhibited radiation-induced G2/M arrest and reduced clonogenic survival in p53-deficient, but not p53-competent, tumour cells. Importantly, SAR-020106 promoted mitotic entry after irradiation in all cell lines: p53-deficient cells were likely to undergo apoptosis or become aneuploid, while p53 wild-type cells experienced a post-mitotic G1 arrest followed by subsequent normal cell cycle re-entry. Following combined treatment with SAR-020106 and radiation, HR-mediated DNA damage repair was inhibited in all cell lines. However, a significant increase in pan-γH2AX-stained apoptotic cells was observed only in p53-deficient cell lines. Efficacy was confirmed *in vivo* in a clinically relevant human head and neck cancer xenograft model.[87] The lack of oral bioavailability of this agent has arrested its clinical development. However, an orally bioavailable Chk1 inhibitor (CCT245737)[88] is entering clinical studies in a range of solid cancers and it is hoped that its development will include combination studies with radiation in disease subtypes that will include head and neck cancers.

Other G2/M-targeted checkpoint inhibitors

The Wee1 kinase regulates entry into mitosis, by negatively controlling CDK1 and 2. In a similar fashion to ATR and Chk1, it is active during normal unperturbed cell division, playing a role in the maintenance of genome integrity. A Wee1 kinase inhibitor (AZD-1775, formerly MK-1775) has been shown to sensitize p53-deficient tumour cell lines to radiation, with abrogation of radiation-induced G2 arrest and premature entry into mitosis.[89] The drug has also been shown to potentiate DNA-damaging agents *in vitro* and *in vivo*,[90, 91] and has reached a number of phase I trials. Cdc25 phosphatase is another G2 checkpoint target[92] and inhibitors have been developed that have shown activity against tumour cells and xenografts.[93]

Targeted immunomodulation as an anticancer strategy

In recent years, after decades of negative studies and false hopes, immunotherapy has emerged as a major new modality in the treatment of many solid cancers.[94] This change in the fortunes of immunotherapy has been underpinned by huge advances in our understanding of the fundamental biological principles that guide the activity of the immune system. In particular, a number of specific immune checkpoints have been discovered that are integral components of normal immune responses. In normal health, these checkpoints function to inhibit T-cells and prevent them from becoming chronically activated or aberrantly targeted against normal tissues. Effectively, they function as negative regulators or 'brakes' on the normal immune response. Many cancers subvert these inhibitory pathways in order to break free from immunosurveillance. Therefore, by activating brakes on the immune system, cancer cells are able to emerge from elimination/equilibrium phase and escape from immune detection and/or immune-related attack.[9]

Proteins that are expressed on activated T-cells, such as cytotoxic T-lymphocyte-associated protein 4 (CTLA4) and programmed death 1 (PD1), are key players that allow many cancers to evade anti-tumour immunity by interfering with the activation and effector phases of immune responses, respectively. CTLA4 is an important control mechanism that influences the activation phase of the immune response. As shown in **Figure 30.5**, when a specific tumour-associated antigen is presented by an antigen-presenting cell (APC) to a T-cell that expresses a T-cell receptor capable of recognizing it, there are two possible outcomes. In the first case, if the T-cell also receives a co-stimulatory signal via B7 on the APC binding to CD28 on the T-cell, the T-cell will become activated and capable of mediating an antitumour effect. However, in becoming activated, the T-cell upregulates CTLA4 on its surface and this is able to out-compete CD28 for binding of B7 on the APC. The net effect is that the T-cell can be switched off or anergized. Therapeutic MAB that target CTLA4 are able to block this negative interaction and enhance T-cell activation. In the effector phase of the immune

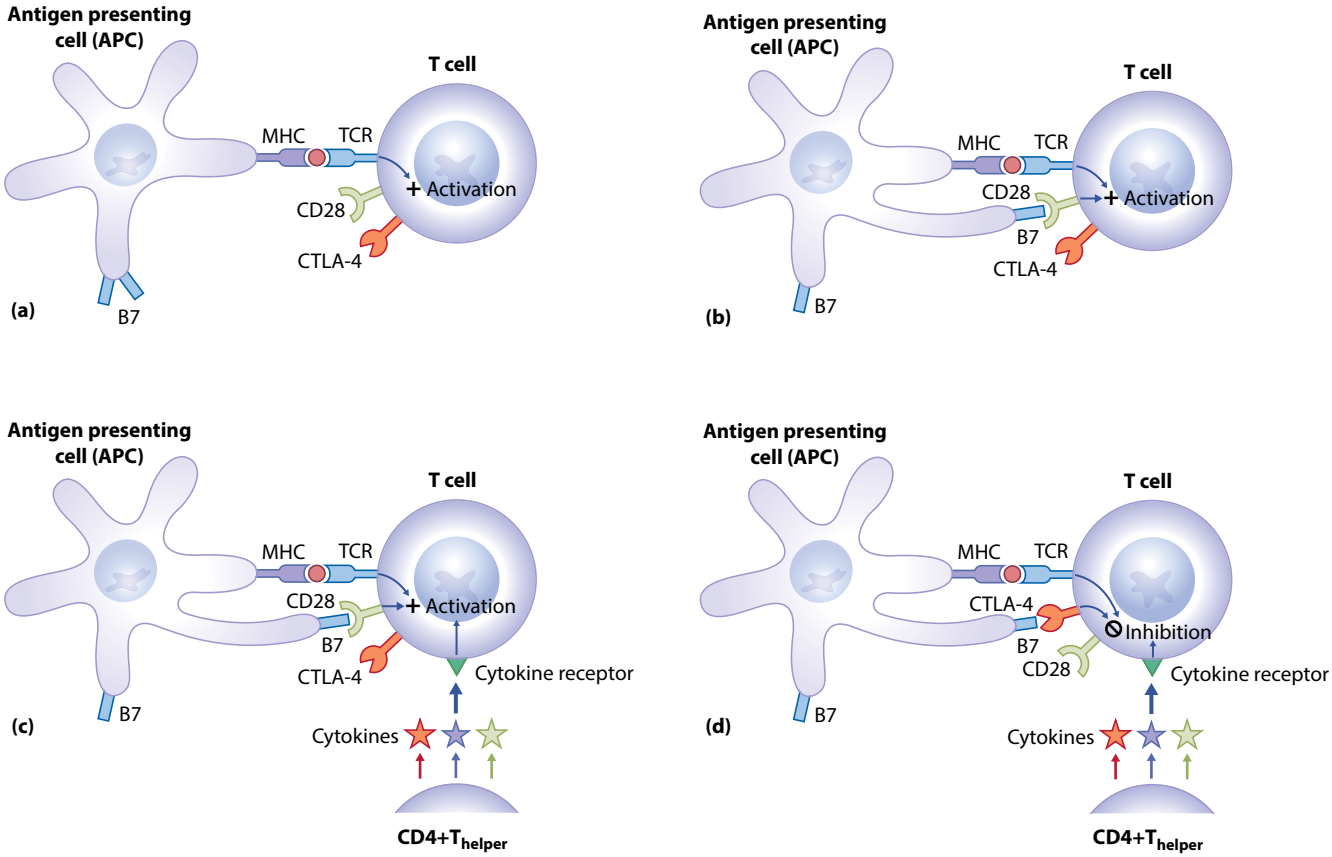

Figure 30.5 The activation phase of the immune response can be switched off by the T-cell protein CTLA-4. **(a)** Presentation of a tumour-associated antigen (TAA) on a major histocompatibility complex via a T-cell receptor leads to a positive signal (signal 1) to the T-cell; **(b)** To become fully activated, the T-cell must also receive a further signal (signal 2) when B7 on the APC binds to CD28 on the T-cell; **(c)** Activation is reinforced by cytokines released by CD4+ T_{helper} cells that bind to cytokine receptors on T-cells (signal 3); **(d)** Activation can be inhibited and the T-cell can be inactivated if CTLA-4 on the T-cell out-competes CD28 for binding of B7 on the APC (shutting off signal 2 and sending a negative message to the T-cell).

response (**Figure 30.6**), an activated T-cell can be prevented from engaging with and killing a tumour cell if the tumour cell expresses the negative regulatory ligand programmed death ligand 1 (PD-L1) on its surface (either constitutively or in response to interferon-gamma secreted by an activated T-cell). This negative interaction between T-cell and tumour cell can be interrupted by administration of specific MAB that block either PD-1 on the T-cell surface or PD-L1 on the tumour cell surface.

In addition to these two pathways, a large number of other checkpoints have been described at the immune checkpoint (e.g. TIM3, LAG3, OX40, GITR). Some of these checkpoints lead to inhibition and others to activation of immune responses. A large number of new therapeutic agents are currently in preclinical or clinical development and it is likely that some of these will reach the clinic in the next few years.

CLINICAL EXPERIENCE WITH CHECKPOINT INHIBITORS

Both anti-CTLA4 and anti-PD1/PD-L1 MAB have demonstrated significant activity in a range of non-SCCHN tumour types, including melanoma,[95–99] lung,[100] bladder[101] and mismatch repair-deficient bowel cancer.[102] Intriguingly, it appears that the likelihood of a patient deriving benefit from immunotherapy may correlate with the mutational burden and, hence, the neoantigenic load carried by their tumour.[103] This mutational load appears to be greatest in melanoma, but head and neck cancers (especially HPV-ve tumours) are also associated with a significant number of mutations.

In the context of SCCHN, there have been initial reports of single-agent activity in patients with relapsed/metastatic disease. The largest experience has accrued with single-agent therapy with the anti-PD1 monoclonal antibody, pembrolizumab. In the KEYNOTE-012 (NCT01848834) study, patients with PD-L1-positive (> 1% staining of tumour cells) tumours were divided into HPV+ve and HPV–ve cohorts and treated with 10 mg/kg of pembrolizumab every 2 weeks. Treatment beyond disease progression was permitted, as long as the patient was judged to be deriving clinical benefit from therapy. Overall, 26 of 51 patients had a reduction in tumour burden and 20% satisfied standard radiological criteria (RECIST v1.1) for response.[104] In a subsequent study, a larger group of 132 patients was treated with a fixed dose

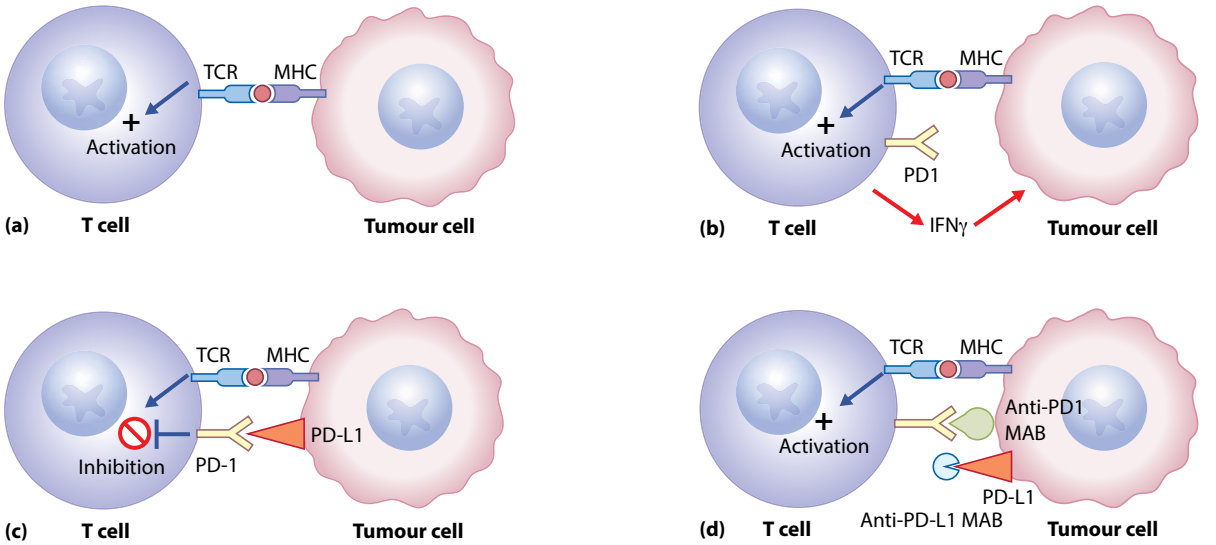

Figure 30.6 PD-1/PD-L1-mediated immune evasion by cancer can be reversed by immune checkpoint-inhibiting monoclonal antibody (MAB) therapy. **(a)** T-cells are frequently capable of recognizing tumour-associated antigens loaded on major histocompatibility (MHC) class I molecules. **(b)** In doing so, T-cells become activated and express programmed death 1 (PD-1) receptors on their surface and secrete interferon-γ (IFN-γ). **(c)** In response, tumour cells can upregulate expression of programmed death ligand 1 (PD-L1), which can bind to PD-1 on T-cells and switch them off. **(d)** Treatment with either anti-PD-1 or anti-PD-L1 MAB can block the interaction between PD-L1 on tumour cells and PD-1 on T-cells and as a result, anti-PD-1 or anti-PD-L1 MAB can reactivate T-cell activation against tumour cells.

of pembrolizumab (200 mg) every 3 weeks. Patients were included irrespective of PD-L1 status. The treatment was well tolerated with only 7.6% of patients experiencing a grade 3 or greater adverse effect. Of 99 patients who were evaluable for preliminary analysis, 18.2% showed a response (all partial responses) and 31.3% of patients had stable disease.[105] There are a number of ongoing randomized phase II and III clinical trials with both anti-PD1 and anti-PD-L1 agents (pembrolizumab [KEYNOTE-040 NCT02252042, KEYNOTE-048 NCT02358031], nivolumab [CHECKMATE-141 NCT02105636], durvalumab/MEDI4736 [HAWK NCT02207530, EAGLE NCT02369874] in patients with relapsed/metastatic disease that are likely to be reported in the next 2–3 years.

The clinical responses to immunotherapy tend to occur rather more slowly than with conventional cytotoxic chemotherapy and may be preceded by a period of disease progression – so-called pseudoprogression. In addition, the side effects of immune checkpoint inhibitors are entirely different from standard chemotherapeutic agents. In particular, by taking the brakes off the immune response, these agents are associated with significant auto-immune adverse reactions, such as skin rash, colitis, hepatitis and endocrinopathy (thyroid, adrenal and pituitary dysfunction). These effects appear to be more common with anti-CTLA4-targeted drugs rather than anti-PD1/anti-PD-L1 agents, but in all instances, require specialist management because they can evolve into serious, even life-threatening, conditions.

COMBINATIONS OF CHECKPOINT INHIBITORS AND RADIATION

There is evidence from both the laboratory and the clinic that radiation therapy can cause immunogenic cell death.[106–108] Furthermore, there are both preclinical and clinical data to demonstrate that immune checkpoint inhibition may enhance this effect and lead to systemic activity of a local therapy (e.g. radiation).[109, 110] These observations, combined with the excitement over single-agent activity of immune checkpoint inhibition, have led to a number of clinical studies that are combining immune checkpoint inhibitors with ionizing radiation. At present, there are no substantial reports of this approach in the literature, but it is likely that studies evaluating palliative hypofractionated radiotherapy and radical standard fractionation (with and without platin-based chemotherapy) will be reported in the coming years. This strategy certainly seems to hold promise, especially as a means of using intensive locoregional therapy as a means of generating systemic activity (and protection) against metastatic disease recurrence.

KEY POINTS

- An increasing understanding of the fundamental biological processes involved in cancer cell formation has resulted in the development and clinical use of drug strategies to treat head and neck cancer.
- Of note, Epidermal Growth Factor Receptor Inhibitors, Tyrosine Kinase Inhibitors, drugs which arrest cell cycle progression and sensitize cancer cells to the effects of radiotherapy have been used in various treatment regimens.
- Exciting improvements in treatment have resulted from the use of drugs which modulate the host immune system.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: maxillectomy, maxillary obturator, rhinectomy, facial prosthesis, dental assessment, dental implants, zygomatic implants and dental rehabilitation.

INTRODUCTION

This chapter deals with the planning and application of maxillofacial prosthodontic and prosthetic techniques for patients requiring prosthetic rehabilitation for surgical defects of the mouth and face. The text will primarily refer to the management of patients with oral, maxillary and mid-facial tumours.

Complex oral and facial rehabilitation aspects of treatment should be led by the maxillofacial prosthodontist in conjunction with the other core members of the multidisciplinary team (MDT) as well as additional extended members such as the dental hygienist and specialist dental/facial prosthetic technicians (See Chapter 97, A combined prosthetic and surgical approach). Where patients are dentate, ongoing liaison with the patient's primary dental care practitioner is also of utmost importance.

Osseointegrated implants are a very important tool in the management of complex oral and facial defects and the appropriate expertise should be available in the MDT to allow their application where clinically indicated either at the time of primary surgery or as part of definitive secondary rehabilitation. An appropriate funding stream for such treatment is also required due to the complexity and cost of these individual bespoke rehabilitative treatments.

Oral and facial rehabilitation treatment seeks to help address, or in many cases palliate, the patient suffering from the negative unwanted effects of surgical and oncological treatment modalities (**Box 31.1**).

BOX 31.1 Negative effects of treatment for H&N cancer

- Altered oral and facial anatomy
- Maxillary and facial defects
- Trismus
- Xerostomia
- Altered dental occlusion
- Bulky soft-tissue flaps
- Altered facial sensation
- Speech and swallowing problems

PRE-SURGICAL ASSESSMENT

All patients with oral, oro-pharyngeal, maxillary and mid-face tumours should be seen and assessed by the maxillofacial prosthodontist at an early stage in the patient journey, especially where there are good reasons to undertake early prosthetic rehabilitation. Dental pathology is extremely common in this group of patients and

appropriate dental management is required for the majority of patients.[1] All dentate patients should have a screening panoramic dental radiograph in conjunction with a detailed oral examination with appropriate decision making regarding dental extractions, restorations and definitive planning for prosthetic rehabilitation in terms of osseointegrated implant placement to support any definitive prosthesis that may be required.

Following a detailed assessment of the patient's dentition, a final decision regarding the definitive treatment plan should be made in the light of the patient's oral and general motivation, whilst taking into account the likely effects of the proposed oncological treatment strategy. Ideally, risk factors such as smoking and alcohol consumption should be addressed where they exist pre-treatment if complex rehabilitative treatments are to be considered. The overall proportion of head and neck cancer patients receiving osseointegrated implant treatment has been reported to be quite low.[2] Careful patient selection is required to ensure that the patient receives the appropriate benefit of the treatment especially where implants are placed primarily at the time of primary oncological surgery.

MANAGEMENT OF THE MAXILLECTOMY DEFECT

Prior to the advent of predictable free vascularized tissue transfer, the management of many maxillectomy defects was via prosthetic obturation. The use of prosthetic obturation has subsequently decreased considerably in modern surgical practice but still has a useful role in the management of patients who cannot receive complex autogenous reconstruction, where the access for subsequent surveillance is deemed to be an advantage or for small well-defined maxillary defects.

The use of a classification based approach to decision-making is a useful one and such classifications such as those by Brown[3] and Okay[4] are helpful in this respect. Brown's surgical-based classification has been widely adopted when considering the decision to reconstruct the maxilla and mid-face surgically whereas Okay's work is more directed to the maxillofacial prosthodontist and is very helpful in the design of maxillary obturator prostheses depending on the remaining dental configuration following surgery.

The decision-making process should be a joint one between the surgeon, the prosthodontist and the patient. It is clearly a multifactorial process and has to take into account the size and location of the tumour, the tumour subtype and histological features, the perceived prognosis for the patient and their fitness for surgery, their current dental status, mouth opening and desire for future dental rehabilitation.

In general terms, the more extensive maxillary defects should be surgically reconstructed with free tissue-transfer techniques. When the defect extends out of level 2,[3] the overall facial result tends to worsen and is more difficult to maintain with a prosthetic obturator (**Figure 31.1**). Defects involving the orbital floor should also ideally be reconstructed wherever possible to prevent the inferior displacement of the globe which results in a poor aesthetic facial appearance (**Figure 31.2**).

Preparation for a maxillectomy combined with prosthetic obturation must begin in advance of the operation with an outpatient visit with the maxillofacial prosthodontist. A clear and detailed surgical treatment plan should be provided to allow adequate planning and prescription for the surgical obturator prosthesis. Specifically, the planned alveolar margins of the resection in the dentate patient are very important to the accuracy of fit of the prosthesis at surgery (**Figure 31.3**). Dentate patients will always require pre-operative impressions for models and prosthesis construction whereas the edentulous patient may not, depending on whether they are currently wearing a well made and extended prosthesis. Often the surgical obturator prosthesis can be constructed with appropriate tooth replacement included but where there are significant time constraints prior to surgery or for the non-denture wearing edentate patient, a simple clear acrylic cover plate can

Figure 31.1 Lip contracture following level 2 maxillectomy and obturation.

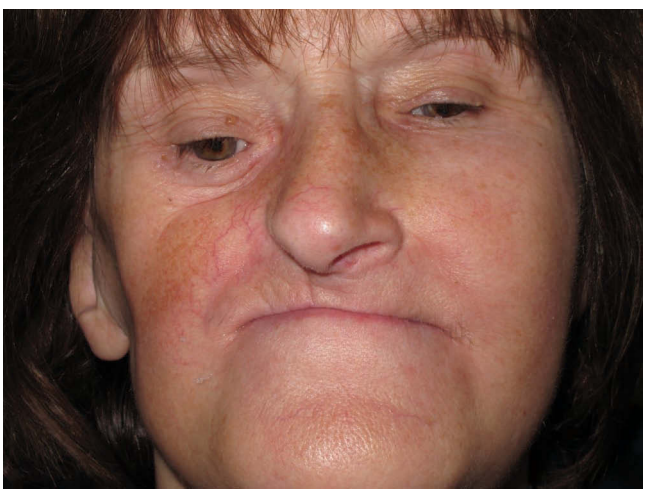

Figure 31.2 Significant drop in right globe position following maxillectomy involving the orbital floor.

Figure 31.3 Marking the cast prior to maxillectomy.

Figure 31.4 Surgical obturator with loops for circum-zygomatic wires.

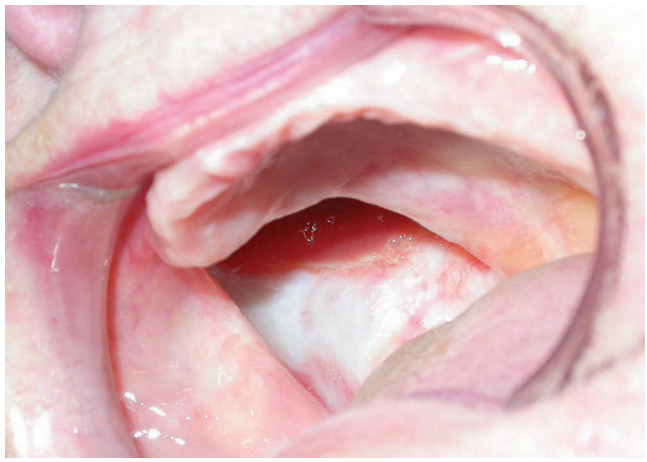

Figure 31.5 Healed split-skin graft in the cheek producing retentive scar band for obturator prosthesis.

be constructed. Depending on the size, extent and location of the proposed maxillectomy defect, the prosthesis should contain appropriate elements designed to assist with the retention of the appliance such as dental clasps or circum-zygomatic loops (**Figure 31.4**). Where ongoing retention difficulties are foreseen by the maxillofacial prosthodontist, specific plans for the concomitant insertion of osseointegrated implants at the time of surgery should be made.

A clear explanation of the various stages of treatment should be given to the patient, including the need for regular follow-up visits with the prosthodontist following surgery, together with what they should expect from the prosthetic obturator.

SURGICAL MODIFICATIONS TO FACILITATE OBTURATOR PROVISION

Where possible, bone cuts through the maxillary alveolus should be undertaken through an edentulous region or through the middle of a dental extraction socket following the removal of the required tooth to facilitate this. This ensures that any remaining abutment teeth have uncompromised periodontal bone support for the future which is so important in their ongoing role in supporting the obturator prosthesis.

The incisions through the hard palate mucosa should ideally be made laterally to the bone cuts to create a keratinized mucosal flap which folds over the cut edge of the palatal bone. This provides a cushioning effect for the future prosthesis which tends to move about this axis to some degree during masticatory function.

The cheek defect should be grafted with a carefully sutured split-skin graft. This results in the production of a scar band within the cheek which helps to retain the obturator prosthesis (**Figure 31.5**). This is essential where a conventional obturator is being provided and this is one of the few areas where retention can be gained. Its use is less important where other forms of retention such as osseointegrated implants are to be used to assist with prosthesis retention.

Where exposed into the resulting defect, the inferior turbinate(s) should be removed to provide more vertical space for the obturator elements of the prosthesis and to prevent future trauma. Once the resection has been completed, the surgical obturator prosthesis should be relined and fitted prior to extubation of the patient. A variety of materials have been advocated to obturate the surgical defect including black gutta percha, silicone putty impression material and foam-based products. The author favours the use of addition-cured silicone putty as it is readily available, easy to use and provides rigid support for the cheek as well as the ability to engage undercuts in the defect which can assist in the overall retention of the prosthesis in the immediate post-operative period. It can

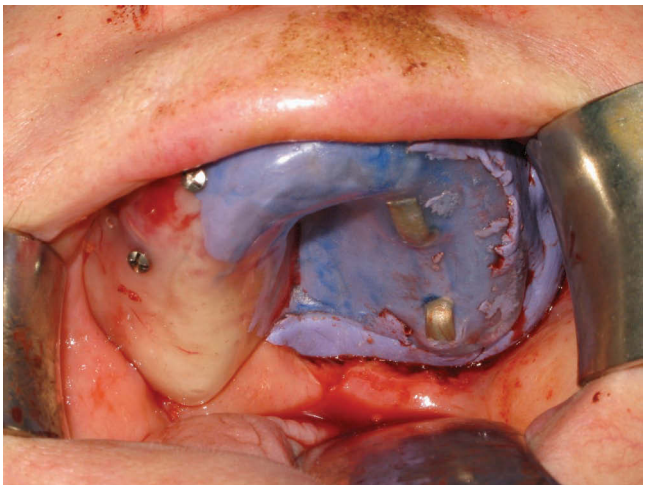

Figure 31.6 A screw retained surgical obturator relined with silicone putty.

Figure 31.7 A simple maxillary obturator prosthesis with integral soft bung to engage defect undercuts.

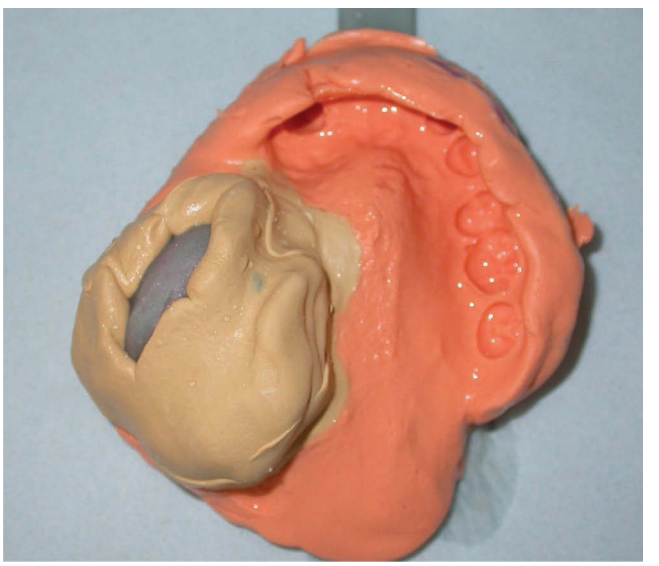

Figure 31.8 A multi-part dental impression.

also assist with haemostasis where there is residual oozing from within the defect.

The fixation of the surgical obturator will depend on the defect size as well as the presence of remaining teeth and residual alveolar bone in the maxilla. Where the defect is small and there are plenty of remaining teeth, dental retention utilizing clasps will usually suffice. In larger defects, additional retention is often required utilizing bone screws and/or circum-zygomatic wires (**Figure 31.6**).

Post-operatively the surgical obturator will require removal and modification as the defect heals and begins to change in dimensions. Smaller defect cases can often be managed in the outpatient clinic whereas larger defects may require a return to the operating room especially where circum-zygomatic wires have been employed as a means of retention. The surgical obturator is generally left *in situ* for 1–3 weeks before it is modified and relined to improve its oro-nasal/oro-antral seal and general comfort for the patient. The patient is instructed on how to remove, clean and replace the prosthesis. The patient is followed up on a regular basis with further modifications being made to the prosthesis until such time as further impressions can be made to construct a more definitive obturator.

Figure 31.7 demonstrates the definitive obturator prosthesis for a patient with a low-level partial maxillectomy. The soft silicone bung material assists in the retention of the prosthesis by engaging the natural undercuts in the defect by means of the surgical technique.

MULTI-PART MAXILLARY OBTURATORS AND THE USE OF OSSEOINTEGRATED IMPLANTS

Many patients experience significant trismus following maxillectomy especially where surgery is combined with radiotherapy.[5] This factor must be taken into account when planning prosthetic obturation of maxillary defects and may lead to the decision to remove further teeth to allow access for the obturator. In partially dentate patients, significant trismus can lead to difficulties in the access for impression making and indeed in the placement and removal of the prosthesis. In many cases, impressions need to be taken in several parts (**Figure 31.8**) and the definitive obturator can also be fabricated with a separate obturator component which is joined intra-orally with the dental prosthesis component. **Figure 31.9** demonstrates this approach for a low-level maxillectomy defect in the posterior maxilla. The obturator component is inserted directly into the defect initially and attaches to the overlying dental prosthesis by means of a magnet embedded into the acrylic surface of the obturator component which combines with another magnet in the intaglio surface of the dental prosthesis.

Where more extensive maxillary defects are to be obturated or in the edentulous patient where retention

Figure 31.9 A 2-part obturator with magnet linkage.

difficulties are anticipated, the use of osseointegrated dental implants may be employed. Mostly these retention aids should be placed at the time of resection especially if radiotherapy is to be utilized post-operatively. **Figure 31.10** demonstrates the use of zygomatic implants to retain a large maxillary obturator in an edentulous patient. These implants achieve very high initial stability and can be used at a very early stage to support the obturator. In this case, the implants are splinted together with a retentive bar to retain the obturator. In such cases, the extent to which the prosthesis needs to engage into the defect is much reduced as this is not required for its retention.

PROSTHETIC MANAGEMENT OF FACIAL DEFECTS

The use of facial prostheses to reconstruct surgical or congenital defects of the nose, mid-face, orbit and external ear is well established and is reviewed very nicely in a recent review article by Ariani et al.[6] The use of silicone-based facial prostheses is a highly effective way of providing the patient with an aesthetic tissue replacement in situations where surgical reconstruction with autologous tissue would be extremely challenging or not possible due to anatomical constraints or patient fitness. The construction of such bespoke prostheses requires great skill on the part of the prosthetic technician and careful planning on the part of the surgical team and maxillofacial prosthodontist to provide a defect of adequate dimensions and with appropriate retentive elements. Whilst the use of skin adhesive products together with the use of mechanical features such as defect undercuts and spectacle frames were the main methods to retain facial prostheses, the last 30 years has seen a shift to retention of facial prostheses with osseointegrated implants.[7-9] Whilst conventional adhesive retained prostheses still have their role, patients find them difficult to locate, subject to dislodgement during daily functions as well as suffering from skin irritation.[10]

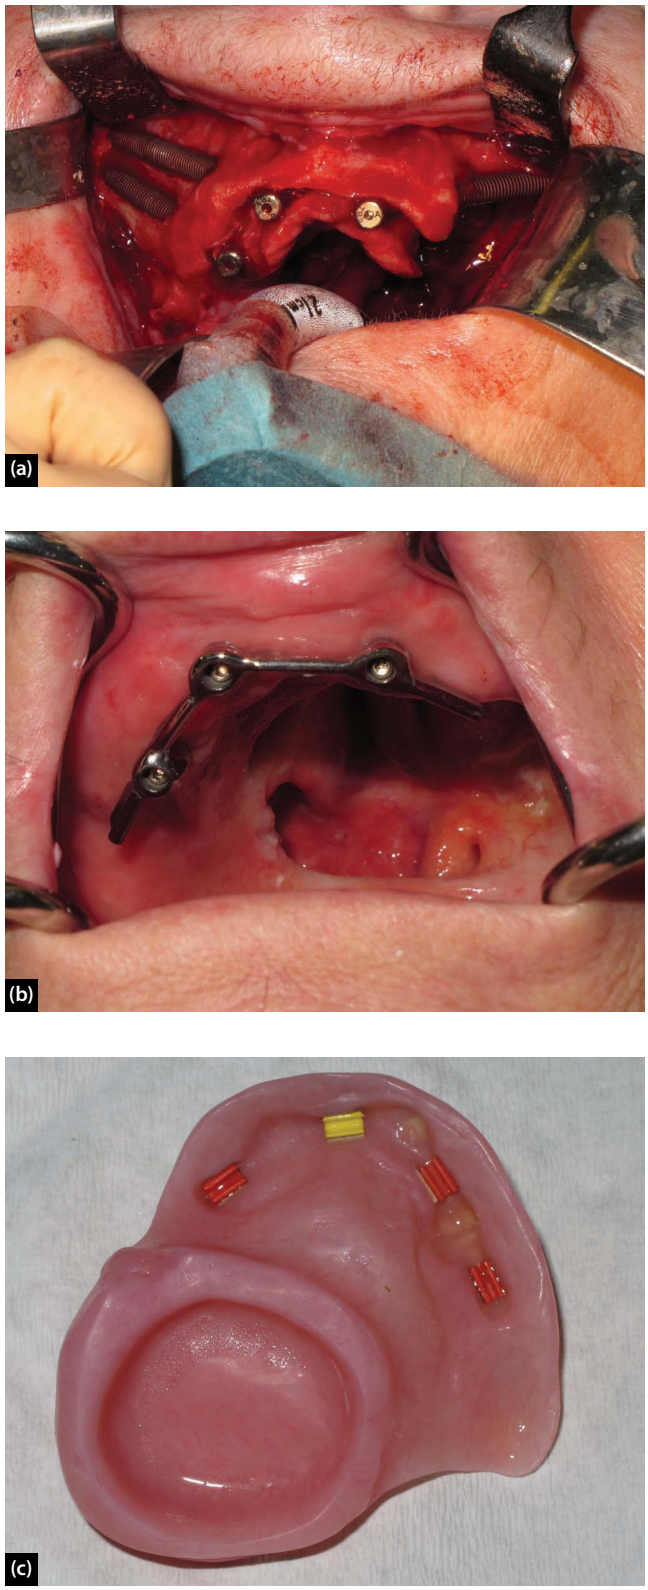

Figure 31.10 The use of zygomatic implants to retain a maxillary obturator prosthesis. **(a)** Multiple zygomatic implants placed at the same time as a left-sided maxillary resection. **(b)** Zygomatic implant retained bar to provide improved support and retention for the removal of the maxillary obturator. **(c)** Maxillary obturator with ink-well obturator componenet and retentive components to fit onto zygomatic implant bar.

A number of pre-prosthetic surgical techniques are widely accepted in order to maximize the benefit from the facial prosthesis[11] depending on the area concerned. Small areas of unsupported tissue should be removed, where possible, to provide a solid margin to support the periphery of the prosthesis. A suitable cavity should be provided to accommodate the prosthesis and this is especially true in mid-face and orbital cases. If possible, the bulk of vascularized flaps in this area should be kept to a minimum or subsequently debulked prior to prosthesis construction. Sharp bony margins of the resection should be smoothed and the use of split-skin grafts is encouraged especially within the orbit as, once healed, they can provide a stable, hair free, and drier surface.

Where rhinectomy is undertaken, preservation of the nasal bones, when oncologically safe, is advantageous as it provides useful vertical support for the prosthesis and for spectacle wear. Reduction of the projection of the nasal septum helps create space within the defect for implant frameworks, where these are employed, and also helps reduce secretions in the area of the prosthesis.

A variety of endosseous implant types have been successfully employed to retain facial prostheses ranging from very short (3–5 mm) 'extra-oral' implants, conventional 'dental' implants and very long (30–55 mm) zygomatic implants.[9]

Figure 31.11 demonstrates the use of horizontally placed zygomatic implants to retain a large mid-face prosthesis.

Figure 31.11 Horizontally placed zygomatic implants used to retain a large mid-face prosthesis.

DENTAL ACCESS SURGERY TO ASSIST TRANS-ORAL PROCEDURES

Trans-oral surgery is increasingly used in the management of benign and malignant processes. However, access for such techniques can be hampered significantly by a range of factors such as trismus, a class 2 skeletal profile and the presence of maxillary anterior teeth. Alternative trans-oral techniques have been reported for pharyngeal pouch repair in patients with trismus[12] as open surgery is perceived to hold higher morbidity for patients. The use of dental extractions to facilitate trans-oral ENT procedures is rarely reported but should be considered in conjunction with the maxillofacial prosthodontist as a means of facilitating surgical access.[13] Tooth replacement with fixed or removable dental prostheses can be subsequently provided depending on the patient's presenting dental status and wishes.

RESTORATION OF THE DENTITION FOLLOWING ABLATIVE SURGERY

Patients presenting with head and neck cancer often present with significant dental issues at time of presentation.[14] There are high levels of dental phobia and anxiety reported in this population of patients and this often results in a degree of dental neglect. Many patients are elderly and a significant proportion of patients are edentulous at the time of presentation. In addition, resective surgery for malignant tumours within or adjacent to the maxillary and mandibular alveolar bone require the removal of sections of the dentition either as a rim or segmental resection to achieve oncologically safe margins. The resulting post-surgical condition of oral cancer patients is therefore highly varied and each one presents a range of challenges in respect to successful dental rehabilitation. Soft and hard free-tissue reconstruction techniques can often lead to the presence of residual bulky soft tissue skin flaps overlying the jaws obstructing the dental envelope (**Figure 31.12a**).

However, there is little doubt that the use of composite free flaps to reconstruct segmental jaw defects has very much improved outcomes for patients and can usefully provide a foundation for osseointegrated implant insertion in selected cases.[4]

Decisions regarding the dentition need to be made prior to surgery to ensure that the patient's subsequent oral function is maximized and that untreated dental pathology does not remain untreated. The patient's wishes and motivation regarding their dentition and subsequent rehabilitation should be taken into account along with their habitual risk factors, the site, extent and behaviour of their presenting tumour and their predicted prognosis. Where radiotherapy is to be used as an adjuvant treatment, the dose, fields and fractionation of treatment and their likely effect on the remaining dentition should be carefully considered when arriving at a suitable treatment plan for the dentition.

Where dental rehabilitation is to be provided, the aims, advantages and limitations of treatment should be

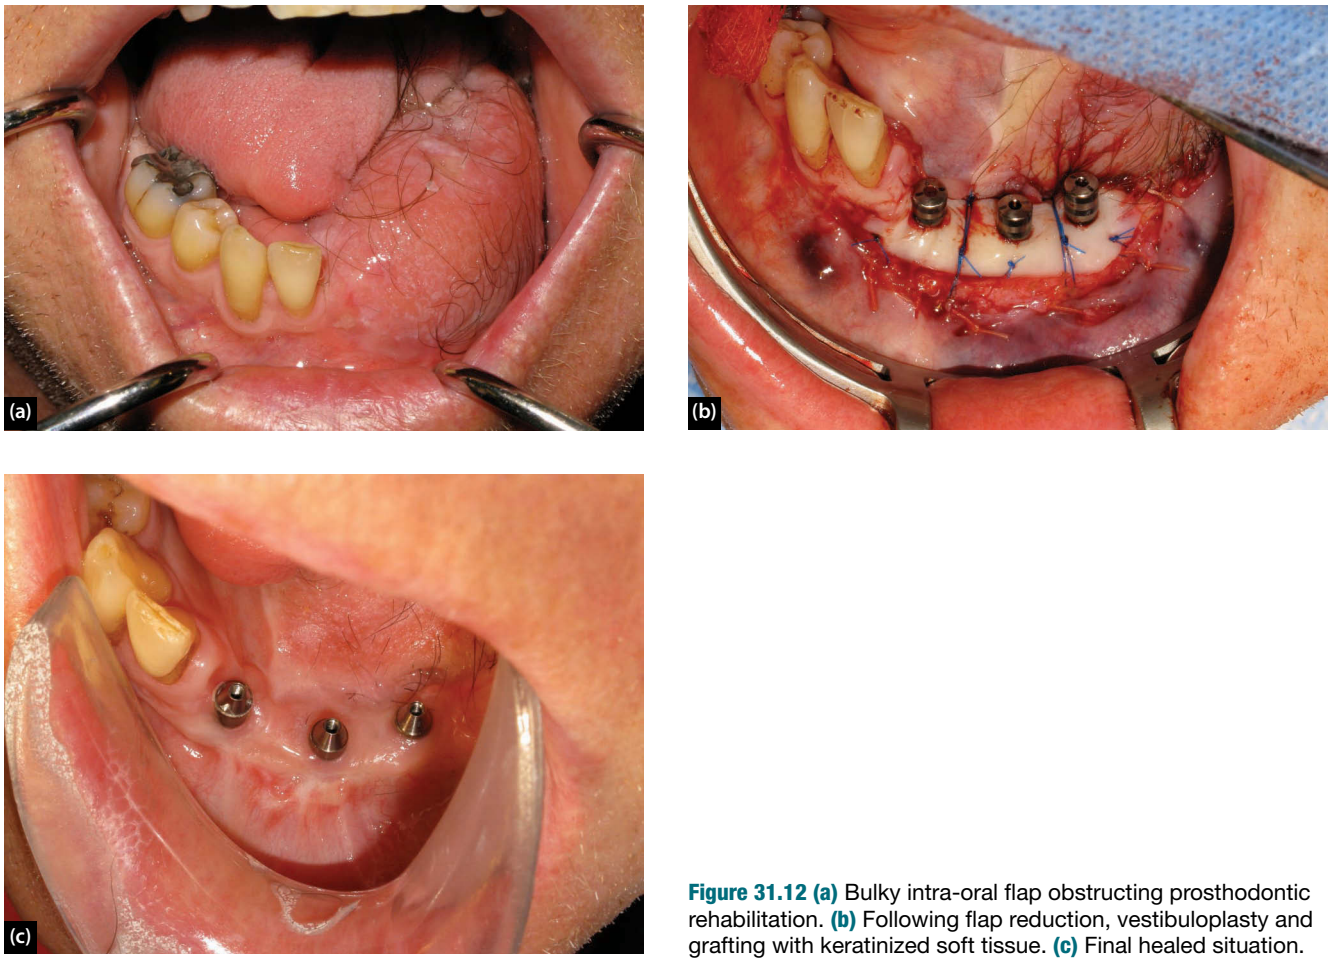

Figure 31.12 (a) Bulky intra-oral flap obstructing prosthodontic rehabilitation. **(b)** Following flap reduction, vestibuloplasty and grafting with keratinized soft tissue. **(c)** Final healed situation.

acknowledged with the patient. Whilst patients can benefit enormously from the cosmetic improvement in appearance following prosthodontic treatment, they are often left with functional problems associated with chewing and swallowing and these are to a large part associated with the degree to which their overall tongue function has been affected by the cancer treatment modalities. In addition, patients always tend to favour chewing on their non-resected side following jaw resection so restoration following a small posterior mandibulectomy is often not required if the patient has a good complement of remaining functional natural teeth.

A small number of patients can receive, tolerate and function reasonably well with conventional fixed and removable dental prostheses following surgery but the majority of patients who have undergone reconstructive procedures within the mouth are often left with aberrations in intra-oral anatomy that are difficult to overcome with simple dental prostheses alone. It is in this context that the maxillofacial prosthodontist relies on the use of osseointegrated implants to overcome these difficulties.

Primary dental implant placement

In some carefully selected patients, there will be a case for the immediate installation of osseointegrated implants at the time of primary resective surgery in order to provide a future effective prosthetic dental rehabilitation within a reasonable timescale (**Figure 31.13**). The placement of implants at the same time as the resective surgery has a number of advantages and potential disadvantages (**Table 31.1**) although a recent systematic review[15] has shown that this is a highly effective treatment in facilitating dental rehabilitation with high levels of implant survival, despite subsequent post-operative radiotherapy.[16] The majority of patients (75%) go on to complete their dental rehabilitation and show improvements in their quality of life (QOL). Not surprisingly, patients receiving post-operative radiotherapy report poorer QOL scores than their counterparts who did not require radiotherapy.[17]

The use of primary osseointegrated implants has been reported mainly in patients with intact mandibles who are undergoing soft-tissue oral resections although there are smaller case reports/case series with placement directly into composite flaps[18] (mainly fibula flaps for mandibular resections) as well as into the maxilla and zygomatic complexes for patients undergoing maxillectomy.[19] Implants should be placed by or in close conjunction with the maxillofacial prosthodontist to ensure that the best prosthodontic result is obtained. The placement of implants into composite free flaps at the time of jaw reconstruction is however fraught with difficulty and there is evidence to suggest that such patients should be treated secondarily.[20]

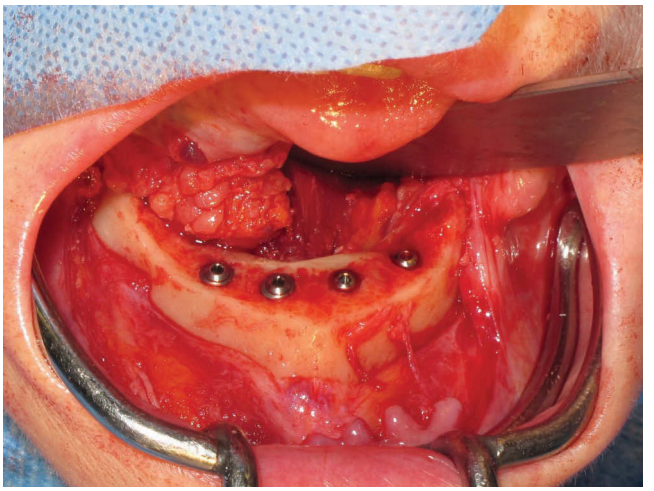

Figure 31.13 Insertion of dental implants into the anterior mandible simultaneously with tumour resection from the floor of mouth.

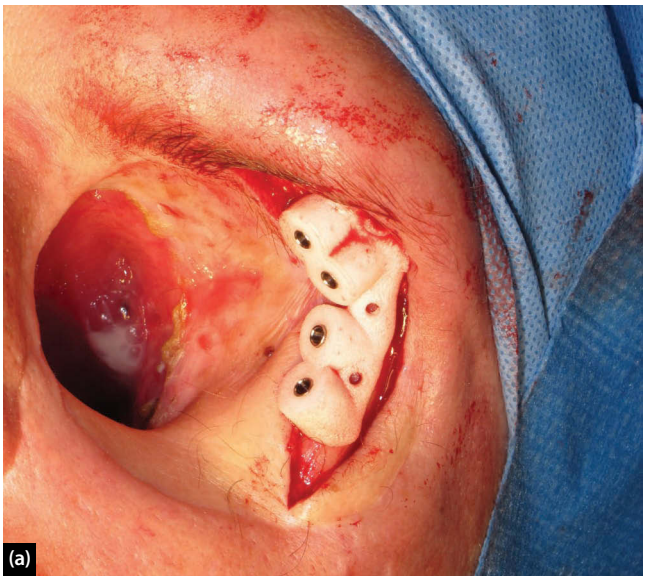
TABLE 31.1 Advantages and disadvantages of primary osseointegrated implant placement

Advantages	Disadvantages
Early rehabilitation	Unknown prognosis for patient
Implants placed before radiotherapy	Unknown oral function post surgery
Psychological patient benefit	Anatomical difficulties for placement
Reduced number of surgeries	Cost implications if implants not used

Rohner et al.[21] described the use of 'pre-fabricated' fibula flaps into which implants are installed by means of CT-based computerized planning and guided surgical techniques with their subsequent transfer to the defect and immediate restoration with a dental prosthesis.. This technique however is not yet in widespread use and is not yet applicable to routine jaw resections required for malignant disease.

Secondary dental implant placement

For many patients, any decisions regarding dental rehabilitation should be left till the patient has fully recovered from the effects of the cancer treatments, their functional deficits identified and their response to the treatment in terms of disease control established. Their motivation for treatment should be ascertained and detailed prosthodontic planning undertaken prior to intervention. CT-based computerized planning techniques are useful where composite reconstructive techniques have been used as they assist in establishing whether adequate bony union has been established following surgery, the presence and position of osteosynthesis plate and screw materials, localized anatomy and the relationship of the proposed prosthesis to suitable implant positions. The use of stereolithographic surgical drilling guides can be helpful in transferring



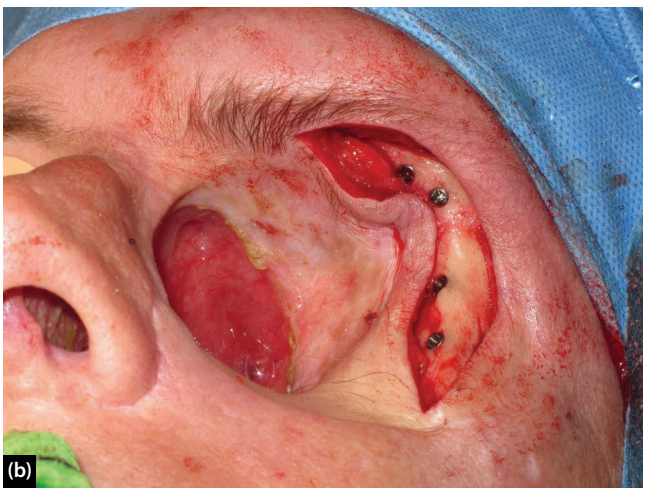


Figure 31.14 (a) The use of a stereolithographic surgical template to guide placement of orbital rim implants. **(b)** Dental implants positioned in the orbital rim according to the pre-operative computer planning.

detailed computer-based planning to the clinical situation (**Figure 31.14**).

Management of the peri-implant soft tissue is another important aspect of care as inevitably excess tissue is present prior to treatment. Reduction and tailoring of skin flap tissue overlying the jaw around the implant fixtures is recommended to allow easy access to the implant, to produce immobile tethered peri-implant tissue and where possible to fashion a new buccal sulcus adjacent to the implants, to facilitate future oral hygiene measures (**Figure 31.12b**). Where radiotherapy has not been used, more aggressive reduction of the soft tissues is possible in conjunction with soft-tissue grafting using palatal mucosa[22] or split-skin grafts[23] to obtain ideal results often with the use of an implant retained dressing plate. In the irradiated patient, simple thinning of the overlying tissues is often all that can be done without risking mucosal breakdown and potential bone exposure.

Implant placement in irradiated jaws

The use of dental implants in the management of irradiated oral cancer patients has been a controversial subject over many years with reports of poor implant survival (as low as 50%) being reported within the literature in some centres.[24, 25] Clearly, radiotherapy is a significant risk factor for failure in these patients and must be carefully considered when planning treatment strategies. However, more recent data are much more encouraging with a recent comprehensive meta-analysis demonstrating an overall mean survival of 83% (range 34–100%) with a mean follow-up of at least 5 years.[26] This study demonstrated no statistically significant differences in survival between implants in irradiated and non-irradiated native jaws but highlighted poorer survival for implants placed into irradiated grafted bone. Changes in implant design, 3-dimensional prosthodontic planning as well as improved / minimalized surgical techniques may account for this improvement in outcomes.

The use of hyperbaric oxygen treatment prior to placement in the irradiated jaw has received much attention with varying results in the literature. Currently there is inadequate information to support its routine use for this indication.[27]

KEY POINTS

- Patients requiring prosthetic rehabilitation for oral and facial defects should be seen pre-operatively with a maxillofacial prosthodontist and anaplastologist.
- Patients requiring a facial prosthesis invariably benefit from osseointegrated implant insertion together with surgical modifications of the resulting defect to maximize the success and aesthetics of the final prosthesis.
- Carefully selected patients should receive osseointegrated implants at the time of resective surgery to maximize dental rehabilitation.
- Osseointegrated implants have high success rates and contribute significantly to improved QOL outcomes in oral, dental and facial prosthetic rehabilitation.
- Radiotherapy reduces implant success and reduces QOL gain from dental prostheses but the use of implants is still of great value in patients who have received radiotherapy.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: interdisciplinary communication, cancer, decision making, communication, head and neck neoplasms and personal autonomy.

INTRODUCTION

The Oxford English Dictionary defines multidisciplinary as 'combining or involving several academic disciplines or professional specialisations in an approach to a topic or problem'.[1] The UK Department of Health has defined the multidisciplinary team (MDT) as a 'group of people of different health-care disciplines, which meets together at a given time (whether physically in one place, or by video or teleconferencing) to discuss a given patient and who are each able to contribute independently to the diagnostic and treatment decisions about the patient'.[2]

Before the early 1990s only a relatively small proportion of cancer patients benefited from their care being managed by a MDT of cancer specialists. Such teams had existed for decades for some cancers in some hospitals but this was the exception not the rule. In the last 15 years MDT working has been deemed to be the standard of care in the management of all types of cancer. In the UK, the drivers for the development of MDT working were the 'Calman-Hine report',[3] the 'The NHS Cancer Plan',[4] the National Institute for Clinical Excellence's Improving Outcomes Guidance,[5]and the ongoing cancer peer review process.[6]

MULTIDISCIPLINARY TEAM WORKING

Multidisciplinary team (MDT) working is seen as the modern standard of care in cancer treatment decision-making.[5] This means that every cancer treatment decision in the UK should be made under the auspices of an MDT. A survey of 2000 MDT members in September 2009 found that there is an overwhelming consensus that MDTs are beneficial to patient care and should remain the cornerstone of cancer treatment.[7] MDTs bring together staff with the necessary knowledge, skills and experience to ensure high quality diagnosis, treatment and care for patients with cancer. MDT working has been advocated in each of the NICE Improving Outcomes Guidance reports and is strongly supported by clinicians.[8]

Despite this enthusiasm from clinicians, the evidence base for MDT working is weak, with most studies looking at outcomes before and after the introduction of the MDT. These studies are confounded by increasing sub specialization, centralization of care and improvements in diagnosis and treatment. However there is increasing evidence that MDTs do improve some clinical outcomes, patient experience and the working lives of team members. The challenges faced when assessing the impact of MDT working on survival in cancer was outlined by Hong et al. in their systematic review on this subject.[9] The definition of MDT is applied variably across centres and any benefits demonstrated may reflect a selection bias of patients with a better prognosis, rather than a real effect.[9] Hong's review included 21 studies which were categorized broadly into retrospective studies and those with cohorts before and after the introduction of an MDT, usually

in a single centre: it was not able to demonstrate a link between MDT working and survival.

There are no randomized controlled trials of MDT working, as it is now ubiquitous. However, in Glasgow, MDT working was introduced into one health board (the 'intervention area'), before other health boards in the west of Scotland (the 'non-intervention area'), allowing a comparison between two similar populations.[10] Before MDT working was introduced, breast cancer mortality was 11% higher in the intervention area than in the non-intervention area. After MDT introduction, breast cancer mortality was 18% lower than the non-intervention area. There was also a reduced variation in survival between hospitals in the intervention area. This study used cancer registry data on 13 722 patients, and the authors adjusted for temporal trends. This large study was published after the systematic review above and the authors provided detail about the definition of MDT working used. Although only one single study in one cancer, the size of the effect is noticeable and it provides the strongest evidence of a positive effect of MDT working on cancer survival to date.[10] Despite this, given the overall weight of evidence, it is not known if MDT working has an effect on cancer survival. Importantly, however, there is equally no convincing evidence of a negative effect. However, even if MDT working did improve survival, the aspect of the process which was responsible for such effects is not known.

MDT working is popular amongst the members of staff who attend it.[7] Specifically in head and neck cancer, a qualitative study of 33 professionals in four focus groups found that the team provided an inclusive environment for planning care. Staff members reported that the team gave support, a chance to stay up to date and an opportunity for discussing difficult cases.[11] However, MDTs are also expensive: best practice guidelines estimate that a radiologist will take 2 hours and a pathologist 2.4 hours to prepare for each hour of team meetings[12] putting the estimated cost of all UK MDT meetings at £50 million a year for preparation and the same amount again for attendance.[13]

MDTs that work well are characterized by clear aims and a shared understanding of goals, clear systems and processes for managing communication and conflicts, and responsive and proactive leaders who run effective team meetings, provide access to resources and reward excellence. These teams can improve patient outcomes and cost effectiveness in a range of settings from primary care to complex hospital care including stoke, cardiac and musculoskeletal conditions. However, MDTs must be supported to work effectively together. The Interdisciplinary Professional Education Collaborative have suggested the following interventions to support MDTs:[14]

- encourage teams to invest time in developing a shared aim
- develop team skills through practice and reflection
- pay attention to internal team relationships
- identify changes in the educational infrastructure required to help sustain interprofessional learning
- use multiple methods of communication to bridge barriers of schedules and geography.

While it is recognized that the evidence base for the value of for MDT team working in clinical decision making is diverse and of limited quality, studies have concluded that time pressures, a lack of information, a lack of nursing input and poor team leadership can have a negative impact on team decision making. Lamb et al. suggest that the 'inclusion of multidisciplinary cancer teams, preparation time into team-members job plans, making leadership skills training available and obtaining more extensive input from nursing personnel should be considered at the national policy level'.[15]

Effective MDT working should result in the outcomes outlined in **Box 32.1**. These outcomes are expected to be more likely in MDTs with a focus on[16]

- teams with the right membership, good attendance, strong effective leadership and opportunities for personal development and training
- good preparation for well organized meetings in the right physical environment with appropriate technology to support effective communication
- patient-centred clinical decision-making
- good team governance and support, with regular data collection and discussion of patient outcomes.

MULTIDISCIPLINARY TEAM WORKING IN HEAD AND NECK ONCOLOGY

In the UK, the National Institute for Clinical Excellence's Improving Outcomes Guidance for Head and Neck Cancer[5] endorses MDT working, together with centralization of

BOX 32.1 Putative benefits of multidisciplinary team working[16, 17]

- treatment and care being considered by professionals with specialist knowledge and skills in the relevant aspects of that cancer type
- patients being offered the opportunity to be entered into high quality and relevant clinical trials
- patients being assessed and offered the level of information and support they need to cope with their condition
- continuity of care, even when different aspects of care are delivered by different individuals or providers
- good communication between primary, secondary and tertiary care
- good data collection, both for the benefit of the individual patient and for the purposes of audit and research
- improved equality of outcomes as a result of better understanding and awareness of patients' characteristics and through reflective practice
- adherence to national and local clinical guidelines
- promotion of good working relationships between staff, thereby enhancing their job satisfaction and quality of life
- opportunities for education/professional development of team members (implicitly through the inclusion of junior team members and explicitly when meetings are used to devise and agree new protocols and ways of working)
- optimization of resources – effective MDT working should result in more efficient use of time which should contribute to more efficient use of NHS resources more generally.

cancer services at regional cancer centres (serving a population of over one million people). Moreover, the guidance states that patients should be managed by MDTs treating at least 100 related cases per annum. Studies suggest that such centralization of services is associated with improved outcomes in head and neck cancer.[18] The guidance recommends that specialized MDTs manage patients with thyroid cancer, patients with salivary gland tumours and patients with skull-base tumours. In addition, the guidance recommends that patients with a sarcoma of the head and neck region should be managed in conjunction with the regional sarcoma MDT.

Box 32.2 shows the suggested core membership for a head and neck cancer MDT in the UK;[5] the guidance characterizes the role of each member of the core team for example clinical nurse specialist, speech and language therapist, dietician. The diverse membership of the core team is essential as almost all patients with head and neck cancer require assessment and management of the airways, speech, nutrition, appearance and pain. **Box 32.3** shows the suggested extended membership for a head and neck cancer MDT in the UK.[5] The members of the extended MDT are there to manage certain patients and, as such, are not required to attend all MDT meetings (in contrast to the members of the core MDT). Specialized MDTs managing thyroid, salivary and skull-base tumours have a different membership to head and neck cancer MDTs. For example, the thyroid cancer MDT should include endocrinologists and nuclear medicine specialists.[5] A national audit published in 2003 highlighted that a high level of attendance was not always being achieved in head and neck cancer: although over 95% of meetings were attended by an oncologist and/or a surgeon and 80% were attended by a speech and language therapist, fewer MDTs had access to other specialists. Only around half included dietitians and/or clinical nurse specialists, and the role of other specialists was even more variable, with teams having a mix of plastic surgeons, restorative dentists and palliative care physicians.[19]

BOX 32.2 Recommended core members of the head and neck cancer multidisciplinary team[5]

Core members

- Surgeons (≥ 3) – the surgeons are likely to be ear, nose and throat (ENT), maxillofacial, or plastic surgeons
- Clinical oncologists (x 2)
  - Restorative dentist
  - Pathologists
  - Radiologist
  - Clinical nurse specialists
  - Speech and language therapist
  - Senior nursing staff from the head and neck ward
  - Palliative care specialist
  - Dietitian
- Team secretary
  - Data manager
  - MDT co-ordinator – the co-ordinator may also take the role of team secretary and/or data manager

EVIDENCE-BASE FOR MULTIDISCIPLINARY TEAM WORKING IN HEAD AND NECK CANCER

The evidence-base for MDT working in head and neck cancer is as diverse as that for other MDTs, with the same enthusiasm from clinicians, but similar problems with study design and confounding variables such as increasing subspecialization. The primary problem with assessing the effectiveness of the MDT is deciding what the measure should be and from which viewpoint it should be measured. A survey of head and neck cancer MDT members from the UK reported that 90% thought MDT discussion resulted in improved timeliness of tests and treatment, 74% thought MDT discussion resulted in improved patient choice, 71% thought that MDT discussion resulted in improved patient involvement in decisions, 95% thought that MDT discussion results in an increase in proportion of patients staged, and 90% thought that MDT discussion results in improved survival rates.[20]

Wheless et al. reported on a prospective study of the effect of MDT meetings on the management of patients with benign and malignant head and neck tumours.[21] Patients were initially assessed by the 'referring attending physician', and the diagnosis, stage of disease and treatment plan recorded. Subsequently, patients were reviewed at the multidisciplinary 'tumour board', and the diagnosis, stage of disease and treatment plan again recorded. The MDT meeting resulted in a change on diagnosis in 1% patients with cancer (6% patients with benign tumours), a change in stage in 12% patients with cancer, and a change in treatment in 24% patients with cancer (6% patients with benign tumours); in the patients with cancer, the treatment was escalated in 15% cases, de-escalated in 5%

BOX 32.3 Recommended extended members of the head and neck cancer multidisciplinary team[5]

Extended members

- Other specialist surgeons
- Anaesthetist
- Gastroenterologists, radiologists, surgeons and other health professionals with expertise in gastrostomy creation, feeding tube placement and support for patients who require tube feeding
- Ophthalmologist
- Pain management specialist
- Nuclear medicine specialist
- Therapeutic radiographer
- Maxillofacial/dental technician
- Dental hygienist
- Social worker
- Benefits advisor
- Liaison psychiatrist
- Clinical psychologist
- Counsellor
- Physiotherapist
- Occupational therapist

cases and changed to a different modality in 4% instances. In a similar study, Brunner et al. found that in almost a third of cases the treatment plan of the referring clinician was changed by the MDT.[22] Treatment plans were more frequently altered if the original plan from the referring clinician did not include surgery or if the histology was not squamous cell carcinoma or skin malignancy. Kee et al. attempted to ascertain if, when a clinician presents their patient at the MDT, the ensuing discussion changes the reported preference of the clinician.[22] In a similar proportion of cases (39%) the preference of the referring clinician did not match the final decision of the MDT. Interestingly however, they also showed that in only 26% of cases where the team and individual clinician disagreed did the referring clinician finally concur with the decision of the team and present it to the patient.[23]

Kelly et al. reported on a retrospective study of the effect of MDT working on so-called 'clinical quality indicators' associated with the management of patients with head and neck cancer.[24] The introduction of the MDT was associated with an increase in PET scanning as a staging investigation, an increase in pre-treatment dental assessments, an increase in pre-treatment nutritional assessments, an increase in the use of chemoradiotherapy for locally advanced cancer, and a decrease in the time period between surgery and post-operative radiotherapy. Birchall et al. reported on a re-audit of the effect on implementing 'consensus standards' (including multidisciplinary head and neck clinics) on the 2-year survival of patients with head and neck cancer.[25] The study compared patients managed in a number of hospitals during two time periods (1996–1997 and 1999–2000). The authors reported that the proportion of patients seen in an MDT increased from 46% to 74% between the two audits and the number having pre-treatment imaging and accurate staging work-up also increased. The overall survival between the two cohorts was not significantly different (64.1% increased to 65.1%), but analysis revealed that those patients were assessed in an MDT had a statistically significantly better survival than those who were not.[25] Although MDT working could have improved the 'non-temporal' standards such as pre-treatment imaging, the correlation between MDT working and increased survival cannot be assumed to be causative. The authors discussed that survival data was probably incomplete, as the deaths reported did not match those of death registrations in the area. Also, temporal trends were not accounted for and confounding factors such as patient selection were not acknowledged.[25]

Similarly, Friedland et al. reported on a retrospective study of the effect of MDT working on the 5-year survival of patients with head and neck cancer.[26] The study compared patients managed by the MDT vs patients managed outside of the MDT within the same hospital over a 12-year period. There was no difference in survival in patients with stage I–III disease, but there was statistically (and clinically) significant improvement in survival in patients with stage IV disease who were managed by the MDT. The authors suggested that the improvement in survival was primarily related to an increase in the use of multimodal therapy, and specifically the use of concomitant chemotherapy and radiotherapy. However, the allocation to management within or outwith the MDT was not randomized, but chosen by the referring clinician; also the MDT patient group had a higher age and more advanced disease. Most importantly however, it is not made clear why some patients were selected to be managed by the MDT whilst others were managed by individual clinicians.

OTHER ISSUES

Patient autonomy

The MDT lacks one important voice, that of the patient.[27] There are little data documenting the patient experience of involvement in MDTs, as it is rarely routine practice: small studies have concluded that patients attending their own MDT allows for better information giving but not necessarily improved involvement in decision-making. Many teams adopt a 'democratic forum model', whereby patients are informed of the decision of the MDT and can accept or decline the treatment proposed. This lacks patient involvement. Shared decision-making (SDM) is a process in which both clinicians and patients work together choosing treatments based on the best available clinical evidence and the patient's preferences. Patients are given information about options, outcomes and uncertainties, and after discussion agree a treatment plan.[28] This concept has been used by Sharma et al. in creating the 'MDT approval model' (**Figure 32.1**).[29] This involves patients in the decision-making process at the very first visit with the patients views taken to the MDT for discussion by the clinical team. Nevertheless, the area of Inter-Professional Shared Decision Making (IP-SDM) is in its infancy as the majority of the research on SDM concentrates on the physician/patient dyad.[30, 31] In two recent systematic reviews of measures to help the implementation of SDM, only 3/40 studies focused on the interdisciplinary approach.[32, 33] Stacey et al. performed a large literature review and theory analysis which identified no models of SDM in the interprofessional context.[34]

Omitting, or not incorporating, patient preference information into the treatment discussion potentially has an effect on decision implementation. In three studies of the implementation of the MDT recommendation in the clinic 'patient choice' caused a change in, or rejection of the MDT recommendation in between 2% and 5% of cases.[35–37] At the same time, patient-centred care is important to MDT members. In the NCAT Survey of MDTs, 95% of respondents felt that 'patient views should always inform the decision-making process' and 'patient views/preferences should be presented to the MDT by somebody who has met the patient'.[7] When the free-text responses from the NCAT survey were analyzed, lack of information about the patient or lack of knowledge of the patient views were seen as the main reason for MDT decisions not being implemented.[38]

Various quantitative measures have attempted to measure the 'patient centredness' of the MDT discussion.

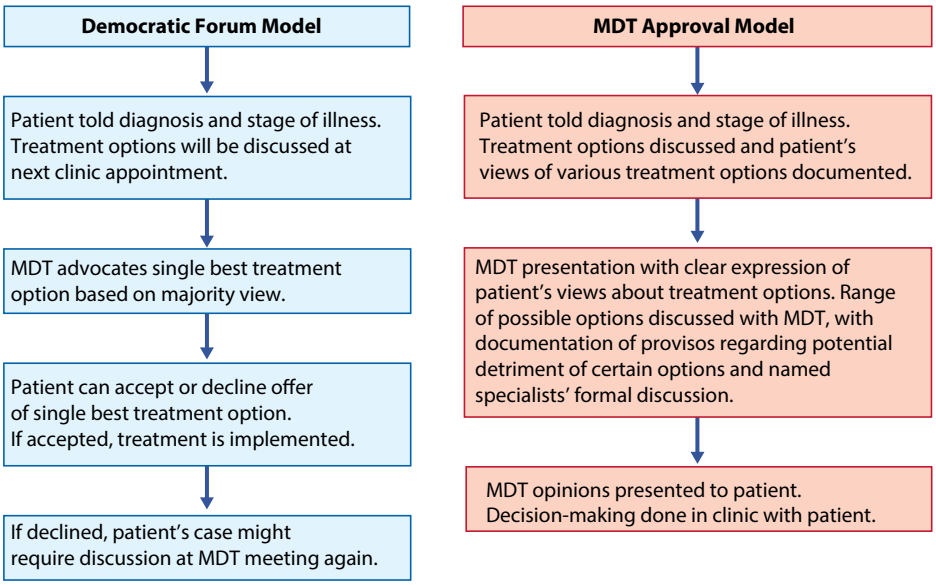

Figure 32.1 Democratic forum model and MDT approval model of decision-making.[29]

Taylor et al. measured the patient-centredness of the MDT decision by counting the number of cases where there was a mention in the MDT discussion of patient-based information.[39] Patient-based information in this study was defined as patient demographics, comorbidities, supportive needs or patient and family preferences. Eight out of the ten observed meetings scored 'poor' or 'very poor' for patient-centred care. The patient information which was included was frequently confined to demographics and most teams rarely considered other patient-based factors. Lamb et al. developed a tool which used Likert scales to quantify 11 aspects of MDT team discussion, including information about the patient, contribution of members of the team and the incorporation of patient views.[15] Teams scored highly in the amount of information given about the clinical history, and radiological information. Teams were found, using this scale, to incorporate patient views into the discussion quite poorly. Moreover, the self-assessment questionnaires completed by the team members suggested that they overestimated the 'patient-centredness' of their decisions.

Qualitative studies have gone further in analyzing how MDT discussions include the patient. Kidger et al. conducted observations and interviews of MDT members and found that the consideration of patient-related factors such as comorbidity information, psychosocial issues and patients' wishes was unstructured when compared with the very structured manner in which the biomedical information was presented.[40] MDT members recognized the importance of 'seeing' a patient rather than an objective representation through information; however information about patient preferences was only really presented when these were strongly held, or ran counter to the recommendation of the team. The team exhibited uncertainty about when and how this kind of information should be incorporated into the discussion. In a similar study, Lanceley et al. reported that the biomedical details of the patient were at the forefront of the discussion, packaging patients into a semi-predictable 'case' which consisted mainly of their biomedical data.[41] Although information such as the ethics of treatment selection or the individuality of the patient was sometimes presented, the team struggled to incorporate this into the 'case' and therefore into the decision. The authors observed that this often led to two strands of narrative about a single patient, which the team had significant difficulties combining.

Clinical decision support systems

Clinical decision support systems are defined as 'systems that are designed to be a direct aid to clinical decision making in which the characteristics of an individual patient are matched to a computerized clinical knowledge base, and patient-specific assessments or recommendations are then presented to the clinician(s) and / or patient for a decision'.[42] Clinical decision support systems have been reported to useful in the MDT, but further research is needed before such technology is introduced into routine clinical practice.[43, 44] Additionally, 'decision aids' are designed to be used before, during or after a clinical consultation by the patient with or without a clinician. In a systematic review of 115 randomized controlled trials, the use of a decision aid was associated with improved patient knowledge, lower decisional conflict, a decreased proportion of patients who were passive in decision-making and fewer patients remaining undecided. There was also a reported increase in patient satisfaction with the decision-making encounter and improved perception of risk.[45] However, most of these studies analyze the use of the decision aid in the context of the clinician-patient dyad rather than an MDT.

MDT working does however allow a new role to be incorporated into the team: that of a decision coach. A decision coach's role is to assess the decisional needs of the patient and then support the patient through decision making, using decision aids and adjuncts if available.[45] Decision coaching can be provided by a member of the team who

is 'trained in decision support and [is] supportive but relatively neutral in the decision'.[46] Decision coaches can help to improve confidence in decision-making and prepare for the decision consultation with positive effects on knowledge, information recall and participation in decision-making.[47, 48] However, in a recently published systematic review, only 10 randomized controlled studies were identified and thus conclusions about the effectiveness of decision coaches were limited. The authors found that although decision coaching can improve patient knowledge, it is difficult to unpick how much of this improvement is due to decision coaching, and how much to the decision aid which is often simultaneously used. The effect on other outcomes such as cost effectiveness, values-choice concurrence and patient satisfaction varies, with some studies reporting a positive effect, and others reporting no difference.[49]

Medico-legal issues

The discussion of a patient at a MDT meeting amounts to a referral to the members of the MDT, and so extends a 'duty of care' to the clinicians within the multidisciplinary care team.[50] As a result, the clinicians are accountable for decisions related to their area of expertise, irrespective of whether or not they contributed to the treatment discussion, and irrespective of whether or not they subsequently treat, or even meet, the patient. It is, therefore, imperative that team members voice any concerns about treatment decisions during the MDT meeting, and ensure that these concerns, and recommendations about alternative treatments, are formally recorded in the documentation relating to the MDT meeting. In such cases, the MDT should inform the patient about the alternative treatment option as well as the 'consensus' treatment option.

CONCLUSION

The creation of formal MDTs ensures that patients are cared for by clinicians with a range of skills, facilitates communication between team members allowing continuity of care, and creates an opportunity for the team to learn together and review patient outcomes against other teams using nationally published datasets.[13]

MDT working is the standard of care in cancer decision-making, however if it is to remain so, the limitations of decision-making in this setting should be acknowledged and overcome. MDT working presents barriers to the incorporation of patient-centred information (such as values, preferences and treatment priorities). If these factors are not taken into account, this may lead to decisions not being implemented, or to a predominance of a paternalistic decision-making style.

Despite the weak evidence base, MDTs are enthusiastically supported by their members and there is increasing evidence that they play an important role in improving patient outcomes and patient experience along with the working lives of team members. Tools are available for teams to reflect on their performance and drive improvement, with a particular focus on regular review of patient outcomes and team relationships.

While there is a recognition that patients with head and neck cancer should be cared for by specialized teams treating large numbers of patients, it is important to emphasize the need to provide care for patients closer to home where possible. Multidisciplinary networks of care providing access to assessment, diagnostics, follow-up and end-of-life care close to home will be vital before further centralization of complex services is considered.

The simple act of bringing together expert clinicians from a wide range of professions and disciplines to discuss and review individual patients and share successes and failures has brought about a revolution in patient management. The head and neck is a diverse and complex cancer site where continuity of care when considering issues with the airway, speech, nutrition, appearance and pain have all been supported by MDT working. Review of outcomes and recruitment into trials will be critical to improving patient outcomes and experience in the future and will all be supported by effective MDT working.

KEY POINTS

- The majority of head and neck cancer decisions in the UK and worldwide are made through a multidisciplinary team (MDT).
- MDT working encourages the involvement of allied health professionals in the assessment, management and rehabilitation of head and neck cancer patients.
- MDT working improves a range of clinical outcomes (such as appropriate staging and clinical trial entry), however, its effect on survival is harder to measure.
- Effective patient involvement in MDT decisions is a challenge and clinicians should develop ways of working which encourage shared decision making.

SEARCH STRATEGY

Data in this chapter is supported by a Medline search using the following keywords: nutrition, screening, assessment, malnutrition, weight, nutritional intervention, immunonutrition, enteral tube feeding, gastrostomy, PEG, RIG, nasogastric tube (NGT), swallow, dysphagia, xerostomia, quality of life, rehabilitation, survivorship and feeding.

INTRODUCTION

This chapter will look at the nutritional considerations from diagnosis, throughout treatment to rehabilitation and survivorship in patients with head and neck cancer. The chapter aims to provide information on several areas of nutrition including nutritional screening, nutritional interventions during surgical and non-surgical oncology treatments, nutritional support, rehabilitation and survivorship.

THE ROLE OF NUTRITION IN HEAD AND NECK CANCER

It is common for patients with head and neck cancer to report difficulties with eating and drinking at presentation due to tumour location. In addition, dietary habits and lifestyle factors may have further compromised their nutritional intake prior to diagnosis.[1] Studies have estimated that between 44% and 57% of patients experience difficulties in eating or unintentional weight loss prior to commencing treatment.[2, 3] Treatment for head and neck cancer can have negative effects on eating and swallowing which can lead to deterioration of nutritional status.[4] These effects will be intensified with multi-modality treatments. In the surgical patient, weight loss can lead to increased complication rates, such as impaired wound healing, reduced immune function and decreased tolerance to treatment.[5] For patients undergoing radiotherapy, weight loss is associated with increased treatment toxicities, more treatment interruptions, poorer quality of life (QOL) and reduced overall survival.[6–8]

It is widely accepted that weight and Body Mass Index (BMI) alone are inadequate measures of nutritional status. The loss of muscle mass that occurs during cancer-related malnutrition is understood to be the major contributor to reduced functional status, increased mortality and other negative outcomes associated with malnutrition.[9] Nutritional intervention for patients with head and neck cancer aims to identify, prevent and treat malnutrition from the point of diagnosis through the entire cancer pathway. Regular dietetic counselling and weighing may help to motivate patients and improve nutrition outcomes and QOL.[10, 11] A specialist head and neck dietitian should be a key member of the multidisciplinary team (MDT) treating patients with head and neck cancer.[1]

Defining malnutrition

Malnutrition is a state of nutrition in which a deficiency or excess (or imbalance) of energy, protein and other nutrients causes measurable adverse effects on tissue/body form (body shape, size and composition) and function and clinical outcome.[12]

Malnutrition may be defined as:

- a BMI < 18.5 kg/m^2
  OR
- a combined unintentional weight loss of > 10% over 6 months (or > 5% in 3 months), in combination with a reduced BMI or low fat free mass index (age and sex specific).[13]

The definition of malnutrition in cancer patients is complicated by emerging terminology such as cachexia and sarcopenia of which there are no universally accepted definitions. These terms attempt to recognize the loss of lean body mass which is compounded by the systemic inflammation and metabolic disturbances which may arise in patients with cancer.[14] Although not routinely used in clinical practice at this time, such terms are appearing more in the oncology literature as the complex mechanisms involved in cancer-related malnutrition become better understood.

Nutritional status has been recognized as a long-term prognostic factor in patients with head and neck cancers for almost 30 years.[15] Malnutrition in patients with head and neck cancer can have a significant adverse impact on clinical, cost and patient-centred outcomes.

Malnutrition has been associated with:

- delayed wound healing and increased risk of post-operative complications and infections[16]
- impaired cardiac and respiratory function due to muscle weakness
- treatment interruptions[16, 17]
- decreased response rates to chemotherapy
- increased risk of loco-regional failure[18]
- increased length of hospital stay
- depression and poor QOL[19]
- increased mortality rate. [8, 20]

Nutritional screening

Nutritional screening aims to identify patients who are malnourished or who are at risk of becoming malnourished during treatment as early as possible. Patients with head and neck cancer should be nutritionally screened using a validated nutritional screening tool.[10, 21] Whilst there is limited good-quality evidence for screening tools specifically for patients with head and neck cancer, there are several validated for use with cancer patients.[10] These include Subjective Global Assessment (SGA) Tool, Patient Generated SGA (PG-SGA) Tool and Malnutrition Screening Tool (MST).

The SGA assesses nutritional status based on features of a patient's nutritional history and physical examination. The PG-SGA is an adaptation of the SGA for assessing nutritional status and is patient generated. Scores identify patients who are well nourished and those who have developed or are at risk of developing malnutrition during treatment and follow-up.[22] The MST consists of two questions relating to weight history and appetite; it is quick and simple to use and compares favourably with PG-SGA. The Malnutrition Universal Screen Tool (MUST) is used widely in healthcare settings across the UK, however it is not validated in cancer.[12] Early identification of high-risk patients and referral to a specialist head and neck dietitian for assessment should be included as part of the planning for every patient with head and neck cancer when treatment options are being considered.[23, 24] Screening should be repeated at regular intervals during the patient pathway.

TABLE 32.1 Factors to consider for nutritional assessment

Diagnosis, specifically regarding tumour site and staging
Nutritional implications of previous treatments
Aim of current treatment plan: cure vs palliation
Single or multimodality treatment plan
Performance status and comorbidity factors
Physical activity level and functional impairment
Medical history that can affect nutritional intake, e.g. diabetes
Current ability to chew and swallow and the likelihood of further impairment due to treatment
Weight history and % weight loss. If not available, signs of weight loss e.g. ill-fitting clothes/dentures
Measurement of muscle mass and recent changes (e.g. hand grip strength)
Changes to appetite, reduced food intake
Modified eating habits or techniques to make it easier to swallow
Avoidance of foods or drinks that are difficult to chew or swallow
Avoidance of eating meals with others or eating in public
Access to food, food preparation facilities and cooking skills
Lifestyle factors, alcohol, smoking, recreational drug intake
% of energy intake from alcohol
Fluid intake
Employment and financial status
Social support network / support at home

Nutritional assessment

Following screening, a full nutritional assessment should be undertaken for patients identified as nutritionally 'at risk'. This should include consideration of a range of factors, illustrated in **Table 32.1**. Assessment should be completed within a pre-treatment clinic and should be repeated at regular intervals during treatment. It is imperative that patients with head and neck cancer are assessed by a specialist head and neck dietitian, and advised and monitored up to the point of surgery and/or non-surgical treatment with respect to their nutritional status. This enables the best possible outcome from treatment interventions in this

high-risk group and should form an integral part of clinical practice for head and neck MDTs.[4]

Pre-treatment optimization

It is essential to optimize patients with head and neck cancer who are malnourished at presentation. Even patients who are managing reasonably normal intake may struggle to reach their energy and protein requirements without individualized dietetic intervention and/or supplementation in some format. Vital factors to be considered when determining appropriate nutritional intervention for patients are:

- Is there evidence of pre-existing malnutrition, indicating the need for pre-treatment nutritional intervention?

Evidence suggests that correcting nutritional deficiencies before surgery reduces the incidence of post-operative complications.[16] Pre-operative feeding for 7–14 days should be offered to patients who present with severe malnutrition and are planned for major surgery, even if the surgery must be delayed.[25, 26]

- Does the patient have a safe swallow?

If the patient is displaying signs of aspiration they should be referred for assessment by a specialist speech and language therapist (SLT).[27] Dysphagia at baseline is a risk factor for requiring earlier and prolonged enteral tube feeding during treatment and should be considered in the pre-treatment stage.

Nutritional requirements

Cancer itself does not have a consistent effect upon either resting energy expenditure (REE) or total energy expenditure (TEE).[9, 28] Indirect calorimetry to determine REE has a high degree of accuracy however it is not usually feasible in clinical practice. Guidelines suggest the use of standard formulas for healthy subjects for estimating REE with the addition of standard values for physical activity level (PAL).[14] Alternatively, standard equations for energy requirements based on healthy subjects (25–30 kcal/kg/day), may be used.

It is suggested that a protein intake of at least 1–1.5 g/kg/day can help to maintain or restore lean body mass. Intakes up to or above 2 g/kg/day are considered safe in patients with normal renal function.[9, 14]

Requirements for fluid and micronutrients are calculated based on daily recommendations for healthy populations.

Nutritional requirements are summarized in **Table 32.2**. Estimations may be less accurate for severely malnourished, morbidly obese and surgical patients.

TABLE 32.2 Estimated nutritional requirements[9, 14]

Energy	25–30 kcals/kg/day depending on activity level, can increase further if major complications
Protein	1–1.5 g/kg/day
Fluid	30–35 mls/kg/day, this increases in presence of infection or excessive fluid losses
Vitamins and Minerals	As per recommended daily allowance for healthy populations unless considered deficient

TABLE 32.3 Criteria for determining people at high risk of developing refeeding problems[21]

Patient has one or more of the following:

- BMI < 16 kg/m^2
- unintentional weight loss > 15% within the last 3–6 months
- little or no nutritional intake > 10 days
- low levels of potassium, phosphate or magnesium prior to feeding

Or patient has two or more of the following:

- BMI < 18.5 kg/m^2
- unintentional weight loss > 10% within the last 3–6 months
- little or no nutritional intake > 5 days
- a history of alcohol abuse or drugs including insulin, chemotherapy, antacids or diuretics.

Refeeding syndrome

Refeeding syndrome may occur when nutrition support is reintroduced in severely malnourished or starved patients. The syndrome is characterized by metabolic disturbances including hypophosphataemia, hypokalaemia, hypomagnesaemia, altered glucose and lipid metabolism, thiamine deficiency and abnormal fluid balance.[29] These effects may result in life-threatening disturbances of organ function and metabolic regulation.

There are no data on the incidence of refeeding syndrome in patients with head and neck cancer although it is a recognized risk in this population due to the high incidence of malnutrition, history of excessive alcohol intake and requirement for artificial nutrition support. The identification of refeeding syndrome may be problematic in this patient group as their underlying clinical condition and oncological treatment may also result in deranged serum electrolyte levels.

The National Institute of Clinical Excellence (NICE) guidelines on nutrition support, 2006, define criteria for patients at risk of refeeding syndrome (**Table 32.3**).

Although the NICE guidelines provide a useful framework for identifying patients at risk of refeeding syndrome, it is acknowledged that their sensitivity and specificity is low and should be interpreted with caution by healthcare professionals with adequate training in nutrition support.[30] In a patient with head and neck cancer for instance, low concentrations of serum potassium, magnesium or phosphate may be related to chemotherapy and is unlikely to represent risk of refeeding in the absence of other nutritional risk factors, i.e. prolonged starvation. Conversely normal electrolyte levels should not be interpreted as an indication of low refeeding risk as due to homeostatic mechanisms, serum concentrations of potassium, magnesium and phosphate may be within normal parameters prior to feeding, even in the starved patient. The advice is to commence oral, enteral or parenteral nutrition cautiously, starting at a maximum of 10–20 kcal/kg/day for

high-risk patients and less for severely high-risk patients (5–10 kcal/kg/day).[21, 30] Introduction of nutrition support should be accompanied by vitamin supplementation and monitoring of electrolyte levels, with repletion of electrolytes as necessary.

NUTRITIONAL INTERVENTIONS AND TREATMENT

Surgery

It has long been recognized that surgical outcome, in any speciality, can be robustly linked to the nutritional status of the patient. Malnourished patients have a higher risk of post-operative complications and long-term adverse effects on QOL. In head and neck surgery, post-operative morbidity and mortality is mediated by poor wound healing, higher risk of flap failure, impaired immune function and a general decreased tolerance to stress of major surgery in those who are nutritionally compromised.[5, 31, 32]

Patients requiring surgery for head and neck malignancy will often have advanced disease and require procedures that will, frequently, further interfere with their ability to maintain an adequate oral intake. It is important when counselling patients about their treatment options that surgeons are realistic with them, their families and the allied healthcare professionals in the treating team about potentials for oral intake both immediately after surgery and in the longer term.

Patients need to be fully informed about the effects of surgery on their swallowing. Studies have shown that swallowing consistently remains one of the top priorities for patients following treatment for head and neck cancer.[33] Patients may already have difficulty swallowing due to the site or stage of their tumour. The effect of tumour resection in the oral cavity, oropharynx, hypopharynx and larynx should be explored at pre-treatment assessment by an experienced MDT. Therefore, the patient expectation should be kept realistic and the functional outcomes explained fully in conjunction with the SLT. Options for maintaining nutrition should be discussed in conjunction with a specialist head and neck oncology dietitian and an individualized management plan formed.

For those patients who are malnourished at presentation, early dietetic input is invaluable in the time leading up to surgery. This allows optimization of their nutritional status and early intervention. If patients are clearly unable to meet their nutritional requirements with oral intake due to dysphagia, odynophagia or aspiration, despite optimization of analgesia and SLT input, an early decision regarding enteral nutrition is required to prevent further nutritional decline. Whether this is via a nasogastric tube (NGT) or a gastrostomy tube is a patient-centred decision, based on the following factors: patient preference, tumour stage, the site of the primary tumour (more likely for oral cavity/oropharynx, less likely for larynx), the likely need for post-operative radiotherapy +/– chemotherapy, the predicted length of time to achieve oral intake of a normal consistency or quantity and institutional expertise.[28]

It is imperative to ensure that patients are assessed, advised and monitored up to the point of surgery with respect to their nutritional status. This enables the best possible outcome from surgery in this high-risk group of individuals. Post-operatively, patients should have a form of enteral nutrition available that can be commenced within 24 hours of their surgery.[10] Depending on pre-operative discussions and the nature of surgery, an NGT may be all that is required if early return to oral diet is anticipated. However, if recovery is more likely to be protracted a prophylactic gastrostomy may be more appropriate. If unforeseen complications occur or recovery is slower than anticipated a reactive gastrostomy is also a possibility. In all instances, an appropriate feeding regimen should be prescribed by a specialist head and neck oncology dietitian to stop any delay in post-operative feeding.

Early oral feeding (day 1–7 post-operatively) in primary laryngectomy patients should be considered as studies indicate no evidence of increased fistula rates when compared with standard protocols for commencing oral intake, traditionally > 7 days.[6] Similarly, early oral feeding protocols following oral cavity surgeries are gaining popularity due to evidence suggesting favourable outcomes such as earlier tracheostomy decannulation and reduced length of stay without an increase in morbidity.[34]

Enhanced recovery after surgery (ERAS)

Enhanced recovery programmes have gained popularity over the last 15 years amongst many surgical disciplines. Historically there have been little data pertaining to head and neck surgery, however a consensus based ERAS protocol for the management of patients undergoing head and neck surgery with free flap reconstruction has now been developed.[35]

There are three main aspects of operative care to ERAS:[36]

- **Pre-operative:** assessment, education and counselling about the procedure and its recovery, avoidance of premedication, same day admission/limited hospital stay, attention to fluid balance, minimization of fasting and carbohydrate loading, nutritional optimization.
- **Intra-operative:** minimally invasive surgical techniques, regional anaesthesia, standardized anaesthetic protocol with the use of short-acting anaesthetics, goal-directed fluid therapy, avoidance of drains and high inspired oxygen concentrations.
- **Post-operative:** early mobilization, early removal of drains, catheters and lines, early oral/enteral intake, optimized pain relief, nausea and vomiting prophylaxis and use of prokinetics/laxatives/chewing gum.

The practice of keeping all patients nil by mouth (NBM) from midnight prior to surgery may contribute to an abnormal physiological state thereby slowing down

recovery after major surgery; the abnormal physiology can be further exacerbated by delayed post-operative feeding. In ERAS protocols, patients are not placed NBM from midnight but are given carbohydrate rich fluids up to 2 hours before surgery (carbohydrate loading).

In patients undergoing colorectal surgery it has been demonstrated that pre-operative carbohydrate loading results in shorter hospital stay, less loss of muscle mass and earlier return of bowel function with no increase in risk of aspiration.[37] In some hospitals in the UK, pre-operative carbohydrate loading has been introduced to patients undergoing head and neck surgery with no concerns.[38] Pre-operative carbohydrate loading involves the administration of 100 g of carbohydrate the night before surgery and 50 g carbohydrate up to 2 hours before surgery. Carbohydrate is provided in specialized nutritional supplements. ERAS programmes often recommend commencing nutrition post-operatively within 4 hours of surgery.[39] Current European nutrition guidelines suggest starting enteral feeding within 24 hours.[26]

The mere presence of a pathway with nutrition as an integral part ensures that this is not a neglected facet of peri-operative care. One of the main ways that ERAS is beneficial is by reducing the 'metabolic stress' of major surgery. This manifests as rising levels of insulin resistance post-operatively, related to the magnitude of the operation performed. Insulin resistance lasts for several weeks following surgery and affects all parts of the body's metabolism. There is reduced glucose uptake in body cells leading to loss of lean body mass and reduced muscle function. Pre-operative carbohydrate loading and early post-operative feeding can help reduce the catabolic response to surgery and thus patients recover quicker with fewer complications.[40] Major head and neck surgery does in fact lend itself to many of these general principles of ERAS.[35] Early dietetic assessment, as discussed earlier, and intervention pre-operatively for life-changing surgery is required to ensure realistic outcomes for patients, which is similar to the fundamental principle of ERAS. Most patients can be admitted on the day of surgery. Nutrition is just one part of ERAS pathways. Early mobilization and optimization of post-operative analgesia are also important.

Immunonutrition

Also known as immune enhanced nutrition, immunonutrition is feed containing various additives in the form of amino acids, nucleotides and lipids. Much of the research concentrates on the substances omega 3 (fatty acids from fish oil) with arginine or glutamine.[41] These additional constituents are thought to upregulate the host immune response, modulate the inflammatory response and improve protein synthesis after surgery.[42]

Many randomized controlled trials and several meta analyses have shown that administration of enteral arginine, omega 3 fatty acids and nucleotides reduce infection rate and length of hospital stay in patients with upper or lower gastrointestinal cancer with the greatest benefit seen in malnourished patients.[42]

Arginine alone promotes healing and modulates inflammation and can be used in an enteral feed in isolation. A recent systematic review and meta-analysis showed that the administration of an arginine-enriched feed reduced both the development of fistulas post-operatively as well as the overall length of stay in hospital.[43] Previous studies have also found that arginine may improve fistulas and wound complications in patients with head and neck cancer.[44] Other studies have found similar tendencies with improved wound infection rates but less convincing effects on fistulas.[45]

With the increasing amount of evidence in the literature, post-operative immunonutrition appears to be emerging as another technique in our armamentarium to reduce length of hospital stay. However, the mechanism remains unclear, as other clinical benefits such as reduced complications and infections have not been consistently demonstrated.[10]

CHYLE LEAKS

An uncommon, but major complication of head and neck surgery is a chyle leak or chylous fistula, particularly if surgery involves the left supraclavicular fossa region. The literature suggests an incidence of 0.5–1.4% for thyroidectomy and 2–8% for neck dissection.[46]

Chyle is a by-product of the absorption and digestion of fat. Fat digestion begins in the duodenum with pancreatic lipase, which hydrolyses triglycerides into monoglycerides and free fatty acids. These in turn interact with bile salts and form micelles. The micelles transport the monoglycerides and free fatty acids across the brush border of the villi of the small intestine. Most of the fat absorbed into the epithelial cells combines with cholesterol, phospholipids and lipoproteins to form chylomicrons. These then enter the lacteals of the villi as milky-looking lymphatic fluid (chyle).

The lacteals coalesce to form the cisterna chyli, which traverses the diaphragm to run superiorly as thoracic duct in the posterior thoracic cavity behind with the oesophagus. As the thoracic duct enters the neck it crosses between the internal jugular vein (IJV) and the anterior scalene muscle. It either terminates at the junction of the left IJV and left subclavian vein or drains directly into the IJV. For this reason, the majority of chyle leaks are on the left, although approximately 5% will occur on the right from the right lymphatic duct.[47]

About 2–4 litres of chyle flows through the thoracic duct on a daily basis. Flow rates vary with the amount of dietary fat consumed. Chyle leaks are classified as low output (< 500 mls/24 hours) or high output (> 500 mls/24 hours). Conservative management is appropriate for low-output leaks; high-output ones are more likely to require definitive intervention. Chyle leaks cause local problems with tissue loss and wound healing as well as systemic effects related to fluid loss and electrolyte dysfunction. Early recognition and treatment is essential to reduce morbidity.

The mainstay of all management strategies is nutritionally based. It is based on the theory that reducing

formation of chyle slows down the flow and thus allows the fistula to heal. A triglyceride level >110 mg/dl is diagnostic of a chyle leak. If the triglyceride level is <110 mg/dl further analysis is required to demonstrate the presence of chylomicrons. A triglyceride level <50 mg/dl usually rules out a diagnosis of a chyle leak unless a patient is malnourished or has been fasted.

The principal aims of nutritional management are to reduce the flow of chyle whilst maintaining nutritional status, ensuring adequate fluid balance and replacing electrolyte losses. Normally, when dietary fat is consumed long-chain triglycerides (LCTs) enter the blood-stream via chyle, medium-chain triglycerides (MCTs) are absorbed directly into the portal system. This important differentiation forms the basis on which nutritional management is based. Therefore, the nutritional management is to use a fat-free or high-MCT product. MCT is recommended because it is directly absorbed into the portal system resulting in less chyle production. Many patients with low-output leaks will respond to this intervention alone, thus making early dietetic input essential.[48] To date, no consensus exists on how to nutritionally manage chyle leaks, how long nutrition management should be pursued, or what constitutes an acceptable amount of chyle output. The nutritional intervention is usually dependent on clinician preference.

If dietary manipulation is unsuccessful parenteral nutrition may be required. This should not be used as first line management except in extreme cases, for example, very high volume leaks (>1000 mls). Further alternative treatments include Octreotide, Orlistat or recourse to surgical intervention.

RADIOTHERAPY +/– CHEMOTHERAPY

Patients should be offered pre-treatment assessment before commencing radiotherapy +/– chemotherapy to ensure

- full assessment of baseline nutritional status
- appropriate dietary advice is provided before commencing treatment to correct nutritional deficiencies
- information is provided on the nutritional implications of treatment, including anticipated need for enteral tube feeding support.

It is recognized that radiotherapy can cause side effects that may limit oral intake and lead to weight loss.[11] The addition of chemotherapy during radiotherapy has been shown to lead to increased locoregional control and an 8% improvement in overall survival, but this has been at the cost of increased toxicity.[49] Chemotherapy agents act as radiosensitizers. Unfortunately, the sensitizing effects are not selective for tumour cells and therefore normal tissue in the radiation field is also subject to more toxic radiation. Addition of chemotherapy to radiotherapy schedules is known to significantly increase grade 3 or 4 mucositis in most patients (~88%) compared to only 20–30% of patients treated with radiotherapy alone.[50] Monoclonal antibody treatments (e.g. cetuximab) given in conjunction with radiotherapy will also increase the incidence of mucositis and other toxicities effecting nutritional intake and hence patients should be managed in the same way as for conventional chemoradiotherapy.[10]

The impact of neoadjuvant chemotherapy schedules on nutritional status and oral intake is poorly understood due to limited studies in this area.[10] It is advised that nutritional status is assessed at regular intervals during neoadjuvant chemotherapy cycles to prevent nutritional decline prior to future radiotherapy treatment.

Intensity-modulated radiation therapy (IMRT) is the most commonly used technique to deliver radiotherapy to the tumour and regions at risk. Whilst the benefits of IMRT include the ability to limit radiation toxicity to the salivary glands and critical pharyngeal structures required for swallowing, thus reducing the chronic toxicities of dysphagia and xerostomia, residual toxicity remains with a high rate of weight loss, mucositis and continued need for nutritional support. Independent predictors of severe toxicity with concurrent chemoradiotherapy have been shown to be older age, advanced T stage, primary site in the larynx/pharynx and neck dissection after radiotherapy + chemotherapy.[51]

Radiotherapy side effects start to impact on the patient between the second and third week of treatment with this reaction continuing and increasing during the fourth, fifth and sixth weeks. Side effects peak approximately 1–2 weeks after treatment finishes.[52] Supportive care during chemoradiotherapy is demanding and often requires extensive oral and skin care, opioid medications, antiemetic medications and intensive nutritional support. Chemoradiotherapy can profoundly affect nutritional intake and swallowing physiology thereby causing significant morbidity and diminished QOL.[53] This impairment of oral food and fluid intake as a result of treatment may further exacerbate pre-existing malnutrition.[54]

Ongoing nutritional assessment and counselling by a specialist head and neck oncology dietitian should be part of the patient's treatment plan with patients being reviewed weekly during treatment.[10, 55] Odynophagia and oral pain when eating may lead to a reduction in the types and selection of foods consumed, often at the expense of adequate nutrition. Modifying the texture and consistency of foods is common during treatment. Increasing the frequency of meals and fortifying with nutrient dense foods will minimize nutrient deficiencies by increasing calories and protein. As treatment progresses, many patients will move to pureed or liquid diets and be more reliant on oral nutritional supplements to meet their nutritional requirements. Some patients may require enteral tube feeding to meet their nutritional needs.

Long-term side effects of chemoradiotherapy are more severe than for radiotherapy alone. Dysphagia, pain and dependence on feeding tubes are more common with chemoradiotherapy compared to radiotherapy alone and have negative effects on QOL.[51, 56] Dysphagia usually improves in the first year following treatment but in some cases swallowing dysfunction may be permanent.[57] In addition, the late effects of chemoradiotherapy can include osteoradionecrosis (destruction of bone within the

oral cavity), dental decay, trismus (reduced mouth opening), hearing loss and pharyngeal or oesophageal stenosis. Most late effects of chemoradiotherapy can impact on a patient's ability to eat and drink. It is important to assess nutritional status and oral intake at review appointments even many years after treatment and refer to a specialist head and neck oncology dietitian for advice if oral intake is compromised.

PALLIATIVE CARE

The specialist head and neck oncology dietitian plays a key role in the palliative care team due to the high incidence of weight loss, dysphagia and enteral tube feeding amongst patients with head and neck cancer.[10]

Collaborative assessments and reviews with an SLT can aid in determining the level of nutritional intervention required based upon the nature, severity and likely progression of dysphagia. Although previous goals for maintaining weight and energy intake may no longer be appropriate, patient comfort and QOL should be optimized, for example providing oral or tube feeding to avoid feelings of hunger or thirst during end-of-life care.[9] It is essential that nutritional care is patient-centred, taking into account the holistic needs of the patient whilst being guided by prognosis and medical management.

NUTRITION SUPPORT METHODS

There are three main methods of nutrition support for patients with head and neck cancer. These are oral nutrition support, enteral tube feeding and parenteral nutrition.

The aims of nutrition support are to[58]

- improve the subjective QOL
- enhance anti-tumour treatment effects
- reduce the adverse effects of anti-tumour therapies
- prevent and treat undernutrition.

Oral nutrition support

Healthcare professionals should consider oral nutrition support to improve nutritional intake for people who can swallow safely and are malnourished or at risk of malnutrition.[21] Oral nutrition support involves providing nutrition to improve intake by several methods. These include

- fortifying food with macronutrients including energy, protein and fat as well as vitamins and minerals
- changing the frequency of meals and types of foods consumed
- using oral nutritional supplements.

Previous therapeutic diets, for example, lipid lowering diets, are also often relaxed to prevent further nutritional decline. Oral nutritional supplements are used extensively in patients with head and neck cancer and there are large varieties available. The type used depends on a patient's current nutrition intake, need and preference. The dietitian initiates oral nutritional supplements when there is a deficit in nutritional intake and/or the patient continues to lose weight even when following a high calorie/protein diet.[58]

Enteral tube feeding support

General nutrition support guidelines recommend enteral tube feeding for patients who are malnourished or at risk of malnutrition and have inadequate or unsafe oral intake and a functional gastrointestinal tract.[21] In the post-operative patient, enteral tube feeding is recommended if it is expected that the patient will be unable to eat for more than 5 days post-operatively or unable to maintain at least 50% of recommended intake orally for more than 7 days.[26] In patients undergoing radiotherapy +/– chemotherapy, the benefits of initiating enteral tube feeding when oral intake is inadequate have been demonstrated in terms of improving nutritional intake and minimizing weight loss.[10]

Enteral tube feeding can be delivered via the nose into the stomach or jejunum (nasogastric or nasojejunal tube), or directly into the stomach or jejunum (gastrostomy or jejunostomy tube). **Table 32.4** details the different types of feeding tubes available. The choice of feeding route depends on the expected duration of feeding, site of tumour, treatment plan and intent and patient choice. **Table 32.5** highlights some of the advantages and disadvantages of enteral feeding tubes. In patients with head and neck cancer the preferred route for enteral nutrition is either a nasogastric and/or gastrostomy tube as the stomach is usually accessible. In some circumstances jejunal feeding may be required, for example, patients who have undergone a pharyngolaryngectomy with gastric pullup.

Nasogastric intubation is a procedure involving the insertion of a polyurethane tube (NGT) through the nose, past the throat, down the oesophagus and into the stomach. Tubes are usually placed at bedside but if placement is difficult fluoroscopic or endoscopic placement may be required. There is a risk that the tube can become misplaced into the lungs during insertion, or move out of the stomach at a later stage. It is essential to ensure that the NGT is in the stomach to prevent any complications. pH testing of the NGT aspirate is used as the first-line test method, with pH between 1 and 5.5 indicative of correct

TABLE 32.4 Enteral tube feeding routes and indications

Insertion route	Tube type	Indication
Nose	Nasogastric	Short-term feeding <4 weeks
	Nasojejunal	Short-term feeding when feeding into the stomach is not possible or indicated
Stomach	Gastrostomy	Long-term feeding >4 weeks
Jejunum	Jejunostomy	Long-term feeding when feeding into the stomach is not possible or indicated

TABLE 32.5 Advantages and disadvantages of enteral feeding tubes

Tube type	Advantages	Disadvantages
Nasogastric	• Usually easy to place at bed side • Inexpensive to place • Ideal for short term (< 4 weeks feeding) • Easy to remove when no longer required	• Easy to dislodge • Tube tip position must always be pH checked and a pH of ≤ 5.5. obtained prior to using tube to ensure that tube tip is in stomach • Highly visible • Tubes can block easily with medication due to small diameter of tubes • Laryngeal irritation • Gastro-oesophageal reflux • Nasal sores and erosion • Risk of feeding into the lungs if tube tip position is not in the stomach
Gastrostomy	• Ideal for long-term feeding (>4 weeks) • pH testing not required to check tube tip position as tube tip inserted and secured in stomach • Discrete as located directly in stomach • Unlikely to be dislodged	• Expensive to place compared to NGT insertion • Cannot be placed at bedside • Risk of infection, bleeding and peritonitis from insertion technique • Major complications can impact on ability to deliver oncological treatment
Nasojejunal	• Non-invasive • Ideal for short term (< 4 weeks feeding) • Easy to remove when no longer required • pH checking not required as tube is placed post-pylorically	• Requires placement under X-ray guidance, in interventional radiology or endoscopy • Easy to dislodge • Not feeding into stomach therefore feeding rates are required to be slower due to no gastric reservoir • Feeding times maybe prolonged due to slower feeding rates • Highly visible • Tubes can block easily with medication due to small diameter of tubes and length (> 130 cm) • Laryngeal irritation • Nasal sores and erosion • Potential GI disturbances • With certain medication there is a risk of reduced medication absorption as bypassing stomach
Jejunostomy	• Ideal for providing post-pyloric feeding • Discrete as located directly in jejunum	• Delivery rate of feed less than feeding into stomach due to lack of reservoir • Small diameter of tube increases risk of tube blocking with medication and/or feed • Tube easily dislodged • Requires operation to insert tube

TABLE 32.6 Characteristics of PEG and RIG tubes

Tube type	Characteristics
PEG	• Usually inserted with a 'pull technique'. Tube is pulled through the mouth into gastrointestinal tract endoscopically • Bumper retained • Usually made of polyurethane • Tube must be advanced and rotated at least once a week 2–4 weeks after initial insertion to prevent buried bumper syndrome • Tube life is usually a number of years • Tube is difficult to dislodge
RIG	• Tube usually inserted with a 'push technique'. Tube is inserted directly into the stomach radiologically • Usually balloon retained • Usually made of silicone • Water in balloon must be checked and replaced weekly after the first 1–2 weeks and tube must be rotated • Tube life is usually 3–4 months • Tube may become dislodged if balloon fails

placement in the stomach. A chest X-ray is used only as a second-line test when no aspirate can be obtained or pH indicator paper has failed to confirm the location of the NGT.[59]

There are two main methods of gastrostomy insertion: endoscopic and radiological placement. A gastrostomy that is placed in endoscopy is known as a percutaneous endoscopic gastrostomy (PEG) and one that is placed in radiology is known as a radiologically inserted gastrostomy (RIG). The key characteristics of PEG and RIG tubes are shown in **Table 32.6**. Grant et al.[60] have shown that procedure-related mortality and other complications are higher in patients with head and neck cancer when compared to mixed populations as well as RIG complications being greater than PEG complications. Clinician experience of tube related complications and what services are

available within a head and neck unit generally determine the method of gastrostomy placement.

NGTs are frequently used after surgery as patients often require non-oral feeding for just a few days to weeks. If oral intake is likely to be impaired for longer than 4 weeks after surgery, a patient may have a gastrostomy placed.

For patients with head and neck cancer being treated with chemoradiotherapy, a feeding tube is either placed prior to treatment (prophylactic) or during (reactive). Studies have suggested that a prophylactic gastrostomy leads to improved nutritional outcomes with less weight loss and may improve QOL during and post-treatment compared to reactive NGT.[10] Conversely, prophylactic gastrostomy tubes may have a negative impact on swallow outcomes and lead to tube dependency,[61] though the association of early gastrostomy tube feeding and long-term swallow impairment has been inconclusive.[62, 63] To date there is no consensus on the optimal route (NGT vs gastrostomy) or timing (prophylactic vs reactive) of tube feeding during oncological treatment for head and neck cancer, meaning this is largely determined by clinician and patient preference.[64]

ENTERAL TUBE FEEDING INSERTION CONTRAINDICATIONS

Before inserting any form of enteral feeding tube, the clinical situation, diagnosis, comorbidities, prognosis, possible contraindications, implications for QOL as well as the patient's wishes should all be considered.[64] Both NGT and gastrostomy placement carry risks and in certain situations their placement is contraindicated.

NGT placement may be contraindicated in the following situations:

- severe facial trauma resulting in fractures to the skull base, cribriform plate, and sphenoid sinus, due to the possibility of inserting the tube intracranially[66]
- significant coagulopathy
- oesophagogastric surgery/injury (e.g. gastrectomy/oesophagectomy/oesophageal perforation)
- distal bowel obstruction, perforation or fistula
- competent patient refusal to consent to procedure.

Gastrostomy tube placement may be contraindicated in the following situations:[65]

- significant coagulopathy
- interposed organs (e.g. liver, colon)
- enlarged liver, portal hypertension, confirmed varices and/or ascites
- peritoneal metastasis/carcinoma/dialysis
- peritonitis
- gastroparesis
- gastric outlet obstruction (unless venting gastrostomy indicated)
- small bowel obstruction
- oesophagogastric surgery (e.g. gastrectomy / oesphagectomy)
- hiatus hernia
- acute / uncontrolled psychosis
- advanced dementia
- clearly limited life expectancy
- competent patient refusal to consent to procedure.

The above contraindications may be absolute or relative and their presence makes tube insertion high risk or unfeasible. Specialist input from the MDT (dietitian, gastroenterologist, radiologist and clinical team), should be sought to determine suitability for tube placement where one of more contraindications are identified.

TYPES OF FEED AND DELIVERY METHODS

Dietitians assess the most appropriate type of enteral feed to give patients with head and neck cancer based on their nutritional requirements, their condition, their previous diet, their mobility and lifestyle and their desire to be fed continuously (via a pump) or in smaller volumes (bolus). For patients with head and neck cancer it is usual to use polymeric feeds (whole protein) with or without fibre. Feeds range from 1 kcal/ml to 2.4 kcal/ml with varying levels of protein.

Continuous and bolus feeding

Bolus and continuous feeding are two ways to deliver nutrition to patients who are tube fed. Bolus feeding is defined as the administration of liquid feed (primarily oral nutritional supplements) by syringe or bolus feeding set. A prescribed volume of feed (typically 100–400 ml) is given at regular intervals throughout the day, for example, four times per day. In contrast, continuous feeding involves the administration of a liquid feed via a feeding pump and pump set. The feed is usually run at a set rate, for example, 125 ml/hr for a set period of time; this can be intermittent, for example, overnight feeding, or continuous over 24 hours.

There are advantages and disadvantages of both feeding methods. The choice of feed delivery method is usually determined by patient preference and enteral feed tolerance. In addition, due to the flexible and intermittent nature of bolus feeding, patients with head and neck cancer are generally able to be more mobile with this type of feeding. This is particularly useful if the patient is attending the hospital daily for treatment. Once a patient has completed treatment, bolus feeding may facilitate a quicker transition back to a pre-morbid lifestyle, (returning to work and social activities) as it physiologically mimics a typical eating pattern.

Bolus feeding may be easier to undertake with a gastrostomy tube rather than an NGT as repeated administration of feed boluses requires increased pH testing with a NGT. It can be poorly tolerated by some patients due to

the volume of feed being delivered over a short period of time. In addition, a primary disadvantage of bolus feeding is that it requires manual dexterity and strength. As such this method of feeding may not be suitable for patients with poor manual dexterity, for example, arthritis of the hands. In such instances, continuous feeding using a pump would be the preferred method.

Continuous feeding is often used when commencing patients on enteral tube feeding to assist gastrointestinal tolerance, particularly for patients immediately post head and neck cancer surgery. This is because it allows the lowest possible hourly feed rate to meet nutritional requirements. It is also advantageous if patients are at home and rely on community nursing to administer their enteral feed as it usually requires only two nursing visits a day to set up and disconnect. It is also useful if patients wish to be fed overnight whilst sleeping. A disadvantage of continuous feeding is attachment to the feeding pump. This can lead to decreased mobility, which may affect QOL, however many feed companies provide carry bags to allow portable pump feeding.

Parenteral nutrition support

Parenteral nutrition is rarely required in patients with head and neck cancer as most patients have an accessible and functioning gastrointestinal tract. National data suggests an incidence of <1% for patients with head and neck cancer.[67] Parenteral nutrition may be used as a temporizing measure in patients with head and neck cancer who have obstructive tumours, making placement of an enteral feeding tube impossible. It may also be used for patients who have a chyle leak that has not responded to oral or enteral diet modification. Parenteral nutrition should be considered for individuals who are malnourished or at risk or malnutrition and have inadequate or unsafe oral/enteral nutritional intake and have a non-functional, inaccessible or leaking gastrointestinal tract.[21] Parenteral nutrition can be stopped once adequate oral or enteral nutrition is tolerated and withdrawal should be planned and stepwise with a daily review of the patient's progress.

REHABILITATION

Rehabilitation has been defined as 'the restoration, to the maximum degree possible, of an individual's function and/or role, both mentally and physically, within their family and social networks and within the workplace where appropriate'.[68] Following treatment for head and neck cancer, patients may have long-term side effects of their treatment which affect their ability to eat, drink and communicate. Due to the very nature of multimodality treatment, side effects can vary significantly between patients with regards frequency, timing, severity and impact on QOL.[69] Surgical intervention may permanently alter the texture of diet that a patient can consume and in some instances result in permanent feeding tube dependency. Patients who have had chemoradiotherapy are at high risk of developing both late and long-term side effects such as xerostomia, dysphagia, odynophagia and trismus. One year post-treatment reports suggest that the majority of patients still experience eating problems due to persisting side effects of treatment.[70]

Studies have identified that pain is a significant problem for patients following radical radiotherapy, often leading to a reduction in dietary intake.[71] Patients suffering from reduced laryngeal elevation, reduced cricopharyngeal opening and non-functional swallow on at least one swallow with any bolus type are significantly more likely to require a texture modified diet and have an intake of less than 50% of estimated nutritional requirements.[72] It has been suggested that up to 50% of patients who have undergone head and neck cancer treatment experience dysphagia and up to 60% report severe xerostomia following treatment with an estimated 10% requiring long-term enteral nutrition.[73–75]

Multidisciplinary rehabilitation programmes involving a specialist head and neck dietitian and SLT have the potential to improve outcomes for oral intake. Guidelines recommend that patients with head and neck cancer receive fortnightly reviews by a specialist head and neck dietitian for at least 6 weeks after treatment. In addition, dietetic support should continue for up to 6 months, or for as long as they require management of long-term side effects, weight loss and enteral nutrition.[10] Further research is required to examine the benefits of these proactive rehabilitation programmes in reducing tube dependency in patients with head and neck cancer.

The level and nature of support between patients will vary, as well as being dependent on local resources and guidance. The nutritional status of patients should be closely monitored so that dietary intervention can be adjusted in a timely manner. Locally, support groups such as 'Back to Eating' should be established to provide patients with an encouraging environment to try new foods during the rehabilitation phase. Patients may be discharged by the dietitian once rehabilitation goals have been achieved, however, there should be an agreed process in place to re-access specialist head and neck dietetic services should this be required.[4]

SURVIVORSHIP

As the incidence of cancer increases, alongside recent improvements in cancer treatment, it is expected that patients with head and neck cancer are living well and beyond their cancer diagnosis and treatment.

Ensuring that good survivorship care, incorporating nutrition, is provided to patients with head and neck cancer may lead to a reduction in future mortality by

- reducing the risk of cancer recurrence
- preventing or managing comorbidities such as diabetes, cardiovascular disease and other cancers
- earlier identification of recurrence.

There is limited evidence available detailing specific dietetic support for patients with head and neck cancer in

survivorship as the long-term consequences of treatment are unknown. Patients are encouraged to follow general health promotion recommendations including dietary advice on maintaining a healthy weight (BMI 18.5–25 kg/m^2), limiting alcohol and eating a balanced diet once they have reached a stable weight and are able to meet their nutritional requirements from food. There have been reports that patients with head and neck cancer suffer increased levels of emotional distress, physical limitations, altered body image and relationship difficulties.[76] It is essential that services for survivorship are developed that support and enable them to cope with these needs and allow them to lead a good QOL for as long as possible.

Some patients may continue to require medical led follow-up long term. However, with younger people being diagnosed with head and neck cancer, because of the association of human papillomavirus (HPV) and oropharyngeal cancer, there are a growing number that can be educated and supported to self-manage at home with remote access and timely re-access to clinics.[69] Many survivorship initiatives are recommending structured holistic recovery packages that incorporate the following:

- holistic needs assessment and care planning
- treatment summaries
- health and well-being events
- advice and schemes supporting physical activity.

The specialist head and neck dietitian plays an integral part in the delivery of such survivorship packages by providing nutritional advice tailored to the needs of the patient with head and neck cancer.

CONCLUSION

A specialist head and neck dietitian is an integral part of the head and neck MDT. There is clear evidence to support the benefits of nutrition throughout a patient's head and neck pathway which starts with nutritional screening and pre-treatment optimization. Nearly all patients undergoing treatment will require nutrition support, most commonly oral or enteral tube feeding interventions. The expected impact of treatment on nutrition as well as potential for long-term difficulties with eating and swallowing should be discussed thoroughly at pre-treatment stage. The decision to provide a nutritional intervention such as insertion of a feeding tube should be patient-centred and consider the impact on QOL. It is especially important to consider the individual patient needs for those having primary chemoradiotherapy where optimal route and timing for enteral tube feeding is not certain. Nutrition intervention usually ends in the rehabilitation and survivorship stage of a patient's treatment pathway and more research in this area is required.

KEY POINTS

- A high proportion of patients with head and neck cancer present with malnutrition due to disease site and process, pre-existing dietary issues and psychosocial factors. Identifying malnutrition with a validated screening tool is recommended early in the treatment pathway.
- Nutritional assessment by a specialist head and neck oncology dietitian is advised prior to treatment to allow optimization of nutritional status.
- Pre-operative feeding for 7–14 days should be offered to malnourished patients who are planned for major surgery, even if the surgery must be delayed.
- ERAS protocols in head and neck surgery are likely to improve outcomes and nutritional aspects include prevention of long fasting times pre-operatively, carbohydrate-loading and early enteral and oral feeding post-operatively.
- All patients undergoing (chemo)radiotherapy for head and neck cancer will require weekly nutritional assessment by a specialist dietitian due to the impact of treatment toxicities on swallow and oral intake.
- Nutrition support methods during treatment typically include oral (texture modification, food fortification, nutritional supplements) or enteral tube feeding (reactive or prophylactic via NGT or PEG).
- Following treatment for head and neck cancer, patients are at risk of developing late and long-term side effects, such as xerostomia, dysphagia, odynophagia and trismus which may impact nutritional status.
- Multidisciplinary rehabilitation programmes which include a specialist dietitian and SLT have the potential to improve outcomes for oral intake and facilitate early enteral tube feeding removal.
- It is essential that survivorship services are developed for patients with head and neck cancer as they may suffer increased levels of emotional distress, physical limitations, altered body image and relationship difficulties following treatment.
- Nutritional interventions during palliative care should aim to maximize patient comfort and QOL.

INTRODUCTION

Radiotherapy for head and neck cancers (HNC) can impart devastating effects on swallowing and communication abilities. Impaired communication and swallowing functions have significant consequences on health and well-being, and limit activities and participation in social situations.

Adverse effects of tumour on swallowing ability prior to treatment are well documented, largely in patients with advanced stage (T3–T4) primary tumours.[1–3] Cancer treatment in most cases, compounds baseline tumour-associated functional deficits. Historically, functional impairments were largely attributed to major surgery. In the last two decades, however, radiotherapy and chemo-radiotherapy regimes have become the main treatment modality to improve locoregional control and offer functional organ preservation for many advanced stage HNC that would have previously required ablative surgery. Despite comparable survival rates after non-surgical organ preservation,[4, 5] it has become increasingly clear that 'organ preservation' does not necessarily result in function preservation, particularly with regard to swallowing mechanics.[6, 7]

Dysphagia is the most commonly cited functional problem after non-surgical organ preservation for HNC, and may ultimately cause aspiration pneumonia, nutritional and hydration compromise, and subsequent reliance on tube feeding. Patients themselves report that swallowing is a top concern before and after treatment with organ-preserving radiotherapy with or without chemotherapy, hereafter referred to as (chemo-)radiotherapy.[8, 9] Speech and voice outcomes are less commonly reported after non-surgical modalities for locoregionally advanced HNC, and pre-treatment data are often lacking in published reports.[10] Nonetheless, recent studies have identified that changes in voice quality are present up to 1 year following organ preservation treatment for HNC,[10] and these changes are also present in those who have been treated for non-laryngeal cancers.[11, 12]

This chapter includes a brief overview of the communication issues experienced by patients with locoregionally advanced HNC treated with non-surgical organ preservation. A review of voice changes after (chemo-)radiotherapy for early glottic cancer is beyond the scope of this chapter. The primary focus of the chapter is an evidence-based review of swallowing outcomes after non-surgical treatment. Swallowing outcomes reported in published literature will be summarized. Predictive factors will be highlighted, in particular, baseline clinical predictors of swallowing. Preventative strategies will be reviewed, including the potential benefits of highly conformal radiation treatment aiming to reduce bystander doses to swallowing-critical structures and swallowing status during radiotherapy. Finally, this chapter will cover the emerging evidence for rehabilitation strategies implemented both prophylactically and following non-surgical treatment for HNC.

COMMUNICATION FOLLOWING CHEMORADIATION FOR HEAD AND NECK CANCER: ASSESSMENT AND MANAGEMENT

Communication outcomes, and in particular voice outcomes, are increasingly relevant in contemporary practice. With changing demographic towards a predominance of HPV-related head and neck disease, patients are now younger at diagnosis with better prognosis for long-term survival. More likely to be employed at diagnosis, impaired communication may well impact on a successful return to work in modern HNC survivors. Organ-sparing chemoradiotherapy preserves, in most cases, the agility of the articulators, and a minimal effect on speech intelligibility should be expected. Nevertheless, both acute and chronic effects of radiotherapy may impart normal tissue effects that cause perceptual differences in speech and voice. Acute toxicities such as ulceration and oral mucositis will impact on comfort when speaking, but resolve in the months following treatment. In addition, radiotherapy fields that include the larynx will inevitably result in voice changes to some extent. Voice is produced by the larynx, which is particularly vulnerable to the effects of radiation. Treatment effects include oedema, fibrosis and hyperemia and erythema.[13] A recent study highlighted that concurrent chemoradiotherapy for non-laryngeal cancers can have a significant, long-term impact on voice production across patient-reported, instrumental and perceptual assessment methods.[11]

A number of assessments are available to assess vocal functioning. Patient reported outcomes can be collected using the Voice-Related Quality of Life (VR-QOL),[14] the Voice Symptom Scale (VoiSS)[15] and the Voice Handicap Index (VHI).[16] Perceptual voice evaluation is usually rated using the GRBAS scale[17] or the CAPE-V. Instrumental evaluation of voice can be conducted for example using laryngeal videostroboscopy. Videostroboscopy assesses symmetry and degree of true vocal fold motion, and vibratory patterns during phonation.

Speech intelligibility is a broader construct of communication, impacted by voice quality, resonance and articulation. A simple, global assessment of intelligibility includes the Understandability of Speech scale as part of the 3-item Performance Status Scale for Head and Neck Cancer.[18] While there are numerous patient reported voice measures, there are few designed specifically for speech. The Speech Handicap Index (SHI) has been validated for use in the HNC population in Dutch and English.[19, 20] Both the VHI and SHI which have been translated and validated for use in a number of languages.[19–21, 27]

Voice therapy after (chemo-)radiotherapy for advanced stage HNC is largely unstudied. Efficacy of behavioural voice therapy has been reported after radiotherapy for early stage glottic cancer,[28] but it is not clear if there is comparable benefit after radiotherapy for advanced HNC. Vocal hygiene (i.e. laryngeal hydration, gentle vocalization) is also empirically recommended to minimize vocal trauma, abuse or maladaptive hyperfunction during the course of radiotherapy and in acute recovery. The role of the speech language pathologists (SLP) during and following radiotherapy is to instruct the patient in vocal hygiene and to prevent maladaptive strategies employed to overcome radiation-induced dysphonia. Following treatment, patients are likely to experience voice difficulties resulting from the oedema and dryness. In the latter stages of treatment and early recovery phase, fundamental frequency be reduced due to greater vocal fold mass and *en bloc* vibratory patterns from bulky, stiff vocal cords. Along with a harsh or rough quality of voice, disturbed frequency of voice contributes to the perceptual changes reported in published studies. Patients may also report vocal fatigue after long periods of talking. Voice problems may persist due to permanent treatment-related changes or vocal abuse resulting from attempts to compensate for transient dysphonia during early recovery.[29]

FUNCTIONAL ASSESSMENT OF SWALLOWING AFTER CHEMORADIOTHERAPY

In recent years, there has been a significant rise in the number of studies reporting swallowing outcomes after organ preservation. To understand the impact of cancer therapy on swallowing function, it is essential that researchers use a range of measures that are sufficiently standardized to allow for future meta-analysis as well as immediate interpretation. One of the challenges in interpreting published data is the heterogeneity of swallowing outcome measures reported in published studies.[30] Much of the radiation oncology literature reports toxicity according to clinician-rated scales such as the Common Terminology Criteria for Adverse Events (CTCAE).[31] While these scales provide invaluable data in relation to a broad range of toxicities, the CTCAE rates dysphagia as function of dietary restrictions, dysphagia symptoms, and enteral/parental nutrition requirements, and lacks sensitivity or specificity to aberrant oropharyngeal swallowing physiology.[6] The broad criteria that define toxicity grades for dysphagia are, unfortunately, not sensitive to physiologic disturbances, asensate dysphagia (e.g. silent aspiration), or specific to pharyngeal dysfunction and downstream effects of dysphagia on quality of life.

Comprehensive dysphagia assessment requires a multidimensional panel of measures, incorporating instrumental examinations of swallowing such as the modified barium swallow (MBS) study (videofluoroscopy) or Fibreoptic Endoscopic Evaluation of Swallowing (FEES), along with clinician-rated and patient-reported outcome measures (PROM). The importance of multidimensional swallowing evaluation has been reinforced by a recent study evaluating swallowing outcomes following radiotherapy. In this longitudinal study of chemoradiotherapy for HNC, it was found that using different methods of swallowing evaluation resulted in complementary, but distinct normal toxicity complication probabilities.[32] The importance of including a broad range of swallowing measures has been further highlighted in the radiation oncology literature with specific guidance to incorporate these multidimensional assessments of swallowing function in Phase III organ preservation trials.[33]

Standardized functional assessments are a critical component of comprehensive clinical care and outcomes research. Functional assessments can include 1) clinician-driven appraisals (e.g. physical examination, instrumental and imaging studies and clinician-rated scales) and 2) patient-reported outcome measures (PROMS) (e.g. quality-of-life questionnaires, symptom inventories). Clinical examinations by speech and language therapists (SLTs – also known as speech language pathologists (SLPs in the USA) include a cranial nerve examination, oral motor assessment, perceptual motor speech and voice ratings, and the clinical examination of the swallow. Observations from these clinical assessment protocols provide the foundation of the functional assessment and offer the advantage of observing speech, voice or swallowing in a more natural environment (e.g. swallowing natural food rather than a contrast agent, or voicing without an endoscope in the mouth or nose), but clinical assessments lack the sensitivity of instrumental studies.

Instrumental examinations and imaging studies are therefore considered the gold-standard because they directly observe the physiology and competency of swallowing, speech or voice production. Instrumental examinations include the MBS study (or videofluoroscopic swallowing study), FEES, and laryngeal videostroboscopy. Indicators of functional status can also be rated as an adjunct to clinical and instrumental studies according to standardized tools such as the Performance Status Scale-Head and Neck (3-items: Normalcy of Diet, Understandability of Speech, Eating in Public), toxicity grading scales European Organization for Research and Treatment of Cancer (EORTC), CTCAE, or simply by record of the presence or absence of gastrostomy or tracheostomy. Functional status scales provide uniform nomenclature for simple, surrogate measures of functioning routinely ascertained in clinical encounters. Each type of functional measure is detailed in the following sections.

Clinical evaluation of swallowing

The importance of the clinical swallowing evaluation is that it provides a baseline on which performance measures can be taken (ideally) before treatment and may predict outcome.[34] A clinical swallowing evaluation is comprised of a number of measures. After completion of a detailed medical history, the clinical examination will include an oromotor evaluation to assess the integrity of the cranial nerves pertaining to swallowing. In addition, swallowing trials will be undertaken to establish the presence of clinical signs of aspiration or overt signs of difficulty. Recent studies have reported on the benefits of the 100 mL Water Swallow Test (WST) as a component of the conventional clinical swallowing evaluation.[35] Offering a low cost quantifiable endpoint from clinical examination, the WST measures swallowing speed, capacity and volume. The WST is easily repeatable at follow-up appointments to monitor changes in swallowing performance. In addition, clinicians can observe for clinical signs of aspiration as is the case in any standard clinical swallowing evaluation. In combination with information gleaned from history taking and oromotor examination, these data signpost referral for a detailed instrumental evaluation of swallowing. The use of a simple, validated tool such as the Performance Status Scale for Head and Neck Cancer (PSS-HN)[36] or Functional Oral Intake Scale (FOIS)[37] should be used in adjunct to the conventional examination to quantify the functional status of the patient with regard to feeding tube dependence and level of oral intake.

Instrumental evaluation of swallowing

A number of instrumental methods are available to examine swallowing function (i.e. physiology, safety or airway protection and efficiency or bolus clearance) in detail. These include solid-state and high-resolution manometry,[37–42] scintigraphy,[43–46] ultrasound,[47–54] transnasal (o)esophagoscopy (TNE),[55, 56] cine magnetic resonance imaging (MRI)[57–59] and advanced computed tomography (CT) techniques.[60, 61] Each of these techniques provides a unique insight into specific features of the deglutition process, however, the most commonly reported technique in the radiation oncology and oropharyngeal dysphagia literature is videofluoroscopy[62] and FEES.[63]

During videofluoroscopy, patients are imaged in lateral and anterior-posterior planes and presented with a range of liquid and food boluses that have been infused with contrast agents, typically barium sulfate. Videofluoroscopic examination of swallowing, commonly referred to as the MBS, allows for visualization and analysis of the oral, pharyngeal and oesophageal stages of the swallow. A number of observations can be made from MBS, including the presence of penetration of material in to the laryngeal airway and tracheal aspiration (quantified per the validated Penetration-Aspiration Scale[64]) and swallowing efficiency (quantified by Oro-Pharyngeal Swallowing Efficiency (OPSE)[45]). More recently the Modified Barium Swallow Impairment Profile (MBSImp) was introduced to comprehensively assess 16 critical components of the oropharyngeal swallow and provide a standardized profile of the physiological swallowing impairment.[45, 65] Based on findings from the MBS, the SLP can establish the nature and extent oropharyngeal dysphagia and develop an individualized rehabilitation plan. Efficacy of tailored swallowing strategies, such as change in posture or modification of the swallowing pattern, can be examined in real-time on the MBS. DIGEST is another method recently developed to measure the severity of pharyngeal stage dysphagia in a manner compatible with CTCAE toxicity grade (1 = mild, 2 = moderate, 3 = severe, 4 = life-threatening/profound) based on the results of the MBS study.[66]

FEES also allows for detailed evaluation of swallowing. While the oral stage cannot be observed and there is white out during the swallow, it provides valuable information on the pharyngeal stage of the swallow and is a useful biofeedback tool, particularly for therapeutic benefit.

Patient-reported outcome measures (PROMS) of swallowing

The patient's perception of their swallowing impairment and how it impacts on their everyday life is arguably a critical outcome of cancer therapy. To that end, PROMs have

gained popularity in recent decades. PROMs complement clinician-rated assessments by quantifying the patient's perceived level of handicap or impairment, and its impact on daily activities and quality of life. More recently, the PROMs have been augmented by carer-reported outcomes to add how dysphagia might impact on quality of life and participation in social situations.[67]

A number of assessments are available that enable clinicians to understand patient's perceived swallowing outcomes following HNC treatment. Specific to HNC, these include, among others, the University of Washington Quality of Life Questionnaire (UW-QOL),[68] the European Organization for Research and Treatment of Cancer (EORTC HN-35),[69] and the MD Anderson Dysphagia Inventory (MDADI).[70] UW-QOL and EORTC are general QOL inventories that include swallowing-specific items, whereas the MDADI is a 20-item inventory focused exclusively on swallowing-related QOL.

The UW-QOL is particularly useful for assessment of multiple domains of functional impairment, and it offers the unique feature of prioritization of key issues for the patient. Research has shown that up to 48% of patients select swallowing as being a priority concern for them 1 year after treatment with 3D-conformal radiotherapy treatment.[8] A recent study of patients treated with parotid-sparing intensity-modulated radiotherapy (IMRT) has found that 40% of patients report swallowing as being a priority concern at 12 months.[9] Popular multi-symptom inventories that include dysphagia symptom items include the MD Anderson Symptom Inventory-Head and Neck module (MDASI-HN)[71] and the Vanderbilt Head and Neck Symptom Scale (VHNSS).[72]

Questionnaires are available to ascertain more details on swallowing-specific quality of life including the MDADI and the SWAL-QOL.[73] Among these, the MDADI was specifically developed and validated for use with HNC patients. Other questionnaires designed to ascertain swallowing symptoms and ability include the EAT-10[74] and the Sydney Swallow Questionnaire (SSQ) that have both been validated for use in HNC.[75] There is consensus that PROMs and clinician-rated measures should be used in concert, because discordance that is recognized between patients' perception of their handicap and clinician-rated observations.

DYSPHAGIA AFTER CHEMORADIOTHERAPY

Outcomes

During (chemo-)radiotherapy, acute damage occurs to the mucosa and soft tissue in the radiation treatment volume leading to an inflammatory reaction and subsequently, mucositis and oedema of the soft tissues.[13, 76, 77] While some improvement of acute symptoms can be expected by 3 months, this is not universal. Persistent, longer-term difficulties have been reported after treatment, months or even years later.[78–81] Commonly reported problems impacting on swallowing safety and efficiency include reduced pharyngeal contraction, reduced base of tongue retraction, incomplete epiglottic deflection, incomplete or delayed laryngeal closure and hyolaryngeal excursion, and abnormal oesophageal opening and stricture.[78, 82–86] While mainly seen in the high dose volume, stricture has been observed in areas that have not been treated in the high dose radiation field, leading authors to suggest that decreased swallowing frequency during treatment may also increase the risk of fibrosis.[83] Jointly, however, current data suggest that aforementioned impairments in laryngopharyngeal physiology are the primary contributors to radiation-associated dysphagia (RAD) rather than stricture. This is particularly the cases for late-RAD, driven often by profoundly impaired pharyngeal propulsion coupled with delayed lower cranial neuropathies.[87] A recent systematic review reported the overall risk of stricture after non-surgical HNC treatment was 7.2% over published series from 1989 to 2008. Interestingly, the rate of stricture was elevated in IMRT series (16.7%) perhaps reflecting intensified regimens of chemoradiation in contemporary organ preservation publications or early methods of IMRT not sufficiently controlling laryngeal and esophageal inlet dose.[88]

A primary observation from instrumental assessment is the presence or absence of aspiration. Penetration of material into the upper airway may be spontaneously cleared by patients, however for some, cumulative penetration or inadequate clearance of airway pharyngeal residue may result in delayed aspiration after the swallow. Aspiration is often silent in upwards of 50% of post-radiotherapy aspirators, and the false negative results of clinical examination in silent aspirators can lead to potentially life threatening aspiration pneumonia. Aspiration is common in patients with HNC. Authors have cited data reporting aspiration rates ranging from 18% to 81% after chemoradiation to all head and neck sites and 18% to 54% in the case of oropharyngeal cancers.[89]

Predictors

Tumour and treatment burden are the most notable clinical predictors of functional outcomes after organ preservation.[90] While data suggest the prognostic significance of the primary and nodal staging per TNM criteria, T-stage appears the most consistent staging variable that impacts the severity of dysphagia, gastrostomy dependence, and aspiration after HNC treatment. Likewise, among sites of HNC treated with radiotherapy or chemoradiotherapy, hypopharyngeal tumours confer the highest risk of developing chronic dysphagia and stricture. Population-level data from the US suggest that patients with oropharyngeal primary tumors have the second highest risk of dysphagia (after hypopharyngeal), followed closely by laryngeal primary tumours.[91] Laryngeal cancers may have performed differently in this study, if small glottis cancers had been stratified out from advanced stage laryngeal cancers that are more likely to manifest dysphagia after treatment.

Treatment intensity significantly impacts functional outcomes. Intensification strategies, whether accelerated fractionation schedules, dose-escalation, or via the addition of systemic agents to radiotherapy regimes, have all been associated with greater toxicity and functional effects in clinical studies. Radiotherapy dose-distribution predicts the degree of swallowing impairment across a variety of

outcome measures.[32] Thus, conformal plans using IMRT have been proposed as a strategy to reduce the burden of dysphagia.[86] It is important to note, however, that swallowing-specific dose-constraints have not historically been included in IMRT algorithms. In fact, unintended elevated bystander doses have been observed in certain swallowing-critical regions of interest including the brainstem, anterior oral cavity (inclusive of critical suprahyoid musculature), and larynx when not optimized in IMRT plans.[92, 93] It follows that the maximal benefit of IMRT on swallowing function may be realized only with swallowing-specific OARs are considered in treatment plans. Significant efforts have been made in the last decade to delineate these regions, and consensus is largely to reduce dose to the pharyngeal constrictor muscle region (particularly SPC) and the larynx , with emerging reports suggesting suprahyoid muscles in the floor of mouth regions as a previously undetected swallowing region of interest.[94–97] Favourable results have also been reported with the sparing of dysphagia-aspiration risk structures (DARS) using IMRT.[89] Given recent reports regarding lower aspiration levels in patients receiving split-field IMRT techniques,[98] potential benefits over whole-field techniques have been discussed in the literature.[94] In addition, de-escalation of total radiotherapy dose is currently proposed in several cooperative group trials in HPV-associated HNC populations who have favourable locoregional control and the potential to live decades with late effects of treatment. Examples of two multicentre studies which have incorporated a dedicated dashboard of multidimentional swallowing measures to explore these areas include the PATHOS and DARS studies.[99, 100]

Likewise, cytotoxic chemotherapy sensitizes tumour and normal tissue to effects of radiotherapy. Thus, treatment intensification by the addition of chemotherapy typically increases swallowing toxicity. Acute and chronic dysphagia is most likely exacerbated when chemotherapy is delivered concurrently with radiotherapy, whereas adverse effects of induction chemotherapy on swallowing function are not established. In fact, induction chemotherapy was found to impart improved local symptoms (diet per PSS-HN, MDADI, and pain scores) prior to definitive local therapy in a trial of oral tongue cancer patients.[101] Favourable long-term swallowing outcomes have also been observed in longitudinal follow-up of patients with locally advanced HNC treated with an induction approach.[102]

Baseline functional status significantly predicts function after treatment. Aspiration, vocal fold paresis, feeding tube dependence and tracheostomy prior to treatment have all been reported as adverse prognostic indicators of functional recovery.[90] That is, organ preservation should not be expected to restore function to the impaired organ. While data suggest that roughly half of patients with vocal fold fixation prior to chemoradiation may recover some mobility, the functional translation of this recovery is not clear.[103, 104] Moreover, aspiration of thin liquids sufficient to necessitate dietary modifications prior to treatment significantly predicts for unsafe oral intake requiring NPO status in long-term survivorship after laryngeal preservation.[85] For these reasons, among others, pre-treatment referral to SLTs for baseline functional assessment has recently been recognized as best practice in patients receiving non-surgical organ preservation by the Triological Society[105] and in the National Institute for Clinical Excellence's Improving Outcomes Guidance for Head and Neck Cancer.[106] It is also a 'top-ten' recommendation from the British Association of Head and Neck Oncologists.[107]

One of the important changes in clinical practice that may contribute to improved swallowing outcomes is the implementation of an individualized approach to tube feeding placement in patients undergoing organ-preserving HNC treatment.[94, 108] As discussed earlier, it is clear that some people may require nutritional support by way of tube feeding simply due to cancer related dysphagia. However, there has been a shift in the clinical practice trends from implementing *prophylactic* gastrostomy feeding in all patients to individualizing decisions on the basis of pre-treatment functioning, nutrition, and tumor burden.[109] Systematic reviews agree that the evidence base regarding optimal tube feeding route is limited at this time.[110] Variation has been reported in approaches to tube feeding in the UK and Australasia.[111, 112] Two primary considerations are timing of placement (prophylactic versus reactive) and the type of tube (nasogastric versus gastrostomy).

Historically, gastrostomy tubes were placed prophylactically in all (or most) patients with locally advanced HNC dispositioned to receive radiotherapy. Recent data, however, suggest that reactive rather than prophylactic feeding tubes are associated with favourable swallowing outcomes and the feasibility of this approach has been established in comprehensive systems that allow for close monitoring of nutrition, hydration and swallowing status during radiotherapy.[113] Rather than placement of prophylactic gastrostomy tubes in patients who may ultimately continue with oral intake during treatment,[114] the use of reactive nasogastric feeding has also been proposed in the literature.[115] Despite more frequent tube displacements, no difference has been reported in patient reported assessments of physical condition or quality of life between those who had nasogastric or gastrostomy feeding.[116]

Prevention and rehabilitation

Improved outcomes in modern trials may be influenced also by more active involvement of rehabilitation professionals such as SLTs and dietitians in recent years. However it is clear from surveys of UK, US and Australasian service delivery that the timing and nature of SLT provision to HNC patients is still variable.[112, 117, 118]

Several studies have examined the potential benefit of prophylactic swallowing therapy for HNC patients, including three randomized clinical studies.[119–121] Proactive swallowing therapy encourages maximal use of the swallowing musculature during radiotherapy. In effort to discourage disuse atrophy, two goals can be outlined in proactive swallowing therapy: eat (that is, continue oral intake during radiotherapy) and exercise (that is, perform targeted swallowing exercise during radiotherapy). Observational data suggest the benefit of maintaining oral intake throughout radiotherapy on long-term diet

outcomes and PROMs.[122, 123] In addition, four institutions have published a range of favourable functional outcomes associated with swallowing exercise during radiotherapy. Prophylactic swallowing exercise has been associated with better swallowing-related quality of life scores,[124, 125] superior base of tongue and epiglottic movement,[126] lower gastrostomy rates,[113] shorter gastrostomy dependence,[113] better post-radiotherapy diet levels[120] and superior muscle composition on post-radiotherapy MRI.[121] Despite many hints of efficacy in these studies, a recent Cochrane review found inconclusive evidence on the benefit of swallowing exercise in this population in large part related to underpowered single institution trials and variable methodology precluding meta-analysis.[128] Data also suggest independent positive associations with both prophylactic swallowing therapy goals: *eat* and *exercise*. That is, patients who both eat and exercise during radiotherapy have the best swallowing outcomes, and patients who either eat or exercise have better swallowing outcomes than those who do neither.[127, 128] Importantly, it has also been raised in the literature that despite fairly uniformly positive findings, studies of proactive swallowing exercise vary in how therapy was delivered and practicalities in individual clinical settings.[94] More recently, there has been interest in the potential of Expiratory Muscle Strength Training (EMST) in the rehabilitation of HNC treatment-related dysphagia. Reduced maximum expiratory pressures have been found in patients with chronic radiation-associated aspiration. Initial findings in the HNC population suggest improved expiratory muscle strength and improved swallowing function following therapy with EMST.[129, 130]

CONCLUSION

In this chapter we have described the impact of disease and treatment effects contributing to communication and swallowing problems following organ preservation protocols for HNC. The SLT is a vital member of the multidisciplinary team. Based on the available evidence, we propose the following key points to optimize functional outcomes.

KEY POINTS

- Refer patients for multidimensional swallowing assessment *before* treatment to tailor proactive swallowing therapy and identify high risk patients.
- Standardize multidimensional swallowing assessments to include clinical swallowing evaluation, instrumental swallowing examination and PROMs.
- Use psychometrically validated, quantitative metrics of swallowing function.
- Implement prophylactic swallowing therapy prior to and during treatment – including targeted swallowing exercise and promotion of oral intake throughout treatment.
- Instruct patients in vocal hygiene during treatment and in the immediate post-treatment phase to prevent secondary voice problems due to vocal hyperfunction.
- Advocate a collaborative approach to care during treatment to minimize side effects such as pain that may impact on the ability to continue swallowing.
- Individualize decisions regarding tube feeding during (chemo-)radiotherapy, with preference towards reactive rather than prophylactic tube placement.
- Establish resources and clinical pathways to work towards tube removal as soon as possible following treatment.
- Implement evidence-based swallowing therapy to address impairments based on instrumental swallowing evaluation.
- Consider highly conformal techniques such as IMRT optimized to spare swallowing critical structures, when possible.
- Consider an individualized approach to treatment de-escalation when possible to reduce toxicity and improve swallowing outcomes.
- Consider the profound effect on health-related quality of life that some HNC survivors may encounter and encourage psychological support to deliver a holistic rehabilitation programme when indicated.
- Ensure systems are in place to monitor and provide interventions for patients with persisting swallowing difficulties after treatment and importantly, late radiation associated dysphagia that can occur even years after functional swallowing.

SEARCH STRATEGY

This chapter is a basic science chapter with information from anatomy texts and scientific papers concerning head and neck anatomy, identified through Medline searches. The anatomical evidence is supported by cadaver dissection studies, as well as the medical literature.[1] The clinical evidence is observational.

INTRODUCTION

> 'Anatomy is to physiology as geography is to history; it describes the theatre of events'
>
> Jean Fernel 1497–1558 France.

A sound appreciation of the intricate anatomy of the neck is essential for any surgeon embarking upon operations in the neck. This chapter provides a detailed and clinically focused synopsis of neck anatomy; covering developmental anatomy, surface anatomy and the triangles of the neck, fascial layers, neck musculature and deep neck spaces, as well as the important structures encountered within in the neck such as major blood vessels, lymphatics and important cranial and cervical nerves. Details of the viscera of the neck, such as the larynx, pharynx, oesophagus, trachea, thyroid, parathyroid and salivary glands are discussed elsewhere.

DEVELOPMENTAL ANATOMY

Structures in the neck that are innervated by the cranial nerves are derived from the branchial apparatus. The six branchial arches begin to emerge from 4 weeks' gestation. Each arch has its own cranial nerve, cartilage and artery. The fifth arch obliterates soon after all the branchial arches become apparent. Between the arches sit internal pouches and external clefts or grooves (**Figure 35.1**). The arches, clefts and pouches give the appearance of a series or slit-like grooves, resembling the gills of fish, hence the term 'branchial' which is derived

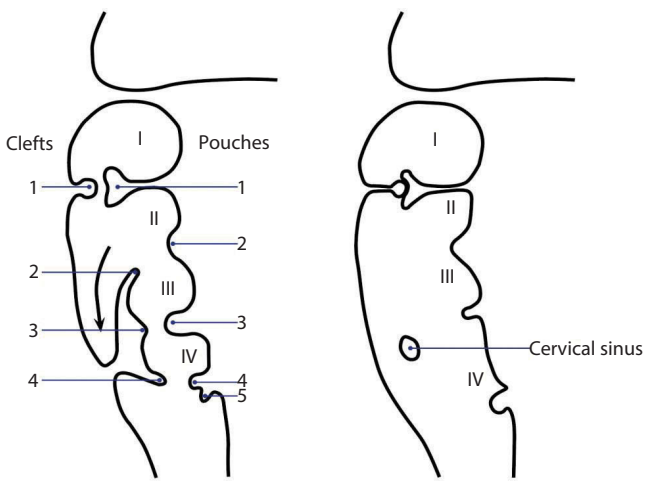

Figure 35.1 Schematic diagram of the branchial apparatus *in utero*.

from the Greek word for gills. The structures derived from the branchial system are outlined in **Table 35.1**.

Congenital abnormalities of the branchial arches can lead to absence or malformation of the head and neck structures arising from the branchial apparatus. This may result in microtia, hearing loss and facial asymmetry and can occur in isolation or as part of a syndrome. Developmental anomalies of the branchial clefts lead to cysts, sinuses or fistulae found in the neck (**Table 35.2**).

First branchial cleft abnormalities are caused by embryonic duplication of the first cleft or first arch and cleft, classified by Work in 1972 into type I and type II respectively.[2] These are rare, representing approximately 5% of branchial cleft anomalies. First branchial cleft abnormalities present as an external fistula tract opening located anterior and inferior to the tragus (type I) or as a fistula tract between an anterior opening close to the angle of the mandible with a posterior opening found in the ear canal or conchal bowl (type II). The fistulae tracts are present from birth and may be asymptomatic or can present with recurrent skin or ear discharge. Treatment is with complete surgical excision of the tract, taking care not to injure the facial nerve. This is particularly relevant with type II lesions which have an inconstant relationship to the facial nerve which may run either deep or superficial to the fistula tract.

Second branchial cleft abnormalities are the most commonly encountered, representing approximately 95% of all

TABLE 35.1 Branchial derivatives

Arch	Nerve	Cartilage	Muscle	Artery	Internal pouch	External cleft
1 Mandibular	Trigeminal (Mandibular branch V3)	Meckel's: Maxilla Malleus Incus	Mylohyoid Anterior digastric Tensor tympani Tensor veli palatini Muscles of mastication	1st aortic arch: maxillary artery	Eustachian tube Middle ear cleft Medial surface of tympanic membrane	External auditory meatus Lateral surface of tympanic membrane
2 Hyoid	Facial	Reichart's: Lesser cornu + upper body of hyoid Stapes superstructure Styloid process	Muscles of facial expression Posterior belly of digastric Platysma Stapedius	2nd aortic arch: stapedial artery	Palatine tonsil	Grows over remaining grooves
3	Glosso-pharyngeal	Greater cornu + lower body of hyoid	Stylopharyngeus Superior & middle constrictor	3rd aortic arch	Inferior parathyroid glands Thymic duct	Obliterated
4	Vagus – Superior laryngeal nerve	Thyroid lamina	Cricothyroid	4th aortic arch: arch of aorta	Superior parathyroid glands	Obliterated
6	Vagus – Recurrent laryngeal nerve	Cricoid Arytenoid cartilages	Inferior constrictor Intrinsic muscles of larynx	6th aortic arch: ductus arteriosus	Ultimobrachial body (forms parafollicular C cells of thyroid)	Obliterated

TABLE 35.2 Congenital branchial abnormalities

Branchial cleft fistula		% of cases	External opening	Internal opening	Associated structures	Symptoms	Management
1st	Work Type I	5%	Anterior and inferior to tragus	External ear canal or middle ear	Lies superficial to facial nerve	Skin or ear discharge	Surgical excision of fistula tract with CN VII monitoring
	Work Type II		Posterior to angle of mandible	Conchal bowl or external ear canal	Inconstant relationship with facial nerve	Skin or ear discharge	Surgical excision of fistula tract with CN VII monitoring
2nd		90%	Anterior border of sternocleidomastoid	Tonsillar fossa	May pass between internal and external carotid artery, runs deep to hypoglossal nerve	Skin discharge associated with upper respiratory tract infections	Surgical excision of fistula tract
3rd and 4th		<5%	Anterior border of sternocleidomastoid muscle, lower neck	Piriform fossa (3rd superior and 4th inferior to superior laryngeal nerve)	4th tract may be associated with thyroid gland	Skin discharge or abscesses, Recurrent thyroiditis (4th)	Surgical excision of tract or endoscopic ablation of internal opening

branchial anomalies. Second cleft fistulae or sinus tracts are found along the anterior border of the sternocleidomastoid muscle, with a tract extending cranially along the carotid sheath which can pass between the internal and external carotid arteries and may run deep to the hypoglossal nerve. The internal opening of a second branchial cleft fistula is found in the tonsillar fossa. Patients present with recurrent skin discharge, often associated with upper respiratory tract infections. Management is with complete surgical excision of the tract, taking care to avoid injury to the carotid arteries or hypoglossal nerve.

Third and fourth branchial cleft abnormalities are rare and are difficult to differentiate clinically so are described together. Third cleft fistulae have a skin opening anterior to the sternocleidomastoid muscle in the lower third of the neck, with an internal opening in the piriform fossa, above the level of the superior laryngeal nerve. Fourth cleft fistulae have similarly located skin openings, however, the internal opening in the piriform fossa is located below the level of the superior laryngeal nerve. Clinical features of third and fourth branchial cleft abnormalities include recurrent skin infections and abscesses. Recurrent thyroiditis is a potential feature of fourth cleft abnormalities as the fistula tract may be closely related to the thyroid gland.[3] Traditional management entails complete excision of the tract, although, more recently, endoscopic ablation of the internal opening within the piriform fossa has been described.[4, 5]

Branchial cysts typically arise from the second branchial cleft, which grows caudally, eventually obliterating the third and fourth clefts in normal development. This creates a potential space known as the cervical sinus, hypothesized to be a site of trapped epithelium which develops into a branchial cleft cyst. Branchial cysts are often asymptomatic and go unnoticed until they enlarge secondary to upper respiratory tract infection. A popular alternative theory for branchial cyst development is cystic degeneration within a lymph node, hypothesized because lymphoid tissue, as well as epithelium, is found within the walls of brachial cysts.[6]

KEY POINTS

- Knowledge of the developmental anatomy is key to understanding neck anatomy.
- Abnormalities of the branchial clefts may present with fistulae, sinuses or cysts.
- Definitive treatment of 1st and 2nd branchial cleft fistulae is complete excision of the tract together with the openings.
- 3rd and 4th branchial cleft abnormalities may be managed with endoscopic ablation of the internal opening.

SURFACE ANATOMY AND TRIANGLES OF THE NECK

Understanding of the surface anatomy of the neck and the structures that can be palpated is essential for surgeons to differentiate pathology from normal anatomy in neck examination. Furthermore, the means to determine the exact location of pathological masses encountered assists with diagnosis. The neck is classically divided into anterior and posterior triangles, which can be further divided into other triangles as described below, helping to compartmentalize the complex anatomy of the neck.

Surface anatomy

The superior border of the neck is defined by the mandible with the deep limits of the floor of mouth anteriorly and skull base posteriorly. The inferior limits of the neck are formed by the upper aspect of the first rib and the first thoracic vertebrae.

MANDIBLE

The lower border of the mandible forms the upper limit of the neck and the division between the neck and the face. The superficial lobe of the submandibular gland is palpable inferior to the lower border of the body of the mandible, just anterior to the angle. The tail of the parotid gland is palpable just posterior to the angle of the mandible.

MASTOID PROCESS

The tip of the mastoid is palpable posterior to the lobule, where the sternocleidomastoid muscle inserts. Anterior and inferior to this the transverse process of the atlas may be palpated.

HYOID BONE

The hyoid is an important bony landmark in the neck. Sitting in the midline of the neck, superior to the thyroid cartilage, the hyoid is a horseshoe-shaped bone with a central body and paired greater and lesser cornus. The greater cornu acts as a guide to the lowermost extent of the marginal mandibular branch of the facial nerve and the level of the hyoid divides nodal levels II and III. The hyoid bone has many muscular attachments; the mylohyoid, geniohyoid and hyoglossus insert onto the superior aspect of the body of the hyoid, whereas the omohyoid, sternohyoid and thyrohyoid muscles insert onto the inferior border. Fibres of the middle constrictor muscles insert into the greater cornu and the stylohyoid ligament attaches to the lesser cornu. Inferiorly the thyrohyoid membrane connects the body of the hyoid to the thyroid cartilage.

Laryngeal cartilages and trachea

The cartilaginous framework of the larynx consists of the thyroid cartilage and cricoid cartilage, which are palpated in the midline of the neck. The arytenoid cartilages lie posteriorly and are not palpable. The thyroid cartilage is shield shaped and is notched superiorly forming a laryngeal prominence that is generally more significant in males than in females. Provided there is no lateral displacement of the larynx the notch can be a helpful surface landmark of the midline of the neck. Inferior to the thyroid cartilage sits the signet ring-shaped cricoid cartilage which is

easily palpable in thin individuals. The cricoid cartilage is at the level of the sixth cervical vertebrae and represents the border between the larynx and trachea, being the first and only complete tracheal ring. It is an important surface landmark to guide placement of the transverse incision used for elective tracheostomy, which is typically between the suprasternal notch and the lower border of the cricoid cartilage in an extended neck.[7] The thyroid and cricoid cartilages are joined by the cricothyroid membrane which is palpable in the midline as an area of cartilage deficiency between the lower border of the thyroid cartilage and the cricoid. This membrane forms an important landmark for emergency front of neck access as it is a relatively avascular plane where temporary airway access can be gained via needle or scalpel cricothyroidotomy. Inferior to the cricoid the cartilaginous rings of the cervical trachea can be palpated.

Thyroid

The isthmus of the thyroid gland can be palpated overlying the second and third tracheal rings. The lobes of the thyroid are located deep to the lower third of the sternocleidomastoid muscles and are not palpable unless enlarged.

Sternocleidomastoid muscle

The sternocleidomastoid muscle has a sternal head which arises from the manubrium and a fan-shaped clavicular head that arises from the medial part of the clavicle. The sternocleidomastoid divides the neck into anterior and posterior triangles, as outlined below. The carotid sheath runs deep to the sternocleidomastoid muscle, the bulk of the muscle provides a degree of protection to the major vessels from penetrating neck injuries. The lymph nodes of the jugular chains are located deep to the muscle. Turning the patient's head towards the side of the neck being palpated relaxes the muscle to allow palpation of the deeper lymph nodes.

Trapezius muscle

The trapezius forms the posterior border of the posterior triangle and the posterior limit of the nodal basins of the neck. Posterior to the trapezius lies the para-spinal musculature and the vertebrae.

Marginal mandibular branch of the facial nerve

The path of the marginal mandibular nerve is important to consider during many neck procedures to avoid inadvertent injury. It originates from the lower division of the facial nerve after the stylomastoid foramen and courses anteriorly and inferiorly from the lower aspect of the parotid gland, extending to the level of the greater cornu of the hyoid at its lowest point.[8] Whilst the exact course of the nerve and number and location of branches may be variable, it is reliably located at the point where it crosses the mandible to leave the neck, running with the facial artery, from which a palpable pulse may be located just anterior to the angle of the mandible. Incisions should be placed below the level of greater cornu of the hyoid, typically two finger breaths below the lower border of the mandible, to avoid injury to the nerve. Many surgical strategies exist to avoid inadvertent injury during neck dissection. Some surgeons advocate raising the flap in the immediate subplatysmal plane and locating the nerve before incising fascia inferior to it to retract the nerve above the level of the mandible, some suggest ligating the facial vein inferior to the lower border of the submandibular gland and retracting the vein and fascia upwards to protect the nerve as the marginal mandibular nerve is reliably located superficially to the facial vessels.

Spinal accessory nerve

The course of spinal accessory nerve is important to appreciate as it can be accidentally injured in procedures in both the anterior and posterior triangles of the neck. After exiting the skull via the jugular foramen, the spinal accessory nerve courses inferiorly and laterally in the neck to provide motor supply to the sternocleidomastoid muscle, which it passes through, and the trapezius. The nerve can be reliably located over the transverse process of the atlas, palpable anterior and inferior to the mastoid tip. It then enters the sternocleidomastoid muscle, typically at the junction of the superior and middle thirds and exits the posterior border of the sternocleidomastoid 1 cm above Erb's point where the cervical plexus nerves emerge from the posterior border of the muscle.[9] The accessory nerve then follows a variable course across the posterior triangle to enter the trapezius muscle at the junction of its middle and lower thirds. The spinal accessory nerve is an important landmark in sub-dividing lymph node levels IIa and IIb.

Carotid artery

The pulse of the carotid artery is most easily palpated at the level of the carotid bifurcation, located between the angle of the mandible and greater cornu of the hyoid, found at the anterior border of the sternocleidomastoid muscle.

Jugular veins

The internal jugular vein (IJV) runs with the carotid artery and vagus nerve in the carotid sheath. The surface marking of the IJV is parallel and slightly lateral to the common carotid artery. The external jugular vein is often visible, running inferior from the angle of the mandible, crossing at the mid-point of the sternocleidomastoid muscle and extending deep to the posterior border of the clavicular head of sternocleidomastoid to meet the internal jugular and anterior jugular veins. The anterior jugular veins run para-midline, superficial to the sternohyoid and thyrohyoid muscles.

Root of the neck

The root of the neck is defined by the manubrium, the sternoclavicular joints and the clavicles, which articulate with the acromion laterally. Above the sternal notch is the suprasternal fossa, also known as Burns space.[10] Chassaignac's triangle (**Figure 35.2**) is the space between the longus colli muscle, the anterior scalene muscle as it attaches to the C6 tubercle (Chassaignac's tubercle) with the subclavian vein as the inferior border. The scalene lymph nodes are located in this space, which should be explored during neck dissection. Lymphadenopathy in this location frequently represents metastasis either from the thyroid or from a primary site below the clavicles which may be of breast, lung, stomach or ovarian origin. The thoracic duct is encountered here, either on the left as a main trunk, or as a network of smaller lymphatic channels on either side. Care must be taken to avoid injury to these vessels to avoid chylous fluid leak during neck dissection.

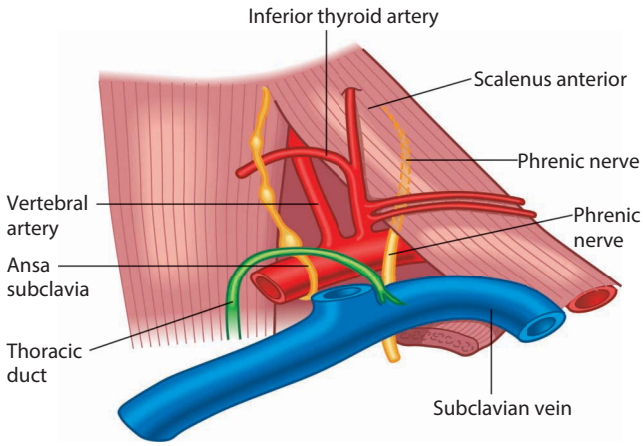

Figure 35.2 Chassaignac's triangle.

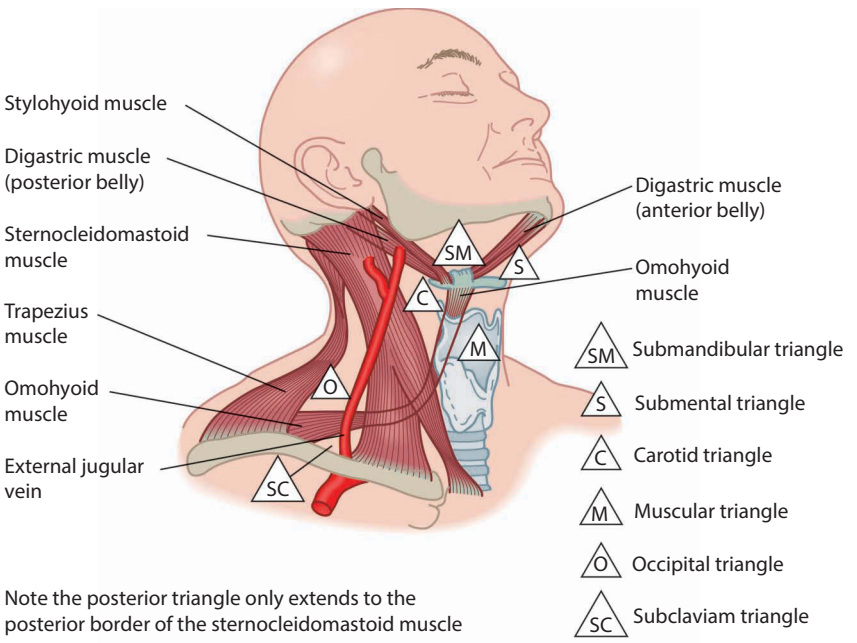
KEY POINTS

- Surface anatomy of nerves and vessels must be considered when planning incisions.
- The marginal mandibular branch of the facial nerve can run as low in the neck as the greater cornu of the hyoid; incisions should be placed below this level to avoid injury to both this nerve and the cervical branch of the facial nerve.
- The spinal accessory nerve runs in the roof of the posterior triangle; all important structures lie caudal to the nerve.

Triangles of the neck

The neck is classically divided into anterior and posterior triangles (**Figure 35.3**), by the posterior border of the sternocleidomastoid muscle. These triangles can be further sub-divided into distinct anatomical triangles known as the submental, submandibular, carotid, muscular and subclavian triangles.



Occipital triangle + Subclavian triangle } Posterior triangle

Submental triangle + Submandibular triangle + Carotid triangle + Muscular triangle } Anterior triangle

Figure 35.3 Triangles of the neck.

TABLE 35.3 Summary of the contents of the anterior triangle

Muscles	Vessels	Nerves	Viscera	Other
Digastric	External carotid artery and branches (except posterior auricular)	Internal and external laryngeal nerves	Thyroid and larynx	Jugular chain of lymph nodes
Stylohyoid and mylohyoid	Internal and anterior jugular vein and tributaries	Nerve to mylohyoid	Submental and submandibular glands	
Superior belly of the omohyoid		Hypoglossal nerve		
Strap muscles				

ANTERIOR TRIANGLE

The anterior triangle is defined by the midline anteriorly, the inferior border of the body of the mandible superiorly and the posterior border of sternocleidomastoid. The majority of the anatomical structures of the neck of importance to the head and neck surgeon are found within the anterior triangle, as summarized in **Table 35.3**. The anterior triangle is further divided into the submental, submandibular, carotid and muscular triangles.

SUBMENTAL TRIANGLE

The submental triangle is a single midline triangle located inferior to the mental process of the mandible in the upper neck, as opposed to the other triangles which are paired on each side of the neck. The boundaries are the anterior bellies of digastric laterally and the body of the hyoid bone inferiorly. The mylohyoid muscle forms the floor of the triangle. The contents include fatty tissue, level Ia lymph nodes and small veins that drain into the anterior jugular veins.

SUBMANDIBULAR TRIANGLE

The submandibular triangle (**Figure 35.4**) is also known as the digastric triangle as it lies between the anterior belly of digastric, which forms its anterior limit and the posterior belly of digastric which acts as the infero-lateral border with the stylohyoid muscle. The superior limit is formed by the inferior border of the body of the mandible. The floor is formed by the mylohyoid muscle anteriorly and the hyoglossus posteriorly. The submandibular triangle contains many important anatomical structures including the facial artery and veins, the marginal mandibular branch of the facial nerve, the submandibular salivary gland and lymph nodes of level Ib.

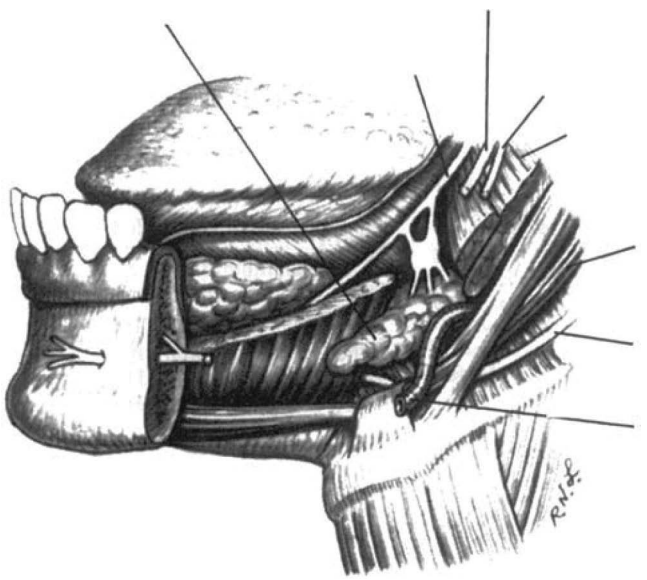


Figure 35.4 Submandibular triangle.

CAROTID TRIANGLE

The carotid triangle is bounded by the posterior border of sternocleidomastoid muscle laterally, the posterior belly of digastric superiorly and the superior belly of omohyoid medially. The contents include the superior part of the carotid sheath, containing the common carotid artery, the carotid bifurcation and the internal and external carotid arteries. The proximal superior thyroid artery, ascending pharyngeal artery, lingual artery, facial artery and occasionally the occipital artery may be found in this triangle. The corresponding veins drain into the jugular vein within the carotid triangle. The vagus nerve, running deep to the vessels in the carotid sheath, the hypoglossal nerve, the superior root of the ansa cervicalis, the superior laryngeal nerve branching from the vagus nerve are all found within the carotid triangle, with lymph nodes of the jugular chain.

MUSCULAR TRIANGLE

The muscular triangle is defined by the lower posterior border of the sternocleidomastoid muscle infero-laterally, the superior belly of omohyoid supero-laterally and the midline. The contents include the lower part of the carotid sheath, the sternohyoid and thyrohyoid muscles, the thyroid and parathyroid glands and the upper aerodigestive tract.

POSTERIOR TRIANGLE

The posterior triangle is bounded by the posterior border of the sternocleidomastoid muscle anteriorly, the anterior border of the trapezius posteriorly and the clavicle inferiorly. The floor is formed by the splenius capitus, levator scapulae and the posterior, middle and

TABLE 35.4 Summary of the contents of the posterior triangle

Muscles	Vessels	Nerves	Other
Omohyoid	Occipital, transverse cervical, suprascapular and subclavian arteries	Cervical and brachial plexus	Lymph nodes
	Transverse cervical, suprascapular and external jugular veins		

anterior scalene muscles respectively from superior to inferior. These muscles are covered by prevertebral fascia and represent the deep limit of resection during neck dissection procedures. The accessory nerve runs across the roof of the posterior triangle, with all other important anatomical structures and lymph nodes positioned caudal to it. Posterior to the trapezius muscle is the cervico-occipital area which contains paraspinal musculature, without lymph nodes or any other anatomical structures of relevance in head and neck surgery. The contents of the posterior triangle are summarized in **Table 35.4**.

SUBCLAVIAN TRIANGLE

The boundaries of the subclavian triangle are the inferior belly of the omohyoid, the clavicle and the posterior border of the sternocleidomastoid muscle. It contains the branchial plexus, emerging between the anterior and middle scalene muscles, the transverse cervical artery and suprascapular artery, which are branches of the thyrocervical trunk. The domes of the pleura with the overlying supra-pleural fascia and the subclavian artery and vein are also found within the subclavian triangle so care must be taken not to injure these structures during neck dissection if retro-clavicular dissection is necessary.

KEY POINTS

- The anatomical triangles of the neck help to compartmentalize the anatomy of the neck.
- The travel from one triangle to another facilitates the concept of neck dissection.
- Sound knowledge of both triangles and contents converts two-dimensional knowledge into three-dimensional surgical reality.

SKIN

Skin of the neck

The relaxed skin tension lines of the neck (**Figure 35.5**) run perpendicular to the fibres of the underlying platysma. These lines create skin creases that run transversely when the skin is not under tension.[11] Wherever possible, surgical incisions should be placed within these skin creases to create cosmetically acceptable surgical scars.

Vascular supply of the skin

The blood supply to the neck skin is derived from branches of the facial, posterior auricular, occipital and subclavian arteries. These arteries, with accompanying veins, form a network within the platysma muscle that supplies the overlying subdermal plexus, from which the overlying skin draws its blood supply. This is an important point to consider during neck surgery as skin flaps should be raised in the subplatysmal plane to preserve the blood supply to the skin, thereby avoiding skin necrosis.

The anterior cervical skin is supplied by branches of the superior thyroid artery and the transverse cervical artery. The posterior cervical skin is supplied by branches of the occipital artery and the deep cervical branches from the costocervical trunk. The superior neck skin derives its blood supply from the occipital artery through its branch to the sternocleidomastoid, the superior fibres of which insert into the upper neck skin. The submental and submandibular branches of the facial artery supply the anterior upper neck. The transverse cervical and suprascapular

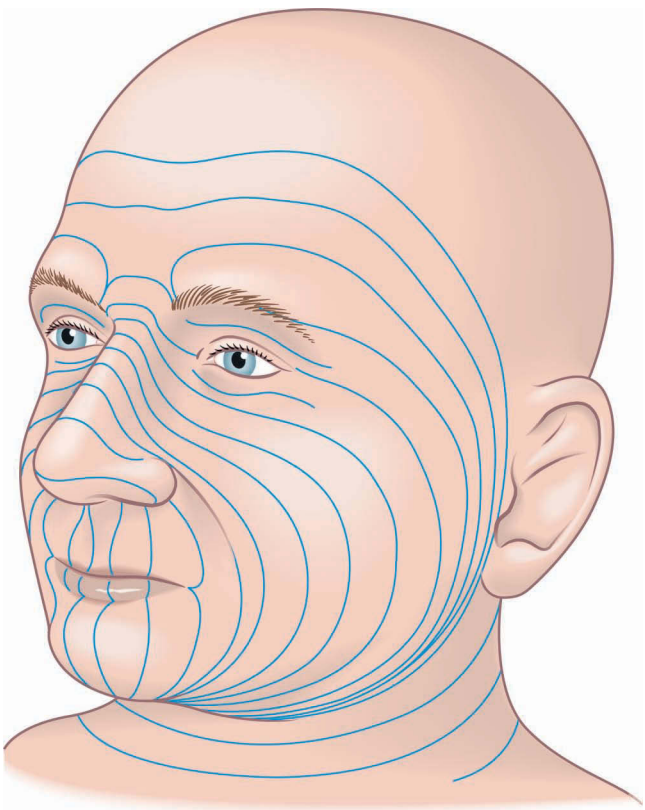

Figure 35.5 Relaxed skin tension lines.

branches of the subclavian artery via the thyrocervical trunk supply the skin of the inferior neck. The venous drainage follows the arterial supply, ultimately draining into the internal and external jugular veins.

Lymphatic drainage of the skin of the neck

In general, the lymphatic drainage of the skin drains into the superficial cervical lymph nodes in closest proximity, with division between anterior and posterior neck zones (**Figure 35.6**). The occipital, post-auricular, supraclavicular and posterior triangle lymph nodes drain the posterior head and neck, including the scalp, whereas the neck skin areas drain into the anterior nodal groups.[12] The anterior neck skin inferior to the hyoid bone drains into the lymph nodes related to the anterior jugular vein, which then drain into the deep cervical chain. The skin above the hyoid bone drains superiorly into the submental and submandibular lymph nodes. Parotid lymph nodes are a common site for occult nodal involvement in skin cancers so parotidectomy should be considered for any neck dissection procedure for skin cancer.

KEY POINTS

- Skin incisions placed within relaxed skin tension lines leave cosmetically acceptable scars.
- Skin flaps should be raised in the subplatysmal plane to avoid skin necrosis.
- Lymphatic drainage of the skin is to the closest superficial nodes; anterior neck and facial skin drains to anterior nodal zones and posterior lymphatics drain posterior neck and scalp.
- The parotid lymph nodes are a frequent site for metastasis from head and neck skin malignancy.
- Skin flap movement is facilitated by elastic properties; these are affected by age, sun exposure and smoking, as well as the presence of infection or previous radiotherapy.

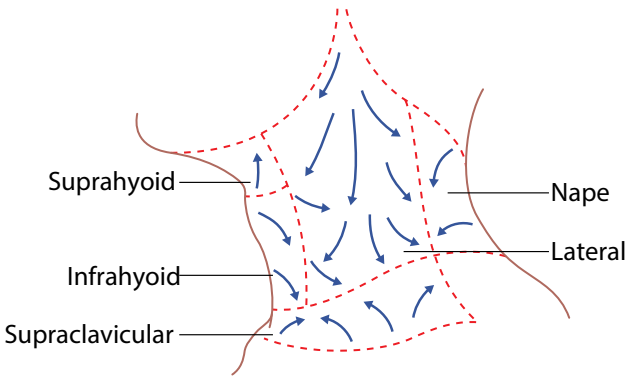

Figure 35.6 Lymphatic drainage of the skin of the neck. The lymphatics of the skin in the suprahyoid region drain to level I, the submental and submandibular lymph nodes. The lymphatics of the skin of the rest of the neck drain to levels II, III and IV, apart from the posterior lateral neck skin lymphatics which drain into the spinal accessory nodes in the posterior triangle.[13]

FASCIAL LAYERS

The neck has superficial and deep fascial planes which encase the structures of the neck (**Figure 35.7**). The deep fascial layer has three distinct layers; the superficial investing layer, the visceral layer and the deep layer. An understanding of the fascial planes of the neck assists in neck surgery as identification of the fascia allows dissection within a safe and relatively bloodless plane.

Superficial cervical fascia

This thin layer of fascia invests the platysma muscle and is penetrated by small vessels supplying the skin, therefore skin flaps are raised in the subplatysmal plane to preserve the blood supply to the skin, as mentioned previously. Inferiorly this creates an aponeurosis that either attaches to skin of the neck or continues inferiorly, becoming continuous with the fascia of the deltoid and pectoralis major muscles.

Deep cervical fascia

INVESTING LAYER

The superficial layer of the deep cervical fascia, also known as the investing layer, forms a fascial cylinder that contains most of the structures of the neck, including all of the nodal stations. Arising from the ligamentum nuchae and the spinous process of the cervical vertebrae posteriorly this layer invests the entire neck, dividing to enclose the sternocleidomastoid, omohyoid, infrahyoid and trapezius muscles. The investing fascia attaches superiorly at the superior nuchal lines and to the mastoid tip and zygoma. The fascia splits to enclose the parotid gland as the parotid fascia, the deep layer of which fuses with the fascia of the internal carotid artery (ICA). Anteriorly the investing layer of fascia attaches to the hyoid bone and to the acromion, clavicle and sternum inferiorly.

CAROTID SHEATH

The carotid sheath is derived from the investing layer of deep cervical fascia, medial to the sternocleidomastoid muscle. It encloses the common carotid artery and the internal and external carotid arteries after the bifurcation, the IJV and the vagus nerve. It is thicker around the arteries, but loose around the IJV allowing expansion during times of increased venous flow. The carotid sheath is connected to other fascial layers by loose areolar tissue.

PRETRACHEAL FASCIA

This middle layer of the deep cervical fascia, known as the pretracheal or visceral layer of cervical fascia, is again derived from the investing layer. It attaches to the hyoid bone superiorly and can be considered as having two parts: the muscular compartment encasing the infrahyoid

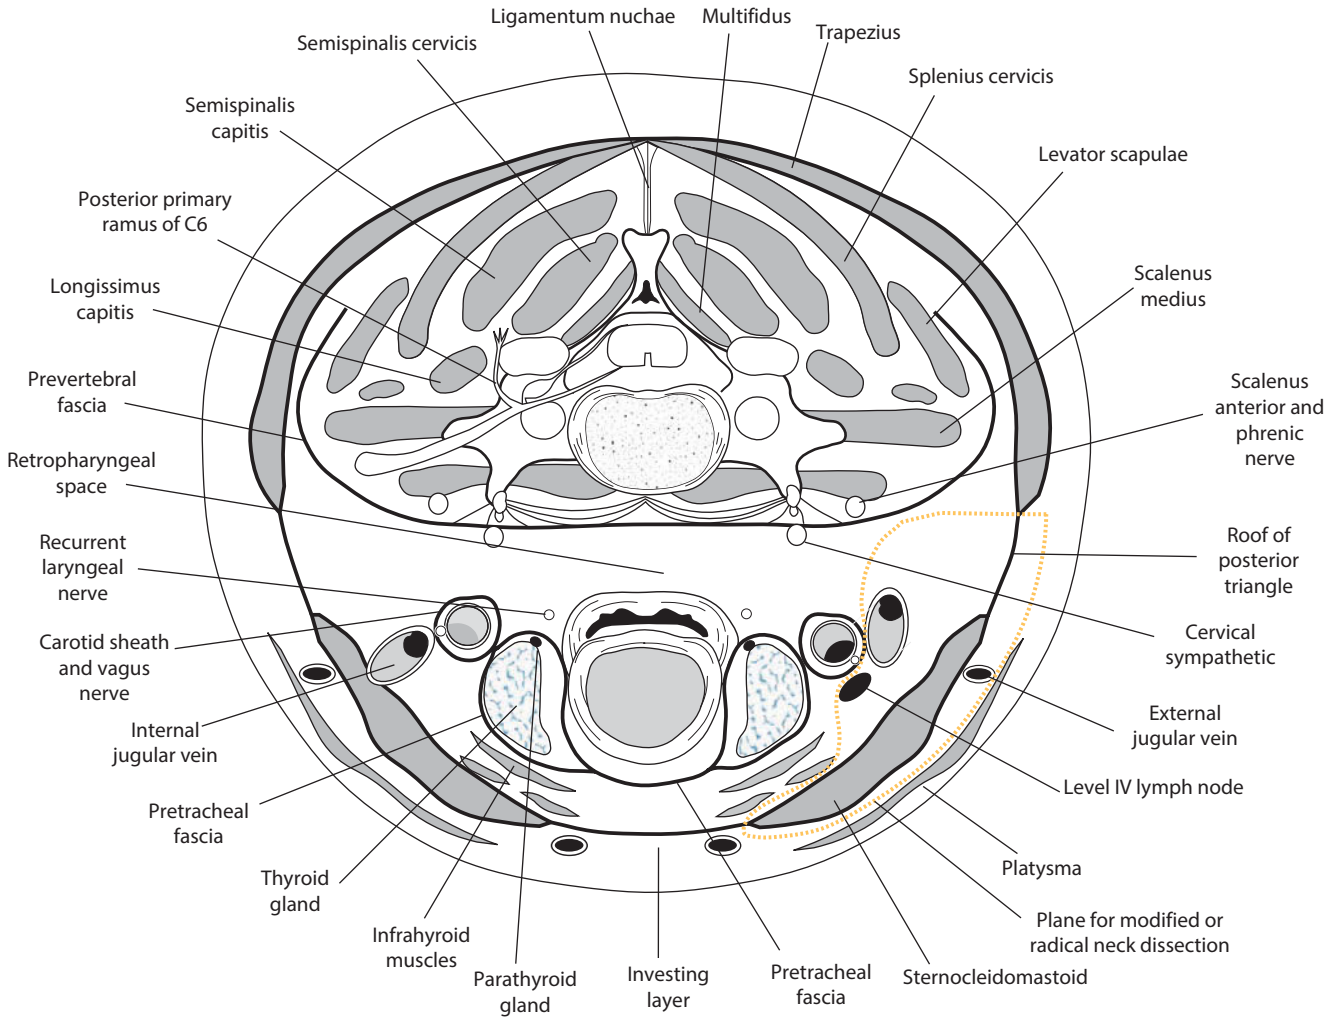

Figure 35.7 Fascial layers of the neck.

muscles and the visceral compartment containing the trachea, the thyroid gland, the pharynx and upper oesophagus. Inferiorly it fuses with the fascia of the superior mediastinum around the great vessels and the fibrous pericardium. Laterally it connects to the carotid sheath by loose areolar tissue.

PREVERTEBRAL FASCIA

The deepest layer of cervical fascia is also known as the prevertebral fascia as it encompasses the posterior neck muscles, the scalene muscles and the vertebrae. It forms the floor of the posterior triangle and represents the deep limit of neck dissection and the plane between the cervical vertebrae and the upper aerodigestive tract, allowing the pharynx to move freely during deglutition. The alar fascia is a supplementary layer of fascia anterior to the prevertebral fascia, extending from the skull base to the posterior mediastinum to the level of the second thoracic vertebra. The danger space, described in 'Retropharyngeal space' below, lies between the prevertebral fascia and the alar fascia.

KEY POINTS

- The fascial planes of the neck form dissection tunnels which can be followed to surgically unlock the neck.
- The investing layer of deep cervical fascia encases all of the nodal zones of the neck.
- The prevertebral fascia is the deep margin of neck dissection surgery, protecting the phrenic nerve and branchial plexus which run deep to the fascia.
- Access and definitive surgery through the fascial planes of neck is best facilitated with tissues under tension and sharp dissection.

NECK SPACES

Between the fascial layers of the neck are several anatomical compartments, containing only loose areolar tissue in healthy subjects. Whilst fascial layers limit the spread of infection, these inter-connected spaces can act as routes of transmission of infection or neoplasia.

Submental space

The borders of the submental space correspond to the submental triangle, as described above, with a superficial limit of superficial cervical fascia and the deep limit of the mylohyoid and geniohyoid muscles. The lymph nodes of level Ia are found within this space.

Submandibular space

The submandibular space is of key clinical significance as it is a route of spread of infection between the neck and floor of mouth. The superior limit of the submandibular space is the mucosa of the floor of the mouth, inferiorly it is defined by the investing layer of deep cervical fascia from the mandible and the hyoid bone. The anterior and posterior bellies of the digastric muscle form the antero-inferior and postero-inferior boundaries respectively. The superficial limit of this space is the investing layer of deep cervical fascia which wraps around the submandibular gland, forming a tough membrane that supports the gland. The mylohyoid muscle runs through the middle of the submandibular space, dividing it into superior and inferior compartments, which communicate around the free posterior edge of mylohyoid.[14] The superior space, also termed the sublingual space, contains the sublingual gland, the deep portion of the submandibular gland and the lingual nerve. The inferior space holds the superficial lobe of the submandibular gland. Both areas contain lymph nodes and branches of the facial vessels.

Between the submandibular gland and the mylohyoid muscle is the loose and distensible epimysium. The deep fascia does not split to enclose the submandibular gland so swelling in this space is limited by the attachments of the mylohyoid muscle and deep fascia. Subsequently distension of this space occurs in a cephalic and medial direction.[15] Ludwig's angina is a life-threatening airway complication of submandibular space infection, characterized by rapid onset of cellulitis of the floor of mouth tissues, causing swelling, induration and tongue elevation resulting in a compromised airway. Submandibular space infections are most commonly odontogenic in origin but can occur secondary to submandibular sialadenitis, lymphadenitis, trauma or after surgery.

Peritonsillar space

The potential space between the palatine tonsil and the superior constrictor muscle is known as the peritonsillar space. The condensation of the pharyngobasillar which forms the tonsillar capsule may be breached by bacterial infections of the tonsil, resulting in abscess formation in the peritonsillar space, also known as a quinsy. Untreated peritonsillar infections may spread to involve the parapharyngeal space.

Parapharyngeal space

The parapharyngeal space (**Figure 35.8**) is an inverted pyramid-shaped space, extending from the petrous temporal bone superiorly to the level of the hyoid. The space is bounded by the superior constrictor muscle medially and the pterygoid muscles, the parotid salivary gland and the mandible laterally. The styloid process and its attachments pass through the space, dividing it into pre-styloid and post-styloid compartments.

The pre-styloid compartment contains fat, connective tissue, the maxillary artery, the inferior alveolar nerve, the lingual nerve and the auriculotemporal nerve. The post-styloid compartment contains the carotid sheath and its contents, the glossopharyngeal and hypoglossal nerves, the sympathetic chain and lymph nodes. The determination between pre- and post-styloid involvement and displacement of the parapharyngeal fat pad are key radiological features which aid in diagnosis of parapharyngeal

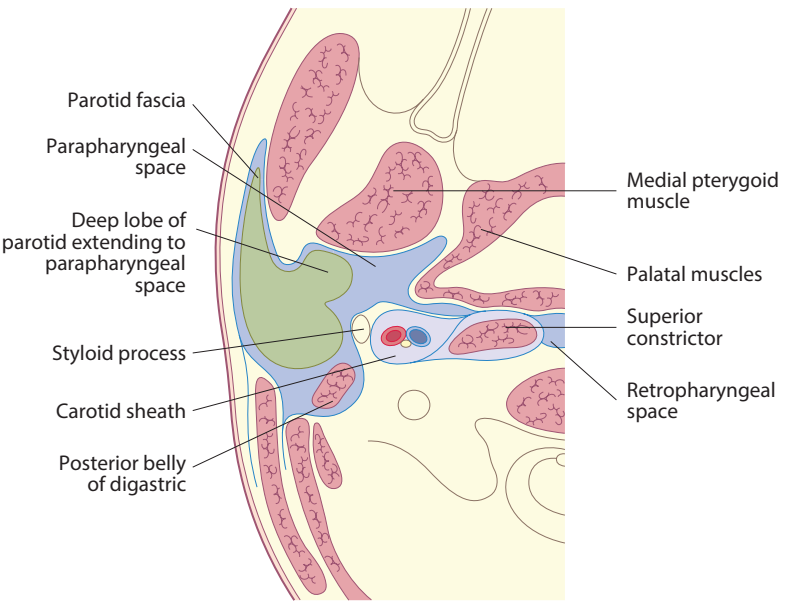

Figure 35.8 Parapharyngeal space.

space neoplasia. Pre-styloid lesions are most commonly associated with the deep lobe of the parotid gland and will deflect the carotid sheath and parapharyngeal fat posteromedially. Lesions in the post-styloid compartment are frequently of neuroendocrine origin, arising from the carotid sheath as carotid body tumours or vagal schwannomas, or neuromas of the sympathetic chain. Post-styloid lesions displace the parapharyngeal fat pad anteriorly. Surgical access to the parapharyngeal space can be challenging and may require mobilization of the parotid gland or lip split mandibulotomy.

The parapharyngeal space is a central connection for other deep neck spaces and as a result is a common site for deep neck abscess formation.[16, 17] Abscesses of the parapharyngeal space may occur because of spread from the submandibular space secondary to oro-dental causes, or from the peritonsillar space. Parapharyngeal space abscesses readily result in airway compromise if untreated. Medial displacement of the tonsil and lateral oropharyngeal wall will be seen but neck swelling or asymmetry may or may not be present. Trismus may also occur secondary to inflammation of the pterygoid muscles. The two parapharyngeal spaces communicate with the retropharyngeal space posteriorly and infection may readily spread into this compartment.

Retropharyngeal space

Between the two parapharyngeal spaces is the retropharyngeal space which is continuous with both. The superior limit of the retropharyngeal space is the skull base and it is continuous inferiorly with the posterior mediastinum, down to the level of the carina. The anterior boundary in the neck is the buccopharyngeal fascia which encases the pharyngeal constrictors, the posterior limit is the alar fascial component of the prevertebral fascia. The only contents of this space are the retropharyngeal lymph nodes, which typically regress by adulthood but can represent a route of metastatic nodal spread from midline or posterior tumours of the pharynx. Radiological evidence of retropharyngeal lymphadenopathy in adults should therefore raise the suspicion of head and neck malignancy.

Infection of the retropharyngeal space may occur indirectly, tracking from the parapharyngeal space or directly secondary to perforation of the pharynx or cervical oesophagus. Retropharyngeal abscesses are more commonly seen in children than in adults, secondary to bacterial infection of the upper aerodigestive tract and may result in airway obstruction due to anterior displacement of the airway.

The alar space, known colloquially as the 'danger space' is a further potential space located posterior to the retropharyngeal space, between the alar fascial component of the prevertebral fascia and the prevertebral fascia itself, extending to the level of the diaphragm. This space is only visible radiologically if distended due to collection within this area. The name 'danger space' refers to the potential for neck infections to readily spread into the thorax and cause mediastinitis.

Prevertebral space

The prevertebral space is the potential area posterior to the prevertebral fascia and anterior to the vertebral column and para-spinal musculature. Spread of infection to this area may occur as a result of traumatic perforation of the pharynx or oesophagus, or because of a breach of prevertebral fascia from retropharyngeal infection. Infection in the prevertebral space can cause spinal osteomyelitis and spinal cord compression. Prevertebral space invasion in head and neck malignancy is a feature which often signifies inoperable disease.

Carotid space

The carotid space is a potential space within the carotid sheath, which is itself formed from a condensation of all three layers of deep cervical fascia. It contains the common carotid artery, the IJV and the vagus nerve.

Parotid space

The parotid space is formed by the investing layer of deep cervical fascia that splits to encompass the parotid gland and therefore contains the facial nerve, the retromandibular vein and the terminal branches of the external carotid artery.

Visceral space

The visceral space is bounded by the middle layer of deep cervical fascia that envelops the thyroid and the trachea anteriorly and posteriorly by the pretracheal fascia. It contains the larynx, hypopharynx, cervical oesophagus, proximal trachea, thyroid and parathyroid glands and lymphatics of level VI.

KEY POINTS

- The inter-connected neck spaces act as potential routes for spread of infection and malignancy.
- Collections within the submandibular space and deep neck spaces readily result in airway obstruction if untreated and can make endotracheal intubation problematic due to distorted and displaced anatomy.
- Parapharyngeal space infection may occur directly or because of spread from the submandibular or peritonsillar spaces.
- The two parapharyngeal spaces communicate with the retropharyngeal space, from where infection can spread into the mediastinum or into the thorax to the level of the diaphragm via the danger space.

MUSCLES

Knowledge of the muscles of the neck is key to understanding neck anatomy, acting as important landmarks in the neck and forming the boundaries of the triangles of the neck. The muscles of the neck may be divided into groups: the superficial muscles, suprahyoid and infrahyoid muscles and the prevertebral muscles.

Superficial neck muscles

PLATYSMA

The platysma is a thin sheet of muscle that encases the neck. It is covered by superficial cervical fascia and is attached inferiorly to the deep fascia of pectoralis major muscle of the anterior chest wall. Superiorly it attaches to the inferior border of the mandible and is often deficient in the midline, however some fibres cross the midline and interweave below the mentum. Inferiorly it is continuous with the fascia of the pectoralis major muscle. The thinness of the platysma means that it has little functional significance; however, it does play a role in depressing the angle of the mouth as some superior fibres blend with the risorius muscle. The muscle derives its blood supply from a plexus of vessels within the muscle, which also supply the skin, as mentioned previously. The arterial supply is from branches of the facial artery superiorly and the suprascapular artery inferiorly, the venous drainage is via the facial vein and internal and external jugular veins. The innervation is from the cervical branch of the facial nerve which runs deep to the muscle (**Table 35.5**).

STERNOCLEIDOMASTOID

The sternocleidomastoid muscle is the most prominent muscle in the neck and is an important landmark as it divides the neck into anterior and posterior triangles along its posterior border. The muscle is encased by the investing layer of deep cervical fascia and lymph nodal levels II to IV are located deep to the muscle. The upper part of the muscle overlies the cervical plexus and the lower half overlies the carotid sheath and the scalenus anterior.

Inferiorly the sternocleidomastoid has both sternal and clavicular origins as two separate heads. The sternal head arises as a thick tendon, attached to the anterior and lateral surface of the manubrium. The clavicular head is fan shaped, arising from the medial third of the clavicle. Superiorly it inserts into the lateral aspect of the mastoid tip and the superior nuchal line. Although classified as a single muscle the two heads are functionally distinct with most of the sternal head attaching to the superior nuchal line and the clavicular head mainly to the mastoid tip. The action is complex; causing tilting of the head to the ipsilateral side and rotation of the head to the contralateral side. When both sides contract simultaneously it aids in head flexion and can assist in raising the thorax when the head is fixed, acting as an accessory muscle of respiration.

The blood supply to the muscle is in three segments. The superior third is supplied from the occipital artery and the posterior auricular artery. The middle third receives blood from a branch from the superior thyroid artery and the inferior third supply is from the suprascapular artery. Perforators from the sternocleidomastoid supply the skin inferiorly which is the basis for the sternocleidomastoid flap. The spinal accessory nerve, which normally passes through the muscle, provides motor function, with sensation and proprioception supplied by the ventral rami of C2–4.

TRAPEZIUS

The trapezius is a key landmark in head and neck surgery as it defines the posterior limit of the posterior triangle. All lymphatic zones and important anatomical structures lie anterior to the trapezius, with only prevertebral muscles and nerves posterior to the muscle. The trapezius is a broad, diamond-shaped sheet of muscle, arising in the midline from the skull to the lower thorax. The superior origin is from the superior nuchal line and the ligamentum nuchae to the level of the seventh cervical vertebra and inferiorly it arises from the spinous processes and interspinal ligaments down to the twelfth thoracic vertebra. Superiorly it has fibres that insert into the clavicle, with inferior fibres inserting into the spine of the scapula.

The trapezius is the main anti-gravity muscle of the shoulder, providing postural stability, and relieves some of the compression load of the head on the cervical spine. The active movements include tilting and turning the head and shrugging the shoulders. The trapezius elevates, depresses and rotates the scapula.[18] The arterial blood supply is via the transverse cervical artery. The accessory nerve provides motor supply to the trapezius muscle with contributions from the cervical plexus derived from C3 and C4 nerve roots. The cervical plexus branches mainly provide proprioception, however studies have proven a contribution to the motor function of the transverse and ascending parts of the

TABLE 35.5 Superficial neck muscles

Muscle	Origin	Insertion	Innervation	Blood supply
Platysma	Inferior border of mandible	Continuous with fascia of pectoralis major muscle	Cervical branches of facial nerve	Plexus with supply from facial artery superiorly, suprascapular artery inferiorly
Sternocleidomastoid	Manubrium, medial 1/3 clavicle	Mastoid tip, superior nuchal line	Spinal accessory nerve, C2–4	Occipital, post auricular, superior thyroid and suprascapular arteries
Trapezius	Superior nuchal line, ligamentum nuchae down to C7 Spinous processes	Clavicle and spine of scapula	Spinal accessory nerve, cervical plexus from C3, C4	Transverse cervical artery

muscle from the cervical plexus branches. Disruption of the motor supply to the trapezius causes shoulder droop and a winged scapula with difficulty in elevating the ipsilateral arm above the head and weakness when shrugging the shoulder. Chronic neck pain is often a feature of trapezius paralysis.

Suprahyoid muscles

The four suprahyoid muscles lie superiorly to the hyoid bone in the neck and act upon the hyoid, elevating it during swallowing, amongst other functions. This group includes the digastric, stylohyoid, mylohyoid and geniohyoid muscles (**Table 35.6**). Whilst not a suprahyoid muscle, rather an extrinsic tongue muscle, we have also included the hyoglossus muscle as it can be a helpful landmark for structures that pass between the mylohyoid and hyoglossus.

DIGASTRIC

The digastric muscle is named as such because it has two bellies, joined in the middle by an intermediate tendon that passes through a sling attached to the lesser cornu of the hyoid bone. The posterior belly arises from the digastric notch on the medial aspect of the mastoid tip. The anterior belly inserts into the digastric fossa of the medial surface of the mandible near the midline. The anterior belly lies superficially to the mylohyoid muscle. The anterior bellies from each side define the submental triangle and the anterior and posterior bellies define the submandibular triangle as described above. The origin of the posterior belly at the digastric ridge is a landmark for the depth of the facial nerve as it exits the stylomastoid foramen.

The arterial blood supply is from branches of the facial artery anteriorly and the occipital artery posteriorly. The nerve supply to digastric reflects its embryological origins from the first and second branchial arch; the posterior belly is supplied by a branch of the facial nerve, the nerve to digastric and the anterior belly is supplied by the nerve to mylohyoid, from the maxillary division of the trigeminal nerve. The digastric muscle depresses the chin to assist in mouth opening and elevates the hyoid during swallowing.

STYLOHYOID

The stylohyoid muscle is related to the posterior belly of digastric, which it runs alongside. Its function is to elevate the hyoid bone during swallowing. It arises from the styloid process of the mastoid tip and it inserts into the lesser cornu of the hyoid bone. A tendon is formed in the mid portion of the muscle that splits around the sling that the digastric tendon passes through. The innervation of the stylohyoid is from the nerve to digastric from the facial nerve and the blood supply is from branches of the facial and occipital arteries.

MYLOHYOID

The mylohyoid muscle forms the floor of the mouth, its function is to support the weight of the tongue and elevate the hyoid bone during deglutition. It arises from the mylohyoid line, on the inner surface of the mandible and inserts into the anterior surface of the body of the hyoid bone. The two muscles meet at the midline, forming a midline raphe from the hyoid to the mentum. The submandibular salivary gland wraps around the free posterior border of the mylohyoid muscle. The mylohyoid is a muscle of the first pharyngeal arch and is innervated by the inferior alveolar nerve, from the mandibular division of the trigeminal nerve. The arterial blood supply is from the branches of the facial artery.

GENIOHYOID

The geniohyoid muscle arises from the genial tubercle on the inner surface of the mandible at the midline and runs deep to mylohyoid to insert into the upper part of the body of the hyoid bone. Like mylohyoid, the geniohyoid provides support to the floor of mouth and elevates the hyoid, but also acts to depress the mandible during mouth opening. The innervation is from C1 nerve roots that run with the hypoglossal nerve and the blood supply is from branches of the facial artery.

HYOGLOSSUS

The hyoglossus lies posterior and deep to the mylohyoid muscle, with fibres originating from the body and greater

TABLE 35.6 Suprahyoid muscles

Muscle	Origin	Insertion	Innervation	Blood supply
Digastric	Digastric ridge, mastoid tip	Digastric fossa, inner surface mandible	Anterior belly: Trigeminal neve Posterior belly: Facial nerve	Anterior belly: Facial artery Posterior belly: Occipital artery
Stylohyoid	Styloid process	Lesser cornu hyoid	Nerve to digastric from facial nerve	Facial artery Occipital artery
Mylohyoid	Mylohyoid line of mandible	Anterior surface of body of hyoid	Inferior alveolar nerve from trigeminal	Facial artery
Geniohyoid	Genial tubercle	Body of hyoid	C1 nerve roots with hypoglossal nerve	Facial artery
Hyoglossus	Body and greater cornu of hyoid	Inserts into tongue	Hypoglossal nerve	Lingual artery

TABLE 35.7 Infrahyoid muscles

Muscle	Origin	Insertion	Innervation	Blood supply
Sternohyoid	Medial clavicle and manubrium	Lower body of hyoid	C1, C2, C3	Superior thyroid artery
Sternothyroid	Posterior surface of manubrium	Oblique line of thyroid cartilage	C1, C2, C3	Superior thyroid artery
Omohyoid	Lower body of hyoid	Scapula	C1, C2, C3	Inferior thyroid artery
Thyrohyoid	Greater horn of hyoid	Oblique line of thyroid cartilage	C1, C2, C3	Superior thyroid artery

cornu of the hyoid before entering the tongue. The lingual vein passes medially and the lingual artery passes deep to hyoglossus. Several important structures run between the mylohyoid and the hyoglossus muscles; the sublingual gland, submandibular duct, lingual nerve, and the hypoglossal nerve. The innervation is from the hypoglossal nerve and it derives its arterial blood supply from the lingual artery.

Infrahyoid muscles

The infrahyoid muscles, commonly termed the 'strap' muscles, lie inferior to the hyoid bone. This group consists of the sternothyroid, sternohyoid, thyrohyoid and omohyoid muscles which have the common action of depressing the hyoid and larynx to modify resonance during voice production. They oppose the elevators of the hyoid, stabilizing the hyoid during action of the mylohyoid and the digastric. They are all innervated by the ansa cervicalis with fibres from C1, C2 and C3.

STERNOHYOID

The sternohyoid is the most superficial of the strap muscles and the largest. It arises from the medial clavicle, the sternoclavicular joint and the upper manubrium and inserts into the lower body of the hyoid bone. The two muscles are joined in the midline at a midline raphe, a relatively bloodless plane that must be dissected to unlock the central compartment for thyroidectomy and tracheostomy procedures.

STERNOTHYROID

Deep to the sternohyoid is the sternothyroid muscle, arising from the posterior surface of the manubrium and first costal cartilage and inserting into the oblique line of the thyroid cartilage. Deep to the sternothyroid lies the thyroid gland, both the sternohyoid and sternothyroid must be retracted to enable access to the thyroid lobes.

OMOHYOID

The omohyoid muscles has two bellies, joined by a flat tendon at the point where the muscle passes over the IJV. The superior belly arises from the lower body of the hyoid bone and runs inferiorly, just lateral to the sternohyoid muscle and deep to sternocleidomastoid and across the IJV. The inferior belly then travels an oblique course to insert into the scapula posteriorly.

THYROHYOID

The thyrohyoid is the smallest of the infrahyoid muscles and attaches the thyroid cartilage to the hyoid bone.

Prevertebral muscles

Contained within the prevertebral fascia are the prevertebral muscles, a group of weak neck flexors. This muscular group can be subdivided into anterior and lateral groups.

ANTERIOR PREVERTEBRAL MUSCLES

The anterior prevertebral muscles lie deep to the prevertebral fascia and anterior to the spinal column and include the rectus capitus anterior, rectus capitus lateralis, longus capitus, longus colli and splenius capitus. Their combined action is to flex and bow the head.

LATERAL PREVERTEBRAL MUSCLES (SCALENE MUSCLES)

The lateral prevertebral muscles, also known as the scalene muscles, are of more significance in head and neck surgery than the anterior group, due to the many important relations of the anterior scalene muscle. The phrenic nerve runs on the superficial surface of the anterior scalene muscle and the second part of the subclavian artery passes posterior to the scalenus anterior, where it gives off the costo-cervical trunk. The transverse cervical, ascending cervical and suprascapular arteries lie superficial to the muscle. The roots of the brachial plexus arise between the scalenus anterior and scalenus medius and emerge on the lateral border of scalenus anterior. The branches of the brachial plexus carry with them a layer of prevertebral fascia, which also encases the subclavian artery and becomes the axillary sheath.

KEY POINTS

- The superficial neck muscles provide important anatomical boundaries and are covered by layers of cervical fascia.
- The supra-hyoid and infra-hyoid muscles act antagonistically to elevate, depress or stabilize the hyoid for speech and swallowing.
- The anterior scalene muscle and its relationships to the phrenic nerve, brachial plexus and subclavian artery provide vital anatomical knowledge relating to the root of the neck and Chassaignac's triangle.

CERVICAL LYMPHATICS

The lymphatics of the neck are divided into superficial and deep systems. The superficial lymphatics drain the skin and perforate the investing layer of deep cervical fascia to drain into the deep system. When affected by malignancy, these lymph nodes will quickly invade the skin necessitating skin resection to ensure complete excision.

The deep lymphatics are associated with fascial condensations and are in proximity to the vessels, nerves and muscles of the neck. Over 80% of lymph nodes in the neck are closely related to the IJV. The deep lymphatic system is divided into nodal groups as depicted in **Figure 35.9**, or classified into nodal levels, demonstrated by **Figures 35.10** and **35.11**.

Lymphatic flow is typically in a downwards direction and may pass through many nodal zones. In the event of metastatic lymphadenopathy from an unknown primary the nodal zone involved can help to predict the primary site due to the somewhat predictable pattern of lymphatic spread, in the previously untreated patient. In the context of previous neck dissection, the pattern of regional lymphatic involvement is much less predictable and may readily involve any remaining lymphatic areas of the ipsilateral neck, the retropharyngeal lymph nodes and the contralateral neck.

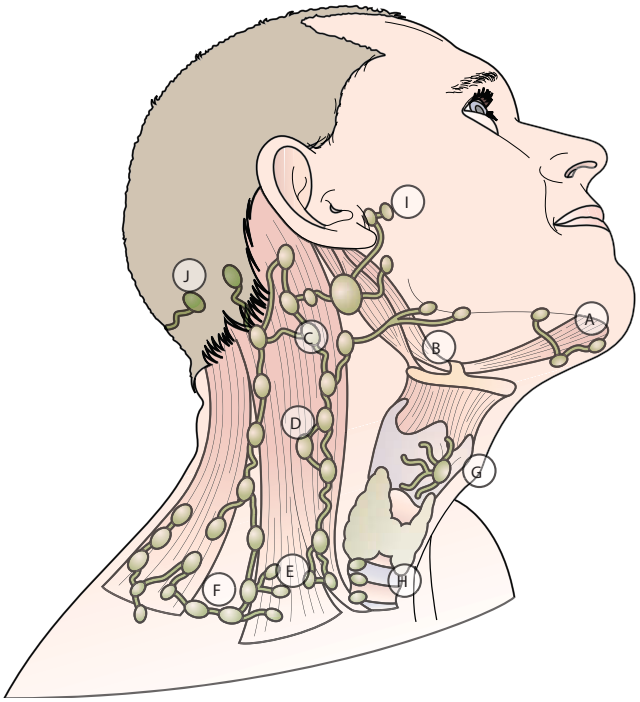

Figure 35.9 Lymph node groups.

Lymph node levels

The classification of lymph node zones into levels originates from the Memorial Sloan Kettering Hospital, New York and was adopted by the American Academy of Otolaryngology Head and Neck Surgery (AAOHNS) in 1991.[19] This clinically orientated classification system was developed by surgeons and radiologists and aims to differentiate nodal areas that drain the visceral structures of the head and neck.

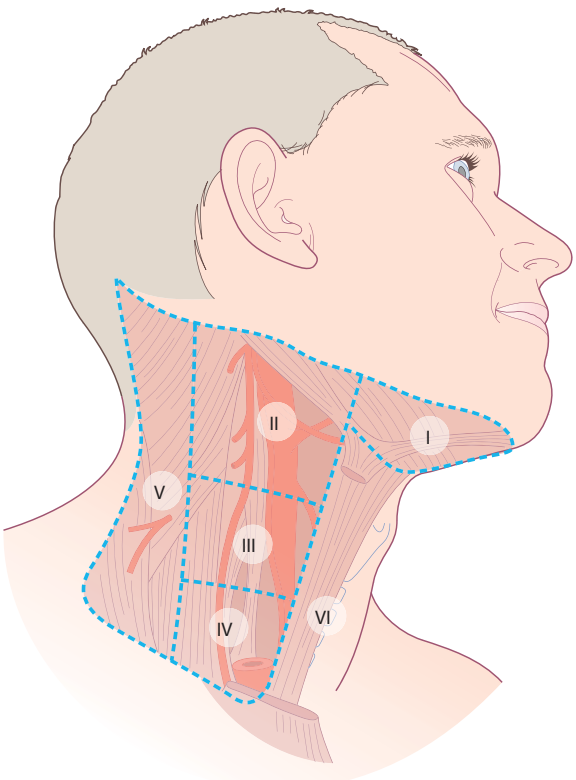

Figure 35.10 Lymph node levels.

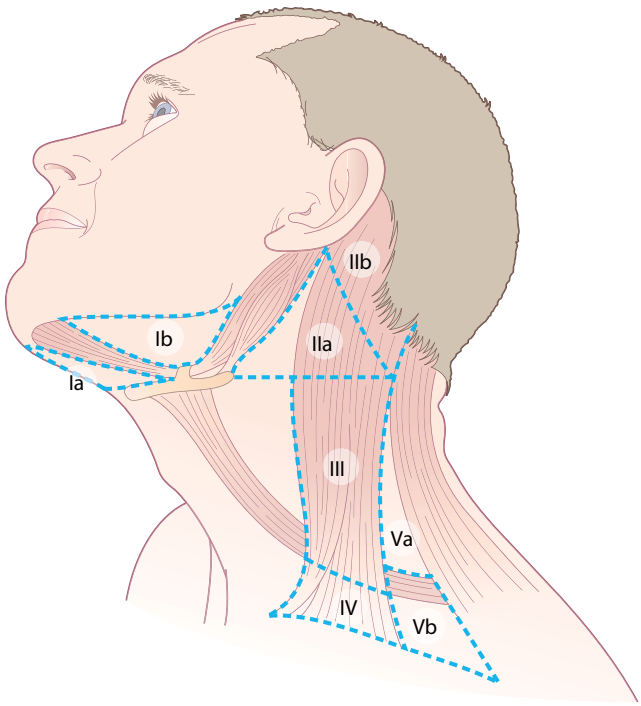

Figure 35.11 Lymph node zones and subzones.

LEVEL IA

This nodal area is a single midline zone, corresponding to the submental triangle, between the two anterior bellies of digastric and the hyoid bone. The submental lymph nodes are located within this level, which provides lymphatic drainage to the anterior floor of mouth, lower lip and ventral tongue.

LEVEL IB

This level is located within the submandibular triangle and contains the submandibular lymph nodes. Drainage from lateral oral cavity structures such as the lateral tongue, floor of mouth and buccal cavity is to these lymph nodes, which are closely related to the facial vessels.

LEVEL II

The lymphatics of level II are the uppermost nodes of the jugular chain, extending from the skull base to the level of the inferior border of the hyoid bone. Level II lymphatics are the first echelon lymph nodes of the oropharynx, but also drain the oral cavity, nasopharynx, hypopharynx and larynx, as well as the parotid gland. Lymphatic drainage from the submandibular and retropharyngeal nodes joins the jugular system at the junctional nodal area, at the lower aspect of level II. The spinal accessory nerve subdivides level II into IIa and IIb as described below.

LEVEL IIA

Caudal to the spinal accessory nerve is level IIa. The presence of nodal disease in IIa mandates dissection of IIb during neck dissection.

LEVEL IIB

Cranial to the spinal accessory nerve is level IIb, also known as Suárez's triangle, named after the Argentinian who first described functional neck dissection in the 1960s. This nodal level covers a triangular area with the apex at the junction of the posterior border of the sternocleidomastoid muscle and the posterior belly of digastric and is bounded inferiorly by the accessory nerve. The occipital artery may be encountered in the superior aspect of this nodal zone.

LEVEL III

Level III refers to the lymph nodes of middle jugular chain, from the level of the inferior border of the hyoid to the inferior aspect of the cricoid cartilage. This zone receives lymphatic drainage from the lower areas of the oropharynx, the hypopharynx and larynx.

LEVEL IV

This zone extends from the level of the inferior border of the cricoid to the clavicle and contains the lymph nodes of the lower jugular chain, which drain the hypopharynx and larynx. The omohyoid muscle crosses the superior aspect of this level. Low in level IV, within Chaissaignac's triangle in the root of the neck, lymph node metastasis may occur from an infraclavicular primary source, typically bronchus or breast. Furthermore, Virchow's node, a supraclavicular lymph node metastasis from upper gastrointestinal malignancy, is located in level IV on the left side of the neck.

LEVEL V

Level V represents the posterior triangle lymph nodes. This zone covers a large area, with a thin layer of fibrofatty tissue over the prevertebral musculature, extending from a superior apex formed by the junction of the trapezius and sternocleidomastoid muscles to the clavicle inferiorly. The anterior limit is the posterior border of the sternocleidomastoid muscle and the posterior limit is the anterior border of trapezius. The spinal accessory nerve runs across the roof of level V and the transverse cervical artery is found in the inferolateral aspect of this zone. The lymphatics of level V receive drainage from all other nodal areas but are also a common location for metastatic involvement from nasopharyngeal or cutaneous scalp primary lesions. Level V is subdivided into Va and Vb by an imaginary horizontal line at the level of the inferior border of the cricoid cartilage.

LEVEL Va

This subzone is the area above the boundary line and contains the lymph nodes related to the spinal accessory nerve, which runs in the roof of level Va. Much of nodal tissue is located caudal to the nerve.

LEVEL Vb

This represents the nodal area below the level of the inferior border of the cricoid cartilage and contains the level V lymph nodes related to the transverse cervical artery and the supraclavicular lymph nodes.

LEVEL VI

This single midline zone, also termed the anterior or central compartment, is located between the common carotid arteries laterally. The superior border is the inferior aspect of the hyoid. The inferior boundary is defined as the innominate artery on the right side of the neck and the corresponding level on the left side.[20] The paratracheal, perithyroid and precricoid (Delphian) nodes are in this zone. Nodal metastasis in this area may arise from primaries in the thyroid, the glottis or subglottic larynx, the apex of the piriform fossa or the cervical oesophagus. Lymph node dissection of the central compartment is commonly performed in conjunction with total thyroidectomy for malignancy or total laryngectomy and may result in postoperative hypocalcaemia because of inadvertent removal of the parathyroid glands which are also located within this nodal zone.

LEVEL VII

This refers to the lymph nodes of the superior mediastinum which may be accessed via the neck, or via an access sternotomy. These lymph nodes may harbour metastasis from thyroid, subglottic or tracheal or cervical oesophageal malignancies. The thymic remnant is also found in this area.

KEY POINTS

- The patterns of lymphatic drainage within the neck are site specific.
- The flow of lymph is from superficial to deep and then from cephalic to caudal direction.
- There are approximately 100 lymph nodes on either side of the neck which range in size from 3 mm to 3 cm with a mean of 1 cm.
- The cervical lymph nodes are divided into levels the dissection of which forms the basis of selective neck dissection.
- Selective neck dissection is based upon site specific drainage and is therefore best suited to the untreated neck.
- Incisions in the neck can alter lymphatic drainage for up to one year after surgery.
- Previous treatment of the neck, in the form of surgery and or radiotherapy, alters lymphatic drainage which can result in unpredictable patterns of metastatic lymphadenopathy, including involvement of the parapharyngeal and retropharyngeal spaces.

NERVES

Knowledge of the anatomy of the nerves of the neck is essential when operating in the neck to avoid unnecessary morbidity from major nerve injury. The important nerves of the neck are the lower cranial nerves, the spinal nerves of the cervical plexus, the cervical sympathetic trunk and the brachial plexus.

Cranial nerves

FACIAL NERVE

The facial nerve is the nerve of the second branchial arch. Its main function is to supply motor innervation to the muscles of facial expression, with smaller branches that also provide motor supply to the posterior belly of digastric and the stylohyoid muscle. After leaving the cranium through the internal auditory meatus and passing through the middle ear space and mastoid, the main trunk of the facial nerve exits the temporal bone via the stylomastoid foramen. It then traverses the parotid gland where it divides into five main branches within the gland. Known as the 'pes anserinus', literally meaning the 'goose's foot', these branches are the temporal, zygomatic, buccal, marginal mandibular and cervical branches; the latter two are the branches found in the neck.

MARGINAL MANDIBULAR NERVE

The marginal mandibular branch of the facial nerve is the main branch of the lower division of the facial nerve. It takes a variable course and may have up to four branches in the neck. The nerve passes antero-medially across the upper neck in the plane just deep to the platysma muscle but superficial to the investing layer of deep cervical fascia. It can extend as low as the greater cornu of the hyoid bone, before passing superficial to the facial vessels and across the mandible to provide motor supply to the depressor anguli oris, depressor labii inferioris and mentalis muscles. Its action is to move the corner of the mouth and lower lip, however the nerve supply to the lower lip is multifactorial, with contributions from the cervical branch of the facial nerve and the platysma muscle, meaning that if any one of these mechanisms is interrupted lower facial asymmetry may occur.

This nerve is most at risk during submandibular gland excision and clearance of lymph node level I for malignant disease. The nerve can be protected by incising the investing layer of deep cervical fascia inferior to the lower border of the submandibular gland or just above the hyoid bone and reflecting the fascia superiorly along with the facial vein, retracting the nerve out of the surgical field.

CERVICAL BRANCH OF THE FACIAL NERVE

The lowest branch of the facial nerve, the cervical branch supplies the platysma muscle. It can be identified travelling antero-inferiorly and may give off multiple branches. Injury to this branch can cause asymmetry of the corner of the mouth due to the contribution of the platysma to the movement of the lower lip.

GLOSSOPHARYNGEAL NERVE

The glossopharyngeal nerve is the ninth cranial nerve and the nerve of the third branchial arch. It exits the skull via the anterior compartment of the jugular foramen, then passes between the IJV and the ICA, before descending anterior to the ICA. It then curves anteriorly around the stylopharyngeus muscle, deep to hyoglossus and either pierces the lower fibres of the superior constrictor or runs between superior and middle constrictor muscles. Fibres are then distributed to the palatine tonsil, mucosa of the pharynx and posterior tongue and minor salivary glands of the oral mucosa and the oropharynx. The glossopharyngeal nerve is historically described as 'the nerve of economy' due to the way it is considered to spread itself thinly between the structures it supplies; providing motor supply to one muscle, special sensory supply to one area, visceral sensation to one organ, parasympathetic fibres to one secretory gland and general sensation to other areas.

The glossopharyngeal nerve has many branches, some of which communicate with other nerves. It sends filaments that communicate with the sympathetic trunk, the vagus and facial nerves. The clinically relevant branches are:

- **The tympanic nerve:** Also known as Jacobson's nerve, this branch supplies the tympanic plexus and is the reason for referred otalgia secondary to pain affecting the oropharynx.
- **The lesser petrosal nerve:** This branch provides postganglionic secretomotor supply to the parotid gland and passes through the infratemporal fossa.

- **Carotid sinus and carotid body branches:** These branches take afferent nerves from the chemoreceptor in the carotid body and baroreceptors from the carotid sinus.
- **Pharyngeal branches:** These branches join the fibres from the vagus nerve and the sympathetic trunk to form the pharyngeal plexus, which sits on the posterior aspect of the middle constrictor muscle. Small nerves from the plexus perforate the muscle fibres of the middle constrictor muscle and innervate the mucosa of the oropharynx. The pharyngeal branches provide somatic sensation. The tonsillar branch anastomoses with the lesser palatine nerves to supply the mucous membrane of the palatine tonsil. Injury to the pharyngeal plexus may lead to swallowing dysfunction.
- **Motor branch:** The main motor branch of the glossopharyngeal nerve innervates the stylopharyngeus muscle.
- **Lingual branches:** These provide common sensation, taste and secretomotor supply to the posterior third of the tongue.

VAGUS NERVE

The vagus nerve derives its name from the Latin word 'vagi', meaning 'roaming', due to the wandering course that it takes from the cranium to the abdomen. It is the nerve of the fourth branchial arch and is the Xth cranial nerve. The vagus nerve leaves the skull via the middle compartment of the jugular foramen. The superior ganglion of the vagus is located just inferior to the jugular foramen and contains cell bodies for afferent fibres of meningeal and auricular branches. Lower in the neck the nerve dilates to form the inferior ganglion which contains afferent cell bodies of the other branches. The accessory nerve contributes a branch to the vagus nerve which provides motor innervation to all of the visceral striated muscle supplied by the vagus. The vagus nerve runs posteriorly in the carotid sheath, between the IJV and common carotid artery. The vagus gives off the following branches in the neck:

- **Auricular branch:** Also known as Arnold's nerve, this branch passes between the mastoid and the tympanic plate to provide sensory supply to the tympanic membrane and skin of the posterior pinna and posterior ear canal; a further mechanism for referred otalgia.
- **Carotid body branches:** This small branch supplements the branches of the glossopharyngeal nerve that supply the carotid body chemoreceptors.
- **Pharyngeal branch:** The vagal contribution to the pharyngeal plexus derives from the spinal accessory fibres that join the vagus nerve before branching off as the pharyngeal branch. These fibres cross the internal carotid to join the pharyngeal plexus, providing motor innervation to the pharyngeal constrictors and soft palate, in combination with the glossopharyngeal nerve and sympathetic trunk.
- **Superior laryngeal nerve:** The superior laryngeal nerve is given off high in the neck and passes inferior to the ICA, before travelling antero-inferiorly towards the larynx. At the level of the hyoid the nerve branches into the internal and external laryngeal nerve. The internal laryngeal nerve penetrates the thyrohyoid membrane superior to the superior laryngeal artery and provides sensory innervation to the laryngeal and piriform fossa mucosa, with some motor contribution to the interarytenoid muscle and motor and sensory supply to the cervical oesophagus and trachea. The external laryngeal branch is much smaller and runs with the superior thyroid artery on the sidewall of the inferior constrictor before piercing it to provide motor supply to the cricothyroid muscle, the only intrinsic laryngeal muscle not supplied by the recurrent laryngeal nerve. The human communicating nerve is an inconstant branch of the external branch of the superior laryngeal nerve, found as a normal variant in approximately 45% of healthy subjects. It is believed to provide additional motor supply to the thyroarytenoid muscle and sensory supply to the subglottic mucosa. This communicating branch may anastomose with the recurrent laryngeal nerve or may directly supply the thyroarytenoid muscle. This branch was first discovered during early anatomical studies of the larynx but later forgotten as it was not felt to have functional significance, however recent histological studies demonstrate positive staining for acetylcholinesterase, thereby proving motor function of this branch.[21]
- **Cardiac branches:** These branches leave the vagus low in the neck to form the cardiac plexus.
- **Recurrent laryngeal nerve:** The path of the recurrent laryngeal nerves differs on each side of the neck. The reason for this asymmetry is rooted in its embryological development as the nerve of the sixth branchial arch. The artery of the sixth arch is the ductus arteriosus which obliterates on the right whilst it descends into the thorax on the left side, taking the left recurrent laryngeal nerve with it. The left recurrent laryngeal nerve leaves the vagus in the lower part of the neck, before looping around the ligamentum arteriosum and arch of the aorta and then ascending back into the neck in the tracheo-oesophageal groove. The right recurrent laryngeal nerve has a more variable path but usually hooks around the subclavian artery before passing medially towards the tracheo-oesophageal groove. The right nerve takes a non-recurrent course in approximately 1% of individuals. The relationship of the recurrent laryngeal nerve and the inferior thyroid artery is variable but of great significance in thyroid surgery as the nerve may run deep to the artery, superficial to it or between its branches, before it perforates the cricothyroid membrane. The recurrent laryngeal nerve provides motor innervation to all the intrinsic laryngeal muscles except cricothyroid and provides sensory supply to the mucosa of the larynx inferior to the vocal folds. A helpful landmark for identifying the recurrent laryngeal nerve is Beahr's triangle (**Figure 35.12**), which is formed by the common carotid artery laterally, the inferior thyroid vessels and the recurrent laryngeal nerve.

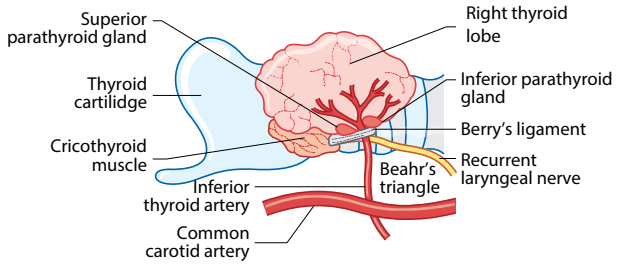

Figure 35.12 Beahr's triangle.

SPINAL ACCESSORY NERVE

The spinal accessory nerve is so called because of the accessory fibres that it contributes to the vagus nerve. This motor nerve constitutes both spinal and cranial origins; fibres from the anterior horn cells in the upper five or six segments of the cervical spinal cord pass intracranially through the foramen magnum to join fibres from the cranial root. The combined fibres then exit the skull via the middle compartment of the jugular foramen, and then pass deep to the styloid process and the posterior belly of the digastric muscle. The nerve then courses across level II, before penetrating the sternocleidomastoid muscle which it supplies, with sensory contribution from the cervical plexus.

The course of the accessory nerve after leaving the sternocleidomastoid varies. It usually leaves the posterior aspect of the muscle one centimetre above Erb's point, where the cervical plexus branches emerge, however the point of emergence is variable and the nerve may not pass through the muscle at all. From the sternocleidomastoid the nerve runs in the roof of the posterior triangle to the trapezius, deep to the investing fascia and superficial to the prevertebral fascia within the fibro-fatty tissue. All-important structures of the posterior triangle are located caudal to the nerve. The nerve reaches the trapezius at the junction of the lower and middle one-third of the anterior surface of the muscle and enters the deep surface of the muscle.

The spinal accessory nerve is thought in most subjects to be the sole motor innervation for the sternocleidomastoid. The trapezius is solely innervated by the spinal accessory nerve in approximately one-quarter of individuals, meaning that in the majority the trapezius also receives a degree of motor innervation from the cervical plexus.[22] In some individuals, the motor branch to trapezius arises from the spinal accessory high in the neck before the accessory nerve enters the sternocleidomastoid muscle so care should be taken in this area to preserve all potential branches. Proprioceptive fibres from the anterior roots of the spinal cord supply the sternocleidomastoid and the trapezius muscles as part of the cervical plexus and may also carry motor fibres. The proprioceptive innervation of sternocleidomastoid is mostly from C2 and C3 and the supply to trapezius is mostly C3 and C4.

The commonest cause of iatrogenic accessory nerve damage is during level V neck dissection, which may be permanent or transient. This leads to denervation of all or part of the trapezius muscle, resulting in difficulty elevating the arm, winging of the scapula and reduced support for the weight of the arm which can lead to intractable cervical nerve root pain.

HYPOGLOSSAL NERVE

The hypoglossal nerve is solely a motor nerve and provides motor innervation to all the intrinsic muscles of the tongue and all extrinsic muscles except palatoglossus, which is supplied by the vagus nerve. After exiting the skull via the hypoglossal canal, the nerve runs deep to the IJV and courses around the vagal ganglion. It then curves around the carotid bifurcation as it heads anteriorly, passing inferior to the greater horn of the hyoid before coursing superiorly, superficial to hyoglossus to reach the tongue. The hypoglossal nerve is susceptible to injury during surgical procedures in the neck, particularly at its lowest point near the hyoid so care must be taken in these areas, to avoid the devastating effect of a hypoglossal nerve palsy on speech and swallowing.

C1 nerve root fibres run with the hypoglossal nerve, giving off a branch known as the descendens hypoglossi that arises at the level of the carotid bifurcation. This branch courses inferiorly, running on the anterior surface of the IJV and joins with cervical plexus branches to form the ansa cervicalis, providing motor supply to the strap muscles.

CERVICAL PLEXUS NERVES

The cervical plexus nerves arise from the anterior rami of the upper four cervical spinal nerves. The cervical plexus lies deep to the prevertebral fascia and passes over the scalenus medius muscle. It has motor and sensory branches (**Figure 35.13**).

The sensory, or cutaneous branches of the cervical plexus emerge from the posterior border of the sternocleidomastoid muscle 1 cm superior to the emergence of the spinal accessory nerve at a point termed Erb's point. These branches provide sensory innervation to the anterior neck, with four named branches:

- **Lesser occipital nerve:** Formed entirely from the C2 root this branch provides supply to the skin posterior to the pinna, up to the superior nuchal line.
- **Greater auricular nerve:** This branch is formed from C2 and C3 nerve roots and runs superiorly from Erb's point, across the sternocleidomastoid muscle towards the parotid gland. It branches into anterior and posterior divisions. The anterior branch supplies sensation to the skin anterior and inferior to the pinna whereas the posterior branch supplies the inferior pinna including the lobule, the skin inferior to the pinna and provides innervation to the parotid capsule. The nerve is often injured during neck dissection or parotid surgery and may have to be sacrificed to enable access to these areas, resulting in insensate lobule and numbness of the upper neck and peri-auricular skin.

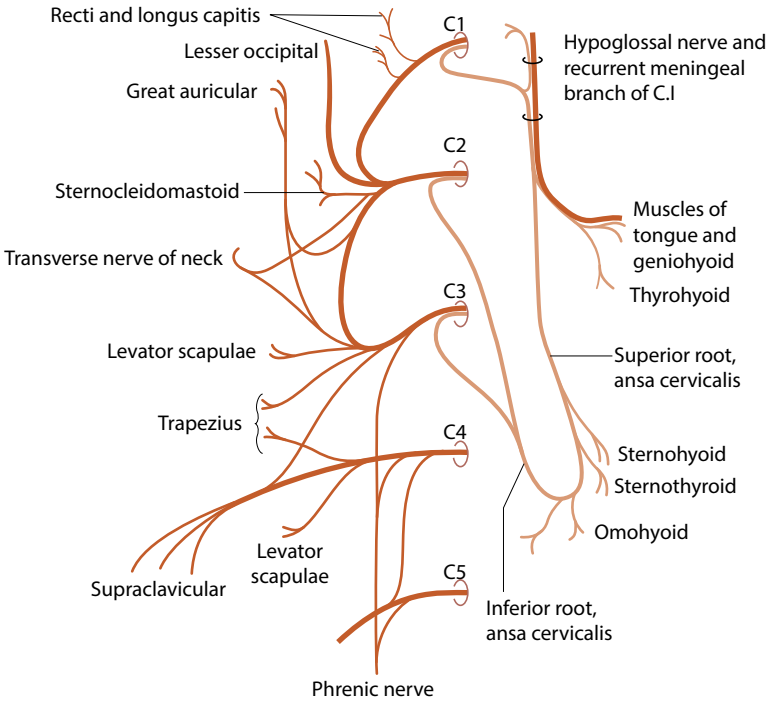

Figure 35.13 Cervical plexus nerves.

- **Transverse cervical nerves:** Fibres from the C2 and C3 nerve roots combine into a single nerve that leaves Erb's point then passes anteriorly and branches multiple times to give sensory innervation the skin of the entire anterior neck.
- **Supraclavicular nerves:** C3 and C4 nerve root fibres combine to form a single nerve which branches after Erb's point into three main divisions. A medial branch supplies an area of skin down to the sternoclavicular joint, the intermediate branch supplies the anterior chest wall skin, down to the anterior axial line. The lateral branch supplies the skin over the deltoid muscle and as far posterior as the spine of the scapula.

The muscular branches are given off segmentally to the prevertebral muscles of longus capitis, longus colli and the scalene muscles. The other muscular branches are the superior and inferior roots of the ansa cervicalis, segmental branches to the sternocleidomastoid and trapezius muscles and the phrenic nerve.

- **Ansa cervicalis:** Named as such from the Latin word 'ansa' meaning 'loop' this nerve is formed from a superior root, the C1 fibres of the descendens hypoglossi and an inferior root from the ventral rami of C2 and C3. The two roots merge over the IJV to form the ansa cervicalis which supplies motor innervation to the infrahyoid muscles: the sternothyroid, sternohyoid, thyrohyoid and omohyoid muscles.
- **Segmental supply to sternocleidomastoid and trapezius muscles:** As previously discussed, whilst the spinal accessory nerve provides the main motor supply to these muscles each also receives motor contribution from the cervical plexus. Branches from C2 and C3 supply the sternocleidomastoid whilst C3 and C4 fibres supply the trapezius. This is evidenced by the preservation of some of the motor supply to these muscles after sacrifice of the spinal accessory nerve during neck dissection. Conversely, shoulder dysfunction may still commonly occur when the accessory nerve is preserved, as a result of injury to the cervical plexus branches that contribute motor innervation to trapezius.
- **Phrenic nerve:** The phrenic nerve is the most significant motor branch of the cervical plexus. Formed from the ventral rami of C3, C4 and C5 the phrenic nerve runs inferiorly on the anterior surface of the scalenus anterior, deep to the prevertebral fascia to provide the sole motor supply to the diaphragm. The phrenic nerve is identifiable as the only structure deep to the prevertebral fascia that runs from lateral to medial. In addition to providing motor supply to the diaphragm it also provides sensory innervation to the central tendon of the diaphragm This is the cause of referred pain to the shoulder tip secondary to diaphragmatic irritation from abdominal or chest pathology that is referred via the C4 root of the phrenic nerve which communicates with the C4 root of the supraclavicular nerve.

CERVICAL SYMPATHETIC TRUNK

The cervical sympathetic trunk runs on the anterior surface of the prevertebral fascia, deep to the carotid sheath. It may have between two and four ganglia but typically has three, the superior, middle and inferior ganglia.

- **Superior cervical ganglion:** This is the largest of the ganglia and provides sympathetic innervation to the skin of the face and neck, including the eyes and eyelids.
- **Middle cervical ganglion:** This ganglion provides parasympathetic supply to the thyroid and parathyroid

glands and has a cardiac branch which supplies the heart, oesophagus and trachea.
- **Inferior cervical ganglion:** Also known as the stellate ganglion when fused with the highest thoracic ganglion, this receives contributions from C7, C8 and T1 and supplies the upper limb, lower neck and the heart.

Injury to the cervical sympathetic trunk may occur during head and neck surgery causing Horner syndrome, characterized by ipsilateral ptosis and meiosis with anhydrosis of the facial skin due to disruption of the oculosympathetic pathway. Horner syndrome is a rare complication of thyroid surgery due to an anatomical variation whereby a communicating branch between the recurrent laryngeal nerve and the cervical sympathetic trunk exists, which is at risk during thyroidectomy.

BRACHIAL PLEXUS

The brachial plexus is formed from the ventral rami of C5 to C8 and T1 and provides motor and sensory supply to the upper limb. It emerges between the anterior and middle scalene muscles and courses posteriorly across the inferior aspect of the posterior triangle, deep to the prevertebral fascia. It is an important structure for head and neck surgeons to appreciate as injury can have a catastrophic effect on the patient. It is most at risk during neck dissection, particularly when operating low in the posterior triangle or if the prevertebral fascia is breached.

KEY POINTS

- Knowledge of the anatomy of cranial and cervical nerves in the neck is key to operating safely in the neck.
- Care must be taken to avoid injury to the accessory nerve in the posterior triangle; all important structures lie caudal to the nerve.
- Supplementary motor supply from the cervical plexus to the sternocleidomastoid and trapezius muscles should be preserved where possible to optimize function.
- During neck dissection, with the fascial layers under tension, the sensory nerves of the cervical plexus travel medially and upwards, allowing sharp dissection away from the important motor nerves of the cervical and brachial plexus.
- There are rare connections between the recurrent laryngeal nerve and cervical sympathetic trunk which, if divided, can result in ptosis following thyroidectomy.

BLOOD VESSELS

The common carotid artery, branching in the neck into the internal and external arteries, provides the main arterial blood supply to the neck, with venous drainage via the jugular venous system.

Common carotid artery

The common carotid artery arises from the arch of the aorta on the left and from the brachiocephalic artery, also termed the innominate artery, on the right side. It does not normally give off branches, however, the vertebral, superior thyroid, inferior thyroid, ascending pharyngeal or occipital arteries may arise directly from the common carotid as normal variants.

The common carotid artery travels in the carotid sheath with the IJV and the vagus nerve. The cervical sympathetic trunk lies deep to the carotid sheath. The common carotid artery branches into internal and external branches at the level of the greater cornu of the hyoid bone. At the point of the bifurcation the artery dilates to form the carotid sinus, which contains stretch receptors innervated by the glossopharyngeal nerve which are the body's main baroreceptors. The carotid body lies deep to the bifurcation and contains chemoreceptors innervated by the glossopharyngeal nerve.

External carotid artery

The external carotid artery gives off multiple branches after the bifurcation which supply the viscera and muscles of the neck and face. The external carotid gives off six branches before dividing into two terminal branches within the parotid gland (**Table 35.8**). Although the superior thyroid artery is the first branch to be encountered, the ascending pharyngeal branch may arise first but is located deep to the main trunk and may not be readily visible. When ligating the external carotid artery for epistaxis, the ascending pharyngeal branch was traditionally preserved, because of its supply to the skull base and dura.

Internal carotid artery

The internal carotid artery (ICA) has no branches in the neck and lies deep and lateral to the external branch after the bifurcation. It runs beneath the posterior belly of digastric to enter the skull via the carotid canal and provides blood supply to the intracranial contents, with the vertebral artery via the circle of Willis. Important relations of the ICA are the IJV which runs antero-laterally to the artery and the pharynx, superior laryngeal nerve and pharyngeal vessels which are situated medial to the artery.

TABLE 35.8 Branches of the external carotid artery

Branch	Location	Supplies
Ascending pharyngeal	Deep	Oropharynx, hypopharynx, skull base, dura
Superior thyroid	Anterior	Thyroid, sternocleidomastoid
Lingual	Anterior	Tongue
Facial	Anterior	Tongue, tonsil, superficial facial soft tissue
Occipital	Posterior	Sternocleidomastoid, occiput
Posterior auricular	Posterior	Pinna, post-auricular skin
Superficial temporal	Terminal	Temporal region, scalp
Maxillary	Terminal	Deep facial tissues, mandible, nasal cavity

The cervical sympathetic trunk and its superior ganglion lie deep to the internal carotid.

Subclavian artery

The right subclavian artery arises from the brachiocephalic artery, whereas the left arises from the arch of the aorta, in a similar arrangement to the common carotid arteries. The subclavian arteries travel laterally towards the arm. The first part of the subclavian artery, from its origin to the medial aspect of the anterior scalene muscle, gives off the vertebral artery, the internal thoracic artery and the thyrocervical trunk, from which the inferior thyroid artery, suprascapular artery and the transverse cervical artery arise. The first part of the subclavian artery lies deep to sternocleidomastoid and the strap muscles but may extend above the clavicle so is at risk during procedures in the supraclavicular fossa. The second part of the artery runs deep to the anterior scalene muscle and gives off the costocervical trunk and the dorsal scapular artery. The third part passes lateral from the edge of the anterior scalene towards the arm and has no branches in the neck.

Internal jugular vein

The lateral or sigmoid dural venous sinus continues into the neck as the internal jugular vein (IJV). The jugular bulb lies within the floor of the tympanic cavity. After exiting the skull via the jugular foramen, the IJV travels inferiorly in the carotid sheath, anterior and lateral to the carotids. The IJV receives tributaries from the inferior petrosal vein, the common facial vein, the pharyngeal venous system and the superior and middle thyroid veins. Important relations of the jugular vein include the carotid arteries as mentioned above and the vagus nerve which runs posteriorly in the carotid sheath. The sternocleidomastoid muscle lies superficial to both the IJV and the carotid arteries, providing protection from penetrating trauma. The posterior belly of digastric and the inferior belly of the omohyoid muscle both cross over the IJV.

Inferiorly the IJV drains into the brachiocephalic veins on both sides, with only one valve before draining into the superior vena cava and eventually into the right atrium. Because of backflow from the right atrium the IJV has a pressure wave. The thoracic lymphatic duct drains into the posterior aspect of the IJV, at the intersection with the subclavian vein in Chassaignac's triangle.

Facial veins

The venous drainage of the face and oral cavity is via the facial and lingual veins which then form a venous plexus in the submandibular triangle. These may drain into the jugular vein with one single tributary that drains into the common facial vein or there may be many tributaries. The common facial vein also receives some drainage from the retromandibular vein which passes through the parotid gland.

Superficial jugular veins

Both the anterior jugular vein and the external jugular vein are part of a variable superficial venous system that drains the face and scalp. They drain into the subclavian vein, where valves exist to prevent backflow; thus the superficial jugular veins have low pressure, unlike the IJV.

KEY POINTS

- It is important to remember the ICA has no branches in the neck and lies deep and lateral to the external carotid.
- Both the internal and external carotid arteries are intimately related to the glossopharyngeal nerve and the pharyngeal and laryngeal branches of the vagus nerve, as well as the vagus nerve itself, the hypoglossal nerve and the cervical sympathetic trunk.
- Access to lymphatic level II is facilitated by retraction of the digastric; when doing so it is important to remember that vital vascular structures lie immediately deep to the muscle.
- When dissecting the hypoglossal nerve difficult bleeding can be encountered from the venae comitantes nervi hypoglossi and from a network of veins draining the thyroid, face and tongue known as the thyroglossofacial confluence which empty into the IJV in this location.
- Division of the common facial vein facilitates access to the hypoglossal nerve.
- When ligating any important vascular structure in the neck given a name, transfixion of the vessel should be considered to avoid haemorrhage.
- During thyroidectomy there are only two structures encountered within the para-carotid tunnel. These are the non-recurrent nerve and the middle thyroid vein; care should be taken when dividing this close to the IJV.

SUMMARY

Preservation of function when operating in the neck is more important than ever in this era of conservation surgery and improved survivorship from head and neck cancer. Functional neck surgery is not possible without a sound understanding of neck anatomy. This chapter covers the clinically relevant surgical anatomy of the neck to highlight the key areas any surgeon operating in the neck should be aware of. Advances in head and neck imaging aids surgeons in planning operations by providing detailed anatomical imaging, however, a sound knowledge of head and neck anatomy from texts and most importantly from clinical experience of operating in the neck remains key to providing patients with the highest standards of surgical care.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the contribution that Mr Owain Rhys Hughes made to this chapter.

SEARCH STRATEGY

Data in this chapter may be updated by a search of PubMed using the keywords: clinical examination AND neck OR salivary glands, Head and Neck neoplasms AND Lymphatic metastases OR Neck metastases.

INTRODUCTION

Clinical examination of the neck should accompany a thorough history and appropriate ear, nose and throat assessment. It is performed in either acute or elective settings, during assessment of a primary upper aerodigestive symptom, primary neck lump complaint or surveillance following treatment.

INSPECTION

The patient should ideally be exposed from the clavicles. Observe for lumps, skin changes and scars. Ask the patient to point to any lump if one is not obvious. Patients with midline lumps should be observed whilst drinking a sip of fluid and protruding the tongue. The thyroid gland is enveloped in pre-tracheal fascia along with the trachea. It will rise with laryngeal elevation during swallowing. Ask the patient to hold the fluid in the mouth before swallowing, giving the examiner time to concentrate on any movement. A thyroglossal cyst will elevate with tongue protrusion, being attached via the thyroglossal duct remnant to the foramen caecum of the tongue. Ask the patient to open their mouth, observe the lump and then ask them to protrude the tongue. Pemberton's sign is elicited by asking the patient to sit and raise the arms.[1] Venous congestion with facial plethora or cyanosis may indicate thoracic outlet obstruction for which a retrosternal goitre is a cause. Examination of the oral cavity to assess the parotid and submandibular ducts should accompany a thorough neck examination.

Examine the relevant cranial nerve function. Metastatic lymphadenopathy in the region of the accessory nerve can cause reduced function. It is important to note this prior to any proposed surgery. Parapharyngeal tumours may cause impairment to the nerves from which they arise, for example, Glomus vagale or Schwannoma of the sympathetic chain, or can cause compression to other lower cranial nerves.

Examine the scalp and external ear closely for lesions where appropriate. Skin conditions often cause level V reactive lymph nodes. Cutaneous squamous cell carcinoma and melanoma, often previously excised, may metastasize to the parotid lymph nodes and cervical nodes.

In the acute presentation, observe the patient for how the neck is held and for neck movements. Acute torticollis in a septic patient, usually a child, is indicative of severe inflammation and pain. Reduced range of neck movement in a septic patient may indicate a deep neck space abscess.

PALPATION

Have a set method that is reproducible. The location of the noted pathology in the neck should lead the examiner to consider a list of differential diagnoses (**Table 36.1**).

TABLE 36.1 Basic differential diagnosis of neck lumps

Lymph node group	Differential diagnosis
IA (submental)	Lymph node Thyroglossal cyst Dermoid cyst Plunging ranula
IB (submandibular)	Submandibular gland pathology Lymph node Cystic hygroma / lymphangioma (both can affect the entire neck)
II (upper jugular)	Lymph node Parotid gland pathology Branchial cyst Parapharyngeal pathology (e.g. Paragangliomata or nerve sheath tumours)
III (mid jugular)	Lymph node Branchial cyst Parapharyngeal pathology Laryngocoele
IV (lower jugular)	Lymph node (including Virchow's node on the left)
V (posterior triangle)	Lymph node Lipoma Cervical rib
VI (anterior compartment)	Thyroid gland pathology Thyroglossal cyst Parathyroid neoplasm Lymph node Direct extension of a laryngeal neoplasm

Figure 36.1 Palpation of the neck.

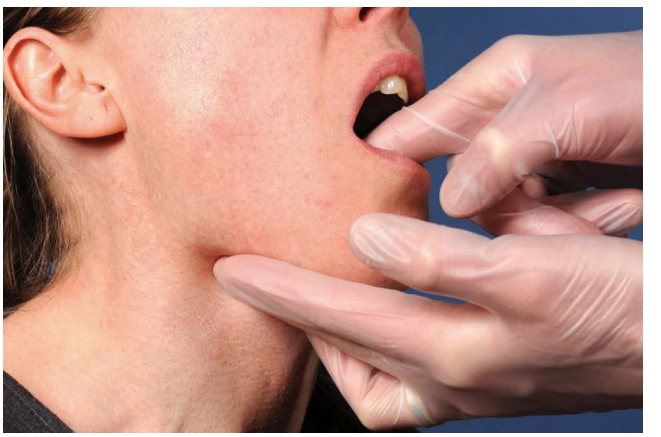

Figure 36.2 Bimanual palpation of the salivary glands.

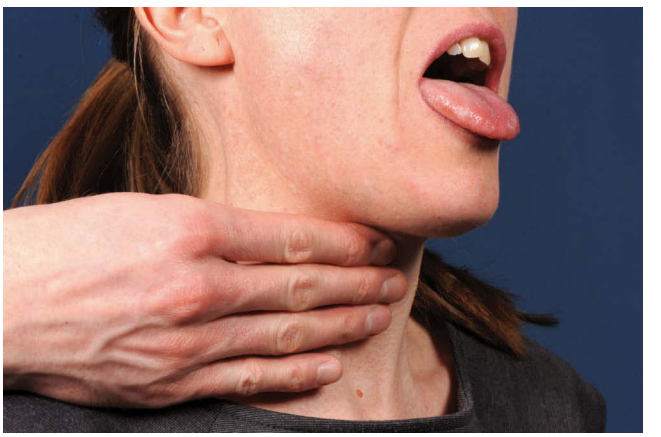

Figure 36.3 Palpation of a suspected thyroglossal cyst.

Each side of the neck should be examined individually, not simultaneously as this may cause excessive vagal stimulation through carotid sinus massage. The neck should be slightly flexed with the head tilted to the side of examination. This relaxes the neck muscles, in particular the sternocleidomastoid, allowing palpation of structures deep to it. The flats of the fingers should be used to palpate in a slow sweeping manner and should not resemble piano playing (**Figure 36.1**). The author always starts at level IA, sweeping posteriorly into IB before examining the jugular chain lymph nodes from level II to IV. The fingers then pass from medial to lateral above the clavicle before sweeping superiorly, anterior to the trapezius, towards the mastoid tip, covering level V. The post-auricular region, occipital and parotid regions are then palpated. Bimanual palpation of the salivary glands should be performed for any salivary lump (**Figure 36.2**). A suspected thyroglossal cyst is palpated in the same manner as during inspection (**Figure 36.3**). Finally the thyroid gland is palpated. This organ can be examined with both hands and the swallowing assessment repeated if necessary. Thyroid nodules may be palpable in 4–7% of the population, rising with age.[2] When detected as a part of an examination for other symptoms, thyroid nodules are not classified as 'incidentalomas' (as they are when detected with imaging) since they are by definition palpable. These nodules require investigation with serum thyroid-stimulating hormone (TSH), thyroid ultrasound with fine-needle aspiration where appropriate. Bear in mind normal anatomical structures which may seem pathological; the transverse process of the C2 vertebra, a prominent carotid bifurcation or occasionally patients may be aware of a normal internal jugular vein on voluntary valsalva.

PERCUSSION

Percussion over the sternum may give an indication of the extent of a retrosternal goitre or other upper mediastinal mass.

AUSCULTATION

Auscultation of the carotid arterial flow is often advocated for patients with symptoms suggestive of cerebral insufficiency. A study of 2000 patients found that 'critical auscultation' had a sensitivity of 83% and specificity of 40% in detecting carotid bifurcation lesions.[3] It concluded that auscultation is not capable of excluding carotid lesions. Auscultation over the larynx and trachea may help further characterize stridor, especially helpful in children.

CLINICAL EVALUATION OF CERVICAL LYMPHADENOPATHY

The majority of clinical neck examinations are performed to assess the cervical lymph nodes. The site, size, number, consistency, fixity to surrounding structures and overlying skin appearances should be assessed. For lymph nodes considered to contain metastatic head and neck malignancy, the affected site or sites should be classified according to the level(s) of the neck. The concept of 'levels' of the neck was first proposed by Shah in 1990.[4] Subsequently the Committee for Neck Dissection Classification of the American Head and Neck Society published several consensus documents further defining these levels.[5,6] The most recent anatomical boundaries of the neck levels are summarized in **Table 36.2** (**Figure 36.4**). Physical examination alone has a sensitivity of 81% and specificity of 77% in detecting metastatic lymphadenopathy.[7]

TABLE 36.2 Classification of neck levels

Lymph node group	Anatomical boundaries
IA (submental)	Laterally the anterior belly of digastric muscles, inferiorly the hyoid bone, superiorly the mandible.
IB (submandibular)	Anteriorly the anterior belly of digastric muscle, superiorly the body of the mandible, posteriorly the vertical plane defined by the posterior border of the submandibular gland (updated in 2008). This level includes the submandibular gland.
II (upper jugular – divided into A and B)	Medially the vertical plane defined by the posterior border of the submandibular gland (updated in 2008), laterally the posterior border of the sternocleidomastoid muscle, superiorly the skull base and inferiorly the inferior border of the hyoid bone. The vertical plane defined by the accessory nerve divides level II into A, anterior and medial and B, posterior and lateral.
III (mid jugular)	Medially the medial aspect of the common carotid artery (2008), laterally the posterior border of the sternocleidomastoid muscle, superiorly the inferior border of the hyoid bone, inferiorly the inferior border of the cricoid cartilage.
IV (lower jugular)	Medially the medial aspect of the common carotid artery, laterally the posterior border of the sternocleidomastoid muscle, superiorly the inferior border of the cricoid cartilage, inferiorly the clavicle.
V (posterior triangle – divided into A and B)	Medially (anterior) the posterior border of sternocleidomastoid muscle, posteriorly the anterior border of the trapezius muscle, superiorly the convergence of the sternocleidomastoid and trapezius, inferiorly the clavicle. It is divided by the horizontal plane from the inferior border of the cricoid arch into levels VA, superior and containing the nodes around the accessory nerve and VB, inferior containing the nodes around the transverse cervical vessels. Level VB incorporates the supraclavicular nodes, except Virchow's node in level IV.
VI (anterior compartment)	Laterally the medial aspect of the common carotid arteries, superiorly the hyoid bone and inferiorly the suprasternal notch.

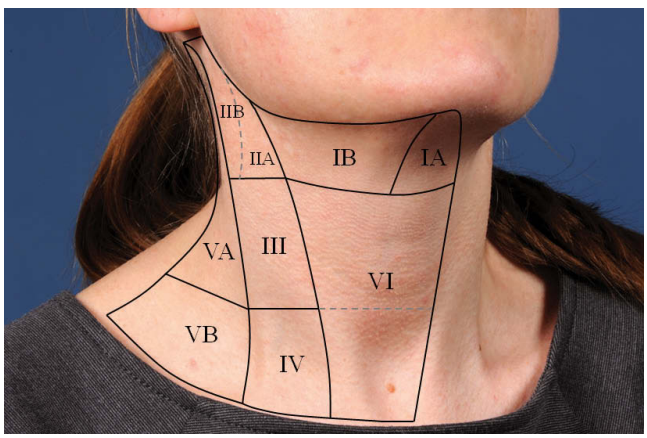

Figure 36.4 Anatomic boundaries of the neck levels.

KEY POINTS

- All patients presenting with head and neck symptoms should undergo a thorough clinical examination of the neck.
- The site of any neck pathology should lead the examiner to consider the potential differential diagnoses.
- Lymphadenopathy secondary to head and neck malignancy should be described according to the involved levels of the neck.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: head and neck cancer, head and neck infections, neck masses, imaging, CT, MRI, ultrasound, PET-CT.

IMAGING TECHNIQUES

Various imaging techniques are used in the evaluation of patients presenting with a neck mass or a 'hot' neck and in the staging and post-treatment follow-up of head and neck cancer. These include plain X-rays, ultrasound, CT, MRI, and PET-CT. Radiologists are increasingly being involved in image-guided biopsies, aspirations of collections in the neck, botox injections in selected post-surgical patients to improve speech or reduce salivary flow and embolizing/stenting vessels in patients with uncontrollable bleeding. Contrast studies including videofluoroscopy and angiography have an important role in selected cases.

The ENT surgeon is often unsure as to which investigation to request and this chapter will aim to clarify this based on the currently available evidence in the literature. However, there is no escaping from a meticulous history and examination in reaching a clinical diagnosis and imaging should be used to confirm this diagnosis and not used as a blanket screening examination.

Imaging modalities have been discussed in more detail in the relevant organ-specific chapters but some brief observations are provided below.

PLAIN X-RAYS

The use of plain X-rays in the head and neck is limited to detecting ingested radio-opaque foreign bodies, assessing the dentition in head and neck cancer patients and those presenting with abscesses around the floor of mouth as well as confirming the presence of air (**Figure 37.1**) or evaluating bony hard masses (**Figure 37.2**).

ULTRASOUND (US)

US is quick, non-invasive, readily available, inexpensive and does not use ionizing radiation but is heavily operator dependent. It is widely used in children for evaluating neck lumps, lymph nodes, the thyroid and salivary glands and in guiding fine-needle aspiration (FNA) or core biopsies. US is particularly helpful in evaluating whether a node appears reactive (**Figure 37.3a**) and can therefore be safely ignored or more complex (**Figure 37.3b**), requiring FNA and further investigation.[1–3]

COMPUTED TOMOGRAPHY (CT)

CT is used extensively in staging head and neck cancer patients and for detecting masses or abscesses in the deep

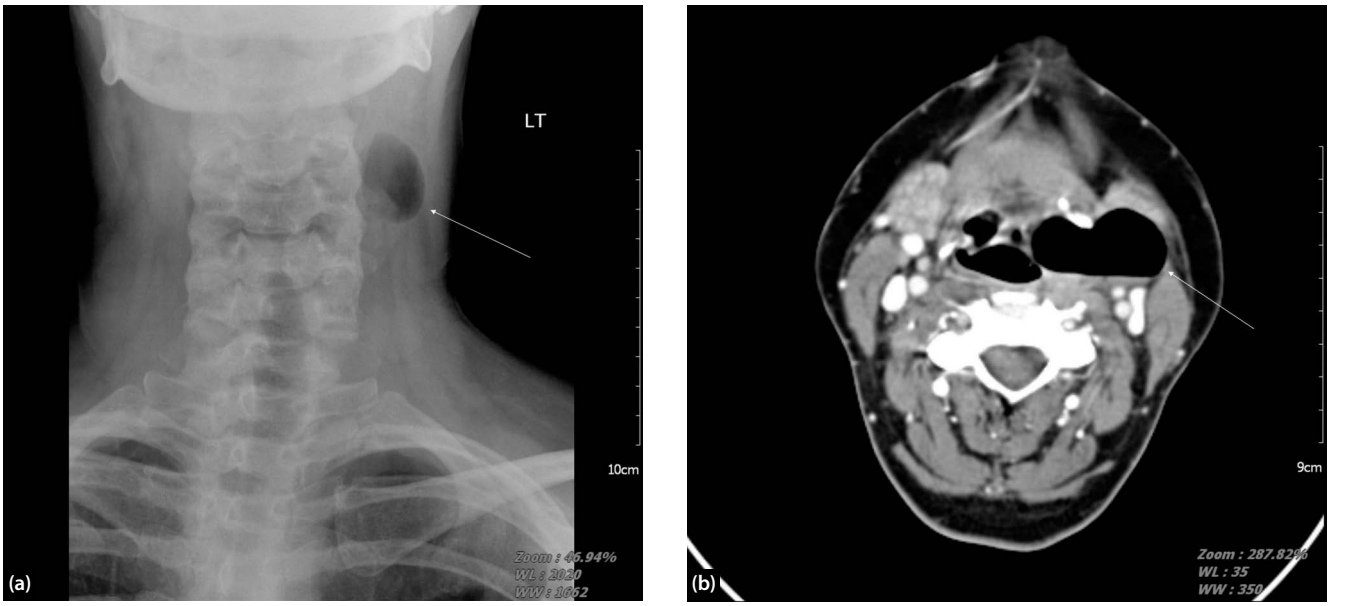

Figure 37.1 Plain X-ray (a) and axial contrast enhanced CT **(b)** showing a left-sided laryngocoele (arrow) in a patient initially referred with a soft swelling for ultrasound.

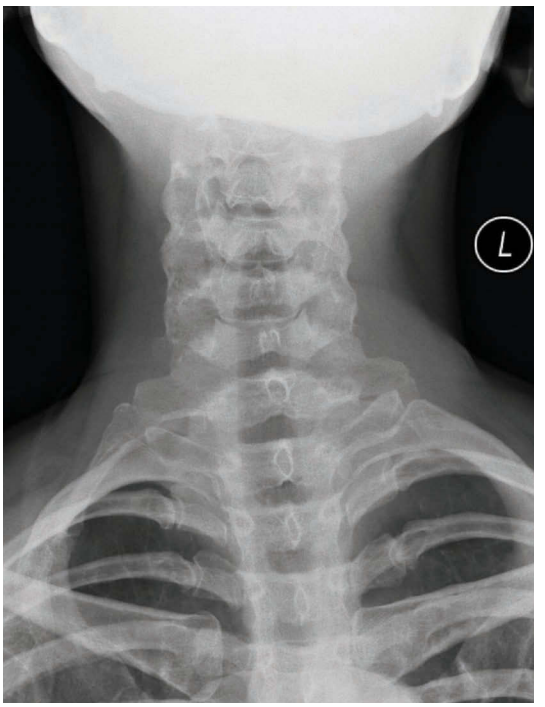

Figure 37.2 Bilateral cervical ribs, larger on the right: patient presented with a bony hard mass in the right supraclavicular region.

spaces of the neck. With the advent of multi-detector scanners, the entire neck can be scanned in a few seconds and a volumetric data set obtained, allowing reconstructions in any plane. Because of its relatively low soft-tissue resolution, intravenous iodinated contrast agents are necessary. Dual-source scanning is the latest breakthrough in CT technology and early results are promising for imaging the neck.[4] Radiation dose is an important consideration on CT and dose reduction can be achieved by special in-built features in most modern CT scanners as well as manually altering settings such as mAs and KV, without affecting diagnostic image quality.[5, 6] Artefact from dental amalgam can be negated by gantry tilt but the combination of this facility and volumetric scanning is not available on all scanners.[7] Cone-beam CT has an evolving role in head and neck imaging.[8]

MAGNETIC RESONANCE IMAGING (MRI)

MRI produces images with very good soft-tissue contrast and does not use ionizing radiation but is contraindicated in certain patients with pacemakers, ferromagnetic intraocular foreign bodies, cochlear implants, cerebral artery aneurysm clips and valve prostheses. The long acquisition times result in neck images that can be easily degraded by movement and swallowing artefact.

POSITRON EMISSION TOMOGRAPHY (PET)

PET is a functional imaging technique that depicts tissue metabolic activity and all hypermetabolic cells, not just malignant cells, accumulate the tracer resulting in increased activity as measured by standard uptake value (SUV). The commonest tracer used is fluorine-18-labelled 2-fluoro-2-deoxy-D-glucose (FDG), which has a half-life of 110 minutes. The combination of CT and PET allows accurate anatomical localization. PET-CT is especially useful in assessing patients presenting with a metastatic neck node and no overt primary, the so-called cancer of unknown primary, and in the post-treatment patient, where differentiation between post-treatment fibrosis and residual/recurrent tumour can be difficult. Head and neck PET-CT is complicated by the fact that various structures such as Waldeyer's ring (lymphoid tissue of the

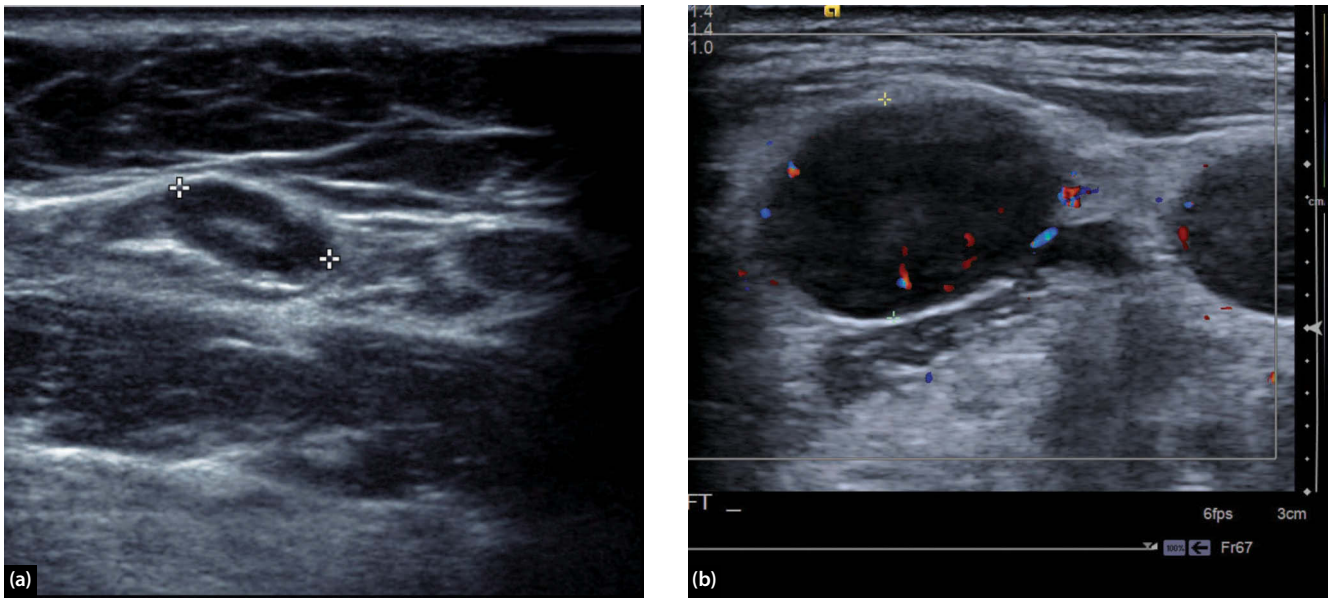

Figure 37.3 US showing a reactive node with a normal echogenic hilum **(a)** and a metastatic node showing loss of its normal architecture and increased peripheral vascularity **(b)**.

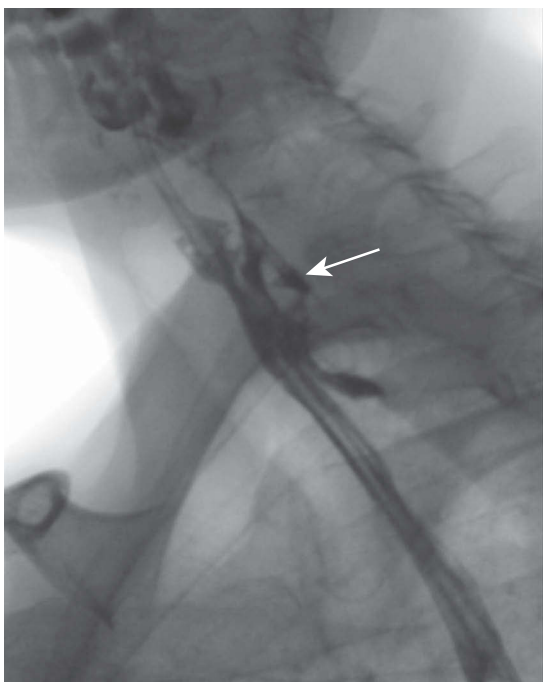

Figure 37.4 Contrast swallow post-laryngectomy showing an inferior leak (arrow) extending into the superior mediastinum.

nasopharynx, tongue base, palatine tonsil, soft palate and posterior pharyngeal wall), the salivary glands, nasal turbinates and cervical muscles normally show FDG uptake. The feasibility of MRI and PET in the staging of head and neck cancer is also being evaluated.[9]

CONTRAST SWALLOW

Contrast swallows are important in assessing for the presence of leaks in the early phase after laryngeal and pharyngeal surgery (**Figure 37.4**) while videofluoroscopy is important in assessing head and neck cancer patients presenting with dysphagia before or after treatment.

HEAD AND NECK CANCER

Imaging plays an important role in assessing the extent of primary tumour and any metastases.[10, 11] Many tumours can initially be staged by CT as the chest and liver can be imaged at the same time as the neck, allowing the detection of distant chest, liver or bone metastases and any synchronous lung or gastrointestinal tumours. MRI is particularly useful for evaluating intracranial spread in nasopharyngeal and other skull-base tumours and the oral cavity in patients where the images are degraded by dental amalgam artefact. Diffusion-weighted MRI is being increasingly used in the head and neck to help with differentiating benign from malignant tumours, squamous cell carcinoma from lymphoma, suppurative lymphadenitis from metastatic nodes, recurrence from post-radiotherapy fibrosis as well as nodal staging.[12–16]

Small mucosal tumours are easily assessed clinically but larger tumours require cross-sectional imaging to assess the size, location and deep extension of tumour, involvement of surrounding structures and presence of distant metastases.

Lymph node status is one of the most important prognostic factors in head and neck cancer and various studies have shown that imaging is more reliable than clinical palpation.[17, 18]

NASOPHARYNGEAL CANCER

The most common cancer of the nasopharynx is undifferentiated or poorly differentiated carcinoma that has a close relationship to the Epstein–Barr virus. Other cancers

that may arise in the nasopharynx include lymphoma, adenocarcinoma, adenoid cystic carcinoma, melanoma, plasmacytoma, chordoma and sarcoma. This chapter will concentrate on nasopharyngeal carcinoma that has a high incidence in the Chinese population, even after they have emigrated.

Nasopharyngeal carcinoma

Nasopharyngeal carcinoma (NPC) is different from other head and neck squamous cell tumours in its aggressive local infiltration and propensity for metastatic spread despite apparently early primary lesions. Patients may present with a neck mass, nasal obstruction, blood-stained nasal discharge, headaches, ophthalmoplegia, hearing loss and tinnitus. The aim of imaging is to accurately map the primary tumour and to detect any extension especially to the skull base and deep fascial planes as well as nodal and distant metastases.

CT allows assessment of the primary tumour, neck nodes, chest and liver in one examination but MRI is superior in demonstrating the tumour soft-tissue extent, any intracranial extension and skull-base bone marrow changes.[19–22] Dynamic contrast-enhanced MRI may be useful in characterizing NPC as higher stage tumours show some parameters of increased permeability and perfusion.[23] PET-CT is useful in staging, assessing for recurrence and in evaluating the nasopharynx in patients presenting with neck nodes and no obvious primary.[24–27] Huang et al.[28] showed that intratumoral heterogenicity of FDG uptake across NPC tumours significantly correlated with tumour aggressiveness and predicted patient outcome while various authors have shown a correlation between SUV and outcome.[29–34] Ng et al. suggest a combination of PET-CT and head and neck MRI as the initial staging examinations for NPC patients, with MRI superior in detecting locoregional invasion and retropharyngeal nodes and PET-CT more accurate in determining cervical node metastases.[35] However King et al. showed that the additional use of PET-CT did not upstage or change management when compared to MRI in their cohort of patients.[36] Imaging may allow differentiation of NPC from lymphoma as NPC is often asymmetrical with a propensity to invade widely and deeply into muscle tissue, fat spaces, neural foramina and skull base while lymphoma is more symmetrical, shows homogenous enhancement and has a propensity to involve Waldeyer's ring.[37–39]

An understanding of the pathology of nasopharyngeal cancer is essential in order to correctly interpret imaging at the time of staging and subsequent follow-up.[40] Most nasopharyngeal tumours originate in the fossa of Rosenmuller and tend to spread submucosally with early infiltration of the palatal muscles and obstruction of the Eustachian tube (**Figure 37.5**). The most common spread is laterally with infiltration of the parapharyngeal and masticator spaces with potential involvement of the mandibular nerve and intracranial spread. Anterior spread of tumour into the nasal fossa can result in erosion of the maxillary sinus and infiltration of the pterygopalatine fossa and thence along the maxillary nerve onto the foramen rotundum (**Figure 37.6**). NPC can spread superiorly to erode the clivus (**Figure 36.7**), petrous apex, sphenoid sinus and foramen lacerum. Inferiorly it can extend along the pharyngeal wall to the oropharynx while posteriorly it infiltrates the retropharyngeal space and prevertebral muscles. Nodal metastases (**Figure 37.8**) to all cervical levels including the retropharyngeal group are extremely common and may be the presenting feature but level 2B nodes rather than retropharyngeal nodes appear to be the first echelon nodes in NPC.[41, 42] Tomita et al. showed that primary tumour existence beyond the midline of the nasopharynx was associated with a higher incidence of bilateral lymph node metastases than primary tumour presence within the midline, with incidences of 66% and 18% respectively.[43] Distant metastases to the lung and liver are common.

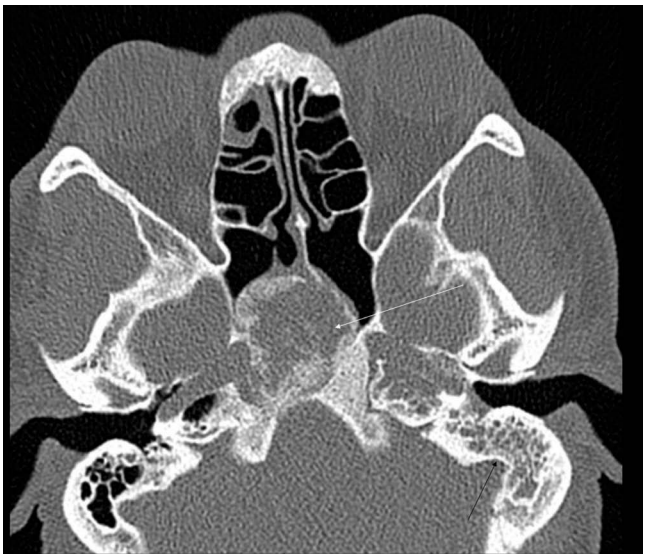

Figure 37.5 Axial CT on bone settings showing nasopharyngeal carcinoma (white arrow) and retained secretions left mastoid air cells (black arrow) due to Eustachian tube obstruction.

Management of NPC is one of the greatest clinical challenges, with radiotherapy, especially intensity-modulated radiotherapy (IMRT), being the primary treatment and chemoradiotherapy used for locoregionally advanced tumours.[44] The aim of post-treatment imaging is to detect early recurrence. As there is usually tumour resolution by 3 months post-radiotherapy, PET-CT is being increasingly used to ensure no residual activity within the primary site or nodes.[26, 45] Differentiating fibrosis from tumour recurrence is difficult on CT and can also be problematic by MRI but 3T-MRI may be comparable to PET-CT in detecting residual or recurrent NPC and contrast-enhanced MRI is useful in detecting perineural spread (**Figure 37.8**).[46–50] The combined use of MRI and FDG PET-CT is more accurate for tumour restaging than either modality used independently.[51] Some authors have suggested plasma Epstein–Barr virus DNA screening and if positive followed by PET-CT while others have advocated the use of CT perfusion in detecting recurrences.[52–54] A systematic review comparing PET-CT, CT

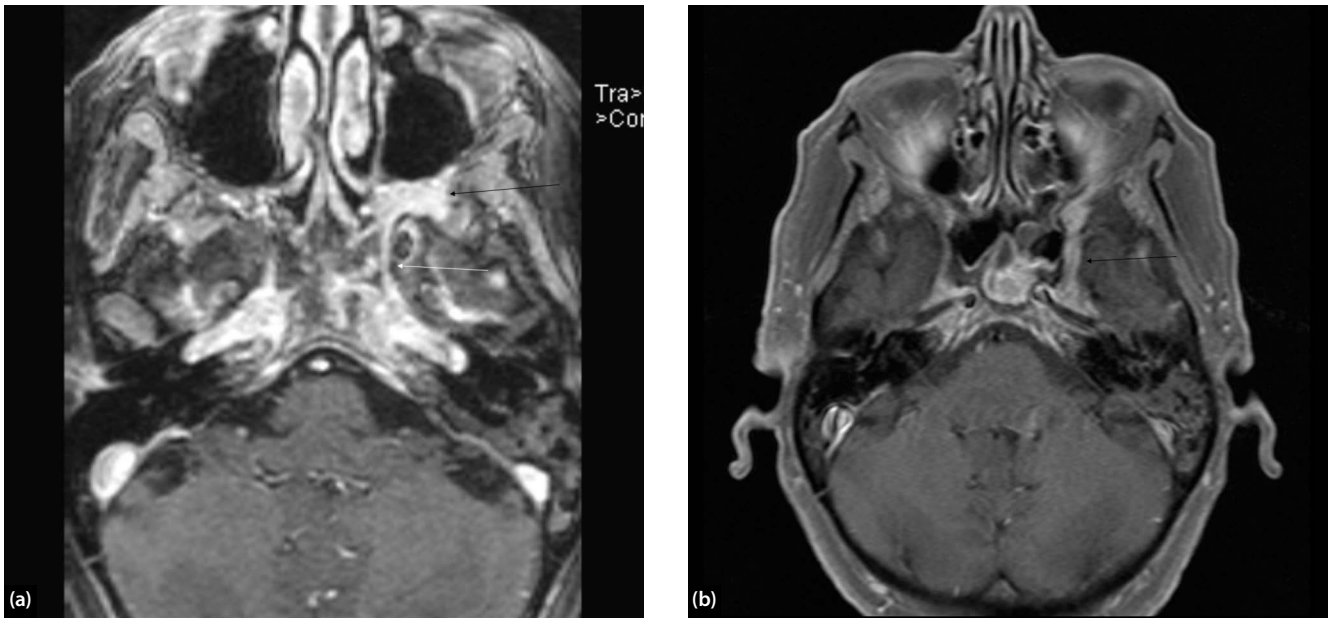

Figure 37.6 Axial VIBE (Volumetric interpolated brain examination) MRI showing left nasopharyngeal cancer (NCC) extending into the pterygopalatine fossa (black arrow) and vidian canal (white arrow) **(a)** and into the foramen rotundum (black arrow) **(b)**.

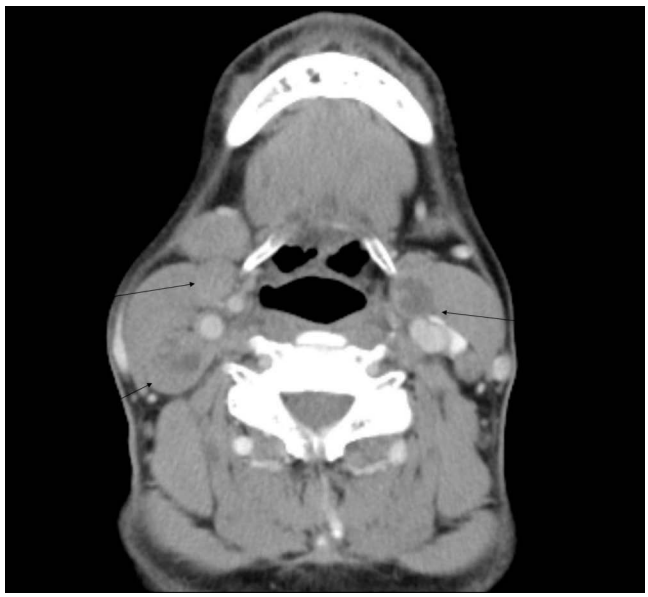

Figure 37.8 Axial contrast-enhanced CT showing bilateral level 2/3 nodes (black arrows) in patient with NPC.

and MR imaging for the diagnosis of local residual or recurrent NPC showed that PET-CT was the best imaging modality.[55] PET-CT should therefore be the imaging modality of choice in the detection of residual or recurrent disease (**Figure 37.9**).

Lymphoma

Non-Hodgkin lymphoma (NHL) is the second most common nasopharyngeal tumour and classically involves Waldeyer's ring.[37–39] Imaging usually demonstrates a well-defined, homogenous, non-necrotic mass that is exophytic rather than infiltrative in nature (**Figure 37.10**).

ORAL CAVITY TUMOURS

The oral cavity is bordered by the hard palate and maxillary alveolar ridge superiorly, the mylohyoid muscle and alveolar mandibular ridge inferiorly, the lips anteriorly, the gingivobuccal region laterally and the soft palate, circumvallate papillae and tonsillar pillars posteriorly. Although the soft palate forms part of the oropharynx, the mucosal layer beneath the hard palate lies within the oral cavity. The centre of the oral cavity is filled by the tongue, the anterior two-thirds of which is part of the oral cavity.

Oral cavity tumours are usually readily apparent clinically and easily amenable to biopsy but challenging for

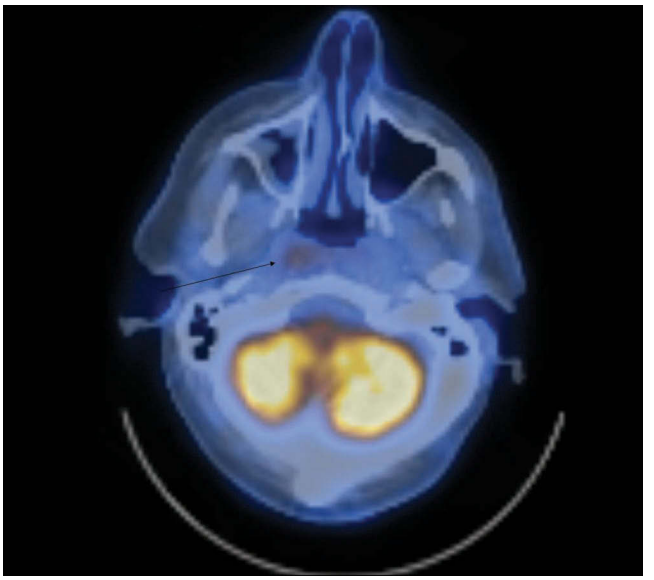

Figure 37.9 Fused axial PET-CT showing activity in the right nasopharyngeal region (black arrow), confirmed histologically to be NPC recurrence.

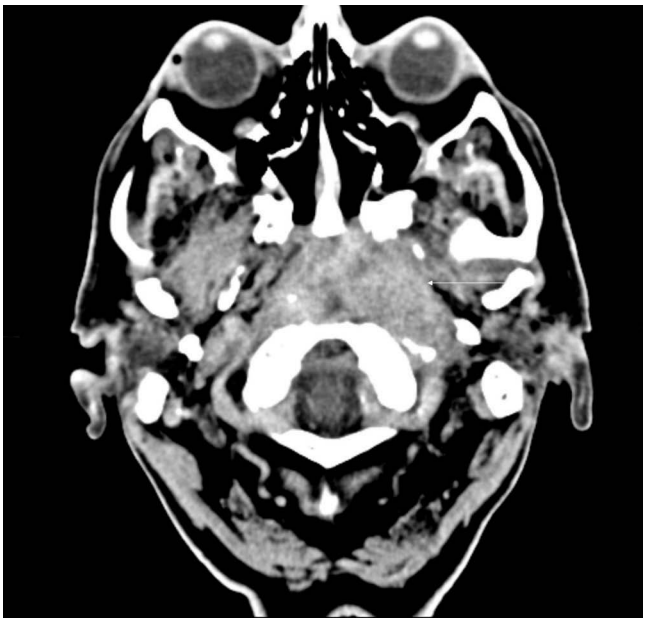

Figure 37.10 Axial CT showing a midline nasopharyngeal mass, biopsy confirmed non-Hodgkin lymphoma.

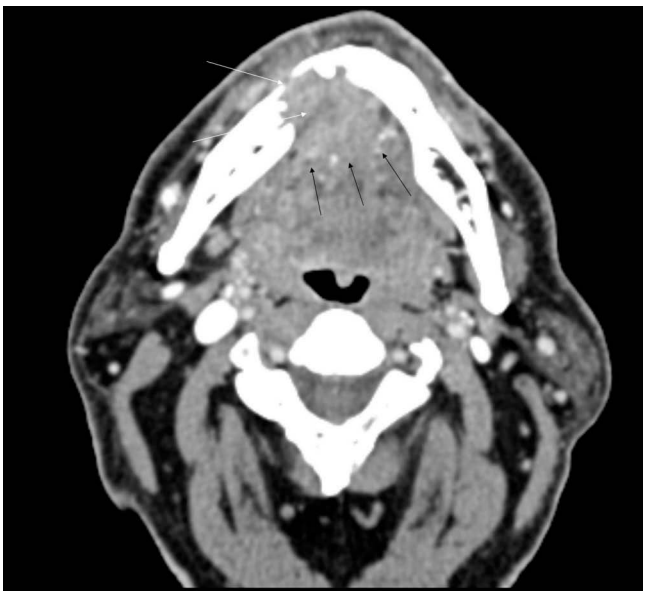

Figure 37.11 Axial contrast-enhanced CT showing anterior floor of mouth SCC crossing the midline (black arrows) with associated destruction of inner and outer cortex of mandible (white arrows).

radiological diagnosis because of the surrounding anatomy and small tumours are often not visualized by imaging. Squamous cell carcinoma (SCC) is the most common tumour that affects the oral cavity and can extend along the submucosa to invade adjacent structures. Despite the invasive character of SCC, bony structures are infiltrated late in the course of disease. The invasion of nerves and vessels is an important aspect in the spread of oral cavity tumours. Vascular invasion results in a greater risk of remote as well as lymph node metastases while perineural extension allows spread far beyond the expected tumour margins. The oral mucosa has bilateral drainage to the level 1 submental and submandibular nodes and any asymmetrically enlarged nodes should be regarded with suspicion. Cervical nodal metastases occur in approximately 50% of patients with SCC of the oral cavity and may be bilateral especially if tumours cross the midline but lymphadenopathy is often occult and not detected clinically or by imaging. The floor of mouth, retromolar trigone (RMT) and ventrolateral tongue are involved in descending frequency by SCC and will be briefly discussed.

Floor of mouth cancer

Most of these tumours are easily diagnosed clinically and occur anteriorly, from where they can extend deeply into the sublingual gland, obstruct the submandibular duct and invade the submandibular space. The key points from the imaging point of view include looking for extension posteriorly along the neurovascular bundle and across the midline (**Figure 37.11**).

Retromolar trigone cancer

The RMT is the triangular mucosa posterior to the last molar and tumours are less easily detected clinically. SCC can arise from the RMT (**Figure 37.12**) or spread into the RMT secondarily from the tongue base or tonsil. Tumours may invade the mandible directly, the inferior alveolar nerve or extend posteriorly along the pterygomandibular raphe, a fibrous band beneath the RMT that extends from the hook of the hamulus of the medial pterygoid to the mylohyoid line on the medial border of the mandibular body. As the buccinator, superior constrictors and orbicularis oris muscles all insert into the pterygomandibular raphe, tumours can extend into the lateral floor of mouth, buccal space, tonsillar fossa or nasopharynx.

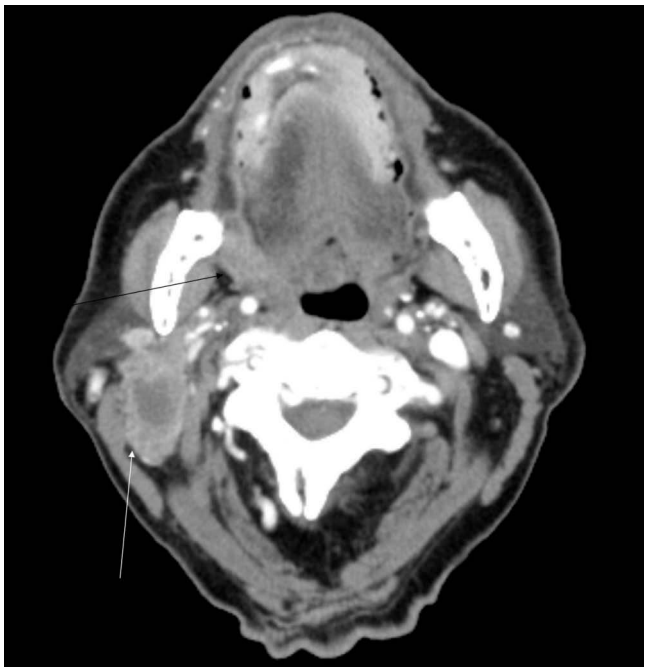

Figure 37.12 Axial contrast-enhanced CT showing a right retromolar trigone tumour (black arrow) with an associated necrotic level 2 node (white arrow).

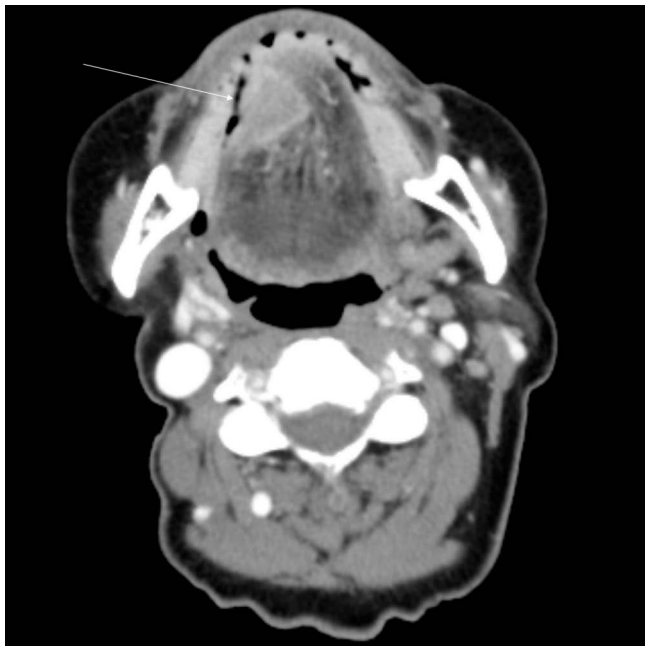

Figure 37.13 Axial contrast-enhanced CT showing right ventral tongue tumour (white arrow) just reaching the midline.

Tongue cancer

The ventrolateral surface of the tongue is the site most commonly involved by tumour (**Figure 37.13**), which can easily invade the intrinsic muscles. Besides assessing for tumour spread into the floor of mouth, tongue base, tonsils, soft palate and mandible, tumour extension across the midline and to the contralateral neurovascular bundle also needs evaluation.

Hard palate, gingival and buccal cancer

The gingiva is the mucous membrane that covers the alveolar bone processes and is attached to the lingual and buccal surfaces of the mandible and maxilla. Gingival and buccal tumours (**Figure 37.14**) may eventually invade the mandibular or maxillary cortex especially in edentulous patients. Hard-palate tumours (**Figure 37.15**) require close evaluation of the bone, best seen in the coronal plane and can spread perineurally along the incisive and greater and lesser palatine canals to the pterygopalatine fossa.

Modalities available for imaging the oral cavity are ultrasound, CT, cone-beam CT, MRI and PET-CT.[56–63] As in other head and neck cancers, CT provides better evaluation of cortical bone while MRI has the advantage of better characterizing local tumour extent, perineural spread and bone-marrow involvement. Dental amalgam artefact poses a frequent diagnostic problem on CT, while swallowing artefact is also a problem with CT but especially so with MRI because of the long acquisition times. Acquiring CT images with gantry tilt that avoid dental metalwork artefact significantly improves sensitivity in the staging of oral and oropharyngeal tumours.[64]

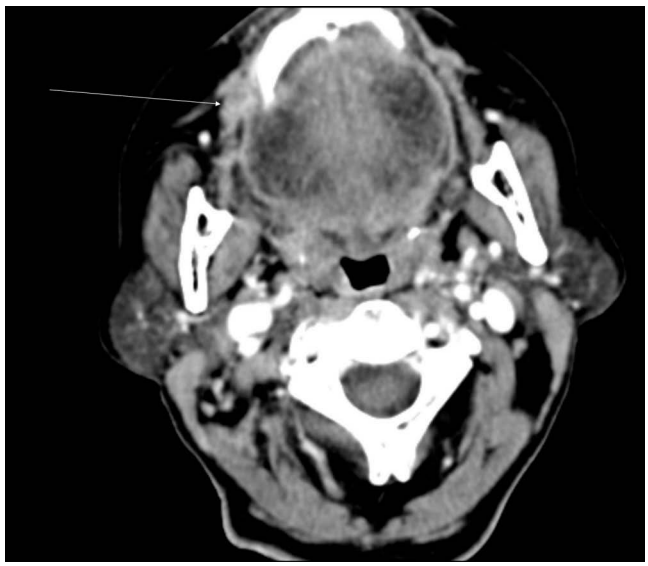

Figure 37.14 Axial contrast-enhanced CT showing right buccal tumour (white arrow).

Various contrast-enhanced CT protocols have been used with a low-flow delayed-phase protocol providing better delineation of the tumour edge compared to a high-flow rate and short-delay protocol but no difference in central tumour enhancement.[65] Intimate apposition of the oral mucosa to the alveolar mucosa makes assessment of small oral tumours particularly difficult with both CT and MRI and cheek puffing has been used as a manoeuvre on CT to separate surfaces.[66, 67] This is not possible with MRI because of long-imaging sequences but the placement of a rolled piece of gauze into the oral vestibule before MRI scanning improves visualization of small tumours.[68]

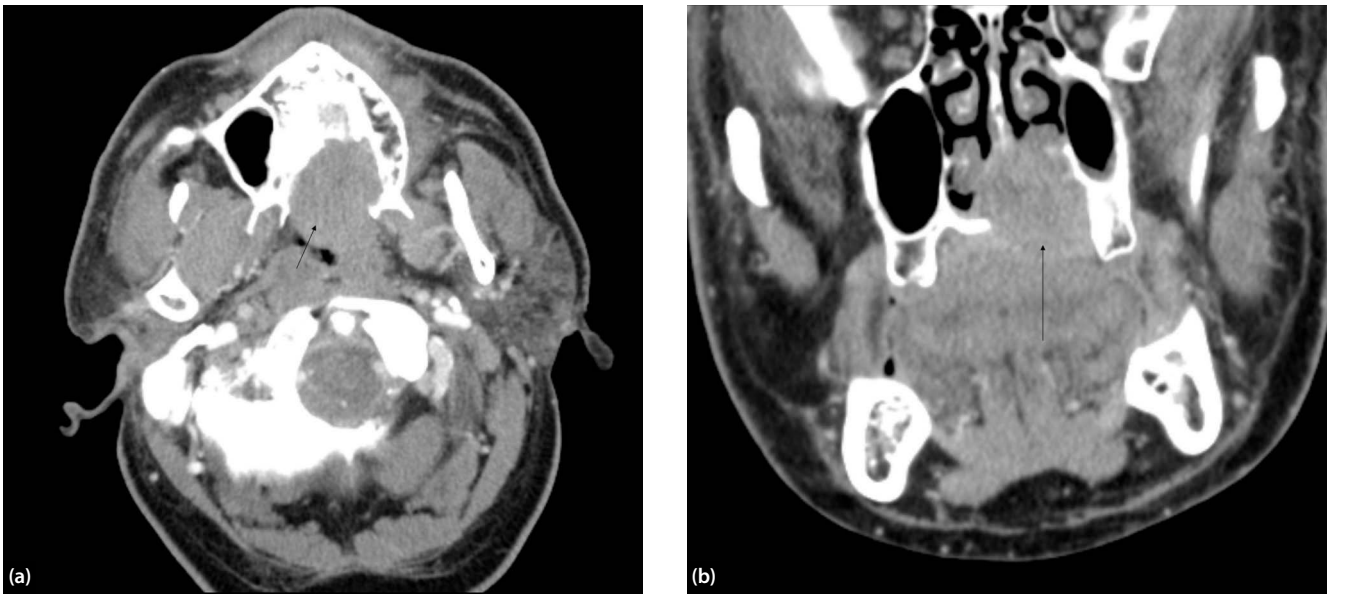

Figure 37.15 Axial **(a)** and coronal reformatted **(b)** contrast-enhanced CT showing left sided destructive hard palate SCC (black arrows) extending into nasal cavity.

MRI is an accurate method for the assessment of oral cavity malignancies, presence of mandibular involvement and the evaluation of depth invasion, with 9.5 mm in one study being the depth cut-off value for determining positive nodes.[69, 70]

In the initial staging of patients with oral cavity tumours, the use of PET with a contrast-enhanced CT is a reliable alternative to the combination of PET/plain CT and a separate diagnostic CT, with a sensitivity of 96% for detecting the primary tumour and a sensitivity of 89% and a specificity of 81% for cervical metastases.[71] An open mouth PET-CT can improve anatomical tumour localization, tumour extent and detection of involvement of adjacent structures when compared to a standard examination.[72] In the study by Seitz et al.[73] PET-CT was not superior to MRI but Baek et al.[74] showed that PET-CT provided further useful clinical information about the primary oral cavity tumour in patients in whom dental artefacts distorted the conventional CT or MRI images. Kim et al.[75] also showed that FDG-PET was more sensitive than CT or MRI in the staging of oral cavity tumours. A SUV nodal maximum of 5.7, either alone or in combination with extracapsular spread, is an independent prognostic indicator for 5-year neck cancer control and survival rates in oral cavity tumour patients with pathologically positive lymph nodes.[76] Furthermore patients with the combination of primary tumour SUV equal to or greater than 19.3 and pathological tumour depth equal to or greater than 12 mm are at greatest risk of poor local control and death.[77] A significant difference has also been shown in maximum SUV on PET-CT between nodes with and without extracapsular spread and a cut-off SUV value of 2.5 is associated with a greater risk of cervical lymph node metastasis.[78] PET and PET-CT however only had a sensitivity of 77.7% and a specificity of 58% in detecting cervical metastases in the primary staging of 473 patients with SCC of the oral cavity.[79] PET-CT and US can be complementary tools in the pre-operative evaluation of patients with SCC of the oral cavity.[80]

Evaluation of whether there is marrow or cortical involvement of the maxilla or mandible by SCC of the oral cavity is crucial for the surgeon to obtain both radical tumour resection and good functional results. In the case of tumours related to the mandible, resection can vary from a shaving of the lingual cortex, rim resection or segmental mandibulectomy. Many surgeons advocate periosteal stripping for tumours adjacent to the mandible at the time of surgery but accurate imaging does help the surgeon plan the treatment options and allows for an informed discussion with the patient prior to surgery. Abd El-Hafez et al. found that PET-CT was more specific than MRI (84% versus 61%) but less sensitive (78% versus 97%) for detection of bone-marrow invasion of the mandible and maxilla, with dental status and tumour origin affecting the diagnostic performance of PET-CT. They concluded that a negative MRI could confidently exclude the presence of bone-marrow invasion while in patients with positive MRI findings, a negative PET-CT was useful in ruling out bone marrow invasion in dentate patients.[81] Gu et al. noted sensitivity, specificity and accuracy of 41.7%, 100% and 84.8% for CT and identical figures of 58.3%, 97.1% and 87% for MRI and PET-CT in the detection of mandibular invasion. The combined use of CT, MRI and PET-CT improved sensitivity to 83.3% without loss of specificity and accuracy but this did not reach statistical significance.[82] Although Vidiri et al. showed that MRI had a higher sensitivity than CT in the assessment of mandibular involvement from SCC of the oral cavity, this did not reach statistical difference.[83] Cone-beam CT (**Figure 36.16**) has been shown to be accurate in predicting bone invasion in patients with oral malignancies, competing well with

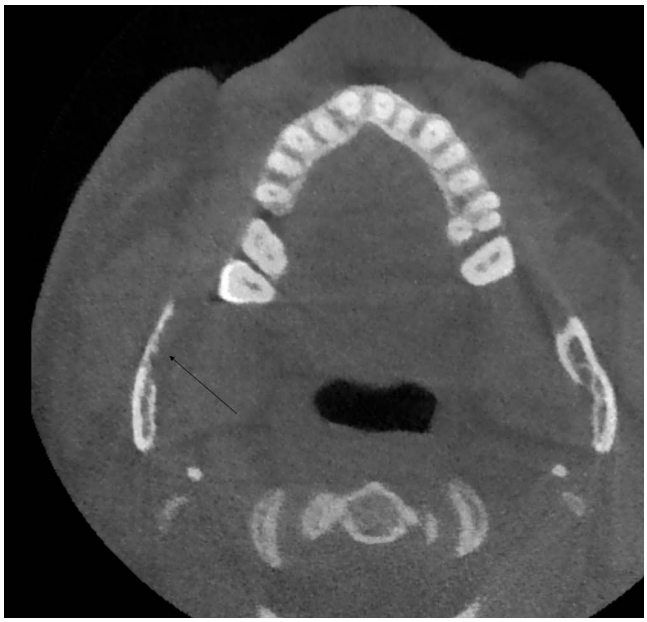

Figure 37.16 Cone-beam CT showing destruction of the inner cortex of the right mandible (arrow) in a histologically proven intraosseous SCC.

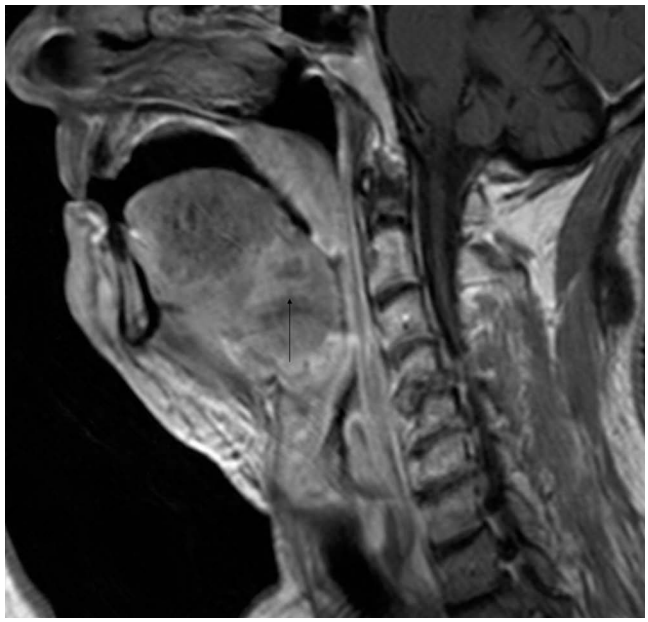

Figure 37.17 Post-gadolinium sagittal T1W MRI showing histologically proven residual tumour (black arrow) six weeks after completing chemoradiotherapy for a large tongue tumour.

CT and single photon emission computerized tomography (SPECT).[84] It therefore appears that CT, MRI and PET-CT all have strengths and weaknesses in assessing bone involvement by SCC and imaging needs to be assessed on a case-by-case basis depending on the site of tumour and local expertise.

Treatment of the clinical N0 neck in SCC of the oral cavity remains a dilemma because of the inability to detect micrometastases on conventional cross-sectional imaging including PET-CT.[85, 86] Although guided FNA seems to correlate best with histological staging for exact N classification compared with CT and PET-CT, it is still not reliable enough to replace elective neck dissection in the N0 neck.[87] The detectability threshold of occult metastases is below the spatial and contrast resolution of CT, MRI and 18FDG–PET in oral cancer patients staged as T1 or T2 and clinically negative neck.[88] Although PET-CT has been shown to perform better than CT or MRI, the sensitivity and specificity of PET-CT in detecting occult cervical metastases varies between 50–64% and 81–97% respectively.[71, 89] There appears to be some value in volume-based PET-CT in patients with clinically node negative oral cancer.[90] Magnetic resonance lymphangiography has limited diagnostic value compared with US with or without fine-needle cytology and CT in the pre-operative staging of the N0 neck.[91] Based on the available evidence, cross-sectional imaging including PET-CT cannot be used in deciding whether to proceed to elective neck dissection or not in N0 patients.

The imaging of post-treatment patients with oral cancer is problematic. The combined use of PET and contrast-enhanced CT for post-treatment monitoring of cancers of the oral cavity has steadily increased in recent years as residual/recurrent disease at the primary site, extent of nodal disease and distant metastases can be assessed. However interpretation of the first follow-up post-treatment PET-CT is challenging and a period of 12 weeks post-treatment is usually recommended to reduce false positive findings.[92, 93] CT or MRI (**Figure 37.17**) rather than PET-CT should be performed during this waiting period of 12 weeks should imaging be required.

OROPHARYNGEAL TUMOURS

The subsites of oropharyngeal tumours include the tongue base and valleculae anteriorly, the tonsils and glossotonsillar sulci laterally, the inferior surface of the soft palate and uvula superiorly and the posterior wall posteriorly.

Tonsillar cancer

Almost all tonsillar tumours originate from the anterior tonsillar pillar (**Figure 37.18**) and commonly spread to the tongue base and soft palate along the palatoglossal muscle and to the pterygomandibular raphe and RMT along the pharyngeal constrictors. Advanced lesions may spread through the pharyngeal wall to the parapharyngeal space (PPS) and along the pharyngeal wall to the nasopharynx superiorly and hypopharynx inferiorly. Once tumour has spread into the PPS it can extend freely to the skull base and into the carotid and masticator spaces.

Tongue base tumours

These tumours are often clinically silent and may spread along the palatoglossal muscle to involve the anterior tonsillar pillar and along the hyoglossal and mylohyoid muscles to the floor of mouth (**Figure 37.19**). Differentiation of

Figure 37.18 Axial contrast-enhanced CT showing large left tonsillar SCC (black arrow) with associated level 2 node (white arrow).

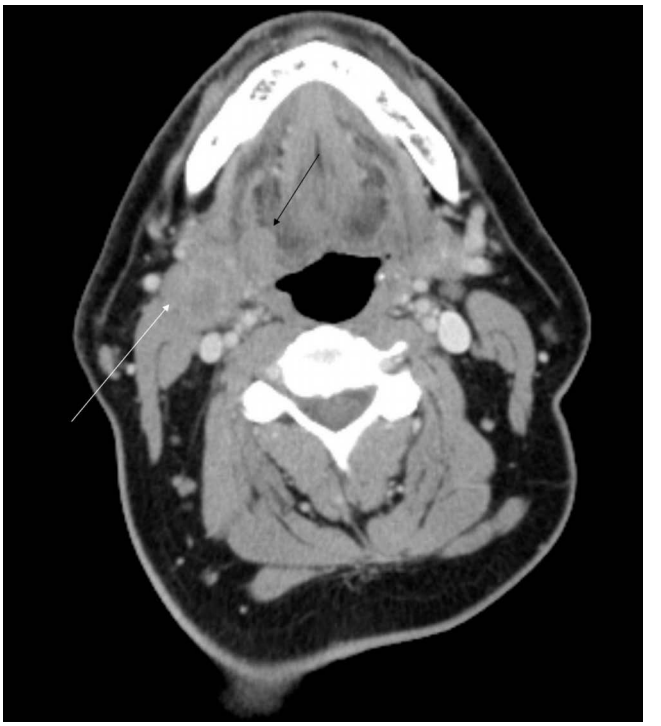

Figure 37.19 Axial contrast-enhanced CT showing right tongue base tumour (black arrow) with associated metastatic right level 2 node (white arrow).

tongue-base tumours from normal lingual lymphoid tissue may be difficult on all cross-sectional imaging.

Soft palate cancer

These tumours usually spread along the tonsillar pillars and in advanced disease on to the nasopharynx.

Posterior oropharyngeal wall cancer

These are rare tumours but more commonly the posterior oropharyngeal wall is invaded by cancers originating from the lateral oropharyngeal wall (**Figure 37.20**). Imaging plays a role in excluding invasion of the prevertebral muscles by demonstrating preservation of the retropharyngeal fat plane with a negative predictive value of 82–97.5% but predicting involvement of the prevertebral space is poor by cross-sectional imaging.[94, 95]

Oropharyngeal tumours spread by direct extension over mucosal surfaces, muscle and bone, along neurovascular bundles and via lymphatic drainage pathways. Imaging needs to evaluate these three routes of spread for accurate staging.[96, 97] Because nodal involvement is the single most important prognostic indicator, accurate assessment of all nodal chains is paramount. Extracapsular spread, detected on imaging by poorly defined nodal margins and surrounding soft-tissue stranding (**Figure 37.21**), is associated with a 3–5-fold increase in local recurrence. US has been shown to discriminate extranodal positive from extranodal negative SCC nodes with comparable accuracy and higher specificity than MRI.[98]

The advantages of staging oropharyngeal tumours with CT are that subtle cortical erosions can be detected

Figure 37.20 Axial contrast-enhanced CT showing large right oropharyngeal tumour involving the posterior oropharyngeal wall (black arrow) and closely apposed to the prevertebral muscles.

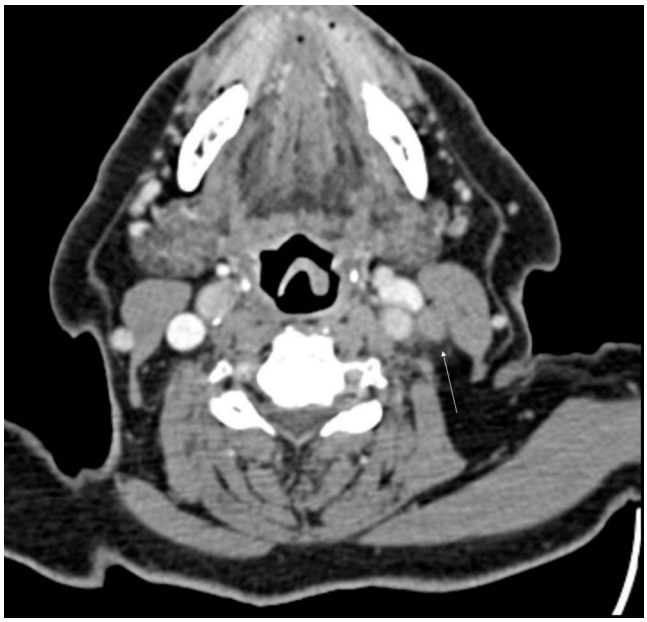

Figure 37.21 Axial contrast-enhanced CT showing a small ill-defined left level 2 node with streakiness to surrounding fat (arrow), histologically confirmed extracapsular spread.

and the chest can be included in the same sitting.[99] MRI is particularly useful in assessing perineural spread (**Figure 37.22**) and bone marrow involvement.[100] It is also an accurate method for measuring tumour invasion depth in the tongue base and this can have a predictive value for nodal metastases, with a cut-off depth of invasion of the tongue base by 14.5 mm for positive nodes.[69]

PET has a higher sensitivity than CT/MRI for detection of primary tumour and cervical metastases but no difference in specificity.[101] The use of a contrast-enhanced CT with conventional PET as a one-step examination has been shown to be a reliable initial staging examination.[71, 102] PET-CT has a higher sensitivity and diagnostic capability than 3T whole body MRI for the detection of distant metastases and second primary tumours.[103, 104] Similarly, PET has been shown to be more sensitive than extended field-multidetector CT for detecting distant metastases albeit with more false positive findings.[105] A pre-treatment PET-CT can be used as a staging tool to aid in treatment planning of SCC of the oropharynx with rates of retropharyngeal and nodal metastases consistent with those in the literature.[106]

Patients often present with a nodal mass and no obvious primary tumour on clinical inspection, the so-called unknown primary, the majority of tumours being in the tonsil and tongue base. PET-CT is particularly good at detecting the unknown primary but is complicated by the normal physiological uptake in these areas (**Figure 37.23**). There is considerable variation in pharyngeal palatine tonsil uptake in normal patients but generally only a small difference between left and right sides and an absolute difference between the maximum SUV between the two sides of 0.83 may be useful in detecting an occult tonsillar carcinoma.[107] Diffusion-weighted MRI is showing some

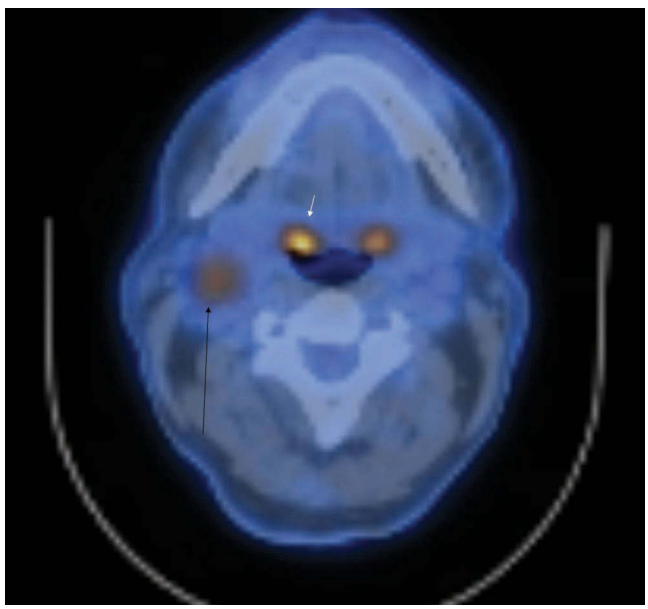

Figure 37.23 Axial-fused PET-CT showing increased activity in the right tongue base (white arrow) in a patient presenting with a right sided neck mass (black arrow) and no apparent primary on clinical examination or conventional CT. Note the normal physiological activity in the left tongue base.

promise in distinguishing between normal lymphoid tissue and SCC of the palatine tonsil.[108]

Oropharyngeal cancer is treated with curative intent by surgery, radiotherapy with or without chemotherapy or a combination of the two. The relationship between tumour volume and local outcome is less pronounced in oropharyngeal cancer compared to other head and neck tumours. However pre-treatment FDG-tumour uptake represents

an independent prognostic factor in patients with oropharyngeal SCC and patients with high FDG uptake may be better treated by surgery followed by radiotherapy with or without chemotherapy.[109] Perfusion CT provides a rapid, reliable and non-invasive technique for assessing tumour vascularity and may predict response to induction chemotherapy and mid-term remission-free survival in patients with advanced oropharyngeal SCC.[110] Treatment of the clinical N0 neck in T1 and T2 oropharyngeal cancer, as in oral cancer, remains a dilemma as CT, MRI and PET-CT all fail to detect the presence of lymph node micrometastases reliably.[86–90]

Response to definitive treatment with radiotherapy with or without chemotherapy is a powerful predictor of outcome.[111] In the post-therapy setting in patients with oropharyngeal cancer, imaging with PET-CT can have considerable influence on clinical decision-making as early detection of residual disease/recurrence enables salvage surgery to be carried out as soon as possible while neck dissection is only performed if there is evidence of residual nodal disease.[112, 113] Accurate assessment of response to treatment is therefore essential to optimize the chance of cure in those patients with residual disease and to minimize unnecessary surgery in patients who have been successfully treated. Several studies have shown that the use of PET-CT is superior to conventional imaging in response assessment as small residual nodes are common following treatment and radiation-induced changes are difficult to distinguish from residual disease using CT or MRI.[114, 115] The sensitivity of PET for detecting residual or recurrent cancer is high, in the range of 84–100%.[116, 117] The timing of PET-CT after treatment is critical to accurately differentiate residual disease from inflammatory changes secondary to treatment and thereby increase specificity. PET-CT performed between 12 and 16 weeks post-treatment has high diagnostic accuracy of response assessment.[118, 119] Should disease progression be suspected in the immediate post-treatment period, then contrast-enhanced CT or MRI and not PET-CT should be performed.[93] Diffusion-weighted MRI 2–3 weeks after completion of treatment has the potential to allow prediction of treatment response at the primary site.[13, 120, 121]

Regular surveillance is especially important in the first 2 years after treatment since the vast majority of disease recurrences are found during this period and PET combined with contrast-enhanced CT can be performed when there is a suspicion of recurrence.[118, 122, 123] However, there does not appear to be a role for blanket surveillance PET-CT at 12 and 24 months for detecting recurrence.[124]

HYPOPHARYNGEAL TUMOURS

Hypopharyngeal cancers are usually SCC and have the worst prognosis among head and neck cancers. They are insidious tumours, commonly presenting with a lump in the neck, secondary to metastatic nodal involvement, or dysphagia, otalgia, weight loss and hoarseness when the recurrent laryngeal nerve is involved. The trend of these tumours to spread in a submucosal fashion makes accurate delineation by cross-sectional imaging of paramount importance in planning treatment. The most important features determining prognosis are the size and local spread of the primary tumour and the extent of nodal involvement.[125]

The hypopharynx extends from the oropharynx to oesophageal verge and is divided into three regions, pyriform sinus or fossa, post-cricoid region and posterior hypopharyngeal wall, with distinct spread patterns of tumours in each region. Tumours arising from the lateral aspect of the pyriform sinus (PS) invade the posterior aspect of the thyroid cartilage and can extend into the paraglottic space and soft tissues of the lateral compartment of the neck (**Figure 37.24**). Tumours arising from the medial aspect of the PS show early laryngeal invasion. Posterior hypopharyngeal tumours (**Figure 37.25**) tend to grow in a cranio-caudal direction while tumours in the post-cricoid region (**Figure 37.26**) tend to invade the posterior aspect of the larynx.

The important points in staging are evaluating all the hypopharyngeal subsites, the larynx, thyroid cartilage, nodal status, distant metastases and any other synchronous primary, especially oesophageal carcinoma.[104, 126,] Imaging usually results in upstaging the tumour.[127, 128] Contrast-enhanced CT performed during quiet breathing is the preferred method of evaluating the hypopharynx due to its shorter acquisition time, facility for multiplanar reconstruction and ability to assess the chest and abdomen in one sitting. Three-dimensional CT laryngography with modified valsalva manoeuvre is informative for the diagnosis of PS apex involvement.[129] CT has also been shown to be a reliable method for assessing tumour volume with CT-based tumour volume being a predictor of outcome after treatment with both radiotherapy and surgery.[130–132]

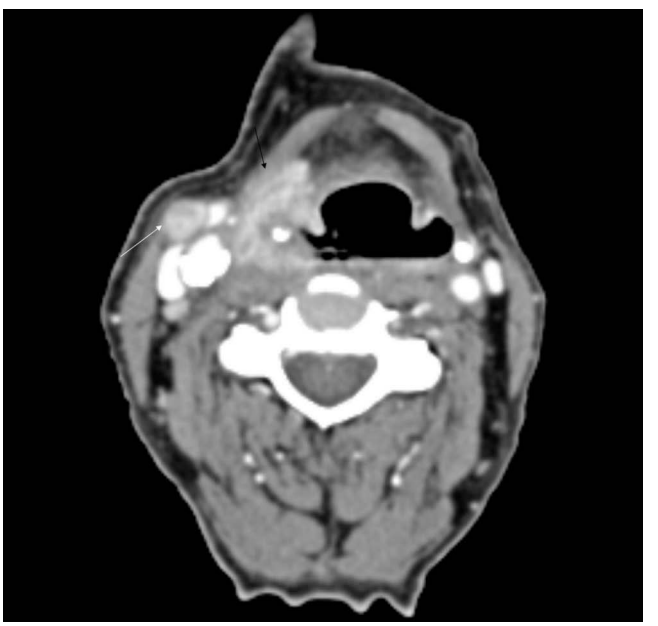

Figure 37.24 Axial contrast-enhanced CT showing right pyriform fossa tumour just extending into the paraglottic space and extralaryngeal soft tissues (black arrow) with associated metastatic level 3 node (white arrow).

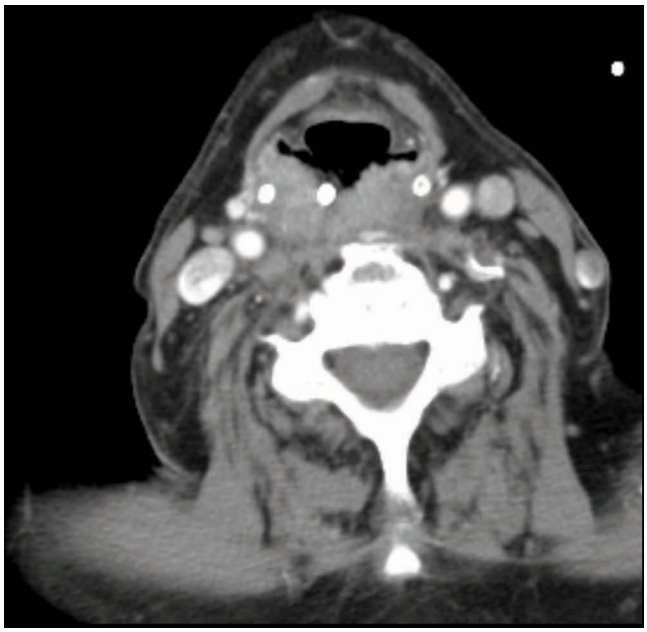

Figure 37.25 Axial contrast-enhanced CT showing a large hypopharyngeal posterior wall tumour extending on to the prevertebral muscles.

Figure 37.26 Axial contrast-enhanced CT showing a post-cricoid carcinoma (black arrow) extending on to the prevertebral muscles.

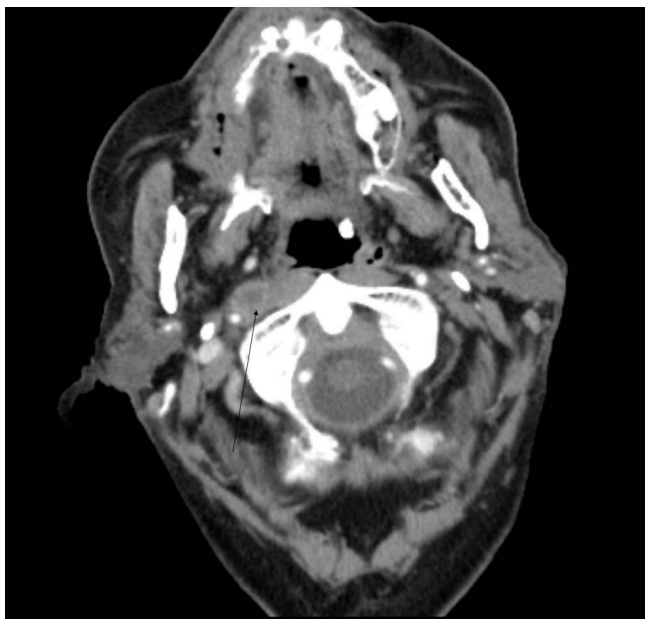

Figure 37.27 Axial contrast-enhanced CT showing a necrotic right retropharyngeal node (black arrow) in a patient with a hypopharyngeal posterior wall tumour.

Correct assessment of nodal status is essential as hypopharyngeal cancer has a high risk for early regional lymph node dissemination and metastatic nodal disease still remains the single most important negative predictor. CT perfusion has been suggested as a way of distinguishing malignant from non-malignant nodes.[133] Deng et al. noted a regional lymph node metastatic rate of 73.9% on CT/MRI images in 88 patients with hypopharyngeal cancer, the highest rates being at level 2 and 3, with bilateral disease a potential risk factor for retropharyngeal node metastases.[134] Tumours originating from the posterior wall of the hypopharynx not only show a significantly higher incidence of retropharyngeal nodal metastases (**Figure 37.27**) as demonstrated by CT and/or MRI than other subsites but have a high incidence of distant metastases resulting in dismal outcomes.[135] FDG-PET has been shown to be helpful in detecting retropharyngeal nodal metastases in hypopharyngeal cancer, which should be suspected in patients with tumours originating from the posterior pharyngeal wall and those with ipsilateral level 5 lymph node metastases.[136]

PET-CT in hypopharyngeal cancer, just as in oropharyngeal cancer, has a higher sensitivity than 3T-MRI or CT for the detection of distant metastases and second primary tumours.[103–105] PET-CT has a high sensitivity for detection of residual and recurrent tumour following surgery and radiotherapy.[125]

LARYNGEAL TUMOURS

Laryngeal carcinoma is the commonest head and neck malignancy, comprising 30–40% of all cases, the vast majority being SCC. Most laryngeal tumours present with hoarseness and less commonly with a neck mass, dysphagia, stridor or haemoptysis. Around 80% of tumours are glottic, arising from the vocal cords, 15% are supraglottic, arising from epiglottis, false cords or aryepiglottic fold (**Figure 37.28**) and 5% subglottic. Some tumours are transglottic involving all laryngeal levels (**Figure 37.29**). Although most laryngeal tumours are mucosal lesions and easily seen endoscopically, cross-sectional imaging frequently demonstrates the limitations of clinical and endoscopic examination in evaluating submucosal disease and cartilage invasion.

Imaging is important to identify the site and size of primary tumour, involvement of laryngeal cartilage and surrounding extralaryngeal structures, state of airway and nodal status.[127, 137–140] Multidetector CT is the preferred modality for evaluating laryngeal carcinoma given its widespread availability and ease of acquisition with

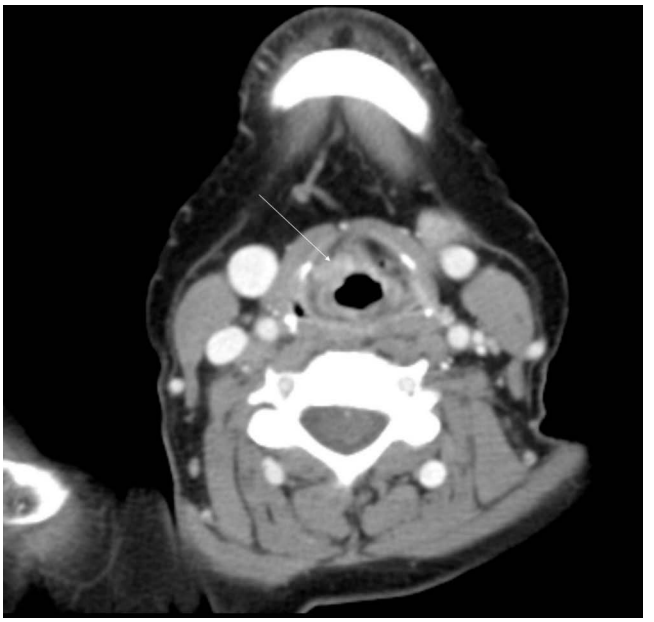

Figure 37.28 Axial contrast-enhanced CT showing a supraglottic tumour (white arrow) involving the epiglottis and right paraglottic space.

Figure 37.29 Axial contrast-enhanced CT showing a large left transglottic tumour (long black arrow) with completely destroyed left arytenoid (white arrow) and sclerotic left cricoid cartilage (short black arrow).

excellent multiplanar reformation while ultrasound, MRI and PET-CT are used as problem-solving tools. Functional imaging of the larynx on multidetector CT in the form of inspiration, phonation and valsalva and virtual laryngoscopy have a questionable role in staging.[141–143] The pretreatment staging accuracy of laryngeal carcinoma by CT has been reported to be between 84.9% and 88.8% on recent studies with problems in distinguishing tumour from peritumoral inflammation, identifying small tumours and predicting cartilage invasion.[142, 144–148] Incomplete ossification of the thyroid cartilage and asymmetric mineralization of the arytenoids make cartilage assessment difficult but the presence of tumour on both sides of the cartilage is said to be a useful imaging finding in predicting cartilage involvement.[149, 150] No statistical difference was seen in a study of 34 patients with laryngeal cancer between MRI and post-surgical pathohistology in tumour extension to the anterior commissure, pre-epiglottic space and subglottis as well as cartilage infiltration but paralaryngeal infiltration was overdiagnosed by MRI resulting in a correct T classification in 76% of those cases.[151] MRI overpredicts thyroid cartilage involvement although there is some evidence that contrast-enhanced MRI may differentiate inflammatory from neoplastic change and demonstrating a normal cartilage signal on MRI is reassuring.[152, 153] MRI is therefore more sensitive but less specific than CT in detecting neoplastic cartilage invasion.

In view of the sensitivity and specificity issues with CT and MRI, US (**Figure 37.30**) is being increasingly used as

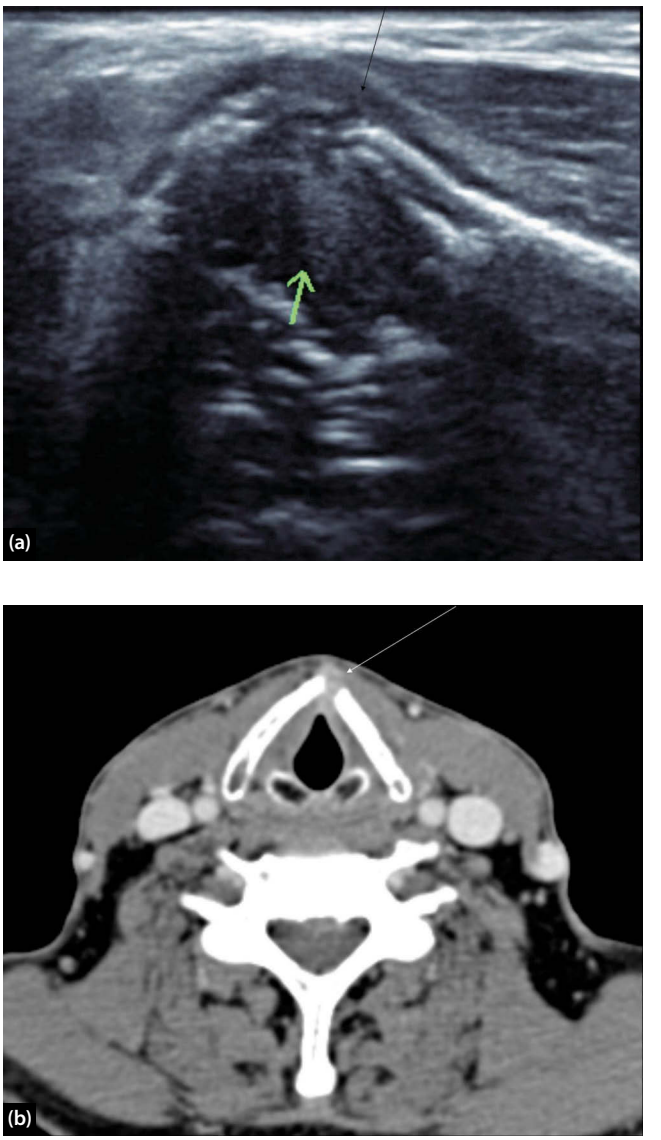

Figure 37.30 US of the larynx (a) showing a sizeable low reflectivity laryngeal tumour (thick arrow) extending through a defect in the thyroid cartilage (black arrow) with the corresponding contrast-enhanced axial CT **(b)** confirming extralaryngeal spread of tumour (white arrow).

a complementary technique in the evaluation of laryngeal cancer, which usually appears hypoechoic on ultrasound.[153] Hu et al. demonstrated an accuracy of 83.3% for US compared to 88.8% for CT and an accuracy of 80% for US compared to 76.5% for unenhanced MRI in the T-staging of glottic cancer, with US only being inferior in demonstrating tumour involvement in the retrolaryngeal structures.[145, 154, 155]

The performance of PET-CT not surprisingly is better than stand-alone PET or CT in patients with cancer of the larynx and can have a major impact on management.[156] However, as in the case of other head and neck tumours, it has no role in predicting the need for surgical neck dissection in the N0 neck.[157, 158]

The treatment of laryngeal cancer consists of surgery including laser resection, total or partial removal of the larynx and radiation therapy, either as a cure or as an adjunct after radiotherapy. Conservative laryngeal surgery preserves a portion of the larynx so that a voice can be produced while obtaining the same local control as that provided by total laryngectomy. Appreciating the normal imaging findings following both partial and total laryngectomy is important in the interpretation of cross-sectional imaging.[159–161] Hemithyroidectomy used to be performed as part of total laryngectomy but this practice is now being questioned and pre-operative evaluation of any thyroid gland involvement is essential in deciding whether to preserve the thyroid gland. [162] Laryngeal oedema following radiotherapy is common, particularly affecting the supraglottis, and may mask recurrence.[163]

Imaging for recurrence following treatment to laryngeal cancer includes CT, MRI and PET-CT.[164] PET-CT is useful in detecting local residual tumour after treatment and has been suggested as a cost-effective means of selecting patients for direct laryngoscopy in suspected recurrence following radiotherapy.[165–167] PET-CT however has too high a false negative rate to warrant deferring neck dissection in the N0 neck in suspected recurrence following treatment.[168]

Lymphoma is a rare tumour of the larynx that classically presents as a large uniformly enhancing submucosal mass showing no necrosis centred in the supraglottis that extends into the glottis. Cervical adenopathy is not usually present and as in SCC, lymphoma may extend into the subglottis, pharynx and laryngeal cartilages.[169, 170] Sarcomas make up about 0.3–1% of all laryngeal malignancies of which chondrosarcomas show specific imaging findings with an expansile defect in either the thyroid or cricoid cartilages (**Figure 37.31**).

Figure 37.31 Axial contrast-enhanced CT showing low grade chondrosarcoma (black arrow) centred around an expanded and remodelled right cricoid cartilage.

NECK LUMPS

The imaging of patients presenting with a neck lump depends on the age of the patient, clinical history and location of the mass.

The majority of neck lumps in children are simply due to reactive lymph nodes secondary to an upper respiratory tract infection, earache or toothache and if small, soft and mobile and associated with an upper respiratory tract infection will usually regress within 3 weeks. In such cases, no imaging is required and the parents are simply reassured and asked to return if the child becomes systemically unwell or if the swelling increases in size. Children with fever, hepatosplenomegaly, weight loss or night sweats and nodes greater than 3 cm should have a chest X-ray, screening blood tests including a full blood count and serology especially for Epstein–Barr virus, and the neck imaged initially by ultrasound.[171] As a general rule, US will differentiate reactive lymphoid hyperplasia from lymphoma and identify abscess formation within nodes[172] and excision biopsy is necessary in only a very small proportion of cases.

Adult lymphadenopathy is more unusual than in children and any adult presenting with a suspicious neck lump should be imaged by US initially and if this appears suspicious or the entire deep extent cannot be ascertained, then CT or MRI are necessary.[173]

In the non-lymphadenomatous neck swellings, can US differentiate between a cystic or solid mass with CT and MRI serving as supplementary examinations in defining the exact anatomy prior to any surgery. The vast majority of cystic masses in children are congenital or developmental in origin and in adults inflammatory or malignant.

Thyroglossal duct cyst (TDC)

This is the most common congenital cystic mass and the second most common benign mass after benign lymphadenopathy. The thyroid primordia migrate down the neck along the thyroglossal duct which runs from the foramen caecum in the base of the tongue to the lower anterior neck and normally involutes in the 8th–10th week of gestation. If any portion of the duct persists, secretions from the epithelial lining may give rise to cysts and as the duct is intimately related to the hyoid bone, most occur either below (65%) or at the level of hyoid bone (15%). Seventy-five per cent of cases occur in the midline and the rest up to 2 cm off the midline.

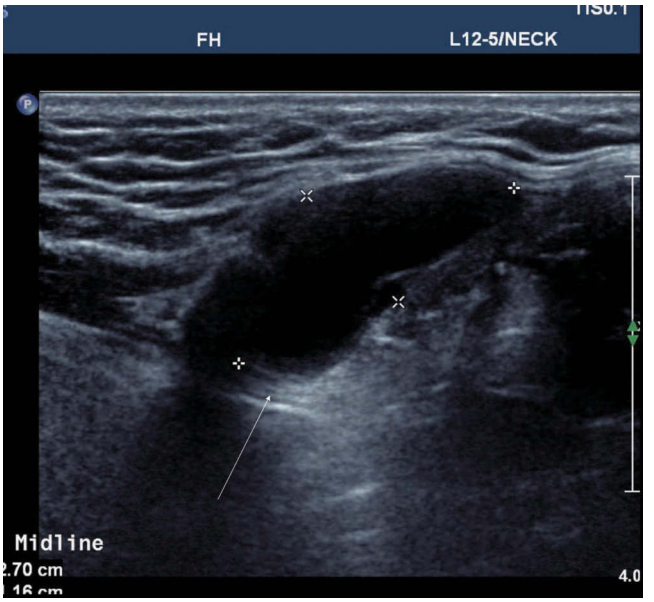

Figure 37.32 US showing a midline infrahyoid homogenous anechoic cystic mass with posterior wall enhancement (black arrow) in keeping with a thyroglossal duct cyst.

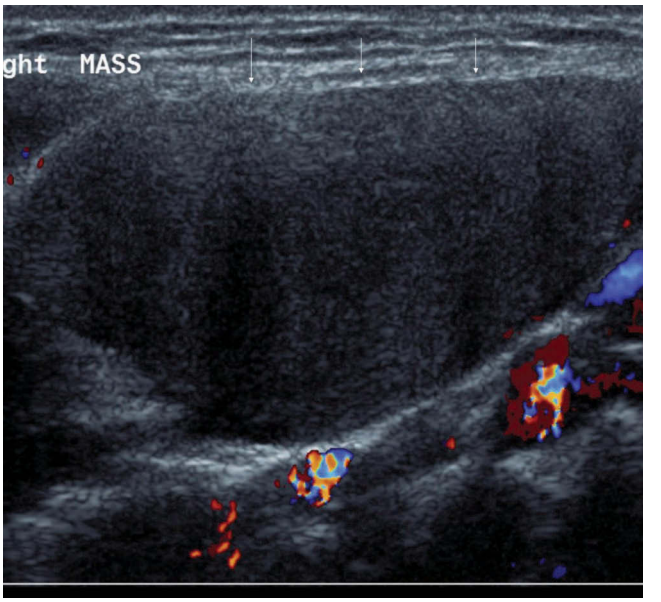

Figure 37.33 US showing an avascular, pseudosolid right level 2 mass in keeping with a second branchial cleft cyst.

On US TDCs (**Figure 37.32**) have a varied appearance ranging from a homogenous anechoic mass with posterior wall enhancement, a pseudosolid mass due to proteinaceous secretions or a mass with a heterogenous echo pattern due to previous haemorrhage or infection. A variable appearance is also seen on CT or MRI depending on the cyst contents but on MRI the cysts are invariably of high T2 signal and variable T1 signal depending on the amount of proteinaceous secretions.

The important imaging points are the relationship of the TDC to the hyoid bone, the presence or absence of normal thyroid tissue and whether any solid material is present within the cyst as there is a 1% incidence of carcinoma, classically papillary thyroid cancer (PTC) within TDC.

Second branchial cleft cyst (BCC)

Second BCCs account for 95% of all branchial cysts, typically occur between 10 and 40 years and classically present as a mass at the angle of the mandible superficial to the carotid sheath, posterior to the submandibular gland and along the anteromedial border of sternomastoid.

The sonographic appearances of second BCCs (**Figure 37.33**) is variable ranging from a classic anechoic simple cyst with posterior wall enhancement to a pseudosolid or heterogenous mass with internal debris and septae.[174] If on US a beak is identified pointing medially, then CT or MRI is warranted to exclude a sinus or fistula. On CT, classic second BCCs appear as homogenous low-attenuation masses with a thin wall and on MRI as masses of high T2 and low T1. On all imaging modalities, BCCs complicated by previous infection or haemorrhage appear as ill-defined, heterogenous, thick-walled masses containing debris and septae (**Figure 37.34**). Such a mass can cause confusion as a completely necrotic node from a head and neck SCC or a PTC may mimic BCC. If the patient is over 40, a smoker and drinks excessive alcohol, then such a mass has to be considered to be a metastatic SCC till proven otherwise and if a primary tumour is not identified clinically or by CT/MRI, then consideration should be given for PET-CT. In a younger patient, the mass is likely to represent a BCC or PTC and it is essential to look for other cystic masses especially around the thyroid gland as the primary tumour is often very small and not necessarily picked up by imaging.[175]

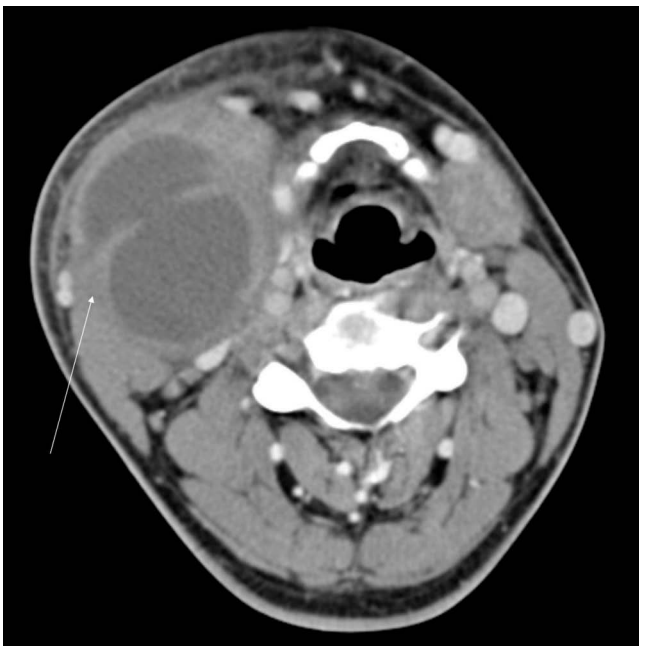

Figure 37.34 Axial contrast-enhanced CT showing a septated thick-walled right level 2 mass (white arrow) displacing the submandibular gland anteriorly and deep to sternomastoid in keeping with an infected second branchial cleft cyst.

Epidermoid/dermoid cyst

The difference between these two entities is histological, the more common dermoid cyst containing skin appendages such as sebaceous glands and hair follicles while an epidermoid cyst is entirely ectodermal. Epidermoids tend to present in infancy with dermoid cysts presenting later and both frequently occur in the submental or suprasternal regions in or close to the midline. These masses are usually well defined on imaging and may have a varied appearance on US (**Figure 37.35a**) varying from an anechoic mass with posterior wall enhancement to a pseudosolid appearance. Fatty content is pathognomic for a dermoid but in its absence, differentiation by imaging is not possible.[176] On CT the central cavity is usually filled with homogenous low-attenuation material (**Figure 37.35b**) but may appear to contain 'marbles' due to fat coalescing into small nodules within the fluid.

Ranula

This is a retention cyst resulting from obstruction of the duct to the sublingual gland and may be simple when confined to the floor of mouth or plunging when extending into the submandibular space. On US a simple ranula appears as a unilocular, well-defined cystic mass in the submental region related to the sublingual gland. It may contain fine internal echoes usually due to the presence of debris from previous episodes of inflammation.[177] On CT a simple ranula will appear as a solitary, low-attenuation, non-enhancing thin-walled mass and on MRI a mass of low T1 and high T2 signal. A plunging or diving ranula (**Figure 37.36**) forms from a ruptured ranula that extends either dorsally or caudally through defects in the mylohyoid muscle, the so-called boutonniere anomaly, into the submandibular space. As these plunging ranulas are effectively pseudocysts, there is usually some associated granulation tissue and may show enhancement on CT or MRI.

Salivary and thyroid gland masses

These will be discussed elsewhere in this section.

Lipoma

The head and neck is a typical site for lipomata which characteristically present as striped or feathery masses on ultrasound, masses of similar low attenuation as the surrounding fat on CT (**Figure 37.37**), and as masses of high T1 and T2 signal and low on fat suppression sequences on MRI.

Nerve sheath tumours

Nerve sheath tumours such as neurofibromas and schwannomas (**Figure 37.38**) may mimic lymph nodes on US as they can appear as diffusely hypoechoic masses with marked vascularity. They can also undergo cystic degeneration and then mimic cystic metastatic nodes.

Vascular malformations

Low-flow vascular malformations are common in the head and neck and comprise venous and lymphatic malformations or a combination of the two.

Venous malformations especially haemangiomas (**Figure 37.39**) are commonly found in the masticator space especially within the masseter muscle and phleboliths are seen in 22% of cases. The aim of imaging is to identify the extent of the lesion and the exact anatomical location.[178, 179] US usually suggests the diagnosis and further cross-sectional imaging is needed to ascertain its extent.

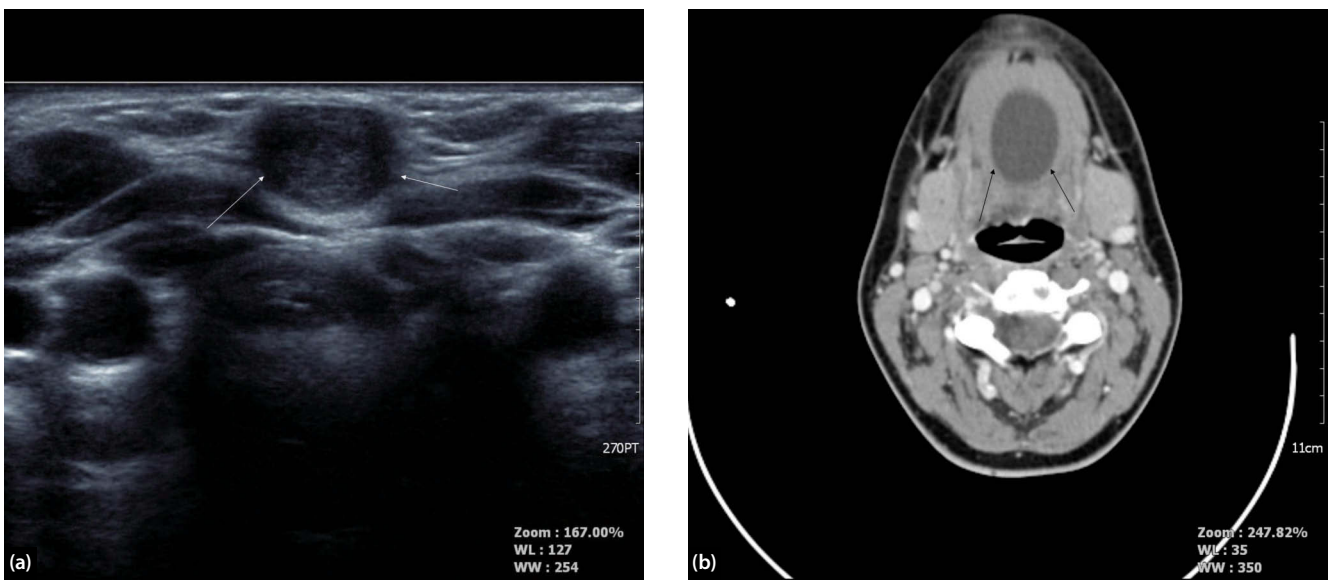

Figure 37.35 US **(a)** showing a midline, infrahyoid mass containing internal echoes (white arrows) in a child, a histologically confirmed dermoid and contrast-enhanced axial CT **(b)** showing a midline cystic floor of mouth dermoid (black arrows) in an adult.

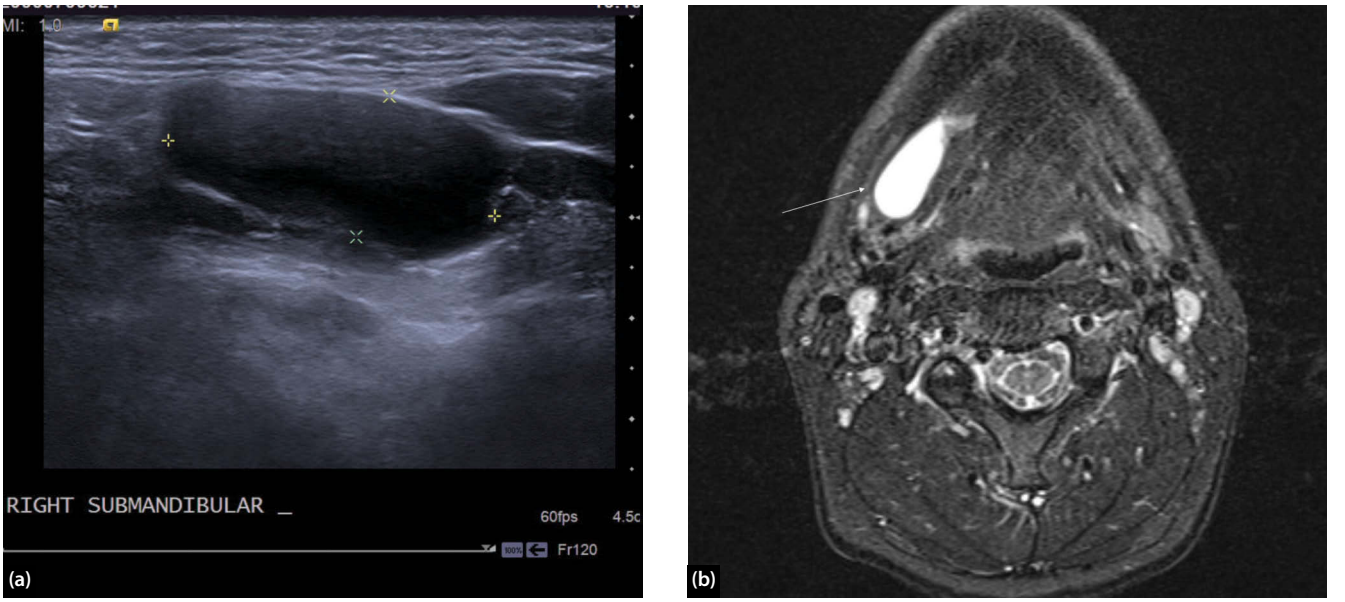

Figure 37.36 US **(a)** and axial STIR (short tau inversion recovery) MRI **(b)** of a cystic plunging ranula (white arrow) extending into the right submandibular space.

Figure 37.37 Contrast-enhanced axial CT showing a large lipoma deep to left sternomastoid (white arrow) and compressing the jugular vein. Note the small intramuscular component of the lipoma (black arrow) extending into levator scapulae.

US appearances are characteristic with the lesion showing a low reflectivity heterogenous echo pattern with multiple sinusoidal spaces. On MRI (**Figure 37.40**) venous vascular malformations show a striking high signal on T2-weighted sequences, including short tau inversion recovery (STIR). MRI is not as sensitive as CT or US in detecting phleboliths but shows the entire extent of the malformations very eloquently.

Lymphatic malformations or lymphangiomas are congenital abnormalities that arise when developing lymphatics fail to establish communication with developing veins.[180] The most common lymphangioma, also called cystic hygroma, typically presents in childhood as a

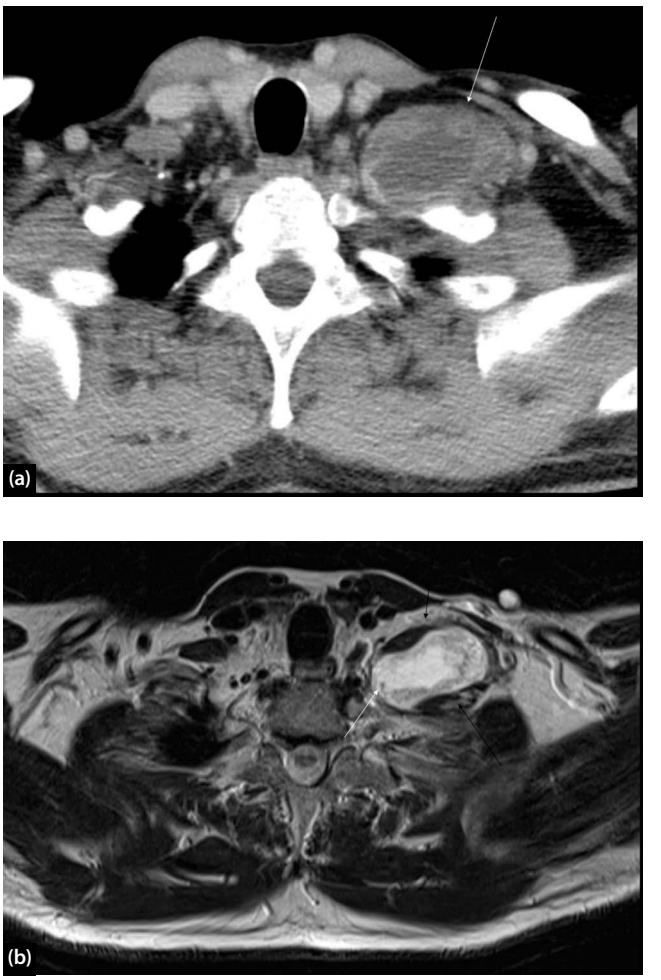

Figure 37.38 Contrast-enhanced axial CT (a) and T2 weighted axial MRI **(b)** showing left interscalene groove schwannoma (white arrows) arising from one of the branches of the brachial plexus.

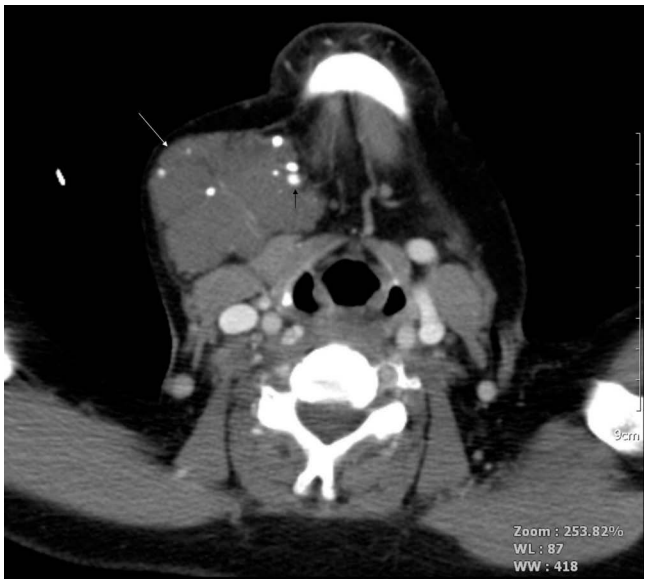

Figure 37.39 Contrast-enhanced axial CT showing a non-enhancing haemangioma (white arrow) containing several foci of calcification (black arrow) in the right submandibular space.

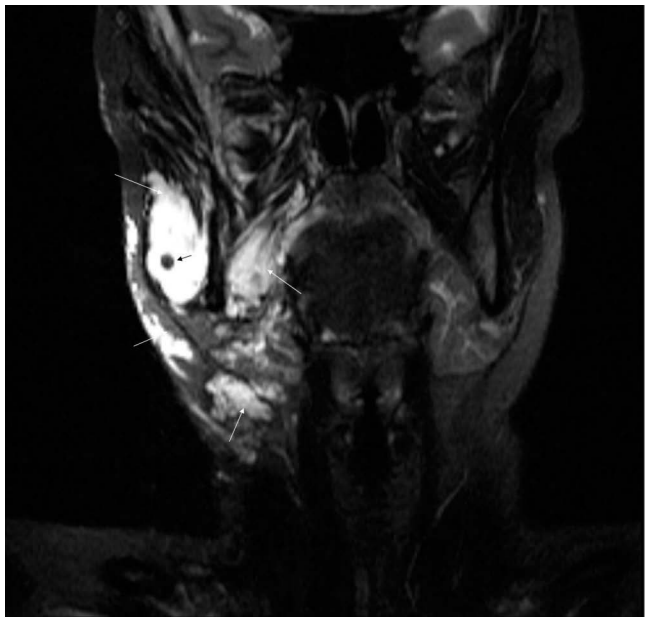

Figure 37.40 Coronal STIR (short tau inversion recovery) MRI showing a multifocal low-flow vascular malformation in the right side of neck involving the skin and several different spaces (white arrows) with a small plebolith (black arrow) within the masseteric component.

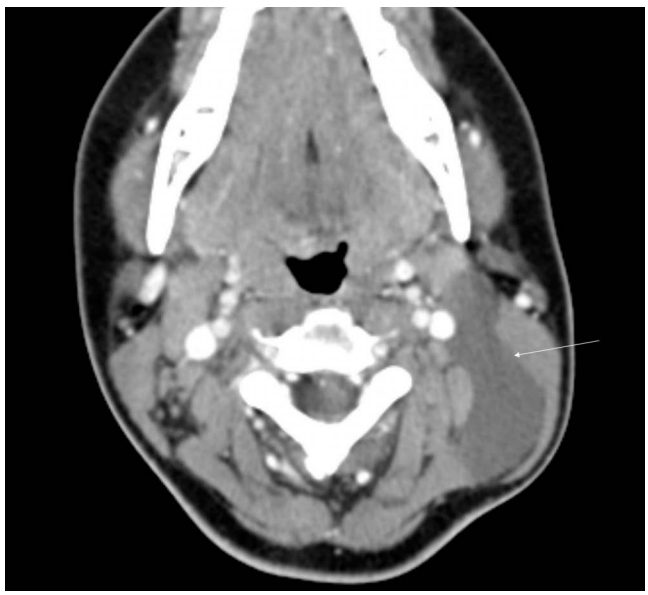

Figure 37.41 Axial contrast-enhanced CT showing a lymphangioma (arrow) within the left lateral compartment of neck deep to sternomastoid and abutting the internal carotid artery.

posterior triangle mass. Imaging usually reveals a multiloculated mass with septa of variable thickness that invaginates between vessels and other normal structures to occupy multiple contiguous spaces (**Figure 37.41**).

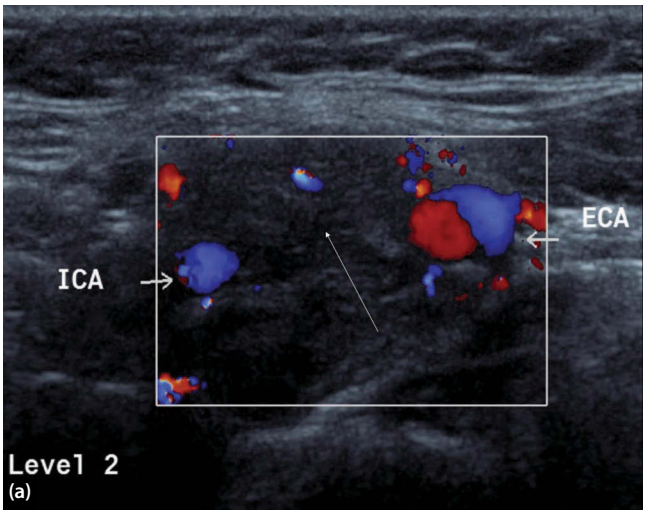
Paragangliomas

Paragangliomas are benign vascular tumours derived from primitive neural crest and occur anywhere along the carotid sheath as far as the skull base, the most common being the carotid body tumour (CBT).[181] CBT occurs at the bifurcation of the common carotid artery with resultant characteristic splaying of the internal and external carotid arteries (**Figure 37.42**). As the tumour increases in size, it may encase the carotid vessels but does not narrow their calibre.[182] Because of its site a CBT can be mistaken for an abnormal lymph node in the upper cervical chain. Other common paragangliomas are the glomus jugulare and glomus vagale arising from the jugular vein and vagus nerve respectively. The glomus vagale characteristically displaces the internal carotid artery anteriorly or medially and the jugular vein posteriorly. Paragangliomas may be familial and in such cases may be multiple and may very rarely show malignant transformation. On US paragangliomas do not appear particularly vascular despite showing avid enhancement on contrast-enhanced CT and MRI. They may show a characteristic 'salt and pepper' appearance on MRI (**Figure 37.43**) with the 'pepper' or low-signal appearance representing flow voids of feeding vessels.

Tuberculosis

Tuberculosis is commonly seen in the cervical lymph nodes but may occasionally be seen in the larynx or pharynx. The posterior triangle and supraclavicular nodes are frequently affected. In the early stage nodes may simply be enlarged and show homogenous enhancement on CT or MRI but later the nodes adopt the classical matted appearance with central necrosis (**Figure 37.44**).[183]

Atypical mycobacterial cervical adenitis is a cause of a unilateral persistent neck lump in a child under 5-years of age, often associated with an overlying violaceous skin appearance. US (**Figure 37.45**) reveals a marked decrease of echogenicity in the early stages and intranodal liquefaction with sinus tracts in the advanced stages.



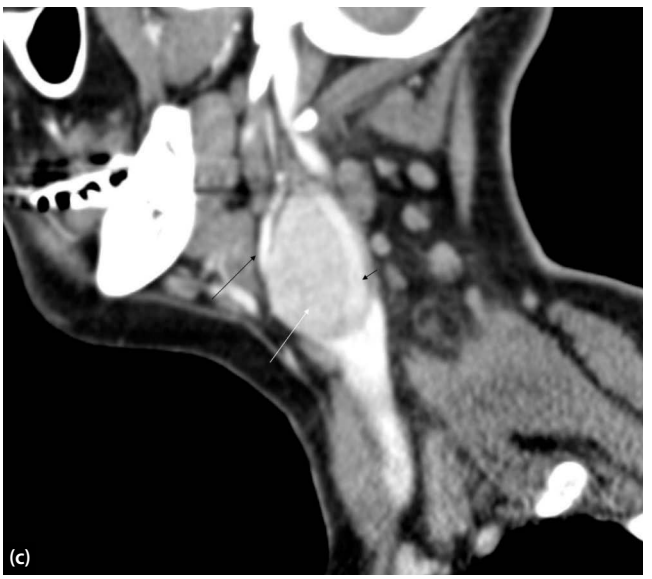


Figure 37.42 US **(a)**, axial **(b)** and sagittal reformatted **(c)** contrast-enhanced CT showing a level 2 mass (white arrows) lying between splayed internal (ICA, short black arrows) and external carotid arteries (ECA, long black arrows) consistent with a carotid body tumour. Note the carotid body tumour is avidly enhancing on contrast-enhanced CT but relatively avascular on US.

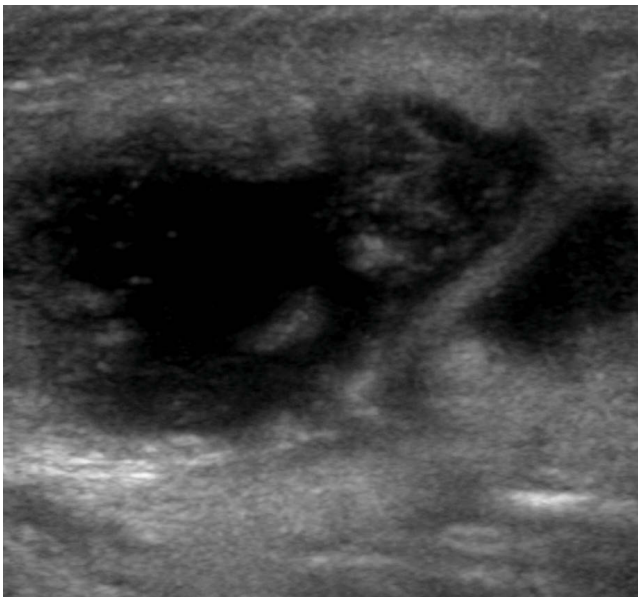

Figure 37.45 US of a child showing an irregular septated mass overlying which clinically was skin violaceous discoloration consistent with mycobacterial cervical adenitis.

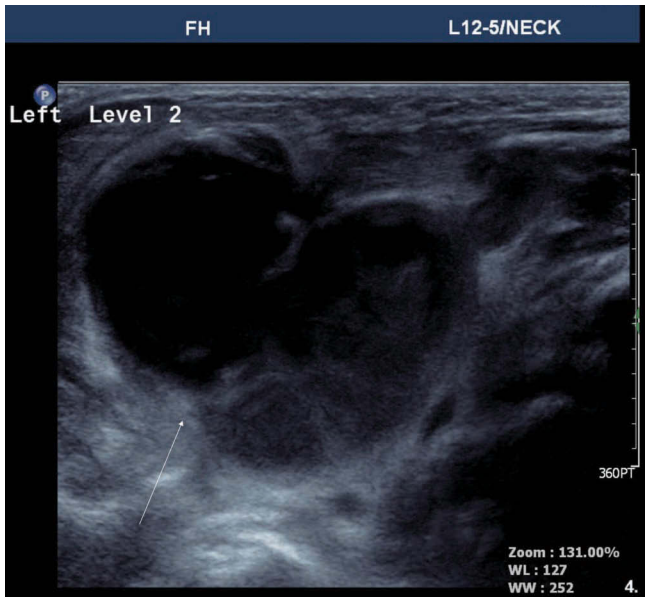

Figure 37.46 US in a child, presenting with neck swelling and fever, showing a suppurative node (white arrow).

THE HOT NECK

Patients presenting with fever, pain, swelling, odynophagia, sore throat or trismus have to be considered to have neck sepsis and require imaging to assess whether surgical intervention is required (**Table 37.1**). The commonest sources are tonsillar or odontogenic infection. US should be the first-line investigation in children (**Figure 37.46**) and any superficial infection but contrast-enhanced CT of the neck and mediastinum is the imaging modality of choice to assess the extent of infection and any complications such as airway compromise, vascular thrombosis, neural dysfunction and ultimately necrotizing mediastinitis.[184–187] These complications may be life-threatening and surgery remains the mainstay of treatment but conservative medical treatment is effective in selected cases.[188] The patient's condition usually precludes the use of MRI but is extremely useful if a discitis and prevertebral abscess are suspected.

US is a very reliable diagnostic tool in the diagnosis of pus collections in the neck with a sensitivity of 96% and specificity of 82% and can show small collections to resolve without surgical drainage.[189] However should a parapharyngeal or peritonsillar abscess be suspected clinically, then CT rather than US should be performed.[190, 191] Meyer et al.[192] argue that as duration of localized symptoms of deep neck infection in children does not predict findings of abscess on CT, it is appropriate to obtain a CT scan upon presentation in all children with concerning symptoms for neck abscess. The findings on CT may include inflammatory stranding and loss of fat planes in cases of cellulitis, enhancing inflammatory phlegmon and abscess formation, characterized by a focal low-attenuation area with a surrounding enhancing rim (**Figure 37.47**). However, occasionally fluid collections without wall enhancement have yielded pus on surgical exploration.[193]

TABLE 37.1 Imaging in the Hot Neck, what the surgeon needs to know

Is there an abscess or just inflammatory change?
If an abscess is present, in which space/spaces?
How large is the abscess?
Extent of abscess
Is the mediastinum involved?
Is the airway compromised?
Is there jugular vein thrombosis?

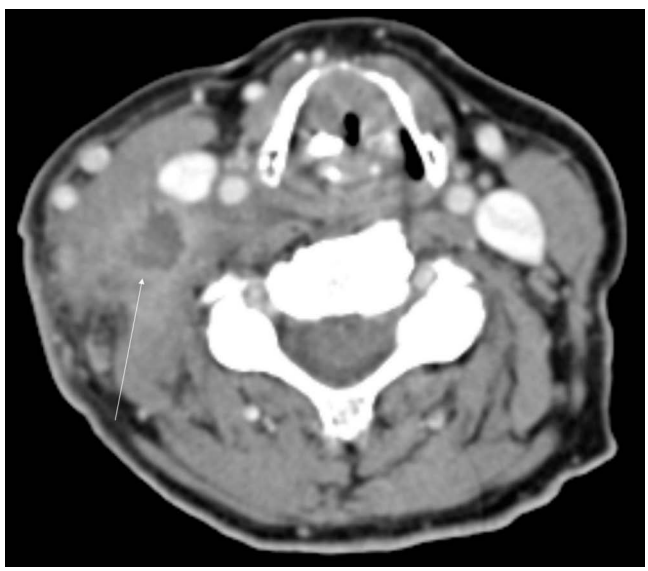

Figure 37.47 Axial contrast-enhanced CT showing a low-attenuation area with surrounding enhancing rim (white arrow) and surrounding inflammatory change consistent with an abscess in the lower neck.

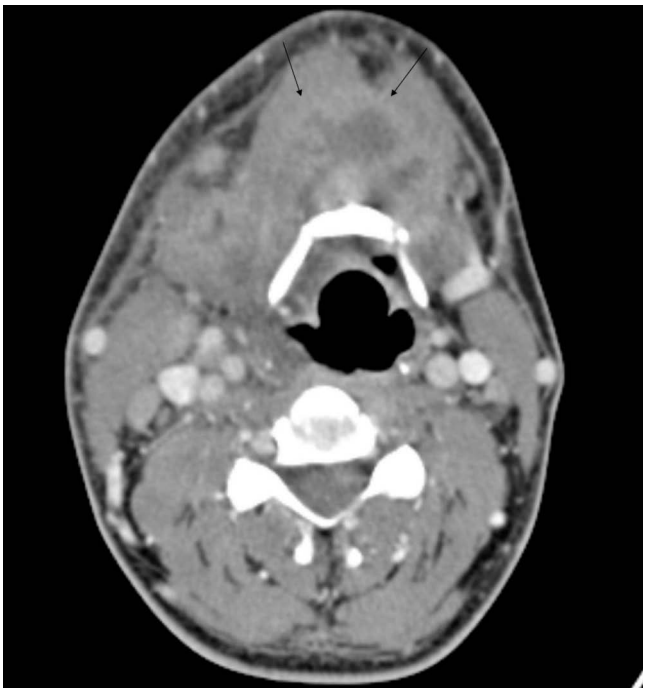

Figure 37.48 Axial contrast-enhanced CT showing an ill-defined phlegmon/abscess (black arrows) in the floor of mouth with an odontogenic source identified in the mandible.

Figure 37.49 Axial contrast-enhanced CT in a child showing an abscess within a retropharyngeal node (black arrow).

Contrast-enhanced CT has a positive predictive value of 79.6–82% for diagnosing deep neck abscesses, increasing to 91.3% when more than one deep neck space is involved but decreasing to 50% in patients with isolated retropharyngeal abscess.[194, 195]

Infections in the sublingual, submandibular and masticator spaces are often odontogenic in origin and these patients should also have an orthopantomogram (OPG) to assess the dentition.[196] Infection originating in the incisors to premolars mandibular teeth usually spread to the sublingual space while infection of the molars spread to the submandibular space (**Figure 37.48**).

Retropharyngeal space infection occurs mainly in children due to suppuration of a retropharyngeal node (**Figure 37.49**) and is usually due to naso- or oropharyngeal infection. Infection from here may track into the posterior mediastinum above the level of the carina.

Tonsillitis is the commonest infection to occur in the pharyngeal mucosal space and usually responds to antibiotics but occasionally patients may develop tonsillar or peritonsillar (quinsy) abscesses that then involve the parapharyngeal and retropharyngeal spaces (**Figure 37.50**).

Cervical lymphadenitis is common in children and refers to inflamed, enlarged and tender cervical lymph nodes, usually due to an upper respiratory tract illness.

It is important to realize that head and neck cancers can present as infection in patients over 40 years with one study quoting a prevalence of 4.9%.[197, 198] In such patients any neck mass that fails to resolve after a course of antibiotics should be further investigated by FNA, endoscopy and cross-sectional imaging.

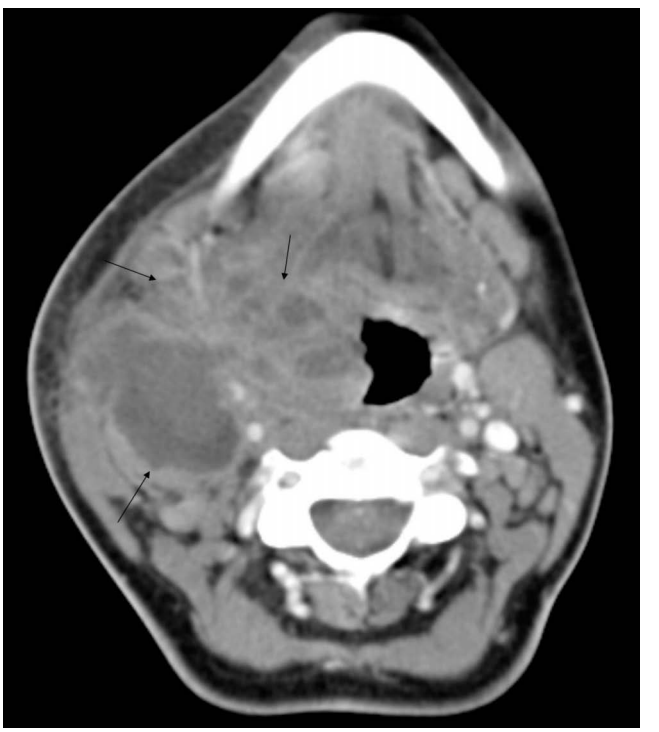

Figure 37.50 Axial contrast-enhanced CT showing a multiseptated abscess (black arrows) occupying multiple spaces arising from untreated tonsillitis.

KEY POINTS

- Imaging of the neck is integral to diagnosis, treatment and follow-up of neck lumps.
- The choice of imaging modalities depends on the clinical scenario and the working diagnosis.
- Dedicated head and neck radiologists can provide invaluable help in diagnosis, especially in complex cases.
- Cross-sectional imaging is mandatory in almost all cases of head and neck cancer.
- Based on the clinical picture, complementary information can be obtained from a combination of imaging modalities.
- All imaging is best done before any surgical intervention to avoid artifacts caused by the surgery.

SEARCH STRATEGY

Data in this chapter may be supported by a Medline search using the following keywords: trauma, cervical, trachea, esophagus, and vascular.

INTRODUCTION

The issue dominating discussion on the management of penetrating neck trauma for the past few decades is whether penetrating neck injuries require mandatory exploration. There has been a distinctive paradigm shift from mandatory exploration towards more selective, conservative management based on clinical evaluation and specialized investigations. Introduction of diagnostic tools such as flexible endoscopy, oesophagography, high-resolution computed tomography (CT), and duplex doppler have improved non-operative evaluation of aerodigestive and vascular injuries. The realization that certain injuries may be treated non-operatively and the management of selected arterial injuries by endovascular techniques have further promoted the concept of selective exploration of the neck.

THE TRAUMA PATIENT: GENERAL PRINCIPLES

Primary survey (survival assessment)

Resuscitation should be performed in accordance with the Advanced Trauma Life Support (ATLS®) principles.[1] The Primary Survey is an initial assessment of factors that cause early deaths in trauma patients. It focuses on factors such as hypoxia, hypovolaemia, tension pneumothorax and head injury.

AIRWAY AND CERVICAL SPINE PROTECTION

The patient is examined for evidence of airway obstruction; this may present as stridor and use of accessory muscles of respiration. The neck should be stabilized with a cervical collar or sandbags until cervical spine injury is excluded. Major facial fractures, in particular mandibular fractures, and large cervical haematomas may compromise the airway. Patients with transcervical gunshot wounds (GSWs) may not have airway problems initially, but must be closely observed as they can rapidly develop airway obstruction. A chin lift and jaw thrust procedure should be done to try to overcome the obstruction. Patients with Glasgow coma scores (GCS) of ≤8 usually require intubation to protect the airway. An endotracheal tube may sometimes be inserted directly into the trachea through a penetrating cervical injury. Cricothyroidotomy must be considered if intubation fails. It should subsequently be converted to a formal tracheostomy within 24 hours, as the small tube is difficult to keep clean, and to prevent subglottic stenosis.

BREATHING

The chest should be examined for chest wall movement and air entry. Tension pneumothorax and haemothorax

are life-threatening conditions; immediate intervention based on clinical diagnosis is mandated before X-rays are obtained. Tension pneumothorax presents with hypoxia, restlessness, hyper-resonance to percussion, decreased air entry, contralateral tracheal shift, and elevated jugular venous pressure. It is decompressed by needle thoracocentesis; a large bore needle is initially inserted through the 2nd intercostal space in the mid-clavicular line, followed by insertion of a chest drain. A large haemothorax is identified by dullness to percussion and decreased air entry, and is also managed with an intercostal drain.

CIRCULATION AND PERFUSION

In the shocked patient, insert two high-flow lines with 14-gauge cannulae in the antecubital fossae. The line should not be inserted on the same side as a vascular injury with massive bleeding, for if there is a venous injury, intravenous fluids will merely bleed out. In the shocked patient, start with two litres of crystalloid; if the blood pressure does not improve, proceed to a transfusion of 0-negative blood, and arrange blood cross-matching. A shocked patient with warm peripheries may have neurogenic shock secondary to spinal cord injury. This would result in low blood pressure and bradycardia, potentially masking a significant vascular injury. Active bleeding from a cervical wound may be controlled with a compressive dressing or digital pressure. Failing this, a large Foley's catheter may be inserted into the wound, the bulb inflated, and the catheter cross-clamped to stop blood pouring through the catheter. This can be a very effective form of haemostasis particularly with bleeding from the subclavian and cervical vessels.[2] Throughout, the patient should remain recumbent, or the neck wound must be covered with an occlusive dressing when the patient sits up, to prevent air embolism.

DISABILITY

The GCS and pupil size and reactivity to light are recorded, and power in the limbs is assessed.

EXPOSURE

All clothing is removed in order to avoid missing associated injuries. The patient is kept warm.

Adjuncts to primary survey

Adequate monitoring, including ECG, pulse oximetry and non-invasive blood pressure monitoring is instituted. A rectal examination to exclude a urethral injury should be performed prior to inserting a urinary catheter. The haemoglobin level, blood glucose and arterial blood gas are checked. Imaging is essential. In a well-resourced trauma centre, this would include cross-sectional CT or MR imaging. Alternatively, cervical spine chest and pelvic X-rays are essential. In a patient with isolated penetrating neck trauma, a chest X-ray and cervical spine X-rays will suffice. Exclude a haemo- or pneumothorax, pneumomediastinum (tracheal or oesophageal injury), and widened mediastinum on chest X-ray. The mediastinal width on a supine chest X-ray should not exceed 8 cm; a widened mediastinum is suggestive of major intra-thoracic injury and must be further investigated with CT angiography. Cervical spine X-ray is used to exclude spinal column injury and prevertebral air (pharyngeal or oesophageal injury). Non-urgent X-rays should be requested only on completion of the secondary survey.

Secondary survey

A detailed head-to-foot examination of the patient is conducted. In firearm injuries, the location of the wounds must be noted and the direction of the tract established so as to determine which anatomical structures may have been injured. X-rays (AP and lateral) are obtained in the absence of an exit wound to locate and determine the tract of the bullet. If the patient has not been intubated, examine the cranial nerves and exclude Horner syndrome. Note the presence of a large cervical haematoma, subcutaneous emphysema, the jugular venous pressure and tenderness over the mandible. If a nasogastric tube has been inserted, the presence of blood in the nasogastric tube should be looked for.

KEY POINTS

- Wounds should not be probed as this may cause massive bleeding from an arterial injury.

Check the peripheral pulses for discrepancy or absence. Examine the distal carotid and superficial temporal artery pulses, and listen for bruits. Again exclude a haemo/pneumothorax and listen to the heart sounds. The abdomen and pelvis should be examined, followed by a full neurological examination during which spinal cord and brachial plexus trauma are excluded. Note the presence of hemiplegia or Brown-Sequard syndrome (hemitransection of spinal cord). The patient should be logrolled in order that the back can be examined for trauma.

History

Take a history with specific reference to the nature of the trauma. Enquire about symptoms pointing to oesophageal injury (haemoptysis, haematemesis, dysphagia, and odynophagia), and recurrent laryngeal nerve or laryngeal injury (dysphonia, stridor). Past medical and surgical history is documented, as well as the time of the patient's last meal.

Further investigations

Any further X-rays that are required after the secondary survey are now completed. Special investigations such as CT scan, ultrasound and gastrografin or barium studies may now be requested in a haemodynamically stable patient.

Full documentation

All injuries are documented and the patient is referred for definitive care.

AETIOLOGICAL CLASSIFICATION

- Penetrating
  - stabs
  - GSW
    - low kinetic energy
    - high kinetic energy
    - shotgun
- blast
- blunt.

Unlike stab wounds and low kinetic energy GSWs, close-range shotgun, rifle, and bomb injuries cause extensive soft tissue trauma.

ZONES OF THE NECK

The neck contains three principal anatomic components i.e. vascular (carotid, vertebral, and subclavian arteries; jugular and subclavian veins), digestive (pharynx and oesophagus) and respiratory (larynx and trachea). Roon & Christensen's classification into three zones is most commonly used for description of the site of cervical trauma (**Figure 38.1**).[3] All three zones contain major vascular, and aerodigestive structures. However injuries to zones I and III are both diagnostically and surgically more challenging.

- Zone I: Sternal notch / clavicle to cricoid cartilage
- Zone II: Cricoid cartilage to angle of mandible
- Zone III: Angle of mandible to base of skull

In a second classification system by *Monson*, the transition between zones I and II is at the sternal notch.[4] Both retrospective and prospective studies and review articles of penetrating cervical trauma fail to take into account these differences in the classification systems used.[4] Although transcervical injuries (injuries that cross the mid-line of the neck) are associated with vascular or aerodigestive injuries in 73–100% of patients, neither classification system takes cognisance of transcervical injuries.

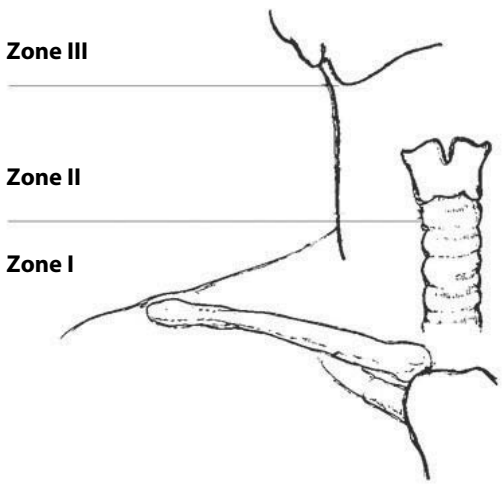

Figure 38.1 Zones I – III: Roon and Christensen classification.

MANDATORY VERSUS SELECTIVE EXPLORATION OF PENETRATING CERVICAL INJURIES

Prior to World War II, non-operative treatment of penetrating neck injuries was associated with a mortality of 15–18%.[5] Following experience in World War II, Bailey in 1944 proposed early exploration of penetrating neck injuries. Coupled with the introduction of antibiotics and tracheostomy, early exploration reduced the mortality rate to 7%.[6] In 1956, Fogelman and Stewart reported that mortality for patients not immediately explored was 35% vs. 6% for those that had been promptly explored. They concluded that all penetrating neck wounds that violated the platysma required surgical exploration.[7] Mandatory exploration of the neck whenever the platysma muscle had been breached subsequently became common practice. In 1963 Stone questioned the need for mandatory exploration for civilian injuries.[8] Ever since that time controversy has reigned about the relative merits of mandatory exploration vs selective exploration for low-velocity gunshot and sharp penetrating cervical wounds. The majority of trauma centres currently advocate some form of selective conservative management.[9]

Mandatory exploration

Proponents of mandatory exploration of stable patients with low-velocity GSWs and stab wounds that breach the platysma muscle consider that the risk of missing an unsuspected vascular or aerodigestive tract injury outweighs the morbidity and expense of negative exploration. They point to the unreliability of clinical evaluation, that diagnostic studies do not have 100% sensitivity to detect oesophageal and vascular injuries, low morbidity associated with negative exploration, additional time and effort associated with expectant observation, and the significant morbidity and mortality associated with delayed detection and repair of oesophageal injury. Yet, vascular and oesophageal injuries can be missed when the neck is explored without the assistance of pre-operative angiography, oesophagography and/or oesophagoscopy.

Selective exploration

Protagonists of selective exploration quote the high rate (36–89%) of negative mandatory exploration,[9–11] good sensitivity and specificity of special investigations such as angiography, doppler, barium swallow, rigid oesophagoscopy, and flexible laryngotracheobronchoscopy; expense of prolonged hospitalization following negative exploration; the fact that many injuries (e.g. thyroid, pharyngeal and certain venous injuries) that are detected at mandatory exploration may be treated conservatively; and that neck exploration leaves an unsightly scar (**Figure 38.2**).

TABLE 38.1 Selective conservative management of penetrating cervical injuries

Series	No of patients	Explored	Endovascular management	Negative explorations	Observed	Mortality
Narrod[12]	77	62 %	NR	15%	29%	0%
Campbell[13]	108	24%	NR	0%	82%	1.2%
Ngakane[14]	109	NR	NR	NR	97%	1.8%
Demetriades[9]	335	20%	NR	15%	80%	0%
Thoma[15]	203	12%	4%	0%	78%	0%
Van Waes[16]	77	8%	1%	0%	90%	0%

NR = not reported.

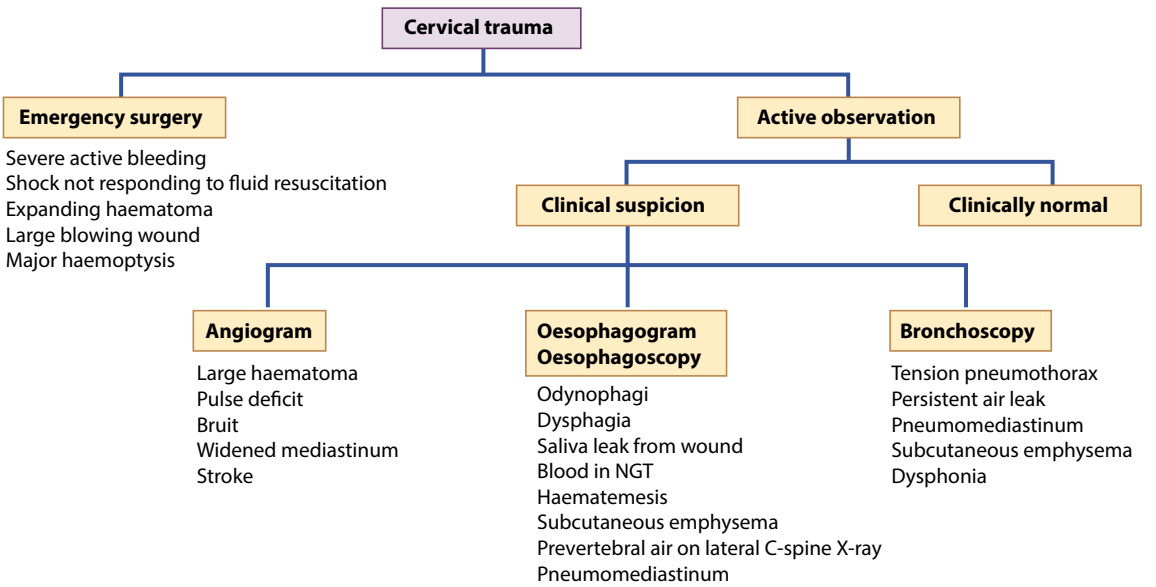

Figure 38.2 Selective surgical exploration algorithm.

Negative exploration in centres practising selective exploration ranges between 9% and 62%.[10–12] The safety of selective conservative management of penetrating cervical injury is apparent from the results of six prospective studies summarized in **Table 38.1**. Mortality in the studies by Campbell[13] and Ngakane[14] was not attributable to cervical injury, but to associated trauma. Two recent prospective studies from our institution have validated the fact that selective non-operative management of penetrating neck injuries is effective and safe.[15, 16]

KEY POINTS

- Indications for emergency surgery with such a selective approach include severe active bleeding, hypovolaemic shock not responding to resuscitation, a rapidly expanding haematoma, a large blowing wound and major haemoptysis.

The remaining patients are assessed clinically and appropriate radiological and endoscopic investigations are done only if there is a suspicion of visceral injury.

While the importance of early diagnosis of occult vascular injury is debatable, delayed diagnosis of oesophageal perforation is accompanied by increased morbidity and mortality.[17, 18] Because of concerns about reliability of physical assessment alone, some protagonists of selective exploration therefore advocate mandatory oesophageal and vascular studies; others have employed active observation with special investigations only if the clinical examination is equivocal.

Active observation with selective special investigations

Demetriades et al. reported in a prospective study of 335 penetrating neck injuries that a combination of clinical and selective investigations yielded a specificity of 85%, and sensitivity of 100% to identify clinically significant vascular and aerodigestive tract injuries. Only 38% of patients with surgical emphysema required exploration. They concluded that selected exploration can be based on careful initial and repeated clinical examinations.[9] They advocate emergency exploration for the absolute indications for neck exploration noted previously. They do not consider soft signs such as shock responding to resuscitation, minor active bleeding, haematoma, dyspnoea,

subcutaneous emphysema, hoarseness, dysphagia or minor haematemesis to be absolute indications for exploration; such patients are assessed individually, taking into account the direction of the injury tract, and the severity of the clinical signs. If the tract courses away from larynx, trachea, oesophagus and carotid sheath, then no further investigations are done. If the tract is directed towards the midline, then contrast oesophagography, and/or endoscopy are done. Chest X-ray is requested if chest pathology is suspected. Hall et al. support this approach in a report on the safety of active observation of children with penetrating injuries in Zone II.[5] Although transcervical gunshots are twice as likely to have visceral/vascular injury as gunshots that do not cross the midline (79% vs. 31%, $p = 0.02$), 80% may be safely managed non-operatively by active observation and selective special investigations.[19]

Spiral CT scanning to evaluate the neck shows promise.[20] When CT scan in the stable patient reveals that the trajectory courses away from vital structures, then employment of invasive studies appears to be superfluous.

SPECIFIC INJURIES

Pharyngeal injury

Hypopharyngeal injury should be suspected in Zone II penetrating injuries, particularly in the presence of dysphagia, odynophagia, voice change, haemoptysis, haematemesis, and surgical emphysema. Flexible nasopharyngoscopy may reveal oedema, blood in the pharynx, or the perforation may be visible if located in the superior hypopharynx. Direct pharyngoscopy should reveal all injuries, but oesophagography is unreliable.[21] In a retrospective study of 47 hypopharyngeal injuries, Stanley et al. reported no complications in supra-arytenoid hypopharyngeal injuries, as opposed to a 22% complication rate for infra-arytenoid hypopharyngeal injuries. They conclude that upper hypopharyngeal injuries may be managed non-operatively; this part of the hypopharynx is capacious, has a low-intraluminal pressure and is enveloped by both the middle and inferior constrictor muscles. The lower hypopharyngeal funnels into the cricopharyngeus segment and is less capacious, has higher intraluminal pressure and is surrounded only by the inferior constrictor muscle; it should explored, repaired and drained like oesophageal injuries.[22]

Oesophageal injury

Early recognition and treatment of oesophageal perforation is the key to favourable outcome. Missed oesophageal injury has high morbidity and mortality. Intervention delays of >12 hours for iatrogenic oesophageal injury has a mortality rate of 40% as opposed to 9% if <12 hours.[17] In a retrospective multicentre study, Asensio et al. compared the outcome of patients that underwent diagnostic studies, with patients taken straight to the operating room. The study revealed a significantly increased oesophageal complication rate (41% vs. 19%), and length of ICU stay with patients having diagnostic studies. They concluded that time delays in instituting active management incurred by investigations associated with selective exploration can lead to increased morbidity and mortality.[18] This report does not however distinguish between the cervical and thoracic oesophagus. Whether their conclusion applies to isolated cervical oesophageal injury is therefore open to question, particularly in view of reports of successful outcome of small cervical oesophageal injuries treated conservatively. However, centres practising selective management of penetrating neck injuries should make rapid diagnosis and definitive repair a priority.

ACCURACY OF DIAGNOSIS OF OESOPHAGEAL INJURY

Dysphagia, haematemesis and odynophagia are symptomatic of penetrating oesophageal injury. Clinical evidence includes surgical emphysema and a salivary leak. X-ray may reveal retropharyngeal air, retropharyngeal oedema, haematoma, tracheal deviation, and a pneumomediastinum. Clinical evaluation has a sensitivity of 80% (50% for stabs, 100% for GSWs), a specificity of 64%, and an accuracy 72%.[17] Sensitivity of barium swallow is 48–100%, and of oesophagoscopy 40–90%.[23, 24] In a prospective study, Weigelt et al. reported 89% sensitivity, 100% specificity and 94% accuracy (AP and lateral views with cineradiography) for barium swallow; flexible oesophagoscopy was unreliable, particularly in the proximal oesophagus as the mucosa cannot be effaced as with rigid oesophagoscopy; rigid oesophagoscopy had a sensitivity of 89%, specificity of 95% and accuracy of 94%; and a combination of oesophagography and oesophagoscopy had a sensitivity of 100%.[17] Wood et al. reported sensitivity of oesophagography of 100% and specificity of 96%, and cautioned that oesophageal and vascular injury can be missed at neck exploration.[25] Flowers et al. and Srinivasan et al. have however more recently reported sensitivities of 100%, and specificities of 96% and 92.4% respectively, for flexible oesophagoscopy to detect the presence of penetrating injury of the oesophagus.[26, 27] Because barium, if aspirated, may induce serious pulmonary problems, it should not be used in trauma patients and an appropriate water-soluble contrast agent (e.g. gastrografin) should be used.

DO ALL OESOPHAGEAL INJURIES NEED TO BE EXPLORED?

Treatment of oesophageal injury varies from observation, to simple repair of the wall +/- drainage of deep neck spaces, to primary diversion of salivary flow to the skin by means of partial or total exteriorization procedures. All high-kinetic injuries should be explored. The management of stab wounds and low-kinetic energy GSWs is more contentious. Wound site, size, mechanism of injury, time delay, associated injuries, availability of and expertise with diagnostic tests such as oesophagography and oesophagoscopy, and availability of theatre time all play a role in determining the management of oesophageal injury. Generally it is recommended that, should barium swallow be positive or equivocal, one should proceed to rigid oesophagoscopy; if positive, then the oesophagus is explored. However, Ngakane et al. concluded from a prospective study of penetrating visceral

injuries of the neck, that should oesophagography reveal minimal leakage of contrast, then patients can be managed conservatively; oesophagography is repeated on day 5, prior to commencing oral feeding.[14] Similarly favourable outcomes of small cervical oesophageal perforations treated conservatively been reported by Mandal et al. and others.[28]

SURGICAL TECHNIQUE

The majority of oesophageal injuries can be repaired primarily. The remainder are repaired by resection and anastomosis, or are simply drained. Intravenous antibiotics and enteral or parenteral nutrition should be instituted. Adequate drainage, suction or dependent, is important as even with a technically sound repair, 13% develop fistulae.[11] If part of the oesophagus has been blown away, if mediastinitis or sepsis is already present, or if oesophageal injury extends into the chest, then a lateral cervical oesophagostomy may be required. There is no evidence to favour a double- or single-layered repair. Local infrahyoid strap or sternocleidomastoid muscle flaps can be used to buttress the repair, or used as an interposition between an oesophageal injury and a vascular or tracheal repair.[29] Barium swallow is done on day 5–7, as 50% of post-operative oesophageal fistulae are asymptomatic and detected only on contrast study.[11] Should a fistula or sinus be present, the drain is retained.

COMPLICATIONS OF OESOPHAGEAL INJURY

Oesophagocutaneous fistulae occur in 9–28% of oesophageal injuries.[29] They occur more commonly with GSWs, but generally close spontaneously. Oesophagotracheal fistulae are repaired with interposition of a muscle flap. More serious complications include abscess formation, mediastinitis, septicaemia and death.

Tracheal injury

Cervical tracheal injury is relatively uncommon, and frequently associated with oesophageal, vascular or spinal injury. Symptoms of tracheal injury include a blowing wound, surgical emphysema, haemoptysis and hoarseness. Chest X-ray may reveal surgical emphysema and pneumomediastinum. The priority is to secure an airway. The trachea can sometimes be intubated through a blowing wound in the neck. Tracheotomy is appropriate in the presence of laryngeal trauma to avoid further injury to the endolarynx, when it is not possible to safely pass an endotracheal tube, or with quadriplegia requiring ventilatory support. Former teaching that nasotracheal or orotracheal intubation should be avoided as it may aggravate an existing tracheal injury or cause a false passage appears to have been overly cautious.[30] Distal tracheobronchial disruptions can be bypassed under direct vision with an introducer passed through a rigid bronchoscope, or by intubating over a flexible bronchoscope. Tracheobronchoscopy can be useful to assess the injury, but the diagnosis is usually readily apparent on exploring the neck for associated injuries. Minor tracheal injuries in patients not otherwise requiring cervical exploration can be managed expectantly. In cases of marked surgical emphysema, a tracheotomy might expedite recovery. Tracheal repair is effected with interrupted sutures. When there is an associated oesophageal or vascular injury, then the repair can be bolstered with a local muscle flap. In selected cases a tracheotomy or an endotracheal tube may be used to protect the tracheal repair.

Vascular injury

The common carotid artery is the most frequently injured major vessel; it accounts for 22% of vascular injuries.[31] Current debate centres on evaluation of the asymptomatic patient, and optimal treatment of vascular trauma. The majority of published series are small, retrospective, and from single centres.

CLINICAL EVALUATION

Hard clinical signs of vascular injury are expanding haematoma, external haemorrhage, absent or diminished distal pulses, ischaemic neurological deficits, or coma. The reported accuracy of clinical evaluation varies widely. Scalafani et al. reported a specificity of 80% and sensitivity of 61%; Meyer et al. reported an accuracy of 68%.[32] Demetriades et al. reported a sensitivity of 100% for clinical detection of significant vascular injury.[33] The widely disparate results may reflect shortcomings of retrospective data collection, and a lack of emphasis placed on clinical decision-making in centres with a bias towards routine angiography or exploration.

INVESTIGATIONS

The gold standard investigation remains 4-vessel arch angiography with selective catheterization. Angiography has the following benefits: identifies the site of injury; identifies subclinical vascular injury including vertebral artery trauma; serves as a roadmap for the surgeon; delineates the extent of crossover circulation through the Circle of Willis; and identifies injuries amenable to endovascular intervention. However, helical CT angiography is largely replacing conventional angiography and has a 90–100% sensitivity and specificity to detect arterial injury.[20] Vascular injuries in Zone II are readily exposed, and with Zone II penetrating injuries, the chance of detecting an asymptomatic arterial injury by angiography is less than 1%, which approaches the complication rate of angiography.[4] With penetrating injuries in Zone II, angiography may therefore be employed selectively for patients with clinical suspicion of a vascular injury, or when the tract of a GSW passes close to vascular structures. Vascular injuries in Zones I and III can however be difficult to assess clinically, and surgical exposure and vascular control are more challenging. Hence pre-operative angiography of suspected vascular injuries in Zones I and III is generally recommended. Demetriades et al. reported that colour-flow duplex Doppler (CFD) imaging, when combined with clinical examination, had a sensitivity of 91% and specificity of 99% to detect vascular injury. CFD only missed an intimal tear which did not require treatment.[33] CFD however requires trained personnel; is not always readily available; is best avoided if there is a suspected cervical column

injury; it may not demonstrate very well the origins of cervical arteries from the aortic arch, the arteries close to the skull base, and the vertebral arteries; and it is difficult to identify individual branches of the external carotid artery.

CAROTID REVASCULARIZATION VERSUS LIGATION

With the introduction of vascular surgical techniques during the Korean War, primary repair of carotid artery injuries was recommended. In 1973 Bradley concluded from two autopsy studies that revealed haemorrhagic brain infarction, that revascularization should not be attempted in patients with severe neurological deficits.[34] Fear about converting an ischaemic into a haemorrhagic infarct by reperfusion and hence worsening the neurological outcome has since been a major concern to vascular surgeons, and has fuelled the dilemma of ligation vs. reperfusion. In 1978 Liekwig and Greenfield showed that patients with severe neurological deficits just short of coma had significantly better results with reperfusion.[35] This was supported by Brown et al. in 1982 who showed that revascularization in patients with pre-operative coma (lack of meaningful response to verbal or noxious stimuli) was indicated when ischaemia had only been present for a short period of time prior to surgery (**Figure 38.3**).[36]

PSEUDOANEURYSMS AND INTIMAL INJURY

Clearly the risk of surgery for pseudoaneurysms (focal, eccentric widening of the lumen extending beyond the arterial wall), intimal defects and intimal flaps, should not exceed the risk of complications developing from the arterial pathology. Pseudoaneurysms, intimal defects and intimal flaps have been managed conservatively.[37, 38] However, studies are small and the safety of a conservative approach particularly with respect to the carotid artery has not been confirmed. Patients managed conservatively should be followed with arteriography to confirm that the lesion does not increase in size.

VERTEBRAL ARTERY INJURY

With the increased availability of angiography, vertebral artery injury is being more frequently recognized.[39] Patients may present with acute bleeding or with late complications of thrombosis, false aneurysms, bleeding, arteriovenous fistulae and stroke. Torrential bleeding may be encountered from a lacerated vertebral artery. Arteriovenous fistulae may present with a bruit, thrill, haematoma, neurological deficits, or cardiac failure. A neurological deficit seldom occurs in the presence of a normal contralateral vertebral artery and intact collateral circulation.[40] Mortality from isolated vertebral artery trauma ranges from 5% to 17% but increases to 50% if there is an associated injury of the carotid artery.[41] The majority of vertebral artery injuries can be managed by angiographic embolization. If the injury is discovered at emergency surgery, the vessel should be ligated. This is fairly simple if the injury is located at a point before the vertebral artery enters the foramen transversarium at the level of the 6th cervical vertebra. Once inside the vertebral canal, ligation may be achieved with ligaclips. Alternately, bone wax should be used to tamponade bleeding, followed by angiographic embolization.

ENDOVASCULAR TECHNIQUES

Endovascular techniques are playing an increasing role in the treatment of both acute and late manifestations of vascular trauma, particularly at the skull base. False aneurysms and arteriovenous fistulae can be treated with covered stents, or by trapping the lesion proximally and distally with balloons or coils, once good cross-flow across the Circle of Willis has been demonstrated (**Figures 38.4** and **38.5**).

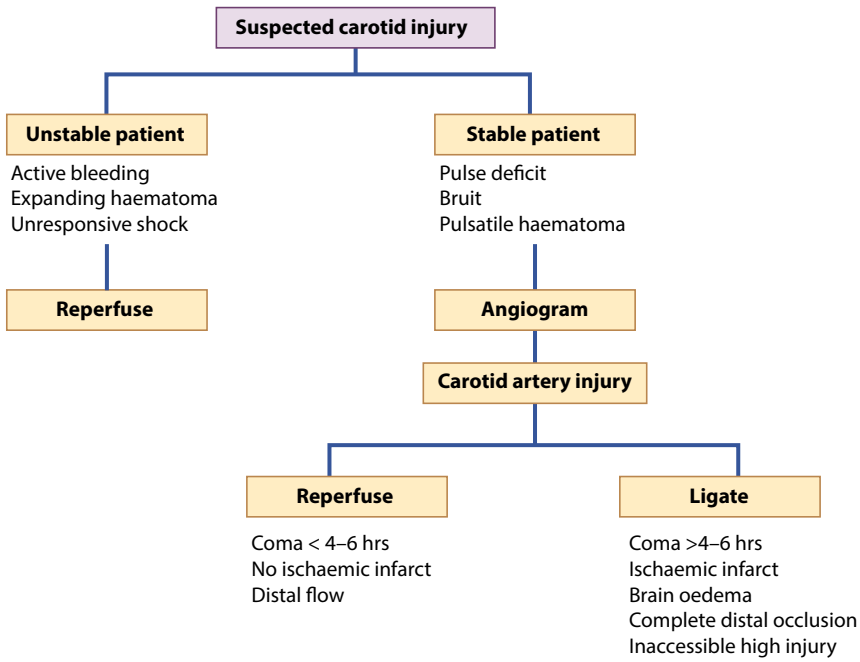

Figure 38.3 Recommended protocol for carotid ligation vs. reperfusion.

Bleeding from branches of the external carotid artery can be controlled by embolization.

VENOUS INJURY

The external jugular vein may be ligated if injured. The internal jugular vein may be repaired by lateral venorrhaphy, or ligated. Should both internal jugular veins have been injured, then at least one vein should be repaired to prevent facial swelling, and sequelae of raised intracranial pressure such as blindness, SIADH and even death. A remnant of the contralateral internal jugular vein or saphenous vein can be used should a graft be required.

Chylous injury

Patients with Zone I injuries rarely develop a chylothorax due to injury to the thoracic duct or right lymphatic duct. Although one can attempt a diet of medium-chain triglycerides, Worthington et al. reported that conservative treatment is uniformly unsuccessful, and advocate early ligation via thoracotomy.[42]

Neurological injury

Significant brachial plexus nerve injury should be repaired within 24–72 hrs.

EXPLORATION OF THE NECK: GENERAL PRINCIPLES

- IVI lines, suction, blood in theatre
- General anaesthesia: crash induction with cricoid pressure
- Airway:
  - nasotracheal/orotracheal intubation
  - cricothyroidotomy or tracheotomy
- Position:
  - supine
  - neck extended, turned to opposite side, if no C-spine injury
- Exposure:
  - chest and face for Zones I and III injuries, to permit additional surgical exposure if required
  - contralateral groin and lower leg to permit harvesting of saphenous vein for grafting
- Approach:
  - localized injury: horizontal skin crease incision, subplatymal flaps
  - wider exploration: long incision along anterior border of sternocleidomastoid muscle
- Additional exposure:
  - Zone I: divide omohyoid muscle; bilateral exploration: apron flap
  - Zone III: anterior dislocation of the mandible.

SUMMARY

Management of penetrating injuries of the neck remains controversial. Reasons for the controversy include paucity of well-designed, large, prospective studies; the uncommon occurrence of oesophageal injury; the variable levels of radiological and surgical expertise at trauma centres confronted with cervical injuries; the wide spectrum of the site and severity of injuries and of aetiological agents, as well as the lack of a uniform classification system when reporting neck injuries.

Figure 38.4 False aneurysm of internal carotid artery, with carotico-jugular fistula following stab wound at base of skull.

Figure 38.5 Trapped false aneurysm and fistula (Figure 38.4), with coils by endovascular technique.

FUTURE RESEARCH

- Significance of delayed repair of cervical oesophageal injury.
- CT scan for initial evaluation of penetrating cervical injury.
- MRI scan for initial evaluation of penetrating cervical injury.
- Endovascular intervention for vascular trauma.

KEY POINTS

- Properly executed, selective management of penetrating injuries of the neck is as safe as mandatory exploration.
- Trauma centres need to design their management protocols in accordance with their investigative and therapeutic capabilities.

SEARCH STRATEGY

Data presented in this chapter are based on a Medline search using keywords listed in the chapter. The main terms included, congenital neck masses and acquired neck masses, inflammatory neck masses, and neck abscesses. It included diagnosis, surgery and management. The evidence of this chapter is mainly evidence levels 3 and 4 with some level 2 evidence. The clinical recommendations are predominantly B and C.

INTRODUCTION

Neck masses or swellings are a common occurrence. In the adult population, approximately 75% of non-thyroid neck masses are neoplastic,[1, 2] and of these 80% are metastatic. Around 75% of these metastatic neck masses are caused by a primary tumour located above the clavicle. In children under 15 years, 90% of neck masses are benign and of these up to 55% may be congenital.[1, 3, 4]

Benign neck masses may be classified as congenital or acquired. The latter group are often enlarged lymphadenopathy, but there may be a wide range of different pathologies involved. The introduction of fine-needle aspiration biopsy / cytology (FNAB / FNAC) with or without the use of ultrasound scan (USS) guidance has now become the gold standard investigation.[5–7]

The evaluation and management of patients presenting with a neck lump should include a systematic and uncompromising clinical approach.[2, 8–10] This must include a thorough history, examination of the upper aerodigestive tract and head and neck, followed by relevant investigations, which may include blood tests and radiological imaging.

History

This should include age, sex, past medical history, travel abroad, the mode of onset and duration of neck mass, associated symptoms including dysphonia, dysphagia, odynophagia, sore throat, referred otalgia, nasal obstruction, cranial nerve neuropathies, weight loss, anorexia, malaise and night sweats.

Examination

The examination should include an inspection of the skin over the skull, face, neck, and of the ears, nose, oral cavity and oropharynx. The fibre-optic endoscope should be used to inspect the nasal cavity, nasopharynx, oropharynx, larynx and hypopharynx.[2, 10, 11] The neck should be examined in a systematic fashion and the number, size, site, shape, texture and involvement of the skin and the deep cervical structures noted. Additionally, while concentrating on the head and neck as a source to explain the presence of a neck mass, it is frequently worth extending the general physical examination to include the chest and breasts in women, including the axillae. Examination of the neck is addressed extensively in Chapter 36, Clinical examination of the neck.

Investigations

The investigations of patient with a neck lump should be tailored to each individual case. All patients with neck lumps should as a minimum be considered for: full blood count (FBC), chest X-ray (CXR) and utrasound guided FNAB / fine-needle aspiration cytology (FNAC).

If an inflammatory mass is suspected, especially in a young patient, the above investigations together with an erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), Epstein–Barr virus (EBV) and cytomegalovirus (CMV) titres, liver function tests (LFTs), lactate dehydrogenase (LDH), Brucella, *Bartonella henselae* and toxoplasma serology may be advisable.[1, 9]

Once a clinical or tissue diagnosis has been made, it is possible to determine what, if any, further tests or imaging is required. If the diagnosis is infective or inflammatory a plain chest X-ray or no further imaging may be indicated. If a neoplastic lesion is diagnosed, computerized tomography scanning (CT), magnetic resonance scanning (MR) and positron emission tomography (PET) scanning alone or a combination may be performed. See details in Chapter 37, Imaging of the neck.[1]

A basic understanding of the different pathologies presenting as a neck lump is essential to direct adequate investigations and conclude an accurate working diagnosis without compromising the patient's clinical outcome. Occasionally, the clinician needs to be conscious that a working diagnosis may be incorrect;[12] hence it is paramount that patients are reviewed frequently during the early stages, to ensure resolution of the mass, if that is the expected outcome, or referral to a specialist for a second opinion if the anticipated diagnosis has not be confirmed, or doubts in the diagnostic accuracy still persist.

CONGENITAL NECK MASSES

LYMPHANGIOMAS

Lymphangiomas are degenerative lesions arising from lymphatics, and can be classified as: simple lymphangiomas, cavernous lymphangiomas and cystic hygromas.[13–16]

Lymphangioma simplex These are also called capillary lymphangiomas. They are composed of thin-walled capillary-sized lymphatic channels, usually asymptomatic and present as a pale, small vesicle-like lesions visible on the skin or oral cavity.

Cavernous lymphangioma Cavernous lymphangioma represent 40% of all lymphangiomas, composed of dilated lymphatic spaces, often with a fibrous adventitia, typically occurring in the tongue, cheeks and lips, and present as a painless diffuse swelling.

Cystic hygroma Cystic hygroma are composed of cysts and sinuses, varying in size from a few millimetres to several centimetres in diameter, usually presenting as a cystic mass containing eosinophilic acellular lymph fluid.

AETIOLOGY

The lymphatic system arises from five primitive sacs (two jugular sacs, two posterior sciatic sacs and a single retroperitoneal sac) developed from the venous system. Endothelial buds from these extend centrifugally to form the peripheral lymphatic system. Two principal theories have been postulated to explain the origin of lymphangiomas:[17, 18]

- Sequestration of lymphatic tissue derived from segments of the primitive sacs, which retain the proliferative growth potential and bear no connection with the normal lymphatic system
- Endothelial fibrillar membrane proliferation from the walls of the cyst, which penetrate the surrounding tissue along the lines of least resistance between muscles and vessels, canalize and produce more cysts.

CLINICAL FEATURES

Although congenital and in most cases present at birth, sometimes they can manifest for the first time in young adults. They can appear anywhere in the head and neck. On palpation they feel cystic and transilluminate. They may remain static or involute, but in some cases they gradually increase in size and occasionally, especially after internal haemorrhage or infection, can grow rapidly potentially risking life-threatening airway obstruction.[13, 19]

DIAGNOSIS AND INVESTIGATIONS

The diagnosis is usually made on clinical grounds but CT and MRI scanning will more accurately determine the size, exact anatomical location, and relationship with important structures as well as aiding surgical planning.[13, 19]

TREATMENT

The management of these lesions is difficult and challenging and many treatment modalities have been described over the years. The treatment strategy varies depending on the anatomical location, size and involvement of surrounding structures. Observation has been proposed by Broomhead[20] as up to 15% of patients may have spontaneous regression. Repeated aspirations may be helpful in the event of rapid increase in size causing pressure symptoms whilst awaiting definitive treatment. Injection of sclerosants such as bleomycin, tetracyclines and alcohol has been suggested, but internal scarring is reported to be unpredictable resulting in difficulty with any subsequent surgery and it is not currently recommended. The intra-lesion injection of OK-432 (Picinabil) has shown promising results.[21, 22] It causes an inflammatory reaction and thrombosis with subsequent necrosis. Surgical excision remains the treatment of choice but it is challenging and is therefore best undertaken by experienced surgeons in specialist centres.[17] Surgery can be helped by the injection of methylene blue into the lymphatic spaces (**Figure 39.1**).

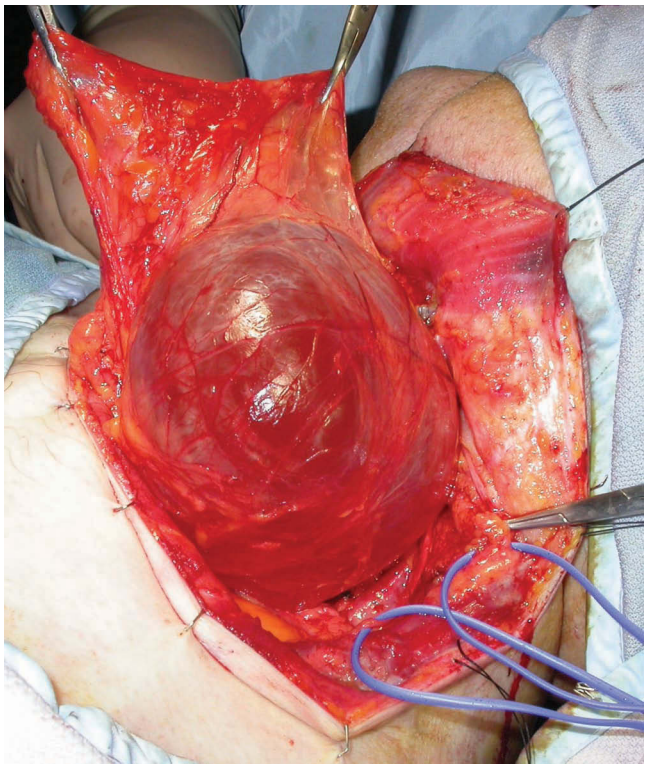

Figure 39.1 Operative picture of a lymphangioma of the supraclavicular region.

DERMOID CYSTS

Dermoid cysts are classified as epidermoid, true dermoid and teratoid cysts, depending on the types of tissues identified pathologically within them.[23] Twenty per cent of all dermoid cysts are found in the neck and 30% of these in the face. They make up 28% of all midline cysts, with no sex predominance.

Epidermoid cysts contain only skin and no other adnexal structures. They are lined with squamous epithelium with or without keratinous material. These are the most commonly encountered variety.

True dermoid cysts are lined with squamous epithelium and contain skin with appendages such as hair, hair follicles, sebaceous glands and sweat glands.

Teratoid cysts are lined either with squamous or respiratory epithelium. They contain all three embryological elements; ectodermal, endodermal and mesodermal elements such as nails, teeth, brain and glandular tissue.

AETIOLOGY

These lesions develop because of ectodermal differentiation of multipotential cells trapped at the time of closure of the anterior neuropore, especially along the lines of fusion, hence their being located along the midline of the neck. In the head and neck other areas of tissue fusion may present with dermoid cysts, such as external angular dermoids, and the nasal dorsum.[23]

Figure 39.2 Thyroglossal cyst.

CLINICAL FEATURES

The peak age of incidence is usually the second and third decade. They can present as a cystic or solid painless mass, usually in the submental region, above or below the mylohyoid muscle. They may infrequently manifest as an acute inflammatory swelling associated with infection (**Figure 39.2**).

DIAGNOSIS AND INVESTIGATIONS

Diagnosis is suggested by the patient's age, the clinical location, and nature of presentation. Ultrasound-guided FNAC may be useful in the diagnosis of these lesions. Cross-sectional imaging such as a CT and MRI can help delineate the extent of large lesions, and aid surgical planning.

TREATMENT

Complete surgical excision is the treatment of choice.[23]

THYROGLOSSAL DUCT CYSTS

Thyroglossal duct cysts are the most common upper neck midline lesion accounting for almost one-third of all congenital neck masses.[24] They can present as a mass or lump, at any level between the foramen caecum and the upper mediastinum, with the majority presenting about the level of the hyoid bone. They are usually sporadic but a rare familial variant has been documented, identified as an autosomal dominant condition in pre-pubertal girls. Thyroglossal duct carcinoma, although rare, may present and be identified by the pathologist in a thyroglossal duct cyst.[25, 26] This is described in the section on thyroid malignancies.

AETIOLOGY

Embryologically the thyroid gland originates from the floor of the primitive pharynx between the first and second

pharyngeal pouches. In addition to the major median swelling, there are smaller paired lateral pouches, which contribute to the parafollicular or calcitonin-secreting C cells. The median pouch loses its lumen, about the 5th week of gestation and breaks into fragments, the lower end dividing into two portions that become the lobes of the thyroid gland. Thyroglossal duct cysts arise from epithelial cells when they cease to remain inactive. The stalk usually atrophies during the 6th week but should it persist as a patent tract, it becomes a thyroglossal duct along which cysts can develop. It may run from the thyroid gland inferiorly, upwards and in the region of the hyoid bone, and the tract may be located behind, through or in front of the hyoid, ending deeply in the junction of the anterior two-thirds and posterior one-third of the tongue, at the foramen caecum. The mechanisms involved in the development of cystic changes is not fully understood.[27] A fistula usually arises from spontaneous drainage of an abscess or more commonly following attempted drainage of a misdiagnosed midline neck abscess, or as a result of inadequate surgical excision associated with leaving an intact hyoid bone.

CLINICAL FEATURES

The majority (~95%) of thyroglossal cysts present as an asymptomatic cystic mass at or about the level of the hyoid bone. It moves on swallowing or on protrusion of the tongue. Up to 5% of these cysts present as an acute inflammatory episode with an infection, and 15% may have an associated discharging fistula.[28] There is no sex preponderance. The mean age of presentation is 5 years, with a range between 4 months to old age. Ninety per cent are in the midline but 10% may be to one or other side, with 95% of these being in the left side; 75% are pre-hyoid with the remaining 25% located above or below the hyoid, and rarely can be found within the mediastinum[24, 29] (**Figure 39.3**).

Figure 39.3 Right branchial cyst.

DIAGNOSIS AND INVESTIGATIONS

Patients with suspected thyroglossal duct cysts should be investigated with thyroid function test and ultrasound guided FNAC. The TSH and T4 levels will determine the thyroid status of the patient. USS may help with the location and diagnosis of the cyst, and will also confirm the presence of a normal thyroid gland in its expected anatomical position. FNAC will demonstrate cystic contents containing colloid. Isotope scan with either Tc^{99} or I^{123} may be useful if the cyst is located above the hyoid or in the posterior tongue, with a view to identifying or excluding the presence of a lingual thyroid. CT or MRI scanning should be considered in the presence of large cysts, when malignancy is suspected and when the possibility of a lingual thyroid has been considered.[30]

TREATMENT

Surgical excision is the treatment of choice, as there is a high probability the cyst may become infected, resulting in loss of normal tissue planes, or scarring of the neck skin and the occurrence of recurrent cyst enlargement causing patient discomfort.[24, 31] The Sistrunk procedure was described in 1920,[32] which resulted in a permanent cure for the majority of cases. Previously the hyoid bone was not excised resulting in recurrence rates of up to 50%,[33] with associated infections.[34] A modification of the Sistrunk technique is currently employed as the standard surgical procedure, without the need to excise the tongue base epithelium. The excision is performed through a transverse midline neck incision just below the cyst. The lesion is dissected from the infra-hyoid strap neck muscles and the laryngeal cartilages. The dissection then proceeds upwards to the region of the hyoid bone. At this point the suprahyoid muscles, i.e. mylohyoid, geniohyoid and genioglossus, are detached from the hyoid bone, while the middle third of the hyoid bone, between the lesser cornu, is cut and mobilized in continuity with the soft-tissue specimen, which includes the thyroglossal duct cyst. The completion of surgery involves further dissection upwards, into the tongue base, to include a core of tissue that should incorporate the tissue tract or raphe between the mylohyoid muscles, a portion of each genioglossus muscles up to the region of the foramen caecum. The technique as described has resulted in a significant reduction in recurrence rates, when compared with simple excision or removal of the cyst alone (Shalang Procedure) (**Figure 39.2**).[35]

Treatment of recurrent cysts and fistulae

Up to 8% of thyroglossal cysts may recur following adequate surgical excision.[36] If a substandard excision, without removal of the central portion of the hyoid bone, had been performed, the classic Sistrunk procedure should be undertaken. However, further surgery following a Sistrunk procedure may be difficult. In these cases, the previous incision scar should be excised and a central compartment neck dissection performed, with excision of the scar tissue up to the foramen caecum.[37, 38]

BRANCHIAL CYSTS

The word 'branchial' is derived from the Greek '*bragchia*' meaning gills. Branchial cysts appear as a developmental failure of the branchial apparatus. Branchial anomalies account for up to 19% of all paediatric cervical masses.[39] They often manifest in young adults with a peak incidence in the third decade. Cysts are usually lined by stratified squamous epithelium except in 10% of cases that may have respiratory epithelium instead; 80% have lymphoid tissue in the outer wall and contain straw-coloured fluid in which cholesterol crystals are found.

AETIOLOGY

Four theories have been suggested to explain the origin of branchial cysts.[40, 41]

Branchial apparatus theory

This theory suggests that branchial cysts represent remains of pharyngeal pouches or branchial clefts, or a fusion of these two elements. The development of the branchial apparatus extends from the 3rd to the 8th week of gestation. This theory would suggest that cysts should be present at birth, whereas the peak incidence is usually in the 2nd to 3rd decade.

Cervical sinus theory

This theory advocates that branchial cysts represent the remains of the cervical sinus of His, which if formed by the second arch growing down to meet the fifth arch. The second arch mesoderm almost covers the neck entirely and forms the platysma muscle.

Thymopharyngeal duct theory

This theory suggests that the cysts are remnants of the original connection between the thymus and the 3rd branchial pouch from which it takes origin. However, a persistent thymic duct has never been described and there has never been a branchial cyst found deep to the thyroid gland.

Inclusion theory

This theory postulates that branchial cysts are epithelial inclusions within a lymph node. This theory is supported by the fact that most branchial cysts have lymphoid tissue in their wall and have been reported in the parotid and the pharynx. This theory also explains why most branchial cysts have no internal opening, are almost unknown in neonates, while the peak age of presentation is much later in life, compared to that seen for most other congenital lesions.

CLINICAL FEATURES

Sixty per cent are located in the upper third of the neck, at the anterior margin of the sternocleidomastoid muscle, although they have been reported in any site of the neck including the parotid gland (**Figure 39.3**).[39] The presentation is a persistent neck swelling in 80% (with 20% intermittent in nature),[42] with 70% appearing cystic although up to 30% may feel solid. In nearly 40% of cases, a history of upper respiratory tract infection prior to noticing the mass can be elicited. Inflamed cysts may be complicated by abscess formation with the possibility of rupture.

DIAGNOSIS AND INVESTIGATIONS

All patients with a suspected branchial cyst should be investigated with at least a FBC and ultrasound-guided FNAC. Ultrasound-guided FNAC yields acellular fluid with cholesterol crystals on microscopy examination. However cytological findings should be interpreted cautiously, given that squamous debris may suggest malignancy. If lymph nodes are necrotic, as seen in squamous cell carcinoma and tuberculosis, they may be difficult to distinguish sonographically from a second branchial cleft cyst, but FNB is usually helpful. CT and MRI scanning is a useful investigation for large cysts to allow surgical planning (**Figure 39.4**).

TREATMENT

Surgical excision is the treatment of choice.[39] This is indicated as branchial cysts have a tendency to become infected, can increase to a large size causing local discomfort, pressure symptoms and obvious cosmetic deformity. The procedure is initiated by a transverse cervical incision made on the neck skin crease overlying the cyst. The platysma is incised and sub-platysmal flaps are elevated. The cervical fascia is incised over the anterior border of

Figure 39.4 MR scan demonstrating a large right branchial cyst.

the sternocleidomastoid muscle, which is retracted laterally. The cyst is then identified and dissected from its fascial attachments and capsule ensuring that the cyst wall is not ruptured. During the dissection the carotid sheath and its contents should be identified and mobilized out of the surgical area. In addition, the marginal branch of the facial nerve, vagus, accessory and hypoglossal nerves should be identified and preserved. The cyst is excised completely and there is usually no need to look for a tract although the tail of the cyst may need to be dissected from the tail of the parotid gland or parapharyngeal space.

KEY POINT

- In patients over the age of 35, cystic neck lumps should be considered metastatic unless proven otherwise. These are usually seen with high-risk HPV-related head and neck squamous cell carcinomas.

BRANCHIAL FISTULAE AND SINUSES

Branchial fistulae are congenital defects consisting of a skin-lined tract, opening internally as a slit on the anterior aspect of the tonsil fossa if it is of second arch origin. The external opening is at the anterior border of the sternocleidomastoid muscle, at the junction of its middle and lower thirds.[27]

Branchial sinuses or branchial pits open along a line between the tragus and the sternoclavicular joint at the anterior border of the sternocleidomastoid muscle but with no internal opening.

AETIOLOGY

They arise from failure of complete development of the branchial apparatus including the first, second, third and fourth arches. During the 4th week of intrauterine life, six branchial arches develop as neural crest cells migrate cranially. During the 5th week, the second branchial arch grows over the third and fourth branchial clefts, forming a cervical sinus. Failure of the cervical sinus to close allows for potential communication with the second branchial pouch in the area of the tonsil fossa, the third pouch in the area of the larynx, and the fourth pouch opening in the pyriform fossa.[27]

CLINICAL FEATURES

Most patients are usually young infants with a discharging sinus, which may or may not have an internal fistulous opening. Clinically, second branchial cleft fistulae are the most common. They have a cutaneous opening along the anterior border of the sternocleidomastoid, usually at the junction of the middle and lower thirds, tracking up between the internal and external carotid arteries ending in the tonsillar fossa. Third and fourth branchial fistulae are rare, opening low in the neck and ending in the pyriform sinus, with an opening that is sometimes visible on endoscopic examination.[43]

DIAGNOSIS AND INVESTIGATIONS

The diagnosis is made on clinical grounds. A contrast swallow or CT fistulogram may be helpful to determine the pathway of the tract, differentiate a sinus from a fistula and aid surgical planning (**Figure 39.5**).

TREATMENT

Surgical excision is the treatment of choice.[44] The excision is performed in a stepladder fashion, removing the mouth of the sinus with an ellipse of neck skin. The tract is followed upwards as high as possible and then another transverse cervical or cervico-facial incision is made. The dissection is then continued to the tonsillar region where the tract usually disappears and should be ligated before it avulses, in order to minimize recurrence of symptoms (**Figure 39.6**).

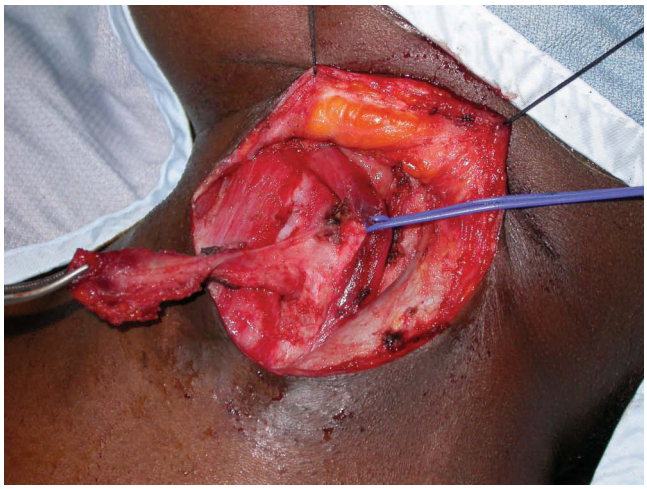

Figure 39.6 Left branchial fistula tract emerging between the constrictor muscles and deep to the omohyoid muscle.

ACQUIRED NECK DISEASES AND MASSES

NON-INFLAMMATORY NECK MASSES

Sebaceous cysts

Sebaceous cysts are skin appendages lesions occurring mainly where there are sebaceous glands and are commonest in hairy skin, particularly in the beard region and scalp.

AETIOLOGY

These cysts develop when the duct of a sebaceous skin gland, responsible for the production of oily sebum protecting the skin, becomes blocked. The retained secretions distend the gland causing progressive enlargement of the cyst.

CLINICAL FEATURES

The lesions can be single or multiple, and of different sizes. They tend to be spherical, smooth and well defined, stretching the overlying skin and the opening of the blocked duct is often visible as a 'punctum'. The cyst may discharge in which case the creamy secreted dry material may accumulate in the centre to form a sebaceous horn, and sebaceous cysts also have a tendency to become infected.

DIAGNOSIS AND INVESTIGATIONS

Sebaceous cysts often display very distinct clinical features and rarely require investigation. They have a non-specific sonographic appearance and FNB/FNAC is not necessary unless there is clinical doubt.

TREATMENT

Surgical excision is the treatment of choice as they are unsightly, have a tendency to grow, burst, get infected and recur. Excision should be done very carefully ensuring that the punctum, and scar if they have been previously incised and drained due to infection, is excised with a small ellipse of healthy skin, to avoid leaving part of the cyst capsule which will lead to the recurrence of the lesion.[45]

Acquired dermoid cysts (implantation dermoids)

Dermoid cysts are usually solitary, with solid and cystic areas containing skin appendages.

AETIOLOGY

Acquired dermoids occur due to a penetrating injury or following surgery resulting in the implantation of dermal or skin structures deep into the subcutaneous tissue.

CLINICAL FEATURES

These cysts present at the site of a penetrating injury and often display solid and cystic areas containing sebaceous material.

DIAGNOSIS AND INVESTIGATIONS

The diagnosis is often made on clinical grounds however ultrasound-guided FNAC may be helpful in some cases where the history of injury is not clear.

TREATMENT

Surgical excision is the treatment of choice. The incision should include the injury tract that should be completely excised in continuity with the cyst to avoid recurrence.[46]

Pilomatrixoma or calcifying epithelioma of Malherbe

Pilomatrixoma is a benign tumour of the prickle cell layer of skin, first described by Malherbe and Chenantais in 1880 as a calcified epithelioma.[47–49] It is most frequently seen in the first two decades of life with two-thirds of these occurring in patients under 10 years of age and is more common in females, with a female preponderance of 3:2. The majority of these tumours (68%) occur in the head and neck region. Malignant transformation has been described but is very rare.

AETIOLOGY

The aetiology is unknown although an episode of local inflammation or trauma may precede their development.

CLINICAL FEATURES

Pilomatrixomas are usually solitary and present as a firm, nodular superficial lesions measuring up to 3 cm in size. There is usually no discolouration but if situated superficially a blue-red colour may be seen.

DIAGNOSIS AND INVESTIGATIONS

Pilomatrixomas have very distinct clinical features. If the diagnosis is suspected, FNAC can be performed. Cytopathological features include the identification of basaloid and squamous cells, calcium deposits and foreign body giant cells.[49]

TREATMENT

Surgical excision is the treatment of choice if the lesion is bothersome or there is doubt about diagnosis. The excision must be carefully performed in the same manner as for an epidermoid cyst as leaving part of the capsule will result in recurrence of the lesion.[50]

Lipomas

Lipomas are benign lesions of the adipose layer. The adipose cells are organized into large lobules divided by loose fibrous septa. Lipomas can be multiple and occasionally can be painful (Dercum's disease). Although the majority of lipomas are sporadic a minority can be familial.[51] The most common familial lipomatosis affecting the head and neck is Madelug's lipomatosis. In the neck region, lipomas may be subfascial or arising within the muscles. They grow very slowly and have a very low risk of malignant transformation.

AETIOLOGY

The aetiology is unknown, however, a history of preceding trauma which leads to breakdown of the adipose layer and abnormal growth has been suggested.[52]

CLINICAL FEATURES

Lipomas usually occur in adults and have a variable size. The tumour has a smooth, lobulated surface with a well-defined edge. They tend to be soft, and as they lie below the dermis, the overlying skin can be moved above the lesion.

DIAGNOSIS AND INVESTIGATIONS

Lipomas have characteristic appearances on USS, and do not require FNAC, unless risk of malignant transformation is suspected. For large lipomas, CT and MRI scanning may be useful in assessing the anatomy and aid surgical planning.[53]

TREATMENT

Surgical excision is the treatment of choice when the lesion is of a large size causing an obvious cosmetic deformity, when there is suspicion of malignancy, or due to patient choice.[53]

INFLAMMATORY NECK MASSES

Acute cervical lymphadenitis

Acute cervical lymphadenitis is common, especially in the paediatric population.[54] It occurs due to viral or bacterial infection in the upper aerodigestive tract, ears, or the skin of the head and neck.

CLINICAL FEATURES

The mass is usually painful and may result in an abscess, in which case the mass appears fluctuant. The patient may be toxic, and the primary infective process is usually evident, although in small children it is not always clear.[55]

DIAGNOSIS AND INVESTIGATIONS

The diagnosis is made on clinical grounds. If the infective episode is severe and the child requires hospital admission, basic haematological and biochemical investigations such as white cell count and CRP levels may aid in diagnosis. Usually, other investigations are not required unless there is clinical suspicion that the patient is developing an abscess, or there are concerns of an underlying neoplastic process. In these situations ultrasound-guided FNAC may aid the diagnosis.

TREATMENT

Treatment is initially empirical, with supportive and broad-spectrum antibiotic therapy, if a bacterial infection is suspected or diagnosed.[56]

Infectious mononucleosis

Infectious mononucleosis or glandular fever is a viral infection caused by EBV that usually affects adolescents and younger adults.[57, 58] EBV infection is also associated with the development of EBV-associated lymphoid or epithelial cell malignancies such as Hodgkin lymphoma, Burkitt lymphoma, nasopharyngeal carcinoma and multiple sclerosis.

AETIOLOGY

EBV is a gamma-herpes virus that infects over 90% of the human population worldwide. It is usually transmitted between individuals in saliva, and establishes replicative infection within the oropharynx as well as life-long latent infection of B cells. Primary EBV infection generally occurs during early childhood.[59]

CLINICAL FEATURES

Primary EBV infection may be asymptomatic or results in a mild self-limiting illness characterized by fever, tonsillitis and lymphadenopathy. If delayed until adolescence or later, it can be associated with the clinical syndrome of infectious mononucleosis, which is characterized by fever, pharyngitis, lymphadenopathy, especially cervical, and malaise. Five per cent of patients develop a maculopapular rash and up to 50% of patients may develop palatal petechiae, acute bacterial tonsillitis usually with a grey fibrinous exudate, splenomegaly and hepatomegaly. In severe cases or in immunocompromised patients, autoimmune haemolytic anaemia, thrombocytopenia, splenic rupture, encephalitis, cranial nerve paralysis and acute

upper airway obstruction as a result of significant tonsillar hypertrophy can develop.[60, 61]

DIAGNOSIS AND INVESTIGATIONS

The diagnosis is made on clinical grounds. The FBC will show more than 50% of mononuclear cells and over 10% atypical lymphocytes. The ESR and CRP will be elevated. Monospot and Paul Bunnell tests will be positive, but may also be negative, especially in the first 2 weeks of the disease. Hepatic enzymes may also be elevated.

TREATMENT

The management is largely supportive with conservative measures, such as rest and hydration. Avoidance of contact sports and heavy lifting is advised for at least 6 weeks, and abstainance from alcohol whilst LFTs remain abnormal.

Broad-spectrum antibiotic therapy may be useful in cases of secondary bacterial infective tonsillitis but ampicillin and its derivatives should be avoided as patients may develop a maculopapular rash. Corticosteroid therapy is advisable in cases of impending airway obstruction, thrombocytopenia and haemolytic anaemia as well as other complications, such as cranial nerve paralysis.[62] Antiviral chemotherapy with acyclovir or famcyclovir has been reported to help in some cases.

Cat scratch disease

Cat scratch disease mainly affects children and young adults with a peak of incidence between 2 and 14 years of age.[63] The disease is more common in the USA where over 24 000 people may be affected every year, but also affects Europe, Africa, Australia and Japan.

AETIOLOGY

Cat scratch disease is caused by the Rickettsia *Bartonella* sp. *Bartonella henselae* is the most common species to cause the widest spectrum of diseases in humans, and cats especially kittens are the main reservoir.

CLINICAL FEATURES

Cervical lymphadenopathy is preceded by erythematous papulae at the site of inoculation. Systemic symptoms such as fever, malaise, anorexia, headache and splenomegaly can occur, but tend to be more common in the immunocompromised patients.

DIAGNOSIS AND INVESTIGATIONS

Serological testing for *Bartonella henselae* is both sensitive and specific for cat scratch disease.[64, 65] More recently polymerase chain reaction RNA of the bacteria has been used for diagnosis.[65]

TREATMENT

Several antibiotics such as gentamicin, rifampicin, ciprofloxacin, and especially azithromycin which is associated with rapid resolution, have been advocated.[65] However, antibiotic use in cat scratch disease without systemic symptoms remains controversial given that infections may resolve without treatment.

Cervical necrotizing fasciitis

This is a rare, but life-threatening infection, which causes progressive necrosis of the skin and subcutaneous tissues.

AETIOLOGY

It results from an odontogenic[66] or tonsillar bacterial infection or may be a complication following deep space neck infections or surgery.[67, 68] *Streptoccocus pyogenes* or *viridans* and mixed anaerobes are the most common aetiological agents.[67]

CLINICAL FEATURES

The diagnosis is made on clinical grounds, with characteristic features such as initial cutaneous cellulitis with disproportionate pain that progresses to necrosis of subcutaneous tissues and skin.

DIAGNOSIS AND INVESTIGATIONS

The white cell count and other inflammatory parameters are raised. An ultrasound or CT scan may show oedema and air pockets of the skin, which are diagnostic features.[67]

TREATMENT

If untreated, cervical necrotizing fasciitis can be fatal, hence early diagnosis and treatment are essential. Intravenous high-dose antibiotic therapy, against aerobic and anaerobic bacteria, with debridement of all necrotic areas, is mandatory.[66, 67]

Chronic cervical lymphadenitis

There is a wide range of chronic inflammatory conditions which may present with cervical lymphadenopathy. They are often associated with systemic symptoms such as malaise, weight loss, anorexia and night sweats, hence the clinical history is very important. These conditions include: HIV and AIDS, sarcoidosis, toxoplasmosis, actinomycosis and tuberculosis (TB). In all cases, excluding TB, lymph node enlargement may be non-specific, hence clinical diagnosis may be difficult.

HIV-AIDS

Acquired immunodeficiency syndrome (AIDS) is a viral disease caused by human immunodeficiency virus (HIV). The infection is classified as:

1. acute infection or seroconversion illness
2. asymptomatic infection
3. persistent generalized lymphadenopathy (PGL)
4. full blown AIDS.

AETIOLOGY

The HIV virus is transmitted via contaminated blood or human secretions. It is prevalent in homosexuals, promiscuous heterosexuals and intravenous drug-abusers.

CLINICAL FEATURES

Up to 30% of seroconverted patients develop PGL and it may be the first manifestation of the disease. As with the acute seroconversion illness, PGL tends to be non-specific and it is characterized by multiple diffuse lymphadenopathy involving two or more extra inguinal sites for <3 months. It may also be an early sign of HIV infection and associated with other manifestations of the disease (**Table 39.1**).[69, 70]

INVESTIGATIONS

When suspected, HIV serology is indicated and diagnostic. FNAC will help the diagnosis of PGL and also assist in elucidating other causes of infection such as TB, Kaposi sarcoma (KS) or non-Hodgkin lymphoma (NHL).

TREATMENT

CD4+ lymphocyte count is the most important reference factor for initiating ART in asymptomatic patients. The large number of available drugs, the increased sensitivity of tests to monitor viral load, and the ability to determine viral resistance, has resulted in a more individualized approach to therapy.[71–73]

Tuberculous adenitis

TB is the oldest documented infectious disease. It is the world's leading cause of death from a single infective agent and is on the increase.[74, 75] Amongst the factors associated with reversal of a previous decline are; increased world travel and a rising incidence of immunodeficiency through HIV infections or intravenous drug abuse. Pulmonary TB is the most common manifestation but extra-pulmonary disease is also increasing in incidence with tuberculous adenitis, or historically named 'scrofula,' being the most common. The word scrofula comes from the Latin 'scrofulae' meaning brood sow. In the middle ages, it was believed that the 'royal touch' of the sovereign of England or France could cure the disease. It was therefore known as the King's Evil. The kings were thought to have received this power having descended from Edward the Confessor, whose legend states he received the power from Saint Remigius. Tuberculous adenitis can affect any lymph node group of the head and neck, including salivary glands and thyroid. Hence it is important to have a high index of suspicion especially in certain ethnic groups where TB may be endemic.

TABLE 39.1 Otorhinolaryngological manifestations of HIV infection

Candidiasis
Hairy leukoplakia
HIV-gingivitis
Necrotizing ulcerative gingivitis
Kaposi sarcoma
Non-Hodgkin lymphoma
Benign lymphoepithelial cyst parotid gland
Benign hyperplasia of the lymphoid tissue
Pneumocystic *carinii neumonia*
Tuberculosis
Opportunistic infections

AETIOLOGY

Mycobacterium TB is an obligate aerobe, non-spore forming slender rod. Humans are the only reservoir and it is usually acquired through contact from a TB infected patient via air-borne transmission. After a short period of replication in the lungs, silent dissemination occurs through the lymphohematogenous system to extra-pulmonary sites including the cervical lymph nodes. This pathophysiological process differs from non-tuberculous atypical mycobacterial adenitis (NTAMA) that is addressed later in this chapter.

CLINICAL FEATURES

Ninety per cent of patients have unilateral involvement mainly of the jugular chain of lymph nodes, followed by the submandibular triangle and the posterior triangle. The lymph nodes are usually firm, painless and present with a characteristic erythematous skin discoloration. If the disease has progressed without being diagnosed, they tend to fistulae, and present with an obvious discharging sinus, or form a 'cold' abscess, which suggests the clinical diagnosis. TB can also affect the ear, nose, pharynx, larynx, salivary and thyroid glands (**Figure 39.7**).[74, 76, 77]

Figure 39.7 Cervical tuberculous adenitis with central necrosis (scrofula).

DIAGNOSIS AND INVESTIGATIONS

Head and neck TB can be very difficult to diagnose, as the clinical features may resemble neoplastic disease, especially when presenting as a single-organ involvement. FBC is non-specific and may be normal. ESR is often elevated. Chest X-ray is mandatory but only up to 20% of patients will have positive changes. Soft-tissue X-rays of the neck may show dystrophic calcification characteristic of TB infection. Mantoux and Heaf test may be non-diagnostic if the patient has been vaccinated against TB, but a grade IV skin reaction on this test may suggest active infection. USS of the nodes will often show multiple, matted nodes but may be non-specific. FNAC can reveal mycobacteria, but is only positive in up to 40% of patients,[78] however, the use of FNAC and polymerase chain reaction allows a quick and accurate diagnosis with high specificity (84%) and sensitivity (100%). Excision biopsy if possible, may be very difficult due to the matted nature of lymph nodes, with an increased risk of bleeding and nerve injury. Alternatively, incisional biopsy of affected nodes should be performed if there is already skin involvement. Samples should be sent for microbiology as well as histological analysis and this should provide the definitive diagnosis. Microbiology analysis may take up to 6 weeks to culture mycobacteria, which may delay treatment. HIV testing is advisable in all patients.[74–78]

TREATMENT

Suspected or proven active tuberculous adenitis is treated with a combination of antibiotics, using a multidisciplinary approach with involvement of respiratory or infectious diseases physicians amongst others.[74, 77] Increasing resistance is currently a significant problem and therefore chemotherapy should be adjusted according to sensitivity. Surgery has a limited role and should only be used as a diagnostic tool or in cases of residual disease.

Non-tuberculous atypical mycobacterial adenitis

Non-tuberculous atypical mycobacteria (NTAM) adenitis is increasingly common in the Western world, and the main difference from tuberculous infection is it tends to affect otherwise healthy immunocompetent children from middle-class families.[79]

AETIOLOGY

Mycobacterium avium and *Mycobacterium avium intracellulare* are the main two pathogens. The route of entry is usually through the oropharynx or the eye, from ingestion of contaminated soil leading to superficial lymphadenopathy in the neck.

CLINICAL FEATURES

Patients affected by NTM are usually young healthy children with multiple cervical lymphadenopathy, but without any symptoms or signs of systemic illness. The enlarged lymph nodes often adhere to skin causing a characteristic red-purple discolouration, with occasional abscess or sinus formation and scarring.[79–81]

DIAGNOSIS AND INVESTIGATIONS

The diagnosis is made on clinical suspicion and confirmation relies on isolating the organisms in culture either through microbiological swabs, FNAC or incisional biopsy.

TREATMENT

Most children may eventually develop their own immunity so a period of observation is advisable especially if the lesion is in the parotid gland. Antibiotic therapy with macrolides such clarithromycin or azithromycin with or without antituberculous therapy has been suggested.[82] In some studies resolution has been achieved in up to 67% of cases, without surgical excision. Surgical curettage with or without antibiotic therapy may be an option and has been used with some success in selected cases especially if full surgical excision may cause significant morbidity.[79] Surgical excision is the ultimate treatment of choice and appears to be more effective than antibiotic therapy alone.[79, 83, 84]

Brucellosis

Brucellosis is primarily a disease of domestic animals and causes contagious abortion or other reproductive problems in cattle (*Brucella abortus*), pigs (*B. suis*), goats (*B. melitensis*), dogs (*B. canis*) and sheep (*B. ovis*). Current pasteurization of dairy products, and other hygienic preventive measures, as well as adequate animal vaccinations has greatly reduced the incidence of the disease in Western countries.[85]

AETIOLOGY

Human spread of *Brucella* spp. occurs by direct contact of infected tissue with the conjunctiva or broken skin, by ingestion of contaminated meat or dairy products, or by inhalation of contagious aerosols.

CLINICAL FEATURES

The clinical features are often non-specific and some infections are subclinical. When the infection is clinically evident, most patients complain of night sweats, chills, undulating pyrexia and malaise. Up to 20% of patients will develop cervical lymphadenopathy and a similar percentage will have splenomegaly.[85]

DIAGNOSIS AND INVESTIGATIONS

When the diagnosis is suspected, blood cultures will often isolate the bacteria and provide a definitive diagnosis. Serology will also provide the diagnosis in those cases where the clinical picture is less obvious.

TREATMENT

This involves combination antibiotic therapy, as single-agent treatment is associated with a 30% risk of relapse. The current WHO recommendation is to use doxycycline 200 mg and rifampicin 900 mg daily for 6 weeks.[86]

Toxoplasmosis

AETIOLOGY

Toxoplasmosis is a worldwide infection caused by *Toxoplasma gondii*, a protozoan transmitted by the ingestion of cysts excreted in the faeces of infected cats, or from eating undercooked beef or lamb.[87]

CLINICAL FEATURES

Congenital infection usually causes hydrocephalus or microphaly. Acquired infections present with generalized malaise, myalgia, fever, cough and a maculopapular rash. If untreated, a chronic phase will develop which may be asymptomatic or present with isolated cervical lymphadenopathy. In immunocompromised patients especially with HIV-AIDS, it may cause encephalitis.[87]

DIAGNOSIS

The diagnosis is made on clinical history and complemented by serology, which will provide confirmation in the majority of cases.[87, 88] The white cell count will show lymphocytosis with atypical mononuclear cells. FNAC may suggest the diagnosis although may be non-specific. Lymph node biopsy will reveal features supporting the diagnosis of toxoplasmosis.[89] CSF analysis may demonstrate the parasite and confirm the diagnosis if there is central nervous system involvement.

TREATMENT

Where treatment is indicated a combination of sulphadimidine, pyrimethamine and folic acid is used.[87] The FBC should be monitored regularly until it becomes normal.

Actinomycosis

AETIOLOGY

Actinomycosis is a bacterial infection caused by *Actinomycosis israelii*, an anaerobic organism which is a commensal in the healthy oral cavity.[90] The organism may become pathogenic when the mucous membrane is injured. Infection is usually associated with severe dental caries and periodontitis.

CLINICAL FEATURES

Patients present with a firm indurated mass with ill-defined edges usually lateral to the mandible. If left untreated the infection may spread to adjacent tissues and may become bony hard. Once the infection is established multiple sinus may develop which discharge pus and watery fluid containing characteristic sulphur granules.

DIAGNOSIS AND INVESTIGATIONS

The diagnosis may be suspected on clinical grounds, which are usually typical. FNAC may show sulphur granules that are diagnostic. Tissue biopsy will again show characteristic colonies with sulphur granules, but the organism may be difficult to culture.[90]

TREATMENT

Therapy is with intravenous benzylpenicillin or cephalosporins in high doses that may be required for at least 6 weeks. However, longer courses of antibiotic treatment for up to 1 year may be necessary in resistant cases or immunocompromised patients. Removal of carious teeth is imperative to eliminate the site of origin of the infection.[90]

NECK ABSCESSES

In this section only the superficial soft tissue neck abscesses will be addressed as the deep neck infections will be addressed in Chapter 40, Neck space infections.

Superficial soft tissue neck abscesses

Cervical abscesses are relatively uncommon in comparison with the number of acute and chronic lymphadenitis that present in the paediatric and adult population. However, small children under the age of 4 years and immunocompromised patients appear to be more susceptible.

AETIOLOGY

Failure of patients to eliminate the organism at the site of attachment to the nasal or pharyngeal epithelium will result of spread of infection via lymphatics causing suppuration. The most common pathogens are: *Staphyloccoccus aureus*, *Streptococcus pyogenes* and in the paediatric population atypical mycobacteria.[56]

CLINICAL FEATURES

The development of the abscess is often preceded by an upper respiratory tract infection although on occasions this may not be obvious from the history, especially in the younger paediatric population.

DIAGNOSIS AND INVESTIGATIONS

Diagnosis is based on clinical suspicion. FBC, ESR and CRP are useful to ascertain the inflammatory origin and monitor progress. USS and CT scanning will be useful to determine whether the mass has a central area of necrosis that may require incision and drainage.

TREATMENT

The treatment involves a combination of supportive therapy, broad-spectrum antibiotics until culture and sensitivity

results are available, plus or minus surgical incision and drainage. Repeated needle aspiration is not usually helpful unless the abscess is arising from a thyroglossal duct cyst in which case incision and drainage is reserved as a last resort after antibiotic therapy and repeated aspiration has failed.[56]

MISCELLANEOUS RARE CAUSES OF NECK MASSES

Organized haematomas

AETIOLOGY

Blunt or penetrating trauma of the neck.

CLINICAL FEATURES

Patients present with a neck mass that usually causes local discomfort and occasionally constant pain.

DIAGNOSIS AND INVESTIGATIONS

A history of trauma is usually present although not always obvious. Ultrasound-guided FNAC will suggest diagnosis but the sonographic appearances depend on the age of the haematoma. If in the liquid state, blood can be aspirated. CT and MRI scanning will display distinct radiological features and determine the anatomical extent. Follow-up USS may be helpful to ensure there is no underlying lesion.

TREATMENT

Surgical excision is the treatment of choice although it may be difficult due to the surrounding fibrosis of the lesions.[91, 92]

Castleman disease

Castleman disease is a rare entity which is characterized by hyperplasia of lymph nodes and capillary proliferation that usually affects adolescents and young adults. Three histological patterns have been described: hyaline vascular type, plasma cell type and mixed type. Two clinical types have been identified; a localized type (ECL) usually of benign clinical course and a multicentric type (ECM) of worst prognosis as it may lead to the development of non-Hodgkin lymphoma.[93–95]

AETIOLOGY

It is unknown, although up to 50% of multicentric variants are caused by Kaposi sarcoma-associated virus (KSHV) a gamma herpes virus that causes KS and primary effusion lymphoma.

CLINICAL FEATURES

Patients usually present with a progressively enlarging lateral cervical lymphadenopathy often associated with an autoimmune iron-deficiency anaemia. ECM may present with B symptoms such as fever, anorexia and weight loss.

DIAGNOSIS AND INVESTIGATIONS

FBC shows iron-deficiency anaemia and the ESR is elevated. FNAC often shows a lymphocytic aspirate that is not normally diagnostic therefore surgical excision is advised for histological diagnosis. Imaging studies are often not useful.

TREATMENT

Anaemia is difficult to treat, as it does not often respond to iron supplements. Surgical excision is usually therapeutic in ECL although it may be difficult in ECM. Treatment with ganciclovir or the antiCD20 B-cell monoclonal antibody, may improve outcome in some patients with ECM. With ECM long-term follow-up is advised, in association with the haemato-oncology team.[93–95]

Kikuchi disease

Kikuchi disease (KD) is a self-limiting disease of lymph nodes that usually affects young women. It is also known as Kikuchi-Fujimoto disease and was first described by Kikuchi from Japan in 1972.[96, 97] Histologically, it is characterized by a histiocytic necrotizing lymphadenitis.

AETIOLOGY

The pathogenesis is unknown, however an autoimmune aetiology has been proposed as some human leucocyte antigen (HLA) class II genes, are more frequent in patients with KD. An association with systemic lupus erythematosus (SLE) has also been reported.

CLINICAL FEATURES

The disease often presents with persistent or intermittent fever as well as tender enlarged cervical lymph nodes. It is self-limiting but it may take up to 3 months to resolve.

DIAGNOSIS AND INVESTIGATIONS

The diagnosis can be confirmed by histopathological analysis of a lymph node following open biopsy.

TREATMENT

The disease is usually self-limiting and does not respond to antibiotic therapy. Supportive therapy with non-steroidal anti-inflammatory drugs may help to alleviate the lymphadenopathy, tenderness and pyrexia.[96, 97]

Kawasaki disease

Kawasaki disease (KWD) is an acute, self-limited vasculitis of childhood although it may also occur in adults. Tomisaku Kawasaki, from Japan, first described the condition in 1967.[98] In some countries, KWD has now surpassed acute rheumatic fever as the leading cause of acquired heart disease in children.

AETIOLOGY

The acute presentation and clustering of cases may indicate an infectious aetiology, however, the exact aetiology is unknown.

CLINICAL FEATURES

The illness is characterized by fever, bilateral non-exudative conjunctivitis, erythema of the lips and oral mucosa, changes in the extremities, rash, and cervical lymphadenopathy. Coronary artery aneurysms or ectasia develop in approximately 15–25% of untreated children and may lead to myocardial infarction and sudden death.[99, 100]

DIAGNOSIS AND INVESTIGATIONS

Diagnosis is based on the recognition of the characteristic sequence of clinical events, none of which are pathognomonic. Establishing the diagnosis may be further complicated by the occurrence of other, seemingly unrelated, clinical features, such as irritability, neck stiffness, sterile pyuria, pneumonitis and hepatitis. There is no laboratory test that can aid in confirming the diagnosis.

TREATMENT

Treatment is with intravenous gammaglobulin therapy and high doses of aspirin.[99, 100]

BOX 39.1 Other rare causes of cervical neck masses

- Sarcoidosis
- Fibromatosis colli
- Rosai–Dorfman disease
- Kimura's disease
- Dermatofibroma
- Prominent transverse process of atlas

KEY EVIDENCE

- This is a heterogeneous chapter addressing multiple benign disorders of the head and neck.
- There is lack of substantive high-level evidence due to the intrinsic nature of the disorders included. In most areas the evidence is at most level 2.
- Troublesome congenital abnormalities of the head and neck region are best treated with surgical excision whenever possible.
- Head and neck tuberculosis is where evidence is higher and should be treated with systemic antituberculous therapy with surgery having a limited role in its management.

KEY POINTS

- Benign disorders and masses of the neck represent a heterogenous group of diseases and its knowledge is imperative for the treating clinician.
- The evaluation and management of the patients presenting with neck lumps should be addressed with a clear systematic and uncompromising approach.
- All patients presenting with neck lumps should undergo ultrasound-guided fine needle aspiration whenever possible.
- The majority of congenital neck masses should be treated with meticulous surgical excision to avoid recurrence.
- Acquired non-inflammatory benign neck masses should be treated mainly with surgical excision to establish the histological diagnosis.
- Acquired inflammatory masses of the head and neck should be treated medically – with antibiotic therapy – and surgery is reserved for diagnosis – if this has not been established clinically or by FNAC – and for incision and drainage of established abscesses.
- Head and neck abscesses can be treated with repeated aspiration if indicated but incision and drainage should be always considered.

SEARCH STRATEGY

Data in this chapter may be updated by a search of Pubmed and Medline using the keywords: deep neck spaces, deep neck space infection, deep neck infection and deep neck space infections.

INTRODUCTION

Neck space infections arise through a variety of aetiological processes and cause a diverse clinical picture. They carry the potential to cause life-threatening complications and death, although in the modern era with availability of broad-spectrum antibiotics, cross-sectional imaging and modern theatre facilities, the mortality rate is low. Nonetheless, appropriate and successful management requires a thorough understanding of the anatomy of the neck, knowledge of usual causative organisms and their sensitivities to commonly available antibiotics, clinical diagnostic skills and formulation of multi-speciality treatment plans with potential input from anaesthetists, microbiologists, oral and maxillofacial surgeons, otorhinolaryngologists, paediatricians and radiologists.

ANATOMICAL CONSIDERATIONS

The cervical fascia invests muscles and organs of the neck thereby limiting and influencing the direction of spread of infection. The relationship of the fascial layers to each other and adjacent structures creates potential spaces and therefore understanding the anatomy of the cervical fascia is key to understanding the anatomy of neck space infections.

The cervical fascia is divided into two layers: the superficial layer that envelops platysma and the muscles of facial expression and the deep layer, which, in turn, comprises superficial, middle and deep layers (**Figure 40.1**).

Superficial (or investing) layer of deep cervical fascia

This is attached superiorly to the superior nuchal line of the occipital bone, the mastoid process, the zygomatic arch, the inferior border of the mandible, the hyoid and the spinous processes of the cervical vertebrae. Inferiorly it is attached to the manubrium, the clavicle and the acromium and spine of the scapula. It forms the roof of the anterior and posterior triangles of the neck.

This layer forms the most superficial fascial boundary of the deep neck spaces and provides a robust barrier to the spread of infection, such that abscesses tend to track deep to it into adjacent, deeper neck spaces, or even into the mediastinum. It is not unusual for compression of deep structures to occur as a consequence of an accumulating abscess contained by the superficial layer of deep cervical fascia even to the extent that airway compromise becomes evident.[1]

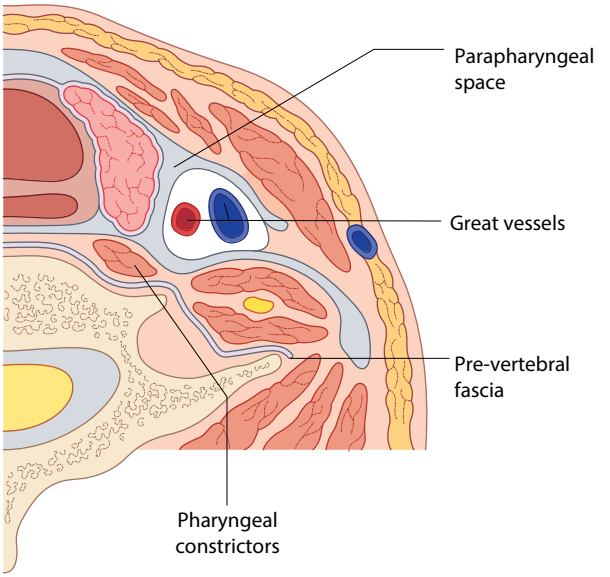

Figure 40.1 Axial section through C7 vertebrae detailing superficial cervical fascia, superficial, investing and deep layers of deep cervical fascia

Middle layer of deep cervical fascia (or pre-tracheal fascia)

This is limited to the anterior aspect of the neck; it splits to invest the thyroid gland, trachea and oesophagus and blends with the carotid fascia laterally. It descends into the superior mediastinum where it blends with the fibrous pericardium. Consequently, it bounds a deep space which extends from the neck into the mediastinum.

Deep layer of deep cervical fascia (prevertebral fascia)

The deep layer of deep cervical fascia (prevertebral fascia) forms part of a fascial sleeve for the prevertebral muscles that surround the vertebral column. It extends from the skull base to the third thoracic vertebra where it fuses with the anterior longitudinal ligament in the posterior mediastinum; it extends laterally as the axillary sheath.

Alar fascia

The alar fascia is a component of the deep layer of deep cervical fascia although it is described separately from it as it lies between the deep and middle layers of deep cervical fascia (**Figure 40.2**).[2]

NECK SPACES

Several deep neck spaces are classically described, created by the boundary layers of cervical fascia described above.

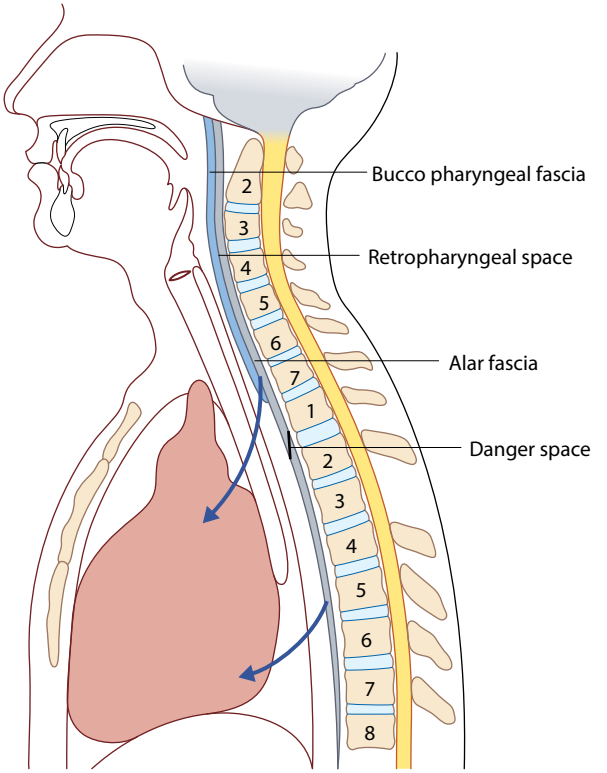

Figure 40.2 Sagittal section detailing retropharyngeal, prevertebral and 'danger spaces'.

Parapharyngeal space (lateral pharyngeal space, pharyngomaxillary space)

The parapharyngeal space (lateral pharyngeal space, pharyngomaxillary space) (**Figure 40.1**) forms an inverted cone with its base bounded by the petrous portion of the temporal bone and its apex at the level of the hyoid. It is crossed by the styloid process and attachments thus dividing the space into pre and post-styloid compartments. The pre-styloid compartment (anterior to the styloid complex) contains fat, connective tissue, the maxillary artery, the inferior alveolar nerve, the lingual nerve and the auriculotemporal nerve. In contrast, the post-styloid (posterior) compartment contains the carotid sheath and its contents, the glossopharyngeal and hypoglossal nerves, the sympathetic chain and associated lymph nodes.

Retropharyngeal space

The retropharyngeal space (**Figure 40.2**), contains lymph nodes and is bounded anteriorly by the middle layer of deep cervical fascia and posteriorly by the alar fascial component of the deep layer of deep cervical fascia. It extends craniocaudally from the skull base to the tracheal bifurcation. A midline raphe is formed by the attachment of the superior constrictor muscles to the alar fascia.

So-called 'danger space'

The so-called 'danger space' is a potential space between the alar fascia anteriorly and the deep layer of deep cervical fascia (prevertebral fascia) posteriorly, which extends craniocaudally from the skull base to the diaphragm.

Submandibular space

The submandibular space (**Figures 40.4, 40.5** and **40.6**), is bounded by the floor of mouth mucosa cranially and the mandible laterally, whilst the anterior and posterior bellies of the digastric muscle form the anteroinferior and posteroinferior boundaries respectively. The mylohyoid muscle lies anteriorly and the stylomandibular ligament posteriorly. The space is divided by the mylohyoid muscle into sublingual and submandibular compartments which contain the sublingual salivary gland and lymph nodes respectively. These compartments are continuous around the posterior free edge of the mylohyoid muscle and the submandibular gland lies within both as it straddles this free edge.

Masticator space

The masticator space, (**Figures 40.7** and **40.8**), lies inferior to the skull base (greater wing of sphenoid and squamous temporal bone) and is bounded by the pharyngeal mucosa medially and the medial surface of the ramus of the mandible laterally. The lateral pterygoid plate, superior constrictor, tensor and levator palatini muscles constitute the posteromedial border and can be subdivided into superficial temporal space superolaterally, deep temporal space superomedially, pterygoid space inferomedially and masseteric space inferolaterally. Communication with the pterygopalatine fossa exists via the pterygomaxillary fissure; the muscles of mastication and the mandibular division of the trigeminal nerve are contained within it.

Visceral space

The visceral space is formed anteriorly by the middle layer of deep cervical fascia that envelops the thyroid and the trachea, and posteriorly by the deep layer of deep cervical fascia. It contains the larynx, hypopharynx, cervical oesophagus, proximal trachea, thyroid and parathyroid glands.

Carotid space

The carotid space is a potential space formed by the carotid sheath, which is in itself formed from all three layers of deep cervical fascia blending together. It contains the common carotid artery, the internal jugular vein (IJV) and the vagus nerve.

Parotid space

The parotid space (**Figure 40.9**), is formed by the superficial layer of deep cervical fascia that splits to invest the parotid gland and therefore also contains the facial nerve, the retromandibular vein, the external carotid artery and its terminal branches.

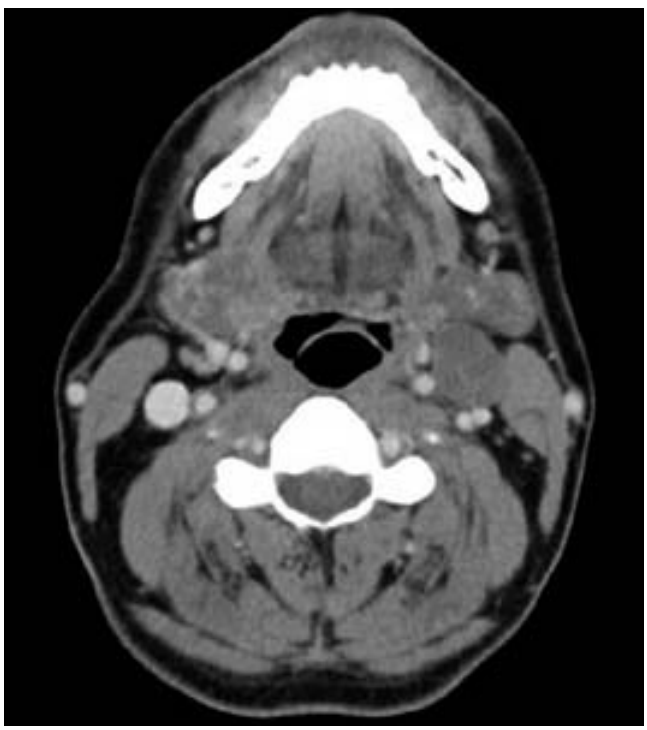

Figure 40.3 Axial contrast-enhanced CT scan demonstrating lymph node abscess in left parapharyngeal space. Note posterior displacement of internal jugular vein and medialization of carotid vessels. Mass effect and mucosal oedema cause subtle asymmetry of the airway at the level of the epiglottis.

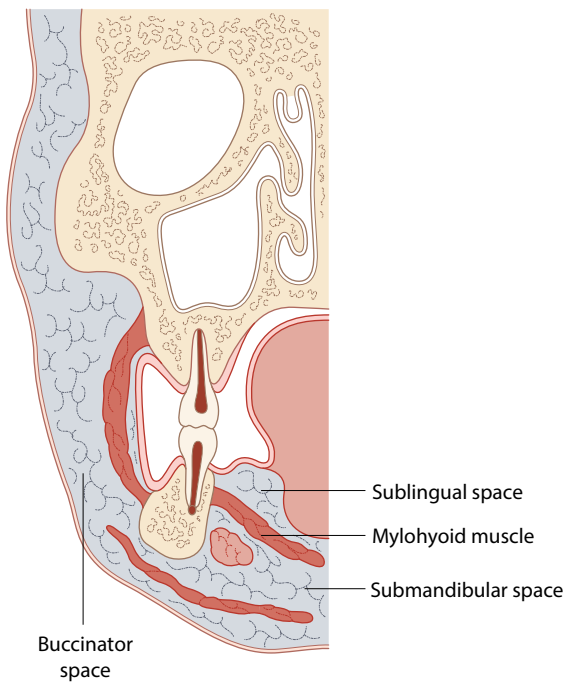

Figure 40.4 Submandibular, sublingual and buccinator spaces.

Figure 40.5 Pointing abscess of the submandibular space.

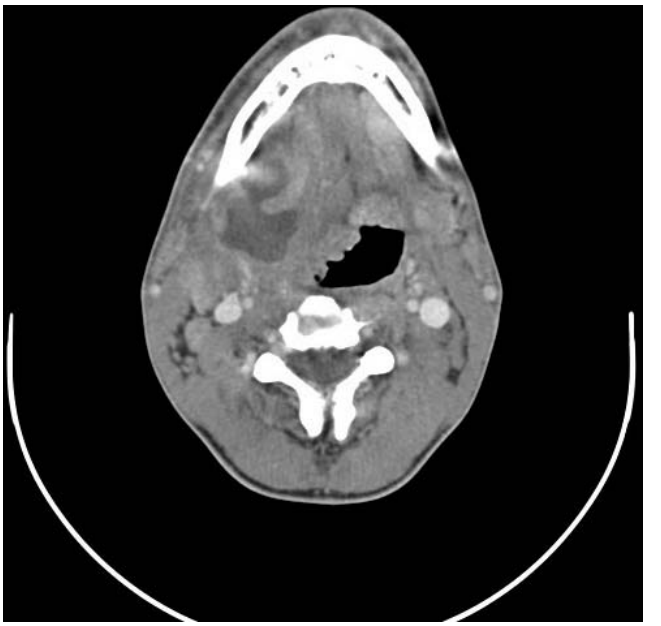

Figure 40.6 Axial contrast-enhanced CT scan showing abscess in the right submandibular space (different patient to Figure 40.5). A large hypodense area medial to the mandible is evident with ring enhancement and oedema affecting the soft tissues superficial and deep to the abscess. The pharyngeal lumen is narrowed and shifted to the contralateral side.

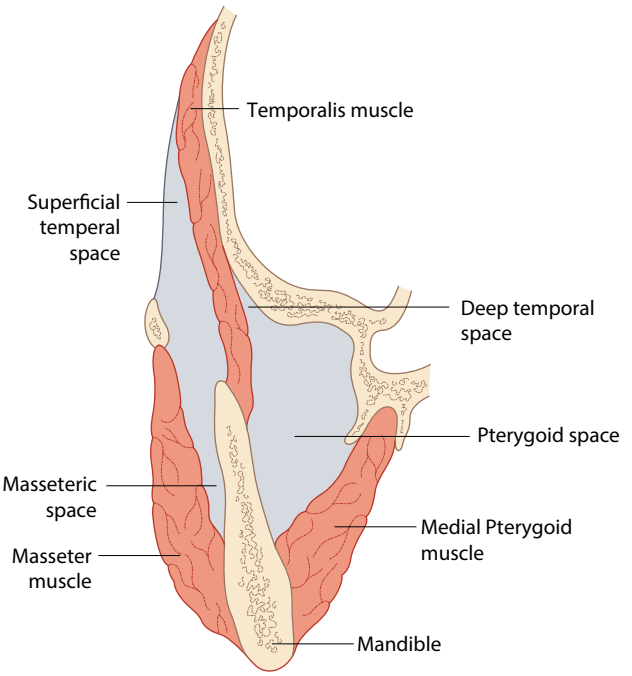

Figure 40.7 The masticator space and subdivisions.

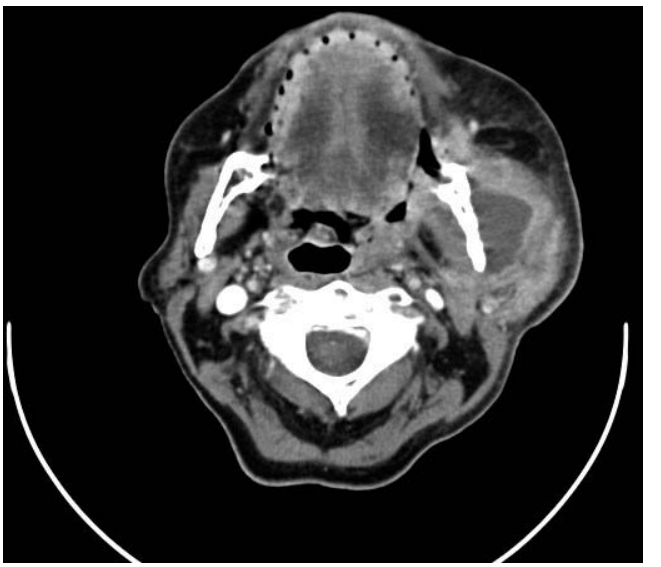

Figure 40.8 Axial contrast-enhanced CT scan showing masseteric space and pterygoid space abscess. Ring enhancement is evident around the hypodense abscess cavity as well as gross soft tissue oedema superficial and deep to the abscess causing asymmetry of the appearance of the external neck and deviation of the pharyngeal lumen contralaterally.

Peritonsillar space

The peritonsillar space lies lateral to the pharyngeal tonsil and medial to the superior constrictor muscle. It contains loose connective tissue and is the site of accumulation of pus in peritonsillar abscess, or quinsy.

It is important to note that direct communication exists between the posterior aspect of the parapharyngeal space and the retropharyngeal space, as well as the anterior parapharyngeal space and the submandibular space. Moreover, peritonsillar space abscess can directly spread to the parapharyngeal space by direct extension, via lymph and/or blood vessels which traverse the superior constrictor muscle.[1–3]

AETIOLOGY

In the pre-antibiotic era, 70% of deep neck space infections (DNSI) were caused by pharyngotonsillitis and 20% by odontogenic infection.[4] Recent published data

Figure 40.9 Parotid space abscess.

demonstrate that odontogenic infection is now the most common aetiological factor causing 31–49% of DNSIs.[5, 6] Peritonsillitis is variably mentioned as the underlying cause in approximately 7–20% of cases[4, 7] whilst in 17–57% of cases the primary source of infection is not clinically apparent.[7, 8]

Retrospective case series which include large numbers of cases describe various aetiological factors including ingestion of foreign body, coexisting Diabetes Mellitus (DM), Human Immunodeficiency Virus (HIV) infection and intravenous (IV) drug abuse although it is notable that the patient demographics from which these series have drawn their cases show considerable baseline variability and it would be inappropriate to extrapolate these findings to groups outwith the study populations. It is worth mentioning other cause of DNSI that have been reported and include mycobacterial infection, mandibular fracture, sialolithiasis, parotitis and thyroid infection.[4, 5, 7, 8]

INCIDENCE

The true incidence of DNSI is unknown. According to Hospital Episode Statistics (HES) data in England during the 12 months to the year ending March 2016 it is recorded that there were 216 admissions for 'drainage of retropharyngeal abscess'. By comparison there were 5246 admissions for 'drainage of abscess of peritonsillar region' during the same period. Other neck space infections are not coded in the data presented.[9]

CLINICAL FEATURES

Pain is the pre-eminent symptom in most patients, and in some published series it is almost ubiquitous.[7] Pain is usually focused at the neck space harbouring the infection, but can also be referred to the ear, cause odynophagia, trismus or torticollis. Other symptoms caused will depend on the site of infection but include dysphonia, dysphagia, sialorrhoea or cough.

The most common clinical signs include swelling in the neck, pyrexia and trismus. Skin fistulae, medial or anterior displacement of the lateral or posterior pharyngeal wall and gingival swelling occur commonly but less frequently.[5, 7, 10, 11]

Most series,[4, 5, 8, 13–16] although not all,[7, 11] demonstrate that males are more commonly affected than females by a ratio of approximately 1.6:1. The majority of patients, male and female, occupy the 20–40 year age range, with an estimated median age in the mid-30s. However, the age range of affected patients is wide and all age groups can be affected. The reasons why patients in their 3rd – 5th decades show the highest incidence of disease, and, why males are more commonly affected is not known. Co existent diseases (see 'Aetiology' above) include dental caries, DM, IV drug abuse and HIV infection.

CLINICAL ASSESSMENT AND INVESTIGATIONS

Assessment begins by taking a full clinical history and performing a thorough examination including fibre-optic nasendoscopy to assess the upper aerodigestive tract mucosa and airway patency simultaneously. Relevant clinical findings will lead the attending clinician to the differential diagnosis and will influence the subsequent lines of enquiry and early / emergent management strategy. Due to the potential for DNSIs to cause significant airway compromise it is essential that the initial assessment of patients is performed with high priority consideration as to whether the patient requires emergency airway management (see 'Airway management' below) or whether the patient is capable of maintaining their own airway for the foreseeable future. This initial assessment is important as it determines whether cross-sectional imaging with the patient in a supine position is safe to undertake. Consequently, it is essential that initial assessment is undertaken by clinicians experienced in the management of patients with airway compromise and who have the necessary clinical skills to be able to achieve a secure airway in the event of sudden deterioration.

When either the airway is secured or it is considered that significant airway compromise is not imminent, then cross-sectional radiological assessment can be undertaken in the form of contrast-enhanced CT as this is considered to be the gold-standard imaging modality.[17, 18] Due to potential communication of the visceral, retropharyngeal, danger and prevertebral spaces with the mediastinum it is imperative to include the mediastinum in the CT scan field. Where there is clinical concern of septic emboli spreading to the brain, lungs or liver these organs are required to be imaged also. Abscesses will demonstrate characteristic rim enhancement on CT imaging and cellulitis may be represented by fluid and fat stranding in the subcutaneous tissues and along fascial planes, whilst

myositis is suggested by enlargement and hyperenhancement of the adjacent musculature. Ultrasound imaging, in contrast, may be helpful to determine whether an abscess has sufficiently liquified to be drained, and may also be useful in targeting attempted drainage.[18] Where the infection is considered to be of dental origin an orthopantomogram is acquired, as it is in the case of infection of unknown aetiology.

Regular observations including pulse rate, blood pressure, temperature and respiratory rate are mandatory – the frequency of such observation being determined by the clinical condition of the patient. Blood is sent for urea, creatinine and electrolytes assays, blood count, including differential white cell count, C-reactive protein and erythrocyte sedimentation rate. Consideration is given as to whether it is appropriate to send blood for microbial culture. Pustulating skin fistulae and obviously infected dental sockets or roots may be swabbed for microbial cultures but routine pharyngeal microbiology swabs **must not** be taken to avoid precipitating an airway crisis as a consequence of triggering the gag reflex. If the clinical condition of the patient dictates it, appropriate venous access should be secured. Finally, it is essential that the patient is managed in a clinical environment commensurate with the severity of their presenting clinical condition.

SPECIFIC NECK SPACE INFECTIONS

- **Ludwig's angina** is considered to be an acute infection of bilateral sublingual and submandibular spaces, and the submental space. It occurs most commonly as a consequence of anterior dental infection.[1] In these patients, as a consequence of the underlying abscess, there is typically gross oedema of the floor of mouth and of the anterior tongue, such that the tongue becomes grossly swollen, protuberant and immobile. The result is significant risk of life-threatening airway obstruction and decision-making with regard to airway management needs to include emergency tracheostomy as a primary treatment option.
- **The parapharyngeal space (PPS), Figures 40.1** and **40.3**, can become infected either primarily or as a consequence of direct spread of infection from the submandibular and/ or the retropharyngeal spaces. A recent study of DNSIs of this space in particular demonstrated different clinical features depending on whether the anterior or posterior parapharyngeal space (APPS and PPPS respectively) is infected. The difference arises due to the anatomical contents of these sub-spaces. The APPS contains fat which in the presence of infection may liquefy, develop into pus and hence abscess formation. The PPPS is rich in lymph nodes and vessels and it is suggested that infection in this space causes lymphadenitis, but is less likely to develop into abscess formation. Consequently, APPS and PPPS infections can have different clinical courses and be managed differently, with a more conservative approach possible in PPPS and aggressive surgical drainage of pus required for APPS.[11] However, the ultimate distinction between the two is made on imaging.
- **Suppurative thyroiditis** – This usually occurs due to abnormal development of the 4th branchial pouch, resulting in a communicating sinus between the pharynx and the thyroid bed; in some cases, a proximal orifice may be identified as a defect in the mucosa of the piriform fossa. Patients with episodic recurrent suppurative thyroiditis need to have this diagnosis considered. Barium swallow examination and/ or cross-sectional imaging with contrast-enhanced CT or MRI may demonstrate the sinus tract, and the orifice will usually be identifiable by careful inspection of the piriform fossa mucosa under anaesthetic using direct pharyngoscopy. There is a preponderance for these affecting the left side of the hypopharynx. Treatment consists of excision of the tract of the sinus including the ipsilateral hemithyroid, although care must be taken to accurately identify the relationship of the sinus to the recurrent laryngeal nerve, as this can be variable.[19, 20] Alternatively, obliteration of the sinus opening in the hypopharynx using monopolar diathermy has been reported to be effective at preventing further infections.[21]
- **Retropharyngeal space abscess** is usually caused in adults by penetrating trauma through the posterior mucosal wall of the pharynx or cervical oesophagus. However, in children it is more commonly secondary to suppuration of retropharyngeal lymph nodes following an upper respiratory tract infection, although retropharyngeal lymph nodes tend to regress after the age of 5 years. Retropharyngeal space abscess is a significant cause of airway compromise, and as a consequence surgical tracheostomy is not uncommonly required.[22, 23] An attempt to intubate the patient using an endotracheal tube by an unprepared anaesthetist may lead to traumatic rupture of the abscess due to pressure from the tip of the intubating laryngoscope and subsequent flooding of the unprotected airway with pus and blood. Once the airway has been appropriately secured the abscess can be drained in a controlled fashion, the incision is made at the most inferior aspect of the collection such that further accumulation of pus will drain through gravity into the pharynx.
- **Masticator space infection** (**Figure 40.9**), usually arises secondary to odontogenic infection or less commonly as spread from infection in the parotid space, submandibular space or peritonsillar space. Trismus is a common clinical finding due to oedema of the adjacent pterygoid muscles.

MICROBIOLOGY AND PHARMACOLOGY

A wide range of aerobic, microaerophilic and anaerobic microorganisms typically colonize neck space infections.[24]

The predominant organism responsible for a given DNSI is influenced by the prime aetiological factor, be it odontogenic infection, penetrating neck trauma, IV drug use etc. The prevalence of these factors may depend on the geography, socio-economic status, and the incidence of predisposing factors such as coexisting DM and HIV infection.

However, there are some similarities reported in the literature with regards to microbiology of DNSIs as *Peptostreptococcus* spp., Viridans Group Streptococci, *Staphylococcus aureus*, *Staphylococcus epidermidis* and *Klebsiella pneumoniae* are commonly present in many reported series.

Typically, broad-spectrum antibiotics are commenced prior to receipt of microbiological results, and in cases of a conservatively managed patient there may be no microbiological input into the case at all. Indeed, even with adequate pus sampling, failure to culture the causative bacteria occurs in approximately 25% of cases, which may be due to the difficulties in culturing anaerobic organisms that are inherently fastidious, or liberal use of antibiotics prior to referral to secondary care facilities.[8] Polymicrobial cultures are commonly seen.[25]

Antibiotic treatment should reflect the diverse nature of the microbiology of the condition, the likely aetiology and consider the possibility of adverse reactions in patients receiving treatment. Broad-spectrum antibiotics are prescribed, either amoxicillin/clavulanate, or 2nd or 3rd generation cephalosporins with metronidazole.[26] Antibiotic prescriptions need to be reviewed in the light of culture results and changed as necessary. Clindamycin and vancomycin are commonly used second-line agents, or potential first-line agents when drug allergy or sensitivity restrict choice. Resistance to antimicrobial agents is rising as evidenced by reported resistance to clindamycin in 11–18%, erythromycin 14%, penicillins 7–8% and aminopenicillins 0–3%[26] of cases.

SURGICAL TREATMENT

The maxim that one should '...never let the sun set on an undrained abscess' has guided management of neck space abscesses for many years especially in an era that predated cross-sectional imaging. Changes in radiological assessment have moved away from plain soft-tissue neck X-rays and now utilize contrast-enhanced rapid acquisition spiral tomographic scanners that permit reconstruction of acquired images in multiple planes and three dimensions. There has consequently been a considerable increase in the sensitivity and specificity of abscess diagnoses on radiological grounds, and with it the opportunity for a more conservative approach to management of selected cases.

Nonetheless, neck space infection is a potentially life-threatening infection; crude mortality rates of up to 2% have been published. The primary responsibility of the treating clinician is to ensure protection of the airway and to consider surgical drainage of pus secondarily. However, not all neck space infections develop into abscesses and even in the presence of an imaging study diagnostic of a small deep-seated abscess there has been a trend towards conservative management ***wherever possible.***[7]

Most published series report the surgical intervention rate, with the reported median confirming that approximately 80% of patients underwent surgical drainage of an abscess – although the range of reported intervention between studies is wide (10–100%)[5, 7, 8, 10, 13, 16, 27] and probably reflects preferred local practice rather than anything else. Usually, in cases without impending airway compromise, surgical intervention follows a period of conservative management of 24–48 hours with a decision taken to surgically intervene if there is a clinical failure to respond (persistent pyrexia, persisting or worsening pain, etc).

If surgical treatment is deemed necessary various treatment options exist. Conventional surgical drainage procedures incise the skin over the area of maximal fluctuance or induration. Following evacuation of the abscess contents, the abscess wall is curetted, and any loculations or boundaries between adjacent and communicating neck spaces (e.g. retropharyngeal, parapharyngeal and submandibular) are broken down – often with digital dissection. In classical Ludwig`s angina it is often necessary to undertake this procedure through multiple transcutaneous stab incisions to ensure that adequate drainage of these spaces bilaterally is achieved. Drains are secured to permit further drainage of pus; it is the author's preference to use soft, non-suction drains that protrude through the incised wound into the abscess cavity, with simple dry gauze dressings adhered distally. The activity of the drain is recorded by the number of dressing changes per 24 hours and they are removed gradually over a period of days. In the case of odontogenic infections the underlying dental infection(s) should be dealt with during the same general anaesthetic.

Consideration has been made of the merits of ultrasound-guided aspiration of pus compared to open surgical drainage and a small prospective randomized trial reported a shorter length of hospital stay (reduced mean length of hospital stay from 5.2 to 3.1 days), a 41% cost reduction and no difference in treatment efficacy or complication rate in the ultrasound aspiration group.[28] Also, microbiology sampling by aspiration rather than by microbiological swabs of an incised abscess has been shown to increase the isolation of anaerobes and reduce the detection of potential skin contaminants.[24, 28, 29]

AIRWAY MANAGEMENT

Maintaining a patent and safe airway is the pre-eminent step in management of patients with DNSI. Mortality can occur as a consequence of asphyxiation and hypoxia as well as delayed septic complications. The widespread use of antibiotics has reduced the morbidity and mortality from pharyngeal oedema and permits a watch and wait policy in selected cases. Conversely, large abscesses causing a precarious airway demand a coherent management

strategy to secure the airway prior to surgical drainage and to maintain the airway post-operatively. The decision as to which management strategy can be adopted is made on a case-by-case basis.

Conventional endotracheal intubation is not always possible due to trismus, reduced neck extension, laryngopharyngeal oedema, mass effect from the abscess and the friable nature of the mucosa that readily obstructs the view due to contact bleeding. It is of utmost importance that induction of anaesthesia does not lead to a situation where neither ventilation nor intubation by conventional means are possible. Algorithms are available online[32] to assist joint anaesthetic/surgical airway management and these should be agreed by the attending teams prior to commencement of any procedure.

Options available to manage the airway are numerous and described elsewhere (see Chapter 72, Upper airway obstruction and tracheostomy).[12, 33] Patients that have impending airway obstruction need to be transferred to a place of safety for airway management. In the UK, this would be to one of the anaesthetic rooms in a hospital operating theatre complex with anaesthetic and surgical staff who have the appropriate experience in attendance. Once a plan of action has been agreed, the surgical and scrub teams prepare the operating theatre in anticipation of the requirement for an emergency tracheostomy in the event of failed intubation and loss of airway. If it is deemed that the patient will tolerate it, it is advisable to infiltrate 2% lignocaine with 1:80000 adrenaline solution into the skin at the site of potential tracheostomy prior to the commencement of the anaesthetic procedure. In the event of an emergency tracheostomy being required, this step does not need to be repeated; the adrenalin will have caused some local vasoconstriction and it lessens the likelihood of flexion/extension reaction from a semi-obtunded patient resultant from the pain of the skin incision.

If there are sufficient concerns that oral or nasal intubation are unlikely to be successful, it is preferable to perform tracheostomy under local anaesthetic as an emergency (as opposed to an emergency 'crash' tracheostomy).

Once the airway has been secured, the abscess can be drained in a controlled fashion as described.

COMPLICATIONS

The incidence of resulting complications reported varies considerably between different published series. Tracheostomy, either planned or 'crash', is reported as necessary in 3–22% of patients[4, 7] and, in general, patients with Ludwig's and retropharyngeal abscess are at higher risk of airway obstruction than those presenting with lateralized abscesses. Other complications include pneumonia, IJV thrombosis, carotid artery aneurysm and rupture, necrotizing fasciitis, skin fistulae and defects, vocal cord and facial palsies, descending mediastinitis, upper gastrointestinal bleeding, iatrogenic bleeding following tracheostomy insertion, septic emboli from IJV thrombosis, sepsis, multi-organ failure and death.

Patients with pre-existing comorbidities are more likely to suffer from complications, as are patients that have infection in more than two neck spaces: in the series published by Kang et al,[34] abscess formation in the retropharyngeal space was always seen in patients that developed mediastinitis. A combined thoracic and cervical exploration may be required to facilitate adequate treatment in those patients.

PAEDIATRIC NECK SPACE INFECTION

It has been reported that neck space infection in children is increasing in incidence[22, 35] although it is not known why. Childhood neck space infection more often results from an upper respiratory tract infection than from odontogenic aetiologies and methicillin-resistant *Staphylococcus aureus* (MRSA) is more frequently isolated from pus samples taken from DNSIs in children than in adults. Two published series have reported positive MRSA cultures in 27% and 42% of cases.[36, 37] There is a rising prevalence in cultures positive for MRSA demonstrated year on year in many other series.[36–40]

The management principles for paediatric DNSI are no different to those required to treat adults; maintenance of the airway is of the utmost importance, appropriate imaging to identify the distribution of affected neck spaces, treatment with broad-spectrum antibiotics until specific sensitivities are known, and a decision made and then frequently reviewed as to whether surgical drainage is indicated, and if so, what form that surgical procedure takes.

Paediatric patients demonstrate different physiological responses to sepsis in comparison to adults and attending clinicians need to understand and respond to alterations in the clinical condition of paediatric patients with rapidity in order to avoid catastrophic deterioration of the airway and/or the cardiovascular system from impending septic shock.

CONCLUSION

Neck space infections are seen in patients of all ages, with and without pre-existing comorbid problems. Assessment and management of the airway is required alongside treatment of the underlying infection with broad-spectrum antibiotics. Life-threatening complications occur frequently which, given the anatomy of the cervical fascia, may be distant to the primary focus of infection. However, mortality is usually an infrequent occurrence with appropriate and timely treatment.

FUTURE RESEARCH

- Ongoing publication of prospectively collated microbiology data pertaining to DNSI to assess changing trends in causative organisms and patterns of antibiotic resistance, ideally across different continents.
- Safety and efficacy of conservative vs. US-guided aspiration vs. surgical management of DNSI in children with small localized abscesses.
- How is the incidence and management of DNSI being influenced by rising incidences of diabetes and obesity?

KEY POINTS

- Understanding of the anatomy of cervical fascial planes is key to diagnosis and management.
- Cross-sectional imaging, where possible, will provide extremely useful information to aid treatment decision-making.
- Generally the mantra 'Never let the sun set on undrained pus' should be adhered to. But, some non-toxic patients with small localized abscesses may be suitable for more conservative management. These patients require very close clinical observation and regular review of their treatment plan in the light of a changing clinical situation.

INTRODUCTION

The importance of the mouth to the otolaryngologist is self-evident. It is the portal of entry for visual examination of the oropharynx, larynx and the opening of the Eustachian tube in the nasopharynx. It is also the portal of entry for many of the surgical procedures undertaken in these regions. Malformations in the mouth, such as cleft palate, may have important consequences for the healthy functioning of the system. Infection or tumours from the mouth may spread to involve the ear, nose and throat. As an example, infection from maxillary teeth may give referred pain to the nasal region, while infection from mandibular teeth may spread to the neck and result in severe (and sometimes fatal) respiratory embarrassment. Due to its close physical (and also evolutionary) relationship to the ear, clinical conditions affecting the jaw joint (temporomandibular joint) may need to be differentiated from those directly involving the ear.

The mouth can be subdivided into the vestibule (external to the teeth) and the oral cavity proper (internal to the teeth). The mouth extends from the lips and cheeks externally to the anterior pillars of the fauces (palatoglossal arches) internally, where it continues into the oropharynx. The roof of the mouth is the palate and separates the oral and nasal cavities. The floor of the mouth is formed by the mylohyoid muscles and is occupied mainly by the tongue. The lateral walls of the mouth are defined by the cheeks and retromolar regions. Opening into the mouth are three pairs of major salivary glands (parotid, submandibular and sublingual) and numerous minor salivary glands (labial, buccal, palatal, lingual).

PALATE

The palate is divisible into two regions: the hard palate in front and soft palate behind.

Hard palate

The skeleton of the hard palate is formed by the palatine processes of the maxillae and the horizontal plates of the palatine bones. The oral mucosa is bound tightly to the underlying periosteum. In its more lateral regions it also possesses a submucosa where the main neurovascular bundles lie (**Figure 41.1**).

The periphery of the hard palate surrounding the necks of the teeth is termed the gingiva and a zone similarly lacking submucosa runs anteroposteriorly in the midline as a narrow, low ridge; the palatine raphe. At the anterior

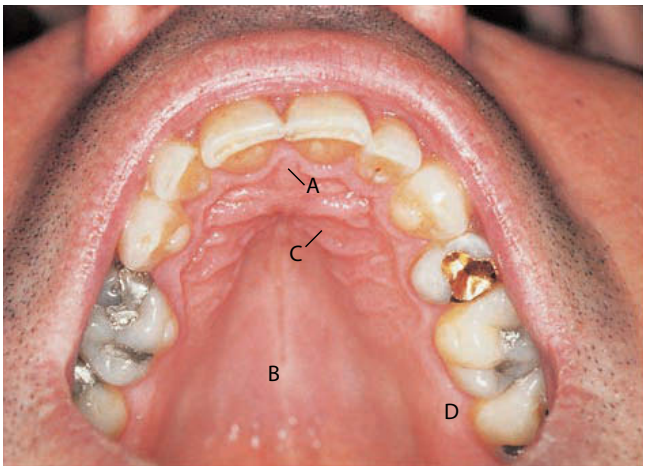

Figure 41.1 The hard palate. A, Incisive papilla; B, palatine raphe; C, palatine rugae; D, alveolus. Reprinted from Ref. 1 by permission from Elsevier.

Figure 41.2 The soft palate and oropharyngeal isthmus. A, Palatoglossal fold; B, palatopharyngeal fold; C, palatine tonsil; D, uvula. Reprinted from Ref. 1 by permission from Elsevier.

extremity of the raphe behind the incisor teeth is a small prominence, the incisive papilla that covers the incisive fossa at the oral opening of the incisive canal. Radiating outwards from the palatine raphe in the anterior half of the hard palate are irregular transverse ridges or rugae. The pattern of rugae is unique for the individual and has been used in forensic science to identify a dead individual.

The submucosa in the posterior half of the hard palate contains minor mucous salivary glands. These secrete through numerous small ducts although, bilaterally, larger ducts collecting from many of these glands often open at the paired palatine foveae. These are two sagittally elongated depressions, sometimes a few millimetres deep, which flank the midline raphe at the posterior border of the hard palate.

The upper nasal surface of the hard palate is the floor of the nasal cavity and is covered by ciliated respiratory epithelium. The lower oral masticatory surface is covered by keratinized epithelium.

Soft palate

The soft palate is a mobile flap suspended from the back of the hard palate, sloping down between the oral and nasal parts of the pharynx (**Figure 41.2**). The boundary between the hard and soft palate may be distinguished by a change in colour, the soft palate being a darker red with a yellowish tint. In its relaxed and pendant position, its anterior (oral) surface is concave, with a median raphe. Its posterior aspect is convex and continuous with the nasal floor. A median conical process, the uvula, projects downwards from its posterior border. Just behind and medial to each upper alveolar process, in the lateral region of the anterior part of the soft palate, a small bony prominence can be felt. This is produced by the pterygoid hamulus, an extension of the medial pterygoid plate of the sphenoid bone.

The soft palate contains an aponeurosis, muscular tissue, vessels, nerves, lymphoid tissue and mucous glands, while some taste buds are situated on its oral aspect.

A thin, fibrous palatine aponeurosis is attached to the posterior border of the hard palate. It represents the expanded tendons of the tensor veli palatini muscles and provides the fibrous skeleton of the soft palate that supports the palatine musculature. The aponeurosis is thick in the anterior two-thirds of the soft palate but very thin further back. The palatine muscles are attached to the aponeurosis.

CHEEKS

The cheeks are covered externally by skin and internally by mucous membrane (buccal mucosa) and have a muscular skeleton, the buccinator. Internally, the pink mucosa of the cheek adheres firmly to the buccinator muscle. Few structural landmarks are visible. The parotid duct drains in the region of a small parotid papilla opposite the maxillary second molar tooth. A whitish line (the linea alba) may be seen at a position related to the occlusal plane of the teeth: this hyperkeratinized line is presumably the result of continuous mild trauma during biting. Yellow patches (Fordyce's spots) representing ectopic sebaceous glands may be evident on the internal surface of the cheek. Their numbers increase in puberty and in later life. Behind the molar teeth, a fold of mucosa can be seen extending from the upper to the lower alveolus, especially when the mouth is opened widely. This fold covers the pterygomandibular raphe that extends from the pterygoid hamulus to the back of the mylohyoid line. The raphe gives origin to the buccinator muscle from its anterior surface and the superior constrictor muscle from its posterior surface. The entrance to the pterygomandibular space lies lateral to the pterygomandibular raphe and medial to the ridge produced by the anterior border of the ramus of the mandible.

Between the lips or cheeks and the teeth lies a slit-like space, the oral vestibule. Where the mucosa covering

the alveolus of the jaw is reflected onto the lips and cheeks, a trough or sulcus is formed which is called the fornix vestibuli. With the teeth in occlusion, a space still exists behind the last molar tooth (retromolar region), allowing for the passage of fluids when the jaws are wired together following fractures. A variable number of sickle-shaped folds containing loose connective tissue run across the fornix vestibuli. The upper and lower labial frena (or frenula) are constant folds in the midline. Other folds may traverse the fornix near the canines or premolars.

LIPS

Like the cheeks, the lips are covered externally by skin and internally by mucous membrane (labial mucosa) that is smooth and shiny and shows small elevations caused by underlying mucous glands. The lips have a muscular skeleton, the orbicularis oris muscle.

The red zone of the lip (the vermilion) is a feature characteristic of man. In the upper lip, the vermilion protrudes externally in the midline to form the tubercle, above which is situated a grooved region termed the philtrum. The lower lip shows a slight depression corresponding to the tubercle.

FLOOR OF THE MOUTH

This comprises a small horseshoe-shaped region beneath the tongue (**Figure 41.3**). Near the base of the tongue in the midline, a fold of tissue called the lingual frenum is seen to extend onto the inferior surface of the tongue. The sublingual papilla is a conspicuous centrally positioned protuberance at the base of the tongue. The submandibular salivary ducts open into the mouth at this papilla. On either side of the sublingual papilla are the sublingual folds, beneath which lie the submandibular ducts and sublingual salivary glands. The muscle forming the floor of the mouth is the mylohyoid muscle.

OROPHARYNX

The oropharynx extends from the soft palate to the upper border of the epiglottis (see **Figure 41.2**). Its lateral wall consists of the palatopharyngeal arch, with the palatine tonsil lying between this arch and the palatoglossal arch anteriorly. The two arches are also known as the pillars of the fauces. The floor of the oropharynx is occupied by the pharyngeal aspect of the tongue.

The aperture of communication between the mouth and pharynx, the oropharyngeal isthmus, is situated between the soft palate above and the dorsum of the tongue below, bounded on both sides by the palatoglossal arches. Each palatoglossal arch runs downwards, laterally and forwards and contains the palatoglossus muscle with its covering mucous membrane. The approximation of the arches, to shut off the mouth from the oropharynx, is essential to deglutition.

Palatine tonsil

The palatine tonsil is a mass of lymphoid tissue situated in the lateral wall of the oropharynx, where it lies within the tonsillar fossa between the diverging palatopharyngeal and palatoglossal arches. It forms the anteroinferior part of Waldeyer's ring of lymphoid tissue. This ring surrounds the openings into the digestive and respiratory tracts and consists of the palatine and tubal tonsils laterally, the nasopharyngeal tonsil (adenoids) and smaller collections of lymphoid tissue in the intertonsillar intervals posterosuperiorly, and the lingual tonsil inferiorly.

The medial (free) surface of the palatine tonsil projects into the oropharynx and usually presents a pitted appearance. These pits, 10–15 in number, lead into a system of blind-ending, often highly branching crypts, which extend through the whole thickness of the tonsil. The deep (lateral) aspect of the tonsil is covered by the fibrous tissue of the tonsillar hemicapsule that can be easily separated throughout most of its extent from the underlying superior constrictor muscle. An important and sometimes large vein (the external palatine or paratonsillar vein) descends from the soft palate lateral to the tonsillar hemicapsule before piercing the pharyngeal wall. Haemorrhage from this vessel can complicate tonsillectomy.

The size of the tonsil varies greatly and at puberty may be approximately 10–15 mm in transverse diameter and approximately 20–25 mm in the vertical dimension. The tonsil starts to atrophy at puberty so that, by old age, only a little tonsillar lymphoid tissue remains.

A more detailed treatment of the oropharyngeal anatomy can be found in Chapter 44, Anatomy of the pharynx and oesophagus.

TONGUE

The tongue is a highly muscular organ of deglutition, taste and speech. It is partly oral and partly pharyngeal in position. It has dorsal and ventral surfaces and a root and an apex.

Figure 41.4 The dorsum of the tongue. 1, Sulcus terminalis; 2, posterior third (pharyngeal part); 3, lingual follicles; 4, pillars of fauces; 5, epiglottis; 6, vallecula defined by median and lateral glosso-epiglottic folds; 7, anterior two-thirds (palatine part); 8, circumvallate papillae; 9, foramen caecum. Reprinted from Ref. 2 by kind permission of Informa Healthcare.

The curved dorsum of the tongue (**Figure 41.4**) shows an anterior, oral part facing upwards and a posterior, pharyngeal part facing posteriorly, the two being separated by a V-shaped groove, the sulcus terminalis. The sulcus terminalis runs anterolaterally towards the palatoglossal arches from a median depression, the foramen caecum that indicates the site of the embryonic thyroid diverticulum that gives origin to the thyroid gland.

The anterior two-thirds of the tongue in front of the sulcus terminalis is related to the hard and soft palates above and has a tapered tip or apex touching the incisor teeth, and a margin in contact with the gums and teeth. On each side, in front of the palatoglossal arch, are four or five vertical folds, the foliate papillae. The dorsum has a longitudinal median sulcus and is papillated and the three remaining types of papillae representing the filiform, fungiform and circumvallate papillae. Of the papillae, all except the filiform papillae bear taste buds.

The keratinized filiform papillae are the most numerous. They are minute conical or cylindrical projections, arranged in diagonal rows extending anterolaterally, parallel with the sulcus terminalis, except at the apex where they are transverse. They have a masticatory function, appearing to increase the friction between the tongue and food, facilitating the movement of particles by the tongue within the oral cavity. The fungiform papillae appear scattered on the lingual margin but also irregularly on the dorsal surface, where they may occasionally be numerous. They differ from filiform papillae by their larger size, rounded (mushroom) shape and deep red colour (due to their thin, non-keratinized epithelium and highly vascular connective tissue core). The circumvallate papillae are cylindrical structures, 1–2 mm in diameter, varying in number from about 8 to 12 and form a V-shaped row immediately in front of the sulcus terminalis. Each papilla is circumscribed by a groove.

The pharyngeal (postsulcal) third of the tongue lying behind the sulcus terminalis forms the base of the tongue and lies posterior to the palatoglossal arches. It forms the anterior wall of the oropharynx and its mucosa is reflected on to the epiglottis posteriorly by a median and two lateral glossoepiglottic folds. The folds surround two depressions or valleculae. The pharyngeal part of the tongue has underlying lymphoid nodules that produce low-surface elevations collectively termed the lingual tonsil. The ducts of small seromucous glands open on the apices of these elevations.

The ventral inferior surface of the tongue (see **Figure 41.3**) is smooth, purplish and reflected on to the oral floor and gums. Anteriorly is a median mucosal fold, the lingual frenum. Lateral to this fold on either side, a deep lingual vein is visible, and lateral to the vein is a fringed mucosal ridge, the plica fimbriata.

ORAL MUCOSA

The lining of the mouth, the oral mucosa, is continuous with the skin at the vermilion of the lip and with the pharyngeal mucosa at the oropharyngeal isthmus. It varies in structure, appearance and function in different regions of the oral cavity.[1] It can be classified into masticatory, lining and specialized mucosae. Masticatory mucosa covers the gingivae (gums) and hard palate. Its epithelium is keratinized (often parakeratinized) and has a dense fibrous lamina propria. It is pink in colour. A submucosa is absent from the gingivae and the midline palatine raphe, but is present over the rest of the hard palate, especially where it contains mucous salivary glands, and also the greater palatine nerves and vessels. The masticatory mucosa is bound firmly to underlying bone or to the necks of the teeth, forming in the gingivae and palatine raphe a mucoperiosteum.

Lining mucosa covers the internal surfaces of the lips and cheeks, floor of the mouth, soft palate, ventral surface of the tongue and the alveolar processes (excluding the gingivae). It is red in colour, having a non-keratinized, stratified, squamous epithelium overlying a loosely fibrous and elastic lamina propria, and the submucosa contains some fat deposits and collections of minor mucous glands.

Gustatory mucosa covers the anterior two-thirds of the dorsum of the tongue. The vermilion (red zone) of the lip that separates the skin from lining mucosa has been regarded by some as being specialized, as it shares features of both lining and masticatory mucosa.[2] The epithelium that attaches the tooth to the gingiva, the junctional epithelium, also has features that distinguish it from all other stratified squamous epithelia (e.g. internal and external basal lamina).

MUSCLES OF THE ORAL CAVITY

Buccinator muscle

The muscle of the cheek is the buccinator (**Figure 41.5**). Above and below it is attached to the outer surfaces of the alveolar processes of the maxilla and mandible by the side of the molar teeth. Behind, it arises from the anterior margin of the pterygomandibular raphe (a thin band of tendinous fibres passing between the hamulus of the medial pterygoid plate down to the posterior end of the mylohyoid line of the mandible). Additionally, a few fibres arise from a fine tendinous band that bridges the interval between the maxilla and the pterygoid hamulus. From these origins the fibres of buccinator pass forwards towards the angle of the mouth. Here, the central fibres decussate, those from below crossing to the upper part of the mouth, those from above crossing to the lower part. The highest and lowest fibres of buccinator continue forwards to enter their corresponding lips without decussation.

The buccinator muscle compresses the cheek against the teeth and gums during mastication and assists the tongue in directing food between the teeth. When the cheeks have been distended with air, the buccinators expel it between the lips, for example, when playing wind instruments. The buccinator muscle is innervated by the buccal branch of the facial nerve. Its arterial supply is derived from the facial and maxillary (buccal branch) arteries.

Reprinted from Ref. 2 by kind permission of Informa Healthcare.

Mylohyoid muscle

The main muscle forming the floor of the mouth is the mylohyoid muscle (**Figures 41.6** and **41.7**). Immediately above it is the geniohyoid muscle. The mylohyoid muscle is a flat, triangular sheet attached to the mylohyoid line of the mandible. The posterior fibres pass medially and slightly downwards to the front of the body of the hyoid bone near its lower border. The middle and anterior fibres from each side decussate in a median fibrous raphe that stretches from the symphysis menti to the hyoid bone.

The mylohyoid muscle elevates the floor of the mouth in the first stage of swallowing. It also aids in elevating the hyoid bone or depressing the mandible when the hyoid bone is fixed. The muscle is supplied by the mylohyoid branch of the inferior alveolar nerve and derives its blood supply from three sources: the lingual artery (sublingual branch),

the maxillary artery (the mylohyoid branch of the inferior alveolar artery) and the facial artery (submental branch).

Geniohyoid

This narrow muscle lies above the medial part of the mylohyoid (**Figure 141.8** and see also **Figure 41.6**). It arises from the inferior genial tubercle (mental spine) on the back of the symphysis menti. It runs backwards and slightly downwards to attach to the anterior surface of the body of the hyoid bone.

The geniohyoid muscle elevates the hyoid bone and draws it forwards. When the hyoid bone is fixed, the geniohyoid muscle depresses the mandible. The muscle is supplied by the first cervical spinal nerve, through the hypoglossal nerve. The blood supply is derived from the lingual artery (sublingual branch).

Muscles of the tongue

The muscles of the tongue comprise both extrinsic and intrinsic muscles, the former extending outside the tongue and moving it bodily, the latter lying wholly within it and altering its shape.

The **extrinsic** musculature is composed of four pairs of muscles: genioglossus, hyoglossus, styloglossus and palatoglossus.

GENIOGLOSSUS MUSCLE

The genioglossus muscle lies near the midline (see **Figures 41.6** and **41.8**). It arises from the superior genial tubercle (mental spine) behind the mandibular symphysis and above the origin of the geniohyoid muscle. From its origin, the fibres fan out as they pass backwards and upwards. The inferior fibres are attached to the upper anterior surface of the hyoid body near the midline. Intermediate fibres pass backwards into the posterior part of the tongue, and superior fibres ascend forwards to enter the whole length of the ventral surface of the tongue from root to apex, intermingling with the intrinsic muscles.

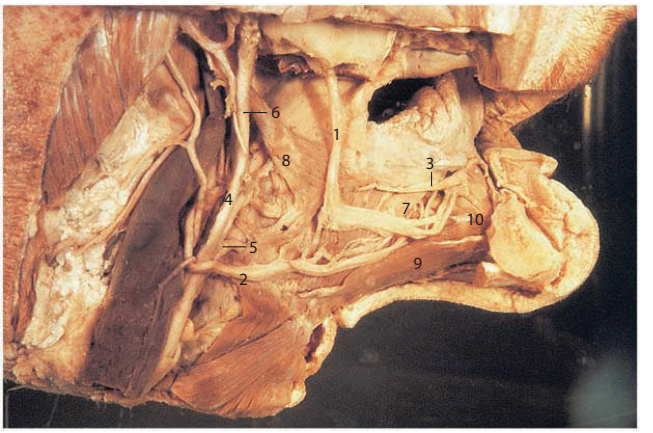

Figure 41.8 Muscles of the tongue and structures on the hyoglossus muscle in the floor of the mouth. 1, Lingual nerve; 2, hypoglossal nerve; 3, submandibular duct (cut); 4, external carotid artery; 5, lingual artery; 6, glossopharyngeal nerve (cut); 7, hyoglossus muscle; 8, styloglossus muscle; 9, geniohyoid muscle; 10, genioglossus muscle. Reprinted from Ref. 1 by permission from Elsevier.

The genioglossus muscle brings about the forward traction of the tongue to protrude its apex from the mouth. Acting bilaterally, the two muscles depress the central part of the tongue, making it concave from side to side. Acting unilaterally, the muscle helps move the tongue to the opposite side. Genioglossus receives its motor innervation from the hypoglossal nerve. Its blood supply is derived from the lingual artery (sublingual branch) and the facial artery (submental branch).

HYOGLOSSUS

This muscle arises from both the greater cornu and from the front of the body of the hyoid bone (**Figure 41.8**). It runs up to insert into the side of the tongue between the inferior longitudinal muscle medially and styloglossus laterally.

The hyoglossus muscle depresses the tongue. It is innervated by the hypoglossal nerve. Its arterial supply is derived from the lingual (sublingual branch) and the facial arteries (submental branch).

STYLOGLOSSUS

This muscle arises from near the apex of the styloid process (anterolateral aspect) and from the styloid end of the stylomandibular ligament (a fibrous cord extending from the tip of the styloid process to the lesser cornu of the hyoid bone) (**Figure 41.8**). From this origin, the muscle runs downwards and forwards to enter the substance of the tongue, decussating with fibres of hyoglossus.

The styloglossus muscle acts to pull the tongue upwards and backwards. The muscle is supplied by the hypoglossal nerve and derives its blood supply from the sublingual branch of the lingual artery.

PALATOGLOSSUS

Although this muscle is most closely associated with the soft palate in function and innervation, it is described here with the other tongue muscles. The palatoglossus arises from the palatine aponeurosis and passes to the side of the tongue within the palatoglossal arch. Acting bilaterally, the muscles narrow the oropharyngeal isthmus and can also help raise the sides of the tongue. Unlike the other tongue muscles, the palatoglossus is innervated, not by the hypoglossal nerve, but by the cranial portion of the accessory nerve through the pharyngeal plexus. Its blood supply is derived from the ascending pharyngeal and facial (ascending palatine) arteries.

INTRINSIC MUSCLES OF THE TONGUE

These comprise four groups: the superior and inferior longitudinal, the transverse and the vertical muscles.

The superior longitudinal muscle forms a thin stratum of longitudinal and oblique fibres lying beneath the lining of the dorsum of the tongue. The inferior longitudinal muscle is a narrow band of muscle beneath the inferior surface between the genioglossus and hyoglossus muscles. The transverse muscle fibres pass laterally from the median fibrous septum to the submucous fibrous tissue at the lingual margin. The vertical muscle fibres extend from the dorsal to the ventral aspects of the tongue in the borders of its anterior part.

When the superior and inferior longitudinal muscles contract, the tongue tends to shorten. In addition, the superior longitudinal fibres also pulls the apex and sides upwards to make the dorsum concave, while the inferior longitudinal fibres pull the apex down to make the dorsum convex. The transverse muscle contracts to narrow and elongate the tongue while contraction of the vertical muscle makes the tongue flatter and wider. Acting alone or in pairs and in endless combination, the intrinsic muscles give the tongue precise and highly varied mobility, important not only in alimentary function but also in speech. All intrinsic lingual muscles are supplied by the hypoglossal nerve and derive their blood supply from the lingual artery.

MUSCLES OF THE LIPS

The muscles surrounding the mouth and contributing to the lips are derived from two different sources. Neighbouring muscles of facial expression converge on the angle of the mouth and pass through into the lips. For the upper lip, these are chiefly from the buccinator and depressor anguli oris, and for the lower lip, the buccinator, levator anguli oris and zygomaticus major. In addition, an accessory muscle, incisivus labii superioris, is present in the upper lip, arising from the floor of the incisive fossa of the maxilla above the eminence of the lateral incisor tooth and running laterally within the upper lip to the modiolus (a zone of muscle intersection just beyond the corner of the mouth). A similar strip of muscle is present in the lower lip, incisivus labii inferioris, arising from the floor of the incisive fossa of the mandible and running laterally within the lip to the modiolus.

The muscles of the mouth are capable of various movements, including closing, protrusion and pursing of the lips. The muscles are innervated by the facial nerve (buccal and mandibular branches) and derive their blood supply from the facial (superior and inferior labial), maxillary (mental and infraorbital branches) and superficial temporal arteries.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE OF THE ORAL CAVITY

Arteries

The main arteries to the teeth, palate and cheeks are derived chiefly from the maxillary artery, a terminal branch of the external carotid. The lips are mainly supplied by the superior and inferior labial branches of the facial artery. The floor of the mouth and tongue are supplied by the lingual arteries. The cheek is supplied by the buccal branch of the maxillary artery.

Teeth in the lower jaw are supplied by the inferior alveolar (dental) artery, a branch of the maxillary artery (see **Figure 41.5**). It lies in the infratemporal fossa where it gives off a mylohyoid branch before entering the mandibular foramen. The inferior alveolar artery then traverses the mandibular canal (accompanied by the inferior alveolar nerve) to supply the mandibular molars and premolars and divides into the incisive and mental branches below the premolar teeth. The incisive branch continues below the incisor teeth (which it supplies) to the midline. The mental artery leaves the mental foramen to supply the chin.

Teeth in the upper jaw are supplied by the posterior, middle and anterior superior alveolar (dental) arteries that form a plexus of vessels. The posterior superior alveolar artery usually arises from the third part of the maxillary artery in the pterygopalatine fossa. It descends on the infratemporal surface of the maxilla to supply molar and premolar teeth, adjacent bone and the maxillary sinus, and provides superficial branches that continue over the alveolar process to supply the gingivae. The anterior superior alveolar artery arises from the infraorbital artery that enters the orbit posteriorly through the inferior orbital fissure to run in the infraorbital groove and canal with the infraorbital nerve. It curves through a fine canal (canalis sinuosus) to supply the upper incisor and canine teeth and the mucous membrane in the maxillary sinus. A middle superior alveolar artery is often present and supplies the premolar teeth.

The gingival tissues derive their blood supply from the maxillary and lingual arteries. In the lower jaw, the buccal gingiva posteriorly is supplied by the buccal artery (a branch of the maxillary artery as it crosses the lateral pterygoid muscle) and by perforating branches from the

inferior alveolar artery. Anteriorly, the labial gingiva is supplied by the mental artery and by perforating branches of the incisive artery. The lingual gingiva is supplied by perforating branches from the inferior alveolar artery and by the lingual artery of the external carotid.

In the upper jaw, the buccal gingiva around the molar and premolar teeth are supplied by gingival and perforating branches from the posterior and middle superior alveolar arteries and by the buccal artery. The labial gingiva of the anterior teeth is supplied by labial branches of the infraorbital artery and by perforating branches of the anterior superior alveolar artery. The palatal gingiva around the maxillary teeth is supplied primarily by branches of the greater palatine artery, a branch of the third part of the maxillary artery in the pterygopalatine fossa.

The hard palate derives its blood supply principally from the greater palatine artery, a branch of the third part of the maxillary artery. The greater palatine artery descends (with its accompanying nerve) in the palatine canal. In the canal, it gives off two or three lesser palatine arteries that are transmitted through lesser palatine canals to supply the soft palate and tonsil (anastomosing with the ascending palatine branch of the facial artery). The greater palatine artery emerges on to the oral surface of the palate at the greater palatine foramen and runs in a curved groove near the alveolar border of the hard palate to the incisive canal. It ascends this canal and anastomoses with septal branches of the nasopalatine artery.

The tongue and floor of mouth are supplied mainly by the lingual artery that arises in the neck from the external carotid artery (see **Figure 41.8**). It reaches the floor of the mouth by passing between the hyoglossus muscle and the middle constrictor of the pharynx. Near the tip of the tongue, the lingual artery anastomoses with its fellow from the opposite side. The branches of the lingual artery in the floor of the mouth are the dorsal lingual branches, the sublingual artery and the deep lingual artery.

The dorsal lingual arteries (usually two or three) arise medial to the hyoglossus muscle and ascend to the posterior part of the dorsum of the tongue. They supply the mucous membrane of the dorsum of the tongue, the palatoglossal arch, soft palate, tonsil and epiglottis.

The sublingual artery arises from the lingual artery at the anterior margin of hyoglossus. It passes forwards between the genioglossus and mylohyoid muscles to the sublingual gland. It also provides a branch that enters a small foramen (lingual foramen) on the mandible, situated in the midline on the posterior aspect of the symphysis, immediately above the genial tubercles.

The deep lingual artery is the terminal part of the lingual artery and is found on the inferior surface of the tongue near the lingual frenum.

In addition to the lingual artery, the tonsillar and ascending palatine branches of the facial and ascending pharyngeal arteries also supply tissue in the root of the tongue. In the region of the valleculae, epiglottic branches of the superior laryngeal artery anastomose with the inferior dorsal branches of the lingual artery.

Veins

As with veins elsewhere in the body, the pattern of drainage for the mouth and associated structures is variable and only a generalized account will be given.

The cheek is drained by the buccal vein that leads to the pterygoid venous plexus in the infratemporal fossa. Venous blood from the lips is collected by the superior and inferior labial veins and drains into the facial vein. The veins of the hard palate accompany the arteries and drain largely to the pterygoid plexus.

Veins accompanying the superior alveolar arteries drain the upper jaw and teeth anteriorly into the facial vein, or posteriorly into the pterygoid venous plexus.

Veins from the lower jaw and teeth collect into several inferior alveolar veins. Some of these veins drain through the mental foramen to the facial vein, others via the mandibular foramen to the pterygoid venous plexus.

No accurate description is available concerning the venous drainage of the gingivae, although it may be assumed that buccal, lingual, greater palatine and nasopalatine veins are involved. These veins run into the pterygoid plexuses (apart from the lingual veins, which pass directly into the internal jugular veins).

There are two sets of veins draining the tongue. The deep lingual vein begins near the apex of the tongue and runs back on its ventral surface (see **Figure 41.3**). It joins a sublingual vein from the sublingual salivary gland, to form the vena comitans nervi hypoglossi. This then passes backwards with the hypoglossal nerve and joins the lingual, facial or internal jugular vein. Dorsal lingual veins drain the dorsum and sides of the tongue and join the lingual veins accompanying the lingual artery. They drain into the internal jugular in the region of the hyoid bone.

Lymph drainage

The principal sites of drainage of lymphatic vessels from orodental tissues are the submental, submandibular and jugulodigastric lymph nodes. However, the manner of drainage is so variable that there is no precise and accurate description.

The cheek, upper lip and lateral parts of the lower lip drain to the submandibular nodes. The central part of the lower lip drains to the submental nodes.

The lymph vessels from the teeth usually run directly into the submandibular lymph nodes on the same side. Lymph from the mandibular incisors, however, drains into the submental lymph nodes. Occasionally, lymph from the molars may pass directly into the jugulodigastric group of nodes.

The lingual and palatal gingivae drain into the jugulodigastric group of nodes, either directly or indirectly through the submandibular nodes. Lymphatics from the bulk of the palate terminate in the jugulodigastric group of nodes.

The lymphatics from the tongue drain to three main regions: marginal, central and dorsal. The anterior region of the tongue drains into the marginal and central vessels

and, behind the circumvallate papillae, the posterior part of the tongue drains into the dorsal lymph vessels. Of particular clinical importance is appreciating that more central regions may drain both ipsilaterally and contralaterally.

Marginal lymph vessels of the tongue that arise from the apex of the tongue and the **lingual frenum area descend under the mucosa to widely distributed nodes.**

- Some vessels enter the submental nodes and also pass to the jugulo-omohyoid nodes. Vessels may cross under the frenulum to end in the contralateral nodes, efferent vessels of submental nodes that are median pass to both sides.
- Some vessels drain to submandibular nodes.
- Some vessels end in jugulodigastric nodes, one vessel often reaching the jugulo-omohyoid node.

Vessels from the lateral margin of the tongue may drain into the submandibular nodes while others end in the jugulodigastric or jugulo-omohyoid nodes. Vessels from the posterior part of the lingual margin traverse the pharyngeal wall to the jugulodigastric lymph nodes.

Vessels draining the central region of the tongue may drain to either or both sides into the deep cervical nodes, especially the jugulodigastric and jugulo-omohyoid nodes. Some pierce the mylohyoid muscle to enter the submandibular nodes.

Vessels draining the dorsum of the tongue in the region of the circumvallate papillae and behind them run posteroinferiorly. Those near the median plane may pass to either or both sides, draining to the jugulodigastric and jugulo-omohyoid lymph nodes.

Innervation

The mucosa lining the mouth derives its sensory innervation chiefly from the maxillary and mandibular divisions of the trigeminal nerve. Additional nerves supply the tongue, including special taste sensation. The muscles of the mouth are supplied chiefly by the mandibular, facial and hypoglossal nerves. The salivary glands are supplied by secretomotor fibres derived from the facial and glossopharyngeal nerves. The innervation of the oral musculature is shown in **Table 41.1**.

SENSORY SUPPLY

Cheeks, lips and palate

The sensory supply to the cheek is derived from the buccal branch of the mandibular nerve (see **Figure 41.5**). This nerve arises from the anterior division of the mandibular nerve within the infratemporal fossa. Initially deep to the lateral pterygoid muscle, it emerges between the two heads of the muscle and runs forwards to supply the mucosa of the cheeks.

The upper lip is supplied by the infraorbital branch of the maxillary nerve (**Figure 41.9**). Running along the floor of the orbit in the infraorbital canal, it enters the face at the infraorbital foramen, where its labial branch runs downwards to supply the upper lip. The mental nerve is a terminal branch of the inferior alveolar nerve and exits the mandible at the mental foramen to supply the lower lip (see **Figure 41.9**).

The sensory nerves to the palate are derived from the greater and lesser palatine and nasopalatine branches of the maxillary nerve (**Figure 41.10**) These nerves pass through the pterygopalatine ganglion. The greater palatine nerve descends through the greater palatine canal, entering the hard palate at the greater palatine foramen. It then passes forwards on the bony palate towards the canine tooth, supplying the gums and the mucosa and

Region	Muscle	Nerve
Reprinted from Ref. 1 by permission from Elsevier.		

glands of the hard palate (excluding the anterior teeth). As it leaves the greater palatine canal, palatine branches are also distributed to the soft palate. The smaller lesser palatine nerves descend through the greater palatine canal to emerge through the inconspicuous lesser palatine foramina and give branches to the uvula, tonsil and soft palate. Fibres conveying taste impulses from the palate probably pass via the palatine nerves to the pterygopalatine ganglion (see **Figure 41.10**) and through it to the nerve of the pterygoid canal and then the greater petrosal nerve to reach the facial ganglion, where their somata are situated. Parasympathetic postganglionic secretomotor fibres run in the facial nerve through its greater petrosal nerve to reach the pterygopalatine ganglion to be distributed in the palatine nerves, thereby reaching palatine mucous glands.

The nasopalatine nerves (**Figure 41.10**) enter the palate at the incisive foramen to supply the anterior part of the hard palate behind the incisor teeth.

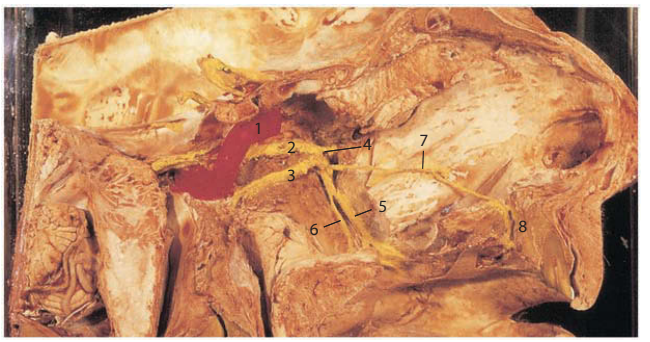

Figure 41.10 The pterygopalatine ganglion. 1, Internal carotid artery; 2, maxillary nerve; 3, nerve of pterygoid canal; 4, pterygopalatine ganglion; 5, greater palatine nerve; 6, lesser palatine nerve; 7, nasopalatine nerve dissected off from nasal septum; 8, nasopalatine nerve at incisive fossa. Reprinted from Ref. 1 by permission from Elsevier.

There is an additional sensory component in the region of the pillars of the fauces derived from the glossopharyngeal nerve which is involved in the gag reflex (see **Figure 41.8**).

The floor of the mouth is supplied by the lingual nerve (see **Figures 41.5** and **41.9**). This nerve arises from the posterior division of the mandibular nerve in the infratemporal fossa.

Teeth and gingivae

The regional supply to the teeth and gingivae is shown in **Table 41.2**. The posterior superior alveolar nerves supply the teeth in the upper jaw, while the inferior alveolar nerve supplies those in the lower jaw.

There are three superior alveolar (dental) nerves that arise from the maxillary nerve in the pterygopalatine fossa or in the infraorbital groove (canal) and these form a plexus of nerves supplying all the upper teeth. The posterior superior alveolar (dental) nerve leaves the maxillary nerve in the pterygopalatine fossa and runs anteroinferiorly to pierce the infratemporal surface of the maxilla, descending under the mucosa of the maxillary sinus. After supplying the lining of the sinus, the nerve divides into small branches that link up as the molar part of the superior dental plexus, supplying twigs to the molar teeth. It also supplies a branch to the upper gingiva and the adjoining part of the cheek.

The variable middle superior alveolar (dental) nerve arises from the infraorbital nerve as it runs in the infraorbital groove, and passes downwards and forwards in the lateral wall of the maxillary sinus. It ends in small branches that unite with the superior dental plexus, supplying small rami to the upper premolar teeth.

The anterior superior alveolar (dental) nerve leaves the lateral side of the infraorbital nerve near the midpoint of its canal and traverses the canalis sinuosus in the anterior wall of the maxillary sinus. Curving first under the infraorbital foramen, it passes medially towards the nose,

TABLE 41.2 Nerve supply to the teeth and gingiva

	Nasopalatine nerve			**Greater palatine nerve**					**Palatal gingival**

turns downwards and divides into branches supplying the incisor and canine teeth. It assists in the formation of the superior dental plexus.

The inferior alveolar (dental) nerve arises from the posterior division of the mandibular nerve in the infratemporal fossa (see **Figures 41.5** and **41.9**). Emerging from beneath the lower head of the lateral pterygoid muscle, it descends to enter the mandibular canal via the mandibular foramen (accompanied by the inferior alveolar artery). Just before entering the mandibular canal, the inferior alveolar nerve gives off a small mylohyoid branch to supply the mylohyoid muscle and the anterior belly of digastric.

In the mandibular canal, the inferior alveolar nerve runs downwards and forwards, generally below the apices of the cheek teeth until, below premolar teeth, it divides into terminal incisive and mental branches. The incisive branch continues forwards in a bony canal or in a plexiform arrangement, giving off branches to the first premolar, canine and incisor teeth, and the associated labial gingivae. The lower central incisor teeth may receive a bilateral innervation, fibres probably crossing the midline within the periosteum to re-enter the bone via numerous canals in the labial cortical plate.

The mental nerve passes upwards, backwards and outwards to emerge from the mandible via the mental foramen between and just below the apices of the premolar teeth to supply the skin of the lower lip and chin (see **Figure 41.9**).

The nerves supplying the gingiva in the upper jaw come from the maxillary nerve via its greater palatine, nasopalatine and anterior, middle and posterior superior alveolar branches. The mandibular nerve innervates the gingiva in the lower jaw by its inferior alveolar, lingual and buccal branches (see **Table 41.2**).

The tongue and floor of the mouth

The sensory supply to the tongue involves both general and taste afferents and reflects the embryological development of the structure. Thus, it can be considered in two portions, the presulcal (anterior two-thirds) and a postsulcal (posterior one-third). The nerve of general sensation to the presulcal part is the lingual nerve, indicating the embryological derivation of this part from the first branchial arch. The lingual nerve also carries taste sensation derived from the chorda tympani branch of the facial nerve. The main nerve supplying general (and taste) sensation to the postsulcal part is the glossopharyngeal nerve, while an additional area in the region of the valleculae is supplied by the internal laryngeal branch of the vagus nerve, indicating the embryological derivation of the postsulcal part from the third and fourth branchial arches.

The lingual nerve originates from the posterior trunk of the mandibular nerve in the infratemporal fossa (see **Figures 41.5**, **41.8** and **41.9**). Here, it is joined by the chorda tympani branch of the facial nerve that supplies taste to the anterior two-thirds of the tongue and parasympathetic fibres that supply the submandibular and sublingual glands via the submandibular ganglion (**Figure 41.9**). Emerging from beneath the lower head of the lateral pterygoid muscle (**Figure 41.5**), the lingual nerve passes forwards medial to the inferior alveolar nerve and is closely applied to the periosteum of the medial surface of the mandible by the side of the roots of the third molar tooth (**Figure 41.7**). Here, the lingual nerve is at great risk during surgical removal of (impacted) lower third molars using a lingual approach. The lingual nerve then passes medial to the mandibular origin of the mylohyoid muscle, which carries it progressively away from the mandible. It passes downwards and forwards on the deep surface of the mylohyoid muscle and then runs below the submandibular duct, which crosses it from medial to lateral (**Figure 41.7**). The nerve next curves upwards, forwards and medially to enter the tongue. The lingual nerve is connected to the submandibular ganglion by two or three branches and, at the anterior margin of the hyoglossus, it forms connecting loops with twigs of the hypoglossal nerve.

Branches of the lingual nerve supply the lingual gingivae, the mucosa of the floor of the mouth and the anterior two-thirds (presulcal part) of the tongue (excluding the circumvallate papillae, which are supplied by the glossopharyngeal nerve).

The glossopharyngeal nerve is present in the neck where it passes around the posterior border of the stylopharyngeus muscle, which it supplies (**Figure 41.8**). It runs forwards on this muscle and either pierces the lower fibres of the superior constrictor muscle or passes between it and the middle constrictor to be distributed to the postsulcal part of the tongue (including the circumvallate papillae). It communicates with the lingual nerve.

The sensory supply to the valleculae of the tongue (the recess between the median and lateral glossoepiglottic folds) is derived from the internal laryngeal nerve. This nerve is a branch of the superior laryngeal nerve and, passing between the superior and inferior constrictor muscles, pierces the thyrohyoid membrane. From here, branches ascend to supply the valleculae.

The parasympathetic innervation of the lingual glands is derived from the chorda tympani branch of the facial nerve that joins the lingual nerve (**Figure 41.9**) and synapses in the submandibular ganglion. Postganglionic fibres re-enter the lingual nerve to the glands. The sympathetic supply to lingual glands and vessels enters the tongue through plexuses around its arteries, arising from the carotid plexus.

MOTOR SUPPLY

The nerves supplying the buccinator and orbicularis oris muscles are derived from the facial nerve that exits the skull at the stylomastoid foramen and then passes into the substance of the parotid gland, where it divides into its terminal branches. The buccinator is supplied by its buccal branch(es) and the lips from the buccal and mandibular branches. The nerve supplying the mylohyoid muscle is the mylohyoid nerve and is seen branching from the inferior alveolar nerve just above the mandibular foramen (**Table 41.1**).

The muscles of the tongue are supplied by the hypoglossal nerve. These muscles develop primarily from occipital

somites that migrate into the developing tongue carrying their nerve supply, the hypoglossal nerve, with them. The hypoglossal nerve is seen in the neck crossing over the internal and external carotid and then the loop of the lingual artery (**Figure 41.8**). It then passes upwards and forwards between the mylohyoid and hyoglossus muscles. Here, the hypoglossal nerve is situated below the deep part of the submandibular gland, the submandibular duct and the lingual nerve. It then passes on to the lateral aspect of the genioglossus muscle, continuing forwards in its substance as far as the tip of the tongue.

The muscular branches from the hypoglossal nerve are distributed to styloglossus, hyoglossus and genioglossus. Numerous slender rami ascend into the tongue to supply its intrinsic muscles.

The nerve to geniohyoid (and to thyrohyoid) arises near the posterior border of the hyoglossus. It is derived from fibres of the first cervical spinal nerve.

TEETH

There are two generations of teeth: the deciduous (primary) dentition and the permanent (secondary) dentition. In the complete deciduous dentition there are 20 teeth – five in each jaw quadrant. In the complete permanent dentition there are 32 teeth – eight in each jaw quadrant. In both dentitions, there are three basic tooth forms: incisiform, caniniform and molariform. Incisiform teeth (incisors) are cutting teeth, having thin, blade-like crowns. Caniniform teeth (canines) are piercing or tearing teeth, having a single, stout, pointed, cone-shaped crown. Molariform teeth (molars and premolars) are grinding teeth possessing a number of cusps separated by fissures. Premolars are bicuspid teeth that are peculiar to the permanent dentition and replace the deciduous molars.

Permanent teeth

There are two incisors, a central and a lateral, in each half jaw or quadrant (**Figures 41.11** and **41.12**). Viewed from the front, the crowns are trapezoid, the maxillary incisors (particularly the central) being larger than the mandibular. They are surmounted by the biting or incisal edges. In side view their labial profiles are convex while their lingual surfaces are concavo-convex (the convexity near the cervical margin being due to a low ridge or cingulum, prominent only on upper incisors). The roots of incisors are single and rounded in maxillary teeth, but flattened mesiodistally in mandibular teeth. The upper lateral incisor may be congenitally absent or may have a reduced form (peg-shaped lateral incisor).

Behind each lateral incisor is a canine tooth with a single cusp (hence the American term cuspid) instead of an incisal edge. The maxillary canine is stouter and more pointed than the mandibular canine. The canine root is single and is the longest of any tooth.

Behind the canines are two premolars, each with a buccal and lingual cusp (hence the term bicuspid). The occlusal surfaces of the maxillary premolars are oval (the long axis is buccopalatal) with a mesiodistal fissure separating the two cusps. The maxillary first premolar usually has two roots (one buccal, one palatal). The maxillary second premolar usually has one root. The occlusal surfaces of the mandibular premolars are more circular or squarer than those of the uppers. The buccal cusp of the mandibular first premolar towers above the very much reduced lingual cusp. In the mandibular second premolar, the lingual cusp is more substantial compared with the first, and frequently presents as two cusps. Each lower premolar tooth generally has one root.

Posterior to the premolars are three molars whose size decreases as one passes backwards. Each has a large

Figure 41.11 Permanent dentition upper jaw. Reprinted from Ref. 1 by permission from Elsevier.

Figure 41.12 Permanent dentition lower jaw. Reprinted from Ref. 1 by permission from Elsevier.

rhomboid (upper jaw) or rectangular (lower jaw) occlusal surface with four or five cusps. The maxillary first molar has a cusp at each corner of its occlusal surface and the mesiopalatal cusp is connected to the distobuccal by an oblique ridge. A smaller cusplet or tubercle (cusplet of Carabelli) usually appears on the mesiopalatal cusp. The tooth has three widely separated roots, two buccal and one palatal. The smaller maxillary second molar has a reduced distopalatal cusp. Its three roots are less divergent and two of them may be fused. The maxillary third molar, the smallest, is very variable in form. It usually has three cusps (the distopalatal being absent) and commonly the three roots are fused.

The mandibular first molar has three buccal and two lingual cusps on its rectangular occlusal surface, the smallest cusp being distal. It has two widely separated roots, one mesial and one distal. The smaller mandibular second molar is like the first but has only four cusps (lacking the distal cusp of the first molar) and its two roots are closer together. The mandibular third molar is smaller still and, like the upper third molar, is variable in form. Its crown may resemble that of the lower first or second molar and its roots are frequently fused. The third molar is often impacted against the second molar, with resultant food packing and inflammation. Third molars are frequently congenitally absent.

Deciduous teeth

The incisors, canine and premolars of the permanent dentition replace two deciduous incisors, a deciduous canine and two deciduous molars in each jaw quadrant. The deciduous incisors and canine are shaped like their successors but are smaller and whiter and become extremely worn in older children. The deciduous second molars resemble permanent ones rather than their successors, the premolars. Each second deciduous molar has a crown almost identical to that of their respective, adjacent first permanent molar. The upper first deciduous molar has a triangular occlusal surface (its rounded 'apex' being palatal) and a fissure separates a double buccal cusp from the palatal cusp. The lower first deciduous molar is long and narrow; its two buccal cusps are separated from the two lingual cusps by a zigzagging mesiodistal fissure. Like permanent molars, upper deciduous molars have three roots and lower deciduous molars have two roots. These roots diverge more than those of permanent teeth, as each developing premolar tooth crown is accommodated directly under the crown of its deciduous predecessor. The roots of deciduous teeth are progressively resorbed by osteoclast-like cells (odontoclasts) prior to being shed.

Eruption

The first deciduous teeth to erupt into the mouth appear at approximately 6 months after birth and, by around the age of 3 years, all the deciduous teeth have erupted. By 6 years of age, the first permanent teeth appear (lower incisors and first molars) and thence the deciduous teeth are exfoliated one by one as they are replaced by their permanent successors. A complete permanent dentition is present when the third molars erupt at around the age of 18–21 years. Information on the sequence of development and eruption of teeth into the oral cavity may be important in forensic medicine and archaeology in helping to age individuals. The data provided in **Tables 41.3** and **41.4** concerning the chronology of tooth development are largely based on European-derived populations and there is evidence of ethnic variation. When a permanent tooth erupts, approximately two-thirds of the root is formed and it takes approximately another 3 years for the root to be completed. For deciduous teeth, root completion is more rapid. The developmental stages of initial calcification and crown completion are less affected by environmental influences than eruption, the timing of which may be modified by several factors such as early tooth loss and severe malnutrition.

Figures 41.13 and **41.14** show the panoramic appearance of the dentition seen with orthopantomograms at 5 and 11 years of age.

For detailed information concerning the structure and function of teeth the reader is referred to standard textbooks.[1]

TISSUE SPACES AROUND THE JAWS

The most common cause of infection of the tissues associated with the mouth is dental caries (tooth decay). As infection may spread from the teeth to the head and neck and become life-threatening, a knowledge of the tissue spaces associated with the jaws is of considerable clinical importance.[3–6] The tissue 'spaces' are only potential spaces that are normally occupied by loose connective tissue. It is only when inflammatory products destroy the loose connective tissue that a definable space is produced. The tissue spaces associated with the mouth are primarily defined by muscles (principally the mylohyoid, buccinator, masseter, medial pterygoid, superior constrictor and orbicularis oris muscles). Knowledge of the normal position of the root apices in relation to some of these muscles is important for an appreciation of the treatment of dental abscesses.[7]

Because of the potential of inflammation associated with the tissues surrounding partially erupted, impacted third molars (pericoronitis), the spaces associated with this region are particularly important and, as they are interconnected, inflammation can spread to involve the tissue spaces of the neck. The submental and submandibular tissue spaces are located below the inferior border of the mandible, beneath the mylohyoid muscle, in the suprahyoid region of the neck. The submental space lies beneath the chin in the midline, between the mylohyoid muscles and the investing layer of deep cervical fascia. It is bounded laterally by the two anterior bellies of the digastric muscles. The submental space communicates posteriorly with the two submandibular spaces. The submandibular space is situated between the anterior and posterior bellies of the digastric muscle. It communicates with the sublingual space around the posterior free border of the mylohyoid muscle.

The sublingual space lies in the floor of the mouth, above the mylohyoid muscles. It is continuous across the midline and communicates with the submandibular spaces over the posterior free borders of the mylohyoid muscles (see **Figure 41.7**).

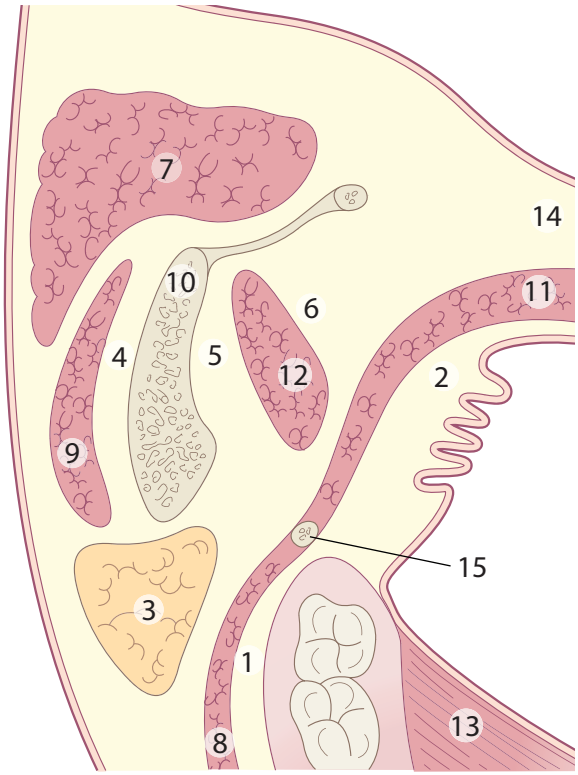

Figure 41.15 Diagram showing the tissue spaces in the retromandibular region. 1, Vestibular sulcus; 2, peritonsillar space; 3, buccal space, filled with buccal pad of fat; 4, submasseteric spaces; 5, pterygomandibular space; 6, parapharyngeal space; 7, parotid space; 8, buccinator muscle; 9, masseter muscle; 10, ramus of mandible; 11, superior constrictor of pharynx; 12, medial pterygoid muscle; 13, mylohyoid muscle; 14, retropharyngeal space; 15, pterygomandibular raphe.

The remaining tissue spaces in the region of the molar teeth are illustrated in **Figure 41.15**. The buccal space is located in the cheek, on the lateral side of the buccinator muscle.

Between the lateral surface of the ramus of the mandible and the masseter muscle is a series of spaces called the submasseteric spaces. These spaces are formed because the fibres of the masseter muscle have multiple insertions on to most of the lateral surface of the ramus.

Between the medial surface of the ramus of the mandible and the medial pterygoid muscle lies the pterygomandibular space.

Behind the ramus of the mandible is located the parotid space, in and around the parotid gland.

The parapharyngeal space is bounded by the superior constrictor of the pharynx and the medial surface of the medial pterygoid muscle. This space is restricted to the infratemporal region of the head and the suprahyoid region of the neck. It communicates with the retropharyngeal space, which itself extends into the retrovisceral space in the lower part of the neck.

The peritonsillar space lies around the palatine tonsil between the pillars of the fauces. It is part of the intrapharyngeal space and is bounded by the medial surface of the superior constrictor of the pharynx and its mucosa.

Most dental abscesses from lower teeth will drain either into the mouth lingually above the mylohyoid muscle (sublingual space) or into the vestibule (above the buccinator) and will have natural drainage. Where, for example, a cheek tooth drains below the buccinator (into the buccal space) or lingually below the mylohyoid (into the submandibular space, especially when involving the second and third mandibular molars), surgical intervention will be required to ensure drainage. As an example, direct spread may involve the submental space and the sublingual and submandibular spaces of both sides, giving rise to Ludwig's angina.

The teeth of the upper jaw have special relevance to ENT surgeons because of their potential close relationship to the maxillary air sinus. The root apices of the maxillary cheek teeth are close to and may even invaginate the maxillary sinus. The permanent tooth most commonly involved is the second molar, followed by the first molar. However, the premolars may also be involved as might the third molar. Following tooth extraction, resorption of alveolar bone and cavitation of the maxillary sinus may significantly increase. During removal of fractured root apices in this region, care must be taken to ensure the root fragment is not pushed into the sinus. Similarly, during root canal treatment, care must be taken not to push any filling material into the maxillary sinus. Routine X-rays may no longer be considered satisfactory in providing sufficient definition of the close relationship between the floor of the maxillary sinus and root apices and cone beam computed tomography may be necessary to provide extra detail (**Figure 41.16**). Due to the close anatomical relationship of the openings of the various air sinuses in the region of the middle meatus, infection of the maxillary sinus may spread to involve other sinuses and vice versa.

THE SALIVARY GLANDS

Salivary glands are compound, tubular, acinous, merocrine glands whose ducts open into the oral cavity. They secrete a fluid, the saliva that, among its many functions, aids in the mastication, digestion and deglutition of food.[8–10]

There are three pairs of major salivary glands: the parotid, the submandibular and the sublingual glands. Numerous minor salivary glands are also scattered throughout the oral mucosa.

Approximately 0.5 L of saliva is secreted per day. Salivary flow rates are approximately 0.3 mL/min when unstimulated, rising to 1.5–2 mL/min when stimulated. During sleep, salivary flow rate is negligible. In the unstimulated state, the parotid gland contributes approximately 20%, the submandibular gland approximately 65% and the sublingual and minor salivary glands the remainder. When stimulated, the parotid contribution rises to 50%.[11]

Parotid gland

The parotid gland is the largest salivary gland. It is a serous gland. The parotid gland is situated in front of the external ear on the face and consequently will not

Sagittal image showing the mesiobuccal (MB) and distobuccal (DB) roots of the maxillary third molar invaginating the floor of the maxillary sinus. The roots of the adjacent maxillary second molar are also very close to the floor of the maxillary sinus, Courtesy of Dr J Davies.

be described further. The parotid duct runs through the cheek and drains into the mouth opposite the maxillary second permanent molar tooth. Its parasympathetic innervation is derived from the lesser petrosal branch of the glossopharyngeal nerve via the otic ganglion.

Submandibular gland

The submandibular gland is irregular in shape and approximately the size of a walnut. It consists of a larger superficial and a smaller deep part, continuous with each other around the posterior border of the mylohyoid muscle (see **Figure 41.7**). It is partially enclosed between two layers of deep cervical fascia extending from the greater cornu of the hyoid bone. It is a mixed, but predominantly serous, gland. The superficial part of the submandibular gland is situated in the digastric triangle. Above, it extends medial to the body of the mandible. Below, it usually overlaps the intermediate tendon of the digastric muscle and the insertion of the stylohyoid muscle.

The inferior surface, covered by skin, platysma and deep fascia, is crossed by the facial vein and the cervical branch of the facial nerve. The lateral surface is in relation with the submandibular fossa on the medial surface of the body of the mandible and the mandibular attachment of the medial pterygoid muscle. The medial (deep) surface is related anteriorly to the mylohyoid muscle and posteriorly to the styloglossus muscle. In its intermediate part, the medial surface is related to the hyoglossus muscle, separated from it by the styloglossus muscle, the lingual nerve, submandibular ganglion, hypoglossal nerve and deep lingual vein.

The deep part of the submandibular gland lies between the mylohyoid muscle inferolaterally and the hyoglossus and styloglossus muscles medially. It extends forwards to the posterior end of the sublingual gland (see **Figure 41.7**).

The submandibular duct is approximately 5 cm long and emerges from the medial surface of the superficial part of the gland behind the posterior border of the mylohyoid muscle. It passes through the deep part of the gland, runs between the sublingual gland and the genioglossus muscle and opens in the floor of the mouth on the summit of the sublingual papilla at the side of the frenulum of the tongue. On the hyoglossus muscle it is crossed laterally by the lingual nerve, some of whose terminal branches ascend on its medial side (see **Figures 41.7** and **41.8**).

The secretomotor supply to the submandibular gland is associated with the submandibular ganglion. This is a small, fusiform body that lies on the upper part of the hyoglossus muscle suspended from the lingual nerve. The motor, parasympathetic root conveys preganglionic fibres travelling in the facial, chorda tympani and lingual nerves (see **Figure 41.9**) to the ganglion, where they synapse. The postganglionic fibres are distributed to the submandibular and sublingual salivary glands.

Sublingual gland

The sublingual gland, the smallest of the main salivary glands, lies beneath the oral mucosa, which is raised as a sublingual fold (see **Figure 41.3**). The gland lies in contact with the sublingual fossa on the lingual aspect of the mandible, close to the mandibular symphysis. It is narrow, flat, shaped like an almond and weighs 3–4 g. The gland is seromucous (but predominantly mucous). Beneath the gland is the mylohyoid muscle, whilst behind it lies the deep part of the submandibular gland (see **Figure 41.7**). The genioglossus muscle lies medial to the sublingual gland, separated from it by the lingual nerve and submandibular duct. The sublingual gland has 8–20 excretory ducts. From the posterior part of the gland, smaller sublingual ducts mostly open separately on the summit of the sublingual fold. From the anterior part of the gland small rami sometimes form a major sublingual duct (Bartholin's duct), opening with or near to the orifice of the submandibular duct.

Minor salivary glands

The minor salivary glands of the mouth include the buccal, labial, lingual, palatal and palatoglossal glands. The buccal and labial glands contain both mucous and serous elements. The palatal glands are mucous glands. They are located in both the soft and hard palate. The anterior and posterior lingual glands are mainly mucous. The anterior glands are embedded within muscle near the ventral surface of the tongue and open by means of four or five ducts near the lingual frenum. The posterior glands are located in the root of the tongue. Around the circumvallate papillae are serous glands (of Von Ebner). The palatoglossal glands are mucous glands and are located around the pharyngeal isthmus.

TEMPOROMANDIBULAR JOINT

As the temporomandibular joint is closely related anatomically to the external acoustic meatus and clinical conditions of the joint may produce symptoms of pain that must be distinguished from those directly associated with the ear, the joint will be considered in this chapter.

The temporomandibular (craniomandibular) joint (TMJ) is a synovial joint. It is formed by the mandibular (glenoid) fossa articulating with the mandibular condyle. The TMJ has a number of unusual features:

1. The joint space is divided into two joint cavities (upper and lower) by an intra-articular disc.
2. The articular surfaces are not composed of hyaline cartilage but of fibrous tissue (reflecting the joint's intramembranous development).
3. A secondary condylar cartilage is present in the head of the condyle until adolescence.
4. Movements of the joint are influenced by the teeth.

The shape of the mandibular fossa does not conform exactly to the shape of the mandibular condyle and this may partly explain why the joint cavity is divided by an articular disc into upper and lower compartments (**Figure 41.17**).[6, 13] The TMJ allows both gliding (upper joint compartment) and hinge (lower joint compartment) movements.

The condyle joins the ramus through a thin bony projection termed the neck of the condyle, a frequent site for a fracture of the mandible. A small depression (the pterygoid fovea) situated on the anterior surface of the neck marks part of the attachment of the lateral pterygoid muscle. The articular surfaces of the condyle are the anterior and superior surfaces. During the period of growth up to early teens, a layer of hyaline cartilage (condylar cartilage) lies immediately beneath the fibrous articulating surface of the condyle.

The joint capsule

The capsule of the TMJ is attached above to the mandibular fossa, extending anteriorly to just in front of the crest of the articular eminence and posteriorly to the squamotympanic and petrotympanic fissures. Below, the capsule is attached to the neck of the condyle. Being a thin

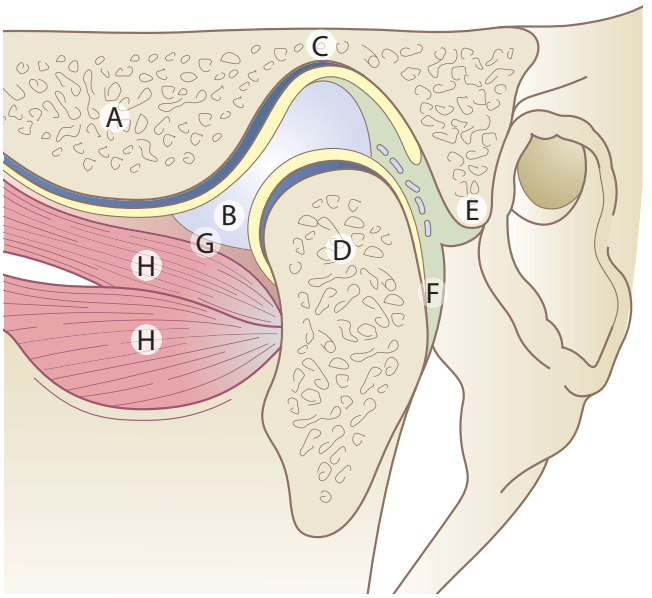

Figure 41.17 The temporomandibular joint showing the articular disc and attachments of the lateral pterygoid muscle. A, Articular eminence; B, articular disc; C, mandibular fossa; D, condyle; E, upper lamina (fibro-elastic); F, lower lamina (non-elastic); G, capsule of joint; H, lateral pterygoid muscle. Yellow layers indicate upper and lower joint cavities, black layers indicate upper and lower fibrous articular surfaces. Redrawn by permission from Ref. 12.

slack cuff, the capsule itself does not limit mandibular movements and is too weak to provide much support for the joint.

The inner surface of the fibrous capsule is lined by a synovial membrane that is reflected over the margins of the articular disc, but the membrane does not cover the articular surfaces of the joint. The synovial membrane secretes the synovial fluid, which occupies the joint cavities and lubricates the joint. Important components of the fluid are the proteoglycans. At rest, the hydrostatic pressure of the synovial fluid has been reported as being subatmospheric, but this is greatly elevated during mastication.[14, 15]

Articular disc

The articular disc (meniscus) is of a dense, fibrous consistency and is moulded to the bony joint surfaces above and below. Blood vessels are only evident at the periphery of the articular disc, the bulk of its central part being avascular. When viewed in sagittal section, the upper surface of the disc is concavo-convex anteroposteriorly and the lower surface is concave. Viewed superiorly, the articular disc is somewhat rectangular or oval in outline. The overall shape of the articular disc is thought to provide a self-centring mechanism, which automatically acts to maintain its correct relationship to the articular surface of the mandibular condyle during mandibular movements. Whereas some regard the functions of the articular disc as helping to spread the joint forces and to stabilize the condyle, others see its function as primarily destabilizing the condyle and permitting it to move more freely.[16]

The central (intermediate) zone of the disc is the thinnest and the collagen fibres are crimped, perhaps evidence that the disc is subjected to tensional, as well as compressional, forces.[17] The margin of the articular disc merges peripherally with the joint capsule. Anteriorly, fibrous bands connect the disc to the anterior margin of the articular eminence above, and to the anterior margin of the condyle below. Medially and laterally, the articular disc is attached to the joint capsule and, just below the medial and lateral poles of the condyle, by triangular zones of connective tissue. Posteriorly, the disc is attached to the capsule by a looser connective tissue, the retrodiscal tissue (pad) that has a bilaminar appearance. The superior lamina is loose and possesses numerous vascular elements and elastin fibres. It attaches to the anterior margin of the squamotympanic fissure. The inferior lamina is relatively avascular, less extensible (as it has few elastin fibres) and is attached to the posterior margin of the condyle. The volume of the retrodiscal tissue appears to increase four to five times as a result of venous engorgement as the jaw is opened and the condyle moves downwards and forwards. The return of the articular disc to its original position may possibly be aided by the elastic recoil of the superior lamella.

Numerous studies have been undertaken to determine the precise attachment of the lateral pterygoid muscle with respect to the articular disc in the hope of explaining any predisposition to TMJ syndrome. Variations in the attachment are seen. The findings indicate that, in the majority of articles (60%), fibres from the superior head of the lateral pterygoid muscle are described as gaining a direct attachment into the capsule of the joint and to the medial aspect of the anterior border of the articular disc (as well as to the condyle). In 30% of articles, only a few muscle fibres are described as inserting into the disc, while in the remaining 10% of articles the superior head of the lateral pterygoid muscle is attached only to the condyle.[18] Very rarely, some fibres from the inferior head of the lateral pterygoid may insert into the articular disc.

Considerable research has been undertaken on the activity of the lateral pterygoid muscle as it is believed by some that impaired activity of the muscle might predispose the joint to developing a pathology. It was originally thought that the two heads of the lateral pterygoid were reciprocal during opening and closing, the inferior head being active in opening the jaw, the superior head during closure, this view has now changed. The superior head has now been demonstrated to be active during opening and the two heads must be considered as acting together as one muscle with functional heterogeneity and with varying amounts of evenly graded activity throughout its range.[19]

Ligaments of the temporomandibular joint

The main ligament limiting lateral movement at the TMJ is the lateral ligament (temporomandibular ligament), which cannot be readily separated from the capsule. It runs

downwards and backwards from the articular tubercle (a bony protrusion on the lateral surface of the articular eminence) to the lateral surface and posterior border of the neck of the mandibular condyle.[19] To help resist posterior movement of the mandibular condyle, the lateral ligament is reinforced by a horizontal band of fibres running from the articular eminence to the lateral surface of the condyle. As there is little evidence of a medial ligament, medial displacement of the TMJ is likely to be prevented by the lateral ligament of the opposite side.

Accessory ligaments of the TMJ are the stylomandibular ligament, the sphenomandibular ligament and the pterygomandibular raphe. However, of these, the only one likely to have any significant influence upon mandibular movements is the sphenomandibular ligament.[20]

The stylomandibular ligament is merely a reinforced lamina of the deep cervical fascia that extends from the tip of the styloid process and from the stylohyoid ligament to the angle of the mandible.

The pterygomandibular raphe is a thin band of tendinous fibres passing between the hamulus of the medial pterygoid plate and the posterior end of the mylohyoid line of the mandible. It gives origin anteriorly to the buccinator muscle and posteriorly to the superior constrictor muscle.

The sphenomandibular ligament runs from the spine of the sphenoid bone to the lingula of the mandible. It represents the remnants of the perichondrium of the cartilage of the embryonic first branchial arch. The sphenomandibular ligament is slack when the jaws are closed, but during jaw movement becomes tense at about the time when the condyle has passed in front of the lateral ligament.[20]

In addition to the above, an additional ligament, the retinacular ligament, has recently been described. This ligament is said to originate from the articular eminence and insert into the fascia overlying the masseter muscle at the angle of the mandible. As the ligament is connected with the retrodiscal tissues, and contains an accompanying vein, it may function in maintaining blood circulation during masticatory jaw movements.[21]

Innervation and vasculature of the temporomandibular joint

Innervation for the joint is provided by the auriculotemporal, masseteric and deep temporal branches of the mandibular nerve. Of particular functional significance are the proprioceptive nerve endings important in the reflex control of mastication.

The vascular supply is derived from the superficial temporal artery and the maxillary artery (anterior tympanic and deep auricular branch). Other branches from neighbouring arteries may also contribute (e.g. deep temporal and transverse facial arteries).

Condylar cartilage

A secondary cartilage is present beneath the fibrous articular surface of the condyle until puberty. Unlike a primary cartilage, this secondary condylar cartilage has less extracellular matrix, the cartilage cells themselves do not undergo cell division and do not align themselves into columns. Although once thought to be a prime causative factor in controlling mandibular growth, the secondary condylar cartilage is now not thought to have any intrinsic growth potentiaton. The condylar cartilage disappears around the age of 16 years.

Clinical considerations of the temporomandibular joint

Estimates indicate that a considerable proportion of the population suffer in varying degrees from TMJ disorders. TMJ disorders are multifactorial in origin, although they may present with common symptoms such as pain in the jaw joint or face, clicking sounds in the joint and limited mouth opening.

Like other synovial joints, the TMJ is prone to inflammatory and degenerative conditions, such as rheumatoid and osteoarthritis. In these situations, damage to the articular surfaces will subject the articular disc to increased friction that may lead to degenerative changes within the disc. The intra-articular disc may gradually become displaced from its normal position between the articular surfaces. With the more usual anteromedial displacement, the posterior part of the disc may end up between the bony articular surfaces and be subjected to abnormal loading. The associated loss of structure may be accompanied by an invasion of blood vessels, with the disc eventually becoming perforated. The accompanying degenerative changes may also result in exposure of bone at the articular surfaces.

Inflammatory changes and increased permeability of the vessels of the synovial membrane may raise the intra-articular fluid pressure and change the composition of the synovial fluid. The synovial fluid in TMJ disorders may show an increased content in molecules such as proinflammatory cytokines (e.g. interleukin, tumour necrosis factor), matrix metalloproteinases and vascular endothelial growth factor. Irrigating and aspirating the joint (arthrocentesis) may reduce symptoms and improve mobility.

TMJ disorders are discussed in greater detail in Chapter 57, Temporomandibular joint disorders.

DEVELOPMENT OF THE FACE AND PALATE

As the neural plate of the embryo invaginates to form the neural tube, neural crest cells (ectomesenchyme) at the margins proliferate and migrate from this site to various parts of the body. There, interacting with the overlying epithelium (epithelial/mesenchymal interactions), the neural crest plays a significant role in normal development, contributing to many systems, such as the nervous system, soft and hard connective tissues. In addition, the cells play a major role in tooth development and give rise to melanocytes.

Development of face

In a 4-week-old embryo, the developing oral cavity (stomodeum) is present as a small, blind-ended pit bounded by five facial swellings (prominences) produced by proliferating zones of mesenchyme lying beneath the surface ectoderm. Much of the mesenchyme is derived from neural crest cells. The five facial swellings are the single frontonasal and the paired maxillary and mandibular processes (**Figure 41.18**). The centrally positioned frontonasal process lies above, the two maxillary processes are located at the sides and the two mandibular processes lie below the mouth. The maxillary and mandibular processes are derived from the first branchial arches. The facial processes are separated by grooves that, in the course of normal development, become flattened out by the proliferative and migratory activity of the underlying mesenchyme. Any disturbance in this process affecting, for example, the number, migration and subsequent differentiation (or apoptosis) and pattern formation of these cells can produce congenital abnormalities such as cleft lip and palate.

At this early stage of development, a membrane (the oropharyngeal membrane) separates the invagination representing the primitive oral cavity from the developing pharynx behind. The oropharyngeal membrane is bilaminar, being composed of an outer ectodermal layer and an inner endodermal layer. This membrane soon breaks down to establish continuity between the ectodermally lined oral cavity and the endodermally lined pharynx. Although not detectable in the adult, the demarcation zone between mucosa derived from ectoderm and endoderm corresponds to a region lying just behind the third permanent molar tooth.

In a 5-week-old embryo, localized thickenings of ectoderm on each side give rise to the optic and nasal placodes. These placodes will invaginate to form the lens of the eye and the olfactory epithelium, respectively. The nasal placodes sink into the underlying mesenchyme, forming two blind-ended nasal pits. Proliferation of mesenchyme from the frontonasal process around the openings of the nasal pits produces the medial and lateral nasal processes. The nasal pits continue to deepen until eventually they approach the roof of the primitive oral cavity, being partitioned from it by oronasal membranes (**Figure 41.19**). By the end of the fifth week, these membranes rupture to produce communications between the developing nasal and oral cavities.

In the 6-week-old embryo, the two mandibular processes fuse in the midline to form the tissues of the lower jaw. Rarely, persistence of a midline groove in this region

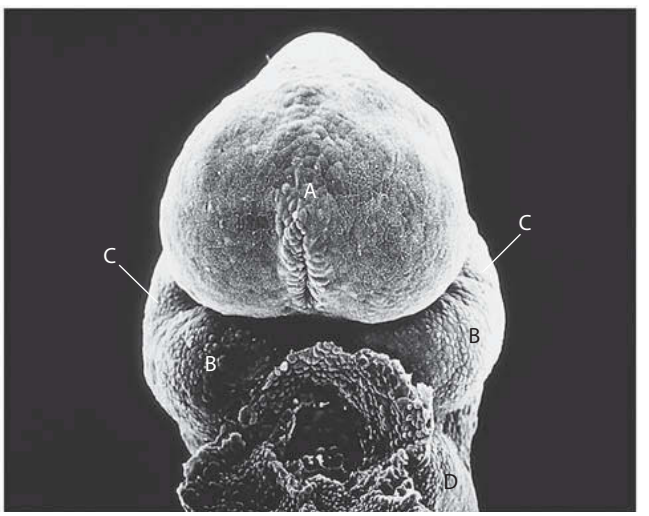

Figure 41.18 Scanning electron micrograph of the face at an equivalent 4-week stage (in the rat). Frontal aspect. A, Frontonasal process; B, mandibular processes; C, maxillary processes; D, pericardial swelling. Reprinted from Ref. 1 by permission from Elsevier.

produces a mandibular cleft. The mandibular and maxillary processes meet at the angle of the mouth (labial commissure), thus defining its outline. Disturbances in this development may give rise to macrostomia (enlarged oral orifice) or microstomia (small oral orifice), or rarely to an astomia (lack of an oral orifice). From the corners of the mouth, the maxillary processes grow inwards beneath the lateral nasal processes and towards the medial nasal processes of the upper lip (**Figure 41.20**). An appreciation of this arrangement helps explain the occurrence of a unilateral or bilateral cleft lip (when the medial nasal and maxillary processes fail to merge successfully) and a median cleft (when the two median nasal processes fail to merge). The severity of a cleft may vary from a barely imperceptible groove to a complete cleft. Between the merging maxillary and the lateral nasal process lies the naso-optic furrow. From each furrow a solid ectodermal rod of cells sinks below the surface and canalizes to form the nasolacrimal duct. Persistence of the naso-optic furrow may produce an oblique facial cleft.

Two differing accounts have been given for the development of the upper lip. One interpretation is that the maxillary processes meet the medial nasal processes, the latter thus forming the middle third of the upper lip. This view is favoured by macroscopic observations of development. The alternative view states that the maxillary processes overgrow the medial nasal processes, merging in the midline to contribute all the tissue for the upper lip. This interpretation is based on the innervation of the fully formed upper lip (i.e. the infraorbital branch of the maxillary division of the trigeminal nerve), the maxillary processes being supplied by the maxillary nerve, the frontonasal process by the ophthalmic nerve. It is of interest to note that, in cases of bilateral cleft lip, the isolated median segment of the lip is innervated by the ophthalmic nerve, although this clearly is a pathological condition. At present, too little is known about the behaviour and any subsequent migration of the mesenchyme of the facial processes and the accompanying nerves after the initial fusion of the maxillary and medial nasal processes. The muscles of the lip, like the other facial muscles, are derived from the mesenchyme of the second branchial arch, and are therefore innervated by the facial nerve.

Fusion between the maxillary and medial nasal processes during the formation of the upper lip involves active epithelial filopodial and adhering interactions, as well as programmed cell death. Slight defects in growth and patterning of the facial mesenchyme or epithelial fusion result in cleft lip with or without cleft palate, the most common and disfiguring craniofacial birth defect. Recent studies of craniofacial development in animal models have identified components of several major signalling pathways, including Bmp, Fgf, Shh and Wnt signalling, that are critical for proper midfacial morphogenesis and/or lip fusion.

Development of the palate

As we have seen at 5 weeks of development, the nasal pit deepens and the nasal placode comes to lie in its roof where it will form the olfactory epithelium. The region of the frontonasal process lying between the two nasal pits forms the primary nasal septum, while the tissue beneath the pits and separating them from the stomodeum forms the primary palate. At this stage, the nasal pits are confined only to the anterior extremity of the future oral cavity, the large region behind at this stage forming a common oronasal cavity (**Figure 41.21a**). Subsequent development is designed to extend the primary nasal septum and primary palate backwards by means of a secondary nasal septum and secondary palate.

During the 6th week of development, a secondary nasal septum grows down from the roof of the stomodeum behind the primary nasal septum, thus dividing the nasal aspect of the common oronasal cavity into two. In addition, a lateral palatal shelf grows out from each maxillary process but, due to the comparatively large size of the developing tongue, is prevented from growing horizontally and becomes oriented more vertically (**Figures 41.21b** and **41.22**).

During the 8th week of development, the tongue 'drops' and the vertically inclined palatal shelves can now occupy a horizontal position (**Figures 41.21c** and **41.23**). The reason for the displacement of the tongue is not known. As the tongue is attached to the mandible, it has been suggested that the descent of the tongue is related to mandibular growth. Conversely, reflex movements of the tongue and/or a change in its shape may be implicated. On becoming horizontal, the palatal shelves contact each other

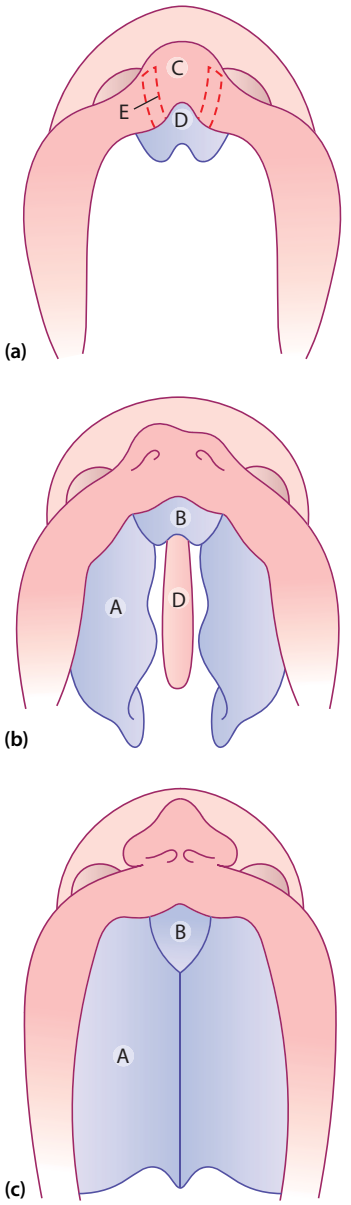

Figure 41.21 Diagram showing the development of the palate (a). By 6th week of intrauterine life; **(b)** during 6th week of intrauterine life and **(c)**. At 9th week of intrauterine life. (and the secondary nasal septum) in the midline to form the secondary palate. The shelves contact the primary palate anteriorly so that the oral and nasal cavities become completely separated from each other. After shelf contact, the medial edge epithelia of the two shelves fuse to form a midline epithelial seam. Subsequently, this seam (together with the epithelium separating the palatal shelves from the secondary nasal septum) degenerates, allowing continuity of mesenchyme to be established across the now intact and horizontal secondary palate. Fusion of the palatal processes is complete by the 12th week of development. Behind the secondary nasal septum, the palatal shelves fuse to form the soft palate and uvula.

The hard palate ossifies intramembranously from four centres of ossification, one in each developing maxilla and one in each developing palatine bone. The maxillary ossification centre lies above the developing deciduous canine tooth germ and appears in the 8th week of development. The centre of ossification for the palatine bone is situated in the region forming the future perpendicular plate and appears in the 8th week of development. Incomplete ossification of the palate from these centres defines the median and transverse palatine sutures. There does not appear to be a separate centre of ossification for the primary palate in man (in other species there is such a centre, forming a separate 'premaxilla').

The muscles of the palate are derived from the lower branchial arches, hence their nerve supply by the pharyngeal plexus. However, tensor veli palatini develops from the first branchial arch, explaining its innervation by the mandibular nerve.

As is evident from the description above, palate formation is a complicated process. The palatal shelves must grow to the appropriate size; the palatal shelves must elevate at the appropriate time on both sides; the medial edge epithelia of the palatal shelves must adhere to form a midline epithelial seam: the midline epithelial seam must degenerate to allow for the establishment of mesenchymal continuity across the midline. Any interference or mistiming of these processes may contribute towards the formation of a cleft palate. Clefts of the palate, like those of the lip, are multifactorial malformations, involving both genetic (polygenic) and environmental factors. Recent research on palatogenesis has concentrated on two main events: palatal shelf elevation and the initial stage of fusion of the shelves.

PALATAL SHELF ELEVATION

This process, during which the palatal shelves move from the vertical to the horizontal position, is thought to occur very rapidly (in terms of minutes and hours rather than days). Although it was once thought that extrinsic forces might be responsible (e.g. forces derived from the tongue or jaw movements), recent research has primarily focused on the search for a force intrinsic to the palatal shelf. Systems which have at one time or another been implicated include differential mitosis, contraction of connective tissue elements such as collagen or mesenchymal cells, changes in vascularity or tissue-fluid pressures. Particular attention has focused on the proposition that the intrinsic shelf elevation force might develop as a result of hydration of ground substance components (principally hyaluronan) in the shelf mesenchyme.[22] In this context, hyaluronan is a highly electrostatically charged, open coil molecule that is capable of binding up to ten times its own weight in water. In support of the possible importance of hyaluronan in palatogenesis, research using organ culture systems have shown that the presence of agents either leading to an alteration in hyaluronan content or size, or that disrupt glycosaminoglycan substitution on proteoglycans, or that alter the balance of matrix molecules secreted via the Golgi complex and hyaluronan produced at the cell surface, all detrimentally affect normal palatogenesis.[1] In addition to hyaluronan, however, other matrix components (including proteoglycans) may also be important during shelf elevation.

FUSION OF THE PALATAL SHELVES

Following palatal shelf elevation, contact is made initially in the middle third of the palate and then extends both anteriorly and posteriorly. The two adjacent medial edge epithelium contact each other and adhere by means of a 'sticky' glycoprotein coating their surfaces. In addition, the epithelial cells develop desmosomes that form a medial epithelial seam. The adherence of the medial edge epithelia is site-specific as palatal epithelia will not fuse with epithelia from other sites (e.g. the tongue).[22]

For normal palatogenesis to proceed, the epithelial seam must be removed for consolidation of mesenchymal tissues across the midline. The signals that are responsible for such a breakdown are not yet fully understood. As a breakdown of medial edge epithelium occurs in single isolated palatal shelves, the process does not depend specifically upon shelf contact.

Factors that may contribute to thinning and then removing the epithelial seam include: growth of the palate (in terms of oronasal height) and epithelial cell migration from the region of the seam on to the oral and nasal aspects of the palate; programmed epithelial cell death (apoptosis); migration of epithelial cells from the epithelial seam into the palatal shelf mesenchyme and their subsequent differentiation into mesenchymal cells (epithelial/mesenchymal transformation).[23] As in other systems, it is thought that signals (e.g. growth factors such as epidermal growth factor and transforming growth factors) emanating from the underlying mesenchyme are ultimately responsible for controlling epithelial degeneration.

CLINICAL AND AETIOLOGICAL CONSIDERATIONS

Malformations of palatogenesis may result in the appearance of clefts. The mildest form of cleft is that affecting the uvula, such a disturbance occurring relatively late in the process of palatal fusion. Disturbances occurring during the early phases of palatal fusion can result in a more extensive cleft involving most of the secondary palate. Should the cleft involve the primary palate, it may extend to the right and/or left of the incisive foramen to include the alveolus, passing between the lateral incisor and canine teeth. Cleft palate may be associated with cleft lip, though the two conditions are independently determined. Dental malformations are commonly associated with a cleft involving the alveolus. A submucous cleft describes a condition where the palatal mucosa is intact, but the bone/musculature of the palate is deficient beneath the mucosa.

As with other situations of epithelial mesenchymal interactions, large numbers of genes, growth factors and their receptors, and transcription factor are involved to ensure that palatal development proceeds normally. These factors have been mapped and show differences at different stages of palatal development, some being more important at the early stages in palate formation, others being more involved at later stages. Their importance in palate development has been shown by experimental manipulation, when their inactivation has been associated with palatal cleft formation. In the early stages of epithelial-mesenchymal interactions, Shh, Fgf10 and Bmp2 and Bmp4 are especially important, as is the orderly release of matrix metalloproteinases (such as those associated with the degradation of versican). During palatal fusion, TGF beta has a prominent role.

With growth of the palatal shelves, there is considerable heterogeneity along the anteroposterior and mediolateral axes of molecules such as Shh, Bmp4, Msx1, Osr1, Barx1. However, the biochemical changes produced by the particular genes, growth factors and signalling molecules are poorly understood.

KEY POINTS

- A detailed knowledge of the anatomy of the mouth and dentition is mandatory for all head and neck surgeons operating in this area.
- For the general ENT surgeon, the anatomy of:
  - **the floor of mouth** is important when dealing with submandibular duct pathology or submandibular duct rerouting, tongue tie, treatment of a ranula and biopsying suspicious lesions;
  - **the buccal mucosa** is important when dealing with parotid duct pathology and biopsying suspicious lesions;
  - **the hard palate** is important when biopsying suspicious lesions;
  - **the soft palate** is important for understanding Eustachian tube pathology, palatal surgery for snoring, and for biopsying suspicious lesions;
  - **the palatine tonsil and lateral pharyngeal wall** are important for tonsillectomy and management of peritonsillar and parapharyngeal abscesses as well as biopsy of suspicious lesions;
  - **the tongue** is important when assessing neurological function after suspected hypoglossal nerve damage or chorda tympani loss, as well as for biopsy of suspicious lesions;
  - **the salivary glands** is important for understanding the principles of parotidectomy and submandibular gland excision;
  - **the temporomandibular joint** is important because of its close relationships to the external ear canal.

For the general ENT surgeon, understanding the development of the face and palate is helpful in understanding a wide range of congenital head and neck abnormalities and cleft palate pathologies in particular.

SEARCH STRATEGY

Data in this chapter may be updated with a search using the following keywords: dental caries, dental plaque, saliva, pulpitis, apical periodontitis, acute dentoalveolar abscess, pericoronitis, periodontal disease, gingivitis, herpetic oral ulceration, aphthous or aphthous-like ulceration and acute ulcerative (necrotizing) gingivitis, dental trauma, cleft lip and palate, alveolar osteitis, cysts of the jaw, ameloblastoma, oral mucosa, oral mucosa infections, herpes virus, oral candidiasis, aphthous ulcer, lichen planus, pemphigus, pemphigoid, graft versus host, orofacial pain, trigeminal neuralgia, cluster headache and temporomandibular disorders.

COMMON DISORDERS AFFECTING THE TEETH AND PERIDONTIUM

Dental caries

Dental caries is a dynamic, multifactorial, bacterial disease of teeth. The initial stage in dental caries is termed the initial enamel lesion. This typically arises at sites where dental plaque (a microbial biofilm adherent to tooth tissues) is persistent. The underlying process in the initial stages involves acid dissolution of calcified dental tissue creating a dynamic imbalance between demineralization and remineralization in favour of the former.

The pathophysiology of dental caries can be described in terms of the interplay of four factors: dental plaque, dental tissues, saliva and the substrate (**Table 42.1**).

Bacteria within dental plaque, most notably but not exclusively *Streptococcus mutans*, will metabolize substrates generating acid by-products at the plaque–enamel interface. A dynamic process with localized demineralization of the adjacent dental tissues countered by attempts at remineralization driven through saliva, will determine whether caries will develop. Dental plaque creates a microenvironment favourable to demineralization where the protective buffering and remineralization properties of saliva are accordingly diminished. The initial stage of

TABLE 42.1 Factors involved in the development of dental caries

Factor	Action
Salivary factors	Saliva has important cleansing, antibacterial and remineralization functions.
Dental plaque factors	Dental plaque is a microbial biofilm adherent to tooth tissues. Bacteria within plaque, most notably but not exclusively S. mutans, ferment carbohydrate substrates, producing acids that can potentially result in localized demineralization of the adjacent dental tissues. Dental plaque creates a microenvironment favourable to demineralization where the protective buffering and remineralization properties of saliva are accordingly diminished.
Substrate factors	Substrates that can utilized by plaque microorganisms to produce acid are considered cariogenic. Refined carbohydrates especially containing sucrose are examples of such substrates. However, naturally occurring substrates such as those found in fruit are also cariogenic.
Dental factors	Risk factors with regard to dental anatomy are those that favour accumulation of plaque and a favourable environment for caries formation. Examples of such factors include narrow fissures, pits, inadequate interdental contact points that allow food impaction, inadequate dental restoration margins.

dental caries involves the alteration of the enamel surface with acid permeating alongside the enamel prism sheaths causing localized enamel dissolution. This initial stage (with no cavitation or dentine involvement) is considered reversible and amenable to focused preventative treatment.

Should enamel caries progress, eventually, the enamel dentine junction is reached with the ultimate persistence of this process leading to cavitation. Caries may progress involving dentine acid dissolution, proteolysis and bacterial invasion of the dentinal tubules. Once the dental pulp is reached, infection and inflammation of the pulp (pulpitis) will follow.

The clinical diagnosis of caries involves detection and evaluation of the severity of the lesion through clinical examination (predominantly visual and tactile inspection using blunt dental probes) coupled with dental radiographic examination.

Operative treatment of dental caries is required as soon as there is surface cavitation with dentine involvement. The operative treatment of dental caries involves removal of carious tissue and restoring tooth integrity with a restoration. The restoration's function is to restore anatomy and prevent ingress of microorganisms into the restored cavity. Such ingress may, in the presence of other cariogenic factors described above, lead to recurrent caries around the restoration.

Non-carious tooth surface loss (tooth wear)

Tooth wear develops secondary to mechanisms that can be grouped as erosion, attrition, and abrasion occurring independently or in combination. An example of a common exacerbating factor is hyposalivation. The potential consequences of long-standing tooth wear include hypersensitivity secondary to dentine exposure, reduced masticatory function and poor dental aesthetics.

EROSION

Erosion can be defined as the non-plaque mediated chemical dissolution of tooth tissue.

This acid dissolution may be secondary to intrinsically derived acid such as the reflux of gastric acid in gastroesophageal reflux disease or through externally derived acids, with dietary consumption of acid food and drink being the most common cause. Predisposing factors such as hyposalivation may predispose to erosion-mediated tooth wear. Erosion may be a contributing factor to both attrition and abrasion secondary to 'softening up' of the calcified dental tissues.

ATTRITION

Attrition is tooth wear secondary to non-masticatory tooth-to-tooth contact. Bruxist clenching may predispose towards attrition.

ABRASION

Abrasion is tooth wear secondary to friction of exogenous material against the tooth surface. Abrasion may be caused by a variety of mechanisms with an appropriate example being overzealous toothbrushing.

Dental infections

The most common dental infections for which patients seek emergency dental care are pulpitis and apical periodontitis (periapical abscess), pericoronitis and periodontal abscess.

PULPITIS AND APICAL PERIODONTITIS

Pulpitis (dental pulp inflammation) occurs most commonly secondary to microbial infection involving a carious lesion. Less common pathways of infection are through a tooth fracture or in a retrograde manner through the apical foramen. Pulpitis is characterized by inflammation within the confines of the pulp chamber resulting in pressure causing occlusion of the blood vessels and necrosis of the pulp tissue. The pain changes from pain exacerbated by thermal stimuli in reversible pulpitis to a dull, throbbing, persistent poorly localized pain of spontaneous onset in irreversible pulpitis. Ultimately, progressive infection of the pulp chamber is followed by an anaerobic bacterial biofilm colonizing the walls of the necrotic root canals leading to asymptomatic necrosis or acute inflammation. The involvement of the periapical tissues via the apical foramen may elicit an acute inflammatory host response resulting in acute periodontitis. Symptoms indicating the development of apical periodontitis are the development of tenderness on application of pressure of the involved tooth. Dentists typically use the end of a dental mirror handle to tap on the tooth to elicit this. Treatment of pulpitis and apical periodontitis is through root canal treatment or dental extraction. Systemic antibiotics are not routinely prescribed.

Further spread of infection into the periapical tissues and formation of an acute dentoalveolar abscess is accompanied by pain, swelling, erythema and suppuration usually localized to the affected tooth. Surgical treatment is the management of choice for most dental abscesses by drainage of pus and elimination of the source of infection typically through root canal treatment or extraction of the tooth. Antimicrobial use should be mainly limited to spreading and severe infections which are still a cause of hospital admissions.

The host response to involvement of the periapical tissues via the apical foramen is predominantly mediated by T cells and macrophages, leading to a chronic periapical granuloma rather than an acute apical periodontitis. This is typically asymptomatic but may eventually be visible on radiographic examination of the apex of the tooth as a well-circumscribed radiolucency.

PERICORONITIS

Pericoronitis is an acute localized infection which develops around partially erupted teeth, with the most common site being around a partially erupted, impacted wisdom tooth. Presentation is with symptoms of pain aggravated by jaw movement and mastication, trismus and halitosis. On examination an inflamed operculum (gum flap) is invariably present around the affected tooth, associated with localized facial swelling, regional lymphadenopathy and inability to open the jaw to the usual range of movement.

Initial treatment may be limited to irrigation under the operculum with an appropriate topical preparation such as chlorhexidine 0.2%. Indications for systemic antimicrobial treatment include the presence of regional lymphadenopathy, trismus or spreading infection. As gram negative anaerobes are predominantly implicated in pericoronitis, metronidazole is often prescribed.

Periodontal disease (plaque related gingivitis and periodontitis)

The gingivae and the periodontium may become inflamed secondary to a variety of pathological causes ranging from autoimmune to infectious causes (**Figure 42.1**). The generic terms gingivitis and periodontitis are usually applied to plaque-related inflammation of these tissues. The aetiology of chronic adult periodontal disease is multi-factorial, involving interaction between dental plaque, genetic and environmental risk factors. Dental plaque differing in microbial composition, forms above (supra-) and below (sub-) the gingival margin. Periodontitis develops when the plaque-related gingivitis results in an increase in depth of the gingival sulcus by mechanisms involving apical migration of the gingival attachment to the tooth root surface, loss of connective tissue attachment and alveolar bone loss. Examples of clinical parameters used by dental surgeons to assess periodontal disease include placing a periodontal probe in the gingival sulcus, measuring pocket depth which allows an indication of periodontal attachment loss. Bleeding on placement of the periodontal probe tip into the gingival sulcus or periodontal pocket reflects the presence of active gingival inflammation (**Table 42.2**). There has been significant research into the aetiology and association between periodontal disease and systemic diseases such as diabetes mellitus and atherosclerotic vascular disease.

Figure 42.1 Chronic periodontitis.

TABLE 42.2 Causes of gingival bleeding

Local	Systemic
Chronic gingivitis	Any condition causing exacerbation of gingivitis (e.g. pregnancy)
Chronic periodontitis	Leukaemia
Acute necrotizing gingivitis	Human immunodeficiency virus infection
Angioma/telangiectasia	Other causes of purpura
	Clotting defects
	Drugs, e.g. anticoagulants
	Scurvy

GINGIVAL PIGMENTATION

Gingival pigmentation is common in dark-skinned races (**Figure 42.2**). Other common causes include amalgam tattoo and melanotic macules. Smoking, tobacco and betel chewing, and drugs such as hydroxycholoroquine and minocycline may also cause hyperpigmentation. Other causes are listed in **Table 42.3**. See also 'Changes in mucosal colour' below.

Figure 42.2 Gingival racial pigmentation.

TABLE 42.3 Causes of oral hyperpigmentation

Localized pigmentations	Generalized
Kaposi's sarcoma	Addison's disease
Malignant melanoma	Drugs, e.g. phenothiazines, antimalarials, minocycline, contraceptives
Melanotic macules	Ectopic ACTH (e.g. bronchogenic carcinoma)
Naevi	Heavy metals
Syndromes:	Syndromes:
Albright	Complex of myxomas, spotty pigmentation and endocrine overactivity
Laugier–Hunziker	Malignant acanthosis nigricans
Peutz–Jegher	Racial
Tattoos (amalgam or graphite)	Localized irritation, e.g. smoking
	Other rare causes, e.g. haemochromatosis, generalized neurofibromatosis, incontinentia pigmenti

GINGIVAL REDNESS

Chronic gingivitis is the usual cause of gingival redness and is usually restricted to the gingival margins and interdental papillae. More widespread gingival erythema in children is usually caused by herpetic stomatitis but, in adults, desquamative gingivitis (typically seen in lichen planus or pemphigoid) or occasionally allergic responses are responsible.

Localized red areas may represent erythroplasia, carcinoma, Kaposi's sarcoma, candidiasis, lichen planus or lupus erythematosus.

Telangiectasia may be a manifestation of hereditary haemorrhagic telangiectasia, primary biliary cirrhosis, systemic sclerosis, or may follow radiotherapy. Haemangiomas are usually isolated but may occasionally be part of a syndrome.

GINGIVAL SWELLINGS

Localized gingival swellings (epulides) may be of local aetiology (irritation) or can be manifestations of pregnancy, a neoplasm or systemic disease (**Table 42.4**). Generalized gingival swelling is most commonly seen in chronic gingivitis, or caused by drugs such as phenytoin, cyclosporin and calcium channel blockers (**Figure 42.3**) and is occasionally hereditary (hereditary gingival fibromatosis). Gingival swelling may also be seen in herpetic stomatitis, leukaemia, Crohn's disease (CD), orofacial granulomatosis, sarcoidosis, amyloidosis, scurvy and other disorders.

TABLE 42.4 Causes of gingival swelling

Generalized	Localized
Local	
Chronic gingivitis	Abscesses
Hyperplastic gingivitis due to mouth breathing	Cysts
	Pyogenic granuloma
	Neoplasms and warts (various)
Systemic	
Hereditary gingival fibromatosis and associated syndromes	Pregnancy
Drugs: Phenytoin Cyclosporin Calcium-channel blockers	Sarcoidosis
	Orofacial granulomatosis
	Crohn's disease
	Wegener's granulomatosis
Pregnancy	Amyloidosis
Sarcoidosis	Neoplasms (various)
Orofacial granulomatosis	
Crohn's disease	
Leukaemia	
Wegener's granulomatosis	
Scurvy	

GINGIVAL ULCERS

Neoplasms, herpetic oral ulceration, aphthous or aphthous-like ulceration, acute ulcerative (necrotizing) gingivitis (AUG) and other bacterial infections (e.g. syphilis, tuberculosis) are some of the conditions that cause gingival ulceration.

Dental trauma

Injury to the front teeth is especially common in, but not limited to, childhood. If a permanent incisor is avulsed then reimplantation as soon as possible is advisable. The tooth can be stored in a suitable medium such as milk pending reimplantation. If the deciduous tooth is avulsed then this should not be reimplanted. Fractures of the crown of the tooth should be attended to by a dentist as quickly as possible. If the fractured fragment can be identified it can be reattached to the tooth rather than a restorative filling material being placed. If there is any soft-tissue injury and a missing tooth fragment, the wound should be explored for the fragment before closure. Dental trauma can be a presentation of non-accidental injury in a child and this, together with the pattern of soft-tissue injury and other points from the history should remind the practitioner to consider this aetiology.

Figure 42.3 Drug-induced gingival swelling.

DEVELOPMENTAL DISORDERS OF TEETH

Abnormalities of tooth development and eruption may occur either as isolated defects or as part of a wider developmental disorder. Cleft lip and palate is an example of a disorder that may affect both tooth development and eruption. A discussion of other syndromes with associated craniofacial deformity and dental developmental disorders is outwith the scope of this chapter and is discussed in Volume 2, Chapter 6, The child with a syndrome. The effect of trauma may range from root dilaceration of a developing tooth or temporomandibular joint (TMJ) injury.

Figure 42.4 Peg-shaped lateral incisor.

Commonly the last tooth in each dental series may be missing or malformed, more commonly in the adult rather than the primary dentition. This is most often seen by the absence of the third molar tooth, followed by the lateral incisor and finally the second premolar. Multiple missing teeth is termed 'hypodontia' and requires a specialist assessment to plan for a functioning adult dentition. The commonest malformed tooth visible is the upper lateral incisor which is termed a 'peg' lateral incisor (**Figure 42.4**). Adhesive dental restorations, orthodontic tooth movement and dental implants have radically changed the outlook for patients with dental anomalies.

Systemic factors such as hypothyroidism may impact the developing dentition and result in delayed dental eruption. Drugs such as cytotoxic medication may result in delayed eruption.

Discoloured teeth

Teeth most commonly become discoloured through habits such as tobacco use, drinking tea, coffee and red wine (**Table 42.5**). It is important to consider iatrogenic causes of discolouration of teeth such as administration of tetracyclines to a child under 12 years of age or to a pregnant or lactating mother (**Figure 42.5**). Excess systemic fluoride intake in the developing dentition may cause a range of defects from white specks to brownish discolouration and surface irregularities (fluorosis). Chlorhexidine mouthwash especially when used for more than a week can cause discolouration of teeth and dental composite restorations.

Mobile teeth

Causes of early tooth loosening and loss are given in **Table 42.6**. The most common reason for tooth mobility is advanced periodontal attachment loss secondary to chronic adult periodontal disease. When trauma causes mobility, this will be evident from the history. It is important to be aware that in rare cases, malignancy may result in loosening of teeth. Rare systemic disease such as Langerhans cell histiocytosis may also result in localized periodontal attachment loss and tooth mobility.

TABLE 42.5 Causes of discolouration of teeth

Extrinsic	Intrinsic
Poor oral hygiene	Trauma
Beverages/food	Caries
Drugs, e.g. iron, chlorhexidine	Restorative materials, e.g. amalgam
Habits, e.g. smoking or betel chewing	Pink spot (internal resorption)
	Drugs — mainly tetracyclines
	Fluorosis
	Dentinogenesis imperfecta
	Amelogenesis imperfecta
	Porphyria
	Jaundice in neonate or infant

Figure 42.5 Intrinsic dental staining.

TABLE 42.6 Pathological causes of loosening and early loss of the teeth

Local causes	Systemic causes	Others
Trauma	Disorders with some immune deficit	Acrodynia
Periodontitis	Down syndrome	Neoplasms
	Diabetes mellitus	Eosinophilic granuloma
	Leukopenia or leukocyte defects	
	HIV disease	
	Juvenile periodontitis	
	Rapidly progressive periodontitis	
	Papillon–Lefèvre syndrome	
	Hypophosphatasia	
	Ehlers–Danlos syndrome (type VIII)	

Non-neoplastic lesions of the jaws

VARIATIONS OF NORMAL ANATOMY

Bony exostoses (tori) are commonly encountered on clinical examination of the oral cavity. Maxillary tori may be noted of the buccal and labial aspects of the alveolus or in the midline of the palate. Mandibular tori are typically present on the lingual aspect of the premolar regions. The presence of multiple tori within the oral cavity especially if associated with extraoral exostoses may raise a clinical suspicion of syndromes such as Gardner syndrome.

DEVELOPMENTAL BONE DISEASE OF THE JAWS

Osteogenesis imperfecta

Osteogenesis imperfecta (OI) is an autosomal dominant disease, with defective type 1 collagen formation. There are four main types with the main characteristic including bone fragility. OI is associated with dentinogenesis imperfecta which presents with widespread structural defects of the dentition and accelerated tooth wear (**Figure 42.6**).

Infections of the jaw bones

ALVEOLAR OSTEITIS (DRY SOCKET)

Alveolar osteitis is a localized osteitis which develops following a minority of dental extractions and is associated with breakdown of the tooth socket clot. Pain is severe, deep seated and localized to the socket and represents inflammation in the bone rather than infection. The cause is unclear but may represent ischaemia of the tissues as the condition is much more common in smokers. There also seems to be a familial tendency to develop a dry socket.

Clinical examination reveals an extraction socket with no clot with inflammation of the surrounding oral mucosa. Treatment is simply by local curetting of the bone walls of the socket allowing a blood clot to reform. Systemic antibiotics are not indicated.

Figure 42.6 Dentinogenesis imperfecta.

OSTEONECROSIS

Osteonecrosis of the jaws may develop secondary to irradiation to the head and neck. In recent years there has been an increased incidence of medication related osteonecrosis of the jaw secondary to use of antiresorptive drugs such as but not exclusively, bisphosphonates and denosumab.

OSTEOMYELITIS

Both acute and chronic forms may occur in the jaw bones. Causes include spreading dental infection in the presence of a complicating factor such as immunosuppression. Osteomyelitis may also complicate an area of osteonecrosis. Treatment is through systemic antimicrobial therapy and surgical debridement.

Metabolic bone disease of the jaws

PAGET'S DISEASE OF BONE

The maxilla is the more frequently affected site and can be significantly increased in size thus creating occlusal disturbances and denture wear. Specific dental complications of Paget's disease include hypercementosis of teeth with the roots fusing with the alveolar bone resulting in ankylosis.

As in other sites, patients with Paget's disease of the jaws have an increased risk of malignant transformation to osteosarcoma.

Cysts of the jaw

Cystic jaw lesions may be classified using a variety of criteria such as developmental, or inflammatory, epithelial or non-epithelial, odontogenic or non-odontogenic. In adults, radicular cysts, which are inflammatory cysts, are the most common type, followed by developmental cysts such as dentigerous cysts (DCs).

The distribution and characteristics of jaw cysts in children are different from those in adults. In children, there is a relatively high rate of developmental cysts, whereas in adults inflammatory cysts are more common. Clinical presentation may vary depending on the type of cyst, size, site and structures affected. Cysts may also become infected with resultant signs and symptoms developing accordingly. It is important to appreciate that odontogenic tumours, both benign and malignant, may present as cystic lesions. Conversely, malignant change has been described to complicate both inflammatory and developmental cysts.

Odontogenic cysts, by definition, are formed from remnants of the tooth forming dental lamina and consequently involve the tooth-bearing regions of the jaws.

Inflammatory dental cysts

RADICULAR CYST

The radicular cyst is the most common inflammatory odontogenic cyst. This cyst arises around the apex or less commonly the lateral aspect of a non-vital tooth. Together with apical periodontitis, periapical granuloma, it is a

consequence of pulp infection and necrosis. The key to diagnosis is to demonstrate non-vitality of the associated tooth. If the tooth is vital a periapical radiolucency is not secondary to a periapical cyst.

If the culprit tooth is extracted, it is possible that cystic remnants of a periapical cyst will form a 'so-called' residual cyst. Treatment of the smaller periapical cyst is by extraction or root canal treatment of the involved tooth. When the periapical cyst is larger, treatment is as above, accompanied by surgical enucleation of the cyst.

Developmental cysts of the jaw

DENTIGEROUS CYST

The most common developmental odontogenic cyst is the dentigerous cyst (DC) and indeed is the most common cyst of the jaw in the paediatric age group. This cyst arises around the crown of an unerupted tooth with the wall of the cyst attached around the cervical margin of the involved tooth, with significant variation in size. DCs are more commonly unilocular but may also be a multilocular. Radiographically, a dental follicle-related radiolucency around an unerupted tooth should measure less than 4 mm from the surface of the tooth to the outer edge of the follicle; consequently any further increases should raise the possibility of cystic change. It is important to bear in mind that odontogenic tumours such as ameloblastoma and odontogenic keratocyst may involve unerupted teeth and present a diagnostic dilemma.

The treatment options include marsupialization or enucleation, with allogeneic or xenogeneic bone grafting. Harvesting of autogenous bone for grafting should be restricted to cases with large cysts and where bone substitute is not available. Enucleation of a cystic jaw lesion allows the entire surgical specimen and not only a biopsy specimen to be examined histopathologically.

Non-odontogenic developmental cysts

NASOPALATINE DUCT CYST

The embryological remnants of the nasopalatine duct may develop into a cyst. This may be an incidental X-ray finding with a radiolucency noted in this area or alternatively a swelling involving the nasopalatine papillary area is clinically evident coupled with the above-mentioned X-ray findings. The vitality of the adjacent teeth is intact.

Non-epithelial bone cysts

ANEURYSMAL BONE CYST

The aneurysmal bone cyst is controversially not considered a true cyst due to the absence of an epithelial lining. Presentation is most common in the mandible of children and young adults as a unilocular cyst. The size range varies with the potential to involve a significant proportion of the mandible. Radiographically, the radiolucency may have a scalloped appearance extending in between the roots of the teeth. Biopsy confirms the cyst cavity to be devoid of an epithelial lining. Healing may occur without treatment or consequence to an attempt at exploratory diagnostic surgery.

AMELOBLASTOMA

Ameloblastoma is an example of an odontogenic neoplasm that presents as a multicystic or unicystic lesion, locally infiltrative into bone marrow. Depending on the stage at diagnosis, the patient may be asymptomatic or at a later stage present with a swelling extensive jaw expansion. Both clinically and radiographically this tumour may need to be included in the differential diagnosis of a cystic lesion of the jaw. Histopathological confirmation is mandatory.

DISORDERS AFFECTING THE ORAL MUCOSA

Oral mucosal disease can be a reflection of anatomical changes or immunological processes within the oral cavity or an indication of systemic processes within the body. There are also a variety of irritants which produce visible changes in the mucosa on clinical examination.

Examining and recording changes of the oral mucosa

The oral mucosa should be examined using a good light source and suitable retractors, such as dental mirrors. The process should be systematic to ensure that all areas are considered and the recording of the findings presented in a reproducible and easily understood manner. The mucosa should be dried during the examination to allow proper visualization of any lesions. It is important to record negative as well as positive findings to avoid doubt in the future regarding changes in particular mucosal areas. Where appropriate, clinical photographs should be taken to record any lesions, particularly if monitoring is planned.

History taking for oral mucosal diseases

When taking a history from a patient with an oral mucosal disease, the clinician should ensure that the description of the presenting symptom is unambiguous. As an example, patients often refer to 'ulcers' in the mouth to mean any sore area. If the patient is using a word or phrase that has a specific meaning, the clinician must clarify the situation by direct questioning, such as 'Tell me what you mean by an 'ulcer''. Often, patients referred by their doctor or dentist may have no symptoms at all and a change in the expected appearance of the oral mucosa would have been noted by the practitioner as part of a routine oral examination.

Benign oral mucosal changes

A variety of oral mucosal changes may be noted on clinical examination that are either developmental, present as a result of normal oral function or are unexplained.

FRICTIONAL KERATOSIS

This is an adaption of the oral mucosa to increased trauma and results in a white thickening of the mucosal surface which often appears to be 'on top of' the existing mucosa. One common area where this can be seen is the area of the dental alveolus in a patient with missing teeth. This mucosa has increased trauma from food rubbing; an area previously protected by the teeth. The keratosis develops as a reactive change over time to reduce damage to the mucosal surface.

LEUKOEDEMA AND NICOTINIC STOMATITIS

This is a more generalized reactive white change to the oral mucosa, again in relation to generalized rather than focal irritation. Most commonly, this is a change seen in smokers where areas most in contact with the hot smoke are affected. This change can be much more prominent where there is a heavy smoke concentration, such as against the posterior hard palate, producing the changes seen in nicotinic stomatitis. In this condition, the dense hyperkeratosis with inflammation of the opening of the minor salivary gland ducts in the palate appear as red spots against the white background of the palatal mucosa.

FORDYCE SPOTS

The oral mucosa is not part of the developmental gut tube and is derived from the same elements that form the skin of the face. Various adaptations take place including the substitution of minor salivary glands for sebaceous glands. However, in some individuals the sebaceous glands still form in some areas and are visible through the mucosa as small yellow/white spots known as Fordyce spots. These are completely benign (**Figure 42.7**), most commonly seen on the buccal mucosa and the patient is normally unaware of them. They are also found on the lips in some individuals and women in particular, can find them a cosmetic problem.

TONGUE COATING

Many patients complain of having a 'coated tongue'. Occasionally this is a true overgrowth of the dorsal surface papillae and these can become stained to give the appearance of a 'brown hairy tongue' (**Figure 42.8**). More often, it is a slight exaggeration of the normal surface, as can happen when changing to a less abrasive diet or dehydration due to illness. A patient can become quite fixated about the appearance of their tongue, even in the absence of any symptoms.

The condition typically improves if the patient avoids habits or drugs that stain the tongue, such as dark beverages, smoking and chlorhexidine mouthwashes. The appearance can be improved by an increase in oral hygiene efforts and daily cleaning of the tongue dorsum by brushing the tongue with a toothbrush, use of sodium bicarbonate or peroxide mouthwashes, chewing gum or sucking a peach stone for 30–60 minutes each day.

GEOGRAPHIC TONGUE

Geographic tongue is a disorder of epithelial tissue turnover on the tongue dorsal surface. Very occasionally it can be found on other parts of the oral mucosa. Normal epithelial replacement occurs in scattered parts of the tongue mucosa at the same time and is not noticed, but in geographic tongue, adjacent epithelial areas have synchronized turnover with thinning of the mucosa as the existing layers are lost. This thinning makes the red colour of the connective tissue more visible and the patient describes red patches on the dorsum of the tongue which then gradually 'heal' as the new epithelium is produced (**Figure 42.9**). This entire process takes about 10 days but may be progressive over adjacent areas of the tongue which leads to the appearance of the condition 'moving' across the tongue. Although it can be a continuous process, it often occurs at intervals of 2 or 3 months in susceptible individuals. Most patients have no symptoms, but a proportion get sensitivity to highly flavoured or spicy foods due to the thinning of the epithelial barrier. This sensitivity is most noticed

Figure 42.7 Fordyce spots.

Figure 42.8 Brown hairy tongue.

Figure 42.9 Geographical tongue.

by children and can be disabling particularly in the very young. With age, the sensitivity reduces and most symptomatic patients require no treatment other than avoiding irritant foodstuffs. Topical anaesthetics such as benzydamine can be helpful if symptoms are particularly bad, but as the cause for the reduced epithelial proliferation is unknown, no 'curative' treatments are available.

MEDIAN RHOMBOID GLOSSITIS

This is an uncommon condition that presents as a red, depapillated and smooth, rhomboidal area, broadly in the centre of the dorsum of tongue. It is usually associated with an invasive candidiasis which is not pathogenic. Multiple oral lesions may occasionally be present, especially a 'kissing' lesion in the palatal vault. Smoking, denture wearing and, occasionally, immune defects including HIV and diabetes are said to predispose to median rhomboid glossitis, but most lesions are seen in healthy adults. No treatment is required as the lesion is almost always asymptomatic, but a biopsy with PAS stain for candida can be useful for reassurance, particularly when the area becomes raised and lumpy.

MUCOSAL SWELLINGS

Thickening, hypertrophy and lumps of the mucosal structures can be reactive to a variety of local irritants or as a result of benign pathology of the oral or submucosal tissues. All of these lesions are typically painless.

Viral warts can produce thickening of the epithelium and are most commonly seen in children. When these present in an adult, immunosuppression is usually the cause and conditions such as HIV should be considered. Both extra- and intraoral warts usually arise as a result of contact with a skin lesion, such as on the hand or fingers, and all must be eradicated to prevent recurrence.

Fibro-epithelial polyps arise from low-level irritation and can be sessile or pedunculated. They only require removal if they are being subject to trauma, but the cause of the trauma should first be removed to prevent a continued increase in size or recurrence after removal. Multiple mucosal polyps, dental anomalies (hypodontia, enamel defects and taurodontism) and occasionally cleft lip and palate are found together in the rare Gorlin-Goltz syndrome and multiple mucosal papillomas with associated gastrointestinal (GI) and thyroid disease are found in Cowden syndrome.

Benign tumours in the connective tissue such as a neuroma, lipoma or minor salivary tumours such as the pleomorphic adenoma will produce small mobile lesions deep in the tissue. Mucoceles – obstructive minor salivary gland lesions – will usually have a history of waxing and waning on a recurrent basis, but may eventually fibrose to leave a firm connective tissue swelling.

Inflammatory swellings can arise on any part of the oral mucosa but are frequently seen on the gingival margin. The source of the irritation is often not obvious but a broken tooth may be a trigger. Pregnancy predisposes to gingival inflammatory swellings; most are pyogenic granulomas but giant cell lesions are also common. These latter lesions may be isolated localized lesions or part of a more widespread disease such as hyperparathyroidism. An X-ray should always be taken in the area of any gingival swelling to ensure that the soft-tissue lesion is not a bony lesion extending into the mouth.

Mucosal swellings can also arise as part of systemic disease including CD/orofacial granulomatosis, sarcoidosis, Wegener's granulomatosis and amyloidosis. Recurrent lip swelling is found in angio-oedema and orofacial granulomatosis.

Changes in mucosal colour

The oral mucosa is pink but as this is a view of the blood in the connective tissue beneath, the exact colour varies with the thickness of the epithelium and the vascularity of the underlying connective tissue. Consequently, the keratinized areas of mucosa such as the hard palate and gingival tissues appear whiter as there is a thicker barrier between the observing clinician and the connective tissue blood vessels.

White lesions of the oral mucosa are most commonly thickening of the epithelium by acanthosis or hyperkeratosis although reduced connective tissue blood flow can be seen in conditions such as submucous fibrosis (**Table 42.7**). An established squamous carcinoma will appear white as there is increased tissue in the area. White lesions are more

TABLE 42.7 White lesions of the oral mucosa

Local	Systemic
Frictional keratosis	Candidiasis
Smoker's keratosis	Lichen planus
Idiopathic keratosis	Lupus erythematosus
Carcinoma	Papillomas (some)
Burns	Syphilitic keratosis
Skin grafts	Inherited lesions (e.g. white-sponge naevus)

frequent, but are less commonly associated with dysplasia than red lesions. A white sponge naevus is a dominant-inherited developmental condition causing characteristic changes within the epithelium. It usually starts in childhood at the posterior buccal mucosa and spreads slowly anteriorly over years giving a characteristic appearance of a 'shaggy' white lesion covering much of the buccal and palatal mucosa including areas not subject to dental trauma such as the buccal sulcus. It is symptomless and requires no treatment.

Red changes of the mucosa usually reflect thinning of the mucosa making the observer more able to see the blood in the connective tissue but they can also arise as a consequence of increased vascularity of the connective tissue, as in the case of dysplasia or malignancy; thus, unexplained red lesions are of greater concern to the clinician. Inflammation of the tissues will also produce red changes to the mucosa, and commonly candida or other causes of mucosal irritation will give this appearance. Focal red lesions can represent capillary haemangiomas and require no treatment unless bleeding becomes an issue, usually secondary to trauma. Multiple focal haemangiomas are seen in the oral and facial tissues as part of hereditary haemorrhagic telangiectasia.

Pigmented lesions can be localized or generalized (see **Table 42.3**). Brown pigmentation is the result of increased melanin in the tissues. Biopsy can differentiate a melanosis (normal melanocyte numbers producing excess melanin) from a naevus (increased number of melanocytes each producing a normal amount of melanin). A melanoma is a rare primary lesion in the mouth.

Grey/blue pigmentation is seen with foreign bodies such as dental amalgam or heavy metal poisoning with lead or arsenic (**Figure 42.10**). These are best diagnosed on biopsy as the material is seen phagocytosed inside giant cells. X-rays are not reliable to demonstrate the small amount of foreign material and are discouraged as an investigation to reduce radiation exposure. Dark blue and purple lesions are mostly venous malformations such as a cavernous haemangioma or a varicosity and are seen in many elderly patients. If these lesions are raised enough to be subject to trauma and bleeding, they can be surgically excised or ablated with cryosurgery.

Figure 42.10 Amalgam tattoo.

Generalized oral mucosal pigmentation is most commonly racial pigmentation, whilst smoking is the commonest acquired cause. In smokers, the pigmentation fades when the habit is stopped. Medicines are another common reason for mucosal pigmentation with drugs as diverse as hydroxychloroquine, imatinib, minocycline and the oral contraceptive pill all implicated. Pregnancy or hormonal changes where ACTH levels are raised can also result in widespread oral pigmentation. Addison's and Cushing's diseases or some small-cell lung tumours are rare causes; for these reasons, an unexplained increase in pigmentation in the mouth should always be investigated.

Isolated or localized pigmentation can also be caused by any of the systemic causes for pigmentation; the observer may simply be seeing the start of the process. Localized lesions tend to have a local cause such as an amalgam tattoo where a tooth apicectomy has been performed, or post-inflammatory pigmentation in an area of trauma. However, the commonest cause is the simple melanotic macule or freckle but this should be confirmed on biopsy to differentiate it from a naevus or early dysplastic change. Peutz–Jeghers syndrome is an autosomal dominant trait characterized by hamartomatous intestinal polyposis and multiple areas of mucocutaneous melanotic perioral pigmentation.

Oral ulceration

Mouth ulcers are a frequent complaint by patients but the clinician must be clear as to what the patient means by 'ulcer'. This can be a term used to mean any sore spot in the mouth to a patient. A true ulcer is a break in the epithelium and may be preceded by a blistering phase in some conditions. It is important that this is clarified when taking the history. As oral ulceration can be a presentation of malignancy, any ulcer which has been present for more than 2 weeks must be investigated.

The common causes of ulcers include local trauma from teeth or sharp edges on dentures, recurrent aphthous stomatitis, Behçet's syndrome) and viral infections after the initial vesicle has burst. Systemic diseases associated with oral ulceration are given in **Table 42.8**.

The history should clearly differentiate a single continuing ulcer episode from recurrent oral ulcers and multiple oral ulcer lesions that overlap in time. Where an ulcer recurs in a specific area repeatedly a local cause should be considered, although ulcerated forms of lichen planus frequently present in this way.

APHTHOUS STOMATITIS

Aphthae are recurrent oral immunological ulcers that are multifactorial in origin and arise as a result of T-cell medicated damage to the mucosal epithelial basal layer (**Figure 42.11**). They are not potentially malignant lesions, occur throughout the GI tract and are characterized as major, minor or herpetiform depending on the presenting features (**Table 42.9**). All are genetically determined and this tendency may cause ulcers to be expressed spontaneously throughout life, or never at all depending upon the family characteristics. The family history is an important

TABLE 42.8 Oral ulceration associated with systemic disease

Causes	Examples
Microbial disease	Herpetic stomatitis Chickenpox Herpes zoster Hand, foot and mouth disease Herpangina Infectious mononucleosis HIV disease Tuberculosis Syphilis
Malignant neoplasms	Squamous cell carcinoma Lymphoma
Skin disease	Erosive lichen planus Pemphigus Pemphigoid Erythema multiforme Dermatitis herpetiformis and linear IgA disease Epidermolysis bullosa
Systemic triggers for ulcers Blood disorders	Rapid growth periods during childhood Haematinic deficiency (ferritin, folate, vitamin B_{12}) Leukaemia Neutropenia Other white cell dyscrasias
Gastrointestinal disease	Coeliac disease Crohn's disease Ulcerative colitis
Iatrogenic causes	Antirheumatic drug therapy Chemotherapeutic agents Acrodynia Radiotherapy

Figure 42.11 Aphthous ulcer.

predictor of the ulcer pattern in an individual. In addition to the genetic susceptibility are a range of health and environmental modifying factors which can promote ulcer formation; the combination of genetic and environmental triggers determine the individual's susceptibility to aphthae. If an individual has had recurrent aphthous oral ulcers since childhood then the genetic component is likely to be the main ulcer determinant, but if there has only been the occasional ulcer until recently it is more likely that a modifiable environmental or health factor could be at play, leaving the opportunity for successful medical intervention. The most common correctable triggers are haematinic deficiencies, where iron (measured as ferritin), folic acid or vitamin B_{12} levels are low. This can happen in the presence of a normal blood count and the absence of anaemia does not exclude a haematinic deficiency. A haematinic screen together with a coeliac screen should be carried out for all patients with recurrent aphthous stomatitis.

TABLE 42.9 Aphthous ulceration

Type of aphthous ulceration	Clinical features
Minor aphthous ulceration	Most common form of aphthous ulceration Less than 10 mm in diameter Last 2–3 weeks Only on non-keratinized mucosa Heal without scarring Can be multiple but fewer than 10 at a time Usually at the front of the mouth Commonly in areas of mucosal trauma
Major aphthous ulceration	Larger than 10 mm in diameter Can last up to 3 months Can occur on keratinized or non-keratinized mucosa Can heal with or without scarring Usually single but 1–3 ulcers can be present at once Usually towards the back of the mouth
Herpetiform ulceration	Least common form of aphthous ulceration Less than 5 mm in diameter Last for up to 2 weeks Heal without scarring Large numbers of ulcers – up to 100 Coalesce in areas to form large areas of ulceration Arise in keratinized and non-keratinized mucosa Similar in appearance to primary herpetic gingivostomatits

As aphthous ulcers are driven by an immunological reaction, the process can be controlled using immunomodulatory therapy. In some cases, altering environmental factors such as avoiding sodium lauryl sulphate (SLS) containing toothpastes or dietary triggers (benzoate, chocolate, cinnamon) can reduce the triggering of lesions to a level low enough to satisfy the patient. In others, the use of topical immunosuppressants or immunomodulators can successfully alter the clinical course of the disease. As the immunological damage happens some days before the ulcer appears, it is critical that the treatment is started as soon as the patient becomes aware of the lesion. By the time the ulcer appears, it is too late for an immunomodulatory drug to be effective and the patient must rely on analgesic solutions or obturative pastes to manage their symptoms. Treatment options for aphthous ulcers are listed in **Table 42.10**. Systemic immunotherapy should only be used by a specialist with appropriate experience.

Erythema multiforme (EM) is an immunological hypersensitivity reaction that can affect many body systems

TABLE 42.10 Treatment options for aphthous ulceration

Treatment modality	Medication	Instructions
Symptomatic	Benzydamine solution	Spray solution onto ulcer or rinse with the solution for one minute before meals to reduce ulcer sensitivity
	Occlusive paste (e.g. orabase) Lignocaine gel	Apply to the ulcer before eating to give relief from discomfort
Topical episodic	Betamethasone mouthwash	1 mg dissolved in 10 ml water, use as rinse for 2 mins twice daily at the onset of ulcer symptoms until ulcer heals
	Beclomethasone Inhaler 50–200 mcg/puff	Give 2 puffs of the powder three times daily directly onto the area with ulcer symptoms starting at the onset of symptoms until the ulcer heals
Topical preventative (*can be combined into a single mouthrinse*)	Betamethasone mouthwash	1 mg dissolved in 10 ml water, use as rinse for 2 mins once daily each day
	Doxycycline mouthwash	100 mg soluble tablet in 10 ml water used as a rinse for 2 mins twice daily
Systemic preventative	Colchicine Azathioprine Mycophenolate mofetil	Used under the direction of a specialist only

individually or together (Stevens-Johnson syndrome). There may be a genetic predisposition to recurrent erythema multiforme and this is seen most commonly in young men. In the mouth, EM presents in much the same way as a primary herpetic gingivostomatitis with widespread oral mucosal inflammation and multiple areas of coalescing ulceration on both keratinized and non-keratinized mucosa. This may be the only clinical lesion, but in other patients the oral lesions may appear concurrently with skin, genital or nasopharyngeal lesions. EM appears to be a type 3 hypersensitivity reaction where a host antibody binds an antigen in the circulation and lodges in capillary tissue, activating complement and initiating localized inflammation and tissue damage. The labial mucosa is often involved, and a serosanguinous exudate leads to crusting of the swollen lips.

The following are possible triggers for EM: infective agents, particularly HSV and mycoplasma; drugs such as sulphonamides, cephalosporins, aminopenicillins, quinolones, NSAID; food additives or chemicals such as benzoates, nitrobenzene, perfumes, terpenes.

The diagnosis can be difficult and a biopsy of perilesional tissue, with histological and immunostaining examination are essential if a specific diagnosis is required. Supportive care is important; a liquid diet and intravenous fluid therapy may be necessary. EM should be treated with high-dose systemic corticosteroids in the acute phase. Preventative therapy with acyclovir can be helpful if recurrent lesions are suspected to be from a HSV reaction.

Mucositis (mucosal barrier injury) is the widespread erythema, ulceration and soreness which commonly complicates chemo-, radio- or chemoradiotherapy. Mucositis appears from 3 to 15 days after treatment, earlier after chemotherapy and radiotherapy. Mucositis invariably follows total body irradiation and external beam radiotherapy involving the orofacial tissues. Up to 90% of patients on traditional chemotherapy develop mucositis although targeted cancer immunotherapy is less likely to give ulcers. Oral mucositis is particularly severe after haemopoietic stem cell transplant and can act as a portal for infection. Mucositis typically presents with pain which can be intense enough to interfere with eating, and significantly affect quality of life, with ulceration and sometimes bleeding.

Management aims to relieve pain, hasten healing and prevent infectious complications. Pain relief is usually with opioids given by patient-controlled analgesia; additionally, benzydamine rinse or spray can aid relief. Oral cooling with ice chips ameliorates chemotherapy-induced mucositis.

Systemic diseases and the mouth

The oral mucosa is a specialized form of skin bridging the gap between the embryonic gut tube ending and the outside world as the head and brain rapidly enlarge. The mouth therefore has a stratified squamous epithelium lining and the transition to the gut 'proper' happens in the oesophagus. Consequently, the oral cavity experiences a transition of diseases between GI and dermatological conditions and skin appendages can result in visible changes in the mouth in some individuals.

DISEASES OF THE SKIN

The immunobullous conditions pemphigus, pemphigoid and lichen planus are commonly present with findings in the oral mucosa. Others seen more rarely include epidermolysis bullosa and linear IgA disease.

Pemphigus and pemphigoid are autoimmune disorders driven by immunoglobulins, where C3 and IgG binding cause loss of adherence of intercellular desmosomes and hemidesmosomes. They result in separation of the cells of the epithelium from each other (pemphigus) and the epithelium from the basement membrane (pemphigoid). Pemphigoid presents with a combination of intact and ruptured bullae but pemphigus has such fragile intraepithelial bullae that they are frequently not seen other than as a white change in the mucosa which is rapidly lost to reveal a red and inflamed submucosa (**Figure 42.12**). There are variations in these diseases depending upon the epitopes of the antigen

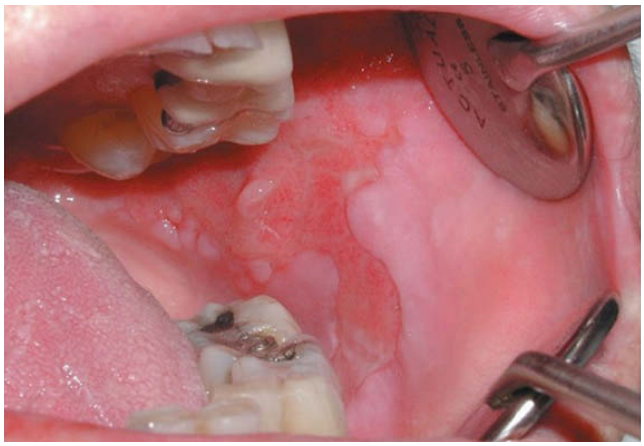

Figure 42.12 Pemphigus.

Figure 42.13 Lichen planus.

targeted by the immune reaction and these small alterations can significantly change the presentation or consequences of the disease processes. There are also differences between the immune target in the skin and oral versions of these conditions such that they can run largely independent courses in the same individual. Pemphigus often will start with oral lesions and later involve the skin whereas pemphigoid can have limited oral and cutaneous versions. Pemphigoid also has a scarring form limited to the mucosa and into the eyes and oesophagus – cicatricial pemphigoid. This is progressive and can be very disabling over time with difficulty opening the mouth and swallowing as well as significant ophthalmological issues.

All patients diagnosed with pemphigoid on the oral mucosa should see an ophthalmologist to manage any conjunctival scarring which may appear with time. Most symptoms from these conditions result from the ulcerative areas left when the bullae burst (pemphigoid) or the epithelium separates internally (pemphigus). This causes widespread discomfort for the patient.

Paraneoplastic pemphigus is suspected when a pemphigus lesion is difficult to manage. It is usually associated with lymphoproliferative disease or thymoma and the oral lesions may be the sole manifestation. A degree of suspicion is needed but an appropriate referral to a general physician for assessment is essential. Biopsies for pemphigoid and pemphigus must be taken from perilesional tissue otherwise no epithelium will be present on the specimen for proper examination.

Lichen planus (LP) is a very common oral condition and in most patients, is asymptomatic. It is a T-cell mediated attack on the basement membrane and basal cell layer of the skin or mucosa and causes a reactive increase in the epithelial width (acanthosis – white appearance) or a reduction in the production of new epithelial cells and a consequent reduction in epithelial width (atrophy/ulceration – red appearance). Both can be present in the same lesion at the same time. On the skin it gives lacy patterns, with itchy purple spots on the wrists, legs and trunk. About 30% of patients have both oral and cutaneous lesions. The oral lesions are frequently asymptomatic and seen as an incidental finding on oral examination. However, oral LP can present in more aggressive ways including atrophic and erosive versions which cause discomfort with spicy and flavoured foods. Lesions tend to be intermittent and recurrent and can be symptomatically confused with recurrent aphthous ulcers. However, LP lesions tend to recur in the same places repeatedly whereas aphthae vary in position. Common sites for LP are the lateral aspects of the tongue and the buccal mucosa (**Figure 42.13**). LP has a low potential for malignant transformation although the individual risks for a lichenoid lesion are not clear. Patients must be made aware of the issue of possible malignancy so that regular monitoring of the lesions can take place. LP is mostly of unknown origin but in some individuals, there is a trigger from amalgam or other dental restorations adjacent to the lesions. This is termed a lichenoid reaction although the lesions on the mucosa are essentially the same as those seen in LP. Drug reactions can also trigger a lichenoid reaction, the commonest of which are ACE inhibitors and beta-adrenergic blockers. Disease-modifying drugs used in connective tissue diseases such as gold, penicillamine and sulphasalazine are used less frequently now but were frequent triggers in the past. Discontinuing these medicines gradually results in an improvement in the condition. Angiotensin-2 receptor blockers do not give this reaction and are a good alternative where an ACE inhibitor is suspected as the cause of the lichenoid reaction.

All three of these dermatoses can also present in limited form in the mouth, affecting the attached gingivae only. This is clinically described as a 'desquamative gingivitis' and the underling condition can be determined by biopsy (**Figure 42.14**).

Management of pemphigus, pemphigoid and LP uses the same algorithmic approach as is used for aphthous ulcers (**Table 42.10**) with the exception of colchicine which has no role in the immunobullous conditions. Additionally, topical clobetasol or tacrolimus as a cream or ointment can be useful for stubborn but localized lichenoid lesions. Tacrolimus as a mouth rinse can be a useful bridge between topical steroids and systemic medication for

Figure 42.14 Desquamative gingivitis.

individuals with widespread lichenoid lesions but is ineffective against pemphigus and pemphigoid in the mouth as they are largely antibody rather than T-cell driven.

Diagnosis of an immunobullous condition in the mouth is by perilesional biopsy with one sample sent for standard histopathology and a second sample for direct immunofluorescence. Indirect immunofluorescence from a blood sample is not accurate as a diagnostic test but can be helpful in monitoring disease activity.

GASTROINTESTINAL DISORDERS

GI conditions are frequently associated with oral symptoms and signs. The consequences for the oral mucosa can be direct disease effects or secondary to nutritional deficiency from GI bleeding or malabsorption. Oral ulcers, candida infections and lichenoid lesions are all exacerbated by haematinic deficiency and thus, blood loss from peptic ulcer disease, inflammatory bowel disease or bowel cancer will impact on the mouth, and may be the presenting symptom.

Coeliac disease is often easy to diagnose in children as there is growth failure. However, adult-onset coeliac is more of a challenge and the nutritional deficiency consequent to malabsorption may exacerbate oral diseases. Commonly ferritin and folic acid levels are reduced when there is small bowel malabsorption and this combination should always raise suspicion. Where necessary a tissue transglutaminase or more specific coeliac test can be run.

Ulcerative colitis (UC) similarly can exacerbate oral conditions that are sensitive to haematinic deficiencies. However, aphthous pattern mouth ulcers can occur during periods of UC activity and the oral lesions tend to settle when the colonic disease is controlled.

Crohn's Disease (CD) is a pan-GI disorder with full-thickness inflammation of the mucosa, lymphatic obstruction and mucosal oedema. Like UC its aetiology is unknown but likely represents a range of aetiologies interacting with the host immune system. First symptoms can commence at any age and localize to any area of the GI tract; akin to UC, exacerbation of oral conditions related to haematinic deficiencies complicates the condition. CD can involve the mouth together with other GI sites and when there is gut disease present the oral features are described as 'oral Crohn's disease'. In children, the oral features may present before GI symptoms.

Oro-facial Granulomatosis (OFG) is a disease which has all the features of CD but is localized to the oral mucosa with no symptomatic GI disease. Over time some will develop GI symptoms and OFG may represent part of the spectrum of CD rather than being a separate entity. As sarcoidosis and tuberculosis can both present in the mouth with similar clinical findings, it is important that these are excluded before a diagnosis of OFG is attributed. The characteristic features of OFG are identified in **Box 42.1**.

Not all of these findings are present in every patient and recurrent or persistent lip swelling usually triggers the referral. These lip swellings are from lymphoedema with the lymphatics obstructed by giant cells. The swelling persists for several days or weeks at a time. Like CD it is likely that the aetiology of the immunological reaction in OFG is multifactorial and varies from patient to patient.

Management of OFG takes two approaches. First, the lymphoedema can be reduced in patients who have a sensitivity to dietary triggers by a 12-week complete exclusion diet. It is not possible to identify these patients other than by the diet and so all OFG patients are started with this regime. The patient needs to exclude benzoate, sorbate, cinnamon and chocolate. This requires a degree of determination by the patient and others in the household if it is to be a success. Advice from a specialist dietician can be helpful. During the exclusion period those patients with dietary hypersensitivity will get progressive reduction of the lip swelling although some of the other intraoral changes will persist. At the end of the exclusion period, the patient can return to a normal diet if exclusion was ineffective or, if it was helpful, individual foodstuffs can be reintroduced one at a time to identify individual items for future avoidance. It is unclear whether these dietary triggers are implicated in the aetiology of OFG or are coincidental issues present in the patient for many years and brought to the fore by the lymphatic obstruction.

The second management approach is to use immunotherapy to eliminate the giant cell reaction and allow the lymphatics to drain freely. This can be tried with topical tacrolimus but usually needs systemic treatment with azathioprine of mycophenolate. Surgical options for OFG management usually produce a poor cosmetic result.

BOX 42.1 Oral features in Crohn's disease

- Lip and/or facial swelling and erythema
- Angular cheilitis
- Oral mucosal tagging
- 'Cobblestone' appearance of the mucosa
- Linear ulcers in the depth of the buccal sulcus
- Non-plaque related full width gingival inflammation

CONNECTIVE TISSUE DISORDERS

Most connective tissue disease affecting the head and neck involves the salivary glands. However, mucosal lesions from lupus erythematosus or loss of tissue elasticity as a result of scleroderma can complicate oral care.

Discoid lupus lesions or those associated with SLE have a clinical appearance like lichen planus but are distinct on biopsy. The lesions are also more commonly found in sites unusual for lichen planus, such as the mucosa of the palate.

Scleroderma either on its own or as part of CREST syndrome poses many challenges for oral care. Once the disease fully takes hold, mouth opening is greatly reduced and dental care including denture provision becomes extremely difficult. When it is clear a patient has oral involvement from scleroderma, an opinion should be obtained from a Restorative Dentistry specialist who can assess the long-term prognosis for the dentition and plan for a future low-maintenance mouth.

GRAFT VERSUS HOST DISEASE

Graft versus host disease (GVHD) is usually the consequence of allogeneic bone marrow transplant but is also seen after autologous stem cell treatment. The oral lesions are similar to a widespread lichenoid reaction and mirror the immunological damage taking place elsewhere in the body. The oral lesions can be painful if erosive or atrophic and can be managed with topical steroids in most cases. However, the patient's physician should be made aware of the oral finding as systemic immunotherapy may be preferred to prevent concurrent damage to other body organs. Herpes simplex virus (HSV) causes primary herpetic stomatitis of the oral and genital areas with oral lesions accompanied by systemic upset and fever. Either HSV1 or 2 can be found in primary or recurrent lesions. Many infections with HSV occur in childhood and are subclinical, often misdiagnosed or passed off as 'teething'. More typically it presents with malaise, anorexia, irritability and fever, anterior cervical lymphadenopathy and a diffuse, purple, boggy gingivitis with multiple vesicles followed by scattered ulcers 1–3 mm in diameter. A full blood picture, white cell count and differential, and viral studies may therefore be required. Specific antiviral agents such as aciclovir are reserved for immunocompromised patients. Recurrent HSV lesions can be seen periorally but can also present as intraoral lesions, most typically on the palate. The patient describes a recurrent 'ulcer' in an area which is unilateral and restricted to a single mucosal nerve branch. Where symptomatic, the intraoral and extraoral lesions can be treated symptomatically. In significant lesions which are disfiguring or persisting, systemic acyclovir is used in preference to topical drug. A continuous low dose of aciclovir can be given each day as prophylaxis against recurrence and can significantly improve the patient's quality of life.

Herpes Zoster virus (HZV) causes similar clinical lesions as found in HSV but the primary infection (chicken pox) has skin lesions as well as the oral vesicles/ulcers and systemic fever. The HZV virus is more neuropathic than HSV and the characteristic difference when recurrent lesions (shingles) appear in the mouth or on the face is pain in the affected area, which may precede the onset of the vesicular rash. Shingles should always be treated with aciclovir to reduce the cumulative nerve damage that can lead to post-herpetic neuralgia. The medication should be started with the onset of pain and continued until the rash has cleared. The dose of aciclovir needed to treat HZV is higher than with HSV and similarly, if daily prophylaxis against recurrent HZV is to be given, the dose must be raised above that used for HSV.

Other herpes group viruses also cause oral mucosal lesions. Epstein–Barr virus (EBV) gives the features of glandular fever during the primary infection and although there is no mucosal recurrent lesion as with HSV, persistence of the virus can be associated with hairy leukoplakia in the immunocompromised and nasopharyngeal carcinoma. Cytomegalovirus (CMV) rarely causes oral issues except in the extremely immunosuppressed patient where widespread atypical oral ulceration can arise, a difficult clinical problem. *HHV8* is associated with Kaposi's Sarcoma oral lesions.

Human papillomavirus (HPV) is present in mucosal warts and multiple wart-like lesions in an adult should raise the suspicion of immunodeficiency. HPV seems not to be associated with oral squamous cell carcinoma although it plays a significant role in oropharyngeal cancer.

Coxsackie viruses can cause hand, foot and mouth disease, and herpangina with oral vesiculation together with systemic symptoms but treatment for the oral lesions is supportive only.

HIV-associated oral lesions have been well documented but with the advent of HAART management these are now rarely seen except in the latter terminal stages of the disease. Consequently, an HIV test should be considered in any patient presenting with an oral condition noted to be associated with immunosuppression (**Figure 42.15**).

FUNGAL INFECTIONS

Candida albicans is the most common fungal organism found in the mouth although other forms such as *C. krusei, C. glabrata C. tropicalis* and *C. dubliniensis* can be

Figure 42.15 Hairy leukoplakia in HIV.

TABLE 42.11 Rare orofacial fungal infections

Infection	Oral manifestations
Aspergillosis	Aspergilloma Rhinocerebral type causes palatal necrosis Disseminated in immunocompromised patients
Blastomycosis	
North American South American (paracoccidioidomycosis) Coccidioidomycosis Cryptococcosis Histoplasmosis Phycomycosis (mucormycosis, zygomycosis)	Oral ulcers, or suppurating granulomas
	Oral ulcers and lymphadenopathy
	Rarely oral ulcers
	Oral ulcers
	Lumps or ulcers
	Antral involvement with palatal ulceration in immunocompromised patients – especially diabetics

TABLE 42.12 Oral *Candida* conditions

Types of candidiasis	Predisposing factors
Acute pseudomembranous candidiasis (thrush)	Local or systemic immunosuppression
Acute atrophic candidiasis (antibiotic sore mouth)	Broad-spectrum antibiotics
Erythematous candidiasis	None, aging
Chronic atrophic candidiasis (denture-related candidiasis)	Denture/appliance-wearing, especially at night
Chronic hyperplastic candidiasis	Tobacco smoking
Median rhomboid glossitis	Tobacco smoking, denture wearing, local immunosuppression
Angular cheilitis	Denture wearing, diabetes, haematinic deficiency, OFG
Chronic mucocutaneous candidiasis	Often immune defect; rarely endocrinopathy

found. These non-albicans species tend to be more resistant to common antifungal agents. Rarer orofacial fungal infections are listed in **Table 42.11**.

Candida spp. is a commensal in many of the population and a swab from the mouth demonstrating *candida* does not denote infection, simply candidial carriage. Quantitative fungal assays can be used where it is important to demonstrate high levels in the mouth. *Candida* can cause a variety of oral infections and appearances (**Table 42.12**). Although acute pseudomembranous candidiasis can produce white lesions in the mouth the clinician will do well to remember that there are many causes of oral white lesions and that every patient with a white lesion should not be assumed to have, and be treated for, candidiasis!

Denture-related stomatitis (chronic atrophic candidiasis) is the most common form of mild, chronic, oral candidiasis. It occurs only beneath a denture or other appliance and, despite its name, is not often sore. Dentures worn throughout the night, or with a dry mouth, favour development of this infection and occasionally there is a mixed infection with staphylococcal species. An accumulation of microbial plaque on and in the fitting surface of the denture and the underlying mucosa predispose to making the clinical appearance persist. This condition is managed exclusively by proper denture hygiene including removing the denture at night, cleaning the denture properly and treating it regularly with an appropriate antiseptic. There is no need for a topical antifungal except in the immunocompromised. If untreated the patient may develop papillary hyperplasia of the tissues beneath the denture which can complicate the provision of a new denture in the future.

Acute oral candidiasis (acute pseudomembranous candidiasis) may complicate systemic, topical or inhaled corticosteroid or antibiotic therapy (**Figure 42.16**). It produces widespread erythema and soreness or the mouth and pharynx, sometimes with thrush.

Figure 42.16 Pseudomembranous candidiasis: 'thrush'.

In some immunocompetent patients, there is persisting erythema in the palatal tissues associated with candida. This is termed chronic erythematous candidiasis and requires no treatment.

Chronic hyperplastic candidiasis (CHC) is a condition that has been considered potentially malignant but the link between CHC and oral cancer is now less clear. Its true nature remains elusive but it is associated with candida invasion into the tissues at the corners of the mouth causing a raised white lesion on the oral mucosa. Histologically, the picture is often that of high-grade dysplasia, but this is a reactive change to the presence of candidial hyphae in the tissues. When systemic antifungals are given, the dysplastic appearance settles and it is essential that where dysplasia is reported in CHC, the patient is given a systemic antifungal and the tissue re-biopsied to ensure that the tissue changes resolve. The fungal invasion and the clinical picture will usually return in time and may need repeated systemic antifungal courses.

Figure 42.17 Angular stomatitis.

Angular stomatitis is a fairly common acute or chronic inflammation of the skin and contiguous labial mucous membrane at the angles of the mouth, bilaterally (**Figure 42.17**). Most cases are in adults and due to mechanical and/or infective causes but, in children, nutritional or immune defects are more prominent causes.

Mechanical factors include dentures with an incorrect facial height, no denture worn in edentulous patients or as a normal consequence of the ageing process in some patients. This can result in overfolding of the mouth corners and leakage of saliva. This is a strong irritant to the skin at the corners of the mouth. Nutritional deficiencies, in particular iron, folate and vitamin B_{12} make this change more likely. It is also seen to be associated with orofacial granulomatosis, diabetes and HIV infection. *Candida spp.* or staphylococci are isolated from most patients and topical miconazole treats both of these organisms. There is a benefit from using a preparation with miconazole and hydrocortisone as it allows for quicker reduction in the inflammation of the skin and the re-establishment of a proper infective barrier. This reduces recurrence of the condition.

Orofacial pain

Most oral pain is from common dental and periodontal inflammatory causes such as pulpitis, periapical periodontitis and pericoronitis. Neurological, vascular and referred causes are less common. Non-dental and idiopathic facial pain are common in specialist settings and present to dentists, general practitioners, neurologists and oral surgeons as well as oral medicine and ENT specialists. Often a patient has multiple referrals to a variety of specialist services from different practitioners and these other specialty contacts must be identified in the history so that collaborative working can take place.

Chronic oral mucosal soreness can arise from persisting ulceration or mucosal atrophy secondary to lichen planus, major aphthous ulceration, geographical tongue and haematinic deficiency states. Other distinct groups of orofacial pain conditions cluster around trigeminal autonomic cephalgias, oral dysaesthesias and temporomandibular disorder.

Glossitis is not a true condition but the term is frequently used. Tongue pain may be related to deficiency of iron, folate or vitamin B_{12}, and may present in association with other deficiency-related oral issues such as angular stomatitis and/or aphthous ulcers. A full blood count and assays of iron (ferritin), folate and vitamin B_{12} are indicated. The clinical appearance of the tongue may show generalized or localized depapillation predominantly of the filiform papillae. The tongue may appear fissured and erythematous but this is a normal variation and not the source of any discomfort reported by the patient. Lichenoid atrophy of the tongue dorsum and candidial invasion of the tongue surface can also give tongue sensitivity and pain and a biopsy is indicated if there is doubt about the cause of the patient's symptoms.

TRIGEMINAL AUTONOMIC CEPHALGIA

The extremes of this group of facial pain and headache conditions are recognized as trigeminal neuralgia and cluster headache. However, it is now clear that this is a spectrum of disorders with any one individual having features closer to either condition or a blend of both. Importantly, patients can move along the spectrum with time changing the presenting symptoms and the treatment needed to remain pain free.

Trigeminal neuralgia (TN) is a condition of unknown origin which causes a characteristic pain on stimulation of a particular sensory nerve area. This is usually on the surface of the face or in the mouth but can be deeper in the tissues and even the teeth and is usually worse over the winter months. If the same condition affects the mucosa of the posterior tongue or pharynx it is labelled glossopharyngeal neuralgia and this has implications for the management options. TN is mostly seen in patients over 50 years of age but there are an increasing number of younger patients presenting. In the classical form TN presents with a trigger area which, when touched, causes a severe but short-lasting pain radiating from the trigger area through the trigeminal distribution. In most cases, this is the maxillary or mandibular divisions of the trigeminal nerve. Usually a single unilateral area is affected. In some cases, the pain may be followed by a burning sensation in the trigger area. Hypoaesthesia in the trigger area should raise suspicion of an intracranial mass lesion such as an acoustic neuroma or a degenerative brain disease, both of which can present with TN. Rarely TN can follow maxillofacial trauma with the trigger in the area of the injury, such as a previous zygomatic or mandibular fracture.

MRI is an essential first investigation when TN is suspected and medical therapy should be instituted quickly. The medication of choice is determined by the patient's other medication, medical and home circumstance and the treating physician's experience with TN patients. Carbamazepine is often the first-line medication but it causes significant sedation, balance disorders, nystagmus and drug interactions. Oxcarbazepine and lamotrigine are effective alternatives with fewer side effects in most patients. Lamotrigine must be introduced over several weeks and is often used once initial symptom control is achieved with carbamazepine.

Surgical treatment for TN is indicated in the young or where the dose of medication is significantly impacting on the patient's quality of life. A microvascular decompression is the treatment of choice where the MRI indicates that a vascular loop is compressing the trigeminal root. This procedure will usually result in a pain-free patient, off medication for several months although lower doses of the anti-neuralgic medicines are needed eventually. Destructive procedures to the trigeminal ganglion are quicker and simpler operations for the less fit patient and stereotactic radiosurgery (gamma knife) requires no operation at all.

Cluster headache (CH) is a condition of unknown origin which has unilateral pain and autonomic efferent features including ptosis, facial erythema/swelling, lacrimation and nasal discharge on the affected side. It has both episodic and chronic forms. The former will give several weeks of daily intense headache and facial pain before terminating abruptly whereas the latter gives daily pain with no respite. In CH the pain lasts several hours, is unbearable for the patient and stops spontaneously after 3–5 hours. It often happens at night or in the evening and there is an association with coffee use. Management is for specialist practice. Inhaled oxygen with the onset of pain can be very effective but triptans have a place in some cases. Chronic CH has been reduced in severity and frequency using verapamil at moderate to high doses; lithium has also been used as a preventative therapy.

ATYPICAL ODONTALGIA

Patients with this condition often have a strange pattern of dental extractions on looking in the mouth. Most often there is a single mouth quadrant where many teeth have been removed in an otherwise healthy mouth. This condition is characterized by intense toothache focused on a single tooth. This usually has no evident disease but the patient is in such intense pain the tooth is eventually root treated and finally extracted. The pain settles but in a few weeks or months returns in the same quadrant of the mouth in an adjacent tooth. The pattern repeats. If, eventually, all of the teeth are removed the pain settles in the edentulous bone with the same characteristic toothache. This appears to be a neuropathic pain problem but even with current medication if can be challenging to treat.

PERSISTENT IDIOPATHIC FACIAL PAIN

This is a diagnosis of exclusion and consequently can reflect the clinician's diagnostic ability as much as the pain problem itself. It is best made by a specialist in oro-facial pain who can exclude some of the rarer but treatable head and neck pain problems. The older term of atypical facial pain should not be used.

ORAL DYSAESTHESIA

Oral dysaesthesias are a group of conditions in which the patient seems to have altered perception of the oral environment such that the mouth feels dry, burning, numb or with a bad taste/smell in the absence of any disease. They are often referred to as burning mouth syndrome although the most common presenting variation is that of a feeling of oral dryness or stickiness in the presence of plentiful oral saliva. These conditions represent a misperception of the normal oral environment rather than a disease of the oral mucosa or supporting tissues. Patients will often have more than one dysaesthesia symptom, such as a burning feeling and a persistent dryness. This condition is often worse as the day progresses, relieved by eating or oral activity and enhanced by stressful life events. Treatment starts by explaining to the patient that there is no disease or oral condition even though this seems to be the case and that the problem is with the 'feeling nerves' in the mouth. It is unclear whether there is a true local neuropathic problem in a dysaesthesia or whether it is an issue with the understanding and interpretation of the neural signals in the brain, as there is some experimental and treatment evidence for both. Very occasionally, similar symptoms can arise from mucosal atrophy as a result of haematinic deficiency and haematinics should be checked if a burning sensation is reported. Where sensory changes are reported, an MRI is a sensible precaution even if there are no cranial nerve deficiencies on testing. Occasionally, dysaesthesia symptoms can result from neuro-degenerative disease. Tricyclic antidepressants are the most effective treatment with nortriptyline having a better side effect profile than amitriptyline. Gabapentin and clonazepam have been used as alternatives. For mild cases, simple oral distractors such as chewing gum are useful. As these conditions are commonly associated with an underlying anxiety disorder, psychological intervention or hypnosis can be useful alternatives.

TEMPOROMANDIBULAR DISORDER

Temporomandibular disorders (TMD) encompass a range of pain and mechanical problems around the TMJ. Patients reporting locking of the joint or indicating pain only in the area of the joint itself have an internal joint derangement and require imaging and surgical assessment.

TMD represents the largest group of non-dental pains presenting in the head and neck. The actual presenting complaint varies from patient to patient but any diffuse head and neck pain which is chronic in nature must have TMD excluded. The core finding in TMD patients is a tendency to anxiety and as such they are a similar demographic to many other medical conditions including burning mouth syndrome, irritable bowel syndrome and fibromyalgia. Indeed, some view TMD as an extension of fibromyalgia to the head and neck with similar symptoms and management strategies.

Pain in TMD patients can be widespread and diffuse, affecting both sides of the face, head and neck or very focused on a single site, such as chronic midface pain, simulating dental pain in the molar teeth. It is characterized by an aching sensation which lasts for many hours or days at a time. In many cases, the pain centres around the masticatory muscles and the patient experiences limited mouth opening with pain when trying to chew. This can be accompanied by clicking of the TMJs and displacement

of the dental occlusion, all of which are compatible with the TMD pain syndrome diagnosis. Focal tenderness of the masticatory muscles is analogous to trigger points found in neck muscle pain or elsewhere in fibromyalgia. The clenching of teeth at night is a common finding in these patients but the muscle pain does not seem to be a direct consequence of this, as many patients clench their teeth and develop no chronic pain.

When the masticatory muscles are the focus for the patient's symptoms a plastic bite splint can be provided by the patient's dentist. If this is combined with a soft diet and supported yawning many patients will get good symptomatic relief. However, if the pain is more diffuse and chronic the use of a tricyclic antidepressant such as nortriptyline at night can aid recovery.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search (as well as the websites Cancerlit and CancerNet) using the keywords: neck mass, head and neck neoplasm, imaging and fine-needle aspiration cytology, and focusing on diagnosis, surgery and management. The evidence in this chapter is mainly levels 3/4 with some level 2 evidence. The clinical recommendations are predominantly B and C.

INTRODUCTION

Embryogenesis and ultrastructure

The salivary glands share a common embryological development, whether they are the major named glands or the minor mucosal salivary glands.

The major salivary glands develop from the 6th to 8th weeks of gestation as outpouchings of oral ectoderm into the surrounding mesenchyme. The parotid develops first, growing in a posterior direction as the facial nerve advances anteriorly so that eventually, the parotid gland surrounds the facial nerve.

After the parotid glands are formed, the submandibular glands develop at 6 weeks and the sublingual glands at 8 weeks. The minor salivary glands arise from oral ectoderm and nasopharyngeal endoderm.

While the parotid is the first to develop, it is the last to become encapsulated, after the lymphatics develop. This results in entrapment of the lymphatics deep to the capsule in the parenchyma of the gland. Salivary epithelial cells can be included within these lymph nodes and this may be important in the development of Warthin's tumours and lymphoepithelial cysts within the parotid gland. The submandibular glands in general become encapsulated before lymphogenesis and usually do not have intraparenchymal lymph nodes.

The major glands lie distant to the oral mucosa, and are connected to the mucosa by excretory ducts. The minor glands lie within the mucosa or submucosa of the oral cavity and oropharynx and either open directly onto the surface of the mucosa or are connected to it via short excretory ducts.[1,2]

Microscopic anatomy

Salivary glands are made up of secretory acini and ducts. The acini can either be serous, mucous, or a mixture of serous and mucous. The secretory cells are categorized into three types. Cells containing small granules are serous and secrete salivary proteins and enzymes. Mucin-producing cells are cylindrical in shape and contain larger granules producing mucoproteins. Seromucinous cells have an intermediate ultrastructure.

The acinar ducts coalesce into intercalated ducts and subsequent striated ducts composed of columnar cells, before uniting into the main excretory duct of the gland.

The intercalated ducts are lined by simple low cuboidal epithelium, and surrounded by myoepithelial cells. The striated ducts have a folded basal membrane, enabling the active transport of substances out of the duct, such as water resorption and active secretion into the ducts. The excretory ducts are lined with a tall columnar epithelium.

Within the major salivary glands the acini are arranged into lobules and lobes within the glands. Each lobule has a single excretory duct. The lobules are linked by dense fibrous tissue containing excretory ducts, vessels, lymphatics, nerve fibres and ganglia to form lobes (**Figure 43.1**).

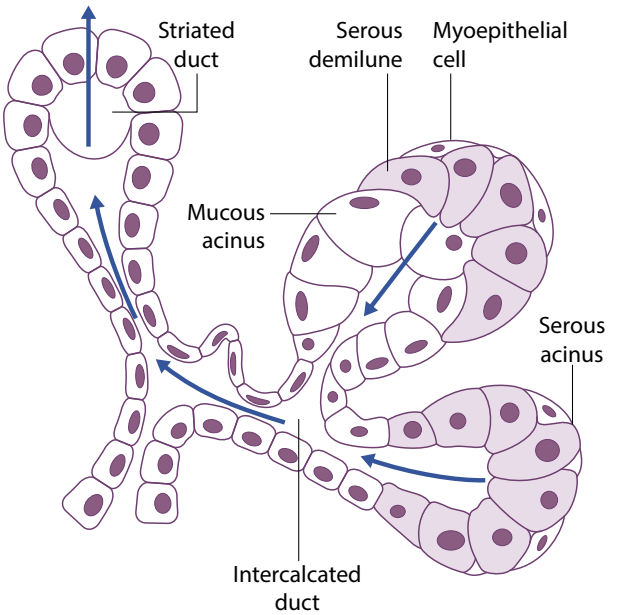

Figure 43.1 Part of a salivary gland showing a serous acinus and mixed serous-mucous acinus.

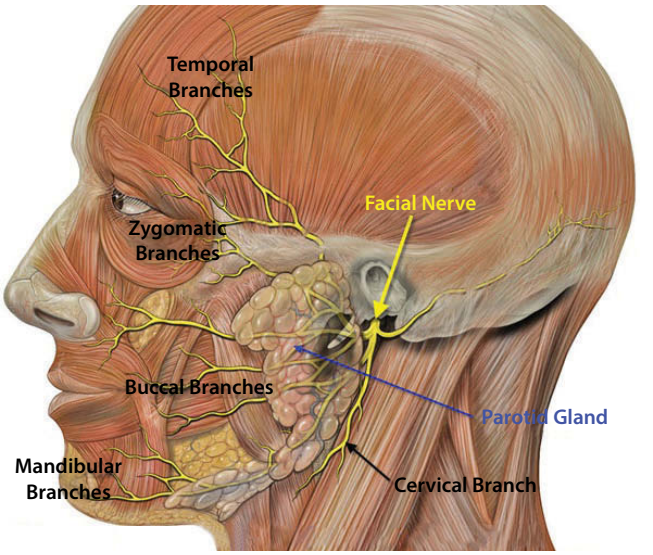

Figure 43.2 Anatomy of the parotid gland.

It is likely that the morphological description is an oversimplification and the products of these cells form an almost continuous series, from serous secretions with negligible amounts of protein-associated acidic carbohydrates, to mucous secretions rich in them.

THE PAROTID GLANDS

Clinical anatomy

The parotid glands are the largest of the salivary glands and are mainly serous, containing only a few mucous acini. Each gland weighs on average 25 g and is irregularly lobulated. It is wedge-shaped on coronal section and laterally extends from the zygomatic arch superiorly to the upper part of the neck inferiorly, where it overlies the posterior belly of digastric and the anterior border of the sternocleidomastoid muscle (**Figure 43.2**). Anteriorly it overlies the masseter muscle and posteriorly it extends below the external auditory canal and onto the mastoid process overlying the lateral process of C1. Medially it fills the gap between the mandible anteriorly the mastoid and the styloid process. It extends close to the lateral wall of the oropharynx and hence the need to examine the oropharynx when assessing the parotid gland (**Figure 43.3**).

The accessory parotid gland is a separate part of the gland usually lying on the masseter muscle between the parotid duct below and the zygomatic arch above.

The superficial (lateral) surface of the gland is concave and covered by the parotid fascia, skin and the posterior border of platysma. Some branches of the great auricular nerve lie superficial to the gland tissue and superficial lymph nodes lie on or deep to the fascia as well as within the gland. The great auricular nerve arises from the cervical plexus and provides sensation to the lower two-thirds of the pinna as well as to the parotid fascia and it is often possible to preserve at least its posterior branch during parotid surgery.

The anteromedial surface lies on the ascending ramus of the mandible and the medial pterygoid muscle as it inserts into the ramus. The gland is wrapped around the temporomandibular joint and joins the superficial surface over the masseter muscle to form the convex anterior border of the gland. The facial nerve and parotid duct emerge from this surface and run forwards deep to the anterior border. As the gland develops from the buccal cavity it grows backwards towards the ear. It envelops the external carotid artery, which divides into the maxillary and superficial temporal artery within the gland. The maxillary artery leaves the anteromedial surface and the superficial temporal artery continues superiorly to exit the gland from its superior surface. The auriculotemporal branch of the mandibular nerve runs deep to the superficial temporal vessels, passes within the capsule adjacent to the neck of the mandible and behind the temporomandibular joint.

The posteromedial surface lies on the mastoid process, the posterior belly of the digastric and the sternocleidomastoid muscles. Medially it overlies the styloid process with its attached muscles (styloglossus, stylohyoid and stylopharyngeus), which separate the gland from the internal carotid artery and internal jugular vein within the carotid sheath. This surface is indented by the external carotid artery prior to its entering the gland. The facial nerve trunk enters the gland high on the posteromedial surface between the mastoid and styloid processes.

Superficial to the maxillary and superficial temporal arteries lie the corresponding veins, which unite to form the retromandibular vein within the gland. The retromandibular vein emerges from the lower pole of the gland and divides into two branches. The anterior branch joins the facial vein before entering the internal jugular vein. The posterior branch joins the posterior auricular vein to form the external jugular vein. The division may occur within the gland and two branches emerge from the lower pole.

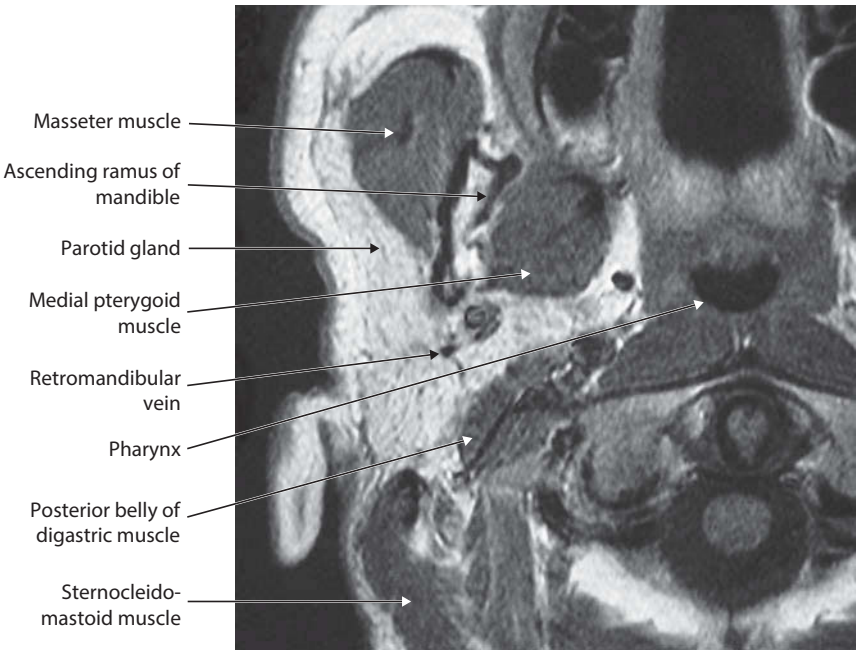

Figure 43.3 Axial MR scan showing the relationships of the wedge-shaped parotid gland, and its division into superficial and deep lobes by the retromandibular vein.

Once the facial nerve enters the gland it divides into two main temporal and cervical divisions. These pass forwards anteriorly dividing further before emerging from the anteromedial surface of the gland. The nerve divides the gland into superficial and deep lobes comprising approximately 80% and 20% of the gland respectively. The nerve lies superficial to the retromandibular vein, which is in turn superficial to the external carotid artery. The vein can be a useful radiological landmark for the nerve.

The capsule

The deep cervical fascia splits to surround the gland and is known as the parotid fascia. It is continuous anteriorly with the fascia covering the masseter as the parotidomasseteric and extends up to the zygomatic arch. Overlying the gland is the superficial musculoapneurotic system (SMAS). This is adherent to the parotidomasseteric fascia in the pretragal area and becomes separate from it as the fascia enters the cheek.[3] The deep part extends to the base of the skull and is thickened between the styloid process and the and the angle of the mandible forming the stylomandibular ligament.

The fascia is largely tough and inelastic but thins anteriorly. Inflammatory oedema pus and rapidly growing tumours contained within the capsule will cause it to stretch and become painful, often in advance of overt enlargement. The relatively thin fascia over the apex of the gland can lead to the spread of sepsis into the parapharyngeal space.

Most parotid tumours arise from the superficial lobe and expand towards the superficial surface but some deep lobe tumours are limited by the stylomandibular ligament and expand into the parapharyngeal space. Tumours arising from adjacent to the stylomandibular ligament may expand both ways to form a dumbbell-shaped mass.

The parotid duct

The parotid duct (of Stensen) is lined by low cuboidal epithelium surrounded by a smooth muscle and fibrous tissue wall. It originates within the gland, enveloped by the deep lobe of the parotid; only small ductules connect the superficial lobe with the duct.[4] It measures approximately 5 cm in length with an internal calibre of about 0.6 mm. It emerges from the anterior border of the parotid gland and travels across the masseter muscle. Having received the duct from the accessory gland it turns medially at the anterior border of the masseter. It pierces buccinator and runs obliquely between buccinator and the oral mucosa before entering the oral cavity at the parotid papilla opposite the second upper molar tooth. The facial nerve and its branches are always observed lateral to the parotid duct.

The surface marking is the middle of a line between the intertragal notch of the auricle and the midpoint of the philtrum, although a recent study suggests it may be lower than this.[5]

The facial nerve

The facial nerve emerges from the stylomastoid foramen just deep to the junction of the cartilaginous and bony parts of the external auditory meatus, usually as a single trunk but rarely as a double trunk. This has been estimated at 3–26.7%. Similar anomalies have been documented in the intratemporal course of the nerve, often associated with other congenital abnormalities. The existence should therefore be especially considered in patients with congenital abnormalities of the pinna or with congenital hearing loss. The main trunk lies approximately 1 cm above the posterior belly of the digastric muscle and it passes downwards and forwards over the styloid process and attached muscles before entering the substance of the gland. This part of the nerve gives off the posterior auricular branch,

which passes upwards to supply the occipital belly of occipitofrontalis, and a muscular branch, which divides to supply the posterior belly of the digastric and the stylohyoid muscles.

On entering the substance of the gland the main trunk divides into upper zygomaticotemporal and lower cervicofacial divisions. Further subdivisions then occur to form five branches – temporal, zygomatic, buccal, mandibular and cervical – supplying the muscles of facial expression. The resulting pattern is known as the pes anserinus. The branching pattern is variable and a number of classifications have been described. McCormack et al. and Davis et al. both described six patterns.[6, 7] Katz and Catalano[8] described five patterns (**Figure 43.4**) and Kwak et al. four, based on the origin of the buccal branch.[9] The cross-innervation between branches and divisions of the facial

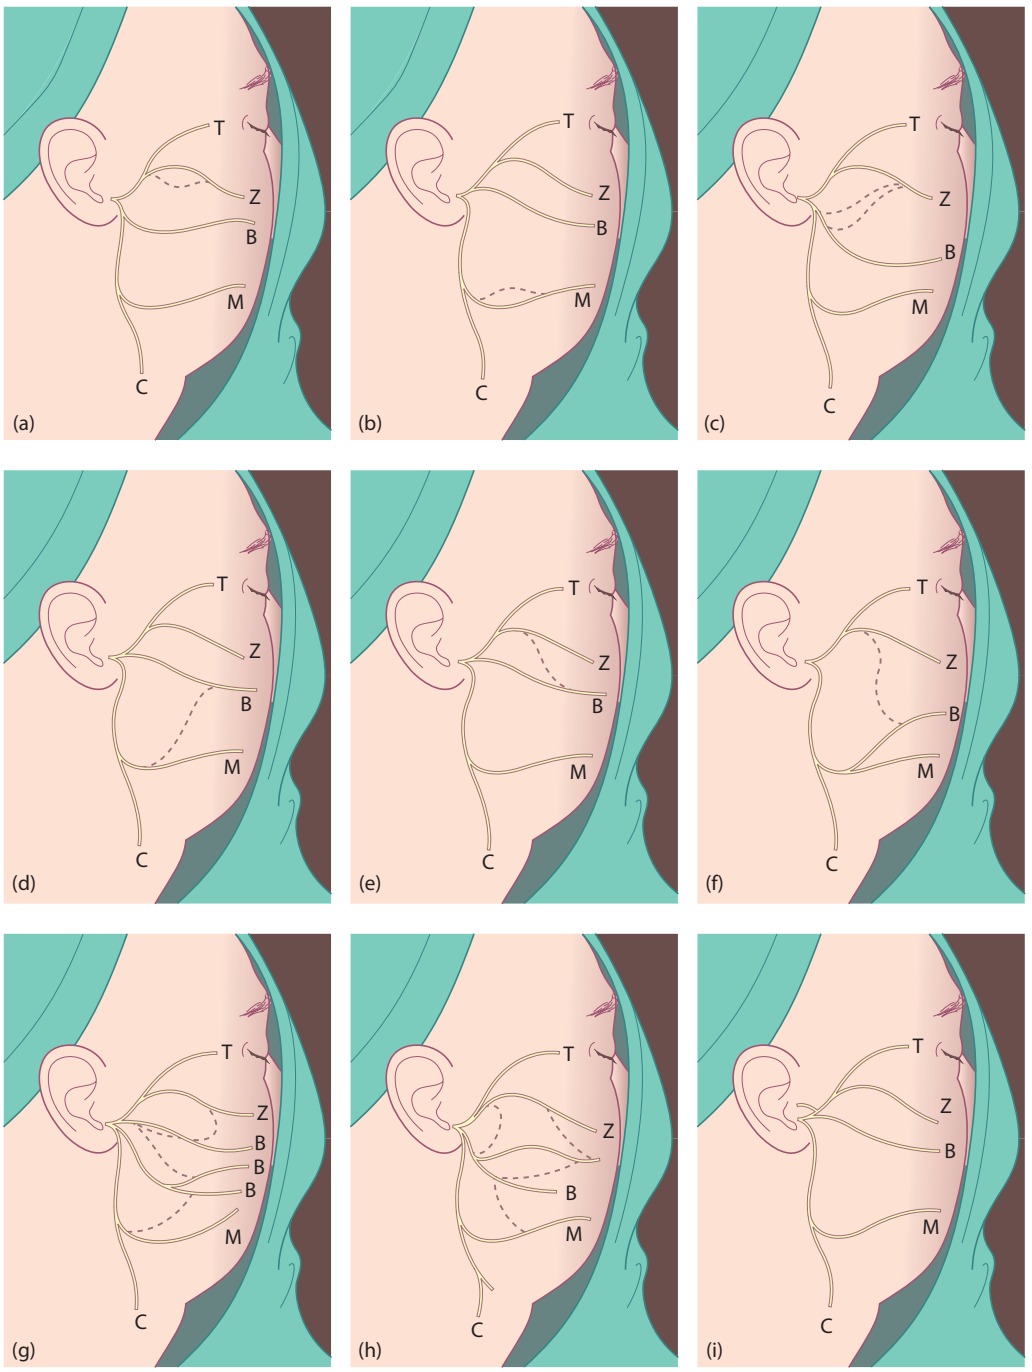

Figure 43.4 Intraparotid branching patterns of the facial nerve. **(a)** and **(b)** Type 1: in this type there is splitting and subsequent reunion of the zygomatic or mandibular branches. **(c)** Type 2: in this type subdivisions of the buccal branch fuse with the zygomatic branch peripherally. **(d)**, **(e)** and **(f)** Type 3: in this type there are major communications between the buccal branch and others. **(g)** and **(h)** Type 4: there are complex branching and anastomotic patterns between the major divisions in this type. **(i)** Type 5: in this type the facial nerve leave the skull as more than one trunk. B, Buccal branch; C: cervical branch; M, mandibular branch; T, temporal branch; Z, zygomatic branch.

nerve is most pronounced between zygomatic and buccal branches and least for the marginal mandibular branch. This explains why significant defects in midfacial movement are rarely seen following injury to the buccal or zygomatic branches and are relatively common following a marginal mandibular injury. An understanding of the variability is essential for those undertaking parotid surgery (see **Figure 43.2**).

Nerve supply

Preganglionic secretomotor fibres are carried from the inferior salivatory nucleus in the medulla along the glossopharyngeal nerve, its tympanic branch, the tympanic plexus and the lesser petrosal nerve to the otic ganglion. Post-ganglionic fibres are carried to the gland via the auriculotemporal nerve.

Sympathetic (vasoconstrictor) fibres are carried to the gland via the plexus on the external carotid and middle meningeal arteries from the superior cervical ganglion.

The gland receives sensory fibres from the auriculotemporal nerve and the fascia receives its sensory innervation from the great auricular nerve (C2).

Vessels

Branches of the external carotid artery supply the gland. Venous drainage is via the retromandibular vein into the external and internal jugular veins.

THE SUBMANDIBULAR GLANDS

The submandibular glands are the second largest of the major salivary glands. They consist of a larger superficial part and a smaller deep part wrapped around the posterior border of mylohyoid. The gland lies in the submandibular triangle formed by the anterior and posterior bellies of the digastric muscle and the inferior margin of the mandible. Each is irregular in shape and weighs 7–16 g.[1]

The lateral surface lies adjacent to the body of the mandible in the mandibular fossa and the origin of the medial pterygoid. The facial artery enters or deeply grooves the gland posteriorly, after emerging from deep to the superior margin of the posterior belly of the digastric. It initially lies deep to the gland before turning anterolaterally to emerge between the gland and the lower border of the mandible.

The superficial part is covered by skin, platysma and a fibrous capsule, derived from the deep cervical fascia. The capsule runs from the greater cornu of the hyoid bone and splits to enclose the gland before blending with the periostium of the mandible along the mylohyoid line medially, and the lower border of the body of the mandible laterally. The fascia is crossed by the facial vein, the cervical branch of the facial nerve and the marginal mandibular branch of the facial nerve.

The medial surface lies on the surface of mylohyoid anteriorly, with the nerve to mylohyoid and submental vessels. Posteriorly the gland overlies hyoglossus, the lingual nerve with its submandibular ganglion, hypoglossal nerve, stylohyoid and posterior belly of the digastric.

The deep part of the gland lies between mylohoid and hyoglossus. It lies between the lingual nerve above and the hypoglossal nerve below.

The submandibular duct

Like the parotid duct, the submandibular duct is approximately 5 cm long. It is formed by the coalescence of numerous ducts within the superficial part of the gland before emerging from the medial surface of this part of the gland, traversing the deep part before running anteriorly along the floor of the mouth between mylohyoid and hyoglossus. It emerges on the summit of the sublingual papilla adjacent to the lingual frenulum after passing between the sublingual gland and genioglossus. Whilst running forwards on hyoglossus, it lies between the hypoglossal and lingual nerves. The lingual nerve crosses the duct laterally at the anterior edge of hyoglossus before branches of the nerve emerge on the medial surface of the duct (**Figure 43.5**).

The size of the duct varies between ducts and along its length. The duct is narrowest at the ostium. In one study the mean duct diameters ranged between 1.5 mm and 0.5 mm.[10, 11]

Vessels and nerves

The arterial blood supply is from the submental branch of the facial artery, a branch of the external carotid.

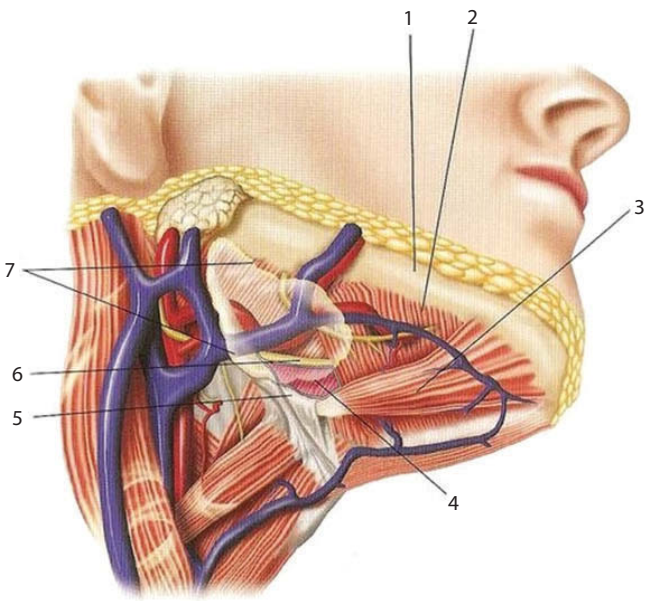

Figure 43.5 Submandibular glands. 1. Mandible. 2. Mylohyoid. 3. Anterior belly of digastric. 4. Submandibular gland. 5. Hyoid. 6. Hypoglossal nerve. 7. Facial artery.

The venous drainage is into the corresponding facial vein. An important anatomical relationship is that the marginal mandibular nerve passes lateral to the vein and, therefore, dissecting deep to the vein, can be used to preserve or identify the nerve.

The submandibular lymph nodes lie adjacent at the medial aspect and anterior end of the superficial part and sometimes within the gland itself. Lymphatics drain into the deep cervical group, particularly the jugulo-omohyoid nodes.

The sympathetic innervation of the gland is from the superior cervical ganglion via the lingual artery. Presynaptic parasympathetic innervation is via the lingual nerve, a branch of the mandibular division of the Vth cranial nerve to the submandibular ganglion. Innervation is initially from the superior salivatory nucleus in the pons passing through the nervus intermedius and carried by the chorda tympani nerve.

Lymphatic drainage goes to the deep cervical and jugular chains of nodes. Perivascular lymph nodes near the facial artery are often involved with cancer originating in the submandibular gland, and these nodes should be removed with submandibular resection.

THE SUBLINGUAL GLANDS

The sublingual glands are the smallest of the paired named salivary glands and unlike the other major salivary glands have no true fascial capsule. Almond-shaped, they lie beneath the mucosa of the floor of the mouth, between the mandible and genioglossus muscle and inferiorly they are bounded by the mylohyoid. The submandibular duct (Wharton's) and the lingual nerve pass between the sublingual gland and genioglossus muscle. Each weighs approximately 4 g.

There is no dominant duct drainage and most of the small excretory ducts (ducts of Rivinus) open directly on the summit of the sublingual fold, but some may open into the submandibular duct itself (Bartholin's duct).[1]

Vessels and nerves

The blood supply is via the sublingual and submental vessels, branches of the lingual and facial vessels. Innervation is similar to the submandibular gland, with sympathetic innervation from the cervical chain ganglia and the parasympathetic supply via the submandibular ganglion.

Lymphatic drainage goes to the submandibular nodes.

KEY POINTS

- The intraparotid portion of the facial nerve has a variable branching pattern.
- The anatomy of the fascial capsules of the salivary glands influences the spread of salivary gland disease.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the following keywords: salivary glands; saliva; production; constituents; pathophysiology of saliva.

INTRODUCTION

Salivary glands produce saliva, which plays an important role in the maintenance of oral health. The largest portion of total saliva volume is produced by three paired major salivary glands: the parotid, the submandibular and the sublingual salivary glands. In addition, there are 600–1000 minor salivary glands present in the mucosal lining of the oral cavity and oropharynx that also contribute to total saliva production.[1] Each pair of glands produces saliva of differing consistency. This variation of consistency depends on several factors including blood flow to the gland, which in turn correlates with volume of saliva produced initially. Further modification of saliva properties results from post-secretion modifications that occur within the salivary gland duct unit.

MICROANATOMY OF SALIVARY GLANDS

The secretory unit of a salivary gland consists of the acinus, enveloped by myoepithelial cells, and distally in order away from the acinus, the intercalated duct, the striated duct and the excretory duct (**Figure 44.1**).

The acinus

All acinar cells contain secretory granules, but the secretory product of acinar cells varies between salivary gland types and this is reflected in the different intracellular secretory granules.

In serous glands, the acinar cells are rich in protein (amylase) secreting granules. In contrast, mucous salivary glands are rich in secretory granules, which contain mucin. The relative abundance of secreting granules in the acinar cells dictates the consistency and composition of the secreted saliva.

Three types of acinus have been described:

- Serous (protein-secreting) – spherical cells rich in zymogen granules
- Mucous (mucin-secreting) – tubular shaped cells; mucin granules are washed out on haematoxylin and eosin preparations giving an empty cell appearance
- Mixed – varying proportions of serous and mucous acinar cells.

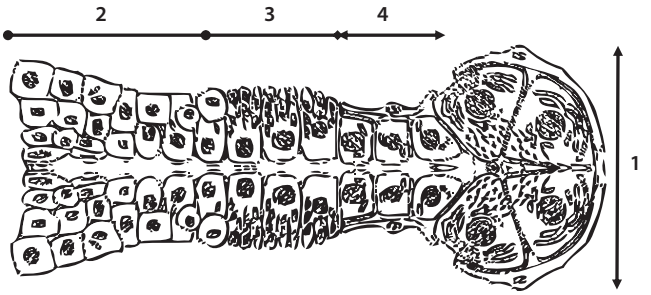

Figure 44.1 Basic salivary duct unit.

Within the acinus, the acinar cells and the cells of the proximal ductal system (intercalated duct) are enveloped by pseudopodia of surrounding myoepithelial cells. They have contractile properties and create the peristalsis action which moves saliva away from the acinus, distally along the salivary duct system.

The lumen of the acinus communicates directly with the lumen of the duct. As seen in **Figure 44.1**, the ductal system, from proximal to distal, comprises the intercalated duct, striated duct and excretory duct.

The intercalated duct

The intercalated duct is lined by low cuboidal epithelial cells rich in carbonic anhydrase. As a consequence, these cells secrete bicarbonate into the lumen and absorb chloride from the lumen. Therefore the intercalated ducts modify saliva composition produced by the acinar cells as it passes to the striated duct. This part of the duct is short and poorly developed in mucinous salivary glands.

The striated duct

The striated duct is lined by simple cuboidal cells that exhibit extensive folding of basal and basolateral plasma membrane. The folds are associated with numerous mitochondria. These cells absorb sodium from the lumen and secrete potassium into the lumen, thereby producing increasingly hypotonic fluid. The faster the salivary flow rate and/or the longer the striated duct, the more alteration of saliva composition will result. Not surprisingly, therefore, striated ducts are short or even non-existent in mucous secreting salivary glands, resulting in minimal or no modification of saliva composition. In contrast, these ducts are well developed in serous glands, resulting in heavily modified salivary composition.[2]

The excretory duct

Excretory ducts are lined by simple cuboidal epithelium proximally and striated cuboidal or pseudostratified columnar epithelium distally. These cells do not perform any modification to the salivary content.

The composition of the duct unit, including the relative abundance of mucin-secreting or protin secreting acinar cells, together with the length of the intercalated and striated ducts, dictate the salivary gland phenotype.

Accordingly the parotid gland is a serous salivary gland with the mucinous to acinar cell ratio 1:1 in the parotid acini. The submandibular glands are mixed but produce predominantly serous saliva. In contrast, the sublingual glands, which are also mixed glands, produce predominantly mucinous saliva.

In addition to the ductal microanatomy, the salivary gland stroma is rich in lymphocytes and plasma cells, which are responsible for the production of IgA, which is secreted into the salivary duct system to be excreted in the saliva.[3]

PHASES OF SALIVARY SECRETION

The production of saliva is an active process occurring in two phases:

1. Primary secretion is produced by the acinar cells and is an active process; the result is a product similar in composition and osmolality to plasma.
2. The primary secretion is then modified as it passes down the ductal system, again by active processes occurring in the cells lining the duct. Broadly, as the primary secretion passes down the duct the primary secretion becomes progressively more hypotonic with decreased sodium and increased potassium concentrations.

In general, saliva comprises 99.5% water, in addition to proteins, glycoproteins and electrolytes. The saliva is high in potassium (7x that of plasma), low in sodium (1/10x that of plasma,) calcium, phosphorous, chloride, thiocyanate, and urea resulting in a pH of 5.6–7.[4]

SALIVARY PHYSIOLOGY

The functions of saliva and the associated individual components are detailed in **Table 44.1**.

SALIVARY FLOW

The average volume of saliva secreted from the major salivary gland in a 24-hour period is 1–1.5 litres (**Figure 44.2**). Secretion from the major glands is inducible and most saliva is secreted during mastication. The basal salivary flow rate is 0.001–0.2 ml/minute/gland, while the stimulated salivary flow rate increases to 0.18–1.7 ml/minute/gland. In contrast, the salivary flow from the minor salivary glands is independent of stimulation and constitutes 7–8% of total salivary output. The saliva produced by minor salivary glands is rich in mucin and is primarily responsible for maintaining oral mucosal lubrication.[1]

In an unstimulated state the contribution of measured salivary gland is:

- submandibular gland: 69%
- parotid gland: 26%
- sublingual gland: 5%.

TABLE 44.1 The major functions of saliva

Function		Responsible component
Oral protection	• Lubrication • Antimicrobial • Growth factors • Mucosal integrity • Lavage/cleansing • Buffering • Remineralization	• Mucins, proline-rich glycoproteins, water • Amylase, complement, defensins, lysozyme, lactoferrin, lactoperoxidase, mucins, cystatins, histatins, proline-rich glycoproteins, secretory leukocyte protease inhibitor, statherin, thrombospondin • EFG, TGF-$_x$,TGF-β, FGF, IGF-1 and IGF-2, NGF • Mucins, electrolytes and water • Water • Bicarbonate, phosphate ions, proteins • Calcium, phosphate, statherin, anionic proline-rich proteins
Digestion and speech production	• Alteration of food constituency • Digestion • Taste (Food solute) • Speech (oral cavity lubrication)	• Water, mucins • Amylase, lipase, ribonuclease, proteases, water mucins • Water, gustin • Water, mucins

EGF, epidermal growth factor; FGF, fibroblast growth factor; IGF1 and IGF2, insulin-like growth factor; NGF, nerve growth factor; TGF-α, transforming growth factor-alpha; TGF- β, transforming growth factor-beta.

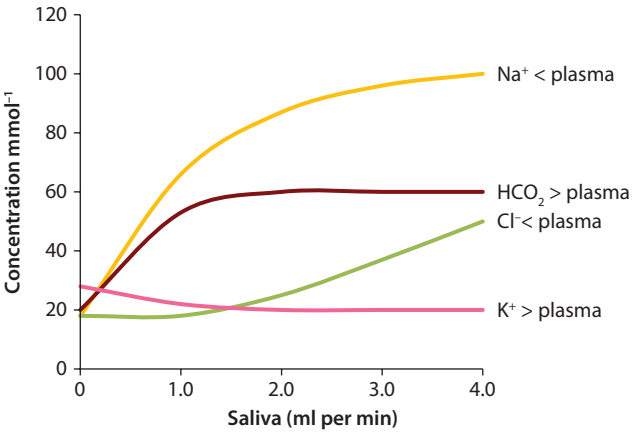

Figure 44.2 Salivary flow rates and changes in ionic composition.

In a stimulated phase the relative contributions of major salivary glands are:

- parotid gland: 69%
- submandibular gland: 26%
- sublingual gland: 5%.

THE AUTONOMIC NERVOUS SYSTEM AND SALIVARY SECRETION

The normal secretion of saliva depends on a centrally coordinated balance of sympathetic and parasympathetic activity. Parasympathetic activity, which is typically tonic, provokes most of the secretion by stimulating exocytosis from the secretory cells and varying the extent of vasodilatation of blood supply of the individual gland as well as stimulating the contraction of myoepithelial cells surrounding the gland acinus and proximal ductal system. In contrast to the tonic stimulation of the parasympathetic system, the sympathetic stimulation tends to be more intermittent and acts in opposition to the parasympathetic input. It is, however, able to modulate the composition of saliva by varying the exocytosis from specific cells lining the duct system.

It follows that the parasympathetic nervous system is the primary instigator of salivary secretion. Interruption of parasympathetic supply to the salivary glands results in glandular atrophy while interruption of sympathetic supply results in no significant change in the gland architecture.

The secretomotor cholinergic parasympathetic fibres for the parotid gland originate in the inferior salivatory nucleus. Fibres travel via the glossopharyngeal nerve initially and then via the lesser superficial petrosal nerve to synapse in the otic ganglion. The post-ganglionic fibres reach the gland through the auriculotemporal nerve. In contrast, the parasympathetic fibres of the submandibular and sublingual glands originate in the superior salivatory nucleus and travel via the hypoglossal nerve originally and then via chorda tympani to the submandibular ganglion; the post-ganglionic fibres release acetylcholine in close proximity to the glands with no true post-ganglionic synapses. In comparison, the adrenergic post-ganglionic sympathetic fibres travel from the superior cervical ganglion in fibres that pass along the external carotid artery and its branches, to reach the glands.[1]

MECHANISMS OF SALIVARY SECRETION

The mechanisms of saliva secretion have been reviewed in detail by Baum.[5] Most of the information presented below comes from the study of rat salivary glands. Little is known of the mechanisms of human salivary secretion, but similarities are assumed to exist in the physiology of salivary secretion across species.

Saliva is produced in response to neurotransmitter stimulation. Both the adrenergic and cholinergic systems have a role in the salivary secretion. Neurotransmitters bind to relevant receptors in the basolateral region of the acini. Noradrenaline, whether from the sympathetic system or circulating following release from the adrenal glands, binds to both α- and β-adrenergic receptors, while parasympathetic derived acetylcholine binds to cholinergic receptors. Secondary message pathways of both types of

receptor depend on guanine nucleotide-binding regulatory protein (G protein) for transduction of the neurotransmitter stimuli. The G proteins that transduce signals following binding of neurotransmitter to the receptors of acinar cells are heterotrimeric molecules consisting of α, β and ɣ subunits. The α subunit is the site of guanine nucleotide binding and probably confers the functional specificity of a given G protein. Binding of a neurotransmitter to a receptor results in conformational change of the intracytoplasmic portion of the receptor, which facilitates association of a G protein. Binding of the G protein provokes replacement of GDP by GTP at the G protein nucleotide binding site and promotes dissociation of the heterotrimer into a free α subunit and a βɣ heterodimer. The resulting GTPase activation of the α subunit catalyzes the hydrolysis of GTP to GDP. The GDP bound to the α subunit then re-complexes with the βɣ complex to restore the original heterotrimeric molecule.

The G protein signal transduction pathways propagate to result ultimately in the generation of cAMP as a result of β adrenergic receptor stimulation and formation of 1,4,5-inositol triphosphate (IP_3) after acetylcholine receptor stimulation. The specific mechanism by which cAMP results in protein exocytosis into saliva remains unclear. However, in rat salivary glands, β-adrenergic receptor stimulation leads to a rise in cAMP levels, and amylase or glycoprotein secretion by the parotid or submandibular glands, respectively.

IP_3 activity is known to result in an influx of extracellular calcium into the acinar cell cytoplasm. The exact mechanism for this effect is unclear, although it has been established that this effect is not voltage activated.

Possible mechanisms for Ca^{++} entry into acinar cells include a direct receptor (IP_3)-gated Ca^{++} channel, a G protein activated Ca^{++} channel or a second messenger activated Ca^{++} channel, but the existence of any of these has yet to be established, although there is some evidence suggesting the synergistic action of IP_3 and its metabolite 1,3,4,5-inositol tetrakisphosphate (IP_4) is important in promoting Ca^{++} influx.

Currently, the most favoured explanation of the mechanism of Ca^{++} entry is termed Capacitative Ca^{++} entry. By this mechanism, dynamic depletion of the intracellular Ca^{++} storage pool provides the concentration gradient that drives sustained Ca^{++} entry. Support for this theory comes from experimental data that show that graded depletion of the Ca^{++} store (using for, for example, the ER uncoupler thapsigargin) have led to similarly graded Ca^{++} entry. Despite this hypothesis, the mechanism of continued depletion of intracellular Ca^{++} is, to date, not established. What is known is that extracellular pH and cytoplasmic Ca^{++} do modulate extra to intracellular Ca^{++} flux.

Acinar cells are water permeable and therefore able to derive fluid from the surrounding blood vessels, the movement of which is, in turn, determined by the vasodilation of the gland microcirculation as well as osmotic and hydrostatic pressure gradients. Whilst acinar cells are permeable the salivary duct system in impermeable to water. That said, active transport processes in the plasma membranes of the cells lining the duct, which result in the removal of sodium and chloride and the addition of potassium and bicarbonate ions as well as proteins, are able to modify the composition of the saliva as it passes along the duct.

MECHANISMS OF ION TRANSPORT IN SALIVARY ACINI

As in all secretory epithelia, fluid transport in salivary gland cells is thought to be driven osmotically by transepithelial concentration gradients. Studies on rat and rabbit salivary glands have suggested three mechanisms that act concurrently resulting in the production of primary salivary fluid secretion.[6]

The first mechanism depends on the combined action of four membrane transport systems (see **Figure 44.3**), namely:

1. a Na^+ -Cl^- co-transporter that is located in the basolateral membrane of the acinar cells
2. a basolateral Ca^{++}-activated K^+ channel (not shown in **Figure 44.3**)
3. an apical conductive pathway for Cl^-, which is presumably a Ca^{++} -activated Cl^- channel
4. a basal Na^+/K^+ ATPase.

In the resting state, K^+ and Cl^- concentration gradients, where the intracellular concentration exceeds the extracellular concentration, are actively created by by a Na^+/K^+ ATPase and a Na^+/K^+ - $2Cl^-$ cotransporter respectively.

Secretory stimulation via the parasympathetic nervous system, as described above, leads to a rise in intracellular Ca^{++} concentration, which, in turn, results in the opening of the basolateral K^+ channel and the apical Cl^- channel.

K^+ and Cl^- then flow along their respective concentration gradients – K^+ into the ECS and Cl^- into the duct lumen – resulting in the accumulation of Cl^- ions into the primary salivary fluid. A consequence of this is a net negative charge of the primary salivary fluid, which promotes the transport of sodium ions from the interstitium into the duct lumen. The resulting osmotic gradient for NaCl, in turn, provokes the transepithelial movement of water from the interstitium to the lumen.

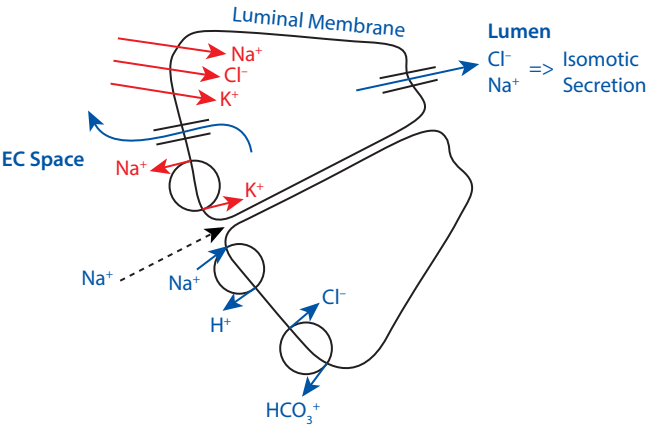

Figure 44.3 The ion exchange that occurs at the salivary acinus via the anion exchange pumps located on the basal and luminal surface of the salivary acinus.

Continued parasympathetic input results in continued transepithelial chloride flux and increased saliva volume. Cessation of parasympathetic stimulus is followed by a fall in intracellular calcium concentration to resting levels, closure of the K^+ and Cl^- channels and the return of the cell to its resting state.

The second mechanism also involves the creation of an intracellular Cl^- concentration gradient. However, in this case this is created by a Cl^-/HCO_3 exchanger acting in tandem with a Na^+/H^+ exchanger. A fall in intracellular chloride concentration as a result of parasympathetically stimulated KCl loss thus leads to entry of more Cl^- in exchange for HCO_3^-. Acidification of the cytoplasm that results from this bicarbonate loss is buffered by the Na^{++}/H^+ exchanger, which uses the extracellular-to-intracellular sodium gradient generated by Na^+/K^+ ATPase, to drive protons out of the cell.

Unlike the first two mechanisms in which chloride is the secreted ion, the third involves active bicarbonate secretion. CO_2 enters the acinar cell across the basolateral membrane and is converted to HCO_3^-, which is lost across the apical membrane via an anion channel, which is possibly the same as the Cl^-/HCO_3 exchanger involved in chloride secretion as described in second mechanism above. Acidification is rectified by the expulsion of a proton by the basolateral Na^+/H^+ exchanger.

FACTORS AFFECTING SALIVARY FLOW

Xerostomia is the term used to describe reduced salivary flow.[7–9] Xerostomia may be subjective or objective. In the former a reduction in saliva is perceived, while in the latter a genuine reduction in saliva flow is detectable. For example, Ship et al. found that, although xerostomia is a common symptom in postmenopausal women, no actual reduction of saliva flow in otherwise normal women is detectable.[7]

In clinical practice, drugs are the most common cause of measurable decreased salivary gland function. **Table 44.2** shows a list of drugs that commonly may affect salivary secretion. Not surprisingly, most of these drugs possess anti-cholingeric or sympathomimetic effects, mechanisms that are known to be essential for normal saliva production. Tricyclic antidepressants and phenothiazine neuroleptics are among the most troublesome as they have particularly strong anticholinergic (antimuscarinic) effects. Ganglion-blocking drugs can also have a similar effect.

Xerostomia may also result from specific disease states that do not involve specific salivary gland pathology. For example, depression and anxiety states and their attendant bystander anticholinergic side effects of the underlying condition may result in measurable xerostomia. Busfield et al. measured the rate of salivary secretion in 42 untreated depressed patients and found it to be decreased in comparison to non-depressed hospital patients and healthy controls. However, there is no relationship between the degree of xerostomia and the severity of depression.[8, 9]

Moreover, xerostomia is an inevitable consequence of dehydration induced by, for example, haemorrhage, diarrhoea, chronic vomiting, polyuria secondary to diabetes and restricted fluid intake or overdose of diuretics.

COLLECTION OF SALIVA

Measuring salivary flow rate facilitates a diagnosis of xerostomia – however, accurate measurement of flow rate is not a trivial matter. Usually, the collection of saliva is performed under three circumstances:

- Unstimulated flow of total saliva
- Stimulated flow of total saliva
- Stimulated or unstimulated flow of an individual gland.

Systemic or local sialagogues may be used to stimulate flow. The archetypal systemic salivary sialagogue is pilocarpine, a parasympathomimetic, although this is rarely used outside research. Local sialagogues are more convenient, with minimal side-effect profiles and are therefore used more commonly in the clinical setting. A commonly used protocol involves the dropwise application of 5% citric acid solution on the dorsum of the tongue. As for collecting saliva, a variety of methods are used. These include spitting, drainage, suction and cotton wool rolls. The particular method used is determined by whether global or individual gland salivary output is the desired endpoint.

For example, saliva produced exclusively by the parotid gland is accurately collected by cannulating the parotid duct with a polythene catheter. Alternatively, a Carlson-Crittenden cup could be used. This device is specifically

TABLE 44.2 Drugs liable to cause xerostomia

Drugs with anticholinergic activity	Drugs with sympathomimetic activity
• Atropine and analogues (hyoscine, ipratropium, etc.) • Tricyclic antidepressives • Monoamine oxidase inhibitors • Phenothiazines and related neuroleptics • Orphenadrine, benzhexol and related anti-Parkinsonian agents • Antihistamines • Ganglion blockers and clonidine • Antiemetics (antihistamines, hyoscine and phenothiazines)	• 'Cold cures' and decongestants containing ephedrine or phenylpropylamine • Bronchodilators (isoprenaline, orciprenaline, etc.) • Appetite suppressants, particularly amphetamines and diethylpropion

designed for the task and involves a collecting chamber that is placed on the buccal mucosa over the ampulla of the duct, which is separated from an outer suction chamber, which ensures that the saliva produced is sucked into the collecting chamber.

Saliva produced by the submandibular and sublingual glands is typically collected using a syringe. Individual gland production is technically impossible due to the close proximity of duct orifices in the anterior floor of mouth or more pertinently by the numerous potential communicating channels between the duct systems of all four glands.

The choice of method used depends on the type of investigation being carried out. In clinical practice, for example in the diagnosis of Sjögren's syndrome, measurement of total salivary flow in the presence and absence of stimulation over a period of 10–15 minutes where saliva is collected by the patient spitting, usually suffices.[10]

SIALOCHEMISTRY

Saliva chemistry may also change in disease and therefore, the chemical composition of normal saliva is an important reference point (**Table 44.3**).

SALIVARY PHYSIOLOGY IN DISEASE

Examples of changes in the concentration of inorganic ions and organic components in saliva in diseased states are shown in **Tables 44.4** and **44.5** respectively. Low flow states, the development of local inflammation and cellular calcified nidi may promote salivary debris (sludge) and calculi formation.

Three diseases that have been studied in terms of sialochemistry in particular detail are Sjögren's syndrome, cystic fibrosis and coeliac disease.

Sjögren's syndrome

The European Community Study Group on Diagnostic Criteria for Sjögren's Syndrome concluded that unstimulated whole saliva flow rate and minor salivary gland biopsy are the two most valuable diagnostic tests. A low resting as well as stimulated flow rate are typical of Sjögren's syndrome. The cut-off values of 0.1 mL/min for resting whole saliva and 0.5 mL/min for stimulated saliva has been considered diagnostic of salivary gland hypofunction and consistent with a diagnosis of Sjögren's syndrome.

Cystic fibrosis

Cystic fibrosis is an autosomal recessive genetic condition that affects 1 in 3000 newborns of Northern European ancestry. Affected individuals are homozygous for mutations of the cystic fibrosis transmembrane conductance regulator (CFTCR) gene. The CFTCR is responsible for regulating chloride ion transport across cell membranes. The net effect of its absence is the formation of exocrine secretions of increased viscosity. That said, the effect on total saliva production is minimal. However, significant

TABLE 44.3 Composition of mixed saliva

	Unstimulated		Stimulated	
Substance	**Mean + s.d.**	**Range**	**Mean + s.d.**	**Range**
Protein (g/L)		1.4–6.4	2.8	1.8–4.2
IgA (mg/L)	194.0

Fluoride (umol/L)	1.5 + 0.68	0.5–3	0.56 + 0.25	0.25–1.2

TABLE 44.4 Changes in the concentration of inorganic ions

Condition	Changes in the concentration of inorganic ions
Sialadenitis	Raised Na^+ , K^+, Ca^{++} and P^+ levels
Radiation damage	Raised Na^+, Ca^{++}, Mg^{++} and Cl^- levels
Sjögren's syndrome	Raised Na^+, Cl^- and P^+ in parotid gland saliva
Cystic fibrosis	Raised Na^+, Ca^{++} and P^+ levels. Mandel[10] suggested that the combined Ca^{++} and P^+ concentrations formed a useful diagnostic index
Aldosteronism	Depressed Na^+ but raised K^+ levels. Mandel[10] suggested that the product Na^+/K^+ could form a useful diagnostic index
Hypertension	Depressed Na^+ levels
Alcoholic cirrhosis	Raised K^+ levels
Hyperparathyroidism	Raised Ca^{++} levels
Diabetes mellitus	Raised Ca^{++} levels
Chronic pancreatitis	Depressed HCO_3^- levels
Psychiatric illness	Possibly raised Na^+ levels
Digitalis intoxication	Raised Na^+ and K^+ levels. Mandel[10] suggested that the product, Na^+ x K^+, could form a useful diagnostic index

TABLE 44.5 Conditions affecting the composition of saliva

Condition	Effect on composition of saliva
Sjögren's syndrome	Raised total protein and β_2 microglobulin levels in parotid gland saliva
Cystic fibrosis	Raised total proteins, amylase, lysozyme in submandibular gland saliva and glycoproteins in parotid gland saliva
Cirrhosis	Raised total protein and amylase in parotid gland saliva
Hyperparathyroidism	Raised total protein
Diabetes mellitus	Raised total protein, IgA, IgG and IgM and raised glucose levels
Sarcoidosis	Depressed amylase and lysozyme levels

changes in the salivary chemistry result in a dramatic elevation in the salivary protein and calcium concentrations. The net effect is a predisposition to salivary duct blockage and an increased frequency of salivary calculi, particularly of the minor salivary glands, resulting in a build-up of calculi around the gingival margins.

Coeliac disease

This condition is characterized by malabsorption of gluten in the intestines. One can detect antibodies (IgA–AGA) to gliadin, a major component of gluten, in saliva and serum. Consequently, salivary serology can be used as a screening test for coeliac disease although it lacks the sensitivity of its serological counterpart.[11]

SIALOLITHIASIS

A deleterious increase in the viscosity of saliva (through, for example, dehydration), reduced flow or even stasis, by mucosal obstruction or inflammation of the lining of the salivary unit with retention of cellular or bacterial debris, may precipitate liathiasis (stone formation) and painful salivary obstruction. The biochemical components of salivary stones vary depending on the gland, as do their resulting imaging appearances (for example, due to the relative calcium composition, 90% of parotid stones are radiolucent whilst 90% of submandibular stones are radio-opaque).

THE EFFECT OF CHEMOTHERAPY AND RADIOTHERAPY

Saliva is critically important for dental hygiene and maintenance. Due to the high turnover of the salivary duct unit component cells, these areas are at extreme vulnerability from bystander tissue effects of ionizing radiation and chemotherapeutic agents. Profound xerostomia is therefore the most common short- and long-term adverse event of non-surgical treatment of cancers of the head and neck. The resulting xerostomia has a profound negative impact on swallowing function and quality of life, as well as commonly resulting in severe dental impairment due to the loss of the bactericidal and lubricating properties of saliva.

SALIVA IN CLINICAL PRACTICE

Saliva is a readily available body fluid that can be easily collected with no adverse events, simply by getting a

patient to spit in a sample bottle. Moreover, the constituents of saliva, in particular soluble DNA or protein, have the potential to become either predictive or prognostic biomarkers. As such, a great deal of effort is ongoing in a research setting to establish the effectiveness of several putative biomarkers in clinical practice. Of the numerous examples that have been investigated to date, the presence of human papillomavirus (HPV) DNA and/or antibodies in the context of HPV-related oropharynx cancer and anti-p53 antibodies as a biomarker for oral cavity cancer outcome.[12]

Saliva has also been investigated as a medium for hormone monitoring but some limitations are evident.[13, 14] Ellison et al. have considered certain technical aspects of salivary progesterone assay and its interpretation and reviewed the utility of these assays for clinical purposes.[15] They concluded that this approach has some value because of the ease of obtaining serial samples from the same individual.[16]

SUMMARY

Salivary production and function is a complex biological process. The fine balance of salivary flow rate, volume and salivary biochemistry are all susceptible to modification altered by normal physiology, drugs, therapeutic strategies (radiotherapy and surgery) and disease states.

KEY POINTS

- Saliva, produced by salivary glands, plays an important role in oral cavity and dental health.
- There are three paired major salivary glands that collectively produce the majority of saliva: the parotid, the submandibular and sublingual glands.
- In addition, there are 600–1000 minor salivary glands present in the mucosal lining of the oral cavity and oropharynx, which also contribute to total saliva production.
- Disease and the side effects of treatment for head and neck cancer, particularly radiotherapy, alter salivary gland physiology and saliva volume and constitution.

INTRODUCTION

The ideal imaging technique would be harmless, widely available, cost efficient, highly diagnostic and reliably repeatable. It should provide excellent multiplanar capabilities and good spatial resolution, while simultaneously identifying all foci of disease involvement that require treatment near and far from the primary presentation site. Unsurprisingly, this single utopian test does not currently exist, although, across a range of modalities in usage, there is a calculated compromise to be struck with individual test strengths balanced against specific weaknesses and side effects (**Table 45.1**). Modern imaging continues to improve and can potentially act as a surrogate marker for pathological tissue diagnoses, select surgical from non-surgical candidates and also help to prognosticate. Through modern electronic radiological systems, today's surgeon is increasingly exposed to these newer diagnostic and interventional practices including guidance systems. In specific instances, image guidance can help to deliver non-surgical efficacious treatments (fluoroscopic salivary intervention, radiofrequency ablation, intra-arterial chemotherapy etc.). Functional imaging methods, such as positron emission tomography/computed tomography (PET-CT) and diffusion-weighted imaging (DWI) for neoplasia, can reflect cell turnover, metabolic consumption, vascular patterning and biological behaviour and this discipline will provide useful adjuncts to conventional anatomical images.

The current salivary gland imaging guidance for UK based clinicians is extracted from the 7th edition of the Royal College of Radiologists (RCR) Guidelines.[1] This document states that 'for salivary gland obstruction, ultrasound (US) or sialography is indicated for intermittent, food related swelling. Occlusal views are useful when US has demonstrated sialectasis but has not shown a calculus. US and/or sialography are also helpful to assess the suitability for minimally invasive management of salivary calculi.' Additionally it goes on to comment that 'for a suspected salivary mass, US is the initial investigation of choice and this can be combined with fine needle aspiration cytology when necessary. US is extremely sensitive and has a high specificity.' When the lesion extends to deeper neck spaces beyond the useful penetration of US, it suggests, 'magnetic resonance imaging (MRI) or computer tomography (CT) should be used, although, increasingly, despite the guideline recommendations, MRI and CT are being used as primary imaging modalities in clinical practice. MRI may be better than CT for malignant lesions in the assessment of local infiltration including perineural spread. Obviously, reliable staging of the thorax, if distant pulmonary metastases were suspected, would require a CT study.' The American equivalent, the similarly structured American College of Rheumatology (ACR) Appropriateness Guidance, currently offers no specific instructions for salivary imaging.

As always, any generic guidance will need to be modified around specific clinical scenarios following a focused

TABLE 45.1 Comparative imaging techniques

	Technique				
	US	**MRI**	**CE-CT**	**Conventional sialography**	**Salivary gland scintigraphy**
Advantages	• Quick examination • Widely available • No patient harm • Possible in poorly cooperative patient • Guides US-guided FNAC/ Trucut[R] • Doppler evaluates vascularity • Elastography for lesion compliance	• Excellent soft tissue contrast • Multiplanar capabilities • No radiation • Less dental artefact • Non-invasive	• Quick • Widely available • Sensitive for calculi • Broad anatomical coverage depicts • 2D and 3D reconstructions in conventional orthogonal planes	• Quick • Widely available • Excellent luminal depiction of glandular duct anatomy	• Quantification of function • Quantification of obstruction • Reproducible • Well tolerated • Easy to perform
Disadvantages	• Highly operator dependent • Non-penetrative at mandible, calculus or air interface • No depiction of deep facial spaces	• Not widely available • Relatively small field of view (cf. CT) • Long examination time (30–45 minutes) • Motion artefact • Contraindications: pacemaker, claustrophobia, non-cooperation of patient	• Radiation dose • Artefact from dental restorations and implants • Iodinated contrast issues around poor renal function and allergies	• Invasive examination (retrograde contrast injection) • Complications: bleeding, traumatic perforation, rupture duct • No information proximal to complete obstruction • Indirect information on parenchymal disease • 4–15% unsuccessful cannulation submandibular duct • Good patient cooperation required • Contraindications: acute sialadenitis, contrast allergy, thyroid disease	• Poor anatomical correlate • Radiation burden (low)

ENT examination. Any subsequent investigation will be primarily symptom-driven.

To this end, the following chapter sequentially considers:

- salivary gland obstruction and sialadenitis
- mouth dryness and glandular hypofunction
- salivary lumps and suspected neoplasms.

SALIVARY GLAND OBSTRUCTION AND SIALADENITIS

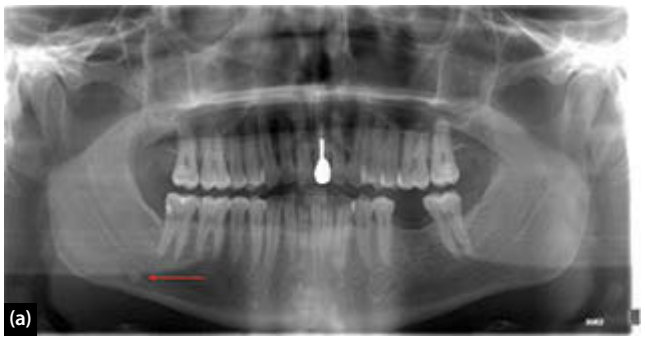
Salivary calculi (sialolithiasis), mucus plugs and ductal strictures account for the majority of cases of salivary gland obstruction. The diagnostic route for patients with obstructive symptoms may include plain radiographs (occlusal view or orthopantogram), ultrasound, conventional sialography, CT or MR imaging.

Sialolithiasis

Studies have estimated the lifetime prevalence of symptomatic salivary calculi to be 0.45%.[2] Calculus disease affects the submandibular gland far more commonly than the parotid, with sublingual and minor salivary glands being affected very rarely.

Stones may be diagnosed on plain radiographs, but ultrasound and CT are more frequently used and more sensitive in the detection of smaller calculi (**Figure 45.1**). Up to 15% of calculi are radiolucent and not visible on plain radiographs alone.

Formal sialography is still widely available but is an invasive test that carries a 4–15% failure rate, and a small risk of provoking acute sialadenitis and ostial injuries with scarring for the inexperienced operator. MR sialography is a newer non-interventional, highly T2 weighted (T2W) technique without requiring ductal cannulation or contrast



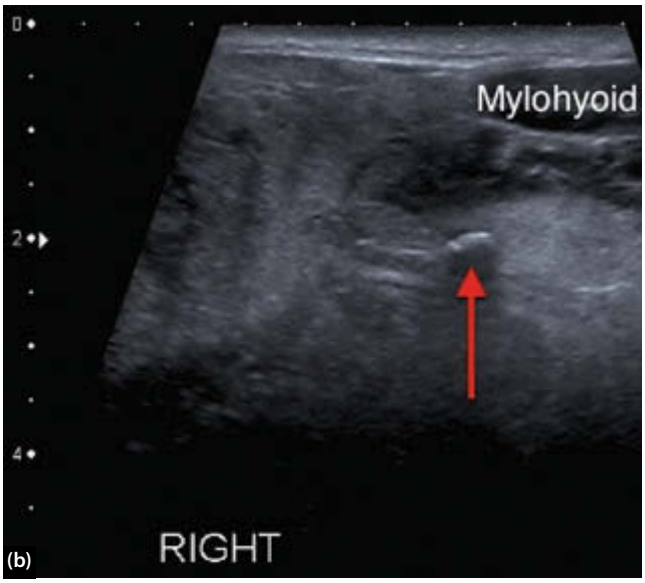


Figure 45.1 Sialolithiasis. **(a)** Orthopantogram demonstrates a right-sided SMG hiloparenchymal calculus projected over the posterior mandible; **(b)** Transverse axial ultrasound image demonstrates an echogenic hiloparenchymal calculus with acoustic shadow; **(c)** A coronally reconstructed, non-enhanced CT image demonstrates a distal left submandibular ductal calculus.

media as it relies upon inherent salivary fluid within the ducts to generate recordable signal (**Figure 45.2a** and **2b**). The reported sensitivity for the MR sialography diagnosis of calculous disease varies from 69% to 91%. Its specificity is 88–97%, the positive predictive value is 93–97% and the negative predictive value is 91%.[3–5]

TABLE 45.2 Advantages of CT, sialography and MRI

	Conventional sialography	Computer tomography (CT)	MR sialography
Invasive	Y	N	N
Radiation dose	+	++	N
Detects calculi	+	++	+/–
Detects mucus plugs	+	–	+/–
Detects strictures	+	–	+
Availability	+	++	+
Cost	low	moderate	high
Therapeutic options	Y	N	N

The advantages of CT, sialography and MRI are summarized in **Table 45.2**.[6]

In cooperative patients, digital subtraction techniques used at sialography will effectively remove the overprojected mandible, cervical spine and skull base, thus demonstrating the ductal opacification with iodinated contrast medium (**Figure 45.3**). In specialist centres utilizing stone retrieval devices, balloon sialoplasties and lithotripsy, a diagnostic sialogram remains a relevant and useful test. Dynamic luminal information and emptying patterns are not achievable at MR sialography. With any sialographic technique, the descriptive terminology needs to be locally agreed and standardized.

In mainland Europe, ultrasound (US) is often used as the initial diagnostic choice for obstructive symptoms and, in experienced hands, it can provide as much or more information than CT or MRI.[7] Glandular volumes and textural subtleties are easily appreciated, while the simultaneous use of a sialogogue has the potential to 'pressure test' the ductal system. The main parotid ducts are easily assessed in their entirety. However, due to the obliquity of the distal submandibular duct near the tongue frenulum, it should be remembered that US may fail to identify a small distal calculi, and complementary occlusal views are recommended.

Salivary strictures

Unlike sialolithiasis, salivary strictures preferentially affect the parotid ducts. Nearly two-thirds are a focal 'point' stricture, with the remainder being multiple beaded or long-segment, more diffuse strictures.[8] US, conventional sialography and MR sialography may all depict the site and nature of the stricture; however, due to lack of luminal detail, CT use is limited in this setting.[9]

Ultimately, identification of the type of obstruction, be it stones or strictures, is important in guiding subsequent treatment decisions. Strictures can be dilated, either under fluoroscopic control or at the time of sialoendoscopy.[10] This is generally well tolerated under local anaesthesia in an outpatient setting. With a variety of retrieval basket designs and fluoroscopic control or endoscopy, removal of calculi is a safe and effective method to treat small, mobile calculi up to 6 mm in size. Correct patient selection is vital for success. Determined by both patient factors and local expertise, larger calculi may require combined stone shattering treatments, sialoendoscopy and a transoral open approach.[11]

KEY POINTS

When presented with an obstructed submandibular gland and unilateral symptoms, care should be taken to ensure that this is due to a benign luminal phenomenon rather than extrinsic compression secondary to floor of mouth or sublingual space pathology (**Figure 45.4**).

Sialadenitis

Acute bacterial sialadenitis with sepsis is usually clinically obvious in often susceptible, dehydrated and malnourished elderly individuals. Unless there is trismus or medial tonsillar deviation to suggest deeper parapharyngeal involvement, a parotid abscess is reliably excluded with US. In the subacute setting, the role of radiology is primarily to exclude an obstructive stone, a significant treatable stricture, neighbouring nodal disease or a masquerading salivary neoplasm. More established chronic sialadenitis will eventually destroy the normal ductal architecture with sialectasia and reduce salivary flow. These persistent but low-level symptoms would still merit US evaluation, sialography and/or scintigraphy to determine whether useful gland function can be preserved as the only real surgical alternative would be excision. With these recurrent episodes, the gland becomes progressively atrophied and echo-reflective at US. With swelling and erythema in the submandibular region, odontogenic sepsis is usually excluded with an orthopantomogram (OPG).

Though multifactorial in origin and often unilateral in occurrence, a non-suppurative recurrent juvenile parotitis is a distinct entity. Emerging evidence suggests that early sialoendoscopy and/or therapeutic interventional sialography may avoid glandular destruction, symptom deterioration and the eventual need for gland excision.[12] Punctate sialectasis follows repeated infections and this clouds the initial precipitating aetiological cause. A US examination is contributory to patient workup and often

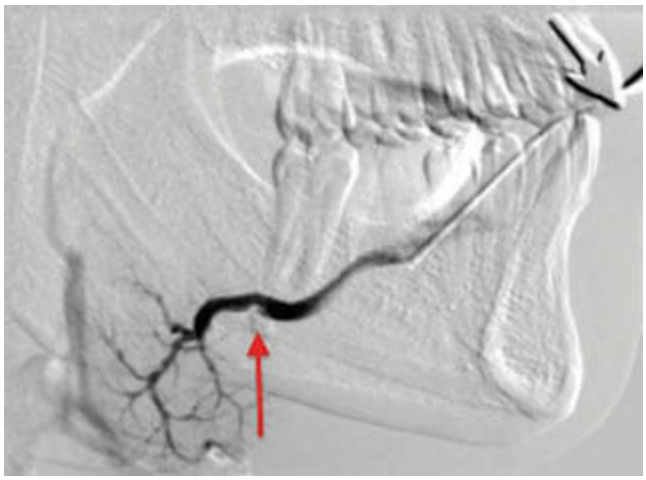

Figure 45.3 Digital subtraction sialography illustrates a right-sided, partially obstructing luminal calculus.

demonstrates a bulky, hyperaemic gland. The ducts may be irrigated with antibiotic and steroid solution at the time of intervention.

Rarer still, TB, actinomycosis, cat-scratch disease, brucellosis and toxoplasmosis can all precipitate acute episodes of sialadenits.

DRY MOUTH AND GLANDULAR HYPOFUNCTION

The clinical presentation of a non-obstructive, non-suppurative multisite glandular swelling or even a unilateral asymmetric, atypical finding may be secondary to a diffuse inflammatory or systemic condition. Although US remains the first imaging modality of choice, it has a limited range of anatomical coverage and the radiologist will need to appreciate that non-mealtime, bilateral salivary

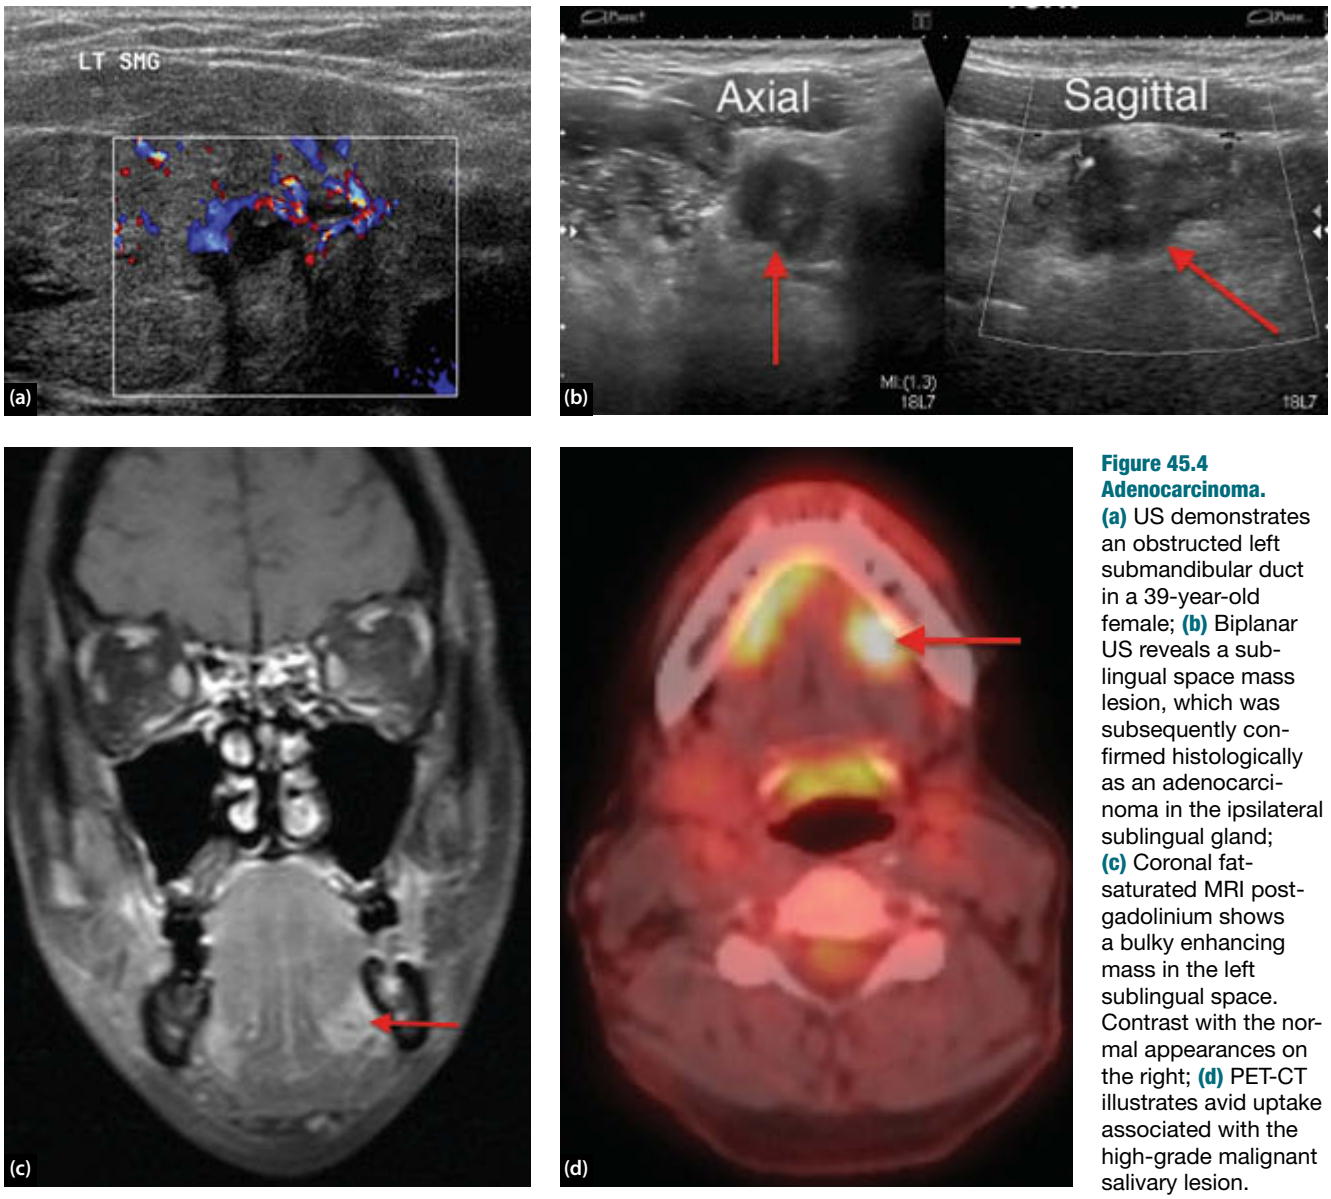

Figure 45.4 Adenocarcinoma. **(a)** US demonstrates an obstructed left submandibular duct in a 39-year-old female; **(b)** Biplanar US reveals a sublingual space mass lesion, which was subsequently confirmed histologically as an adenocarcinoma in the ipsilateral sublingual gland; **(c)** Coronal fat-saturated MRI post-gadolinium shows a bulky enhancing mass in the left sublingual space. Contrast with the normal appearances on the right; **(d)** PET-CT illustrates avid uptake associated with the high-grade malignant salivary lesion.

symptoms with or without constitutional features raises a wider possibility of a more nebulous, potentially multifocal underlying condition.

Sjögren's syndrome

Initially presenting with intermittent swelling of the major salivary glands, primary Sjögren's disease is an autoimmune disorder that will chronically destroy salivary and lacrimal exocrine glands to result in xerostomia and xerophthalmia. With a coexistent systemic arthropathy, such as rheumatoid arthritis, it is termed secondary Sjögren's syndrome. Accelerated dental decay may be seen on an OPG (**Figure 45.5a**). As part of the patient workup, the 2002 American-European Consensus Report revised criteria for the secure diagnosis of Sjögren's disorder includes abnormal sialographic and/or scintigraphy studies with delayed uptake, reduced concentration and/or delayed secretion of tracer material.[13, 14] Scintigraphy involves intravenous injection of approximately 80–100 megabequerels of pertechnetate (^{99}Tc) in an attempt to quantify glandular secretory dysfunction. This tracer is preferentially taken up and secreted via the duct epithelium and counts are acquired over a 30–45-minute period using gamma camera detectors. As a two-phase study, a sialogogue is given midway through the test to define a secretory phase and quantitative time-activity curves are routinely generated. Antibody screening including titration of rheumatoid and anti-nuclear factors as well as anti-Ro (SS-A) and anti-La (SS-B) antibodies may help alongside radiological studies but, ultimately, a labial mucosal biopsy is the most specific diagnostic test.

There are now ample studies documenting the role of US in the non-invasive diagnosis of Sjögren's.

The ultrasonic features described with Sjögren's disease will vary with the stage of presentation with initial hypoechoic, pseudocystic regions and hyperaemia. These 'cysts' may pathologically reflect numerous repeated ductal obstructions due to lymphocytic infiltration and intraparotid nodal hyperplasia.

Chronically, gland volumes are markedly reduced with eventual fatty replacement. Standard fluoroscopic sialography and MRI sialography have been used to evaluate characteristics ductal patterns in affected and the long-established grading system initially proposed by Rubin and Holt[15] is still approximated for both techniques. Larger areas of cavitation, benign lymphoepithelial lesions (BLEL) and parenchymal atrophy will result in globular areas of ductal sialectasia and beading, although, these are not pathognomic features that can also be seen with straightforward chronic sialadenitis. More recently, with MR DW techniques, researchers have attempted to differentiate normal glands from those affected by inflammatory, connective tissue diseases.[16] In longstanding cases, CT will elegantly demonstrate multiple bilateral punctate calcific foci with atrophy (**Figure 45.5b**).

Chronically, with elevated risks of developing marginal zone B-cell lymphomas within parotid or submandibular gland tissue, urgent cross-sectional imaging +/– biopsy is required for an enlarging, painless parotid mass. Currently, no evidence supports interval imaging for surveillance.

With considerations of a wider differential, those having undergone previous head and neck radiotherapy, with occult HIV and adenopathy, with hepatitis C viral infections, occult sarcoidosis or complicating graft-versus-host disease, can all present with similar symptoms and some of these entities will need a high index of clinical suspicion in high-risk individuals.

Figure 45.5 Sjögren's syndrome. **(a)** OPG shows multiple small calcific densities projected over both parotid glands; **(b)** Non-enhanced axial CT shows multiple tiny glandular calculi.

Sarcoidosis

With otolaryngological manifestations in around 10% of patients, cervical adenopathy, parotid or submandibular swellings and cranial nerve palsies are the commonest head and neck presentations of this multisystem disorder. Diffuse, intermittent parotid gland enlargement is usually bilateral but, when asymmetric, an ultrasound guided fine-needle aspiration cytology (USg FNAC) can be useful.[17] Notably, conventional sialography is often normal in the presence of florid systemic features whilst biopsy of the affected tissue or nodal excision is usually diagnostic. Eventually, the normal tissue will be replaced by fat infiltration that can have striking appearances on fat sensitive T1W sequences. A brain and skull base MRI with post contrast images is indicated in the presence of cranial neuropathies or meningism. Radiolabelled gallium scans with associated mediastinal and hilar adenopathy can yield a typical 'lambda' or 'panda' sign, which are not entirely specific radiologic findings.

IgG4-related systemic disease

This emerging and obscure condition was first reported in 2003.[18] It has numerous head and neck manifestations that now encompass both Mikulicz syndrome and Kuttner's pseudotumour with initially enlarged lacrimal and submandibular glands. Affected patients can present with a tentative diagnosis of lymphoma or malignancy due to weight loss and adenopathy. A detailed, relevant clinical history may identify prior multi-organ involvement that may include acute pancreatitis and previous renal failure. The eventual, often delayed but highly treatable diagnosis is securely made on the basis of raised serum IgG4 concentrations. CT or MRI imaging demonstrates bilateral cervical adenopathy, glandular swelling and excessive enhancement of salivary and lacrimal tissue in the context of mild SICCA symptoms (**Figure 45.6a, b, e**).

A typical geographic textural abnormality and hypervascularity is seen on US Doppler imaging (**Figure 45.6c, d**). A FNAC or biopsy is often performed to distinguish this highly steroid responsive protean disorder from a parenchymal mass lesion or a lymphoproliferative disorder. More recently, PET-CT has been proposed to stage and monitor aggressive, multi-focal disease.[19]

It is currently a matter of debate as to whether there is an increased propensity for affected individuals to develop complicating lymphomas. Critically, an early diagnosis and immunosuppressant therapy invariably leads to a dramatic clinical improvement and avoidance of life threatening abdominal, renal and vascular complications.

Radiotherapy

Radiotherapy for head and neck cancers can often induce debilitating xerostomia in a dose-predictable fashion. Other than subjective patient reporting of symptoms and salivary flow studies, conventional sialography and/or scintigraphy are the most commonly utilized tests for further documentation of impaired glandular function and stricture formation.

Follow-up CT studies will initially show avid enhancement and global increased density and, over months, this is followed by irreversible dose-dependant reduction in gland volume with ductal ectasia and fibrosis (**Figure 45.7 a–d**). MR sialography may show a correlation between submandibular gland dysfunction and xerostomia.[20] Parotid doses over 60 Gy inevitably lead to irreversible xerostomia, while mean doses below 24 Gy will usually preserve salivary flow. At MRI, Nomayr et al.[21] documented preferentially larger volume losses during treatment in the parotid tissue rather than the submandibular glands. The parenchymal volumes will alter significantly during treatment when compared with baseline imaging.[22]

US studies[23] describe parenchymal heterogeneity, increased duct conspicuity and lowered vascular resistive indices in previously irradiated glands, and these findings are believed to relate to acute inflammatory infiltrates maturing with resultant chronic fibrosis. With the advent of intensity-modulated radiation therapy (IMRT) techniques, reduced dose delivery can be achieved for selected organs at risk. The prospective, randomized PARSPORT trial confirmed that parotid-sparing IMRT plans improved subjective symptoms,[24] salivary flow rates and scintigraphy results. Where IMRT planning is used, it is now the standard of care to use parotid-sparing planning techniques.

SALIVARY MASSES AND SUSPECTED NEOPLASMS

The 2005 World Health Organisation[25] pathological classification for salivary gland tumour subtypes is generally viewed as complex and the evidence-based data around the ideal management of these rare lesions is relatively poor.

Therefore, local, national and international experiential variations in surgical and radiological practice will exist. Workup may involve all or some of the following: US; USgFNAC; core biopsy; CT staging; MRI; frozen section; and/or surgical excision. Obviously, different sampling techniques will provide variable amounts of histopathological tissue with which to secure a reliable pre- or post-operative diagnosis. Excision of the salivary mass as per local protocols ultimately yields the definitive diagnosis. At added expense, functional imaging tests may go on to provide non-invasive methods of tumour characterization with promising initial results.[26]

Ultrasound (US) and ultrasound-guided fine-needle aspiration cytology (USgFNAC)

Ultrasound is the preferred initial test for palpable salivary gland masses. It is tolerated well, cheap, quick

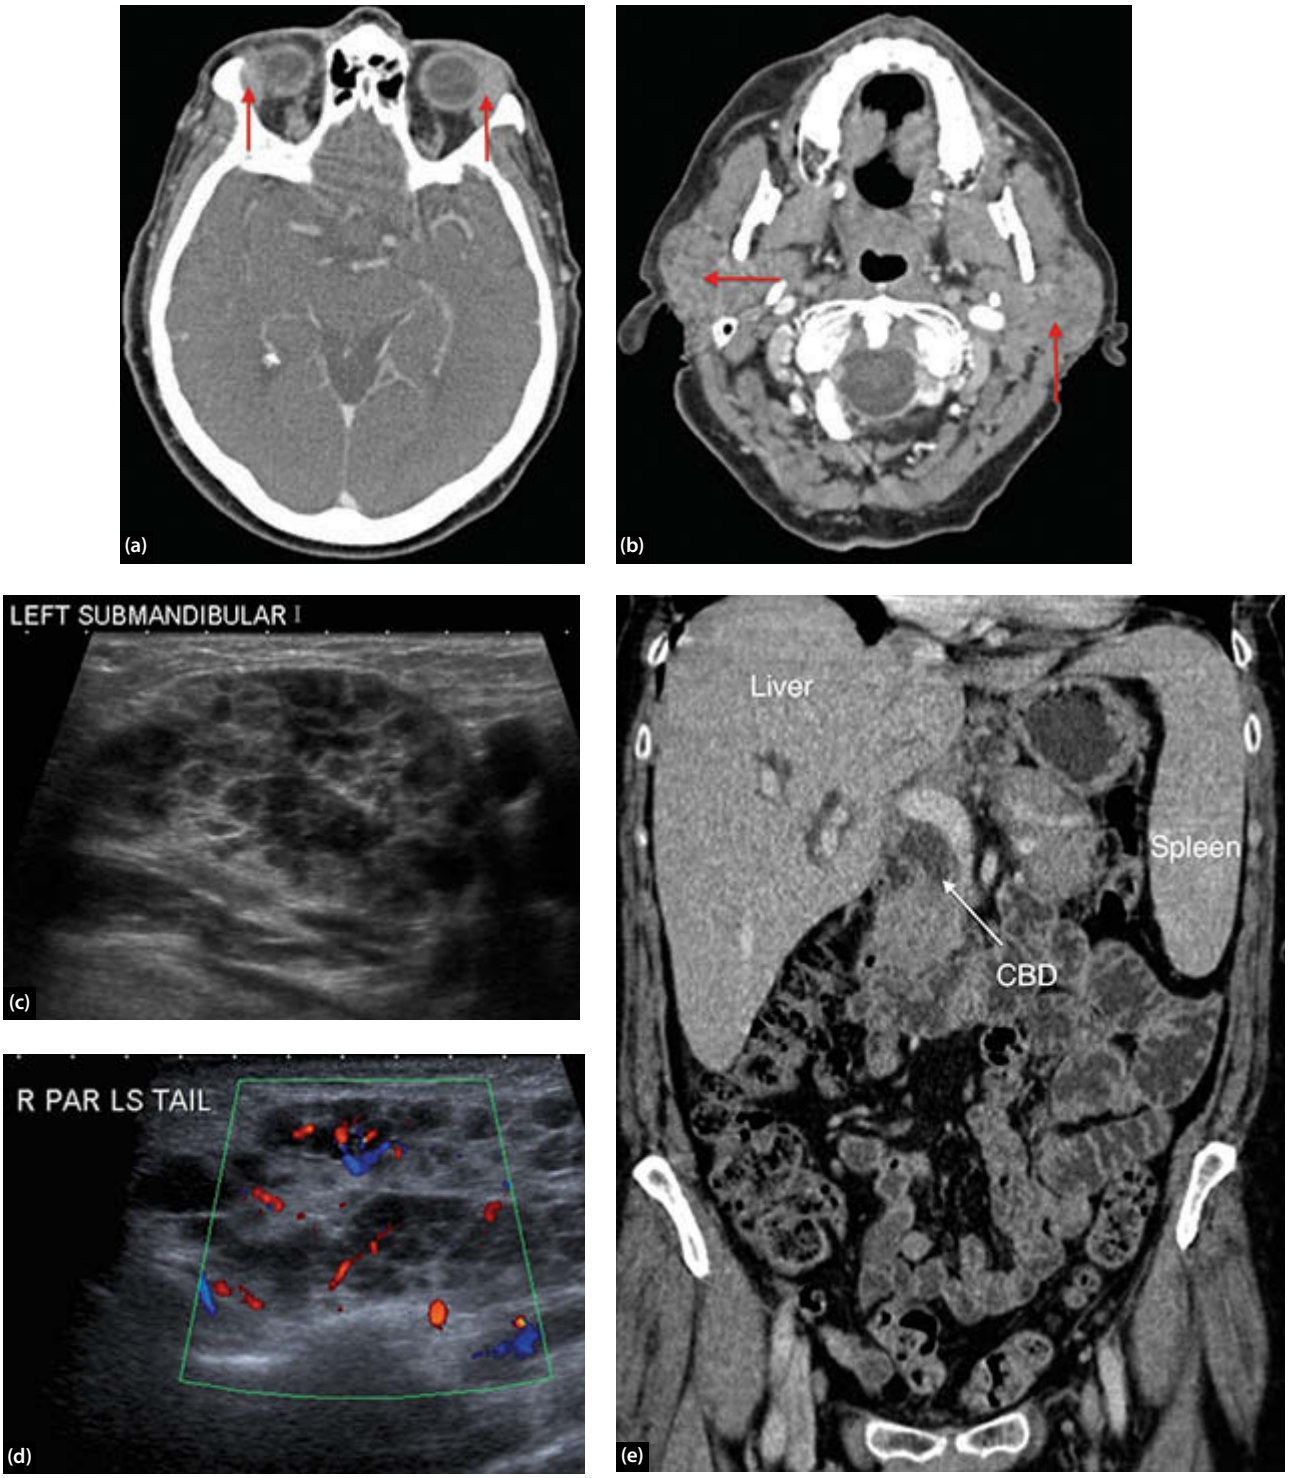

Figure 45.6 IgG4related systemic disease. **(a)** Enlarged, bilateral lacrimal glands; **(b)** Symmetric bilateral parotid gland enlargement; **(c)** Bilateral heterogeneous glands with hypoechoic regions; **(d)** Hyperaemic glandular parenchyma; **(e)** Contrast CT (coronal) shows pancreatitis and hepatosplenomegaly with an obstructed CBD.

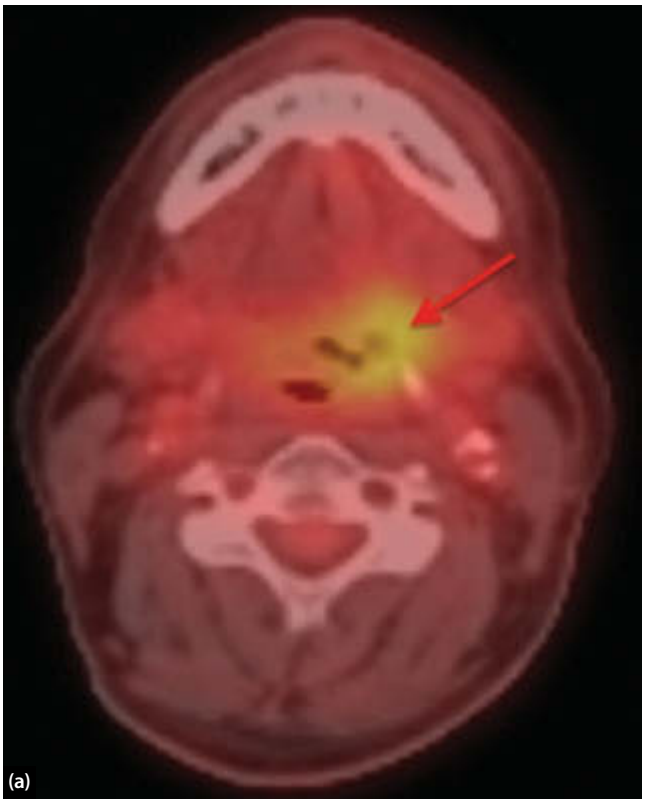
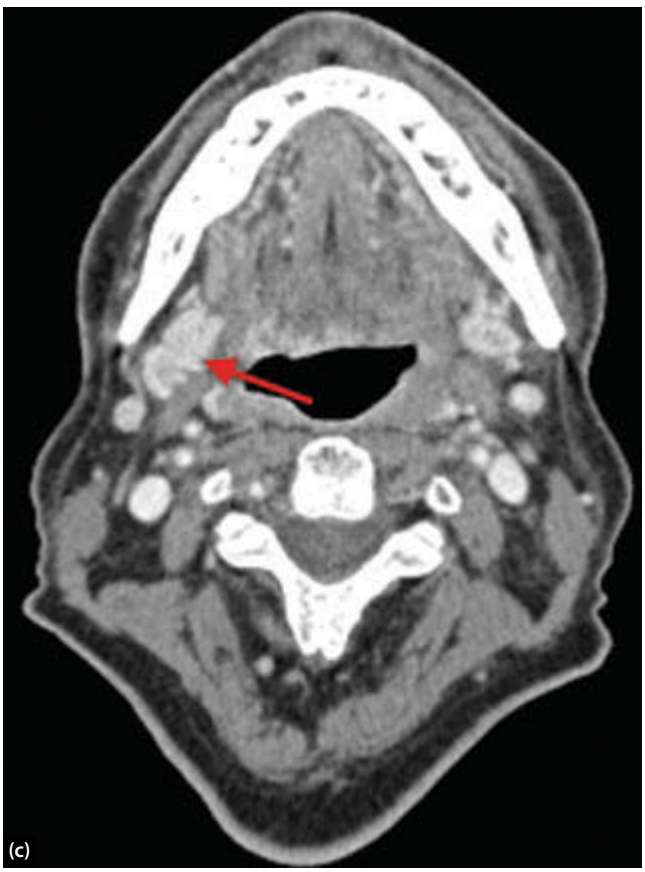
and accessible. It allows image guided biopsies and assessment of coexistent pathologies and cervical nodes. It is, however, operator-dependent. Normal variants such as gland ptosis in the elderly and congenital anatomical mylohyoid defects are readily appreciated.

A reliable pre-operative diagnosis facilitates better informed consent, potential conservative management of benign tumours in the frail, and streamlined operative list management. Radical surgical approaches will only be undertaken in the presence of a confirmed malignancy. The drawbacks of freehand FNAC are well-documented[27] and, where feasible, core biopsy should be performed for a definitive histological diagnosis prior to intervention.





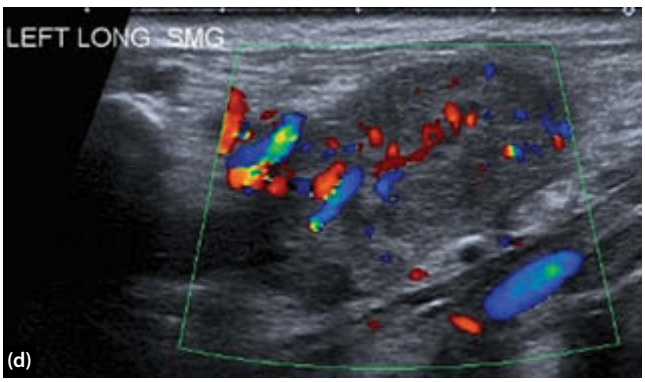


Figure 45.7 Salivary gland changes after radiotherapy. **(a)** PET-CT demonstrates left base of tongue tumour; **(b)** Enhanced CT (sagittal) shows avidly enhancing SMG; **(c)** Enhanced CT (axial) shows avidly enhancing SMG; **(d)** US demonstrates hypoechoic, hypervascular gland.

In 2010, Sriskandan et al.[28] published retrospective data on the accuracy of US alone in discerning benign from malignant lesions for 220 referred parotid lumps. The sensitivity, specificity and diagnostic accuracy for malignancy was 91%, 93% and 93% respectively, with nine false positives and four false negative cases. The majority of pleomorphic adenomas had classic 'benign' appearances; being lobulated, clearly defined, relatively echo-poor and homogenous, however, posterior acoustic enhancement and vascular patterning on Doppler imaging seemed relatively poor discriminators.

Cystic, septated and bilateral disease often correctly suggested benign Warthin's tumours.

As a non-invasive imaging adjunct, sonoelastography uses graduated compressions to assess tissue stiffness. Dumitriu et al.[29] assessed lesional compliance in 74 benign and malignant salivary gland tumours with a histological end point. However, elastography has failed to consistently show significant differences between benign and malignant lesions and is currently unable to eliminate FNA or biopsy from the diagnostic work-up.

USgFNAC without local anaesthetic infiltration is a rapid and safe outpatient procedure with no absolute and a few relative contraindications. Consent will require a discussion of infrequent infective complications, tumour

seeding and haemorrhagic risk. In 1997, the Papanicolaou society[30] published guidelines that estimated that the risk of seeding with small needles (<22 G) was between 0.003% and 0.009%. Standardized cytological categories are: (i) inadequate; (ii) benign; (iii) atypical cells present; (iv) suspicious for malignancy; or (v) overtly malignant.[31] Perhaps unsurprisingly, using pathological correlates, data has consistently shown that the diagnostic accuracy of USgFNAC is most dependent upon the site of aspiration, the number of needle passes, the number of prepared slides submitted and the experience of the individual performing and interpreting the FNAC. It is made more accurate when the individual interpreting the FNAC is the same individual who obtains the aspirate material.[32] It is routinely performed with a 23- or 25-gauge, long bevel needle with a capillary technique as proposed by Zajdela et al.[33] Advantageously, US guidance will avoid hypocellular, necrotic or cystic regions that pose diagnostic challenges. Both air-dried and alcohol-fixed slides are prepared bedside. Flow cytometry and immune-phenotyping techniques or trucut core biopsies will be required if lymphoma is suspected and surgical excision is to be avoided.

Articles concerning USgFNAC yields[34–37] have reported sensitivities ranging from 62% to 98% and specificity ranges from 94% to 100%. For 191 salivary tumours, Howlett et al.[38] conducted a 1-year audit within a rapid-access clinic setting and found a diagnostic sensitivity of 64% and specificity of 100%. Zhang et al. in 2009[39] published data showing that overall accuracy in distinguishing benign from malignant lesions was 79.1% and the sensitivity for salivary neoplasia was 89.4%. In 2011, a retrospective study[40] looked at USgFNAC for 245 parotid and submandibular salivary aspirates without immediate adequacy assessments. A cytological diagnosis was possible in 215 aspirates (87.8%). The sensitivity, specificity and diagnostic accuracy of the test in separating benign from malignant lesions were 75.7%, 100% and 95.8% respectively. In the recent pathology literature, it seems clear that the ideal FNAC is immediately prepared by skilled technicians trained in slide preparation with further on-site 'live' technical expertise available for prompt adequacy assessments; however, this model has significant increased service cost implications. With this model in place, the group quotes an overall accuracy rate for salivary FNAC of between 90% and 95%. The UK National Institute for Health and Care Excellence (NICE) guidelines recommend having a cytopathologist or biomedical scientist to assess the cytology sample adequacy when the procedure is carried out.

In 2007, Howlett et al.[41] considered the additional merits of avoiding surgery for Warthin's tumours in elderly, frail individuals using US-guided core biopsies for 135 superficial parotid lesions. With this same technique, low-grade lymphoma is reliably separated from nodal hyperplasia. The group comments that seeding has only been documented with bigger gauge needles in older studies but, undoubtedly compared with FNAC, there will be an increased risk of haematoma formation and facial nerve injuries.

Benign neoplasms

PLEOMORPHIC ADENOMAS

Given that 90% of parotid pleomorphic adenomas occur within its superficial lobe, these are readily assessed and sampled at USgFNAC (**Figure 45.8a**). Submandibular gland masses and palpable minor salivary gland lesions are also easily sampled. With typical image findings, some authors have proposed that US alone is sufficient prior to surgery.[42] A radiologist's confidence for facilitating a

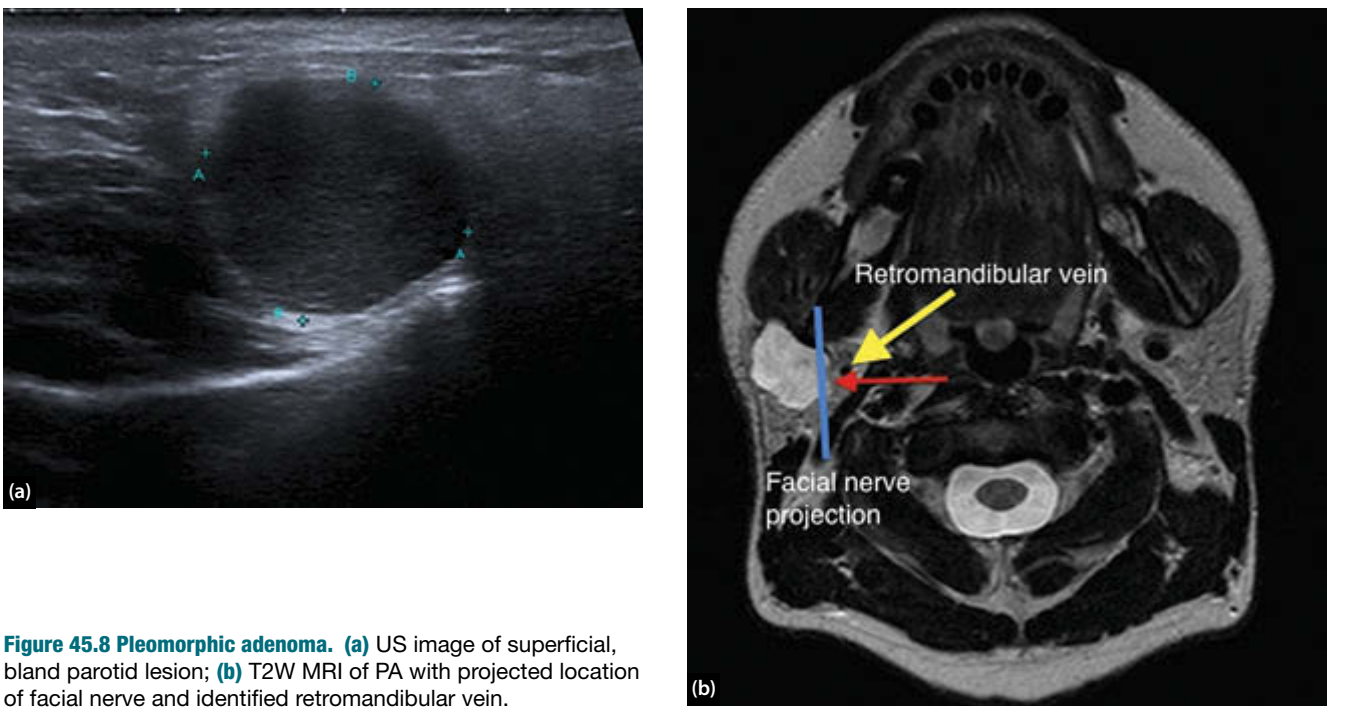

Figure 45.8 Pleomorphic adenoma. (a) US image of superficial, bland parotid lesion; **(b)** T2W MRI of PA with projected location of facial nerve and identified retromandibular vein.

successful superficial parotidectomy or extracapsular dissection is dependent upon the expected position of the facial nerve branches lying lateral to the often-identified retromandibular vein. A commonly used surrogate MR technique to plot the expected facial nerve trajectory from the stylomastoid foramen is described by Ariyoshi et al.[43] using the digastric muscle and the mandibular ramus (**Figure 45.8b**).

Newer T1-like gradient echo sequences (FISP/GRASS and magnetization-prepared rapid acquisition gradient echo sequences) and double echo steady state/reversed FISP sequences have had recent success in actually demonstrating the intraparotid facial nerve.[44, 45]

MRI, with its excellent soft tissue definition and lack of ionizing radiation, is routinely indicated for the rarer deep lobe lesions (**Figure 45.9c** and **d**), ill defined or

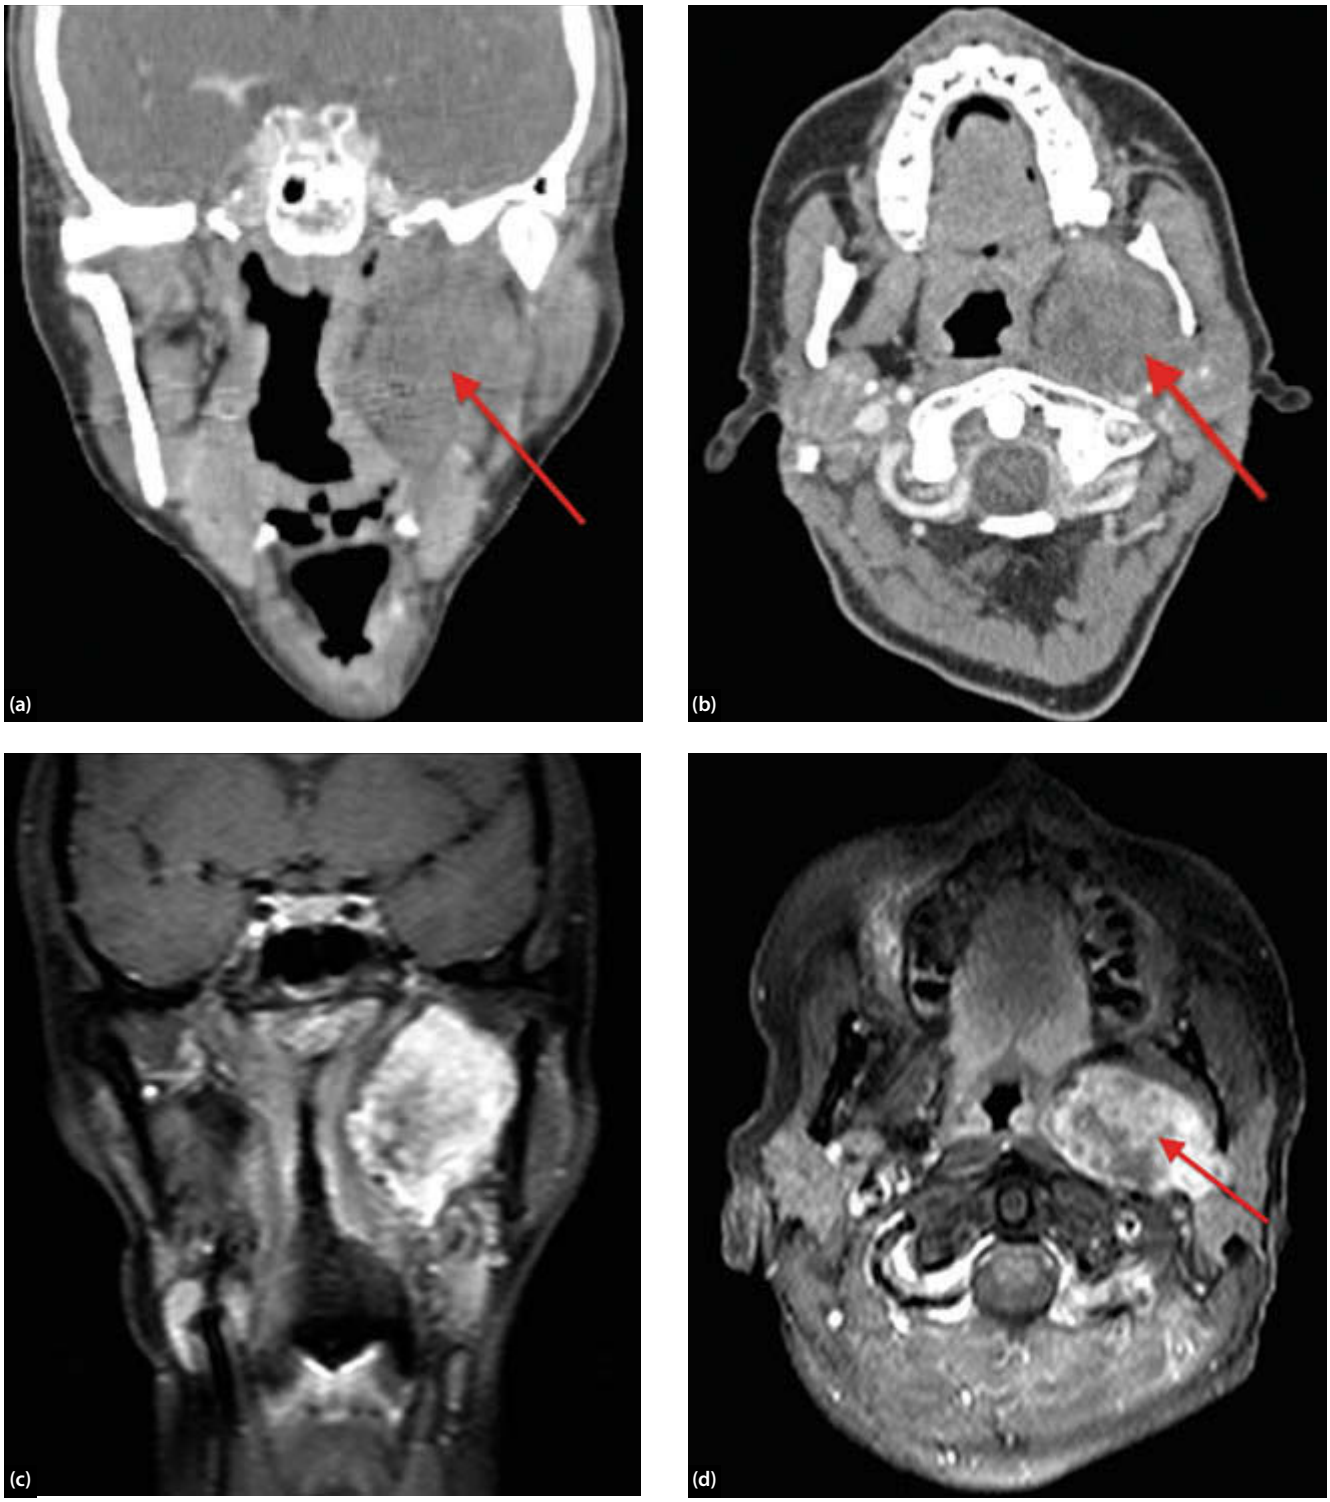

Figure 45.9 **(a, b)** Contrast-enhanced CT images of deep lobe PA; **(c, d)** Post-gadolinium, fat-saturated MR images of deep lobe PA.

infiltrative masses, in the context of facial nerve symptoms or suspected perineural disease and when FNA is suggestive of malignancy. Axial or coronal T2W sequences, fat-saturated contrast-enhanced and DWI are commonly performed. At MRI, pleomorphic adenomas typically follow the signal characteristics of fluid, appearing homogenously low signal at T1W imaging and 'T2 fluid bright'. They demonstrate variable moderate and sometimes delayed enhancement patterns following gadolinium. The thin surrounding capsule and pseudopodia formation of the commonest myxoid/ hypocellular pleomorphic subtype with a relatively higher propensity for recurrence is not visualized at imaging.[46] The less prevalent hypercellular variant is more likely to demonstrate atypical low signal intensity (SI) on T2W images. If a pleomorphic adenoma is managed non-operatively, the risk of malignant transformation is reported to increase with chronicity and this is suggested at MRI with T2W hypointensity (hypercellularity), rapid interval growth, abnormal facial nerve enhancement and ill-defined infiltrative margins. In small case series, DWI shows promising follow-up results.[47]

The literature suggests pleomorphic adenoma recurrence rates of around 1–4% after treatment and these usually occur in the first decade after surgery. In the larger series, two-thirds of recurrent disease is multifocal and the majority should maintain the same benign imaging characteristics of the initial tumour. Recurrent, small subcutaneous nodules are frequently seen and disease can present in a remote site from the operative bed.[48] Routine post-operative surveillance imaging is a costly and contentious issue.

WARTHIN'S TUMOUR

Warthin's tumour is the second most frequent parotid gland tumour with a 10–15% incidence of bilaterality. US highlights a well-defined, somewhat heterogenous, hypoechoic lesion that may be septated and partially cystic. Subacute haemorrhage or proteinaceous material will yield 'T1 bright signal' at MRI and possibly a hypointense signal rim indicative of chronic haemosiderin and blood degradation products. Enhancement is classically poor apart from the vascularized septations and the lesion may have restricted signal on DWI (**Figure 45.10**). A confident pre-operative diagnosis in those with significant comorbidities may avoid surgery altogether.

ONCOCYTOMAS

Oncocytomas most commonly present as solitary lesions in the parotid glands and these rare tumours are difficult to distinguish from benign and low-grade salivary tumours on routine US and MR imaging alone. A case series of nine patients describes a 'vanishing mass' with hypointense and isointense signals on T1 and fat-saturated T2W sequences respectively in eight of the pathologically confirmed lesions.[49] Like Warthin's tumours, these will demonstrate cystic degeneration and have a propensity to bilateral disease (10%).

Malignant neoplasms

The NICE guidelines on improving head and neck cancer outcomes in 2004[50] promoted appropriately set-up and funded fast track 'one-stop' clinical and US assessment clinics to provide same-day tissue biopsies and prompt diagnoses. The most common malignant salivary tumours are mucoepidermoid, adenoid cystic, acinic cell, adeno- and squamous carcinomas. Approximately 20% of all parotid tumours, half of the submandibular gland tumours and more than 90% of sublingual tumours are malignant. Malignant tumours can deceptively show the same imaging characteristics as their benign counterparts.

KEY POINTS

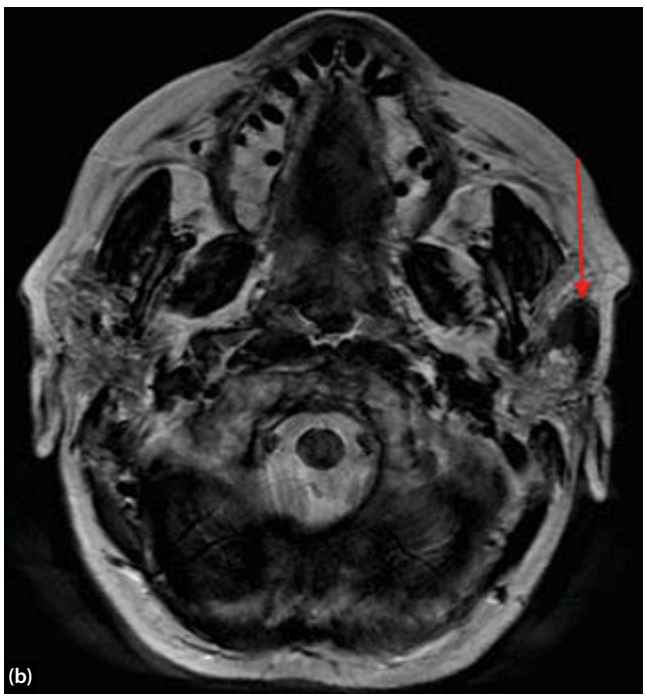
- Common knowledge states that there is an inverse relationship between the volume of the salivary gland and the risk of malignancy.
- It should be remembered that minor salivary glands are present throughout the upper aerodigestive tract including the sinonasal cavity and trachea.
- Intermediate grade and aggressive tumours with metastatic potential are disproportionally more frequent in the sublingual and minor salivary glands.

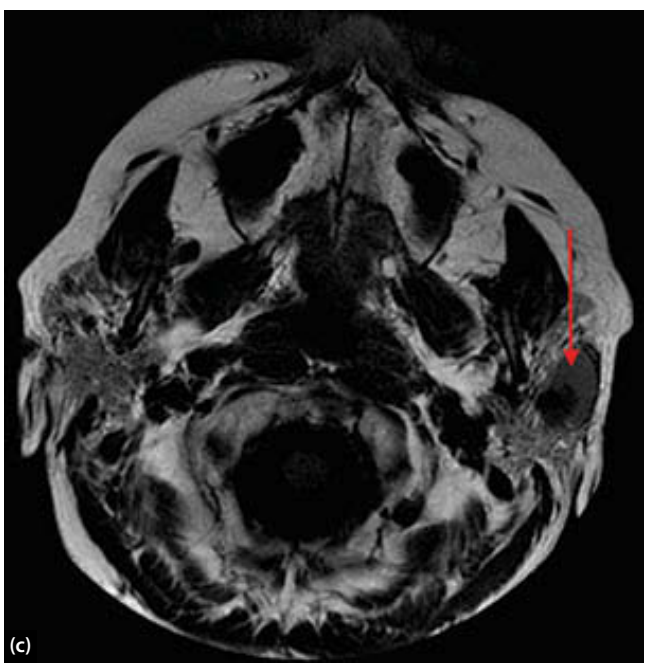
A firm, fixed, painful lesion with rapid growth or possible cranial nerve deficits and local adenopathy strongly suggests malignant characteristics. Image interpretation is primarily focused towards these adverse prognostic indicators.[51] Imaging features more suggestive of malignancy are lesional inhomogeneity, posterior acoustic shadowing and raised inherent vascular flow at US. With a good positive predictive value, ill defined and infiltrative margins imply malignancy. The absence of T2W bright fluid signal with avid enhancement patterns at MRI renders a focal lesion as indeterminate, possibly malignant and this will require prompt surgical excision. MR signal characteristics and tumour grades are poorly correlated. Perineural facial or trigeminal nerve enhancement (best depicted on fat-saturated, post-gadolinium images), obscuration of fat around widened skull base neural foramina, biopsy proven cervical lymph node metastasis, remote lung nodules and destructive bone lesions are highly sensitive indicators of loco-regional and distant metastatic disease.

Contrast-enhanced CT is universally used to stage presenting aerodigestive squamous cell carcinomas and it is sensitive in detecting pulmonary metastasis that would generally preclude curative surgery in high-grade salivary malignancies. However, its routine use in evaluating the salivary gland parenchyma is limited due to poor soft tissue characterization. Moreover, salivary gland lesions may be concealed amongst dental amalgam artefact and the surrounding normal avid enhancing gland parenchyma. A skull base and neck CT study would be complementary to MRI when associated bony erosion is suspected.

MUCOEPIDERMOID TUMOURS

Mucoepidermoid tumours are the most common parotid malignancy, and constitute 12–29% of all salivary





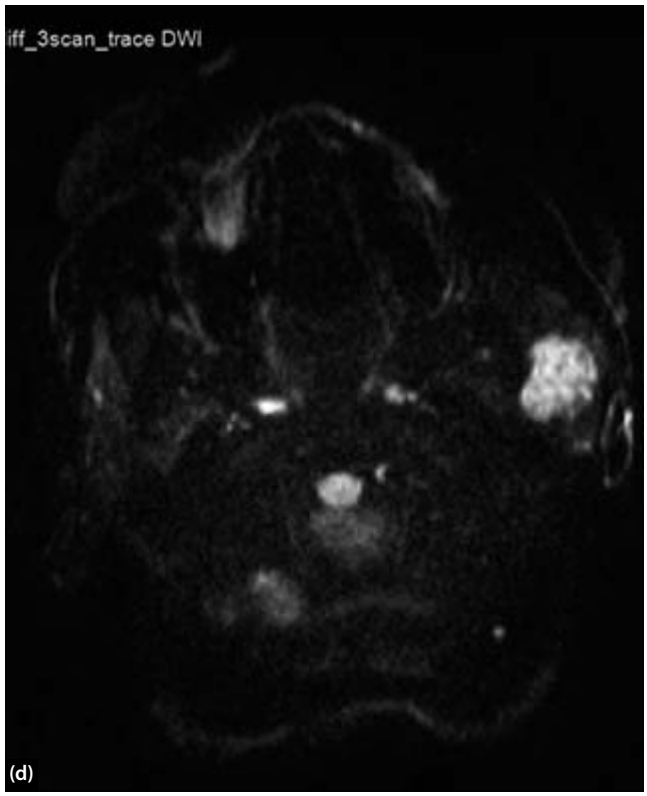


Figure 45.10 Warthin's tumour. **(a)** Axial US of well-circumscribed, heterogenous superficial Warthin's lesion; **(b)** Axial T2W MR of left parotid gland Warthin's tumour; **(c, d)** Diffusion-weighted imaging of a Warthin's tumour; **(e)** matched ADC image demonstrating hypercellularity.

malignancies. Classified into high-, intermediate- or low-grade tumours, they may have abundant fibrous tissue that is hypointense across MR sequences. Cystic change may be present.

ADENOID CYSTIC CARCINOMAS

Adenoid cystic carcinomas are overall the second most common salivary gland lesion but the commonest malignant tumour within the submandibular glands. Cribriform, tubular and solid subtypes exist and cellularity correlates with prognosis. Hypercellular areas tend to yield hypointense signal on T2W sequences and are more common with the solid subtypes.[52] Local perineural spread should be always be sought pre-operatively on contrast-enhanced MR images. Larger tumours may have intralesional bleeds with bright signal foci on T1W imaging.

INTRAPAROTID NODAL METASTASIS: LYMPHOMA, SCC AND MELANOMA

As a drainage pathway to the face, lateral scalp and external auditory canal, occult skin squamous cell carcinoma (SCC) and melanomas may present as parotid masses (**Figure 45.11**). Primary salivary gland lymphomas are more common in immunosuppressed individuals and those with background chronic autoimmune disease such as pre-existent Sjögren's disease. The imaging findings and long clinical histories are suggestive clues. At US, bulky, non-necrotic hypoechoic large intra-parenchymal nodes with distorted hila are also highly suggestive of secondary lymphoma, which will require staged abdominopelvic imaging.

Newer functional techniques

Whilst the overwhelming success of DWI in ENT has been for the evaluation and follow-up of cholesteatomatous ear disease, it has also been studied to differentiate salivary gland tumours. Its spatial resolution is poor but it is always acquired rapidly alongside conventional anatomical imaging. Transient magnetic gradients reflect local intra- and extracellular water diffusion amongst macromolecules, endothelium, cell membranes and hypercellular environments that can characterize pathological tissues in more detail. Quantitative values (apparent diffusion coefficients or ADC values) are obtained routinely and these can be prospectively correlated with subsequent histopathological findings. To dichotomize and oversimplify, high ADC values imply a benign phenotype, while reduced values suggest a greater chance of malignancy. Fluid and vascular flow can confound the validity of results[53] and the different ratios of serous and mucinous salivary glands yield differing ADC values in healthy individuals.[54]

Perhaps less favourable than initial reports, Habermann et al.[55] prospectively considered 136 consecutive parotid tumours and they were significantly and successfully able to separate pleomorphic adenomas and myoepithelial adenomas from other cell types. Despite variation in their biological behaviours, Warthin's tumours, mucoepidermoid, acinic cell and basal cell adenocarcinomas (surgical candidates) were poorly separated with overlapping, somewhat indeterminate results.

The significant histological heterogeneity in salivary neoplasms and small study sizes do not favour the development of these newer techniques. Sumi et al.[56] used intravoxel incoherent motion (IVIM) MR sequences to prospectively study 31 salivary gland tumours with histological correlation and derived parameters that could be successfully used to partition malignant and benign entities. Conceptually, it is thought that densely packed, small malignant cells, with high nuclear : cytoplasmic ratios tend to have poor associated diffusivity.

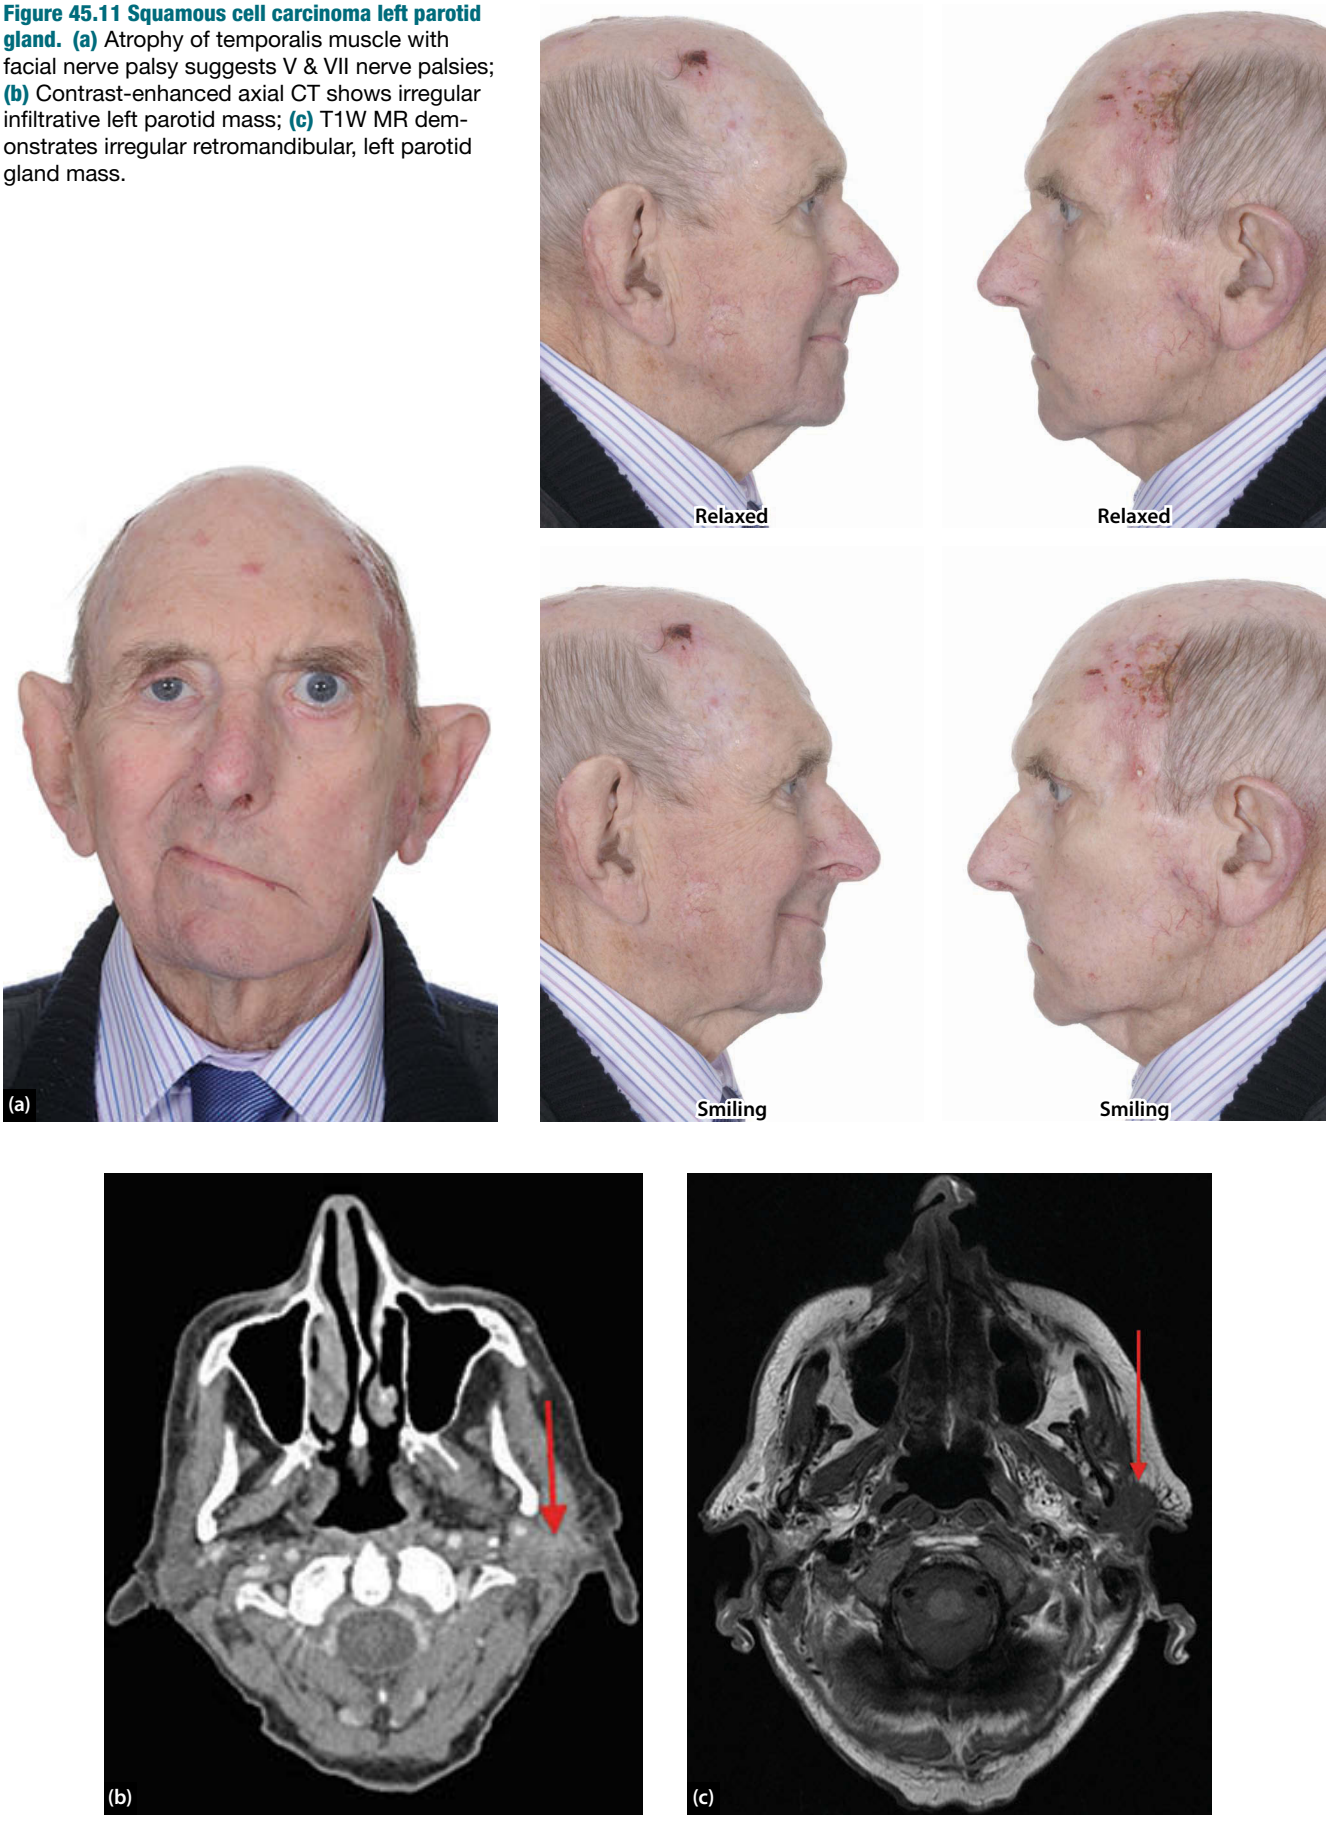
From the wider arena of oncological imaging, dynamic MRI (dMRI) continues to look at correlating enhancement patterns with angiogenesis and cellular-stromal ratios in pathological tissues. A seminal paper by Yabuuchi et al.[57] describes a promising method. Intravenous gadolinium is delivered via a power injector. Having chosen a region of interest, repeated sequential dynamic images are acquired over a period ranging from 0 to 300 seconds. Time-intensity curves (TIC) are then generated with avoidance of cystic regions and large vessel sampling. Plateau type patterns at dMRI are suggestive of malignant foci with rapid enhancement, fast peak times and delayed contrast wash-out. It is proposed that this latter finding may represent extravasation of contrast material through abnormally permeable endothelium in tumour beds.

MR proton spectroscopy can be used to characterize choline/creatinine ratios and, in 2005, King et al. showed that larger ratios imply a benign phenotype.[58]

Using combinations of these techniques, researchers are moving towards multiparametric evaluation to anticipate likely tumour behaviour, prognostics and treatment response. In 47 patients with major salivary lesions, Yabuuchi[59] retrospectively considered the added merits of combining DWI measurements with dynamic contrast-enhanced MRI. This revealed further improvements in the pre-operative separation of malignant and benign lesional characteristics with the former group illustrating rapid peak times and delayed wash-out.

At PET-CT, diffuse, supra-normal increased uptake in the salivary glands is occasionally seen incidentally in low-grade asymptomatic inflammatory disorders and connective tissue diseases. PET-CT has a well-defined role in mucosal HNSCC; however, its role in focal salivary glandular pathology is far less clear with small study sizes. The reality is that by this stage of assessment the patient would usually already have had an USgFNAC. The ability to differentiate benign from malignant disease is dependent on glycolytic activity and potential exists to misclassify hypermetabolic, benign lesions (Warthin's tumour, oncocytomas) from intermediate/low-grade malignant tumours with low metabolic activities. The real potential is for a single test to stage high-grade tumours with a propensity for occult bony metastasis.

Figure 45.11 Squamous cell carcinoma left parotid gland. **(a)** Atrophy of temporalis muscle with facial nerve palsy suggests V & VII nerve palsies; **(b)** Contrast-enhanced axial CT shows irregular infiltrative left parotid mass; **(c)** T1W MR demonstrates irregular retromandibular, left parotid gland mass.



KEY POINTS

- A specialist opinion and detailed history directs the appropriate imaging.
- US is the best initial test in most circumstances.
- Fine-needle aspiration of a mass is a robust test when good cytological support is available.
- Facial nerve symptoms or localized nodal disease is likely to signify malignant disease.

SEARCH STRATEGY

A literature search was performed using Medline and included the following keywords: non-neoplastic salivary disorders, benign salivary disorders, as well as all the main subject headings. A few earlier references are included where they are pertinent and only the relevant references have been cited.

INTRODUCTION

A wide range of non-neoplastic disorders of the salivary glands can arise, although the more common are sialolithiasis, mumps, acute suppurative sialadenitis, Sjögren's syndrome (SS) and drug-induced xerostomia. Disease of the glands typically manifests as swelling (**Table 46.1**) and/or oral dryness (**Box 46.1**). The present chapter provides an overview of non-neoplastic disorders of the salivary glands, but also focuses upon the common disorders likely to be of relevance to otorhinolaryngologists.

CONGENITAL SALIVARY GLAND DISEASE

Salivary gland agenesis

Agenesis of one or more of the major salivary glands is uncommon. There can be variation in the number of absent salivary glands and hence the degree of associated xerostomia, dysarthria and/or dysphagia varies accordingly. Lack of saliva predisposes to dental caries, gingival and periodontal inflammation, candidosis and acute suppurative sialadenitis in any existing glands, although in children severe dental caries may be the only initial sign of underlying salivary gland agenesis.[1]

The precise incidence of major salivary gland agenesis is difficult to establish due to the asymptomatic nature of many affected individuals but it may have an estimated incidence of 1 in 5000 live births,[2] with males more likely to be affected than females. Familial clustering of salivary gland agenesis has occasionally been reported but many instances are isolated, non-familial and non-syndromic.[3] Salivary gland aplasia can be associated with other ectodermal defects, in particular lacrimal apparatus abnormalities (the salivary glands and lacrimal puncta both develop at about the 4th to the 8th weeks of embryonic life as a consequence of ingrowths of ectodermal tissue into the underlying mesenchyme).[1] Autosomal dominant aplasia of the lacrimal and salivary glands is due to a defect being loss-of-function mutations in the fibroblast growth factor 10 (*FGF10*) gene at chromosome 5p13-p12125.

TABLE 46.1 Non-neoplastic causes of salivary gland swelling

Unilateral	Bilateral
• Acute suppurative sialadenitis • Recurrent parotitis of childhood • Sialolithiasis and other causes of ductal obstruction • Sjogren's syndrome (and associated non-Hodgkin lymphoma • IgG4-related disease • Sarcoidosis • Chronic non-specific sialadenitis • Xanthogranulomatous sialadenitis • Amyloidosis • Others	• Mumps • HIV salivary gland disease (and related disorders) • HCV sialadenitis • Sjogren's syndrome (and rarely bilateral non-Hodgkin lymphoma) • IgG4-related disease • Sarcoidosis • Sialosis • Pneumoparotitis • Iodine containing contrast media and radioactive iodine • Drugs (rare) • Others

BOX 46.1 Non-neoplastic causes of long-standing reduced salivary output

- Drugs (many)
- Radiotherapy of the head and neck
- Sjogren's syndrome and related disorders
- Chronic graft-versus-host disease
- IgG4-related disease
- Sarcoidosis
- Salivary gland agenesis
- HIV salivary gland disease
- HCV sialadenitis
- Others (e.g. long-standing anxiety, depression)

Associations with hypohidrotic ectodermal dysplasia (ED)[4] and lacrimal-auriculo-dentodigital (LADD; Levy-Hollister syndrome) reflecting defects of *FGF10* gene[5] and ectodactyly-ED syndromes have been reported. Bilateral parotid gland aplasia in a patient with Down syndrome has been reported[6] and agenesis of the major salivary glands in association with an absence of the lacrimal puncta of one side also observed.[7]

The management of children with absence of salivary glands follows that of long-standing oral dryness due to Sjögren's syndrome.[8]

KEY POINTS

- Lack of saliva predisposes to dental caries, gingival and periodontal inflammation, candidosis and acute infective sialadenitis, although in children rampant dental caries may be the only initial sign of underlying salivary agenesis.
- Salivary gland aplasia is rare, may occur in isolation or be associated with other ectodermal defects, in particular lacrimal apparatus abnormalities.
- The management of children with absence of salivary glands follows that of long-standing oral dryness due to Sjögren's syndrome.

INFECTIONS OF THE SALIVARY GLAND

Viral and bacterial infections are the most common infectious disorders of the salivary glands, although very rarely other infectious agents can be involved (**Table 46.2**). In addition the salivary glands may be the site of asymptomatic viral infection – particularly some of the herpes group (e.g. human herpesvirus 6 (HHV-6), cytomegalovirus and perhaps human herpesvirus 8 (HHV-8)), while saliva can contain low amounts of a wide range of infectious agents including hepatitis B virus, hepatitis C virus (HCV), HHV-8 and human immunodeficiency virus (HIV).[9, 10] There is little evidence, however, that saliva is a common fluid for the transmission of HCV or HIV.

Of note, xerostomia is more likely with viral (e.g. HCV and HIV) than bacterial infection of the salivary glands. The infections that can arise in the salivary glands are summarized in **Table 46.2**; however, as some of these are rare and/or have no specific salivary gland features, the present discussion will focus upon the more common infections of the salivary glands.

Mumps (epidemic parotitis)

Mumps is an acute generalized paramyxovirus infection of children and young adults. Mumps typically affects the major salivary glands, although involvement of other structures can occur including the pancreas, testis, ovaries, brain, breast, liver, joints and heart.[11]

Mumps is transmitted via the droplet route, and has an incubation time of approximately 14–18 days. Patients present with initial pyrexia, chills and facial pain. The parotids are typically bilaterally enlarged, although this may initially be unilateral. There is often swelling of the submandibular glands together with lymphadenopathy, giving rise to profound facial and neck swelling. Rarely sublingual swelling may be so profound as to cause elevation of the tongue and dysphagia and dysarthria. The salivary swelling tends to diminish after approximately 4–5 days and may precede more complicated aspects of the illness. There have been a small number of reports of transient facial nerve weakness in association with the parotid gland enlargement in mumps.[12]

Orchitis may develop approximately 4–5 days after the onset of parotitis. Typically only one testicle is affected, though occasionally there can be bilateral involvement. Orchitis tends to arise in post-pubertal boys, and rarely gives rise to serious long-standing disease.

Mumps can give rise to a lymphocytic or viral meningitis, which commences a few days after the development

TABLE 46.2 Infections of the salivary glands

Common	Uncommon
• Acute suppurative sialadenitis • Mumps • HIV-associated salivary gland disease • HCV-associated sialadenitis	• Human T-lymphocytic virus 1 (HTLV-1) • Epstein–Barr virus (EBV) • Cytomegalovirus (CMV) • *Mycobacterium tuberculosis* • Non-tuberculous mycobacteria • Arachna spp • *Haemophilus influenzae* • *Escherichia coli* • *Treponema pallidum* • *Eikenella corrodens* • 'Cat scratch' bacillus • Caffkiya anaerobia • *Actinomycosis israelii* • *Actinomycoses eriksonii* • *Samonella enteritidis* • *Salmonella choleraesuis* • *Histoplasma* spp • *Candida* spp • Cysticercosis

of parotitis. It should be noted that meningitis can occur in the absence of salivary gland disease. Other neurological manifestations include retrobulbar neuritis and encephalitis. Deafness is possible, but rare. Pancreatic infection may give rise to mild upper abdominal pain, but acute and long-term complications are unusual. Likewise, while cardiac, hepatic and joint infection can occur, they are rare and do not generally cause notable complications.

The diagnosis of mumps is typically based upon the clinical picture; however, it may be confirmed by detection of viral-specific immunoglobulin G (IgG) and immunoglobulin A (IgA). Viral culture is possible, but generally unnecessary as serological methods are highly sensitive.

There is no specific treatment for mumps, analgesia and appropriate fluid intake being the mainstays of therapy. It has been suggested that corticosteroids may be effective for severe parotitis, but generally these are not required unless the patients have other systemic symptoms such as orchitis.

Mumps can generally be prevented with appropriate vaccination (measles, mumps and rubella (MMR)). The effectiveness of the MMR vaccine is evidenced by outbreaks of mumps as a consequence of suboptimal uptake of vaccination.[13]

KEY POINTS

- Mumps patients present with initial pyrexia, facial pain, enlarged parotid glands usually bilateral, and swelling of the submandibular glands together with lymphadenopathy and, rarely, sublingual swelling.
- Mumps salivary swelling tends to diminish after approximately 4–5 days.
- Serious and not infrequent complications of mumps include orchitis and viral meningitis.

HIV salivary gland disease

Salivary gland manifestations can arise in up to 10% of adults and children with untreated HIV infection. Clinical syndromes of HIV infection of the salivary glands include HIV salivary gland disease per se, bacterial sialadenitis, intra-parotid lymphadenopathy, primary or metastatic non-Hodgkin lymphoma and Kaposi's sarcoma.[10] There have been rare reports of sialolithiasis possibly secondary to atazanavir (that has also been linked to renal and biliary lithiasis),[14] ranula formation of the sublingual gland[15] and submandibular gland swelling due to cytomegalovirus infection as part of immune reconstitution inflammatory syndrome (IRIS).[16]

HIV salivary gland disease is a distinct disorder characterized by recurrent and/or persistent major salivary gland enlargement and xerostomia. The parotid glands are most frequently affected, there often being profound bilateral enlargement. Submandibular gland involvement is considered to be rare.[17] Salivary gland disease tends to arise in late HIV infection, although occasionally can be the first manifestation. A higher rate of male to female ratio of involvement has been reported, but this probably reflects the epidemiology of the patients that have been previously reported. HIV salivary gland disease may be associated with HLA-DR5, and is part of a more generalized disorder termed diffuse infiltrated lymphocytosis syndrome (DILS) characterized by CD8+ T-cell infiltration of the lungs, salivary glands and lacrimal glands.[3] There is increasing evidence that salivary gland inflammation and cyst formation are driven by infection with BK polyomavirus (BKPyV) and thus, as expected, HIV salivary gland disease is a virally driven opportunistic infection in an immunodeficient host.[18, 19]

The clinical picture of HIV salivary gland mimics that of Sjögren's syndrome; however, there are distinct histopathological and serological differences between the two disorders. Patients with HIV disease generally do not have anti-Ro or anti-La antibodies – but do have hypergammaglobulinaemia. The minor salivary gland histopathology is generally similar to that of Sjögren's syndrome, being dominated by perivascular, periacinar and periductal lymphocytic infiltrates with the formation of CD20+

lymphocyte dominated lymphoepithelial islands/complex and lymphoid follicles.[20]

Multicystic lymphoepithelial lesions, sometimes termed cystic lymphoid hyperplasia (CLH) or benign lymphoepithelial lesion (BLEL) or benign lymphoepithelial cysts (BLEC), may also occur. The exact cause of the lesions is not known but it has been suggested that they are due to ductal ectasia of entrapped salivary gland inclusions arising within lymph nodes.[21, 22] Cystic change can also arise following intra-glandular ductal obstruction by hyperplastic lymphoid tissue. It is estimated that swellings associated with CLH arise in up to 6% of adults and 10% of children infected with HIV. Transformation to non-Hodgkin lymphoma is a rare complication of CLH.

The diagnostic process of HIV salivary gland disease is similar to that of Sjögren's syndrome although, unlike the latter, histopathological involvement of the minor salivary glands may not be evident in HIV salivary gland disease or CLH. Fine-needle aspiration biopsy (FNAB) is sometimes, but not always, helpful for diagnosis as it allows rapid exclusion of malignancy.[20, 23] Radiological imaging (e.g. ultrasound, computed tomography (CT) or magnetic resonance imaging (MRI) is essential to establish the cause of any swellings of salivary glands in HIV disease, and in particular to exclude the possibility of malignancy.[17]

There is little information regarding the specific management of HIV salivary gland disease and the associated cystic swellings.[17] Clinical signs are usually non-progressive, and hence therapy is only indicated if there is notable cosmetic deformity or xerostomia. While it has been suggested that anti-retroviral therapy (ART) will reduce the swelling of HIV salivary gland disease, there is more evidence that protease inhibitors of ART may increase swelling (sometimes as a consequence of far accumulation within the gland)[24] and lessen salivary secretion.[25] Other, perhaps less practical, suggested therapies are repeated aspiration, tetracycline sclerosis or surgical removal of an enlarged gland.[26] External radiation (e.g. 8–10 Gy) can cause transient improvement, although higher doses (e.g. 24 Gy) can cause resolution of disease for at least several years – without causing severe xerostomia.[27]

The salivary gland dysfunction of HIV disease increases the risk of caries and lessens quality of life, hence there is a need to lessen the symptoms of xerostomia and provide preventative oral health care.[28]

Xerostomia independent of salivary gland involvement may arise in HIV infection as a consequence of some nucleoside analogue HIV reverse transcriptase inhibitors or protease inhibitors.[25]

KEY POINTS

- HIV salivary gland disease is characterized by recurrent or persistent major salivary gland enlargement, usually of the parotid glands with or without oral dryness. It tends to arise in late untreated HIV infection and can affect both children and adults.
- Clinically it mimics Sjögren's syndrome but there is an absence of anti-Ro and anti-La antibodies in HIV salivary gland disease.

BEST CLINICAL PRACTICE

- ✓ Treatment is only indicated for notable cosmetic deformity or xerostomia.
- ✓ Anti-retroviral therapy (ART) may lessen the onset of HIV salivary gland disease and may reduce swellings.
- ✓ The swellings of HIV salivary gland disease may respond to local radiotherapy. Doses of 24 Gy may cause long-term resolution of swelling without causing severe xerostomia.
- ✓ Other suggested therapies include repeated aspiration, tetracycline sclerosis or surgical removal of an enlarged gland.

Hepatitis C virus infection

Unlike the other hepatotropic hepatitis viruses, HCV frequently gives rise to a wide spectrum of extra-hepatic manifestations that include salivary gland disease. HCV-associated salivary gland disease arises in around 80% of infected patients.[29]

Xerostomia is the predominant symptom of HCV-associated salivary gland disease[30] and objective evidence of reduced unstimulated whole sialometry has been observed in 13–33%, although some groups of patients with HCV disease seem to have normal salivary flow rates – despite the presence of HCV in saliva.[30, 31]

The histopathological features of HCV-associated sialadenitis have similarities to those of Sjögren's syndrome, there being a lymphocytic infiltrate of salivary tissue in both. Whereas the infiltrate is periductal in the latter, in HCV sialadenitis it is pericapillary. In addition there is a more dominant cytotoxic T-cell infiltrate in HCV disease than Sjögren's syndrome.[31–33]

Transgenic mice expressing HCV genes develop sialadenitis, thus confirming the notion that HCV gives rise to salivary gland disease.[34] Nevertheless, the precise pathogenesis of HCV-related salivary gland disease remains unclear, particularly as the presence of HCV RNA in saliva does not correlate with clinical or histopathological evidence of salivary gland dysfunction.[31]

HCV infection may occasionally give rise to non-Hodgkin lymphoma (usually low grade B cell tumours); indeed, the salivary glands are a common site of lymphoma in HCV-infected individuals with 'Sicca' like symptoms. There remains, however, no association between HCV infection and the pathogenesis of Sjögren's syndrome.[32]

As with other disorders that give rise to oral dryness, patients with HCV sialadenitis require treatment of the xerostomia and the associated increased risk of common oral disease such as caries and gingival inflammation.

Acute suppurative sialadenitis (suppurative parotitis; bacterial sialadenitis; bacterial parotitis)

Acute suppurative sialadenitis is an uncommon disorder characterized by painful swelling – usually of the parotid

glands (suppurative parotitis), purulent discharge from the duct of the affected gland, associated dysgeusia and cervical lymphadenopathy. When disease is severe there may be accompanying pyrexia, malaise and a risk of abscess formation.

Acute suppurative sialadenitis can affect children and adults. Prematurity may be a risk factor for disease in childhood, and sialadenitis can occur in newborns.[35–37] The highest incidence is seen in children aged 3–6 years.[38] Immunodeficiency and concurrent illness may predispose to childhood suppurative parotitis. Of interest, an aseptic sialadenitis has been observed in pre-term children receiving long-term orogastric tube feeding.

In adults, it is most commonly seen in elderly, dehydrated, patients although long-standing xerostomia (e.g. Sjögren's syndrome) and radiotherapy-induced xerostomia are additional risk factors, as well as other predisposing factors such as poor oral hygiene, diabetes mellitus, HIV disease, the placement of a Sengstaken-Blakemore tube,[39] endoscopic retrograde cholangiopancreatography (ERCP), continuous positive airway pressure therapy,[40] and the use of total parenteral nutrition. Ductal obstruction (e.g. sialolithiasis, malignancy or foreign bodies), unusual anatomy of Stenson's duct,[41] positioning of the head during long surgical procedures,[42, 43] possibly after implant placement,[44] malar augmentation with poly-L-lactic acid injections,[45] and infection as a consequence of bacteraemia may also predispose to acute suppurative sialadenitis. Coprophagia gave rise to recurrent submandibular sialadenitis in one patient. Rarely infection may be acquired nosocomially[46] and following intra-glandular injection of botulinum neurotoxin for drooling.[47]

The causative organism of acute suppurative sialadenitis is often not found; however, facultative anaerobes, particularly *Staphylococcus aureus* and *Streptococcus viridans* have frequently been reported to be of aetiological significance. In addition a wide range of other bacteria including gram negative bacilli, strict anaerobes such as *Bacteroides* spp, *Fusobacterium nucleatum* and *Peptostreptococcus anaerobius* have been identified in affected individuals.[48, 49] Rare organisms associated with acute suppurative sialadenitis include methicillin-resistant *Staphylococcus aureus*,[50] *Bartonella henselae*, *Treponema pallidum*[51] and *Eikenella corrodens*.[48] There have been rare reports of acute sialadenitis associated with primary mycobacterium tuberculosis,[52] pre-existing *Mycobacterium tuberculosis* and non-tuberculous mycobacterial infection.[53, 54] Other rare infections have included *salmonella* spp,[55] *Neisseria meningitides*, *Fusobacterium necrophorum* (Lemierre's disease)[56] and *Burkholderia pseudomallei* (Meliodosis).[57, 58] **Table 46.2** indicates other possible bacterial infections of the salivary glands.

The diagnosis of acute suppurative sialadenitis is usually straightforward – being based upon the history and clinical picture. Microbiological culture of pus, under both aerobic and anaerobic conditions, may reveal the causative agents, although specific relevant tests may be useful if a particular infection seems likely.

The benefits of sialography for the diagnosis of acute suppurative sialadenitis remain unclear. Some authorities suggest that such investigation is contraindicated (probably when there is notable disease), while others suggest that it may resolve any causative ductal stricture. Sialography may reveal areas of ductal stricture and sialectasis, the latter are most likely with recurrent disease. Scintiscanning is generally unhelpful but may sometimes reveal the underlying cause (e.g. poor salivary gland function). Ultrasound scanning is useful as it may identify sialoliths, ductal anomalies, fluid collections and parenchymal disease of probable Sjögren's syndrome or HIV disease. Additional cross-sectional imaging may be essential if abscess formation is suspected.

COMPLICATIONS

There is a risk of abscess formation as a consequence of duct ectasia, primary parenchymal involvement (most likely with submandibular gland infection) or infection of subcapsular lymph nodes.[38] Facial nerve palsy secondary to parotid abscess formation with sialadenitis is rare, but possible.[59] Extension to the neck spaces is also possible (see Chapter 40, Neck space infections).

THERAPY

Effective hydration and antibiotics are the mainstays of therapy of uncomplicated acute suppurative sialadenitis. Empirical antibiotics used are anti-staphylococcal penicillins (e.g. flucloxacillin, amoxycillin or co-amoxiclav), cephalosporins or clindamycin based on local protocols, but these may change if a causative organism is identified. Intra-ductal injection of antibiotics is unlikely to be of practical benefit. A recent literature review concluded that cephalosporins and fluoroquinolones achieve high levels of concentration in saliva and are likely to exert an effective anti-bacterial action (although, interestingly, phenoxymethylpenicillin and tertacyclines do not).[60]

Surgical drainage should be considered if there is a lack of clinical improvement after 3–5 days of antibiotic therapy, any unlikely facial nerve involvement, any involvement of deep fascial spaces, or abscess formation within the parenchyma of the gland. Superficial parotidectomy may be required if disease becomes recurrent or chronic.[61, 62]

KEY POINTS

- Acute suppurative sialadenitis presents with painful swelling – usually of the parotid glands (suppurative parotitis), purulent discharge from the duct of the affected gland, dysgeusia, cervical lymphadenopathy, pyrexia and malaise.
- Acute suppurative sialadenitis usually affects adults although children may rarely be affected. Risk factors for acute suppurative sialadenitis are centred around causes of persistent obstruction of the ductal system and/or reduced salivary production.

BEST CLINICAL PRACTICE

- ✓ The diagnosis of acute suppurative sialadenitis is primarily clinical with microbiological culture of pus, under aerobic and anaerobic conditions.
- ✓ Ultrasound imaging is probably the most useful diagnostic radiological investigation.
- ✓ Effective hydration and antibiotics are the mainstays of therapy of uncomplicated acute suppurative sialadenitis. Typical antibiotics may include anti-staphylococcal flucloxacillin, amoxycillin (or co-amoxiclav), cephalosporins or clindamycin.
- ✓ Surgical drainage should be considered if there is a lack of clinical improvement after 3–5 days of antibiotics, facial nerve, deep fascial space involvement, or abscess formation within the parenchyma of the gland.

CHRONIC NON-SPECIFIC SIALADENITIS

Chronic non-specific sialadenitis is an uncommon disorder, usually of adulthood, characterized by recurrent and/or persistent enlargement of usually one major salivary gland. The parotids are more commonly affected than the submandibular glands.[63] Patients can have episodes of disease akin to acute suppurative sialadenitis. Affected patients are generally well, have no systemic disease likely to cause sialadenitis, although many have a history of recurrent parotitis of childhood or previous sialolithiasis.

In most instances, chronic non-specific sialadenitis reflects abnormalities of the ductal system – the recurrent infection having caused or worsened any ductal strictures. Likely causes of this disorder are small sialoliths and, less commonly, external pressure and resultant ductal defects due to dentures,[64] congenital ductal defects or radiotherapy-induced salivary gland damage. The strictures have a damming action causing salivary stasis and liability to infection with resultant chronic, and possibility acute, inflammation.

The investigation of chronic non-specific sialadenitis is similar to that of acute suppurative sialadenitis, although often microbiological examination of saliva will be unhelpful clinically. Sialochemistry is not helpful. Sialography will almost always reveal strictures and/or associated distortion of the major ducts, although there can also be variable sialectasis. Imaging studies may reveal small causative sialoliths. Chronic non-specific sialadenitis has no specific histopathological features, although there may be duct dilatation (sometimes with squamous metaplasia), acinar atrophy, interstitial fibrosis and a periductal inflammatory infiltrate comprised predominantly of lymphocytes and sometimes plasma cells and eosinophils.

The clinical course of the chronic non-specific sialadenitis is highly varied; about 50% of patients have eventual spontaneous resolution of symptoms after up to 5 years, but as many as 40% will have symptoms that warrant surgical intervention.[65] Although there is a recent report of parotid duct carcinoma arising within chronic sialadenitis,[66] chronic non-specific sialadenitis does not have any notable malignant potential.

The management of any acute infection associated with chronic non-specific sialadenitis follows that of acute suppurative disease. In addition, sialagogues such as chewing gum, duct and glandular massage, improved oral hygiene and therapeutic sialography have been suggested to be useful, but there are no supporting data.[67] Unless the cause is likely to be a sialolith, subtotal or total surgical removal of the affected gland may be the only useful treatment.[62, 63, 68]

KEY POINTS

- Chronic non-specific sialadenitis is an uncommon disorder, usually of adulthood, characterized by recurrent and/or persistent enlargement of usually one major salivary gland. The parotids are more commonly affected than the submandibular glands.
- Patients can have episodes akin to acute suppurative sialadenitis but affected individuals are well and have no systemic disease likely to cause sialadenitis, although they may have a history of recurrent parotitis of childhood or previous sialolithiasis.
- Clinical course can be highly varied with up to 50% having spontaneous resolution but up to 40% may warrant eventual surgical intervention.

BEST CLINICAL PRACTICE

- ✓ Investigations might include ultrasound scanning, sialography, CT or MRI to define the ductal structure and/or identify the presence of sialoliths.
- ✓ Treat acute episodes as for acute suppurative sialadenitis with hydration and appropriate antibiotics.
- ✓ Sialagogues, glandular massage and improved oral hygiene and therapeutic sialography seem logical but there is no supporting evidence.
- ✓ Subtotal or total gland removal maybe the only useful treatment for the chronic, non-infected state unless sialoliths can be identified.

RECURRENT PAROTITIS OF CHILDHOOD (JUVENILE RECURRENT PAROTITIS)

Recurrent parotitis of childhood is characterized by recurrent parotid inflammation usually associated with non-obstructive sialectasis of the parotid gland. Recurrent parotitis can arise at any age, but the usual age of onset is 3–6 years. Childhood onset disease is usually more common in males, but interestingly, adult onset disease normally arises in females.

The disease is characterized by localized pain and swelling that may last up to 14 days. Fever and overlying erythema are common, and occasionally white mucopus can be expressed from the parotid duct. Recurrent parotitis of childhood tends to be unilateral rather than bilateral.

The number of attacks varies from 1 to 5 per year, but some patients may have up to 20 episodes of swelling per year. The frequency of recurrence tends to peak between 5 and 7 years of age, and up to 90% of patients have resolution of disease by puberty.

Sialography and ultrasonic scans reveal sialectasis, but this feature can also be observed in the non-affected glands of the opposite side. Serum amylase may be elevated.[69] The precise aetiology of recurrent parotitis remains unclear, but certainly almost all affected patients are otherwise well. There is no evidence that viral infection underlies this disorder. No gross immunological abnormalities have been described in large numbers of affected persons and there is no evidence of an associated genetic anomaly.[69]

Analgesia is the mainstay of therapy. Antibiotics do not shorten attacks. Intraductal saline with or without dilatation of Stenson's duct, intraductal antibiotics (or methyl violet to induce sclerosis) have been proposed as have included sialoendoscopy,[70, 71] ductal dilatation with a sialoballoon, but there are no reports of the outcomes of large series of treated patients. A report indicated that sialography with high concentration iodinated oil caused a 100% reduction in recurrence of juvenile recurrent parotitis of 87 patients.[72] Suggested invasive procedures include ligation of Stenson's duct, transection of chorda tympani or transection of Jacobsen nerve in the middle ear. Radical methods such as total or sub-total parotidectomy have also been proposed[72] but as the disease tends to resolve spontaneously there seem little place for such invasive measures. There is a recent report of Huangqi and bear bile capsules or granules reducing the frequency of swellings of recurrent parotitis of childhood.[73]

KEY POINTS

- Recurrent parotitis of childhood is characterized by recurrent painful unilateral parotid swelling usually associated with non-obstructive sialectasis of the parotid gland.
- The cause of recurrent parotitis of childhood is unknown although affected individuals are otherwise well.
- The usual age of onset is 3–6 years. The number of attacks varies from 1 to 5 per year, but up to 20 episodes may occur per year. The frequency of recurrence peaks between 5 and 7, and up to 90% of patients have resolution of disease by puberty.

BEST CLINICAL PRACTICE

✓ Analgesia is the mainstay of therapy. Antibiotics do not shorten attacks. A variety of other non-surgical and surgical therapies have been proposed, sialography or sialoendoscopy being the most promising of these.

IgG4-RELATED DISEASE

IgG4-related disease is a rare fibroinflammatory disorder characterized by elevated serum levels of IgG4 and multiorgan inflammation that can thus manifest with a plethora of possible manifestations. The disease has predominantly been described in Asian patients (particularly in Japan) but affected individuals have been reported in the Western World. Disease onset is usually in the 7th decade with males more likely to be affected than females (other than those with sialadenitis and dacryodenitis where there is an equal gender distribution or slight female predominance). Probable IgG4 sialadenitis has been reported in at least one child.[74]

The salivary glands are commonly affected, and in the past the features were termed 'Mikuliz disease' 'Kuttner tumour' or 'chronic sclerosing sialadenitis'. The submandibular gland is commonly affected, although the parotids, sublingual glands and minor salivary glands can occasionally be affected. The salivary gland features manifest as long-standing and generally asymptomatic swelling, sometimes, but not always, with symptoms of xerostomia.[75, 76]

The (many) other associated features of this disorder are well reviewed elsewhere[76–78] but include:

- lacrimal gland (IgG4 dacryoadenitis): swelling, keratoconjunctivitis sicca (sometimes), other features
- pituitary gland (IgG4-realted hypophysitis): headache, visual field deficits, diabetes insipidus, lactation
- thyroid (IgG4-related thyroiditis): malaise, oedema, neck swellings
- pancreas (Type 1 autoimmune pancreatitis): upper abdominal pain, obstructive jaundice, impaired glucose tolerance
- biliary tract (IgG4-related sclerosing cholangitis): obstructive jaundice
- lung (IgG4-related lung disease): cough
- prostate gland (IgG4-related prostatitis): urinary frequency
- retroperitoneal cavity (IgG4-related retroperitoneal fibrosis): fever, malaise, aortic aneurysm
- lymph nodes (IgG4 lymphadenopathy): lymph node enlargement.

Thus in specialist ENT clinics, patients may present with symmetrically swollen upper eyelids, salivary glands, cervical lymphadenopathy[79] and sometimes symptoms of ocular and/or oral dryness.

Histopathological examination of IgG4-related sialadenitis salivary gland lesions reveals a dense lymphoplasmacytic infiltrate, large irregular follicles with expanded germinal centres and acinar atrophy. Obliterative phlebitis, in which there is obliteration of venous channels by the lymphoplasmacytic infiltrate, is said to be a characteristic feature as is storiform fibrosis,[80] although this last feature may not always be evident in affected salivary glands.[81] Unlike Sjögren's syndrome there is an absence of lymphoepithelial lesions in IgG4-related sialadenitis. Immunohistochemistry of affected salivary gland tissue of IgG4-related disease reveals an abundance of IgG4+ plasma cells that may constitute up to 50% of the plasma cell infiltrate (although this may be absent if there is extensive fibrosis). The normal lobular architecture of the glands are usually preserved and the inflammation may be localized to one site or throughout a gland.[75]

There may be a hypergammaglobulinaemia and serum levels of IgG4 are always elevated and there is an absence

of circulating anti-Ro and anti-La antibodies.[76] In view perhaps of the sometimes non-diffuse nature of the disease within salivary glands, sialography may not always demonstrate any notable ductal abnormalities, although punctate of globular sialectasis may sometimes be observed.[82] Ultrasound scanning may reveal salivary gland enlargement and hypoechoic areas[82] while MRI may similarly demonstrate salivary gland swelling, but may not delineate the nodal (i.e. hypoechoic) areas.

The aetiopathogenesis of IgG4-related disease is reviewed well elsewhere.[76, 78, 80] The precise cause or trigger of this fibrotic disorder is not known although disease is driven by an excess production of type 2 T-helper cells and regulatory T-cell cytokines (e.g. IL-10) and transforming growth factor (TGF) -β, the latter then driving fibrosis.

There are no randomized controlled trials (RCTs) of the management of the oral aspects of IgG4-related sialadenitis and where disease is asymptomatic no therapy may be warranted. Short-term glucocorticoids may cause an increase in saliva production in affected patients.[83] This response contrasts with that of Sjögren's syndrome and may reflect the possibly localized involvement of the salivary glands in IgG4-related disease. Azathioprine or calcineurin inhibitors have been employed for some of the non-salivary elements of IgG4-related disease and, perhaps as expected, rituximab has been reported to reduce the salivary gland swelling of a small number of patients.[84, 85] Surgical excision of an affected gland is often advocated.[86]

Malignancy can arise in patients with IgG4-related disease (including one report of an unspecified cancer of the tongue) but there is no evidence that the risk of malignancy at any likely site of IgG4 related disease is increased in comparison to that of appropriate control populations.[87]

KEY POINTS

- IgG4-related disease is a multiorgan fibroinflammatory disorder that can give rise to painless enlargement, sometimes with dysfunction of the submandibular and other major salivary glands.
- Disease usually arises in middle to late life. The diagnosis typically rests upon the presence of elevated serum levels of IgG4 and histopathological evidence of a lymphoplasmacytic infiltrate with a high percentage of IgG4+ cells and the presence of fibrosis. Ultrasound scanning may demonstrate multiple hypoechoic areas.
- There is no evidence that IgG4 disease increases the risk of malignancy of the salivary or lacrimal glands.

BEST CLINICAL PRACTICE

- ✓ While IgG4-related sialadenitis has some of the clinical features of Sjögren's syndrome, the serological, histopathological and radiological features of the two disorders are distinctly different.
- ✓ Surgical excision of affected salivary glands may be helpful, as may high dose systemic corticosteroids. Patients with multiorgan disease may benefit from systemic immunosuppression. The long-term outcomes of IgG4-related disease are presently not known.

Xanthogranulomatous sialadenitis

Xanthogranulomatous sialadenitis is a very rare disorder manifesting itself as a solitary painless swelling within a major salivary gland.[88] It is histopathologically characterized by the presence of lipid-laden macrophages (xanthoma cells or foamy macrophages) with chronic and acute inflammation as well as non-caseating granulomas. The investigation of this disorder is similar to that of a salivary gland malignancy. It has been suggested that xanthogranulomatous sialadenitis may arise as a consequence of FNAB, but there are few supporting data. Excision would seem to be the logical treatment, particularly in view of the presence of Warthin's tumour in association xanthogranulomatous sialadenitis of one patient.[89, 90]

Sialolithiasis

Sialolithiasis is a common disorder characterized by the formation of a calculus (sialolith) usually within the ductal system of a gland. Sialoliths can arise in both the major and minor salivary glands – indeed, necropsy studies revealed that 1% of submandibular glands can have sialoliths while sialomicroliths (microscopic stones/concretions) are present in almost all submandibular, and some parotid glands. Sialoliths are more common in the submandibular glands (e.g. 83% of one sample) than the parotid (10%) or sublingual (7%) glands,[36] and are more common in females than males, and are much more likely in adults than in children. The minor salivary glands, particularly of the upper lip, can be affected.[91]

Sialolithiasis does not always give rise to clinical signs or symptoms, indeed the presence of sialoliths on ultrasound scans of salivary glands of patients without clinical problems is not uncommon.[72] Obstruction of a major duct will give rise to pain and swelling, typically in the submandibular gland, with gustation or eating. The swelling is diffuse, develops rapidly and is often associated with a burning-like local pain. The swelling is generally non-tender and gradually resolves over a few hours. Longstanding sialolithiasis may give rise to acute suppurative sialadenitis or chronic non-specific sialadenitis. Sialoliths of minor salivary glands give rise to painless hard swellings that rarely form mucoceles.

The likely cause of sialolith formation remains unknown,[92] although stasis caused by sialomicroliths, with resultant inflammation and fibrosis and further stagnation of calcium-rich fluid can be a driver for sialolith formation. However, sialomicroliths need not be the origin of all sialoliths. The sialoliths are composed of both organic and non-organic material, the central medulla being the more organic. The high proportion of sialoliths in the submandibular gland possibly reflects the high alkalinity and calcium content of submandular saliva together with its strong parasympathetic secretory drive. Calcium phosphate is the predominant salt of the calculi, laid down as concentric shells of about 10 micrometres thickness.

It is suggested that sialoliths may be associated with diabetes mellitus, hypertension and/or chronic liver

disease, and possibly nephrolithiasis,[93] but not to water hardness.[94] Patients with hyperparathyroidism may have an increased incidence of sialolithiasis, and individuals with both hyperparathyroid disease and sialolithiasis have a greater risk of nephrocalcinosis than those without sialolithiasis.[93] An association between the anti-HIV agent atazanavir and sialolithiasis has been reported.

INVESTIGATIONS

Plain radiographs (e.g. lateral skull and occlusal views for suspected submandibular stones) may reveal a sialolith – provided it is large and radiopaque. However, as many as 30% of sialoliths, particularly of the parotid glands, are radiolucent. Ultrasound scanning can detect both radiopaque and radiolucent sialoliths (see Katz et al.[72] for useful review). Sialography may also be helpful but can be technically difficult when investigating the submandibular gland. Pan-oral tomograms are not helpful in view of their tomographic nature, although CT and possibly MRI may be of some benefit. Where available, sialoendoscopy (SE) may be a first-line investigative tool.

TREATMENT

When small and accessible, it may be possible to express a sialolith from the submandibular duct by manual palpation, and many sialoliths can also be simply removed via a transoral approach – if within the anterior segment of the submandibular duct.[95, 96] This does, however, carry a risk of stricture formation.[97] Transcervical surgical removal of an affected gland can often be the only effective treatment for calculi in the posterior aspect of the duct or within the gland, particularly when there is lithotripsy and/or sialoendoscopic methods are not available (see below). A submental approach that lessens postoperative scarring, provides good cosmetic outcomes and is no more time consuming than other approaches has also been suggested.[98]

The management of sialolithiasis has been significantly advanced by the introduction of minimally invasive, gland-sparing, therapies, which can often be undertaken under local anaesthesia in children and adults.[99, 100] These methods include interventional SE (that includes endoscopy plus possible laser cutting of intraductal fibrosis), with or without extracorporeal shock wave lithotripsy (ESWL) – although ESWL is not available in the US. Interventional SE may be used for both diagnosis and treatment, and the latter is particularly useful for small distal sialoliths, particularly when there are multiple stones. When SE is unsuccessful for small distal sialoliths, or the sialolith is proximal, mobile or intraparenchymal there may be a need for ESWL followed by SE (with basket retrieval of the fragments). Sialoliths of up to 10 mm will require ESWL and SE and there may be a need for an open surgical approach.[101] Intracorporeal lithotripsy (i.e. sialolith fragmentation with XeClexcimer, flash-lamp pulsed dye, Ho:YAG or erbium:YAG) is now possible as the fibres of the lasers are of small diameter,[102] but the lasers are expensive, the procedure is time-consuming and there is a risk of perforation of the duct and possible abscess formation that will necessitate surgical removal of the gland.[100]

The majority of studies of minimally invasive therapy of sialolithiasis have been of submandibular disease. However, these techniques seem to be equally applicable to parotid sialoliths.[103] The outcomes of interventional sialoendoscopic methods are highly favourable. Surgeon-based results report sialolith removal being achieved in up to 93% of patients and relief of symptoms being reported by up to 95%.[102, 104] Patient-orientated outcomes of minimally invasive procedures report resolution in 86% of patients with sialolithiasis and a significant improvement of quality of life and in the Glasgow Benefit Inventory (GBI).[105] Significant adverse side effects such as upper airway obstruction are rare.[106] Minimally invasive procedures are also applicable to the management of ductal obstruction due to stenosis and mucous plugging.[107–109] Minimally invasive methods are increasingly available across the globe, although the equipment is costly and, as with all new surgical procedures, there is a need for clinicians to be appropriately trained to lessen operating times, minimize morbidity and ensure that surgeon- and patient-reported outcomes are high.

Preliminary data suggest that systemic therapy with the alpha-1-blocker alfuzosin may reduce symptoms associated with ductal stenosis of the parotid gland or post-lithotripsy therapy of parotid sialoliths[110] but there is a need for prospective studies to confirm the exact benefits of this treatment.

KEY POINTS

- Sialolithiasis is a common disorder due to formation of calculi (sialoliths) usually within the ductal system of a gland.
- Sialoliths are more common in the submandibular glands (e.g. 83% of one sample) than the parotid (10%) or sublingual (7%) glands, are more common in females than males, and are much more likely in adults than in children.
- Sialolithiasis presents as pain and swelling, typically in the submandibular gland with gustation or eating. The non-tender swelling is diffuse, develops rapidly, is often associated with a burning-like local pain and resolves over a few hours.
- Long-standing sialolithiasis may give rise to acute suppurative sialadenitis or chronic non-specific sialadenitis.

BEST CLINICAL PRACTICE

- ✓ Investigations include plain radiographs and ultrasound scanning. Sialoendoscopy, where available may also be useful.
- ✓ When small and accessible, manual expression of a stone from the submandibular duct is often feasible, and many can also be removed surgically if within the anterior segment of the submandibular duct, but this carries a risk of stricture formation.
- ✓ Minimally invasive procedures such as sialoendoscopy with or without extracorporeal lithotripsy would seem the highly effective for the removal of many sialoliths.
- ✓ Surgical removal of an affected gland may, however, be the only effective treatment for some cases of sialolithiasis.

OTHER INFLAMMATORY DISORDERS

Chronic sarcoidosis can give rise to xerostomia and salivary gland enlargement in up to 9% of affected patients, which often occurs as part of Heertfordt's syndrome.[111] Parotid gland swelling can also arise (sometimes in association with facial nerve palsy)[112] and while the swelling is usually unilateral, there have been reports of bilateral parotid gland enlargement in sarcoidosis.[113] Reports of Crohn's disease affecting the minor salivary glands[48] are probably unexpected, in view of the widespread nature of oral lesions of the disorder; however, involvement of the major glands is rare. Major salivary gland enlargement due to Wegener's granulomatosis[114] has been reported but again is rare.

DRUG-ASSOCIATED SALIVARY GLAND DISEASE

A wide range of drug-related salivary disorders can arise. These predominantly comprise swelling and/or xerostomia (**Table 46.3**).[115]

Salivary gland swelling due to iodine-based agents

Mild acute sialadenitis (sometimes termed 'iodide mumps') can arise in response to iodine-based contrast media (e.g. for percutaneous coronary interventions).[116–118] This disorder tends to be transient.

Radioactive iodine, used for the treatment of thyroid cancer, can cause transient sialadenitis; indeed, sialadenitis is the most frequent non-thyroid complication of radioactive iodine therapy. This sialadenitis manifests itself as transient xerostomia, and unilateral or bilateral salivary gland enlargement, the parotid being particularly affected.[119] The clinical features develop within 24 hours of iodine therapy and are suggested to resolve within a week. However, inflammation may persist, particularly when doses of radiation have been high, and cause permanent loss of function of one or more glands and give rise to pain and reduced swallowing.[120, 121] One study found that 20% of 852 major salivary glands of 213 patients who had received high dose radioiodine therapy had scintigraphic evidence of reduced function, with good correlation between symptoms of xerostomia and degree of salivary gland dysfunction (particularly when the submandibular glands were affected).[122] The risk of long-term symptomatic sialadenitis secondary to iodine 131 (I-131) may possibly be predicted from sustained high salivary gland-to-background uptake ratio (SUR) of I-131 as demonstrated with scintigraphy of post-therapy glands.[123]

The risk of radioactive iodine-induced sialadenitis can be reduced by use of lemon confectionary – these increase salivary flow, increasing the speed of carriage of radioactive iodine through the glands and hence reducing the time of glandular radiation exposure. There are recent reports of sialoendoscopy being an effective procedure for patients with long-standing sialadenitis of the parotid or submandibular glands secondary to radioiodine therapy, the sialadenitis being due to mucous plugs, ductal debris and/or stenosis.[124] It has been suggested that thymus honey may be a means of lessening sialadenitis of radioiodine, but there is no supportive evidence.[125]

TABLE 46.3 Salivary gland manifestations of drug therapy

Xerostomia	Salivary gland swelling	Sjogren's syndrome	Salivary gland pain	Saliva coloured red
• Atropine and analogues (antimuscarinics) • Tricyclic antidepressants • Serotonin re-uptake inhibitors (SRIs) • Antihistamines • Antiemetics • Tranquillizers (antipsychotics) • Decongestants • Bronchodilators • Appetite suppressants • Amphetamines • Lithium • Omeprazole • HIV protease inhibitors • Disopyramide • Dideoxyinosine • Didanosine • Diuretics • Interleukin-2 • Retinoids • Others	• Anti-thyroid agents • Chlorhexidine • Cimetidine • Clonidine • Ganglion-blocking agents • Insulin • Interferon • Iodides • Isoprenaline • Methyldopa • Nicardipine • Nifedipine • Nitrofurantoin • Oxyphenbutazone • Phenothiazines • Phenylbutazone • Ritodrine • Sulphonamides	• Hydralazine • Levamisole • Practolol • Procainamide • Sucralfate	• Bethanidine • Bretylium • Clonidine • Cytotoxics • Guanethidine • Methyldopa	• Rifabutin • Rifampicin

Salivary gland swelling due to other agents

A wide range of non-iodine-based drugs has been suggested to give rise to transient painful swelling of the salivary glands, and in particular the parotid glands. A recent systematic review of 84 case reports of drug-induced parotitis (i.e. swelling and pain) concluded that l-asparaginase, clozapine and phenylbutazone would seem to be the most likely agents to cause medication-associated swelling of the parotid (and presumably other major) salivary glands.[115] However, many other drugs have probably also given rise to parotitis and include: methyldopa, IFN-α, oxyphenbutazone, ramipril, trimethoprim/sulfamethoxazole, nicardipine, nifedipine, chlormethiazole, methimazole, naproxen, nitrofurantoin, sulfadiazine, captopril, cytarabine, cimetidine, ranitidine and thioridazine.[115, 126] Protease inhibitors of HIV may cause bilateral salivary gland enlargement. Bilateral sialadenitis observed in one adult following naproxen therapy was thought to be allergic in origin as the affected patient also had a cutaneous rash. Salivary gland swelling has been reported in one patient with organophosphorus poisoning.[127]

KEY POINTS

- Mild transient, bilateral, painless sialadenitis may arise with a number of drugs, particularly l-asparaginase, clozapine and phenylbutazone.
- Transient sialadenitis secondary to radioiodine is not uncommon and 20% of patients can develop long-standing symptoms that may warrant sialoendoscopic intervention.
- A wide spectrum of other drugs can cause salivary gland enlargement.

XEROSTOMIA

Dry mouth is a common complaint in many elderly persons.[128–130] This is a probably a consequence of a large number of drugs (more than 500) that can cause xerostomia and the high frequency of polypharmacy in the elderly. The principal mechanism of drug-induced xerostomia reflects anticholinergic or sympathomimetic actions, hence the drugs most commonly implicated in xerostomia are tricyclic antidepressants, benzodiazepines, atropinics, beta-blockers and anti-histamines, and thus it is common in patients treated for hypertensive or mental illness (**Table 46.3**). While often promoted as having less anticholinergic actions than the tricyclics, the serotonin reuptake inhibitors (SRIs) still cause some dry mouth. Some other newer drug therapies, including omeprazole, anti-HIV protease inhibitors, the nucleoside analogue HIV reverse transcriptase inhibitor didanosine, trospium chloride, elliptinium, tramadol and new generation antihistamines, may all cause drug-induced xerostomia.

Some drugs can give rise to primary Sjögren's syndrome-like disease. These include hydralazine, Busulfan, quinidine sulphate and thiobendazole; however, this clinical disease can be transient. In addition, affected patients may not have high levels of immunological markers of Sjögren's syndrome, hence it seems unlikely that this is true Sjögren's syndrome.[131]

KEY POINTS

- There are more than 500 drugs that can cause dry mouth but the principal mechanism of action of xerostomia is anticholinergic and sympathomimetic; therefore, tricyclics, benzodiazepines, atropinics, beta-blockers and anti-histamines are the commonest culprits.
- Drugs may also give rise to salivary gland swellings.

SOME DISORDERS ASSOCIATED WITH ORAL DRYNESS

Radiotherapy-associated salivary gland dysfunction

Xerostomia is the most common complaint of head and neck cancer survivors that have received radiation therapy, with a prevalence of 93% during radiotherapy (RT) and 74–85% following RT.[132] The prevalence of RT-induced xerostomia varies with respect to RT field, dose, regimen and technique. The introduction of intensity-modulated radiation therapy (IMRT) has led to a significant reduction in the prevalence of xerostomia after RT. A recent systematic review comparing the effect of different techniques of RT on xerostomia scores confirmed a significant overall benefit in favour of IMRT with a hazard ratio of 0.76 (95% CI: 0.66, 0.87; $p < 0.05$).[133]

Radiation-induced xerostomia and hyposalivation typically commence early during treatment: during the first week after exposure to 10 Gy, a 30–50% decrease in salivary flow can be observed;[134] after 7 weeks of conventional RT (70 Gy), salivary flow can diminish to approximately 20% of the baseline flow rate.[135] Radiation-induced salivary gland dysfunction is considered irreversible,[136] although a slight recovery of salivary function 12–18 months after treatment completion has been reported.[137]

Two separate mechanisms seem to cause radiation damage to salivary glands. The first mechanism involves selective cell membrane damage resulting in altered intracellular signal transduction and defects in cellular functioning.[138, 139] The second mechanism includes the loss of secretory cells as a result of progenitor cell death.[140]

Whatever the mechanism, the impact of RT-associated hyposalivation upon the mouth and patient well-being can be significant. The rapid reduction in saliva gives rise to dysarthria, dysgeusia, difficult mastication and dysphagia. The inhibition of taste sensation and the impairment of chewing and swallowing can adversely impact upon a patient's nutritional status. Patients may experience intraoral burning sensation and an increased sensitivity to salty and spicy foods. Wearing dentures may be extremely

uncomfortable due to the reduced surface tension between the dry mucosa and the prosthesis.[141] Clinically the lips can become dry, desquamated and fissured, and the oral mucosa atrophic, pale and hyperemic. Patients with long-standing RT-induced xerostomia have an increased risk of caries, oral candidal infections (e.g. acute pseudomembranous candidiasis, angular cheilitis and median rhomboid glossitis) and acute suppurative sialadenitis of the parotid glands.[132, 142, 143]

PREVENTION OF RT-INDUCED HYPOSALIVATION

There remains no means of reversing any RT-induced damage of the salivary glands, although IMRT has reduced the frequency and severity of this complication. Several additional strategies have been proposed to prevent RT-induced salivary damage, particularly the use of the radioprotectant amifostine. A meta-analysis in 2006 of four investigations concluded that amifostine is effective in reducing the chances of developing Grade 2–3 acute xerostomia and late xerostomia by 76% and 67% respectively ($p < 0.05$) compared to placebo.[144] Two later randomized trials confirmed these findings,[145, 146] but two other studies failed to demonstrate a reduction in the incidence of acute and late xerostomia in participants receiving concomitant chemoradiotherapy and amifostine.[147, 148]

Intravenous amifostine can cause adverse side effects such as hypotension (62% of patients) and nausea, which seem to occur less frequently when amifostine is administered subcutaneously.[149] There is no evidence to suggest that amifostine may have a tumour-protective activity and reduce efficacy of anti-cancer therapy.[150] As all of the randomized studies of amifostine involved patients who were receiving conventional RT, is not clear if the addition of amifostine to IMRT is beneficial in reducing xerostomia.

There have been seven randomized double-blind placebo controlled trials investigating the effect of pilocarpine in preventing the incidence of xerostomia when administered during the course of RT and up to 3 months after. Four RCTs showed no significant difference between treatment and placebo groups with respect to xerostomia,[151–154] although a significant improvement in both subjective and objective outcome in treatment versus placebo was observed in others.[155, 156] Scarantino reported a moderate improvement in the average unstimulated salivary flow in the pilocarpine group (P value < 0.05), whereas no difference was noted following parotid stimulation or with regard to subjective outcome.[157] However, detailed information on dose distribution – the most important prognostic factor for developing salivary dysfunction – was generally lacking in the reports of the RCTs. As a consequence, there remains little robust evidence to suggest efficacy of pilocarpine in preventing xerostomia and hyposalivation associated with RT.

A phase II study suggested that following submandibular gland transfer out of the main RT field (to the submental space) 81% of patients had no or minimal xerostomia at the end of RT. Similar results were reported by Zhang et al.[158] A multicentre phase III comparative randomized trial reported better outcomes of submandibular salivary glands transfer with respect to prophylactic pilocarpine[159] in terms of xerostomia reduction. Surgical complication associated with this technique include facial oedema (13.6%), submental swelling (19%), shoulder weakness (4.5%) and neck numbness (6.8%).[160] The long-term efficacy of this approach has been demonstrated in a non-randomized study by Liu et al.[161] However, this invasive procedure is only applicable to patients with cancers requiring surgical resection as part of their treatment and it remains invasive, expensive and time-consuming.[162]

A recent randomized feasibility trial of the potential benefit of acupuncture showed that the individuals receiving acupuncture concurrently to RT had significantly lower xerostomia scores and greater salivary flow rate than the group randomly assigned to receive standard care.[163] The results were in agreement of another small study.[164] At present there remains no good evidence that acupuncture is an effective means of reducing the risk of RT-associated xerostomia.

MANAGEMENT OF RT-INDUCED HYPOSALIVATION

The management of RT-induced salivary gland hypofunction remains challenging, as there is no means of reversing the salivary gland damage. There are a number of promising modalities, but their long-term efficacy requires to be appropriately determined.

Sialagogues

Patients often suck confectionary or chew gum to lessen any oral dryness, but these have only short-term, if any, benefit and can increase the risk of caries if they contain sucrose.

The parasympathomimetic muscarinic secretagogues pilocarpine and cevimeline have been used to treat the xerostomia. Pilocarpine is a relatively non-selective muscarinic receptor agonist whereas cevimeline is an acetylcholine analogue that selectively stimulates the M3 muscarinic receptors in salivary glands.[165]

Cevimeline is not commercially available in Europe but has been shown to increase salivation after head-and-neck irradiation in animal studies and in two RCTs involving human patients. In dosages of 30 mg three times daily, cevimeline-treated subjects had significantly greater increase in the unstimulated salivary flow rate, but not stimulated, than patients receiving placebo. The subjective sensation of xerostomia, assessed via visual analogue scale (VAS) and questionnaire, improved in the cevimeline group but only in one study.[166] In a recent double-blind multicentre, randomized, placebo-controlled study, using the same dosage of cevimeline daily, the investigators observed that the grade of xerostomia decreased for both cevimeline-treated and placebo-treated patients over the course of the treatment.[167]

Six randomized double-blind trials have investigated the efficacy of pilocarpine in the treatment of radiation-induced dry mouth. The majority of these studies reported that pilocarpine (15 mg to 30 mg per day) is effective in lessening the sensation of oral dryness (measured by a VAS) and increasing salivary flow rate in post-RT setting, although adverse side effects are frequent, dose-dependent and can be problematic.[168–173] Topical pilocarpine (spray or lozenge) has been introduced in the attempt to minimize adverse side effects; results of clinical trials were, however, disappointing and did not encourage further investigations.[174, 175]

Oral mucosal lubricant/salivary substitutes

A wide variety of salivary substitutes are commercially available across the globe for the management of xerostomia of any cause. Available salivary substitutes are characterized by different composition and viscosity; they contain mucin, carboxymethylcellulose, hydroxyethylcellulose, xanthan gum, linseed or polyethylene oxide. While these agents may lessen symptoms transiently they have no lasting beneficial effects. The majority of studies of the efficacy of these agents have included a small numbers of patients, have rarely been well-designed RCTs and have had a variety of different end points. As a consequence a recent Cochrane review concluded that no salivary substitute could be recommended for the treatment of long-standing oral dryness of any cause.[176] The major disadvantages of salivary substitutes consist of their transient temporary activity, taste, excessive viscosity and cost. About 40% of patients discontinue the use of saliva substitutes and prefer to sip water as required.[177]

Other strategies

Although some available studies suggested acupuncture could provide symptomatic relief, three independent systematic reviews concluded that there remains insufficient evidence to support acupuncture as a standard treatment for RT-induced dry mouth.[178–180] More recently a multicentre randomized crossover study found that acupuncture, compared with oral care, produced significant reductions in patient reports of severe dry mouth, but no significant changes in either stimulated or unstimulated saliva measurements over the treatment.

A Phase I study of transfer of the *Aquaporin 1* (*Aqp1*) gene via retroductal cannulation of the parotid glands demonstrated an early positive response to adenoviral-mediated *Aqp1* cDNA transfer to a single previously irradiated parotid gland. Six of 11 patients had enhanced parotid flow rates and reduction in dry mouth symptoms.[181]

Electrostimulation of salivary glands via the lingual nerve has been demonstrated to reduce the symptoms of dry mouth and increase salivary flow.[182, 183] The effect of an intra-oral electrostimulating device is presently being assessed in a large RCT of patients with RT-induced salivary dysfunction.

KEY POINTS

- Radiotherapy of head and neck malignancies can cause profound oral dryness and salivary gland acinar destruction when the radiotherapy is directed through the major salivary glands.
- The degree of xerostomia reflects the duration and dose of radiotherapy.
- The xerostomia is irreversible and patients have oral symptoms akin to those of Sjögren's syndrome.

BEST CLINICAL PRACTICE

- ✓ Double blind, randomized controlled trials have conclusively established that oral and perhaps high dose topical pilocarpine may reduce the frequency and severity of radiotherapy-induced xerostomia and associated symptoms.
- ✓ IMRT reduces the frequency and severity of long-term salivary gland hypofunction.
- ✓ Radioprotectants such as amifostine may be of advantage in preventing radiotherapy-induced xerostomia.
- ✓ There remains no effective means of reversing or reducing the effects of established RT-associated xerostomia although a number of potentially promising therapies are presently in trial.

Sjögren's syndrome

Sjögren's syndrome is the second most common autoimmune connective tissue disorder, characterized by xerostomia and xerophthalmia due to profound lymphocytic infiltration into the salivary and lacrimal glands.[184]

Sjogren's syndrome can be broadly classified as primary disease of which there are only symptoms and signs affecting the eye and mouth, and secondary Sjögren's syndrome in which there is xerostomia, xerophthalmia and associated connective tissue disorder – most frequently rheumatoid arthritis or systemic lupus erythematosus. This classification is possibly more simplistic, as many patients with primary Sjögren's have a spectrum of other systemic, and often autoimmune phenomena.

Sjogren's syndrome occurs in 0.2%–3% of populations, seems to have no geographic or ethnic associations but is possibly nine times more common in women than men. Disease is usually detected in the 4th–6th decade of the patient's life, although Sjögren's syndrome can arise in younger adults and occasionally in children under 10 years of age. Sjögren's syndrome probably remains underdiagnosed, possibly reflecting the generally mild nature of the clinical signs in some patients. In addition, there is an increasingly wide range of other disorders that may give rise to clinical features similar to those of Sjögren's syndrome – notably infection with HIV, HCV and chronic graft-versus-host disease. Many asymptomatic people have circulating ANAs relevant to Sjögren's syndrome, but these are generally present in low titre and are not indicative of a future risk of Sjögren's syndrome.

The clinical manifestations of Sjögren's syndrome are well detailed elsewhere[185] and for the purposes of this text, only the oral and salivary features of Sjögren's syndrome

will be discussed. Nevertheless it is important to appreciate that primary disease can give rise to arthralgia (in 75% of patients) and myalgia (45%); that each may arise before the onset of lacrimal or salivary gland symptoms, xerosis (30%), vasculitic and other cutaneous rashes; and that up to 15% of patients may have Raynaud's phenomenon.[185] Thus, like secondary Sjögren's, the primary disease can significantly impact upon the function, well-being and quality of life of affected individuals.

The oral dryness of Sjögren's syndrome (both primary and secondary) can be profound, giving rise to dysarthria and dysphagia. The oral dryness leads to retention of food on the teeth, mucosa and gingiva and thus increases the frequency of caries (particularly cervical disease) and acute gingivitis. Patients with Sjögren's syndrome do not appear to have an increased predisposition to periodontitis per se.

There is an increased liability to candidal infection, notably acute pseudomembranous candidiasis, and median rhomboid glossitis, chronic atrophic candidiasis (denture-associated stomatitis) and angular cheilitis. The long-standing oral dryness of Sjögren's syndrome increases the liability to acute suppurative parotitis.

The poor salivary output can lead to dysgeusia and loss of taste – many affected persons report most foodstuffs taste 'cardboard-like'.

Affected patients may have intermittent swelling of the major salivary glands – notably the parotid glands, this often reflects non-specific inflammatory change within the glands. Solitary enlargement of a salivary gland may reflect chronic sialadenitis, acute suppurative parotitis and, importantly, non-Hodgkin lymphoma.

Sjogren's syndrome is a potentially malignant disorder having a 4.3% risk of malignancy with a standardized incident rate of 18.9. Low-grade marginal-zone lymphoma related to mucosa-associated lymphoid tissue (MALT) is the common lymphoma but others can also be follicle-centre, diffuse B cell lymphoma (DBCL) or lymphoplasmacytoid lymphoma.[186, 187] Risk factors for malignancy in Sjögren's syndrome include splenomegaly, lymphadenopathy, salivary gland enlargement(s), low C4, high β-2 microglobulin, low CD4 T-cells, low IgM and mixed cryoglobulinaemia. Therapy is usually cyclophosphamide, doxorubicin, vincristine, prednisolone (CHOP) and the outcomes are extremely good, with the 5-year survival rates being 85–100%.

The aetiopathogenesis of Sjögren's syndrome is complex and the precise cause, like many other autoimmune connective tissue disorders, remains unknown. There may be some genetically determined risk factors for its development, but while HIV and HCV infection may give rise to some of the histopathological and clinical features of Sjögren's syndrome, there is no evidence that this autoimmune disorder has an infectious aetiology. Similarly, the malignancies of Sjögren's syndrome are also not thought to be driven by viral or other infections.

DIAGNOSIS

The diagnostic criteria (and hence the relevant investigations) have been subject to considerable debate over the last 10 years. Until recently, there were the American European Consensus Group (AECG) criteria and the American College of Rheumatology (ACR) criteria. A detailed critique of these is available elsewhere[188] but essentially the two systems comprised generally similar diagnostic steps of detection of clinical symptoms and signs of lacrimal and salivary gland dysfunction, specialized investigation of lacrimal and salivary gland structure and function (e.g. radiological and histopathological investigations), the presence of circulating antibodies (anti-Ro and anti-La) and the exclusion of other disorders likely to give rise to a similar clinical picture (e.g. HIV or HCV disease, sarcoidosis, chronic graft-versus-host disease, IgG4 disease and perhaps, although very rarely, amyloidosis).

The AECG classification was the most widely accepted system and formed the basis of the diagnosis of Sjögren's syndrome in possibly the majority of major units across the globe. It was based on the presence of two subjective and two objective criteria of dryness, a salivary gland biopsy grade 3 or 5, and the presence of relevant circulating autoantibodies.[188] Although the AECG classification took into consideration only anti-SSA/-SSB antibodies (Anti-Ro/La), perhaps as expected a number of other autoantibodies are frequently detected in patients with Sjögren's syndrome. The most frequent autoantibodies are antinuclear antibodies (ANA), in up to 80% of the patients, and rheumatoid factors (RF).[189] According to the AECG criteria, salivary gland function could be assessed by unstimulated whole salivary flow, parotid sialography or salivary gland scintigraphy. However, it was shown that the addition of salivary gland ultrasonography can significantly improve the diagnostic performance of the AECG criteria. However in 2016 a unified system was agreed – the American College of Rheumatology/European League Against Rheumatism (ACR/EULAR) criteria – that is based upon a scoring system, based upon objective features of LGB histopathology, presence of anti-Ro/La, ocular staining score, Schirmer test and whole saliva flow rate.[190]

Central to the diagnosis of Sjögren's syndrome is the histopathological detection of pathognomonic features within salivary gland tissue. This comprises an infiltrate of mononuclear lymphocytes and other cells of chronic inflammation that are scored as foci of 50 lymphocytes, plasma cells and macrophages (focus lymphadenitis). A focus score of number of foci per 4 mm^2 is determined and for Sjögren's syndrome this must be greater than 1. In addition, unlike IgG4 disease, germinal centres are present in Sjögren's syndrome; indeed, it has been suggested that the presence of germinal centres may be a predictor of non-Hodgkin lymphoma development later in life.[185] As expected there is loss of salivary acini and peri-ductal fibrosis. Histopathological studies are typically performed on labial gland biopsy (LGB) tissue but as might be expected there can be considerable variation in the diagnosis of Sjögren's syndrome by histopathologists from different specialties and centres across the globe.

The classification system(s) may not always be helpful but Sjögren's syndrome is the likely diagnosis when a middle-to-late aged female has signs of ocular and oral dryness, is not on medication or has systemic disease likely to give rise to such a clinical picture and there are some radiological, serological and/or histopathological features suggestive of

such a process. In these circumstances, it would seem to be medicolegally sound to indicate that, while there is a risk that the disease is not Sjögren's syndrome, there is sufficient evidence to warrant the patient and attending clinicians being aware of the possible risk of lymphoma.

TREATMENT

Salivary substitutes

A number of synthetic salivary substitutes are available for the management of xerostomia, a number of them supplemented with calcium, phosphate and fluoride ions in order to prevent demineralization. However, since none of them can completely comply with the highly complex nature of saliva molecules, patients find them generally unsatisfactory – unless the xerostomia is mild. As a consequence of the variable effectiveness of these agents and sometimes their high financial cost to patients, many affected individuals resort to simply sipping water regularly.[189, 190] Moreover, as stated in a comprehensive review by Furness et al,[176] there is no conclusive evidence about their effectiveness for caries prevention.

Chewing gum

Salivary stimulation with sugar-free chewing gum may enhance salivary flow, increasing pH and buffer capacity.[191] The addition of substances such as polyols and carbamide apparently does not improve the caries-preventive effect of the chewing process itself.[192] However, these actions are likely to be transient, and full-denture wearers may be unable to use them – even when the manufacturers state that these agents are suitable for them.[193]

SYSTEMIC AGENTS

Sialagogues

Two muscarinic acetylcholine receptor agonists (pilocarpine and cevimeline) are licensed for the treatment of dry mouth symptoms due to Sjögren's syndrome. These agents stimulate the muscarinic acetylcholine receptors M1 and M3 present on salivary glands, leading to increased secretory function. No study has compared the efficacy and safety of these two drugs.

The clinical benefit of orally administered pilocarpine has been reported in large randomized, placebo-controlled clinical trials. A dosage of 5 mg pilocarpine four times daily resulted in increased whole saliva flow and improved dry mouth, dry eyes, nasal, vaginal and skin dryness.[194–196]

Pilocarpine therapy can also reduce the frequency of oral and ocular symptoms related to xerostomia and xerophthalmia. Data from RCTs have revealed a high frequency of adverse events associated with pilocarpine use, including sweating, increased urinary frequency and flushing (observed in 43%, 10% and 10% of patients, respectively).[197] These data suggest that pilocarpine may be of benefit in the symptomatic management of Sjögren's syndrome, but studies have not included patients with absolute xerostomia, who may have the most severe oral symptoms of long-standing oral dryness.[198]

Several double-blind studies confirmed that cevimeline significantly reduces symptoms of xerostomia and dry eyes in patients with Sjögren's syndrome.[199] The best results in RCTs were achieved with a dose of 30 mg/8 h.[200] The adverse effects of cevimeline mirror those of pilocarpine, with increased gastrointestinal symptoms and rigor but reduced urinary frequency in the case of cevimeline.[201]

Bethanechol, which has both muscarinic and nicotinic agonist actions, was suggested to be of potential use in the management of drug-induced xerostomia, but had never been objectively assessed.[202, 203]

Available data, including that of a placebo-controlled study,[204] suggest that the cholinesterase inhibitor pyridostygmine may be of benefit in the treatment of drug-related xerostomia, although there are no data on the efficacy of this agent in the management of other common disorders giving rise to xerostomia.

Bromhexine (32–48 mg daily) may increase salivary and lacrimal flow in patients with Sjögren's syndrome;[205, 206] however, there are little published data on the precise oral benefits of this therapy other than those of one study and the results of an animal study that suggested that bromhexine does not significantly alter the development or severity of Sjögren's syndrome-like disease.[207]

Biological therapies

Several studies have analyzed the use of biological agents in primary Sjögren's syndrome, including interferon alpha (IFN-a), anti-TNF (tumour necrosis factor) agents and B-cell targeting therapies.

Open label studies suggested that intramuscular (e.g. 1×10^6 IU/week) and parenteral (3×10^6 three times weekly) IFN-a increase the lacrimal and salivary flow of patients with primary and secondary Sjögren's syndrome.[208] Subsequent open and single blinded studies also suggested that IFN-a-containing lozenges (150 IU IFN-a 3 times daily) might reduce the severity of xerostomia in primary and secondary Sjögren's syndrome, clinical benefit being observed in some patients after 9 weeks therapy.[209, 210] Despite the promising results of these preliminary studies, a large RCT – including 497 of the 569 patients treated with IFN-a to date – observed that therapy with IFN-a tended to improve only unstimulated salivary flow and was associated with gastrointestinal adverse events.[211]

Two antiTNF agents, a monoclonal antibody against TNF (infliximab) and a recombinant soluble TNF receptor (etanercept) have been tested as potential therapy for primary Sjögren's syndrome. An openlabel study in 16 patients with Sjögren's syndrome demonstrated the efficacy of infliximab, based on subjective and objective measures.[212] However, the positive results were not confirmed in a subsequent RCT including 103 patients.[213] Etanercept, a recombinant soluble TNF receptor, has been tested in two small studies (one RCT, one prospective) revealing no significant difference in the main sicca characteristics and symptoms associated with Sjögren's syndrome after treatment.[214, 215]

As Sjögren's syndrome is characterized by B-cell hyperactivity, a large number of clinical trials investigated the efficacy of biologic agents with the B-cell depleting antibody rituximab. Two small placebo-controlled

RCTs comprising 47 patients demonstrated considerable improvements in sicca features, salivary flow rate, ocular tests results, fatigue and quality of life scores after treatment with rituximab.[216, 217] More than 10 uncontrolled trials found a reduction in extraglandular features in patients treated with rituximab, compared with placebo.[197] Two large double-blind studies have been undertaken in France and the UK to understand if rituximab can be used in large populations of patients with Sjögren's syndrome. The TRACTISS study in UK should be completed in mid-2014, whereas the results of the TEARS study have been recently published, indicating that rituximab infusions did not produce sustained or substantial alleviation of symptoms or improvement in disease activity in adults with recent-onset or systemic Sjögren's syndrome.[218]

Corticosteroids

While systemic corticosteroids may be beneficial for the management of accompanying connective tissue disorders, there are conflicting data of the precise benefits in reducing the oral or ocular symptoms of Sjögren's syndrome. The results of one randomized study suggested that prednisolone (30 mg on alternate days) was effective[219] in reducing dry mouth symptoms but failed to enhance salivary flow rate. Conversely increased salivary flow rate was demonstrated after corticosteroid irrigation of the major glands (e.g. with prednisolone 2 mg/ml saline).[220] The use of glucocorticoids in clinical practice in primary Sjögren's syndrome is not supported by reliable scientific evidence, since the available studies (all but one uncontrolled) have substantial methodological flaws in their design.[197] Additionally the use of systemic corticosteroids has been associated with a high rate of adverse events, including increased appetite and weight gain,[221] and a twofold higher frequency of diabetes mellitus compared with age-matched and gender-matched individuals without systemic autoimmune diseases.[222]

Antimalarials

Antimalarials such as chloroquine and hydroxychloroquine are widely used for treating Sjögren's syndrome. The main effect seems to be due to inhibition of the antigen-processing ability by macrophages and monocytes, leading to decreased production of interleukin-1 (IL-1), IL-6, TNF-a and interferon-g (IFN-g). Although no large RCTs exist to date, hydroxychloroquine may improve salivary functions by inhibition of glandular cholinesterase with a benefit sustained after 3–9 months of hydroxychloroquine use as reported in a retrospective study.[223–226]

Immunosuppressive agents

The immunosuppressive agents tested in Sjögren's syndrome are cyclophosphamide, azathioprine, methotrexate, leflunomide, mycophenolic acid and cyclosporine A. Unfortunately, present evidence suggests that these agents have limited benefits for sicca features and are associated with an unacceptable rate of adverse events (ranging between 41% and 100%).

The discovery of a soluble ligand of the TNF cytokine family, BAFF/BlyS (B lymphocyte stimulator), which is a prominent factor in B-cell differentiation, homeostasis, and selection, led to consideration of its use as a potential therapeutic target. Very recent data from a two-phase II open-label study on belimumab, a monoclonal anti- body targeting soluble BAFF, suggest this approach may have promise in primary Sjögren's syndrome[227] and further investigation is warranted.

Other strategies

It has been suggested that electrostimulation[228] and acupuncture[229] may increase salivary flow in some patients with Sjögren's syndrome, but good clinical evidence for such claim is lacking. Similarly the *in vivo* potential benefits of gene therapy (utilizing viral vectors of aquaporin) remain unknown. However, a recent study examining the distribution of AQP5 in the labial salivary gland cells concluded that salivary gland hypofunction in Sjögren's syndrome is probably not caused by reduced presence of AQP5.[230]

The results of one placebo-controlled investigation suggested that a herbally-based agent with vitamin supplements (LongoVital®) caused a prolonged increase in unstimulated salivary flow and reduction in Rose Bengal scores in a group of patients with Sjögren's syndrome. It has been suggested that evening primrose oil, rich in fatty acids important in inhibiting 2-series prostaglandins, may enhance salivary flow in some patients with Sjögren's syndrome.[231]

KEY POINTS

Head and neck manifestations of Sjögren's syndrome include:

- xerostomia, which can be profound, giving rise to dysarthria, dysphagia, increased frequency of caries and acute gingivitis but not periodontitis per se
- increased liability to candidal infection – notably acute pseudomembranous candidosis, and median rhomboid glossitis, chronic atrophic candidosis (denture-associated stomatitis) as well as angular cheilitis and acute suppurative parotitis
- dysgeusia and loss of taste – many affected people report most foodstuffs taste 'cardboard-like'
- intermittent swelling of the major salivary glands – notably the parotid glands; this often reflects non-specific inflammatory change within the glands
- solitary enlargement of a salivary gland, which may reflect chronic sialadenitis, acute suppurative parotitis and, importantly, non-Hodgkin lymphoma
- a possible 4% risk of non-Hodgkin lymphoma of major salivary glands.

BEST CLINICAL PRACTICE

- ✓ In treatment of xerostomia in Sjögren's syndrome, there is no evidence at present that systemic and immunologically active agents reduce the oral dryness of Sjögren's syndrome.
- ✓ Therapies such as electrostimulation may be promising therapeutic approaches in the future.

Chronic graft-versus-host disease

Allogeneic hematopoietic stem cell transplantation (allo-HSCT), the transfer of hematopoietic stem cells from one individual to another, is widely employed for the treatment of hematologic malignancies.[232] It has also been used to treat autoimmune or other non-malignant diseases such as immunodeficiency or haemoglobinopathies.[233, 234]

Chronic graft-versus-host disease (cGVHD) is the most important complication in long-term survivors after allogeneic hematopoietic stem cell transplantation, with nearly 50% of patients developing the disease.[235] Symptoms of cGVHD generally present within the first 3 years after HSCT and may affect only one organ or be widespread.[236]

Oral cGVHD can present as oral mucosal lesions (ulcers, lichen-type features and hyperkeratotic plaques) and salivary gland dysfunction. A reduction of the mouth opening due to the perioral deposition of collagen may also occur.[237, 238] The prevalence of oral mucosal lesions after allo-HSCT has been estimated to range between 45% and 83% among cGVHD patients.[239]

Salivary dysfunction of cGVHD has been documented since 1977,[240] and is characterized by Sjögren's syndrome-like manifestations, including hyposecretion of saliva and tears.[241] The early diagnosis of salivary gland dysfunction related to cGVHD is a key factor in the investigation of the cGVHD in other organs, since the clinical features of cGVHD often initially manifest in the mouth.[242]

A recent cross-sectional study revealed that xerostomia was reported by 77% of the patients with cGVHD.[238] Of note, just 27% of these patients had signs of hyposalivation. cGVHD affecting the salivary glands is characterized histopathologically by intralobular periductal lymphocytic infiltration (often with associated fibrosis) and exocytosis of lymphocytes into intralobular ducts and acini.[243] Immunohistochemical studies demonstrate a lymphocytic infiltrate of primarily CD41 and CD81 T lymphocytes as well as the presence of Langerhans cells and CD681 macrophages.[244] Sialochemical changes, with a reduction in the antioxidant capacity[245] and protein content, have also been observed.[246] Oral cGVHD may also be associated with recurrent superficial mucoceles, probably secondary to a damage to excretory salivary ducts.[247]

Patients affected by cGVHD have a higher risk of developing secondary solid tumours, in particular squamous cell carcinoma and salivary gland neoplasms. Kruse et al. reviewed the literature regarding the development of oral malignancy after HSCT over the last 30 years and found that cGVHD was present in 76.6% of cases before they developed the malignancy.[248]

Local therapy of cGVHD of salivary glands is aimed at stimulating the salivary flow with sialagogues and symptoms relief with salivary substitutes. Partially successful therapy is reported for pilocarpine,[249] which, however, can be problematic in patients with graft-versus-host disease involving the gastrointestinal tract for the increased secretion of gastric fluids.[250] It has been reported in a small case-series report that cevimeline treatment might improve xerostomia symptoms in patients with cGVHD.[251]

SOME SALIVARY GLAND SWELLINGS

Sialosis

Sialosis (sometimes termed sialoadenosis) is an uncommon non-neoplastic and non-inflammatory disorder giving rise to bilateral non-painful enlargement of the major salivary glands. Sialosis tends to arise in middle to late life with peak incidence in the 5th and 6th decades, although there have been reports of children being affected.[252, 253] There is a slight female predominance. The parotid glands are typically affected; indeed, often the enlargement is profound. The enlargement develops slowly and there may be some decrease in salivary flow, but xerostomia is not a common or dominant accompanying symptom.

The precise cause is unknown. The underlying pathogenesis is thought to reflect a neuropathy, in particular a neuropathy that results in dysregulation of autonomic control comprising a loss of parasympathetic activity and increased sympathetic drive, leading to an unopposed increase in protein content within the acinar cells.[254] This would thus explain the association of sialosis with diabetes mellitus and perhaps hypothyroidism, malnutrition, and alcoholic and other causes of hepatic cirrhosis. Sialosis has also been described in association with puberty and menopause, and as a reaction to antihypertensive medication. In diabetes mellitus the onset of sialosis seems to be unrelated to the duration or metabolic control of the endocrine disease.[254]

Salivary gland enlargement may affect up to 68% of individuals with bulimia nervosa. The aetiology of increased salivary gland size in bulimia nervosa remains unclear; however, it is suggested that binge eating may result in functional hypertrophy of the salivary glands. Alternatively, mild damage due to passage of fluid into the gland, autonomic neuropathy, endocrine disease or past alcohol use has also been suggested to cause this problem. Of note, a salivary gland enlargement may correlate with the frequency of bulimic symptoms and with levels of serum amylase. There presently remains no specific management for a salivary gland enlargement associated with bulimia nervosa; however, cessation of vomiting is generally associated with resolution of the parotid swelling.

Of interest, oral mucosal disease that affects the opening of Stenson's duct can give rise to painless swelling of one parotid gland, for example if a bulla forms around the opening. There is one report of a patient with pemphigus vulgaris developing recurrent bilateral non-suppurative parotid enlargement secondary to dehydration and possible mucus plug formation secondary to pemphigus vulgaris.[255] Sialosis is histopathologically characterized by acinar cell hypertrophy and atrophy of striated ducts associated with oedema of the interstitial connective tissue. Ultimately there is widespread fatty replacement of acini.

There is no defined therapy for sialosis. Management is typically directed towards correcting any underlying systemic disorder; however, sialosis associated with diabetes

mellitus, other endocrine disorders or hepatic cirrhosis is often resistant to treatment. Rarely, surgical reduction of parotid glands (e.g. superficial parotidectomy) may be required, although this clearly carries some risks. There remains one report of pilocarpine successfully resolving sialosis associated with bulimia nervosa.[256]

KEY POINTS

- Salivary gland enlargement due to sialosis may be associated with diabetes, hypothyroidism, malnutrition, hepatic cirrhosis, puberty, menopause and antihypertensive medication.
- Treatment is often difficult with endocrine and hepatic causes of sialosis being particularly resistant, even if the underlying disorder is addressed. Surgical reduction of the glands may be possible but should be a last-resort intervention

Pneumoparotitis (pneumosialadenitis, wind parotitis)

Pneumoparotitis is characterized by the presence of air within the parotid gland due to the reflux of pressurized air from the mouth into the parotid duct. The swelling may be unilateral or bilateral, and tender or non-tender. There may be crepitus and frothy saliva and air bubbles may emanate from the parotid duct during massage of the gland. The swelling of the parotid gland resolves over minutes to hours, although occasionally may take several days to resolve. Rarely, air may escape from the parotid gland giving rise to subcutaneous emphysema of the face and neck, mediastinum and possible pneumothorax.

Pneumoparotitis is most likely in people where raised intra-oral pressure is common – for example, wind instrumentalists, balloon and glass blowers. There are rare reports of pneumoparotitis secondary to bicycle tyre inflation, dental procedures using air powered equipment, cough associated with chronic obstructive airways disease, cystic fibrosis, whistling, nose blowing and the Valsalva manoeuvre to clear the ears. Occasionally pneumoparotitis may be self-induced, possibly reflecting mental illness. There have been reports of pneumoparotitis due to spirometry and, rarely, pneumoparotitis can arise without an identifiable cause.[257, 258] In most instances there is no associated infection (e.g. acute suppurative sialadenitis) or chronic sialadenitis, but both are possible.[259]

There is often no need for detailed investigation as the history is often suggestive of the cause. Sialography may demonstrate air bubbles within the duct and may also show sialectasis if repeated episodes of pneumoparotitis have resulted in infection and resultant sialadenitis. Ultrasound scanning can demonstrate similar features,[260] as may CT[261, 262] and, presumably, MRI.

Pneumoparotitis rarely warrants active treatment as there are few symptoms, the cause is usually easy to identify and there is a low risk of acute or chronic sialadenitis. Cessation of the factor causing the increase in intra-oral pressure results in generally complete resolution of signs but as this may interfere in the employment of musicians it is unlikely that many will follow this path. Pneumoparotitis is rare.

KEY POINTS

- Any persistent or significant rise in intra-oral pressure may cause pneumoparotitis.
- Management involves avoiding raised intra-oral pressures.

RANULA

Ranulas are cystic lesions that develop from extravasation of saliva, possibly following trauma to the sublingual gland or obstruction of the ducts.[263] The term ranula is the Latin word for a small frog, and it is used for the condition because it causes croaking speech and an oral ranula resembles a frog's belly. Ranulas have a prevalence of 0.2 cases per 1000 people.[264] Ranulas are connective tissue lined swelling of extravasated saliva. They usually manifest as a soft, blue-tinged swelling of the floor of mouth, are detected in the second decade of life and may have a female predisposition – although there are rare reports of ranulas in neonates that have required *ex utero* intrapartum treatment (EXIT). Lesions may be classified as simple (or intra-oral) when they lie above the mylohyoid, and deep or plunging when they invade below this muscle.[265] Plunging ranulas usually manifest as a painless persistent or recurrent neck swelling and, rarely, may spread to the upper chest wall. Respiratory obstruction secondary to a simple or plunging ranula is rare.[266]

A congenital predisposition to the development of plunging ranula has been suggested based on the observation of a larger number of ranulas in some ethnic groups and among siblings.[267] An increased occurrence of ranulas has been documented in HIV-infected individuals, which could be due to a blockage of the salivary gland by inflammation and peri-ductal fibrosis as part of HIV-associated salivary gland disease.[15]

Diagnostic confirmation typically necessitates radiological imaging appropriate for soft tissue swellings, possibly together with cytological examination of FNAB.[268]

Several surgical approaches and techniques for oral and plunging ranulas in paediatric and adult patients have been proposed, with a rate of success that ranges from 0% to 100%.[263] Among these, excision of the sublingual gland is associated with the lowest rate of recurrent disease, although it might give rise to several complications.[269] These include injury to the lingual nerve or Wharton duct, with possible stenosis, obstructive sialadenitis and ductal laceration. Bleeding and hematoma have also been observed following this procedure.[270]

A medical treatment for ranula based on the oral administration of nickel gluconate has been described and tested by Garofalo et al.[271] At low doses, nickel is thought to promote enzymatic functions and tissue-repairing process in salivary glands. The authors reported promising results in their case series, with no recurrence and lower incidence of side effects after medical treatment.[271]

HETEROTOPIC SALIVARY GLAND DISEASE

Heterotopic salivary gland disease is the presence of salivary gland tissue arising outside the normal distribution of the minor and major salivary glands (hence excludes accessory salivary gland tissue and salivary gland material associated with branchial cleft anomalies).[272] Heterotopic salivary gland tissue has been documented in the middle ear,[273] larynx,[274] lower neck,[275] chest wall,[276] sternoclavicular joint, and brain.[277] The exact mechanism of salivary gland heterotopia is uncertain, with a possible explanation being the entrapment of salivary tissue during embryogenesis or heteroplastic changes of epithelial tissue.[278] Generally these are asymptomatic incidental findings, although they can manifest as a mass or draining sinus.

Radiological imaging with or without histopathological examination of lesional tissue are the usual diagnostic procedures with complete surgical excision being the treatment of choice.[276] Neoplastic transformation of heterotopic salivary gland tissue is possible but rare.[279]

LYMPHOEPITHELIAL LESION

Lymphoepithelial lesion is an uncommon disorder that manifests itself as a recurrent or persistent swelling typically of the parotid gland. The submandibular gland may be affected in approximately 15% of individuals. Generally the swelling is non-painful.

Affected patients do not have clinical features of Sjögren's syndrome or features of other disorders likely to give rise to xerostomia, although they do have an increased risk of non-Hodgkin lymphoma. The histopathological diagnosis of BLEL is important as the clinical features mimic those of salivary gland malignancy, and histopathologically there can be some confusion with lymphomas. Surgical excision is the usual treatment of a BLEL.[280]

EXCESS SALIVATION (SIALORRHOEA)

Although excess salivation is uncommon, it can be distressing to both patients and carers. True excess salivation is extremely unusual, although it may sometimes arise following drug therapy. The majority of patients with excess salivation have difficulties in salivary control rather than hypersalivation.

There are no specific investigations for sialorrhoea, and the cause is often established from the clinical history.

There are few controlled studies of possible treatment for excess salivation. Young adults with likely long-term illness such as cerebral palsy may benefit from surgical relocation of the submandibular ducts together with removal of the sublingual glands. Likewise, the parotid ducts may be relocated to pass out in the tonsillar fossa.

Anticholinergic agents such as transdermal scopolamine or benztropine have been suggested to be of long-term benefit but more recently intra-glandular injection of botulin toxin has been found to be of application for the treatment of hypersalivation in adults[281, 282] and children[283] with a myotropic lateral sclerosis, cerebral palsy, Parkinson's disease and other causes of excess salivation.

A lower dose of RT (8–12.5 Gy) has been suggested to be effective for excess salivation of patients with amyotropic RT; indeed, in view of the often shortened lifespan of affected individuals, this may be a useful treatment for this disabling salivary disorder.

DROOLING

Drooling is the unintentional loss of saliva from the mouth,[284] common in normally developed babies but considered abnormal after age 4.[285] Drooling may arise as a consequence of impaired neuromuscular function, though less frequently it can be due to an increased production of saliva (idiopathic or drug-induced). In children, the most common cause of drooling is cerebral palsy, which persists in 37–58% of these individuals.[286, 287] In adults, drooling can be observed in 45% of patients affected by Parkinson's disease.[288] Neurological disorders also associated with drooling are cerebral palsy, amyotrophic lateral sclerosis and facial palsy.[289]

Drooling can give rise to a wide spectrum of clinical and functional complications such as impaired speech and eating, perioral skin breakdown, bad odour and infection. Aspiration-related and pulmonary complications are possible.[290]

Drooling is known to be difficult to treat. Management can be conservative or more invasive. Conservative treatments include changes in diet or habits, oral-motor exercises, intra-oral devices such as palatal training devices, and medical treatments such as botulinum toxin injections. More invasive treatments include surgery or radiation.

Behaviour modification to promote swallowing has been advocated for many decades but results are inconsistent, it requires motivation and is time-consuming.[291] Pharmacological therapy for drooling encompasses the use of anticholinergic agents, such as glycopyrrolate, benztropine andscopolamine to decrease saliva secretion through the parasympathetic autonomic nervous system. A systematic review investigated the efficacy of oral agents in the treatment of drooling concluding that, although effective, no one drug was preferable.[292]

Recently botulinum toxin, a neurotoxin that prevents the secretion of saliva by inhibiting the release of presynaptic acetylcholine, has emerged as a potential treatment for the management of drooling. The effectiveness of botulinum toxin has been reported in several clinical trials. A recent meta-analysis (2013) concluded that botulinum toxin decreases the severity of drooling with statistical significance in both adult and paediatric populations.[293] The duration of effect can vary from 6 weeks to 6 months.[294] However, there remains the need to establish the ideal dose and form of application. Botulinum toxin treatment may cause increased saliva thickness (3.9%), dysphagia (3.3%), xerostomia (dry mouth) (3.3%) and pneumonia (2.2%).[293]

Various surgical procedures have been suggested for treatment of drooling. These procedures all encompass an alteration in the anatomy of the salivary glands and include salivary gland excision, denervation of the salivary glands, and relocation or ligation of the salivary ducts.[295, 296] The most common surgical approach is the submandibular duct relocation. Ranula formation and submandibular duct obstruction have been reported in 8% of patients after submandibular duct relocation.[297] Resection of the major glands are not without their side effects, of course, the most frequent being xerostomia, visible scar and facial nerve weakness.[290, 298]

Radiation is rarely applied for the risk of xerostomia, loss of taste and development of malignancy of the approach.[299, 300] It is typically reserved for elderly patients who are not candidates for surgery and cannot tolerate medical therapies.[301]

KEY POINTS

- Sialorrhoea is uncommon.
- The common causes of drooling include cerebral palsy, amylotropic lateral sclerosis, traumatic brain injury, stroke and Parkinson's disease.
- Persistent drooling leads to angular cheilitis, excoriation of the lower facial skin and wetting of clothes.
- There are no specific investigations for sialorrhoea, the cause often being established from the clinical history.

BEST CLINICAL PRACTICE

- ✓ Young adults with likely long-term illness such as cerebral palsy may benefit from surgical relocation of the submandibular ducts together with removal of the sublingual glands. Likewise, the parotid ducts may be relocated to pass out in the tonsillar fossa.
- ✓ Intra-glandular injection of botulin toxin has been found to be of application for the treatment of hypersalivation in adults and children with amylotropic lateral sclerosis, cerebral palsy, Parkinson's disease and other causes of excess salivation.
- ✓ A low dose radiotherapy (8–12.5 Gy) is useful for patients with shortened lifespan and a disabling salivary disorder.
- ✓ Transdermal scopolamine or benztropine may be helpful

FREY'S SYNDROME (GUSTATORY SWEATING)

Frey's syndrome (FS), also called gustatory sweating or auriculotemporal syndrome, is reported as the most disturbing sequela in patients at more than 5 years after parotid surgery for benign disease.[302] It is characterized by facial warmth, flushing and sweating over the distribution of the auriculotemporal nerve and/or greater auricular nerve, stimulated by any gustatory stimulus.[303] The information found in the literature concerning the incidence of FS shows a great variation, ranging from 2.6%[304] up to 97.6%.[305] Rustemeyer et al.[302] reported that 23.5% of patients undergoing parotidectomy developed FS an average of 12 months after surgery, but only 44% of these patients were symptomatic. Gustatory sweating syndrome secondary to submandibular gland surgery or trauma is also possible, although they do not involve the auriculotemporal nerve.

The aetiology of FS is not entirely known. It is commonly explained as 'misdirected nervous regeneration'. During parotidectomy, the postganglionic parasympathetic fibres of the auriculotemporal nerve, which supplies the parotid gland, and sympathetic fibres supplying local sweat glands are sectioned. During the regeneration process, parasympathetic fibres may grow along the distal ends of sympathetic fibres to the skin vessels and sweat glands. Thus, a gustatory stimulus produces sweating accompanied by flushing and heating.[306, 307] The time necessary to regenerate the postganglionic parasympathetic nerve fibres could explain the latent period between intra-operative facial nerve injury and the onset of FS; in most reports, this interval has ranged from 5 weeks to several months after parotid gland surgery, but unusual cases have presented many decades (30 years) after surgery.[308]

Although this syndrome has been reported primarily after parotid gland surgery,[309] it has also been observed after temporomandibular joint trauma or surgery[303, 310, 311] and carotid endarterectomy.[312] In childhood it can be a complication of forceps injury, frequently misdiagnosed as food allergy.[313]

Minor's starch iodine test, allowing visual confirmation of the blue-black reaction in the sweating area, is thought to be the gold standard of diagnosis.[314]

Many patients with FS do not wish any therapy.[315] Currently, the most effective treatment is the subcutaneous infiltration of botulinum toxin A in the affected area, with a benefit lasting for 1.5 years for 60% of the patients.[316]

Data concerning the efficacy of prevention strategies for FS remain inconclusive. A systematic review concerning the effectiveness of the a surgical approach (sternocleidomastoid muscle flap) to prevent FS after parotidectomy suggests that total prevention is unlikely to be achieved with any technique because FS is found, to some degree, in all treated sample groups.[317]

KEY POINTS

- Gustatory sweating syndrome is a rare sequela of salivary gland surgery.
- Gustatory sweating syndrome presents as facial warmth, flushing and sweating over the distribution of the auriculotemporal nerve following a gustatory stimulus.
- Botulinum toxin injection may be helpful if treatment is needed.

SOME MINOR SALIVARY GLAND DISORDERS

Mucoceles

Mucoceles are probably the most common disorder of the minor salivary glands, typically presenting as single blue or translucent sessile swellings on the lower lip.

Mucoceles occur in both genders and in all age groups, the peak age of incidence being between 10 and 29 years. They are rare in infants, although can occur in neonates.

The lateral aspect of the lower lip is the most common site of recurrence of mucoceles, but other common sites include the floor of mouth and the ventral surface of the tongue. The usual clinical presentation is of a single, recurrent, fluctuant, painless, well circumscribed bluish swelling that ruptures easily to release viscid salty mucus. Occasionally mucoceles can be multiple or develop suddenly at mealtimes.

The majority of mucoceles are the extravasation type, in which duct damage causes pooling of mucus in the adjacent connective tissue. Retention mucoceles, the less common variant, arise after partial or complete obstruction of the excretory duct (e.g. a sialolith – although rarely clinically or histopathologically detected) leading to retention of glandular secretions and dilation of the duct. Extravasation mucoceles may be more frequent in young patients, whereas retention mucoceles may occur most often in middle to late life.

Some mucoceles may resolve spontaneously but large, recurrent or unsightly mucoceles often require to be surgically excised, or removed by laser or cryotherapy. Other therapies of less well proven efficacy include intralesional corticosteroid injections and gamma-linolenic (oil of evening primrose).[318]

Subacute necrotizing sialadenitis

Subacute necrotizing sialadenitis (SANS) is a rare non-specific inflammatory disorder of adults of unknown aetiology affecting the minor salivary glands. It presents as a rapid onset painful, non-ulcerated swelling of minor palatal salivary glands. Almost all reported affected patients have been male. SANS tends to be self-limiting, symptoms and signs resolving within 2 weeks, and is not associated with necrotizing sialometaplasia.[319–321]

Necrotizing sialometaplasia

Necrotizing sialometaplasia is an uncommon disorder that typically affects the minor salivary glands of the palate, although may rarely involve other minor salivary glands and, very unusually, the major salivary glands.[322] It presents typically as a palatal swelling that breaks down to give rise to localized, irregular ulceration.

Lesions can be large – up to 5 cm in diameter – and can give rise to local paraesthesia or anaesthesia; however, they generally heal within 4–90 days. Affected patients may have systemic features such as pyrexia, chills and malaise. Despite the sometimes extensive area of ulceration, bony involvement is rare. There have been rare reports of airway obstruction and excessive bleeding with hypovolaemia due to large areas of sialometaplasia.[323]

Necrotizing sialometaplasia is thought to arise from local ischaemia, possibly caused by direct trauma (e.g. from a denture or as part of an anorexia nervosa bulimia nervosa pattern),[324] placement of dental local anaesthetics, recreational cocaine use, RT, alcohol, tobacco smoking, upper respiratory tract infections, allergic disease, oral intubation and other surgical procedures, or sickle cell disease.

Of note, it may be clinically and histologically confused with malignancies such as a squamous cell carcinoma, mucoepidermoid carcinoma or non-Hodgkin lymphoma. Necrotizing sialometaplasia is characterized histopathologically by acinar necrosis with squamous metaplasia of the ductal epithelium. This latter feature underlies the possible diagnostic confusion between necrotizing sialometaplasia and squamous cell carcinoma.

Necrotizing sialometaplasia is usually self-limiting; however, in view of the possible clinical similarity between necrotizing sialometaplasia and oral malignancy, careful histopathological examination of biopsy material is essential. Any likely causative factors should be identified and removed.[325]

Cheilitis glandularis

Cheilitis glandularis (suppurative stomatitis glandularis) is a rare disorder that usually arises in adults (but can occur in children) manifesting as labial swelling and ulceration. The disease is localized almost exclusively to the lower lip, especially the contact zone between the lips, although there have been occasional reports of the condition affecting the upper lips and palate.[326] Affected individuals usually have swelling, eversion and protrusion of the lower lip secondary to inflammation of the minor labial salivary glands. The orifices of the minor salivary gland ducts are dilated and inflamed, and a mucopurulent secretion may be expelled from the ducts when the lip is compressed.

The precise aetiology remains unknown, although associations with syphilis and other more ill-defined bacterial infections, poor hygiene, tobacco use, actinic exposure and emotional disturbance have been suggested. A genetic predisposition has also been proposed but there are no substantial supportive data. The connection with actinic damage is perhaps supported by 6 of 22 affected patients in one series being albino.[327]

Cheilitis glandularis may be classified into three types based upon the severity of the disease – simplex, superficial suppurative and deep suppurative. The last two types represent a stage where there is bacterial infection, being clinically characterized by increased inflammation, suppuration and ulceration of the lip. The deep suppurative type has also been termed cheilitis apostematosa or myxadenitis labialis, while the superficial suppurative has also been termed Baelz's disease.

The histopathological findings are non-specific but include local chronic sialadenitis, mucous/oncocytic metaplasia and mucin in ducts. Dysplastic epithelial changes may occasionally occur, but although associated carcinoma of the lower lip has been reported, cheilitis glandularis is still considered to be a benign disorder that should be managed by conservative means.[326–328] There are no detailed randomized studies of the treatment and surgery; for example, vermilionectomy has been suggested to be effective. However, albeit rarely, mucoceles can occur following surgery.

The term suppurative stomatitis glandularis has also been suggested to describe cheilitis glandularis. Indeed, the terminology used in the previous relevant literature is confusing. Granulomatous cheilitis is unrelated to cheilitis glandularis, the former being a localized presentation of sarcoidosis, orofacial granulomatosis or Crohn's disease.[329]

Inclusion of salivary gland tissue

Cyst-like areas of radiolucency are seen in the region of the angle of the mandible. Such inclusions are also possibly the origin of rare intraosseous salivary gland tumours.[330]

FUTURE RESEARCH

There are many unknowns in the aetiology and treatment of non-neoplastic salivary gland disease. Perhaps the most relevant areas of investigation for the treatment of such disease remain:

- the establishment of the pathogenesis of HCV-related sialadenitis
- the determination of the aetiology of Sjögren's syndrome
- the development of strategies for the prevention and treatment of radiotherapy-induced salivary gland disease and, indeed, other causes of non-drug-related oral dryness.

KEY POINTS

- Non-neoplastic disease of the salivary glands is dominated by the symptom of oral dryness (xerostomia) and/or the sign of salivary gland enlargement.
- Oral dryness is typically caused by drug therapy or Sjögren's syndrome.
- Enlargement of one submandibular gland is likely to be sialolithiasis, while enlargement of one or both parotid gland(s) has a much wider range of non-malignant causes.
- While the investigation of salivary gland disease has advanced greatly there remains no reliably effective means of lessening oral dryness that is unrelated to drug therapy.

SEARCH STRATEGY

Data in this chapter are based on a PubMed search using the keywords: pharynx, nasopharynx, oropharynx, hypopharynx, laryngopharynx, constrictor, sphincter, elevator, oesophagus, adenoidectomy, tonsils, adenoids, Waldeyer's ring, soft palate, cervical oesophagus, thoracic oesophagus, abdominal oesophagus, Valsalva, tonsillectomy and post-tonsillectomy bleed.

ANATOMY OF THE PHARYNX

INTRODUCTION

Shaped like an inverted cone, the 12–14 cm long musculofascial tube that is the pharynx hangs down from the pharyngeal tubercle at the skull base and fuses with the oesophagus below at the level of the lower border of the cricoid cartilage. It is the continuation of the common pathway for respiration and digestion that begins with the oral cavity.

The pharynx acts as a single physiological structure in its role as the common aerodigestive pathway and its mucosal lining is shared with that of the auditory tubes, the nasal cavity, the oral cavity and the larynx. Functionally, in addition to directing air into the laryngeal inlet and food into the digestive tract, via the auditory tube, it also assists in the equalization of pressure within the middle ear and aids in vocalization of sound to facilitate speech.

An understanding of the anatomy of this region is vital to the otolaryngologist. Inflammatory and neoplastic diseases of the pharynx and oesophagus are common in the general population and form a substantial proportion of surgical work. With the advent of transoral surgery for pharyngeal cancers, in addition to the conventional knowledge of anatomy of this region, there is a need to appreciate the anatomy from 'inside out'.

SUBDIVISIONS OF THE PHARYNX

Anatomically, the pharynx is divided into distinctive subdivisions – the nasopharynx, the oropharynx and the hypopharynx (laryngopharynx) – the boundaries of which are purely arbitrary and based on their anterior communications with the respective nasal, oral and laryngeal cavities (**Figure 47.1**). Each of these subdivisions has a variety of structures within them of clinical relevance. The muscular wall and the layers of the wall, common to all the subdivisions, will be dealt with in separate sections.

Nasopharynx

The superior aspect of the pharynx, the region above the soft palate and behind the choanae, is the nasopharynx. This space has a roof, two lateral walls, a posterior wall and a floor, and it communicates with the oropharynx

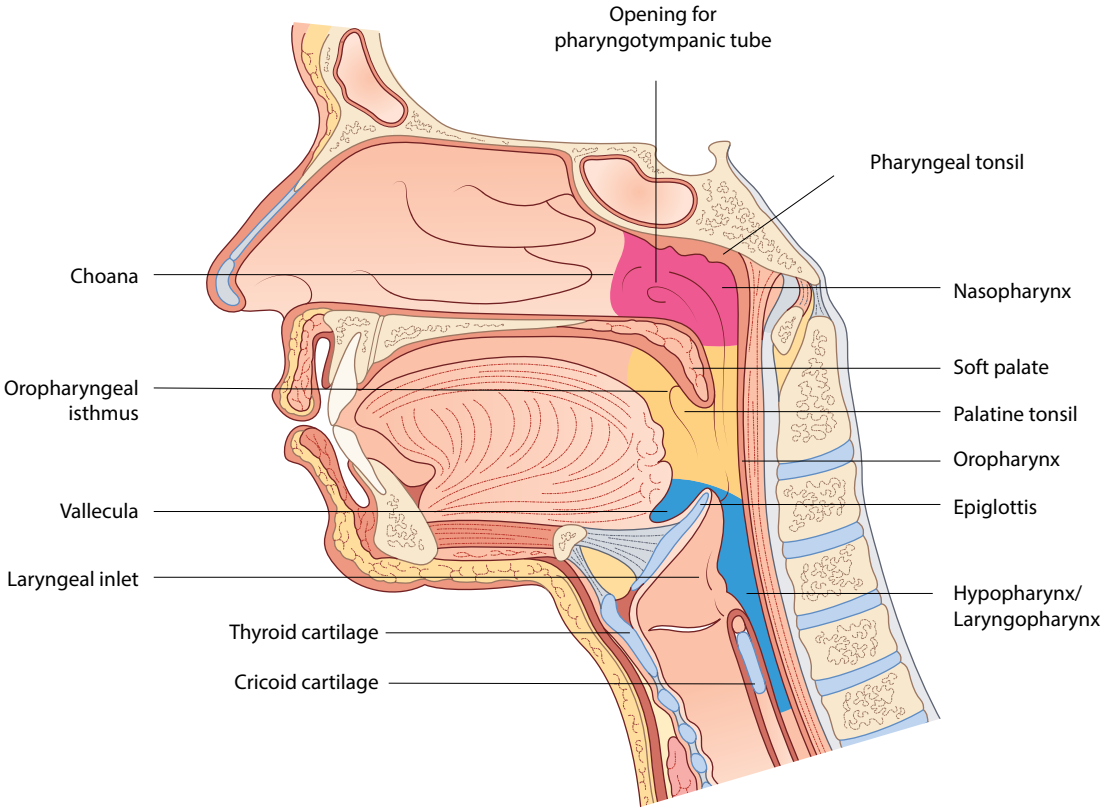

Figure 47.1 Sagittal section of the head and neck.

below via the pharyngeal isthmus posterior to the soft palate and anterior to the posterior pharyngeal wall. The important subsites within this space are the opening for the pharyngotympanic tube (also known as the auditory tube or the Eustachian tube), the pharyngeal recesses and the nasopharyngeal tonsils (or the adenoids).

The nasal cavity communicates posteriorly with this space and, thus, the anterior boundary of the nasopharynx is that formed by the right and left posterior nasal apertures, or the choanae, separated in the midline by the vomer, its bony septum. The posterior ends of the inferior and middle conchae from the lateral walls of the nasal cavity project medially into each choana. With the exception of the soft palate, the walls of the nasopharynx are rigid and the cavity thus always patent, allowing for unhindered flow of air, in sharp contrast to the cavities of the oropharynx and the laryngopharynx, which open and close on swallowing and with respiration.

The roof and posterior wall of the nasopharynx are contiguous due to the sloping nature of the inferior body of the sphenoid bone and the basilar part of the occipital bone, and it continues down to the level of the junction of the hard and soft palate. The bony deep structures within this region are often referred to as basisphenoid. Within the mucous membrane of the roof and posterior walls is a collection of lymphoid tissue known as the nasopharyngeal tonsil, maximal in size during childhood and contributing to the defence of the upper respiratory tract. Unlike oropharyngeal tonsillar tissue, there is no clear plane of cleavage in the nasopharyngeal tonsil, which makes excision less precise and complete during adenoidectomy (see **Boxes 47.1** and **47.2**).

The floor of the nasopharynx is formed by the soft palate (dealt with in detail below). The posterior and lateral walls of the nasopharynx are composed predominantly of the superior constrictor muscle and its overlying mucosa. Within the lateral wall sits the pharyngeal orifice of the pharyngotympanic tube, approximately 1–1.5 cm from the posterior end of the inferior turbinate at the level of the superior border of the palate – or the floor of the nose. This tube connecting the middle ear and the nasopharynx allows, by its transient opening and closing, the equalization of air pressure on both sides of the tympanic membrane. It is formed primarily by fibrous tissue and cartilage but also by bone, and it is more horizontal and approximately half its adult length at birth, allowing for easier spread of infection back and forth from the nasopharynx into the middle ear cavity in this age group. The orifice of this tube is covered with a cartilaginous projection, the torus tubaris, orientated posterosuperiorly, with the longer extension situated posteriorly and extending in a craniocaudal direction, which gives it its comma-shaped appearance. It also forms the anterior boundary of the pharyngeal recess, or fossa of Rosenmüller, situated posterosuperior to

BOX 47.1 Within the nasopharynx: the nasopharyngeal tonsils or adenoids

Size	Rapid growth during infancy, involutes during ages 8–10 and atrophies in later life. At its largest at age 5
Site	Roof and posterior wall of nasopharynx
Shape	Described as a truncated pyramid, with a vertically oriented median cleft, its apex directed towards the nasal septum and its base at the junction of the roof and posterior wall of the nasopharynx
Surface	Free surface has anteriorly and laterally radiating folds from the bursa of Luschka – a median blind recess or the pharyngeal bursa. This extends deep into the tonsil in a posterior and superior direction
Structure	Predominantly respiratory epithelium, ciliated in nature, on its lateral and inferior parts. Also contains occasional patches of keratinized stratified squamous epithelium. Anchored at its superior pole via a connective tissue hemicapsule onto which the tonsillar fibrous framework attaches
Supply	An anastomosis of the following arteries: ascending pharyngeal and ascending palatine arteries, tonsillar branch of facial artery, pharyngeal branch of maxillary artery and artery of pterygoid canal. Occasionally, an emissary vessel (off inferior hypophysial artery) to basisphenoid bone supplies the nasopharyngeal bed – a possible culprit in persistent haemorrhaging post adenoidectomy
Significance	Part of Waldeyer's ring of tonsillar tissue, contributing to the defence system of the upper respiratory tract
Surgical/clinical considerations	Inflammation of this tissue: **adenoiditis**, predominantly in children (peak age 5) when it causes persistent chronic otitis media infections, problems with nose breathing and intermittent sleep apnoea
	Adenoidectomy or the surgical removal of nasopharyngeal tonsils: blind curettage, suction diathermy or suction micro-debridement. During blind curettage, important to avoid hyperextending the cervical spine as arch of the atlas (cervical vertebra C1) may pierce through prevertebral fascia and cause infection and instability of the C-spine

the torus tubaris, which is the site of the tubal tonsils which, when present, constitute an additional component of Waldeyer's ring of tonsillar tissue (**Figure 47.2**). The superior constrictor and overlying mucosa forms its floor while the skull base forms the superior and posterior border. This fossa is the commonest site of the origin of nasopharyngeal carcinomas and should be targeted in biopsies of the nasopharynx in the context of carcinoma of the unknown primary. The fold of mucosa projecting inferiorly from the cartilaginous ridge of the pharyngotympanic orifice is the salpingopharyngeal fold, formed by overlying mucosa and the levator veli palatini and salpingopharyngeus muscles, the latter of which passes inferiorly and laterally to merge with the lateral pharyngeal wall.

Anteriorly, the epithelium of the nasopharyngeal wall is predominantly respiratory in nature, ciliated and pseudostratified, with goblet cells. More posteriorly, non-keratinized stratified squamous epithelium predominates and this continues into the oro- and laryngopharynx. At the point where the two types of epithelium meet – the transitional zone – instead of cilia, columnar epithelium with short microvilli are present, continuing superiorly to meet the nasal septum and laterally the pharyngotympanic tubal orifice towards the soft palate and lateral pharyngeal wall.

The sensory innervation of the nasopharynx is via the pharyngeal branch of the maxillary nerve, transmitted from the middle ear cavity via the pharyngotympanic tube. Posterior to the tubal orifice, the pharyngeal branch of the pterygopalatine ganglion supplies the majority of the mucosa. This branch passes through the palatovaginal canal along with a branch of the maxillary artery, its pharyngeal branch.

Oropharynx

The oropharynx continues caudally from the nasopharynx, connected to it via the pharyngeal isthmus. The boundary between the naso- and oropharynx is the start of the common aerodigestive tract and the site where the oral cavity, larynx and hypopharynx communicate. It therefore has dual functionality, coordinating breathing and swallowing. The space has anterior, lateral, posterior and superior walls and it communicates with the oral cavity via the oropharyngeal isthmus. The clinically relevant anatomical subsites within the oropharynx are the base of tongue and valleculae in the anterior wall, the palatine tonsils, the tonsillar fossae, the tonsillar (faucial) pillars and the glossotonsillar sulci in the lateral walls, and the inferior surface of the soft palate and the uvula in the superior part of the space. In addition to tonsillitis and peritonsillar abscesses within this region, the palatine tonsils and base of tongue are common sites of malignancy, in particular human papillomavirus-associated squamous cell carcinoma. Foreign bodies (typically, fish bones or food debris) may become lodged either in the palatine tonsils or in the valleculae.

The clinical boundaries of the oropharynx differ from those commonly indicated in anatomy textbooks as described above. It is bounded superiorly by a horizontal line drawn at the level of the hard palate, inferiorly by a horizontal line drawn through the floor of the valleculae and anteriorly by a vertical plane defined by anterior boundary of the palatoglossal folds (which contain the palatoglossus muscles and the overlying mucosa) to include the posterior third of the dorsum of the tongue. The posterior wall of the oropharynx is the extent of the posterior pharyngeal wall bounded by the imaginary lines drawn from the superior and inferior limits described above.

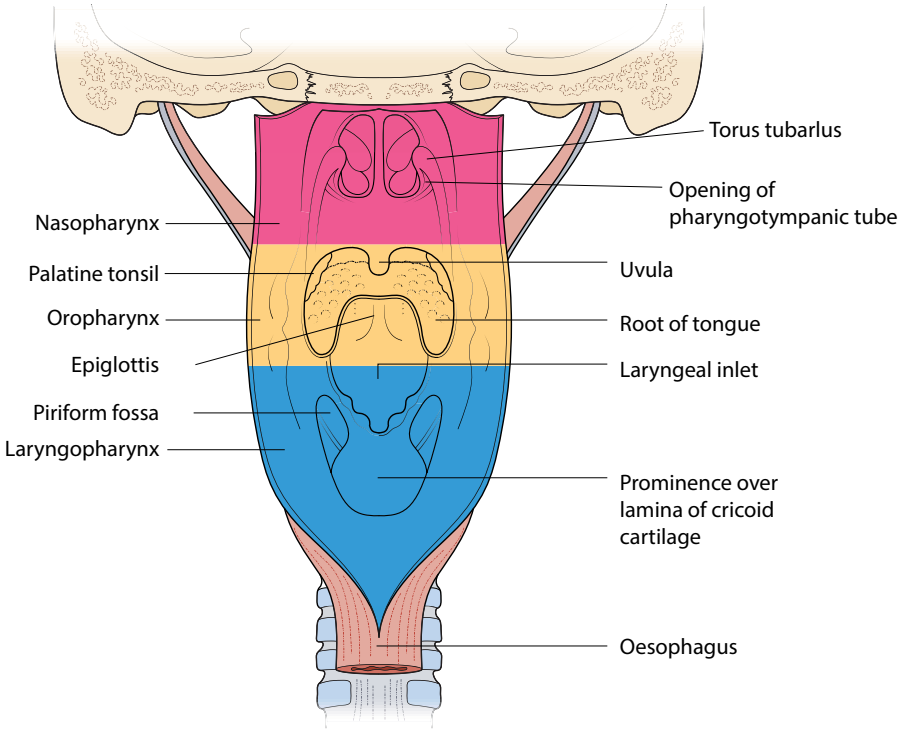

Figure 47.2 Features of the pharynx (posterior view with the pharyngeal wall opened).

The superior boundary of the oropharynx is the soft palate. This structure is suspended from the anterior bony projection of the palatine part of the hard palate and is essentially a mobile flap that opens and closes on swallowing. The point of demarcation between the soft and hard palates can be felt with ease and may demonstrate a change in colour, the soft palate possessing a yellowish discolouration on a base of a darker region than that of the anterior hard palate. Within the thick mucosal fold that is the soft palate, the soft palate muscles – five in total – and the thin and fibrous palatine aponeurosis, the neurovascular structures, the mucous glands and the lymphatics all lie in close proximity. All the soft palate muscles are attached to the palatine aponeurosis, which also encloses the small musculus uvulae muscle close to the midline. In the midline, the conical-shaped uvula containing the small musculus uvulae muscle forms the inferior free border and dangles down to extend into the oropharyngeal isthmus. The lateral aspects of the soft palate wall blend in with the lateral pharyngeal wall.

The lateral walls of the oropharynx have two prominent folds bilaterally, the faucial pillars. The anterior communication between the oral cavity and the oropharynx is via the oropharyngeal isthmus and is demarcated by the bilateral anterior palatoglossal arches, their underlying muscles and the horizontal intrinsic tongue musculature. Situated more posteriorly are the palatopharyngeal arches comprising the palatopharyngeus muscle and its overlying mucosal layer (**Figure 47.3**). Within the space between these two mucosal folds sit the palatine tonsils in the tonsillar fossae, the third component of Waldeyer's ring of lymphoid tissue.

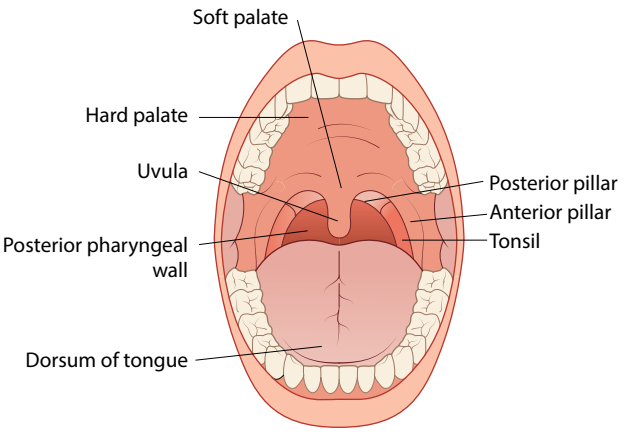

Figure 47.3 Oropharyngeal isthmus and tongue.

The posterior third of the dorsum of the tongue slopes downwards from the sulcus terminalis to form the anterior vallecular wall of the oropharynx (**Figure 47.4**). The nodular appearance of the mucous membrane in this region is largely due to the aggregations of lymphoid follicles – the lingual tonsils – which complete Waldeyer's ring. A midline ridge, or fold, of mucous membrane extending from the tongue to the anterior lingual surface of the epiglottis, the median glossoepiglottic fold, divides the valleculae into two shallow right and left depressions. Similar mucosal folds limit the valleculae laterally. These lateral glossoepiglottic folds extend from the lateral aspect of the epiglottis to the pharyngeal wall, not to the tongue as the name would suggest. These are sometimes referred to as the pharyngoepiglottic folds. The nerve supply in

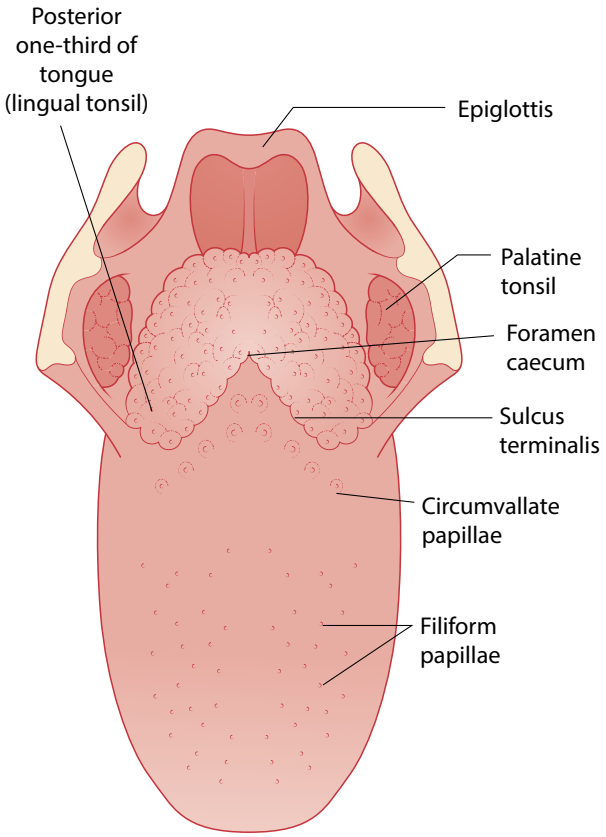

Figure 47.4 Anatomy of the tongue. The posterior third is part of the oropharynx.

this region of the oropharynx is via the internal laryngeal nerve, a branch of the vagus nerve. The mucosa in rest of the oropharynx is supplied predominantly by the glossopharyngeal nerve and to a lesser degree by the lesser palatine nerve.

PALATINE TONSILS

The palatine tonsils (**Box 47.2**) lie in the tonsillar fossa between two tonsillar pillars – the palatoglossal and the palatopharyngeal folds – and can be variable in the depth to which they are embedded between the folds. Previous infections, particularly peritonsillar abscesses, can cause apparent asymmetry of the palatine tonsils. True asymmetry is uncommon and should raise concerns about potential malignancy or parapharyngeal masses pushing the tonsil medially.

Palatine tonsils are characterized by multiple craters on their surface, which are formed by crypts passing deep into the parenchyma of the tonsil. The pitted epithelium of the tonsillar tissue has an intratonsillar cleft within the substance of the tonsil. Histologically unique, the palatine tonsils consist of lymphoid tissue covered by squamous epithelium. Unlike the other components of Waldeyer's ring, the palatine tonsil is encapsulated. This provides a convenient plane of dissection when performing tonsillectomy. The floor of the tonsillar bed is formed by the superior constrictor, and is separated from the tonsil by a thick condensation of pharyngeal submucosa, the tonsillar capsule, which is, in essence, an extension of the pharyngobasilar fascia. This capsule is further separated from the superior constrictor by a thin film of loose areolar tissue.

The palatine tonsils are supplied by the tonsillar artery, a branch of the facial artery that gains access to the tonsil by penetrating the superior constrictor to enter the inferior pole of the tonsil. There is additional arterial supply from the ascending palatine, lingual, descending palatine and ascending pharyngeal arteries. The venous drainage of the palatine tonsils is via a plexiform arrangement, deep to the tonsils, the pharyngeal venous plexus. The large external palatine vein descends from the soft palate and passes close to the lateral surface of the tonsillar capsule; this vein is most commonly divided in tonsillectomy and is the likely culprit in persistent post-tonsillectomy bleeds. The lymphatics of the tonsil drain to the jugulodigastric lymph node area.

The tonsils receive their nerve supply from the tonsillar plexus, a complex meshwork of nerves originating from the tonsillar branches of the maxillary nerve and the glossopharyngeal nerve. The fibres of the maxillary nerve are distributed to the lesser palatine nerves (although they pass through the pterygopalatine ganglion, they do not synapse there) and via these nerves are then combined with the glossopharyngeal nerve to form their plexiform arrangement of nerves around the tonsils. This plexus also supplies the oropharyngeal isthmus and the soft palate. An offshoot of the glossopharyngeal nerve, the tympanic nerve, also supplies the tympanic cavity and the tympanic membrane. Consequently, any pathology affecting the tonsils or the tonsillar fossa may present as pain referred to the ear.

WALDEYER'S RING

The pharynx in its nasopharyngeal and oropharyngeal part has a number of gut-associated lymphoid aggregates that make up what is known as Waldeyer's ring. This circumpharyngeal ring of mucosa-associated lymphoid tissue is at the entry point to the aerodigestive tract and its role almost certainly one of immune maturation and sampling. These include the adenoids posterosuperiorly, the superolateral tubal tonsils, anterolateral palatine tonsils and the anteroinferior lingual tonsils. The tubal tonsils are not always present. As well as these discrete aggregates, there are numerous areas of lymphoid tissue that are sited in the lamina propria just beneath the epithelium as well as collections of this tissue in the intertonsillar intervals. The former collections can often be seen on the posterior pharyngeal wall as small areas of salmon-pink, slightly raised swellings.

Hypopharynx

The hypopharynx (laryngopharynx, in anatomical textbooks) is the junction between the oropharynx and the oesophagus (**Figure 47.5**). Shaped like a funnel with much of its anterior segment missing, it extends from the level

BOX 47.2 Within the oropharynx: the palatine tonsils

Size	Varies according to age and pathological status – increase rapidly in size until ages 5–6 and at maximal size during puberty. Involution starts at puberty. Little lymphoid tissue exists in old age
Site	Within the lateral wall of the oropharynx, located between the palatoglossal and palatopharyngeal folds in the tonsillar bed, and surrounded by the tonsillar capsule
Shape	Ovoid mass of lymphoid tissue associated with the mucosa of the oropharynx and with a fixed position, long axis from superior to inferior to posterior
Surface	Free medial surface has a pitted appearance, with about 10–20 pits in total, which lead into blind-ending crypts that travel through the full thickness of the tonsils. The tonsils sit in a hemicapsule made up of connective tissue
Structure	Varies according to age and pathological status – they may be hypertrophied or inflamed, so difficult to say what is normal. Healthy tonsils have fissure-like crypts that are in contact with each other. The **recessus palatinus**, or **intratonsillar cleft**, is situated within the substance of the tonsil
Supply	Several anastomosing arteries but predominantly the tonsillar artery off the facial artery (a branch of the external carotid artery) Venous drainage is via the paratonsillar vein – external palatine vein – within the tonsillar hemicapsule, and via a plexiform venous drainage system outside the tonsillar hemicapsule Lymph drains to the jugulodigastric node of the deep cervical lymph node group
Sensation	The tonsillar branch of the glossopharyngeal nerve (CN IX) and the lesser palatine nerve (off the maxillary division of CN V2). Diffuse nerve supply
Service	The right and left tonsils are part of Waldeyer's ring of lymphoid tissue that provides first line defence to the upper respiratory tract
Surgical/clinical considerations	**Tonsillitis** refers to inflammation of the palatine tonsils. Pain can be referred to the middle ear due to innervation from different branches of the same cranial nerve (glossopharyngeal nerve). The tympanic branch of the glossopharyngeal nerve also supplies the middle ear, causing **referred pain** to the ear from the tonsils The internal carotid artery is 2.5 cm posterolateral to the tonsils A **peritonsillar abscess** or quinsy occurs outside the tonsillar capsule. Drainage is achieved by directly incising the most prominent bulging part of the collection, usually using topical anaesthetic spray **Tonsillectomy** or the surgical removal of the palatine tonsils: indications are recurrent acute infection of the tonsils, treatment for acute peritonsillar abscesses or for treatment of airway obstruction due to enlarged tonsils. Methods employed are the guillotine method or dissection in the plane of the fibrous hemicapsule, which is followed by electrocautery or ligation of the vessels. Usually performed under general anaesthetic but can be done using local anaesthetic infiltration of the region and/or nerve block. By separating the fibres of the superior constrictor muscle, the glossopharyngeal nerve can be accessed The paratonsillar vein (or external palatine vein) running within the tonsillar capsule is the usual culprit for a **post-tonsillectomy bleed**. This vein is commonly divided in a tonsillectomy

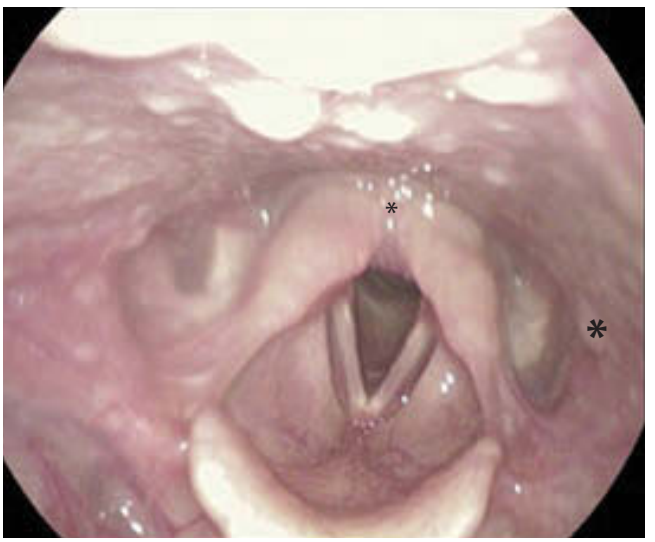

Figure 47.5 Endoscopic view of the hypopharynx during Valsalva manoeuvre allowing assessment of the upper postcricoid area (small asterisk – postcricoid area; large asterisk – pyriform sinus).

of the hyoid bone (or the superior margin of the epiglottis, delineated on either side by the lateral glossoepiglottic folds of the vallecular walls) to the lower margin of the cricoid cartilage at vertebral level C6 where the pharynx terminates and the oesophagus begins. The missing anterior segment corresponding to the laryngeal inlet, the aditus, is the communication between the larynx and the pharynx. This oblique area is bounded superiorly by the epiglottis, the posterior surfaces of the arytenoids and the cricoid cartilage inferiorly and laterally by the aryepiglottic folds. The mucosa in the hypopharynx is predominantly stratified squamous epithelium with goblet cells. Clinically, this region is often demarcated by imaginary lines: a horizontal line drawn posteriorly at the level of the cranial border the hyoid bone divides the hypopharynx from the oropharynx above and a horizontal line at the level of the caudal boundary of the cricoid cartilage indicates the start of the cervical esophagus below.

In its key position behind and to either side of the larynx, the hypopharynx is the crucial area in maintaining a

safe swallow and preventing aspiration of fluids and food boluses. It is made up of a number of subsites according to the International Union against Cancer (UICC) TNM (see Chapter 4, Staging of head and neck cancer) classification and tumours in this region have a poor prognosis due to their vague symptoms and the tendency to enlarge and metastasize prior to detection.

- The **posterior pharyngeal wall** extends from the horizontal line drawn at the level of the superior margin of the hyoid bone (or floor of the valleculae) to the level of the inferior border of the cricoid cartilage, and from the apex of one piriform recess to the other. Three overlapping constrictors form the posterior wall of the laryngopharynx to the level of the vocal cords. Beyond this point, the inferior constrictor is the main component of the wall behind the cricoid lamina and to the level of the upper margin of the cricoid cartilage. As the inferior constrictor is in reality composed of two separate muscles –thyropharyngeus and cricopharyngeus –this fusion point of these muscles, Killian's dehiscence, is a site of potential weakness and the site of pharyngeal pouches. This is discussed in more detail in 'Pharyngeal muscles' below.
- The bilateral **piriform recesses** or fossae extend from either side of the epiglottis from the lateral glossoepiglottic folds to the upper end of the oesophagus. They are broader superiorly and narrower inferiorly, and lie on either side of the laryngeal inlet. The recesses are formed by the larynx bulging into this part of the pharynx, leaving the bilateral anterolateral recesses. They are lined with mucosa and bounded medially by the quadrangular membrane of the larynx. The lateral boundaries are the thyrohyoid membrane superiorly and the thyroid cartilage inferiorly. Foreign objects commonly lodge in the recesses, and tumours can silently expand within the space asymptomatically until metastatic lymphadenopathy manifests.
- The pharyngo-oesophageal junction, or **postcricoid area**, fills out the rest of the hypopharynx. It extends from the level of the arytenoid cartilages and connecting folds to the inferior border or lamina of the cricoid cartilage, thus forming the anterior wall of the hypopharynx. The corresponding mucosa and submucosa extend from the inferior aspect of the arytenoids to the lower margin of the cricoid cartilage, and the lateral margins merge with the medial wall of the piriform recesses at the level at which the cricoid cartilage makes an anterior bend.

PHARYNGEAL WALL

The pharyngeal wall is composed of five discrete layers, two of which are fascial layers. The five layers, from deep to superficial, are the mucous membrane, submucosa, pharyngobasilar fascia, muscular layer and buccopharyngeal fascia or loose areolar sheath.

Mucosal layer

The mucosa of the nasopharynx is typical respiratory mucosa and is made up of ciliated, pseudostratified columnar epithelium. The rest of the pharynx is lined by non-keratinized stratified squamous epithelium. This change occurs at the transitional zone at the lower end of the nasopharynx.

Submucosal layer

Beneath the mucosa is a layer of submucosa, also termed lamina propria, which is made of connective tissue containing elastic tissue. In addition to the mucosal layer, it is host to a number of aggregates of gut-associated lymphoid tissue that forms Waldeyer's ring. The submucosa is thick and blends in with the fibrous pharyngobasilar layer, which also forms the tonsillar capsule.

Pharyngobasilar fascial layer

The pharyngobasilar fascia is the next layer and is firmly adherent to the skull base in the region of the occipital bone and petrous temporal bone. Superiorly, the fascia is thicker and fuses with the buccopharyngeal fascia to form a dense fibrous structure that suspends the pharynx from the base of skull. The muscular wall does not fully reach the skull base and this fascial layer is important in maintaining the integrity of the pharynx.

Muscular layer

The muscular layer is made up of three pharyngeal constrictor muscles that interlock like three cones or flowerpots one inside the other, with each layer overlapping the next layer. Their anterior aspects communicate with the spaces immediately in front of them, the nasal, oral and laryngeal cavities. The constrictor muscles have bilateral anterior attachments to the aforementioned cavities and sweep backwards from there to fuse on the posterior aspect of the pharynx at a midline raphe, the pharyngeal raphe. The muscular framework of the pharynx is dealt with in more detail below.

Buccopharyngeal fascial layer or loose areolar sheath

The final layer of the pharynx is a thin areolar layer covering the pharyngeal constrictors that is also continuous with the covering of the buccinator muscle. This layer contains the pharyngeal plexus of veins and nerves.

MUSCLES OF THE PHARYNX AND SOFT PALATE

The muscles of the soft palate and pharynx work in unison and are therefore dealt with together here.

Pharyngeal muscles

The pharyngeal muscular wall (**Figure 47.6**) is relatively thin and comprises three circular constrictor muscles, all of which act to enable the reflex of swallowing to ensure prompt propulsion of the food bolus by a coordinated peristaltic wave into the oesophagus. They are assisted by three longitudinal muscles, which act as elevators and dilators of the pharynx. The constrictors sit within each other like three stacked cones or cups and overlap on their posterior aspect. Although the framework of the pharynx dangles down from the base of the skull, and from the pharyngeal tubercle in particular, the muscular wall does not originate from the bony skull. Instead, the fibrous submucosal thickening of the pharyngeal wall, the pharyngobasilar fascia, stretches across like a curved but rigid sheet attached to the nasopharyngeal wall and fills the gap between the superior constrictor muscle below and the base of the skull above. In effect, the pharyngobasilar fascia is the fourth cone or cup stacked into the muscular constrictors below and is the main component for maintaining the patency of the nasopharynx in its task of guaranteeing unhindered flow of air for breathing.

All of the constrictors are supplied by the pharyngeal and superior laryngeal branches of the vagus nerve through the pharyngeal plexus.

THE THREE CONSTRICTORS

The superior constrictor is the thinnest of the constrictors and shaped like a quadrilateral sheet slung from one side of the pharynx to the other to form the superior part of the pharyngeal wall. Its function is to constrict the upper region of the pharynx. It arises from the pterygoid hamulus (but occasionally also from the posterior surface of the medial pterygoid plate) and the pterygomandibular raphe running from the pterygoid hamulus to the retromolar trigone, and from the posterior end of the mylohyoid line on the mandible. A few of its fibres originate from the side of the tongue. The pterygomandibular raphe is the fibrous condensation that extends between the buccinator and the superior constrictor muscles. The muscle fibres of the latter run backwards and upwards from their anterior attachments to fuse in the midline on the posterior aspect of the pharynx at the median pharyngeal raphe. Some fibres project upwards and attach to the base of the skull indirectly via the pharyngobasilar fascia, which attaches to the pharyngeal tubercle, a bony projection just anterior to foramen magnum. Posteriorly, the lowermost fibres sit comfortably within the overlapping middle constrictor muscle and reach the level of the laryngeal vocal folds. On the lateral aspect, the superior and middle constrictors do not overlap and a gap exists through which the stylopharyngeus muscle passes downwards to insert into the pharyngeal wall. Through the same gap, the styloglossus muscle as well as two nerves – the glossopharyngeal and the lingual – pass forwards in the direction of the tongue.

The fan-shaped **middle constrictor** arises from the inferior end of the stylohyoid ligament and the greater and lesser horns of the hyoid bone and its fibres fan out in several directions. Most of its fibres wrap around in the same manner as the superior constrictor fibres to join the median pharyngeal raphe while the upper fibres also encircle the lower posterior fibres of the superior constrictor. The lowest fibres of the middle constrictor muscle that angulate downwards in a dorsoventral direction also terminate at the level of the laryngeal vocal cords, along with those of the superior constrictor. The muscular anterior wall here is incomplete between the middle and the inferior constrictors and is covered by the thyrohyoid membrane, which forms part of the anterior wall in the hypopharynx. On the superolateral aspect of this membrane, the internal laryngeal nerve and the superior laryngeal artery and vein pass medially.

The inferior constrictor, the thickest of all the constrictors, is generally described as two muscles, the thyropharyngeus and the cricopharyngeus. Thyropharyngeus originates from the oblique line of the thyroid lamina,

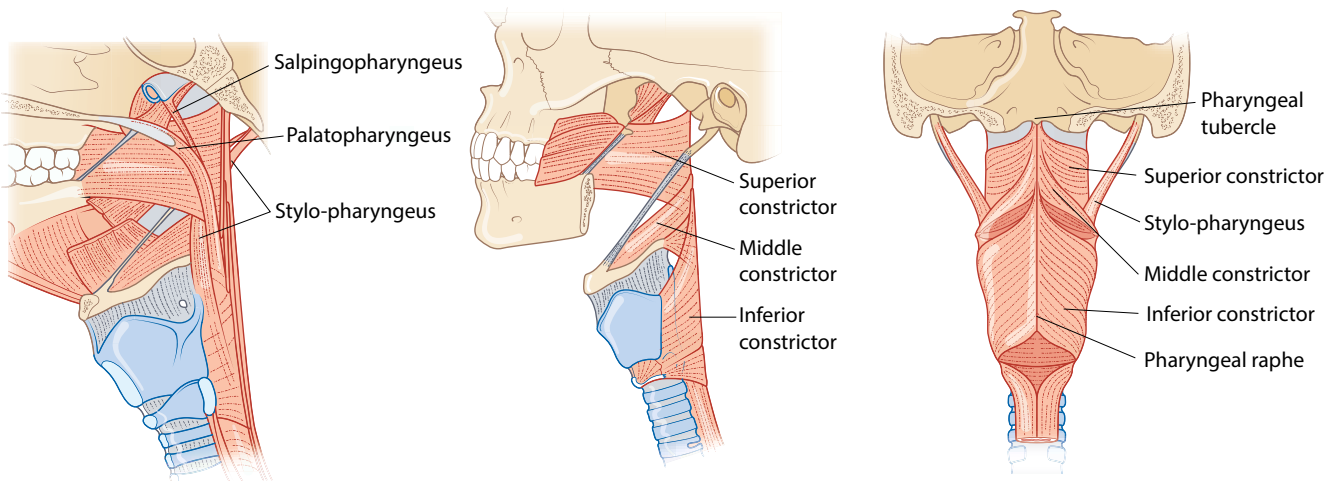

Figure 47.6 Muscles of the pharynx: (a) sagittal section, **(b)** lateral view and **(c)** posterior view.

from a small strip of lamina behind it and a small part of the inferior thyroid horn as well as from a part of the tendinous fascia overlying and looping over the cricothyroid muscle. Its fibres pass upwards posteromedially to join at the median pharyngeal raphe, although some of its fibres cross over the raphe to fuse with the contralateral muscle. Its upper fibres overlap with the middle constrictor fibres. Cricopharyngeus arises from the lateral aspect of the cricoid cartilage, emerging from between the attachment for the cricothyroid muscle and the inferior thyroid horn. It is distinctively different from all the other flat constrictor muscles in that it is thicker and rounder and its fibres pass horizontally to encircle the cricoid arch without fusing in the midline at the pharyngeal raphe. This is the sphincter of the pharynx, which is also continuous with the circular muscular coat of the upper oesophagus below. By default, this sphincter is closed and only opens momentarily during swallowing, and it can thus pose problems when passing an endoscope past this point. Swallowing will overcome any resistance encountered.

The innervation, attachments and functions of the three constrictor muscles of the pharynx are summarized in **Table 47.1**. The attachments are illustrated in **Figure 47.7**.

The inferior laryngeal artery and vein as well as the recurrent laryngeal nerve pass upwards deep to the inferior constrictor's lower margin.

The potentially weak area at the junction of thyropharyngeus and cricopharyngeus has clinical implications. The mucosa between these two muscles has little support from the pharyngeal musculature and is known as the pharyngeal dimple or, more commonly, Killian's dehiscence. The specific site of weakness is on the posterior aspect, in the midline, of the fusion point of these two muscles. This area is important in the pathogenesis of pharyngeal diverticulae, which form as a prolapse of mucosa and submucosa of the pharynx just above the cricopharyngeus muscle at the level of the sixth cervical vertebra. The resulting pharyngeal pouch (**Figure 47.8**) then becomes a convenient reservoir for trapping some or all of the passing food bolus. Halitosis and regurgitation are, unsurprisingly, the hallmarks of the condition. The specific aetiology of a pharyngeal pouch is, however, unknown. It is thought that malfunction of the upper oesophageal sphincter may contribute to the condition.

Despite the initial posterior expansion of any prolapse, prevertebral fascia prevents any further expansion in that direction. Thus, any larger prolapses usually project more laterally and inferiorly, mainly to the left side of the pharynx, which is the more exposed of the two sides. In a progressively enlarging prolapse, the pouch can potentially push the oesophagus to one side and thus sit in line with the rest of the pharynx. Consequently, dysphagia and cachexia may result, and pouch contents are more liable to spill into the larynx causing respiratory infections. The aetiology of the formation of a pharyngeal pouch is thought to involve a sequence of events originating from

TABLE 47.1 Constrictors of the pharynx

Muscle	Innervation	Anterior attachment	Posterior attachment	Function
Superior constrictor	Vagus nerve	Pterygomandibular raphe and adjacent bone on the mandible and pterygoid hamulus	Pharyngeal raphe	Constricts the pharynx
Middle constrictor	Vagus nerve	Greater horn of hyoid bone (upper margin) and adjacent margins on lesser horn of the hyoid bone and the stylohyoid ligament	Pharyngeal raphe	Constricts the pharynx
Inferior constrictor	Vagus nerve	Cricoid cartilage, oblique line of the thyroid cartilage, and the ligament that is between these two attachments and crosses the cricothyroid muscle	Pharyngeal raphe	Constricts the pharynx

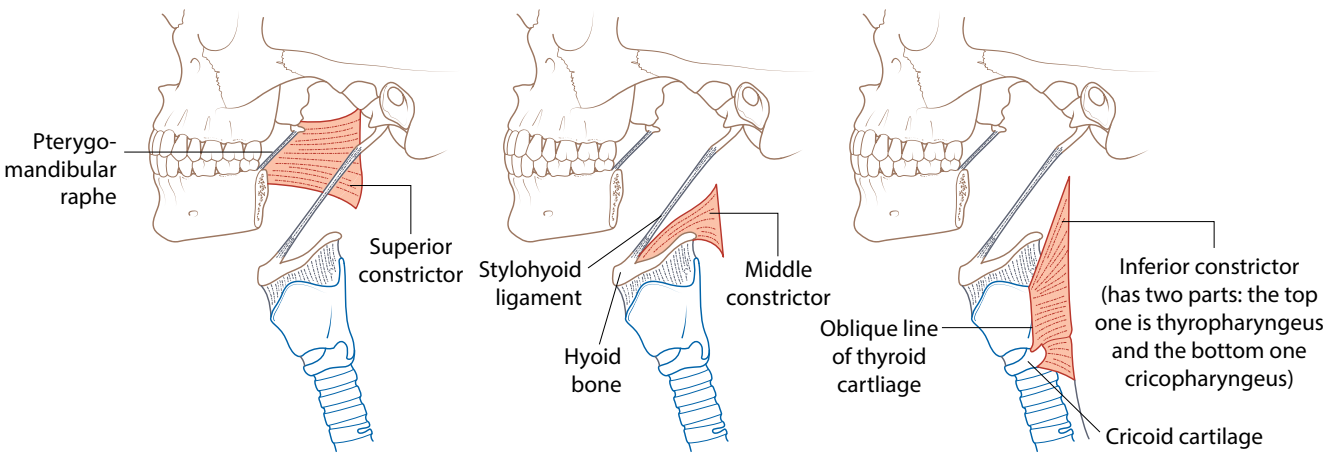

Figure 47.7 Attachments of the constrictor muscles of the pharynx: 1 – superior constrictor, 2 – middle constrictor, 3 – inferior constrictor.

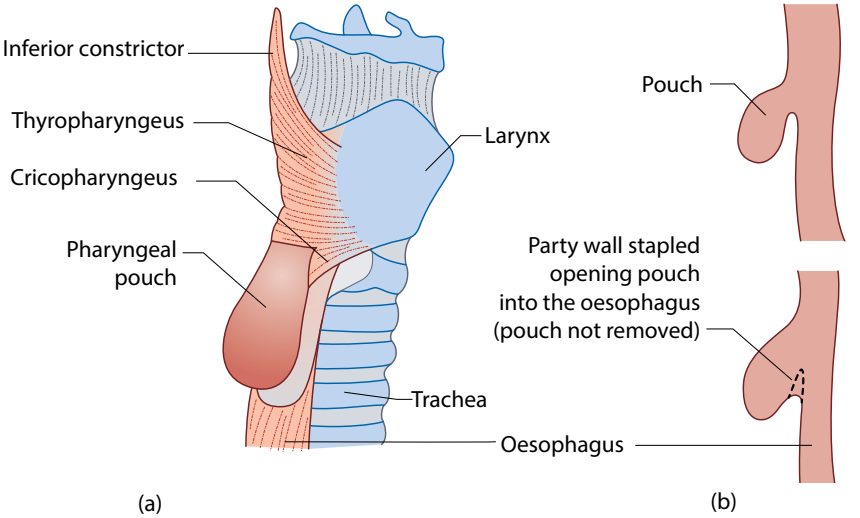

Figure 47.8 Anatomy of a pharyngeal pouch and stapling.

discoordinated swallow which elevates the pressure adjacent to the dehiscence and delays the relaxation of the cricopharyngeus sphincter below.

THE THREE DILATORS AND ELEVATORS

In addition to the three constrictor muscles that form the external muscular wall of the pharynx, three longitudinal muscles act to elevate and dilate the pharynx. These are the stylo-, palato- and salpingopharyngeus muscles. The first two are named based on their origins on the skull base; salpingopharyngeus, in contrast, has a long and slender shape with a wider distal end, the structure of which is reminiscent of the Greek trumpet bearing its name (salpinx).

The stylopharyngeus muscle is a long conical muscle that descends inferiorly between the external and internal carotid arteries. Curiously shaped, it is cylindrical above but flat below, and is markedly slender. It enters the pharynx between the superior and middle constrictors. It originates from the medial side of the base of the styloid process, within the temporal bone, and inserts into the posterosuperior border of the thyroid cartilage alongside the palatopharyngeus muscle. Some of its fibres also merge with the lateral glossoepiglottic folds, the lateral boundaries of the valleculae in the oropharynx. Its action is to raise the pharynx and assist in peristaltic movement of the food bolus. An important relation is the glossopharyngeal nerve which, en route to the tongue, curves from medial to lateral on its posteroinferior border and innervates it. All the other pharyngeal muscles are innervated by the pharyngeal nervous plexus, although cricopharyngeus is also innervated by the recurrent and external laryngeal nerves. Stylopharyngeus elevates both the pharynx and the larynx.

Palatopharyngeus is as much a pharyngeal muscle as it is a muscle of the soft palate. It has two heads and thus two actions. While both heads lie in the same plane, they are separated by levator veli palatini, a soft palate muscle. Its thicker anterior head originates from the posterior border of the hard palate and the anterior and superior surfaces of the palatine aponeurosis respectively. Its posterior head also originates from the superior surface of the palatine aponeurosis, but from further back on it. These two heads fuse at the lateral border of the palatine aponeurosis, are joined by fibres of salpingopharyngeus and arch downwards from here to insert into the posterior border of the thyroid lamina alongside stylopharyngeus and salpingopharyngeus. As it makes its way down as a single muscle covered in submucosa and mucosa, it forms the posterior faucial pillar, or palatopharyngeal arch. This muscle has a dual purpose: it elevates the larynx and pharynx and constricts the palatopharyngeal arch to assist in swallowing and, additionally, enables the concave shape of the oral surface of the palate with its arch.

The fibres of palatopharyngeus originating from the anterior head are horizontal at the level of the first cervical vertebra and form the palatopharyngeal sphincter. Contraction of these fibres lifts up the posterior pharyngeal wall in what is reminiscent of a ridge, Passavant's ridge, which is in direct contact with the superior surface of the soft palate during swallowing. No consensus has been reached on the origins of Passavant's ridge, some sources stating that it could be superior constrictor, and others that a completely different muscle acts as a sphincter at this point. What is clear is that there is a change of mucosal type along the line of this sphincter, from the ciliated, columnar respiratory epithelium above to the stratified squamous epithelium below.

Shaped like a long and slender trumpet, the salpingopharyngeus muscle arises from the lower part of the cartilaginous pharyngotympanic tube and descends internally in the salpingopharyngeal fold and inserts by blending into the palatopharyngeus muscle. The action of this muscle is to elevate the pharynx, although it may also serve to assist the soft palate muscle, tensor veli palatine, in opening the cartilaginous part of the pharyngotympanic tube during swallowing.

The innervation, origin, insertion and functions of the elevators of the pharynx are summarized in **Table 47.2**. Their attachments are illustrated in **Figure 47.9**.

Box 47.3 summarizes the openings in the pharyngeal wall musculature.

Soft palate muscles

Sloping down from the hard palate into the nasal and oral parts of the pharynx is the mobile flap which is the soft palate (**Figure 47.10**). It is the fibromuscular continuation of the hard palate and acts as a partition between the oropharynx and the nasopharynx. The failure of this structure and the consequences related to this are clearly seen in children born with a cleft palate, who struggle with feeding as well as normal speech production due to velopharyngeal incompetence.

The boundary between the soft and hard palate is easily palpable and is characterized by a subtle change in colour; the soft palate is characterized by a yellowish discolouration on a background of a darker red than that visible in the region of the hard palate. The soft palate is essentially a thick mucosal fold that holds within it an aponeurosis, muscles, neurovascular structures, lymph nodes and mucous glands. In its relaxed state, it is pendulant and a midline raphe is visible on its concave oral surface. The soft palate requires an intact central fibrous aponeurosis

TABLE 47.2 Elevators of the pharynx

Muscle	Innervation	Origin	Insertion	Function
Palatopharyngeus	Vagus nerve	Upper surface of palatine aponeurosis	Pharyngeal wall	Elevates the pharynx and closes the oropharyngeal isthmus
Stylopharyngeus	Glossopharyngeal nerve	Medial side of base of styloid process	Pharyngeal wall	Elevates the pharynx
Salpingopharyngeus	Vagus nerve	Inferior aspect of pharyngeal end of pharyngotympanic tube	Pharyngeal wall	Elevates the pharynx

Where?	Structures traversing
Above the superior constrictor	The cartilaginous portion of the pharyngotympanic tube, the tensor and levator palati muscles and the palatine branch of the ascending pharyngeal artery. All of these structures pass through the pharyngobasilar fascia
Between the superior and middle constrictor muscles	The stylopharyngeus muscle, styloglossus muscle, the glossopharyngeal and lingual nerves
Through the thyrohyoid membrane to enter the piriform fossa	The internal laryngeal nerve and superior laryngeal vessels
Below cricopharyngeus	The recurrent laryngeal nerve and inferior thyroid artery pass superiorly into the larynx deep to the cricopharyngeus muscle

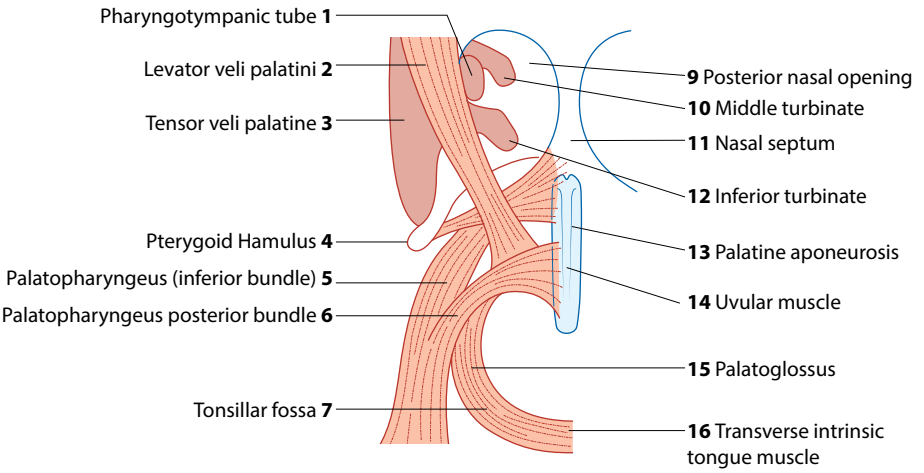

Figure 47.10 Posterior view of the soft palate showing the muscles acting on the left-hand side.

formed by the fused expanded tendons of the tensor veli palatini muscles upon which the muscles attached to the palate can act. The aponeurosis is attached posteriorly to the palatine part of the hard palate and has a midline raphe. The soft palate has a thicker anterosuperior portion near its insertion with the hard palate. As the palate travels posteroinferiorly, it gradually thins out, giving off the characteristic curved lower border appearance as it merges with the palatoglossal muscles which insert into it. In the centre is the conical uvula, part of its free inferior border, which can vary in length (but is typically longer in those who snore or have sleep apnoea) and projects downwards. The uvular muscles are embedded in the aponeurosis which splits to surround them. From the uvula, the two muscles of the pharyngeal arches – palatopharyngeus and palatoglossus – diverge laterally and inferiorly and insert into the intrinsic muscles of the tongue. The mucosa of the soft palate is covered in mucinous glands as well as minor salivary glands, and some taste buds exist on its oral surface.

The muscles of the palate do not act independently but work in unison to facilitate the swallowing reflex to close off the nasopharyngeal sphincter on initiating a swallow. All of the five paired soft palate muscles are attached to the palatine aponeurosis, the latter of which also encloses the small musculus uvulae muscle in the midline. These muscles can be classified according to their anatomical function: tensor veli palatini, levator veli palatini and the musculus uvulae raise the soft palate; palatoglossus (also an extrinsic tongue muscle) and palatopharyngeus (also a pharyngeal muscle) elevate the tongue and pharynx to close off the oropharyngeal isthmus during swallowing.

ELEVATORS OF THE SOFT PALATE

Tensor veli palatini is a veil-thin triangular muscle arising from the scaphoid fossa of the sphenoid bone, the lateral lamina of the pharyngotympanic tube and the spine of the sphenoid. It descends on the lateral surface of the medial pterygoid plate and then forms a tendon that hooks around the pterygoid hamulus to spread out to form the palatine aponeurosis. Its two sides fuse in the median raphe. Upon bilateral contraction, the muscles tauten predominantly the anterior part of the soft palate and depress the arch. Unilateral contraction of the muscles moves the soft palate in the direction of the pull. A primary function of the tensor veli palatini muscle is also presumed to be associated with opening the pharyngotympanic tube during swallowing and yawning to allow for equalization of nasopharyngeal and middle ear air pressure. This explains why patients with cleft palate will almost universally have otitis media with effusion; due to a failure of the midline connection, the tensor veli palatini cannot pull open the pharyngotympanic tube and, so, aeration of the middle ear as well as protecting it from the transmission of infections from the pharynx is negligible. The tensor veli palatini is the only muscle of the palate that is supplied by a branch of the mandibular division of the trigeminal nerve – the nerve to medial pterygoid. The rest are supplied by the cranial part of the accessory nerve via the pharyngeal plexus.

Levator veli palatini is a cylindrical muscle that arises from a small tendon on the inferior, roughened, portion of the petrous temporal bone, known as the quadrate area, situated in front of the inferior opening of the carotid canal. Some of its fibres also originate from the lower part of the cartilaginous pharyngotympanic tube and yet more from the vaginal process of the tympanic bone. It inserts onto the nasal surface of the palatine aponeurosis and sits between the two heads of the palatopharyngeus muscle, forming a rounded belly. The levator muscles pass anteromedially and together they form a V-shaped sling just above and behind the palatine aponeurosis, which allows elevation and slight retraction of the vertical posterior part of the soft palate when closure of the nasopharynx is required. The soft palate then touches the posterior pharyngeal wall, closing off the nasopharyngeal isthmus to prevent nasal regurgitation during speech and swallowing. Additionally, its fibres also pull the lateral nasopharyngeal wall anteromedially to narrow that space. The effects of levator veli palatini on the pharyngotympanic

tube and its role in the equalization of air pressure are controversial. This muscle, along with the palatoglossus, palatopharyngeus and uvular muscle, are all supplied by the cranial part of the accessory nerve via the pharyngeal plexus.

Musculus uvulae lies between the two laminae of the palatine aponeurosis and arises from the posterior nasal spine on the palatine bone as well as from the superior surface of the aponeurosis. It sits above the V-shaped sling formed by the two levator veli palatini muscles and runs backwards above it to insert into the uvular mucosa. Most of this small muscle is fused in the midline. Its function is to act in conjunction with the levator veli palatini muscles to retract and thicken the mid-third of the soft palate, thus closing the nasopharyngeal isthmus. As the two muscle bellies run at 90 degree angles to each other, when they contract, a 'levator eminence' is formed. This helps in the finally sealing off of the nasopharynx during swallowing.

ELEVATORS OF THE PHARYNX AND TONGUE

As a pharyngeal wall muscle, **palatopharyngeus** has been discussed in the section on pharyngeal muscles. Its role as a soft palate muscle is to elevate the pharynx and pull it forwards and medially. Additionally, the muscles acting together also draw the palatopharyngeal arches together and approximate them, enabling closure of the oropharyngeal isthmus.

Palatoglossus is both an extrinsic tongue muscle and a soft palate muscle. It arises from the palatine aponeurosis, on its oral surface, where it is continuous with the contralateral muscle, and projects anteriorly, inferiorly and laterally to the side of the tongue, forming the palatoglossal fold anterior to the palatine tonsil on its way down. A few of its fibres extend into the dorsum of the tongue, while others pass into the parenchyma of the tongue to intermingle with the intrinsic musculature. Unlike the rest of the extrinsic and intrinsic tongue muscles, palatoglossus follows the innervation of the soft palate muscles and is innervated by the cranial part of the accessory nerve and its pharyngeal plexus. Its action is to elevate the root of the tongue and to approximate the two palatoglossal arches when closure of the oropharyngeal isthmus is required.

The innervation, origin, insertion and functions of the elevators of the muscles of the soft palate are summarized in **Table 47.3**. Their attachments are illustrated in **Figure 47.11**.

BLOOD SUPPLY OF THE PHARYNX

The pharynx has a rich vascular supply from a number of branches of the external carotid artery. Much of the superior pharynx is supplied by the ascending pharyngeal artery. This artery arises from the medial external carotid and passes superiorly, giving off branches to the pharynx. A palatine branch passes over the edge of the superior constrictor to supply the soft palate and internal pharynx as well as the pharyngotympanic tube. There are additional supplies from the tonsillar artery and ascending palatine branch of the facial artery as well as, more inferiorly, from the superior and inferior laryngeal arteries.

Venous drainage is via the internal submucosal and the external pharyngeal venous plexus, which sits predominantly on the posterior aspect of the middle constrictor. The venous plexus drains into the internal jugular vein and, to an extent, connects with the pterygoid venous plexus. The venous plexus is a common cause of significant

TABLE 47.3 Muscles of the soft palate

Muscle	Innervation	Origin	Insertion	Function
Tensor veli palatini	V3, mandibular nerve via the branch to the medical pterygoid muscle	Scaphoid fossa of the sphenoid bone, fibrous part of the pharyngotympanic tube and the spine of the sphenoid	Palatine aponeurosis	Tenses the soft palate and opens the pharyngotympanic tube
Levator veli palatini	Vagus nerve via the pharyngeal branch to the pharyngeal plexus	Petrous part of the temporal bone anterior to the opening for the carotid canal	Superior surface of the palatine aponeurosis	The only muscle to elevate the soft palate from the neutral position
Palatopharyngeus	Vagus nerve via the pharyngeal branch to the pharyngeal plexus	Superior surface of the palatine aponeurosis	Pharyngeal wall	Depresses the soft palate, moves the palatopharyngeal arch towards the midline and elevates the pharynx
Palatoglossus	Vagus nerve via the pharyngeal branch to the pharyngeal plexus	Inferior surface of the palatine aponeurosis	Lateral margin of the tongue	Depresses the palate, moves the palatoglossal arch towards the midline and elevates the back of the tongue
Musculus uvulae	Vagus nerve via the pharyngeal branch to the pharyngeal plexus	Posterior nasal spine of the hard palate	Connective tissue of the uvula	Elevates and retracts the uvula and thickens the central region of the soft palate

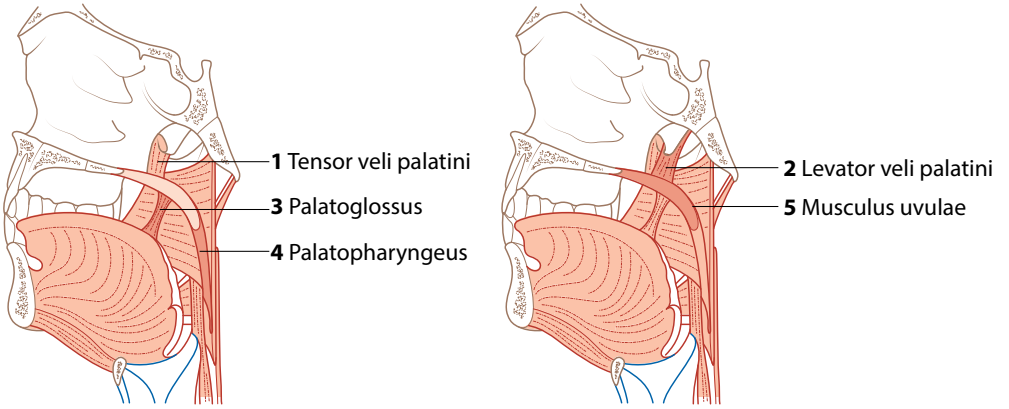

Figure 47.11 Soft palate muscular attachments.

bleeding in operations of the pharynx and can, on occasion, be very difficult to control.

The vascular supply of the soft palate is equally rich, but it mainly originates from the lesser palatine artery of the maxillary artery, and the ascending pharyngeal artery and its palatine branches in particular. These arteries form a complex anastomosis with the ascending palatine artery, a branch of the facial artery.

PHARYNGEAL PLEXUS OF NERVES

The motor and the majority of the sensory supply to both the pharynx and the soft palate come from the pharyngeal plexus. This is a meshwork of interconnecting nerves on the posterolateral surface of the pharynx and it is formed by contributions from the pharyngeal branches of the vagus nerves, the glossopharyngeal nerves and the sympathetic branches of the superior cervical ganglion. Mixed nerves then exit the plexus and either descend or ascend over the external surface of the pharyngeal constrictors, in particular over the middle constrictor, to supply the deeper layers of the pharyngeal wall, the muscles and the mucosal surfaces.

The motor fibres of the plexus originate in the cranial root of the accessory nerve and are carried by the pharyngeal branch of the vagus nerve to supply all of the pharyngeal muscles, apart from the stylopharyngeus muscle (which is supplied by the glossopharyngeal nerve) and the tensor veli palatini (which is supplied by nerve to medial pterygoid, a branch of the mandibular division of the trigeminal nerve). These motor fibres travel between the internal and external carotid arteries to enter the superior margin of the middle constrictor. At this point, it joins the hypoglossal nerve – close to where it curves around the occipital artery – via a miniscule filament, the ramus lingualis vagi. In addition to innervation via the pharyngeal plexus, the inferior constrictor, namely cricopharyngeus, also receives contributions from braches of the vagus nerve, the external and recurrent laryngeal nerves.

Sensory fibres predominantly originate from the glossopharyngeal nerve to provide the sensory supply to the majority of the oropharynx. The valleculae lying within the oropharynx are, however, supplied by the internal laryngeal nerve off the vagus nerve as well as by the lesser palatine nerve, a branch off the maxillary division of the trigeminal nerve. Part of the nasopharynx is supplied principally by the maxillary branch of the trigeminal via the pterygopalatine ganglion. Sensation within the laryngopharynx is via the internal laryngeal nerve.

The sensory supply of the palate originates from branches of the pterygopalatine ganglion, namely the greater and lesser palatine nerves, which travel with the arteries of the same name. The site of their entry into the palate is a useful landmark for performing local anaesthetic blocks, as it enters 1 cm medial to the region of the second molar.

LYMPHATIC DRAINAGE OF THE PHARYNX

The lymphatic drainage of the pharynx is complex due to the length of the structure and the rich lymphatic supply. It is especially important in malignant disease, as metastatic spread is particularly common from cancers affecting the pharynx. Awareness of this pattern of spread is important when assessing which parts of the lymphatics to treat prophylactically.

The nasopharynx lymph drains to the retropharyngeal lymph nodes and deep cervical lymph nodes. In nasopharyngeal cancer, the nodal stations involved are principally the retropharyngeal nodes and level 2 nodes (in approximately 70% of cases), with spread to levels 3, 4 and 5 also occurring to a lesser extent (45%, 11% and 27% respectively).

Lymphatics channels within the oropharynx pierce through the superior constrictor to principally drain into the deep cervical lymph nodes, particularly the jugulodigastric or tonsillar node situated just below the angle of the mandible (level 2). On occasion, lymph can also drain into level 3 and 4 nodes, although drainage to these distant levels without affecting the upper neck nodes is uncommon.

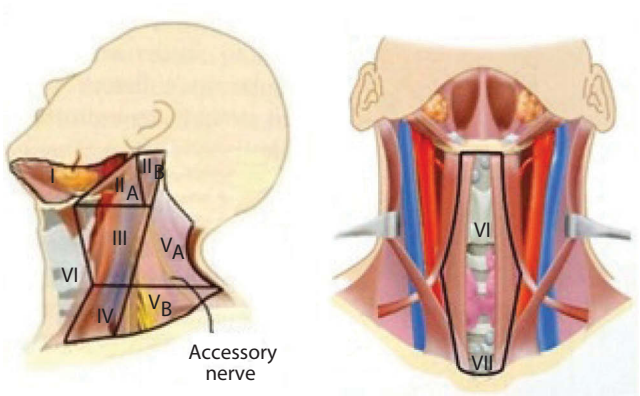

Figure 47.12 The lymph nodes of the neck.

The hypopharynx drains to all levels of the deep cervical nodes, principally to levels 2, 3 and 4. Overall the commonest level of drainage is to level 3 (**Figure 47.12**).

ANATOMY OF THE OESOPHAGUS

INTRODUCTION

The immediate continuation of the pharynx and a conduit for food and fluids into the stomach is the 25 cm long oesophagus, a flattened muscular tube that extends from the level of the inferior border of the cricoid cartilage (sixth cervical vertebra) to the cardiac orifice of the stomach at the level of the eleventh thoracic vertebra. It is the narrowest part of the digestive tract (excluding the appendix) and has three anatomical narrowings along its course. It courses anterior to the vertebral column in the neck and passes through the superior and inferior mediastinal spaces on the posterior aspect of the thorax to the diaphragm, which it penetrates via the oesophageal hiatus at the level of the tenth thoracic vertebra. Thus the oesophagus has a cervical, thoracic and abdominal component. Within the neck, despite originating in the midline, it gradually veers to the left until it reaches the root of the neck. From there it continues again in the midline, and is back to its original vertical orientation. At the level of the fifth thoracic vertebra, it veers yet again to the left but reverts back to being a midline structure. At the level of the seventh thoracic vertebra, it veers to the left again and continues in this course until it pierces through the oesophageal hiatus of the diaphragm. As it descends from the cervical region into the thoracic and then abdominal region, the oesophagus also follows the curvatures of the vertebral column in the anteroposterior plane.

Knowledge of the oesophagus is of considerable interest to otolaryngologists; rigid oesophagoscopy is a relatively common procedure, pharyngeal pouch repair may be complicated with perforations of the oesophagus, foreign bodies routinely lodge within the oesophagus, strictures of the tube require the skilled use of dilators to avoid complications. An intimate knowledge of the anatomical constrictions and oesophageal relations are vital to avoid formation of false passages and inadvertent entry either into the mediastinal cavity or the adjacent pleural spaces and lungs.

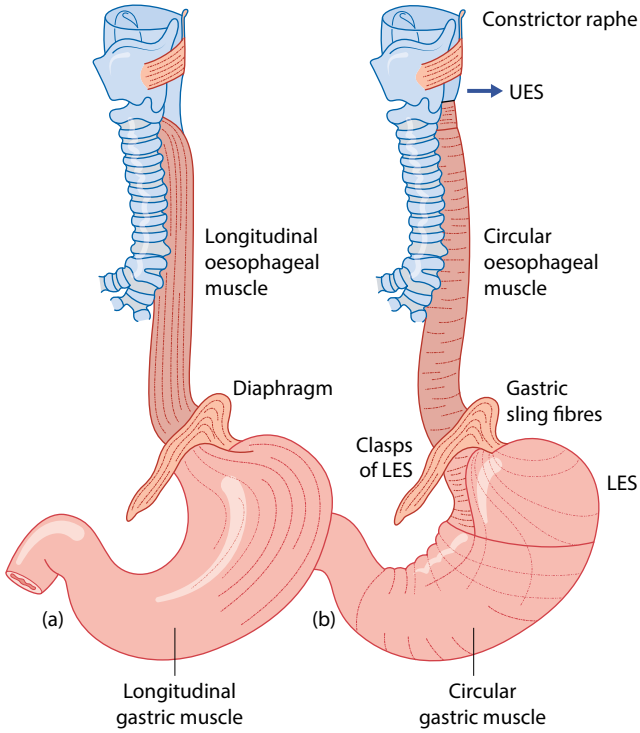

Figure 47.13 Longitudinal and circular muscle in the oesophagus.

Muscles of the oesophagus are shown in **Figure 47.13**.

SUBDIVISIONS OF THE OESOPHAGUS

The oesophagus has three arbitrary subdivisions, primarily based on its course from neck to abdomen as it traverses the neck, the thorax and enters into the abdomen (see above). These are the cervical, thoracic and abdominal oesophagus.

Cervical oesophagus

The superiormost region is the cervical oesophagus. It lies immediately posterior to the trachea and is adherent to the trachea via loose connective tissue. Bilaterally, close to a groove between the two structures, the recurrent laryngeal nerves pass superiorly to pass into the larynx behind the cricothyroid joint to innervate the intrinsic musculature of the larynx. At the level of the thyroid gland, the oesophagus is generally slightly to the left of midline. Posteriorly, the oesophagus rests on the vertebral column formed at this level by the bodies of the sixth and seventh cervical vertebrae and the prevertebral fascia overlying the longus colli muscle. It is flanked on both sides by the common carotid artery, within the carotid sheath, as well as the lower poles of the thyroid gland. To its left, the thoracic duct ascends for a short distance on its way to deposit its contents at the confluence between the subclavian vein and the internal jugular vein.

Thoracic oesophagus

Within the superior mediastinum, the thoracic oesophagus runs slightly to the left of midline initially before passing posterior and to the right of the aortic arch to enter the posterior part of the inferior mediastinum (**Figure 47.14**). Here, it descends to the right of the descending thoracic aorta, although it veers to the left along its course to the oesophageal hiatus of the diaphragm and thus is situated anterior to the descending aorta in the inferior part of the thorax.

In the superior mediastinum, the anterior relations of the oesophagus are the trachea and the left recurrent laryngeal nerve. Its left lateral relations at this point are the terminal part of the aortic arch, the left subclavian vein, the thoracic duct, the left recurrent laryngeal nerve and the left pleura. In the posterior mediastinum, the anterior relations are the left main bronchus, the tracheobronchial lymph nodes, the pericardium and the left atrium. Immediately posterior to the oesophagus are the vertebral bodies of thoracic vertebrae one to four, the thoracic duct sandwiched between the azygos vein and the descending aorta, as well as the right posterior intercostal arteries, and the hemiazygos and accessory azygos veins. At the terminal end of the thoracic part, the descending aorta lies between the oesophagus and the vertebrae.

The left side of the oesophagus lies close to the mediastinal pleura superior to the arch of the aorta except where the thoracic duct and left subclavian artery intervene. The right side of the oesophagus is adjacent to the mediastinal pleura and lung except where the azygos vein intervenes. The thoracic duct enters the thorax through the right side of the aortic hiatus of the diaphragm and runs up along the right side of the oesophagus until, at the level of the fifth thoracic vertebra, it crosses to the left side. From here, it continues up to drain into the junction of the internal jugular vein and the subclavian vein.

The left and right vagus nerves form a plexus that covers the oesophagus, giving off cardiac and pulmonary branches. Lower in the thoracic oesophagus, the plexus once again forms a number of nerve trunks that accompany the oesophagus through the oesophageal hiatus.

CONSTRICTIONS OF THE OESOPHAGUS

The thoracic oesophagus has three constrictions that are not evident in the collapsed oesophagus but can be visualized when air is insufflated into the oesophagus, as is done during oesophagoscopy or when contrast medium is swallowed for radiological examination. The narrowest part of the oesophagus is at the cricopharyngeal sphincter, the commencement of the oesophagus and point of termination of the pharynx. This is generally at approximately 15 cm from the incisor teeth. Below this point, three further anatomical constrictions can be expected along the course of the oesophagus through the thorax and into the abdomen (**Figure 47.15**).

The first constriction within the oesophagus itself is formed when it is crossed over by the arch of the aorta at approximately 22 cm from the incisor teeth. This is immediately followed by a further constriction occurring at approximately 27 cm from the upper incisor teeth and caused by the left main bronchus crossing over it. These two constrictions are often considered as one constriction. The final constriction, at 38 cm from the incisor teeth, occurs as it passes through the diaphragm just prior to the start of the abdominal part of

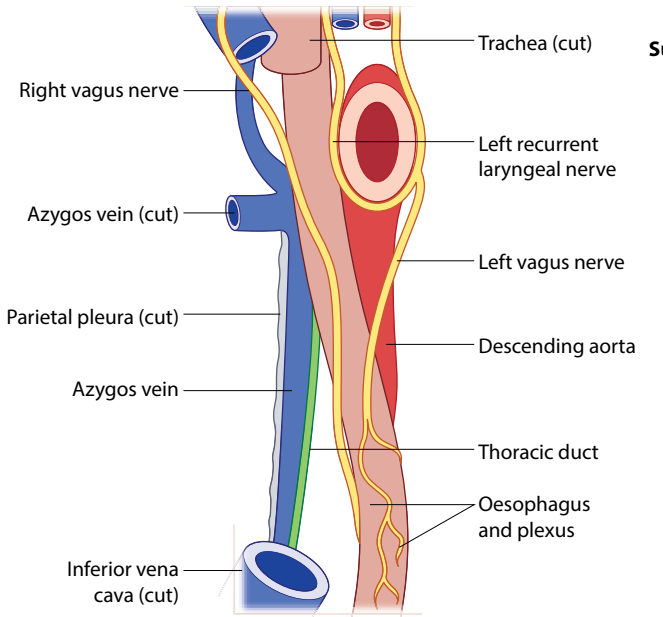

Figure 47.14 The intrathoracic part of the oesophagus.

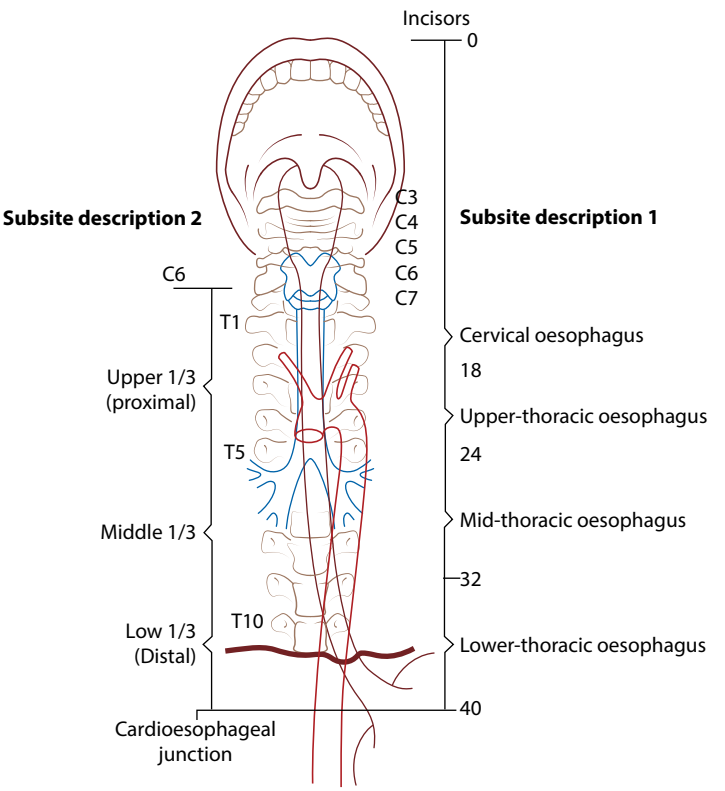

Figure 47.15 Oesophageal constrictions.

the oesophagus. Should the left atrium be enlarged for any reason, it can occasionally cause indentation onto the oesophagus on the anterior aspect just below the left main bronchus.

These constrictions and knowledge of the measurements from the incisor teeth are of considerable importance clinically when instruments are passed through the oesophagus, which can cause serious damage should the functional anatomy of this area not be fully appreciated. All measurements are approximate for an adult.

Abdominal oesophagus

The abdominal section of the oesophagus is the shortest of the three sections and emerges through the right crus of the diaphragm at the level of the tenth thoracic vertebra, left of the midline. It lies in the oesophageal groove on the posterior aspect of the left lobe of the liver before passing to the left to enter the stomach. The right border of the oesophagus continues into the lesser curvature of the stomach in the shape of a truncated cone to become continuous with the cardiac orifice of the stomach. It is covered with peritoneum overlying the lesser sac. The left border of the oesophagus, however, is separated from the fundus of the stomach by the cardiac notch. It is contained within the superior part of the lesser omentum due to the peritoneal coverings that encompass it on its lateral and anterior aspects. On its posterior surface, peritoneum is reflected to the diaphragm. This is part of the gastrosplenic ligament connecting the stomach and the spleen. The oesophageal branches of the gastric artery travel through this ligament to arrive at the abdominal part of the oesophagus. Even further posteriorly are the left phrenic artery and the left crus of the diaphragm. The vagus nerve travels alongside the oesophagus but its relation to the structure is varied as the oesophagus traverses the diaphragm. The left vagus nerve, with its two to three trunks, is usually located on the anterior aspect. The thick, single right vagus nerve is situated posterior to the oesophagus.

OESOPHAGEAL WALL

The oesophageal wall is made up of four discrete layers. These are, from the lumen outwards, the mucosa, submucosa, muscularis propria and adventitial layers. The oesophagus lacks a distinct serosal covering. As a result, direct tumour spread is easily facilitated, often complicating surgical resection. In addition, in the event of oesophageal perforation, the absence of a serosal layer makes repair more difficult.

Mucosal layer

The mucosal layer is lined by a continuation of the non-keratinizing stratified squamous epithelium which has an abrupt change in the lower oesophagus on entering into the stomach at the so-called Z line. This jagged line at the gastro-oesophageal junction is the area at which the mucosa changes to columnar epithelium which lines the stomach. The oesophageal mucosa above is characteristically greyish-pink and smooth; the gastric mucosa below is reddish-pink and has a number of bulges and depressions on its surface. This change is clearly visible at endoscopy. In life, the oesophageal mucosa is thick; superiorly it is more red and thicker. Inferiorly, it is paler. At rest, the mucosa is arranged into longitudinal folds; which disappear upon distension of the oesophagus.

The mucosal layer has three distinct sub-layers: (i) non-keratinizing epithelium which covers the entirety of the inner surface of the oesophagus, with the exception of the lower oesophageal sphincter, at which squamous and columnar epithelium meet and coexist; (ii) a thin layer of connective tissue, the lamina propria; and (iii) the muscularis mucosae comprising irregularly arranged longitudinal fibres of smooth muscle extending from the oesophagus into the rest of the gastrointestinal tract.

Submucosal layer

The submucosal layer loosely connects the mucosa to the underlying muscular layer. It also penetrates into the longitudinal ridges of the lumen of the oesophagus. It contains the larger blood vessels and Meissner's plexus of parasympathetic fibres and numerous mucinous glands, lymphocytes and plasma cells. The oesophageal mucinous glands are small tubulo-acinar glands. These mucous glands have acini arranged like grapes on a stem. Secretion from these glands is important in oesophageal clearance as well as to render the oesophageal tissue resistant to acid. The elastic fibres of the submucosal layer play an important role in closing the lumen after the dilatation caused by peristalsis.

Muscular layer (muscularis externa)

The muscular layer is responsible for oesophageal motor function and is composed of an outer longitudinal and an inner circular coat of muscle fibres. These layers are typical to the intestine. The longitudinal layer forms a continuous coverage of the oesophagus, apart from the upper 4 cm. Here, the fibres diverge posteriorly to form two longitudinal bands which pass in a superior and anterior direction to attach to the cricoid cartilage. The circular fibres are continuous, on the posterior aspect, with the corresponding muscular layer of the constrictor muscle superiorly and the muscles of the stomach. Generally, the longitudinal layer is the thicker of the two layers.

The proximal third of the oesophagus consists exclusively of striated (or skeletal) muscle, whereas the distal third is made up of smooth muscle. Between these two regions is a mixture of both striated and smooth muscle, a zone of transition in which the proportion of smooth muscle increases continuously, so that it, alone, exists in the lower part of the oesophagus. The oesophagus has two physiological sphincters, namely the upper oesophageal sphincter, which is composed principally of the lower

fibres of cricopharyngeus and is therefore anatomically strictly outside the oesophagus, and the lower oesophageal sphincter at the junction of the oesophagus and stomach. The physiological function of these is dealt with in Chapter 48, Physiology of swallowing.

Adventitial or fibrous layer

The external fibrous layer of the oesophagus consists of adventitia and dense connective tissue with elastin fibres and also contains small vessels, nerve fibres and lymphatic channels. This covers the oesophagus and connects it with its neighbouring structures. As mentioned above, the oesophagus is unique in that it has no serosal layer, unlike the rest of the digestive tract.

BLOOD SUPPLY OF THE OESOPHAGUS

The cervical oesophagus gets its main blood supply superiorly from the inferior thyroid artery of the thyrocervical trunk. The thoracic section of the oesophagus gains some of its blood supply segmentally from branches of the descending aorta or by branches of the bronchial and oesophageal arteries. Approximately five oesophageal arteries arise from the aorta anteriorly and these descend to supply the oesophagus by forming a vascular chain on the oesophagus itself. The vascular chain anastomoses with the branches of the inferior thyroid artery above as well as with the branches of the left phrenic and left gastric arteries below. The abdominal oesophagus is thus supplied by the left gastric and left inferior phrenic arteries. A dense blood supply and the anastomotic nature of the oesophageal blood supplying it render the organ virtually immune to infarction.

The venous drainage is initially via a complex network or plexus of veins that lies in the submucosal layer. Drainage from here is into a perioesophageal venous plexus, the point of origin of the oesophageal veins. The cervical oesophagus drains into the inferior thyroid vein via the brachiocephalic veins. The thoracic part of the oesophagus drains predominantly into the azygos veins, but also to a lesser extent into the hemiazygos and intercostal veins in the thorax, as well as to the bronchial veins. Inferiorly, the abdominal oesophagus drains into the left gastric vein. It meets the oesophageal vein at the lesser curvature of the stomach and drains from here into the portal vein. Knowledge of this anastomosis occurring at the level of the central diaphragmatic tendon (vertebral level T8) between the portal and systemic venous system is useful when diagnosing oesophageal varices. Portal obstruction can result in the formation of oesophageal varices in these veins, and throughout the upper gastrointestinal system, which, if ruptured, can result in life-threatening haemorrhaging.

INNERVATION OF THE OESOPHAGUS

The oesophagus also receives its innervation from dual sources. This is traditionally referred to as the sympathetic and parasympathetic supplies, although innervation is received from the vagus as well as the spinal nerves via different pathways and synapsing in different nuclei. Its sympathetic supplies, both motor and sensory, are from the spinal segments of T1–T10. Sympathetic and parasympathetic innervation regulates smooth muscle activity and glandular secretion.

The upper striated muscles of the oesophagus are supplied by multiple small branches arising from the recurrent laryngeal nerves as well as postganglionic sympathetic fibres from the middle cervical ganglia hitching a ride along the inferior thyroid arteries. The more distal smooth muscle fibres of the lower oesophagus are supplied by the oesophageal plexus, a meshwork of parasympathetic and sympathetic fibres hosted by the vagus and recurrent laryngeal nerves below the level of the lung roots.

Intrinsic innervation of the oesophagus is provided by the thin nerve fibres and numerous ganglia of the intramural myenteric and submucosal plexi. Auerbach's plexus (also known as the myenteric plexus) is formed by the ganglia that lie between the longitudinal and the circular layers of the tunica muscularis. Meissner's plexus (also known as the submucous plexus) is formed by those ganglia that lie in the submucosa. Despite their different functions – Auerbach's plexus regulates contraction of the outer muscle layers and Meissner's plexus regulates secretion and the peristaltic contractions of the muscularis mucosae – they are interconnected by a network of fibres.

The perception of pain in the oesophagus is limited and is more likely to be due to stretching of the external muscular coat rather than actual mucosal awareness. This may explain why localization of pain to a site within the oesophagus is very difficult, although referred pain is common.

LYMPHATIC DRAINAGE OF THE OESOPHAGUS

An extensive submucosal lymphatic system exists within the oesophagus. The upper oesophagus drains into the lower deep cervical and paratracheal and upper mediastinal nodes. The thoracic section drains into the posterior mediastinal nodes and the tracheobronchial nodes. The abdominal section drains into the left gastric nodes as well as the coeliac nodes. The lymph drainage, however, does not follow this pattern strictly. Within the walls of the oesophagus, there are lymphatic channels which allow the flow of lymph within the organ itself. Some lymph may pass directly into the thoracic duct.

KEY POINTS

- Within the nasopharynx, the **pharyngotympanic/auditory tube** connecting the middle ear to the pharynx opens out. This connection helps to equalize pressure behind the tympanic membrane within the ear but, as with all connections, it has the potential for spreading infections from one site to the other, predominantly from the nasopharynx to the middle ear.
- Although there is plexiform venous drainage around the tonsillar hemicapsule of the palatine tonsils, the paratonsillar vein (or external palatine vein) runs within the capsule and is the usual culprit for a **post-tonsillectomy bleed**.
- The glossopharyngeal nerve also supplies the middle ear (the tympanic branch) and thus **referred pain** to the ear during an episode of tonsillitis or after any surgical procedure in the peritonsillar area is not unusual.
- Nasopharyngeal tonsils can be problematic when inflamed in **adenoiditis**. The lymphoid tissue here is prominent in children but generally atrophies after puberty. Enlarged adenoids can cause mouth-breathing, and may block the pharyngotympanic tube.
- **Peritonsillar abscesses** – quinsies – occur outside the tonsillar hemicapsule. The internal carotid artery is about 2.5 cm lateral and posterior to the tonsil and this is thus a potential danger zone when incising peritonsillar abscesses.
- The valleculae, between the dorsum of the tongue and the epiglottis, is a common site for **small foreign bodies** to lodge.
- The piriform recesses at the side of the laryngeal inlet are also potential sites where **foreign bodies may lodge**. The space also allows for **malignancies** to grow to a substantial size asymptomatically, at which point they present with metastatic cervical lymphadenopathy.
- Killian's dehiscence, at the junction formed by the two muscles (thyropharyngeus m. and cricopharyngeus m.) forming the inferior constrictor, is a site of potential weakness. A defect or weakness here can result in the formation of a **pharyngeal diverticulum**.
- The cricopharyngeus muscle, which is circular and a sphincter, remains closed most of the time. This can pose problems when an **endoscope** is required to get beyond this point into the oesophagus but is generally overcome by getting the patient to swallow, and thus relax the sphincter momentarily.
- Three anatomical constrictions of the oesophagus, measured by their distance from the incisor teeth to allow for endoscopic examinations, are at 15 cm, 23–27 cm and 38 cm.

SEARCH STRATEGY

Data in this chapter are based on a PubMed search using the keywords: swallowing, transit times, pharyngeal pressure, bolus formation, mastication and taste.

INTRODUCTION

Swallowing requires the coordinated activity of muscles in three regions of the head and neck: the oral cavity, the pharynx and larynx, and the oesophagus. This complex sequence of motor behaviour is part reflex and partly under voluntary control. It has been extensively investigated using a variety of techniques including videofluoroscopy, endoscopy, radiography, ultrasound, electromyography (EMG) recording and functional MRI, together with observations on individuals with dysphagia. Swallowing as a motor behaviour is so complex that some details have remained difficult to resolve. The literature is often contradictory, particularly the earlier studies based on inferential analysis of radiographic data. Careful analysis of swallowing using newer techniques shows that there is a surprising amount of variation between individuals. This chapter will survey the current state of knowledge concerning the normal anatomy and physiology of swallowing and what might be considered as the limits of normality, essential to the understanding of dysphagia. Neural control and the coordination of breathing and swallowing will also be addressed.

STRUCTURES INVOLVED IN SWALLOWING

Swallowing involves the passage of a bolus of food or liquid from the oral cavity to the stomach via the pharynx and oesophagus. During this passage, the bolus passes over the entrance to the laryngeal vestibule which thus needs to be closed if food or liquid is not to enter the airways (**Figure 48.1**). The musculature involved is extensive, including muscles controlling the position of the lips, elevation and depression of the jaw, position and degree of contraction of the tongue, the degree of constriction and length of the pharynx, closure of the laryngeal inlet, the cricopharyngeal sphincter and the muscles of the oesophagus and oesophageal sphincter. This section will simply outline some key anatomical features and functions of the structures involved. For a more detailed account of the anatomy of the relevant muscles and the larynx, a suitable textbook of anatomy should be consulted.[1]

The elevators and depressors of the jaw play a key role in bolus preparation before the swallow is initiated by grinding and reducing the food between the teeth. Two groups of muscles that move the jaw can be recognized: the supramandibular muscles and the inframandibular muscles. The supramandibular muscles are attached between the mandible and the skull and comprise the muscles of mastication, temporalis, masseter and the medial and lateral pterygoid muscles. As the consequence of their attachments, they principally act as jaw elevators, though the inferior head of lateral pterygoid is active during jaw depression by acting to protract the mandible. The inframandibular muscles are composed of the suprahyoid and infrahyoid muscles of the neck and act indirectly on the mandible through their actions in raising or lowering the hyoid bone. Bolus formation is also a function of the

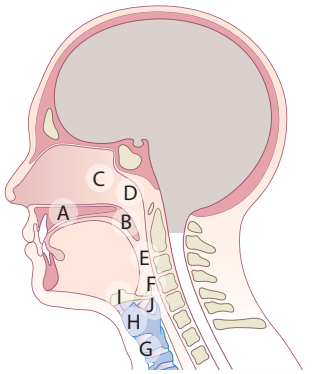

Figure 48.1 A mid-sagittal section of the head and neck showing the location of the major structures involved in swallowing. muscles of the tongue. Two groups of tongue muscles can be recognized, the intrinsic muscles of which are mainly responsible for changing the shape of the tongue. The extrinsic muscles with one attachment outside the tongue are responsible for altering the position of the tongue in the mouth. The actions of these two groups of tongue muscles are not entirely independent since changes in tongue shape will result in changes in tongue position and vice versa. For example, flattening the tongue by the verticalis muscles will protrude the tongue as its bulk is displaced, while downward movement of the tongue by the hyoglossus muscle will tend to lower the sides of the tongue but not its centre. The actions of the tongue and jaw muscles in bolus formation are aided by that of the sphincter of the lips orbicularis oris in maintaining a seal, the buccinator muscle of the cheek in returning food from the vestibule into the oral cavity and thus ensuring that food remains in place between the occlusal surfaces of the molar teeth, and the soft palate in preventing nasal regurgitation and premature movement of material into the oropharynx. It is now recognized that the palate does not seal off the oropharynx completely during bolus formation (see below).

On leaving the oral cavity, food enters the pharynx, a midline tube approximately 15 cm long, continuous with the oesophagus inferiorly while above the soft palate it is continuous with the nasal cavities anteriorly. The anterior wall of the pharynx below the soft palate is incomplete and composed of the posterior part of the tongue superiorly and the larynx inferiorly, with the laryngeal inlet forming a posterior-facing opening on the anterior wall. As a consequence of these anterior anatomical relationships, the pharynx is divided into three regions: nasopharynx, oropharynx and laryngopharynx, corresponding to those structures that lie anterior to the appropriate part of the pharyngeal tube.

The pharyngeal wall proper is composed, like the whole of the gastrointestinal tract, of four layers or coats which, from the outside in, are the areolar, the muscular, the submucous and the innermost mucous membrane. The muscular layer is composed of circular and longitudinal muscles. There are three circular muscles – the superior, middle and inferior constrictors – with the inferior constrictor being further subdivided into a thyropharyngeus and a cricopharyngeus part. These constrictor muscles are arranged as a triad and are usually described as being arranged in the form of three stacked cups with the inferior constrictor being on the outside and the middle and superior constrictors lying inside. The fibres of the superior and middle constrictors extend inside the inferior constrictor to approximately the level of the vocal folds. With the exception of the cricopharyngeus, the constrictor muscles are paired and attach to a posterior midline raphe. The cricopharyngeus forms a distinct sphincter, the cricopharyngeal sphincter, at the point where the laryngopharynx joins the oesophagus and it contains a high proportion of elastic fibres to aid its sphincteric function. There are two discrete longitudinal muscles on each side, the palatopharyngeus and the stylopharyngeus, which, despite their names, both attach inferiorly to the posterior border of the thyroid cartilage.

The larynx is formed of a series of cartilages in the wall of the upper part of the trachea, the main cartilages being the thyroid, cricoid arytenoid and epiglottis. The thyroid, cricoid and arytenoid cartilages articulate at two synovial joints – the cricothyroid and cricoarytenoid joints – formed between the cartilages of the same name. Movements at these joints result in changes of position of the vocal folds to allow lengthening or shortening, opening or closing. The larynx is suspended from the hyoid bone by the thyrohyoid membrane and thyrohyoid muscle. When the suprahyoid and infrahyoid muscles move the hyoid bone, they also alter the height of the larynx. The epiglottis projects above the hyoid behind the posterior part of the tongue and is attached to the posterior aspect of the thyroid cartilage. The epiglottis is capable of movements to aid in the closure of the laryngeal inlet, although the mechanism by which movements are produced remains unclear (see below). Attached between the epiglottis anteriorly and the arytenoid cartilages posteriorly is the quadrangular membrane, the superior margin of which forms the boundary of the laryngeal inlet. Within this superior border are the aryepiglottic muscles that control the inlet, together with the small thyroepiglotticus muscle that may help to depress the epiglottis to prevent aspiration. Adduction or closure of the vocal cords by the intrinsic muscles of the larynx provides a further line of defence to the accidental ingestion of food or foreign objects.

The oesophagus is a muscular tube continuous with the pharynx. It has a short cervical course before it enters the thorax where it lies posteriorly in the midline and descends, piercing the diaphragm and entering the stomach.

THE SEQUENCE OF EVENTS IN THE NORMAL SWALLOW

In any land-living mammal that does not normally swallow its food whole, different stages of swallowing can be identified as having evolved in order to ensure that food is transported from the mouth to the stomach safely.[2]

Swallowing is a continuous process with overlapping events that may be artificially divided into three distinct phases: oral (preparatory and transit phase), pharyngeal and oesophageal. This evolutionary division is also convenient for descriptive purposes. **Figure 48.2** illustrates the key stages in the swallowing process as traditionally described.

Oral phase for liquids

ORAL PREPARATORY PHASE

In the oral preparatory phase, liquids are taken into the mouth and held either on the floor of the mouth or against the hard palate by the upward movement of the tongue. Throughout this first phase, the soft palate is kept lowered by the contraction of the palatoglossus and palatopharyngeus. The posterior tongue is simultaneously elevated, thus preventing uncontrolled spillage of the bolus into the pharynx. Liquids require minimal processing and are marginally diluted with saliva before swallowing. The airways remain open during this phase. Traditionally, the oral cavity was thought to be sealed posteriorly but this may not always be the case, as described in the following section.[3]

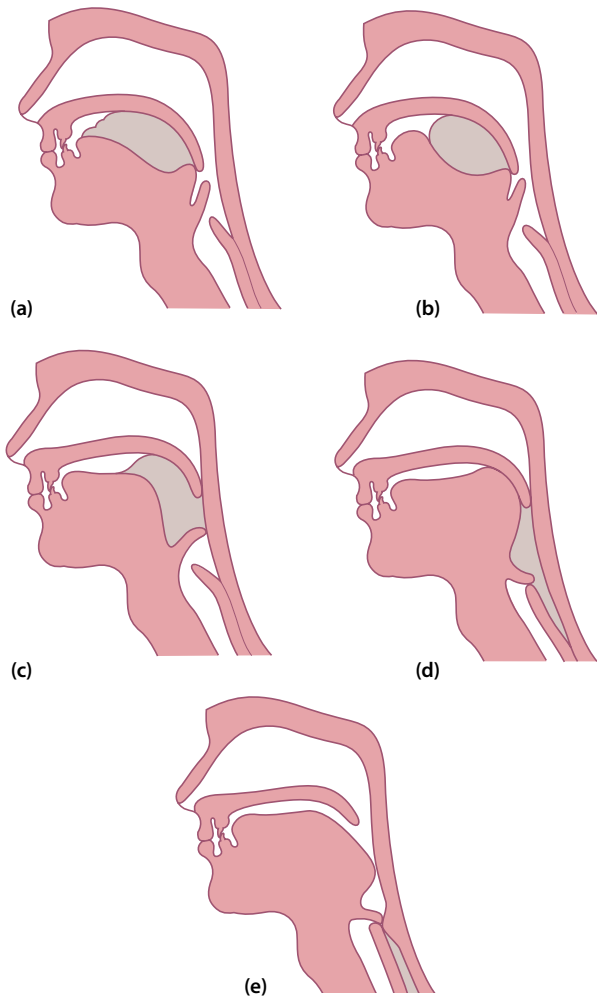

Figure 48.2 Oral and pharyngeal stages of a normal swallow: (a) oral phase, food is reduced and the bolus prepared; **(b)** the bolus is moved to the posterior part of the tongue; **(c)** the bolus contacts the trigger points in the oropharynx and the pharyngeal phase is initiated; **(d)** the bolus is moved past the closed larynx; **(e)** the bolus enters the oesophagus.

ORAL TRANSIT PHASE

The bolus is transported through the palatoglossal and palatopharyngeal arches into the oropharynx. The tongue is moved by the action of the intrinsic muscles together with the genioglossus elevating the tongue tip and blade of the tongue towards the hard palate. Orbicularis oris and buccinator remain contracted, keeping the lips and cheeks taut and the liquid central in the oral cavity. Liquid boluses are accommodated in a shallow midline gutter that forms along the dorsum of the tongue, probably as a result of the styloglossi and the genioglossi, aided by the superior longitudinal and transverse fibres of the intrinsic muscles.

A prerequisite for oral transit is mandibular elevation. Although the mouth does not have to be fully closed during swallowing, it is hard to swallow with the mouth more than a little open. The stabilization and elevation of the mandible is necessary for adequate lingual pressure generation. The proximity of the tongue to the palate helps to compress the bolus. The elevation and fixing of the mandible also assist the suprahyoid muscles in raising the hyoid bone. The elevation of the floor of the mouth is accompanied by lifting the tongue under the action of the stylohyoid. Simultaneously, the tongue is flattened, probably as a result of the contraction of the hyoglossus and some of the intrinsic lingual muscles, thus moving the bolus backwards. Patterns of lingual movement during swallowing can vary but, most commonly, the elevated, flattened tongue pushes the bolus against the hard palate, and the sides of the tongue seal against the maxillary alveolar processes, helping to move it posteriorly. The greatest amount of pressure appears to be generated by the anterior lingual segment.[4] Contraction of the styloglossus and mylohyoid completes the elevation of the back of the tongue. These tongue movements are simplified during sequential swallowing, as the frequency and speed of swallowing increase.[5] As the bolus reaches the back of the tongue, now deeply grooved, the soft palate is elevated by the levator and tensor veli palatini to protect the nasopharynx from the entry of food and to close the airways superiorly.

Oral phase for solids

When swallowing solid food, the process is slightly different. Food is mixed with saliva and reduced to smaller particles by the process of chewing. This can vary in duration considerably, from less than 1 second to as much as 10 seconds. When the bolus has been converted to a suitable consistency to be swallowed, it is transferred to the oropharynx, valleculae and posterior part of the tongue, where it may be retained for a few seconds prior to swallowing, sometimes referred to as ‘retrolingual loading’.[3]

During this time chewing can continue and the bolus is progressively added to, until a swallow is initiated and the pharyngeal phase begins. Thus, the oral preparatory, oral transport and pharyngeal phases overlap when solid food is being swallowed.

Chewing is essential to fragmenting solids, using a combination of shearing and compression forces. The mandible is moved by the action of the jaw elevators – the temporalis, masseter and medial pterygoid – and jaw depressors. Parotid salivary flow is increased in association with this action. The lips maintain a tight seal under the action of the orbicularis oris while the buccinator performs a similar function for the cheeks. In this way the sulci are closed, the vestibule normally remains empty, and any food that enters the vestibule is returned to the oral cavity proper. This, along with lateral and rotatory tongue movements, ensures that the food remains positioned under the occlusal surfaces of the molar teeth. Lateral and rotatory tongue movements ensure that the food is positioned under the occlusal surfaces of the teeth. Lingual forces will differ according to the physical properties of the bolus. These movements are cyclical in phase with movements of the jaw and hyoid bone. As the jaw is depressed, the tongue is also depressed and moves anteriorly. As the jaw is elevated, the tongue is retracted so that it no longer lies under the anterior teeth as they are brought together by jaw elevation. This helps to ensure that the tongue is not bitten during chewing.

It used to be thought that the soft palate was depressed throughout this phase, but it is now known that there is not a tight posterior seal and that the oral and oropharynx remain in communication.[6]

Pharyngeal phase

The pharyngeal phase begins at the point of the bolus leaving the oral cavity to enter the pharynx until it passes into the oesophagus. During this involuntary phase the respiratory and digestive streams cross and so it is important that this reflex behaviour occurs as automatically as possible to prevent blockage of the airways or aspiration into the lungs. As the bolus is moved back by the tongue to enter the pharynx, a sequence of events is initiated that ensures that the airways are protected during bolus transport. Diaphragmatic contraction is inhibited making simultaneous breathing and swallowing impossible under normal circumstances.[7] The nasopharynx is sealed off from the oropharynx by activation of the superior pharyngeal constrictor and contraction of a subset of palatopharyngeal fibres to form a variable, ridge-like structure (Passavant's ridge) against which the soft palate is elevated.

As the bolus enters the oropharynx and touches key trigger points, a patterned response is initiated in which the constrictors relax to dilate the pharynx, while the pharynx and larynx are raised by the longitudinal muscles. Solid boluses are propelled over the epiglottis by the action of the constrictors contracting in sequence. The larynx is then closed by contraction of the muscles of the laryngeal inlet, predominantly those of the aryepiglottic folds. The initiation of swallowing involves contact of the food with the palatoglossal and palatopharyngeal (faucial) arches or with the mucosa overlying the posterior pharynx in the region that is innervated by the glossopharyngeal nerve. Work conducted using simultaneous videofluoroscopy and endoscopy suggests that the 'trigger point' for this initiation may be the 'summation of afferent signals for the entire oropharyngeal sensory field', rather than a single point.[3] However, this may not be the case for the swallowing of secretions, as saliva may gather as deep as the piriform sinuses, until a critical mass is reached upon which a swallow response is triggered. Bolus properties may also influence this timing, for example, carbonated drinks or cold fluid temperature can reduce these latency times.[8] Bolus material is seen in the valleculae and even the piriform sinuses in 60% of liquid and 76% of solid swallows before the swallow is initiated.[3] This calls into question the term 'premature spillage' (where the bolus is viewed in the laryngopharynx prior to a swallow trigger) as an indicator of dysphagia. It is often said that, once the bolus of food has passed the palatoglossal and palatopharyngeal arches, swallowing becomes reflexive. While it is true that swallowing is automatic once initiated, many people can voluntarily delay their swallowing up to a certain point.

Lack of clarity exists around the precise temporal relationships of subsequent events involving movement of the food from the posterior part of the tongue into the oropharynx and airway protection. As the bolus is moved into the oropharynx, a reflex closure of the glottis is initiated in which there are preparatory movements of the vocal folds and the laryngeal inlet prior to a full closure of the larynx.[3] Endoscopic studies have shown that the first swallowing event is arytenoid movement towards the midline.[9, 10] These movements are even seen when the bolus enters the oral cavity.[10] More commonly, the true vocal folds achieve maximal closure prior to laryngeal elevation, but for some the glottis may not be fully adducted until elevation is complete.[10] Furthermore, it appears there may be variance from person to person and from swallow to swallow, with a range of laryngeal closure duration from 0.31 seconds to 1.07 seconds.[11] Events may alter according to bolus consistency and the nature of the swallow. For example, during sequential swallowing of drinks, some individuals retain an elevated laryngeal position; others demonstrate a pattern of laryngeal 'bobbing' with the larynx semi returning to a resting position between swallows. Apnoea onset occurs approximately 0.19 seconds prior to the elevation of the larynx.[7] A completely sealed larynx requires full adduction of the vocal folds and hence glottic closure by medial movement of the arytenoid cartilages. This is achieved by the combined efforts of the thyroarytenoid, interarytenoid and lateral cricoarytenoid muscles. The ventricular folds approximate, tensing of the edges of the laryngeal opening and lowering of the epiglottis.[7]

The bolus enters the pharyngeal space, which is widening as it is raised, said by some to resemble the engulfing of prey by a snake.[2] This is partly due to the relaxation of the pharyngeal constrictors and partly to the anterior

movement of the pharynx as the hyoid bone is drawn forward under the elevating action of the suprahyoid muscles. It is thought that the geniohyoid is largely responsible for displacing the hyoid anteriorly, and the mylohyoid superiorly.[12] Laryngeal elevation also occurs as the suprahyoid muscles move the hyoid bone anteriorly, contributing to pharyngeal dilation. Raising the larynx narrows the laryngeal inlet, moving it towards the pharyngeal surface of the epiglottis as the laryngeal cartilages move anteriorly, tucking under the bulge of the posterior tongue, i.e. out of the path of the bolus. This action helps to expand the hypopharyngeal space and relax the cricopharyngeal sphincter, which is also raised by several centimetres. The bolus moves into the oropharynx, contacting the epiglottis, which then moves downward. This movement is usually described as occurring in two distinct stages, with the first bringing the epiglottis from a vertical to a nearly horizontal position and the second moving the upper third of the epiglottis to below the horizontal to cover the narrowed laryngeal aditus. The precise contribution of active and passive mechanisms to this two-phase closure is unclear. Some authors state that both actions occur passively due to movements of adjacent structures and forces generated by compression of the pre-epiglottic adipose fat pad, and within the ligamentous attachments of the epiglottis, or by a combination of the two.[13, 14] Others claim that the second epiglottic movement is generated actively by the action of the thyroepiglottic and hyoepiglottic muscles.[15] In favour of an entirely passive mechanism, it has been claimed that these muscles are too sparse to generate adequate force and that some of their attachments are not consistent with such an action.[14] Throughout this stage of swallowing, respiration remains suspended.

As the food passes over the posterior part of the curved epiglottis, it is diverted into the lateral food channels and the piriform fossae. Evidence has shown that solids tend to go straight over the epiglottis, while liquids are diverted laterally. This is possibly a characteristic of bolus properties rather than swallow biomechanics.[3] Multiple swallowing post-bolus is often classed as a sign of impairment. Clearance swallows occur in the healthy population even with water, more so with older adults.[16]

The true and false folds guard the entrance to the airways with the true vocal folds adducted to prevent ingress of foreign bodies. The protective cough reflex can then be used to remove the object. This strong expiratory airflow is assisted by abdominal muscles and compression of the lungs.

The pharynx constricts behind the bolus as the superior constrictor muscle contracts. The bolus is carried down the pharynx by a coordinated peristaltic wave in which the three constrictor muscles contract in the appropriate sequence, driving the bolus towards the oesophagus. The head of the bolus moves faster than the wave of the pharyngeal contraction suggesting that the kinetic energy imparted to the bolus as it is expelled from the mouth may be sufficient to carry it through to the pharynx. The tongue driving force is a positive pressure that squeezes the bolus towards the laryngopharynx. It is generated by the upward movement of the tongue pressing the bolus against the contracting pharyngeal wall and requires a tight nasopharyngeal seal. A hypopharyngeal suction pump is caused by the elevation and anterior movement of the hyoid and larynx, which creates a negative pressure in the laryngopharynx, drawing the bolus towards the oesophagus, aided by a more negative pressure inside the oesophagus. The pharyngeal constrictors generate a positive pressure wave behind the bolus. Their sequential contraction may facilitate clearance of any pharyngeal wall or piriform sinus residue.

At the end of this phase, the bolus is propelled towards the cricopharyngeal sphincter. At rest, this sphincter is closed by active contraction. Prior to the bolus arriving and the sphincter opening, the cricopharyngeus relaxes. The sphincter is then opened actively by the combined action of the suprahyoid muscles in moving the larynx anteriorly and superiorly and passively by pressure from the arriving bolus.

Oesophageal phase

The oesophageal phase begins after the relaxation of the cricopharyngeal sphincter has allowed the bolus to enter the oesophagus. This is a true peristalsis in which a relaxation in front of the bolus and a constriction behind the bolus move it towards the stomach. Sequential waves of contractions of the oesophageal musculature subsequently propel the bolus down to the lower oesophageal sphincter, which opens momentarily to admit the bolus to the stomach.

Swallowing timings

The timings of the stages of swallowing have been extensively investigated. Once the food is of a suitable consistency to swallow, transit from the mouth to the oropharynx takes 1–2 seconds, with up to a further second for the bolus to traverse the pharynx to the cricopharyngeal sphincter. The bolus then passes through the oesophagus to the stomach. The time taken for oesophageal transit has been estimated by a variety of techniques. Healthy oesophageal clearance time for a single swallow is estimated at 10–15 seconds,[17, 18] although a shorter time of 3 seconds is needed for liquids.[2] In the preparatory stage, it is unclear what determines when the bolus is to be moved into the oropharynx. An important factor is likely to be bolus consistency as sensed by mechanoreceptors in the oral cavity. The sensory control of swallowing will be discussed below under ‘Neural control’.

NEURAL CONTROL

Neural control of the complex activity of healthy swallowing involves a number of different regions of the central nervous system (CNS). In common with all complex motor behaviours, swallowing is organized and coordinated by a hierarchical series of structures within the brain.

This extends from the motor neurons within the motor nuclei of the brainstem and spinal cord (for ventilation) up to the cortex. The act of swallowing, as with all movement, is regulated by sensory feedback, although the importance of this has only been fully recognized relatively recently.[19] There are probably still some areas of the CNS involved in swallowing that remain to be identified but there is a consensus as to the main regions involved. The initiation of swallowing is normally characterized as being either a voluntary act (volitional swallowing) or a reflex (reflexive swallowing) as the result of stimulation of the appropriate mucosa in the oral cavity. This might occur during saliva accumulation or by the presence of food or liquid. However, it is now recognized that this distinction is not absolute. During mastication, for example, a volitional act, the encountering of a hard object will cause mastication to cease, suggesting a continuum of control between the purely volitional and purely reflex components of swallowing.[20] Although there may be a continuum because of the fact that, as swallowing is partly a reflex activity and partly voluntary, its neural control is divided between two major regions of the brain: the cerebral cortex and the brainstem. Studies have shown that several regions of the cortex contribute to the voluntary control of swallowing. It is also recognized that, as with any voluntary movement, the movements of swallowing are also regulated by the basal ganglia and the cerebellum.[21, 22] Due to the close anatomical and physiological relationships between swallowing, ventilation and mastication, there is also extensive overlap in the brainstem areas controlling these functions. There is an absolute requirement that neural control of these various processes ensures that they are coordinated.

The cortical control of swallowing involves projections to numerous groups of motor neurons. The areas of the cortex that have been most frequently cited as being involved in the control of swallowing include the primary motor and sensory cortices, premotor and supplementary cortices, posterior parietal cortex, cingulate cortex (especially the anterior cingulate gyrus) and the insula and frontal operculum.[23] Corticobulbar projections to motor nuclei controlling muscle groups are bilateral but, in the case of projections controlling pharyngeal muscles, asymmetric so that one can speak of a swallowing dominant hemisphere. As is the case for speech, this asymmetry is not related to handedness but it is the left hemisphere that is usually stated as being swallowing dominant though not with the same high frequency as speech.[24, 25]

Within the cortex, evidence suggests that the frontal swallowing centre is organized somatotopically with different regions controlling different stages of swallowing. This is substantiated by studies employing transcranial magnetic stimulation of the frontal swallowing centre.[24] These studies show that the lower precentral gyrus and posterior inferior frontal gyrus control the oral phase of swallowing. The voluntary initiation of swallowing (oral phases, see above) involves bilateral areas of the prefrontal, frontal and parietal cortices. These include the face areas of both the primary sensory and motor cortex, as well as the prefrontal swallowing areas which are located just anterior to the face region of the precentral gyrus in the primary motor cortex, corresponding to Brodman's area. Stimulation here produces swallowing activity in the appropriate muscles of the oral cavity, pharynx, palate and larynx.[26] Volitional swallowing also activates the cingulate cortex, anterior cingulate gyrus, supplementary motor cortex and insula just prior to the onset of the swallow. It has been proposed that activity in these regions prior to the swallow occurring controls the initiation, including motivation to swallow, and planning of the act of swallowing.[23]

Reflexive swallowing (see 'Pharyngeal phase' above) is thought to involve primary motor cortex, premotor cortex and areas of sensorimotor cortex within the parietal lobe.[27, 28] In most people, swallowing control is asymmetrical with the projection from one hemisphere being larger than the other. It has been hypothesized that this explains both the prevalence of swallowing problems following stroke and the recovery that occurs in most patients over a period of weeks. Damage to the hemisphere that is the source of the greater projection to the swallowing structures in the brainstem would account for the initial difficulty. Recovery then occurs as the intact projection from the undamaged hemisphere is reorganized.[29]

It can be seen that both volitional and reflexive swallowing involve the primary sensory and primary motor cortices consistent with the role, more generally, of these cortical areas in the control of fine distal motor movement. As might be expected, sensory feedback is needed to control swallowing, just as would be the case for any other movement.[19] The satisfactory execution of swallow needs to take account of the properties of the bolus being swallowed such as its size, texture and consistency. These properties are relayed to the primary sensory and motor cortices during the reflexive phase where they influence the intensity and speed of pharyngeal muscle contraction to ensure that the bolus is safely moved through the pharynx and on to the oesophagus.[30, 31] This role of the motor and sensory cortex in controlling force of contraction of muscles is consistent with what has been observed in other volitional movements.

The inference from animal studies is that the control of swallowing is bilateral, but in humans the organization of corticobulbar projections from the cortex to the relevant motor nuclei appears more complex. Cortical projections to the muscles of the larynx, pharynx, palate and upper face are bilateral while projections to other muscles can be either unilateral or bilateral.[32]

Other cortical areas that have been implicated in swallowing include the frontal operculum, the orbitofrontal cortex and the superior temporal gyrus.[24] The insula lies deep to the lateral fissure and is covered by the operculae of the frontal, parietal and temporal lobes and strokes here can induce dysphagia.[33] In addition to its role in swallowing as outlined above, taste is also represented in this region. It has been suggested that the insula may be involved in integrating the taste of a swallow with the movement of swallowing. The superior temporal gyrus has also been identified as a possible region of the cortex involved in integrating taste, but also food imagery, with swallowing.[34] This suggests that cortical control of swallowing

is hierarchical, with precentral areas of the cortex being influenced by deeper and more caudal centres.[24]

Cortical control of movement is regulated by reciprocal projections between the cortex and basal ganglia and between the cortex and the cerebellum. It is becoming evident that these regions of the brain also play a part in the control of swallowing. The evidence that this is the case in humans comes mainly from investigations of swallowing disorders in disease. Connections pass from cortical regions through the basal ganglia and back to the cortex via nuclei in the thalamus in the form of a series of recurrent loops. The basal ganglia were first recognized as having a role in movement because of the very obvious movement disorders that occur in basal ganglia disorders such as Parkinson's disease. However, it is now recognized that the basal ganglia regulate many other aspects of cortical function. Disorders of the basal ganglia affecting movement can be characterized as hypokinetic, with too little movement (e.g. in Parkinson's disease), or hyperkinetic, with too much movement (such as in Huntington's chorea). The effects of Parkinson's disease upon swallowing are consistent with its effects upon movement generally, with hypokinetic tongue movements that impair transport of food into the pharynx, poor bolus formation and poor pharyngeal transport including slower laryngeal movements.[21] The cerebellum also has reciprocal connections with the cerebral cortical regions controlling movement and functions to monitor executions of movements and act as an error detector. Though there are relatively few investigations into the occurrence of dysphagia in cerebellar disease and the results are inconclusive, it would appear that the cerebellum does play a part in motor control of swallowing.[22]

The cortex is crucial in the voluntary initiation of swallowing and integration with movements of the face and associated structures. However, cortical structures are not essential for a coordinated swallow, which can occur in the presence of significant brain damage in these regions. There are important areas within the brainstem necessary for the control of swallowing and these are located particularly within the medulla. Descending pathways project to these medullary swallowing centres from the frontal swallowing areas within the cortex. These probably include pathways in both the dorsolateral and ventromedial descending systems through the ventral and lateral corticobulbar tracts. Whether swallows are volitional or reflexive, the pattern of the swallow is similar because it is the brainstem that executes the patterns of swallowing movements in both cases.

Most of our knowledge of the role of these regions in swallowing control comes from experimental studies in animals. The results of these studies clearly have limitations when one attempts to apply them to humans.[35] Within the medulla there are a number of neuron groups involved in the control of swallowing.[36] Swallowing is initiated by touch sensation or pressure from the liquid or food within the posterior part of the oral cavity, epiglottis or oropharynx. Thus, the nuclei receiving afferent input from these regions, which include the nucleus tractus solitarius and the spinal trigeminal nucleus, are very important. Afferent input from the jaw, muscles of mastication, lips and tongue is also essential to the control of swallowing, not just during the pharyngeal phase as outlined above but also during the oral phase. The oral cavity contains an unusually high concentration of mechanoreceptors. These protect delicate tissues from the high forces generated during mastication, to trigger the reflex and to sense the size and consistency of the bolus, also as part of the trigger mechanism.

The efferent pathways from the medulla and pons to the muscles involved in swallowing involve several cranial motor nuclei. The most important are the nucleus ambiguus for the muscles of the palate, pharynx and larynx, the hypoglossal nucleus for the muscles of the tongue, and the motor nuclei of the trigeminal and facial nerves for the muscles of the jaws and lips. In addition, motor neurons within the cervical spinal cord control the muscles of the neck including the infrahyoid muscles.

Between these input and output pathways are interposed two main groups of neurons that appear to be essential for the coordination and regulation of swallowing by the medulla. The first lies in the dorsal region of the medulla above the nucleus of the solitary tract. A second group lies more ventrally around the nucleus ambiguus. These two neuronal groups are sometimes referred to as the lateral and medial medullary swallowing centres. A variety of evidence, much of it emanating from the laboratory of Jean,[37] supports the view that these two neuronal groups are vital in the control of swallowing. The dorsal group would appear to be the site of convergence of sensory input from the various nuclei and is probably important in the sequencing of swallowing. The ventral group distributes outputs to the various cranial nerve motor nuclei. Outputs from this region are not simply excitatory. In any reflex system, excitation of agonist muscles and their synergists will be accompanied by inhibitory outputs to the corresponding antagonist muscles.

The correct sequencing of events for healthy swallowing is thought to be controlled by a central pattern generator (CPG).[37] CPGs are groups of neurons capable of generating outputs that will ensure the basic sequencing of a movement in time and space in terms of the muscle contractions needed for automatic movements such as swallowing, ventilation and locomotion.[38] The action of many CPGs is based upon pacemaker-type activity of a subset of neurons that is responsible for the initiation of the rhythmic activity.[38] In this respect, swallowing is similar to ventilation, and both of these motor behaviours are linked to masticatory movements.[39] Given the close relationship between swallowing and ventilation, it seems to be inevitable that there will be central coordination of these processes. The idea of a central mechanism coordinating and regulating respiration and swallowing was first hypothesized over 30 years ago.[40] The exact neural organization is still unclear[41] and is one of the many areas for further investigation for a fuller understanding of the control of swallowing.

RESPIRATION AND SWALLOWING

The act of swallowing involves a crossing of the stream of liquid and food with that of breathing and this occurs within

the pharynx. This crossing of the alimentary and ventilatory streams is an evolutionary consequence of the transition in vertebrates from sea to land living. A variety of mechanisms have evolved to ensure that, during normal swallowing or vomiting, no material can be aspirated into the lungs through the larynx. Aspiration can have serious consequences, such as asphyxiation caused by airway blockage, or occult aspiration with resultant complications, although recent work has shown that aspiration can occur, although rarely, in the absence of a swallowing problem.[42, 43]

Respiration and swallowing are inextricably linked, finely coordinated and are under tight neural regulation (see above). Efficient transport of food and drink to the oesophagus has to co-occur with maintenance of a safe airway and prevention of material entering the lower respiratory tract (**Figure 48.3**). The main sphincteric mechanisms protecting the airways are the soft palate, guarding the pharyngeal isthmus, and those guarding the laryngeal aditus. There appears to be an individual swallowing respiration pattern that matures in the teenage years and is remarkably consistent thereafter.[45] Even following laryngectomy, where there is no risk of aspiration, breathing continues to be suspended during a swallow.[46] Furthermore, the length of breathing suspension appears to be longer in this case group, which is thought to be associated with longer pharyngeal transit times, compared to individuals with a larynx.[47]

Figure 48.3 Aspiration into the upper trachea. Reproduced by permission of the BMJ Publishing Group from Leslie et al.[44]

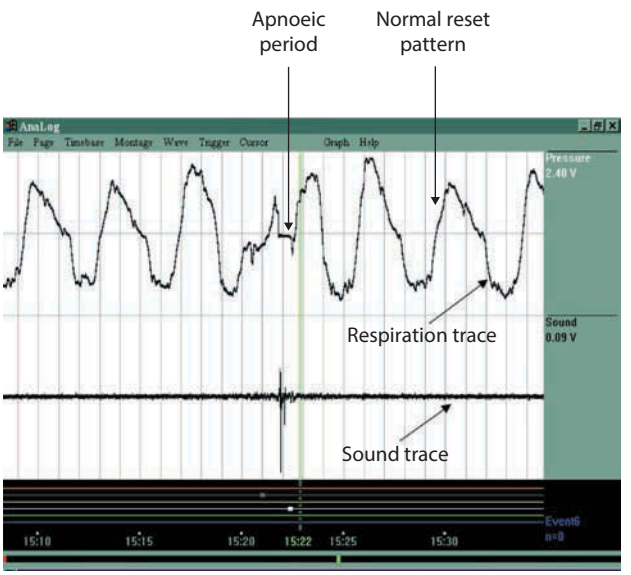

Figure 48.4 Swallow apnoea.

Swallow apnoea

Despite these methodological caveats, some general principles emerge. Clearly, ventilation has to be suspended during pharyngeal transit of the bolus (**Figure 48.4**). This is known as the period of swallow apnoea and is typically less than 1 second in length, corresponding to the duration of the reflex part of the swallow in its pharyngeal phase.[48, 49] The duration of apnoea increases with larger bolus volumes.[45] The effect of bolus consistency is less clear. There is evidence to suggest that solids increase apnoeas with the onset preceding the actual swallow, due to the risk posed by retrolingual loading,[50] but sample numbers are too small to be unequivocal.[49] Gender effects are conflicting, with men having longer durations due to differences in structure[51] and women having longer durations linked to increased cricopharyngeal opening.[45]

Phase of respiration when swallowing occurs

Swallowing tends to occur during the expiration phase of respiration. Expiration on swallowing is longer in duration, compared with quiet respiration.[52, 53] Expiration occurs after 80–100% of healthy swallows.[51, 54, 55] This is likely to be a protective mechanism, as any material left in the laryngeal vestibule post-swallow will be moved to the pharynx rather than sucked into the lungs. The diaphragm is responsible for a downward pull on the trachea and therefore the larynx. On the expiratory phase, at mid to low lung volume, this pull reduces, decreasing resistance and enabling the larynx to elevate during swallowing.[56]

Post-swallow inspiration is more common in populations with impaired swallowing.[55, 57] Furthermore, respiratory disorders such as chronic obstructive pulmonary disease (COPD) can compromise this phase regulation necessary for safe swallowing.[58] Much of the research on the respiratory–swallowing pattern is based on small single boluses of less than 10 mL. This pattern appears to alter with larger boluses, with a greater number of swallows occurring during the inspiratory phase[59] and require a greater lung volume than smaller boluses.[60]

TASTE

Taste buds are the receptors for taste and are located on the surface of the tongue, soft palate and epiglottis.

Each taste bud contains approximately 50–100 cells and has a life span of 10–14 days, and they are under constant regeneration.[61] They mature into one of three types of taste cell: type I detects salt; type II sweet, bitter and umami; and type III sour.[62] Saliva facilitates the movement of taste molecules to the taste bud and its composition is important for taste perception. Taste-related impulses are transmitted via the facial, glossopharyngeal and vagus nerves to the olfactory area of the cortex. The biomechanical swallowing response can alter with different taste flavours. For example, a sour bolus (e.g. lemon juice) may increase oral tongue pressures and tongue-to-palate contact times, although some dispute this.[63, 64] Furthermore, a sour bolus seems to have a longer transit and clearance duration in the distal oesophagus.[65, 66]

AGE EFFECTS

Infancy

In infancy, the anatomical relationships of the tongue, mandible and hyoid bone are much closer, requiring a highly coordinated pattern of suckle–swallow and respiration. Newborn feeding is primarily reflexive, and is dependent on a rooting reflex to latch on to a nipple or teat. Suckling requires the generation of intraoral pressure via lip seal around the source and the posterior tongue moving towards the soft palate. On average, infants generate two to seven tongue pumps per swallow.[67] Jaw movement creates an external pressure on the nipple or teat, encouraging liquid flow into the oral cavity. Swallow apnoea is mainly attributed to the larynx tucking under the tongue base and the arytenoids tilting forwards. Complete epiglottic inversion is not consistently present up until the age of 5 years.[68] From 0–5 months biting is an immature upwards mandible movement. The oral preparatory phase becomes more refined with the maturation of the oral cavity. Preliminary chewing begins with introduction of a more textured diet around 4–6 months. At approximately 1 year, the infant is more able to use grinding chewing movements, which continues to mature up to the age of 16.

Presbyphagia

Presbyphagia is defined as normal age-related changes in swallowing in healthy adults. Sarcopenia is the term used to describe the age-related decrease in muscle mass, strength and coordination. As a consequence of this process, older people have generally weaker oral phase movements, including reduced tongue strength.[69] Although still able to achieve adequate lingual pressures for swallowing, these pressures are generated more slowly than in younger people.[70, 71] Loss of dentition is common, reducing the number of opposing dental units for biting and grinding. Ill-fitting dentures may further hamper the oral preparatory phase. Changes to smell and taste also occur as part of the ageing process, impacting on the pleasure of eating and appetite. The pharyngeal phase is often longer in duration, with prolonged hyolaryngeal excursion. The pharyngeal wall can thin over time, creating a larger vault at rest, consequently reducing maximal constriction and pharyngeal pressure generation.[72–76] Sensory changes may account for a slower swallowing response time.[70]

Breathing and swallowing coordination may also decrease with age, with overall longer periods of apnoea. The combination of these changes may account for the higher incidence of laryngeal penetration of fluids in older individuals.[77, 78] Cricopharyngeal sphincter opening times are longer in duration. There is also a higher incidence of cricopharyngeal bars, which can impede bolus flow.[79] Overall, swallowing transit times are longer, but mean differences between younger and older age groups are small.[75, 76]

WHAT CONSTITUTES THE NORMAL SWALLOW?

Much of the data on the swallowing process comes from observations of populations with impaired systems. Studies of healthy groups are often of small numbers with young age ranges and many of the difficulties in swallowing are linked to age or age-related diseases. As more information emerges, the performance envelope of what constitutes 'normal' is growing. The process of swallowing a series of controlled volume and/or consistency boluses ('command swallows') does not equate with that of eating a meal.[6] When evaluating reports, the reader needs to be clear about age, sex, bolus type and other variables. It is clear that there is uncertainty and some scope for variation in the normal swallow.

KEY POINTS

- Swallowing is a cyclical and irregular process, not a stepwise progression.
- Healthy swallowing has a wide range of parameters.
- Neural control is divided between the cortex and the brainstem.
- Cortical control of swallowing is bilateral, although one hemisphere is usually dominant.
- Airway protection is activated in advance of the pharyngeal stage of swallowing.
- Impaired respiration patterns will affect swallowing and vice versa.

CHAPTER 49

CAUSES AND ASSESSMENT OF DYSPHAGIA AND ASPIRATION

Helen Cocks and Jemy Jose

Introduction 769
Causes of dysphagia and aspiration 769
Assessment of dysphagia and aspiration 775
References 779

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: dysphagia, aspiration and swallowing, with focus on aetiology and diagnosis.

INTRODUCTION

Dysphagia

Dysphagia is a term used to describe difficulty with swallowing solids, liquids or both. It implies impairment of one or more of the phases of swallowing. Dysphagia usually arises as a complication of another health condition. It can be divided into oropharyngeal (high) dysphagia and oesophageal (low) dysphagia.

Dysphagia is common, with epidemiologic studies suggesting that as many as 22% of the population over the age of 50 are affected.[1, 2]

Aspiration

Aspiration is the entry of food or liquid into the airway below the true vocal folds.[3] It may be due to incompetent or inadequate airway protection, ill-timed, uncoordinated events before, during or after the swallow has triggered.[4] Silent aspiration is defined as foreign material entering the trachea or lungs without an outward sign of coughing or attempts at expulsion.

The link between aspiration and aspiration pneumonia remains elusive. Although an association has been identified in stroke patients there are no such data available in head and neck cancer (HNC) patients. In general, aspiration should be kept to a minimum but no clear guidelines exist as to the amount of aspiration that can be tolerated by patients with dysphagia. In a study looking at a mixed group of neurological and HNC patients, only 25% had a history of pneumonia despite over 50% presenting with aspiration.[4] Additional factors may need to be present for pneumonia to develop, such as poor oral hygiene, immobility,[5] neutropenia[6] and malnutrition.

Aspiration pneumonia has been shown to be the most common cause of mortality during hospital admission,[7] followed by nosocomial infections.[8] Prolonged, repeated aspiration of small amounts of material and chronic chest infections has been associated with the development of interstitial pulmonary fibrosis.[9] Diffuse alveolar scarring can occur across a period of time, reducing the ability of lung tissue to transfer oxygen to the bloodstream.

CAUSES OF DYSPHAGIA AND ASPIRATION

Dysphagia can be associated with anatomical, neurological, muscular or psychological causes, with aspiration often developing secondary to dysphagia. This section does not provide exhaustive coverage of possible causes but considers those causes more commonly seen in practice.

Congenital

Most patients present in the paediatric age group, though some may present later in life.

CLEFT LIP AND PALATE

Cleft lip and palate is often associated with nasal regurgitation. The child is unable to suck due to an inadequate seal within the oral cavity resulting from

the lip/palatal defect. This condition is usually picked up intrauterine or at routine neonatal examination soon after birth; however, mild variants of the condition can have a delayed diagnosis.

CEREBRAL PALSY

Cerebral palsy can cause significant oral muscular incoordination resulting in dysphagia, drooling and aspiration as saliva and food pools in the anterior floor of mouth and fails to trigger the pharyngeal phase of swallowing. Assessment involves clinical evaluation of swallow with videofluoroscopy (VF) in cases where there is concern about aspiration. Treatment options include speech therapy or physiotherapy measures, improving posture and relocation of submandibular ducts. Enteral feeding may be required in some patients.

VASCULAR RINGS

Vascular rings around the oesophagus due to malformation of great vessels, usually due to aberrant subclavian artery, double aortic arch or anomalous left pulmonary artery, can cause dysphagia. Extrinsic compression is noted on barium swallow and computed tomography (CT) angiography or magnetic resonance angiography (MRA) is diagnostic.

ATRESIS, CLEFTS AND FISTULA

Laryngeal clefts, tracheoesophageal fistula and oesophageal atresia all present with both dysphagia and airway difficulties depending on the type and severity of the condition. Diagnosis is made at endoscopy.

CONGENITAL VOCAL CORD PALSY

Congenital unilateral vocal cord palsy usually presents with a hoarse cry. There can be swallowing difficulties and aspiration during feeding. Diagnosis is made on endoscopy.

Infective

Infections of the oral cavity, larynx, pharynx and neck spaces can present with dysphagia. These are covered elsewhere in the book (see Chapter 69, Acute infections of the larynx; Chapter 51, Pharyngitis; and Chapter 40, Neck space infections)

Inflammatory

GASTRO-OESOPHAGEAL AND LARYNGOPHARYNGEAL REFLUX

The most common inflammatory process that causes dysphagia occurs secondary to gastro-oesophageal reflux disease (GORD).

GORD can result in erosions, ulcerations and even stricture formation in the lower oesophagus, which cause dysphagia and even food bolus impaction.

Dysphagia and other throat symptoms are also seen with laryngopharyngeal reflux (LPR), which can present with subtle laryngeal findings of erythema and oedema of posterior larynx; however, a recent systematic review has shown poor sensitivity and specificity for these findings, with many being seen in 64–93% of healthy subjects'[10] laryngoscopy findings. Flexible oesophagoscopy, 24-hour pH monitoring and oesophageal manometry studies often aid in making the diagnoses. GORD is discussed in greater detail in Chapter 53, Oesophageal diseases, and LPR in Chapter 77, Reflux disease.

PATTERSON–BROWN–KELLY SYNDROME

Patterson–Brown–Kelly syndrome is the association of dysphagia with atrophic gastritis and iron-deficiency anaemia. It affects mainly middle-aged and elderly women. The dysphagia is due to hyperkeratinization with web formation in the postcricoid region and can be seen on barium swallow, but it may not always be found at rigid endoscopy. The dysphagia and the hyperkeratinization are treated with iron replacement, but the web may need dilatation. The condition is associated with the development of postcricoid carcinoma in a small percentage of patients. Other features of iron deficiency anaemia – smooth tongue, angular stomatitis and koilonychias – may be seen.

EOSINOPHILIC OESOPHAGITIS

Eosinophilic oesophagitis (EoO) is an emerging condition characterized by oesophageal symptoms and infiltration of the oesophageal epithelium with eosinophils for which no other cause can be found. Other causes of eosinophilia need excluding and these include GORD, infection, malignancy, collagen vascular disease and inflammatory bowel disease (IBD). The condition has yet to be fully understood but it is thought that food allergy plays a large role in its development.

It was originally thought to be a form of GORD and a paediatric condition, but it is now known to be most common in middle-aged men. It is most frequently seen in Caucasians and has predominance in developed countries. Prevalence of EoO has increased in the last decade but this may be due to better understanding and detection. A community study in Sweden reported a prevalence of 4 in 1000 in 2016.[11] The British Society of Gastroenterology has set up a national registry.

Presenting symptoms of EoO can vary according to the age of the patient. In children, presentation is with failure to thrive and food refusal. Adolescents can have other symptoms such as chest/epigastric pain and vomiting and in adults symptoms can be of dysphagia, odynophagia and heartburn. Often adults present with food bolus obstruction.

Investigation is with gastroscopy and biopsy, and diagnosis is made on the finding of more than 15 eosinophils per high-powered field at microscopy. Allergy testing with RAST can be helpful in identifying allergens.

Management of EoO involves modification of diet. In severe situations, this involves exclusion of six predominate

food groups (wheat, dairy, fish, eggs, soy and peanuts) and the introduction of an elemental diet to allow improvement. Once improvement is seen at biopsy, food groups can be gradually reintroduced and the effect again judged by mucosal response at biopsy.

Other treatment is with topical steroids, a fluticasone or budesonide inhaler sprayed into mouth and swallowed dry with avoidance of eating and drinking for 30 minutes. A side effect of this is candidiasis.

Gold-standard monitoring of the condition is serial gastroscopies. Absolute blood eosinophil count has been found to correlate significantly with oesophageal eosinophil density and there is some evidence for use of absolute blood eosinophil level as a marker of disease.[12]

Stricture formation can occur as a complication of the condition and dilatation may be required.

SYSTEMIC AUTOIMMUNE DISORDERS

Systemic autoimmune disorders[13] are associated with dysphagia in a large proportion of cases, though the mechanism differs between disease groups. Diagnosis of this group of conditions is based on the clinical picture and autoantibody profile. Control of the disease with steroids and immunosuppressive drugs does not usually improve the dysphagia.

Scleroderma and 'CREST' syndrome

Scleroderma and 'CREST' syndrome (calcinosis, Raynaud's, oesophageal involvement, sclerodactyly, telangiectasis) are progressive disorders of connective tissue. Smooth muscle cells are replaced by collagen fibres, resulting in fibrosis. Anti-nuclear antibodies and anti-centromere antibodies are raised in this condition. The lower oesophagus is often affected, resulting in poor peristalsis, severe GORD with stricture formation and Barrett's oesophagus.

Systemic lupus erythematosis

Systemic lupus erythematosus (SLE) is a progressive systemic inflammatory disease involving skin, joints and internal organs that can affect the oesophagus and can cause oral mucosal ulcerations. The dysphagia tends to be mild.

Dermatomyositis

Dermatomyositis is a diffuse inflammatory condition affecting skin and skeletal muscle associated with underlying malignancy in a high percentage of patients. Dysphagia is seen in up to a third of affected patients and may be secondary to hypopharyngeal and upper oesophageal involvement. It usually presents with symmetrical proximal muscle weakness and skin changes. Diagnosis is made by a muscle biopsy.

Pemphigus, mucosal pemphigoid and epidermolysis bullosa

These conditions are characterized by blistering, either subepidermal (pemphigus) or submucosal (mucosal pemphigoid and epidermolysis bullosa). The oral cavity, pharynx and oesophagus can be involved, leading to scarring and stricture. Diagnosis is made by skin biopsy showing typical antibodies with direct immunofluorescence. Contrast swallow can have a characteristic appearance. There is often a good response to steroids.

Sjögren's disease

Sjögren's disease causes dysphagia due to xerostomia. Anti-Ro (SS-A) antibody levels are raised in 70% of cases and anti-La (SS-B) in 40%. However, a negative blood test does not exclude the condition. Biopsy of the minor salivary glands of the lip will show lymphocyte infiltration and aid the diagnosis.

Traumatic

FOREIGN BODY/FOOD BOLUS OBSTRUCTION

A foreign body in the pharynx or oesophagus is the most common traumatic cause of dysphagia. Patients often present with accompanying drooling. It is important from the history to determine whether it is a sharp foreign body or a soft food bolus obstruction.

A variety of foreign bodies are ingested by children and patients with learning difficulties, the most common being coins. The size and shape of the foreign body will dictate where it lodges, but common sites are the cricopharyngeus, at the level of the aortic arch and at the cardia.

Food bolus obstruction from large pieces of meat (with or without bone) is not uncommon, particularly in those who cannot or do not chew well and in patients with oesophageal stricture. Patients present with painful dysphagia and, if obstruction is complete, there will be drooling of saliva. Laryngoscopy may confirm pooling of saliva. Neck examination may reveal subcutaneous emphysema if pharyngeal or oesophageal perforation has occurred. A lateral soft-tissue radiograph of the neck shows loss of natural lordosis of the C spine, widening of the prevertebral space and often an air bubble in the oesophagus. A radio-opaque foreign body may be seen. Urgent rigid or flexible endoscopy might be required if the foreign body does not pass spontaneously and with sharp foreign bodies. If perforation is suspected, it may be necessary to perform a contrast swallow with a non-ionic contrast, which has the added advantage of not interfering with subsequent oesophagoscopy as it is clear.

CAUSTIC BURNS

Burns due to accidental or deliberate ingestion of acid or alkaline substances cause dysphagia. Initial oedema and ulceration can result in stricture formation and perforation.

HEAD, NECK AND SPINAL TRAUMA

Trauma to the head and neck, chest or cervical spine may be accidental or iatrogenic and may involve blunt trauma, penetrating injuries or compression effects or

a combination of these. Neck injuries may disrupt the swallowing mechanism directly or indirectly by affecting the cranial nerves IX to XII. This is discussed in greater detail in Chapter 38, Neck trauma. Head injuries can produce a variety of neurological defects resulting in paresis, paralysis or loss of coordination of the swallowing mechanism, which may not become apparent until the patient resumes consciousness, starts feeding again and aspiration results.

Neoplastic

Both benign and malignant tumours may cause dysphagia either by mechanical obstruction, intra- or extraluminal, or due to neuromuscular invasion. A number of studies have shown that the severity of dysphagia and its complications depend on tumour size and site.[14–20] One study showed that 50.9% of patients with pharyngeal tumours had dysphagia at presentation compared with 28.6% of patients with laryngeal tumours and 28.2% with oral lesions of stage T2 or more.

In the oral cavity, most tumours are malignant and of these 95% are squamous cell carcinomas (SCCs). The patient may present with a lump in the mouth or with an ulcer that may result in odynophagia. Dysphagia can be caused by tongue fixation. In the oropharynx, most malignant tumours are squamous cell in origin. Dysphagia is often due to pain but involvement of the tongue base and/or soft palate can result in problems with tongue fixation and regurgitation respectively. The tumour is often seen on examination. In the hypopharynx, rare benign tumours such as leiomyomas, lipomas and fibrolipomas can be found which cause dysphagia. The majority of tumours, however, are SCCs, with 60% occurring in the piriform fossa. Large tumours can cause significant swallowing problems with alteration of diet to softer textures. Weight loss is not uncommon and symptoms of aspiration such as cough associated with swallow and recurrent chest infections should be asked about. Small tumours and tumours of the postcricoid region or the cervical oesophagus can be more difficult to diagnose. The patient may only complain of a feeling of 'something in the throat', like a crumb being stuck. At examination it is important to look for pooling of saliva and any localized oedema, which might raise suspicion. In cases where there is a high index of suspicion or an obvious tumour, an assessment of the upper aerodigestive tract (UADT) and staging of the tumour is made, usually under general anaesthetic. Cross-sectional imaging MRI or CT is also helpful.

In the oesophagus, benign leimyomas can be found occasionally but the majority of tumours are squamous carcinomas. Adenocarcinomas may develop at the lower end and may arise from gastric metaplasia, as seen in Barrett's oesophagus. Dysphagia of short duration in an elderly male who smokes and drinks and which progresses from solids to liquids is typical for this type of tumour. Examination may show weight loss and anaemia and cervical lymphadenopathy advanced disease, but there may be little to find in early disease. Oesophageal lesions are best dealt with within the upper gastrointestinal multidisciplinary team and investigated with flexible gastroscopy and cross-sectional imaging.

External compression of the oesophagus due to goitre and thyroid malignancies, thymoma and enlargement of mediastinal lymph nodes, seen in metastatic disease and lymphoma, is not uncommon and investigations primarily involve cross-sectional imaging and tissue diagnosis.

Post-treatment dysphagia

Patients who have undergone treatment for HNC often suffer significant dysphagia and aspiration. Longer oral and pharyngeal transit times, greater amounts of oral and pharyngeal residue, shorter cricopharyngeal opening durations, and poor swallow efficiencies are seen. Swallow function is significantly worse with higher tumour stage, and patients with oral or pharyngeal lesions have worse swallow function than patients with laryngeal lesions.[20, 21] A multicentre study found a much higher proportion of HNC patients aspirated (76%) than did patients with neurogenic, medical, gastrointestinal diseases.[4] These effects are long-standing, with one study reporting that 44% aspirated at 5 years and beyond their original treatment.[22]

Chemoradiotherapy is, in many centres, the standard treatment for locoregional advanced tumours, particularly of the oropharynx, larynx and hypopharynx. Despite the encouraging results in terms of locoregional control and survival, significant functional impairment has been documented. This is discussed in greater detail in Chapter 34, Speech voice and swallow rehabilitation after chemoradiation, but the salient points are covered here.

Common problems include: reduced tongue strength and control, decreased tongue base movement towards the posterior pharyngeal wall, decreased laryngeal elevation, reduced epiglottic inversion, delayed pharyngeal swallow, frequent residue in vallecula and piriform sinuses and frequent penetration of the laryngeal vestibule and frank aspiration.[23] A prospective study found that 30% of HNC patients treated by chemoradiotherapy developed aspiration pneumonia, despite being fed by tube.[24]

The radiation dose delivered to the superior and middle pharyngeal constrictors, longitudinal muscles and palatopharyngeal fold appears to be significantly related to swallowing outcomes.[25] Intensity-modulated radiotherapy (IMRT) is designed to reduce doses to the major salivary glands, constrictor and masticatory muscles and the mandible. While studies have demonstrated improved salivary function,[26] swallowing function is not always improved.[27] This may be because it is impossible to spare key structures such as the tongue base and soft palate due to tumour site. The pharyngeal phase of swallowing depends on precise interaction of these muscles with tongue base movement, pharyngeal contraction and hyolaryngeal excursion. Gastric tube dependence has been noted for 13–33% at long-term follow-up after chemoradiation.[24]

These problems can also occur following surgery, but are perhaps more predictable. Reconstruction using

regional and microvascular flaps along with rehabilitative therapy has been shown to be beneficial, allowing some compensation.[28, 29] A shift in surgical techniques towards transoral resections involving the use of the laser and the robot have resulted in reduced anatomical and functional disruption and in improved swallowing outcomes, even when radiotherapy and chemotherapy are used in the adjuvant setting.[30, 31]

Functional endoscopic evaluation of swallowing (FEES) is very helpful in the post-treatment HNC patient and is easily performed in the outpatient clinic setting. A functional evaluation including a pharyngeal squeeze manoeuvre,[32] forced breath hold, maintenance of glottic closure and dry swallow can be made and a range of fluid and food can be given. Food colouring can be added to improve the view. Bolus flow during swallow, laryngeal penetration and aspiration and pre- and post-swallow residue in the vallecullae, piriform fossa and postcricoid area should be documented.

Oesophageal motility disorders

These disorders can produce severe dysphagia in the absence of visible abnormalities, the diagnosis being made by manometry.[33] However, before the diagnosis of a dysmotility disorder is made, it is important to exclude a tumour or structural abnormality by endoscopy or radiology.

ACHALASIA CARDIA

Achalasia cardia is the classical condition in this group wherein the lower oesophageal sphincter fails to relax and allow food to pass into the stomach. It is caused by degeneration or absence of the ganglion cells (myenteric plexus of Auerbach) in the oesophageal wall. The condition is indistinguishable from Chagas disease, seen in patients from South America and due to infection by *Trypanosoma cruzi,* which destroys the ganglion cells. Patients present with difficulty in swallowing fluids initially and progressively difficulty with solids. Barium swallow will demonstrate a 'bird's beak' tapering on the oesophagogastric junction and dilatation of the lumen above it. Manometry studies can be used to detect failure of the lower oesophageal sphincter to open even before the features on barium swallow appear.

OESOPHAGEAL SPASM

Diffuse oesophageal spasm is a condition characterized by non-effective peristaltic waves of high amplitude in the oesophagus, causing angina-like chest pain. Barium swallow and manometry demonstrate non-propulsive peristaltic waves and incomplete lower oesophageal sphincter relaxation.

PRESBYDYSPHAGIA

Presbydysphagia refers to swallowing difficulties due to ageing which affect all stages of swallowing. The oral phase is affected by loss of teeth and tongue connective tissue, reduced strength of mastication and weakness of the velopharyngeal reflexes. The pharyngeal phase is affected by decreased elevation of the larynx and prolongation of the pharyngeal transit time. In the oesophageal stage, there is prolongation of the upper oesophageal sphincter relaxation time and the oesophageal transit time with ineffective tertiary peristaltic waves. However, these age-related changes and abnormalities, seen on barium swallow, are evident in one-third of otherwise healthy elderly individuals. Therefore, it might be that age-related changes reduce functional reserve such that problems develop more easily when disease or generalized weakness from systemic illness ensues.[34]

Neurological

Neurological causes of dysphagia[35] mostly affect the oropharyngeal phase of swallowing. Usually, the motor, sensory and coordinating centres for swallowing are affected directly by the disease and it is unlikely that the dysphagia would present as an isolated symptom without the other characteristic features of the neurological disease. In general, patients who present with an acute disorder causing dysphagia, such as a stroke, tend to improve with time, whereas patients with chronic neurological disorders will experience progressive swallowing difficulties. Diagnosis of the specific swallowing problem in these conditions is made by a careful assessment including a detailed head and neck examination. Speech and swallowing assessments include water swallow test to help screen for risk of aspiration and VF. Constant re-evaluation is often needed.

CEREBROVASCULAR ACCIDENT (STROKE)

Cerebrovascular accident (stroke) is probably the most common neurological disorder causing Dysphagia, by affecting the cortex or the corticobulbar tracts (pseudobulbar palsy) or by affecting the bulbar nerve nuclei (bulbar palsy). Recovery takes place within the first week in the majority of patients. Factors contributing to the dysphagia include delayed triggering of the swallowing reflex, cricopharyngeal dysfunction and reduced tongue control and pharyngeal contraction and cough. Loss of pharyngeal sensation associated with the dysphagia correlates well with aspiration, aspiration pneumonia being a major cause of death after a stroke. Following a stroke, studies suggest that 25–70% of patients have dysphagia initially, with 10–30% continuing to have dysphagia and aspiration even after recovery.[1, 2]

PARKINSON'S DISEASE

Parkinson's disease is progressive and characterized by the triad of resting tremor, bradykinesia and rigidity, patients having difficulty in starting, performing and stopping a movement. The dysphagia is associated with changes in striated muscle under dopaminergic control and smooth muscle under autonomic control and is mostly due to

abnormalities in the oral preparatory and pharyngeal phases of swallowing. The oral phase of the swallow is affected by rigidity of the tongue musculature with inefficient, non-propulsive, back and forth movement of tongue which prevents food being delivered into the oropharynx. In the pharyngeal phase there is delayed contraction of the pharyngeal muscles. Findings on VF include impaired motility, hypopharyngeal stasis, aspiration and poor movement of the epiglottis.

MULTIPLE SCLEROSIS

Multiple sclerosis is a demyelinating disease affecting the brain and spinal cord. There can be either a relapsing–remitting or a progressive course. Swallowing problems and aspiration tend to occur in end-stage disease in up to a third of the patients. Reduced pharyngeal peristalsis and delayed swallowing reflex are the most common features. However, the demyelinating lesions can occur in a single cranial nerve or cause a general dysfunction of all three phases of deglutition.

MOTOR NEURONE DISEASE

Motor neurone disease (amyotrophic lateral sclerosis) is a progressive disease that affects the corticobulbar and corticospinal tracts. Progressive swallowing difficulties affect mainly the oral and oropharyngeal stage of swallowing. Twenty-five per cent of patients present with swallowing problems and most develop problems as the disease progresses. Swallowing problems together with dysarthria and anarthria account for much of the misery of this disease.

MYASTHENIA GRAVIS

In myasthenia gravis there are antibodies to acetylcholine receptors, impairing the function of the neuromuscular junction of striated muscles. The hallmark of this condition is fatigability. There is bulbar muscle weakness manifested by slow and weak tongue movements, fatigue of swallowing and food residue in the oropharynx. There may be laryngeal penetration and aspiration. The diagnosis is a clinical one supported by the presence of acetylcholine receptor antibodies

RECURRENT LARYNGEAL NERVE PALSY

Isolated recurrent laryngeal nerve palsy can be associated with dysphagia and aspiration of liquids due to decreased pharyngeal gradient pressures and decreased glottic closure, as well as inferior constrictor and cricopharyngeus muscle dysfunction. Combined superior and recurrent laryngeal nerve injury will have a greater impact due to the ipsilateral sensory deficit.

Medication-induced/pharmacological

Drugs can cause dysphagia directly by causing oesophagitis, or as part of their pharmacological action or normal side effects.[36] Swallowing tablets with insufficient water or just before going to bed can cause oesophagitis as oesophageal transit time is longer during sleep. The oesophagus at the level of the aortic arch is most commonly injured by both lack of neutralization by saliva and contact by acid-producing drugs with a pH of less than 3, such as tetracyclines, doxycycline, vitamin C and ferrous sulphate. Broad-spectrum antibiotics and chemotherapeutic drugs may cause secondary viral ulceration or fungal infections. Stevens–Johnson syndrome is a more serious complication of antibiotic therapy with an acute erosive pharyngitis and oesophagitis causing dysphagia as well as delayed oesophageal strictures.

Anticholinergics, tricyclic antidepressants and calcium channel blockers decrease oesophageal peristalsis and tone of the lower oesophageal sphincter. Xerostomia is a common side effect of many medications such as antihypertensives, ACE-inhibitors, anticholinergics, antiemetics, antihistamines, diuretics and opiates.

Miscellaneous

GLOBUS PHARYNGEUS

Variously described as ‘foreign body sensation in the throat’, ‘lump in the throat’ and ‘frog in the throat’, globus sensation in the throat should not be associated with genuine dysphagia. This should be ascertained with a detailed and specific history from the patient. Investigations and management of this condition are discussed in Volume 2, Chapter 34, Foreign bodies in the ear, nose and throat. It is imperative to rule out a lesion in the hypopharynx, remembering especially not to miss an inconspicuous pathology in the postcricoid area. Similarly, a small group of patients with oesophageal malignancy may also present with this symptom.[37] Therefore, flexible nasendoscopy, transnasal oesophagoscopy and barium swallow tests should be used as appropriate in these patients.

PHARYNGEAL POUCH

A pharyngeal pouch is a pulsion diverticulum that occurs at an area of weakness between the two parts of the inferior constrictor at Killian’s dehiscence. The pouch first develops in the midline, but as it enlarges it expands to one side, most frequently the left. Manometric studies suggest that it is associated with high intrapharyngeal pressures with a high resting tone in cricopharyngeus that is slow to relax.[38] Patients first present with dysphagia and regurgitation of undigested food but recurrent chest infections can result from aspiration due to overflow of food into the larynx. Diagnosis is confirmed by a barium swallow. For more information on the aetiology and management of this condition, see Chapter 52, Cricopharyngeal dysphagia.

Box 49.1 lists the causes of dysphagia.

BOX 49.1 Causes of dysphagia

Congenital
- Cleft lip and palate
- Cerebral palsy
- Vascular rings
- Atresis, clefts and fistula
- Congenital vocal cord palsy

Infective
- Acute and chronic infections of pharynx/larynx
- Neck space infections

Inflammatory
- Gastro-oesophageal reflux disease
- Laryngopharyngeal reflux
- Patterson–Brown–Kelly syndrome
- Eosinophilic oesophagitis

Autoimmune
- Scleroderma
- Systemic lupus erythematosus
- Sjögren's syndrome
- Pemphigus, epidermolysis bullosa
- Dermatomyositis

Traumatic
- Foreign body
- Food bolus obstruction
- Caustic burns
- Head and neck trauma

Neoplastic
- Benign tumours
- Malignant tumours

Motility disorders
- Achalasia cardia
- Oesophageal spasm
- Presbyoesophagus

Neurological
- Cerebrovascular accident
- Parkinson's disease
- Multiple sclerosis
- Motor neurone disease
- Myasthenia gravis
- Vocal cord palsy

Miscellaneous
- Post-treatment dysphagia
- Pharmacological
- Globus pharyngeus
- Pharyngeal pouch

ASSESSMENT OF DYSPHAGIA AND ASPIRATION

Assessment of dysphagia typically includes both clinical and instrumental evaluation. **Figure 49.1** provides a suggested algorithm for the clinical assessment of dysphagia.

History

Patients complain of difficulty in swallowing food or liquid easily and there can be a sensation of food sticking. They will often localize the level of this sensation. In high (oropharyngeal) dysphagia, there is difficulty in preparing and transporting the food bolus through the oral cavity, as well as initiating the swallow, and this may be associated with aspiration or nasopharyngeal regurgitation. In low (oesophageal) dysphagia, patients complain of food sticking low in the neck, retrosternally or at the epigastrium. This localization has low diagnostic specificity. Around 30% of oesophageal dysphagia is localized above the suprasternal notch.

The history should include the onset, duration, progression and severity of the symptoms, as well as the types of food that give problems. Typically, malignant dysphagia presents with a short and progressive history, a change to softer textures and more liquid consistency, with associated weight loss. Conversely, in neuromyogenic dysphagia it can be more difficult to swallow fluids.[39]

Patients may complain of a number of other UADT symptoms:

- **Regurgitation**, which can be immediate or delayed, can give an indication as to the level of the problem. Delayed regurgitation of undigested food is typically seen in patients with a pharyngeal pouch.
- Symptoms of **retrosternal discomfort, belching and early satiety** indicate GORD.
- **Odynophagia** (pain on swallowing), is associated with infection, neoplasia or GORD.
- **Hoarseness** may indicate laryngeal fixation due to tumour or vocal cord palsy.
- **Choking or coughing**, during or after eating, or frequent chest infections may suggest aspiration.
- **Referred otalgia** via the IX and X cranial nerves is usually secondary to an UADT tumour and a poor prognostic sign.
- **Associated neurological symptoms** such as bulbar dysfunction, dysarthria, diplopia, limb weakness and fatigability can be seen in motor neurone disease and myasthenia gravis. Tremor, ataxia and unsteady gait are features of Parkinson's disease.

Examination

Examination should exclude any obvious structural cause, and assessment should be made for signs of associated systemic or neurological dysfunction and for signs of complications of dysphagia such as weight loss and malnutrition and pulmonary problems due to aspiration.

The oral cavity and oropharynx should be examined carefully, looking for obvious mucosal ulceration or lesions and oral dryness/xerostomia. Palatal raise and gag reflex and tongue movement are assessed and any wasting or fasciculation of the tongue noted. Asking the patient to say 'la' and 'ka' can assess anterior and posterior tongue elevation. Dentition and the presence and fit of dentures are assessed; oral competency and buccal tension can be confirmed by testing for facial nerve function.

The pharynx and larynx should be examined with flexible nasendoscopy, assessing for an UADT lesion, vocal cord mobility and pooling of saliva in the piriform fossa

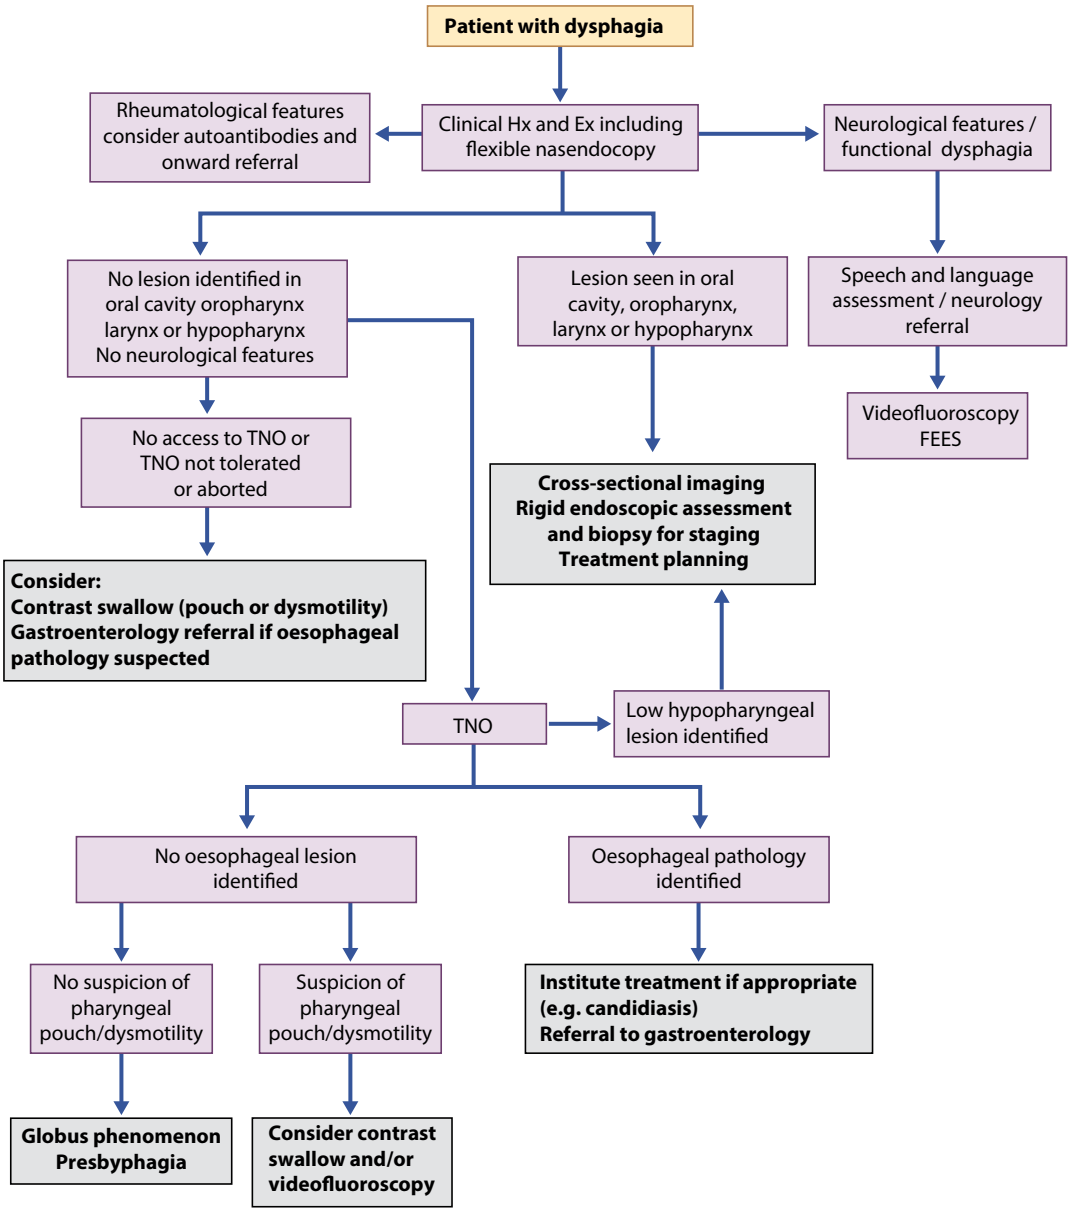

Figure 49.1 A suggested algorithm for clinical assessment of a patient with dysphagia. TNO, transnasal oesophagoscopy; FEES, fibre-optic endoscopic evaluation of swallowing.

or postcricoid area, which is suggestive of an organic cause of dysphagia. Where facilities are available, the flexible endoscopy should be performed using a transnasal oesophagoscope which will enable concurrent assessment of the larynx, pharynx and the entire oesophagus.

Lower cranial nerve function is assessed for loss of tongue movement, wasting and fasciculation, loss of gag and cough reflexes, loss of pharyngeal and laryngeal sensation and loss of vocal cord mobility.

The neck is examined for lymphadenopathy and other neck masses, thyroid enlargement, loss of laryngeal crepitus and the integrity of the laryngeal cartilages.

General physical and neurology examinations should look for evidence of malnutrition, weight loss, chest disease, epigastric tenderness and abdominal swellings, loss of coordination, fasciculation and tremor.

Investigations

Clinical findings dictate further investigations. In the case of upper UADT lesions, investigation is to assess and stage the tumour with panendoscopy and cross-sectional imaging. However, history and examination may not reveal the cause of dysphagia though it may suggest that the cause is either lower than the hypopharynx or has a neurological or functional basis. Further investigations aid examination and assess the function of the swallowing pathway and are also used to assess the risk of aspiration.

BLOOD TESTS

A full blood count and indices should be obtained in all patients to exclude anaemia as a cause or effect of

the dysphagia. Liver and renal function tests together with serum calcium levels should be acquired when nutrition is impaired or metastases are suspected. Thyroid function tests are indicated if dysphagia is caused by a goitre or thyroid malignancy. Creatine kinase levels may be elevated in myopathies.

BEDSIDE ASSESSMENTS

Bedside assessments of swallowing are not standardized and offer poor reliability when used alone. A water swallow test (WST) of a defined volume of water (30 mL) and looking for abnormal voluntary cough, post-swallow cough or throat clear or voice has been shown to have about a 50% sensitivity for aspiration and 80–92% specificity.[40–42] It is used to screen patients with neurological dysphagia at risk of aspiration and is a useful adjunct to instrumental testing.[43] In the HNC population, WST using 100 mL has been found to be 67% sensitive for aspiration but less specific (46%).[20] The value of WST is in identifying patients who require instrumental testing.

Evan's blue dye test[44, 45] is used to assess the presence of and aspiration in the tracheostomized patient. The presence of blue dye from the tracheostomy site is assessed after a test swallow. Detailed treatment of swallow assessment can be seen in Chapter 50, Functional investigations of the upper gastrointestinal tract.

QUESTIONNAIRE-BASED ASSESSMENTS

There are a number of self-reported (University of Washington Quality of Life,[46] M.D. Anderson Dysphagia Inventory[47] and SWAL-QOL[48]) and observer-rated questionnaires that can be useful adjuncts in the assessment of dysphagia in the head and neck population. The most used observer-rated instrument is the Performance Status Scale for Head and Neck (PSSHN).[49] Swallow performance is assessed by: (i) eating in public (scale 1–5) and (ii) normalcy of diet (scale 1–10). These instruments are discussed in greater detail in Chapter 28, Measures of treatment outcomes.

INSTRUMENTAL TESTING

Fibre-optic endoscopic evaluation of swallowing

A fibre-optic endoscopic examination of the UADT should be performed in all cases of dysphagia. The assessment of swallow (fibre-optic endoscopic evaluation of swallowing – FEES)[50, 51] as part of this is very useful in identifying aspiration and secretion management and for visual biofeedback for the patient when trying compensatory procedures to aid swallowing and reduce aspiration. This test can be performed at the bedside and is best if a digital recording is made. Different textures of foodstuffs can be given which can be dyed with food colouring to enhance visibility. Bolus flow during swallow, laryngeal penetration and aspiration, and post-swallow residue should be documented. Endolaryngeal sensation can also be assessed. The procedure is described fully in Chapter 50, Functional investigations of the upper gastrointestinal tract.

Direct pharyngo-oesophagoscopy

This is an examination to visualize and biopsy the pharynx and upper oesophagus under general anaesthetic. It is performed to biopsy and stage all cases of UADT tumour and in patients who complain of food sticking. It allows inspection of the postcricoid area, which is not seen so well during flexible endoscopic assessment of the upper gastrointestinal tract. It is used to examine pharyngeal pouches and to facilitate their treatment.

A major drawback of this assessment technique is the need for a general anaesthetic. In the UK, use of the rigid endoscope to examine the lower one-third of the oesophagus is discouraged owing to the higher risk of complications.

Gastroscopy

Gastroscopy (or oesophagogastroduodenoscopy – OGD) is the endoscopic examination of the oesophagus and stomach. It is used to assess, stage and biopsy oesophagitis, Barrett's oesophagus and tumours. It is poor at detecting disease of the hypopharynx.

Transnasal oesophagoscopy

The relatively new technique of transnasal oesophagoscopy (TNO)[52] uses a narrow-bore flexible scope to assess the oesophagus under local anaesthetic in the clinic setting. It has been shown to be reliable at assessing and diagnosing oesophageal pathology. Studies have shown that around 40% of patients being referred to otolaryngologists with swallowing problems can have concurrent oesophageal pathology, justifying inclusion of this procedure as one of the investigative options for dysphagia.

The major clinical advantage of TNO is the lack of sedation-related morbidity and mortality that is associated with OGD under sedation. It is also more cost-effective than OGD.

Manometry

This is the measurement of oesophageal pressures at rest and during swallowing to diagnose motility disorders.[53] A catheter with pressure transducers along its length is placed in the oesophagus and a multichannel system records the contraction amplitude, duration, coordination and velocity of each peristaltic wave. It is particularly helpful in patients with atypical chest pain and unexplained causes of dysphagia. Conditions with almost pathognomonic manometric findings include achalasia, diffuse oesophageal spasm and scleroderma.

Twenty-four hour ambulatory oesophageal pH monitoring

This is regarded as the most accurate method of diagnosing GORD.[53] It is especially useful when standard investigations such as flexible oesophagoscopy and barium swallow (see below) are normal in a patient with typical symptoms, or in patients with atypical symptoms. A pH sensor placed 5 cm above the manometrically defined lower oesophageal sphincter continually monitors the pH over the test period, while the patient records their symptoms, mealtimes, going to bed and getting up in a

diary card or with an event marker on the pH recorder. Normal oesophageal pH varies between 5 and 7 and GORD is present when the pH is less than 4. The results are expressed as the percentage of time the pH is less than 4 over a 24-hour period – the DeMeester score.[54]

RADIOLOGICAL INVESTIGATIONS

There are two radiological assessments of swallowing that are important in the assessment of dysphagia: contrast swallow and VF.

Contrast swallow

The traditional barium swallow includes both static and dynamic assessment of swallow. The patient is given a cup of liquid barium to swallow and the bolus is followed fluoroscopically to the stomach. Improved visualization of mucosal detail can be obtained by using effervescent granules of barium producing an air contrast study. It is useful to diagnose intrinsic disease (diverticulae, stricture or web, tumour and dysmotility) and extrinsic disease (compression from thyroid or cervical osteophytes). It has poor sensitivity for other pharyngeal disease. It may show reflux disease, but it is not a very sensitive as it fails to pick up 40% of cases.[55] Oesophageal motility is also assessed with swallows in different positions.

Tertiary and disordered contractions can be seen – these patients not uncommonly present with pharyngeal symptoms. The use of barium is contraindicated when there is a risk of aspiration since it can cause pneumonitis. Urgent physiotherapy is necessary in cases of aspiration. In these situations a low molecular weight, non-ionic, water-soluble contrast medium should be used as this is less irritant and should cause minimal complications.

Videofluoroscopy (VF)

VF is a true dynamic assessment of swallowing and is considered to be the gold standard for evaluating the swallowing mechanism.[56] The passage of measured volumes and viscosities – liquid, puréed and solid foods – is observed in both the lateral and anteroposterior plane and a recorded study made. It is a comprehensive test for all phases of swallowing but particularly useful for the oral and pharyngeal phases. The study is interpreted and assessment made of bolus preparation and propulsion. If detected, aspiration can be measured on scales such as the penetration–aspiration scale.[57] Manoeuvres can be tested to reduce aspiration, including swallowing during breath-holding, with or without a chin tuck, and with or without a head turn towards the affected side. VF is particularly useful in patients with neurological disease, and in patients after treatment for HNC.

Computed tomography

Patients with malignant dysphagia should have a CT examination of the neck, chest and abdomen to stage their disease, as should those with dysphagia due to extrinsic compression.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) of the brain or skull base is indicated when a neurological cause of dysphagia is suspected such as multiple sclerosis, cerebral tumours and intracranial extension of a nasopharyngeal carcinoma. It is particularly useful for lesions around the foramen magnum and the brainstem. It is also used to diagnose vascular anomalies.

BEST CLINICAL PRACTICE

- ✓ Be aware of the wide and varied causes of dysphagia in adults and children.
- ✓ Take a detailed current and past medical history to provide clues as the possible aetiology.
- ✓ Comprehensively examine the H&N including the lower cranial nerves.
- ✓ A fibre-optic endoscopic examination of the UADT should be performed in all cases of dysphagia .
- ✓ Look for signs of malnutrition.
- ✓ Perform FBC in all patients with dysphagia.
- ✓ Consider TNO where there is access to this.
- ✓ Consider instrumental assessment of swallowing – FEES and VFSS.
- ✓ Where there is a concern of a malignant cause arrange cross-sectional imaging and UADT assessment under general anaesthetic.
- ✓ Consider a BaSw in cases of pharyngeal pouch and dysmotility.

KEY POINTS

- Dysphagia is common: 22% of over individuals over 50 are affected.[1,2]
- Aspiration pneumonia is the highest cause of mortality associated with hospital admission.[7]
- Stroke is the commonest neurological cause of dysphagia and aspiration.[1, 2]
- 76% of HNC patients have been shown to aspirate. This is higher than those with medical, neurological or GI problems.[4]
- VFSS is considered the gold standard for evaluation of swallow and should be used in conjunction with FEES.[56]
- 30% of patients treated with CRT develop aspiration pneumonia despite tube feeding.[24]
- Radiation dose to the superior and middle constrictor is significantly related to swallow outcome.[25]
- Laryngeal signs show poor sensitivity and specificity for LPR.[10]

SEARCH STRATEGY

Data in this chapter are based on searches of Medline, EMBASE and the Cochrane Library using the keyword Dysphagia, focusing on upper GI functional investigations. The articles referenced by these authors were also reviewed. The data are supplemented by further searches of specialized books.

INTRODUCTION

This chapter seeks to describe functional investigations of the upper digestive tract. A full investigation usually requires multidisciplinary input involving an otolaryngologist, speech and language therapist, radiologist and gastroenterologist, and a focused diagnostic examination with appropriate selection of instrumental assessment. The physiology of normal swallowing has been fully described in Chapter 48, Physiology of swallowing. The underlying aetiology for dysphagia is of anatomical, neurological, muscular or psychological origins. Early diagnosis and effective management of dysphagia reduce the incidence of pneumonia and improve quality of care and outcomes.[1]

INVESTIGATIONS

When to refer for a swallow assessment

Referral guidelines for swallowing assessments have been published for specific conditions. For example, patients with acute stroke should have a swallowing screening test, conducted by a trained healthcare professional before administrating any food, fluid or medication.[1] If a problem is identified, a specialist swallowing assessment should follow within 72 hours. Head and neck cancer patients referred for treatment that will affect swallowing should be assessed by a speech and language therapist and a plan for method of feeding devised.[2] As well as specific conditions, there are certain risk factors that require consideration. For example, a referral for a swallowing assessment is indicated for a tracheostomized patient if there is co-occurring neurological involvement following head and neck surgery, or there are signs of a problem such as evidence of secretions or ingested material on suctioning.[3] However, not all patients with a tracheostomy will have dysphagia.

Patients' perceptions of their swallowing do not always relate to function and therefore symptoms can be underreported.[4] The person may not be aware of a swallowing difficulty, or may attribute their problem to something else. Therefore, healthcare professionals need to be vigilant to the signs and symptoms, taking into account some of the more covert features and refer on for a specialist swallowing assessment as indicated. Some of the signs and symptoms of dysphagia include: coughing during or after eating and drinking, wet-sounding voice after eating and drinking, drooling, repeated chest infections, weight loss and dehydration.

Clinical swallowing evaluation

A clinical swallowing evaluation (CSE) is usually the first step in a functional assessment of the digestive tract and is primarily a screening assessment. The purpose is to identify and differentiate dysphagia symptoms, to assess severity and form a hypothesis regarding the underlying

anatomical and/or physiological causes. Swallow physiology cannot be directly observed if the breakdown is at the pharyngeal or laryngeal level. Sensory changes can mask any outward signs of difficulty such as coughing on swallowing. A CSE typically involves a detailed case history including relevant risk factors such as respiratory status and oral hygiene, an oropharyngeal and oromotor examination and an observation of a swallowing trial.

Currently, there are no published, standardized tests for a CSE. They have been criticized for their poor reliability and sensitivity when used in isolation. Reliability increases with the inclusion of a water swallow test (WST).[2, 3] Testing with measured amounts of water is more reliable than using trial water swallows,[5] probably due to a more defined pass or failed criterion. For example, a systematic review reported that a 30 mL WST could predict pneumonia in a hospital geriatric unit.[6] A combination of features identified on the oropharyngeal examination further increases the sensitivity for the detection of aspiration. For example, the presence of any two features from abnormal voluntary cough, absent gag reflex, dysarthria, dysphonia, post-swallow cough, throat clear or voice change improves validity over single items (sensitivity 92%, specificity 67%) in determining aspiration risk.[7]

A CSE may not be appropriate for certain populations, including patients with dementia or profound learning disability. For such groups, one may be limited to systematic observations of mealtime behaviours. Observations may include specific eating problems such as drooling or food pocketing, ability to self-feed, caregiver feeding skills, body and head positioning, behavioural issues such as agitation, sensory problems such as visual perceptual disorders and distraction by other stimuli. A systematic review of assessment tools for mealtime observations[8] identified two instruments with acceptable psychometric properties; the Minimal-Eating Observation Form-version II[9] and the McGill Ingestive Skills Assessment.[10]

A CSE may also include non-imaging equipment such as cervical auscultation, a cough response test using nebulized citric acid[11] and pulse oximetry. Cervical auscultation amplifies the sounds associated with breathing and swallowing. The flat diaphragm of a stethoscope is placed on the side of the thyroid cartilage. Several acoustic features of the swallow are noted, such as the release of subglottic air and epiglottic movement. There is disagreement over which sound or silent interval corresponds to which feature.[12–14] Swallowing sounds can be influenced by bolus volume and fluid viscosity.[15, 16] Furthermore, it appears that only a proportion of clinicians can achieve high inter- and intra-rater reliability.[12, 17]

Pulse oximetry measures oxygen desaturation. The intricacies of the respiratory–swallow cycle are described in Chapter 48, Physiology of swallowing. Aspiration of material can interrupt this cycle, impacting on arterial blood oxygenation. When used as part of a CSE, baseline measures need to be taken over a sufficient period of time and monitored for any changes following swallowing trials.[6] The sensitivity and specificity for pulse oximetry in identifying aspiration in the stroke population is questionable.[18]

Poor performance or uncertainty based on a CSE will influence the decision to perform a more in-depth, instrumental assessment.

When to refer for an imaging swallowing assessment

Screening assessments aim to identify whether someone has dysphagia, but cannot identify why the dysphagia is occurring. Instrumental tests have an important role in the identification of risk and safe management of aspiration, planning targeted interventions and provide outcomes on the effectiveness of treatment. The American Speech and Hearing Association (ASHA) and the Royal College of Speech & Language Therapists (RCSLT) have published guidelines on the conduct of instrumental swallowing assessments.[19, 20] ASHA's suggested criteria on when a swallow imaging assessment is indicated for assisting in making a diagnosis and/or planning dysphagia management include the following:

- The patient's signs and symptoms are inconsistent with the CSE findings.
- There is a need to confirm a suspected medical diagnosis and/or assist in the determination of a differential medical diagnosis.
- There is either nutritional or pulmonary compromise or a question of whether the oropharyngeal dysphagia is contributing to these conditions.
- Safety and efficiency of the swallow remain a concern.
- The patient is identified as a swallow rehabilitation candidate and specific information is needed to guide management and treatment.

An instrumental examination may be indicated for making the diagnosis and/or planning effective treatment in patients with suspected dysphagia based on the clinical examination and the presence of one or more of the following:

- The patient has a medical condition or diagnosis associated with a high risk for dysphagia, including but not limited to neurologic, pulmonary or cardiopulmonary, gastrointestinal problems; immune system compromise; surgery and/or radiotherapy to the head and neck; and craniofacial abnormalities.
- The patient has a previously diagnosed dysphagia and a change in swallow function is suspected.
- The patient has a communication or cognitive problem and is unable to complete a CSE.
- The patient has a chronic degenerative disease or a disease with a known progression, or is in a stable or recovering condition for which oropharyngeal function may require further assessment for management.

RADIOLOGICAL ASSESSMENTS OF SWALLOWING

There are two distinctly different barium swallows available for the evaluation of dysphagia: the traditional

barium swallow, and videofluoroscopy (also called a modified barium swallow or dynamic swallowing study). Logemann[21] published one of the first articles to describe a videofluoroscopic swallowing study (VFSS) as a diagnostic procedure for oropharyngeal dysphagia.

Videofluoroscopic swallowing study

A VFSS is a recorded radiographic study of the swallowing structures, their movement and coordination. Unlike a barium swallow, it is a dynamic assessment of swallowing. It tracks a radio-opaque bolus from the oral cavity to the upper oesophagus in the lateral or anterior–posterior plane and for this reason it has been deemed the 'gold standard' swallowing assessment. The examination typically involves a speech and language therapist, radiologist and/or radiographer. The presence of a radiologist is considered best practice for paediatric VFSS.[20] Other professionals who may be involved include physicians, surgeons, nurses, physiotherapists and occupational therapists. Specific referral procedures will vary according to local guidelines. Referring sources may include medical practitioners and designated referring speech and language therapists (SLTs). Patients must undergo an appropriate CSE prior to VFSS being undertaken in order to determine suitability and to direct the content of the examination.

PROCEDURE

Patients are not required to fast prior to a VFSS. Where possible, they should be positioned in their usual eating/drinking position. Test boluses are mixed with radio-opaque material to enable visualization. Consideration needs to be given to rheological characteristics, visibility and adherence or coating when adding substances such as barium. Guidelines for mixing the different commercially available radio-opaque substances are available from www.SteeleSwallowingLab.ca.[22, 23]

A VFSS should be systematic to allow for comparison within and between patients. Test boluses are given in increasing volume to minimize the risk of large amounts of aspiration. A range of different food textures may then be assessed, in a graded fashion. The majority of the VFSS is usually conducted in the lateral plane. An anterior–posterior view will give further information about symmetry of laryngopharyngeal movement and laterality of any residue. An oblique head position may be used to further investigate the upper oesophageal area. The number of test items will be limited in order to keep radiation dose to a minimum. The test may include a trial of compensatory strategies, for example an airway protection technique, a chin tuck position. These may then form part of an intervention plan.

Images are recorded digitally, for later analysis and interpretation. Patients may be shown the examination as part of shared decision-making and participation in management plans. If biomechanical movements are to be measured, a metal ring of known diameter (e.g. coin) is taped in the midline to the underside of the chin for calibration. Specific patient safety procedures need to be in place, i.e. access to suctioning in cases of gross aspiration as well as clinician safety guidelines for protection to radiation exposure.

CONTRAINDICATIONS AND RISKS

The examination is conducted in the radiology department and therefore patients need to be medically stable enough to attend and participate in the procedure. The referring clinician needs to consider whether the individual has the ability to cooperate with the examination, such as the ability to maintain the appropriate position and respond to instruction. Caution is needed when gross aspiration is suspected or where there is a history of respiratory distress/arrest due to aspiration. Patient pregnancy is another contraindication due to radiation exposure to the fetus. Needless to say, a VFSS cannot be performed on individuals who have been placed nil by mouth for reasons other than dysphagia (e.g. before general anaesthetic). Reports of adverse reactions to radio-opaque contrast are rare but could be life-threatening and therefore an alternative investigation needs to be found.

ANALYSIS

Interpretation of a VFSS includes a description of bolus flow, reactions to a misdirected bolus, presence of airway invasion, residue and variations from the normal anatomy and physiology. The rater considers the efficiency of bolus preparation and propulsion, and safety or airway protection. An analysis of oropharyngeal swallowing requires a thorough understanding of the normal swallow biomechanics in the context of influencing factors (i.e. gender, age). Typical anatomical abnormalities detected on VFSS include pouches, diverticulae, osteophytes, cricopharyngeal web and fistulae. A number of biomechanical measurements can be derived from the examination such as timing of swallow onset, hyolaryngeal movement, oropharyngeal movements, airway protection mechanisms, upper oesophageal opening. The presence of penetration, aspiration and residue and patients' response to it is recorded.

The reliability and validity of VFSS interpretation has been reported.[24–26] Reliability improves when examinations are group rated, viewed in slow time as well as real time, and judged using validated scales.[27, 28] Examples of rating scales include the MBSImps (a 17-point scale recording oropharyngeal swallowing impairment) and the penetration–aspiration scale (recording the depth of airway invasion and the patient's response to it).[27, 29, 30] Consideration needs to be given to the controlled nature of a VFSS and how much this reflects natural eating and drinking. Stability (i.e. the level of agreement between swallows of the same texture and volume) can vary between bolus consistencies. One study has demonstrated poorer stability for semi-solids than for liquids.[31] The clinician needs to integrate these findings when preparing the report, including recommendations for feeding and an intervention plan.

LIMITATIONS

There are several limitations of this assessment technique:

- Radiation exposure to the patient, especially for repeated or lengthy studies. However, 3 minutes of videofluoroscopy examination gives the equivalent radiation exposure as two cervical spine radiographs.[32] Scattered radiation exposure to the surroundings is within acceptable levels.[33]
- The cost of equipment and involvement of several specialist staff is high.
- There can be difficulties with positioning patients such as those who are bedbound or have difficulty with head control.
- The properties of barium are designed to coat structures, so liquid and food containing barium do not behave in the same way as normal liquids or food.
- Limited or inferred information only is gained about mucosa and secretions, sensation, inter-bolus pressure and glottic closure.

Barium swallow

The traditional barium swallow includes both static and dynamic components to identify intrinsic disease (tumours, diverticula, webs and dysmotility) and extrinsic disease (cervical osteophytes, enlarged thyroid gland). The oesophageal lumen is distended with liquid barium, or coated in thick barium and distended by gas to show intrinsic irregularities and extrinsic impressions. Static imaging with plain radiographs provides information on structural abnormalities (e.g. Zenker's diverticulum, cervical osteophytes), but these static images have little else to contribute to the investigation of dysphagia.[34]

Oesophageal motility is assessed with multiple single swallows in different positions, including recumbent (unlike in a videofluoroscopy assessment of oropharyngeal dysphagia), to assess peristalsis without the effect of gravity. Continuous and single swallows are observed separately as a second swallow obliterates peristalsis of the first.

If oropharyngeal dysphagia and aspiration are suspected, bolus sizes need to be kept small and the investigation should proceed cautiously, or a videofluoroscopy examination should be undertaken instead.

Both the oral and pharyngeal areas should be examined even if the complaint is only oesophageal as 35% of patients have simultaneous disorders of the pharynx and oesophagus[35] and the level of the lesion does not necessarily correspond to the site of the patient's symptoms.[36] Perlman et al.[35] give a comprehensive account of the interpretation of observations and dysphagic characteristics in the oesophageal stages of swallowing.

CT and MRI

These techniques both show structural lesions, for example intracranial disease causing neurogenic dysphagia.[37] More recently, high-speed MRI has been used for dynamic analysis of swallowing in both healthy volunteers and patients with dysphagia.[38, 39] MRI is a non-invasive test that gives both anatomical and functional information on swallowing that can be a useful addition to traditional assessment tools.[40] This technology is costly and still experimental and there is only limited published normal control data for comparison. These tests also require the participant to be supine while swallowing, which does not reflect normal swallowing activity.

ENDOSCOPIC EVALUATION OF SWALLOWING

Fibre-optic endoscopic evaluation of swallowing

A fibre-optic endoscopic evaluation of swallowing (FEES) affords a different perspective from a VFSS. It allows a direct view of nasolaryngopharyngeal anatomy and physiology, assessment of swallowing function and any compensatory interventions to facilitate swallowing performance.[41, 42] The equipment is portable so the test can be conducted at the bedside. This is particularly useful for vulnerable groups such as an intensive care unit setting. The endoscopic view can give specific information on secretion management (an important indication of aspiration),[43] the impact of fatigue (as the scope can be held in position for some time) and laryngopharyngeal sensation. Sensation may be measured quantitatively using FEES with sensory testing (FEESST), which requires additional equipment to deliver air pulses of differing intensity, duration and frequency through an additional port in the endoscope.[44] The patient can view their swallowing simultaneously, which is particularly useful for teaching swallowing manoeuvres.[45] The test may be conducted by an otolaryngologist and/or a trained SLT. In the latter case, any suspicious lesion, dysfunction or pathology needs to be referred back to the patient's medical team. Published guidelines are available from RCSLT[41] and ASHA.[46]

PROCEDURE

Patients are not required to fast prior to a FEES. They should be positioned in their usual eating/drinking position. First, the nostrils are examined using the tip of the scope to assess which side provides the wider access. Local anaesthesia is not routinely administered, to avoid desensitizing the pharyngeal or laryngeal mucosa. Topical anaesthesia or a decongestant may be applied to the nares only, for patients who have difficulty tolerating the procedure. The nasendoscope is coated in a water-based lubricant to ease its passage through the inferior meatus of the nasal passage. Four different views allow observation of anatomy and physiology during swallowing as follows:

- Nasal passage for elevation of the dorsal side of the velum (**Figure 50.1a**).

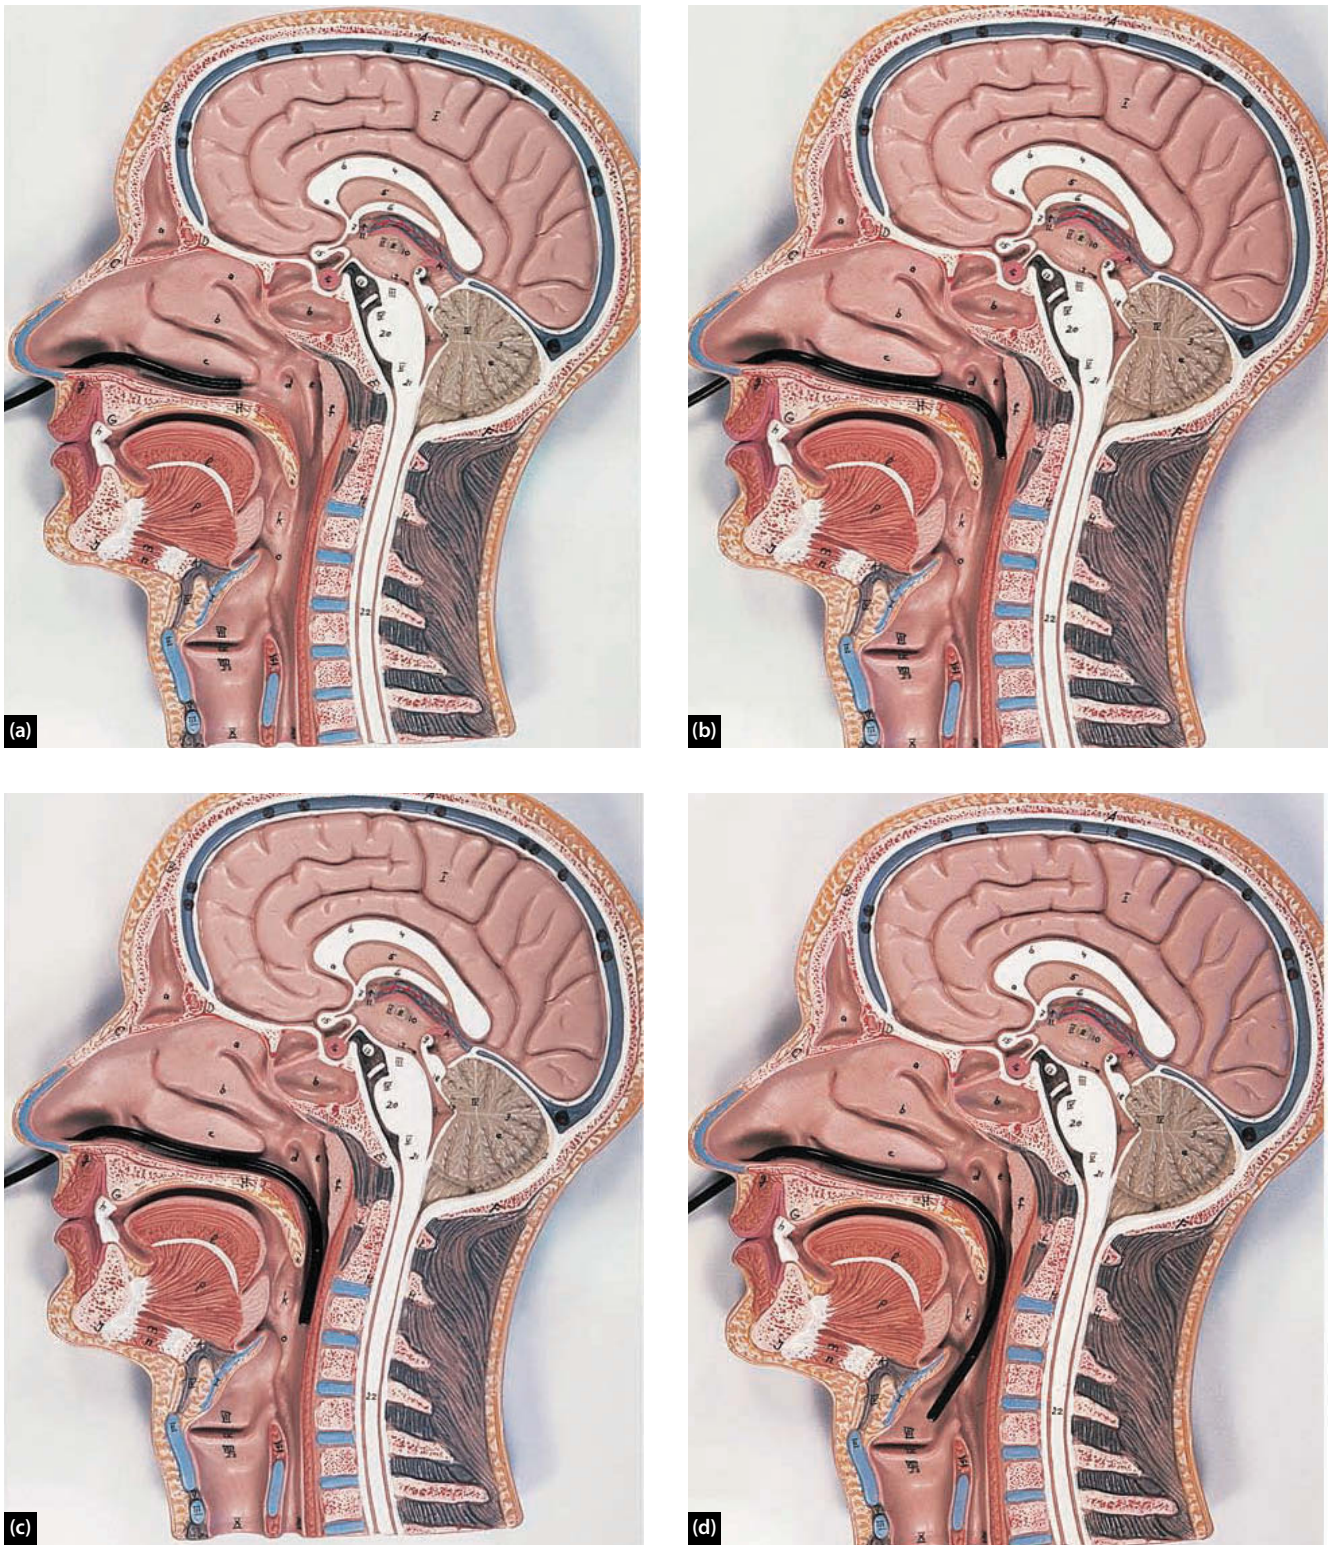

Figure 50.1 Endoscopic evaluation of swallowing. Nasendoscope positioned to view **(a)** dorsal side of velum, **(b)** nasopharynx, **(c)** oropharynx, and **(d)** hypopharynx/laryngopharynx.

- Nasopharynx for velopharyngeal competency, nasal reflux and lateral and posterior pharyngeal walls (**Figure 50.1b**).
- Oropharynx for base of tongue, epiglottis and larynx (**Figure 50.1c**).
- Hypopharynx for pyriform fossae, vocal folds and upper trachea (**Figure 50.1d**).

A functional evaluation is conducted prior to the introduction of any food or liquid. Examples of this include

a pharyngeal squeeze manouevre,[47] forced breath hold to assess maintenance of volitional glottic closure and a dry swallow. A range of fluid and food can be given, without requiring the addition of radio-opaque contrast. Food colouring is added to enhance visibility. For patients with severe dysphagia, the swallow trial may just consist of an ice chip as described by Langmore.[42]

Similar to VFSS, compensatory strategies may be introduced and their effectiveness evaluated. Images are recorded digitally, for later analysis and interpretation. Specific patient safety procedures need to be in place, such as guidelines for epistaxis or laryngospasm. Local guidelines on sterilization and infection control need to be followed.

CONTRAINDICATIONS AND RISKS

FEES has a good safety record, but it may be unsuitable for those patients who are drowsy or are unable to cooperate. Caution is needed in patients with a history of bronchospasm or laryngospasm, vasovagal response, cardiac instability, severe epistaxis or a physical obstruction to the passing of the scope. Adverse reactions to the topical anaesthetic are rare, but clinicians should take an adequate case history, adhere to recommended doses and have resuscitation measures available.

ANALYSIS

Interpretation of a FEES includes a description of bolus flow, reactions to a misdirected bolus, presence of airway invasion, residue and variations from the normal anatomy and physiology. Specific measurements relating to initiation of the swallow (also referred to as 'dwell time') may be taken.[48] The presence of post-swallow residue and airway invasion are recorded.

LIMITATIONS

There are a number of limitations of FEES, including:

- There is no view for evaluation of the oral stage of swallowing.
- There is loss of view ('whiteout') during the swallow due to pharyngeal constriction around the endoscope lens.
- Quantitative measures of structure displacement (e.g. hyoid elevation) are not possible.
- Ability to estimate amount of aspirated material is limited.

VFSS and FEES are widely used as instrumental assessments of oropharyngeal dysphagia in routine clinical practice. They are complimentary functional investigations.[49, 50] The features of each examination are summarized in **Table 50.1**.

Transnasal oesophagoscopy

Transnasal oesophagoscopy (TNO) is now a widely available technique for visualization of the upper digestive tract without the need for sedative drugs. This is discussed in greater detail in Chapter 49, Causes and assessment of dysphagia and aspiration. The role of TNO in functional investigations of the upper digestive tract is mainly in the exclusion of structural pathology, such as strictures or malignancies, and also in the diagnosis of other pathology, such as oesophagitis, through visual assessment and biopsy.[51]

MANOMETRY

Manometry provides additional swallowing information and evaluates pressure changes from pharyngeal and oesophageal muscle activity, particularly in patients with motility disorders.[52]

TABLE 50.1 Comparison of VFSS and FEES

Considerations	FEES	VFSS
Equipment	Nasoendoscope, camera, monitor, digital recorder, microphone	Fluoroscopy, digital recorder, monitor
Personnel	Otolaryngologist and/or SLT	Radiologist and/or radiographer, SLT
Safety	Mild patient discomfort	Radiation exposure
Accessibility	Highly portable, repeatable	X-ray department only; repeated assessment limited by radiation
Oral stage	Not observed	Well seen
Pharyngeal stage	Direct assessment before and after swallowing, not during	Well seen
Oesophageal stage	Not observed	Can be observed
Aspiration/penetration	Accurate assessment	Accurate assessment
Pharyngeal sensation	Sensory response to the scope can be observed	Only inferred
Range of boluses	All ranges of food and drink	Radio-opaque contrasts alter viscosity, texture and taste of food/drink
Fatigue effect on swallow	Easily assessed	Limited by radiation and expense

Pharyngeal manometry

Pharyngeal manometry provides information regarding the amplitude and duration of pharyngeal contractions and upper oesophageal sphincter (UOS) relaxation during swallowing. Rates of pressure change are greater in the pharynx than the oesophagus. Clinically, this test gives an indication of the strength and consequently the efficiency of essential swallowing movements. This can assist in understanding the nature of the swallow breakdown, particularly with motility disorders and post-swallow pharyngeal residue. Manometry can be used in conjunction with the tools mentioned above, i.e. videofluoroscopy (manofluoroscopy) or endoscopy (manovideoendoscopy). It may be used as a stand-alone measure, when the swallowing physiology has already been studied and is known. However, when used alone, it will be susceptible to technical difficulties with accurate sensor placement and reduced inter- and intrareliability.

Three main measures of timing and pressure generation are derived from the procedure:

- base of tongue to pharyngeal wall pressure generation
- lower pharyngeal pressure
- UOS relaxation.

A healthy swallow is characterized by rapid onset of pharyngeal pressure generation, a drop in UOS pressure in response to laryngeal elevation and a return to baseline pressure measurement post swallow.

PROCEDURE

Pharyngeal manometry is moderately invasive, requiring placement of a specialized catheter through the nose and into the oesophagus. This needs to remain in the correct position during swallowing, which can be problematic due to the upward movement of the larynx. The distal tip needs to remain in the UOS, for the assessment of cricopharyngeal relaxation. The proximal end of the catheter is secured with tape against the face. Microcatheters are required if this test is to be performed in children. Patients may require a little time to accommodate to the catheter *in situ*. Measurements are taken at rest and during swallowing.[52]

Research reporting normative data is available. Readings can differ according to age, gender, viscosity and bolus volume[53, 54] so a standardized approach is necessary for comparisons. There is less variation in resting UOS pressures.[53] Measurements appear consistent across swallows, limiting the need for repeated trials.[55, 56] Training is required for interpreting results, with just short training affording high levels of reliability.[57] The measures derived are useful outcome measures for guiding and evaluating treatment.

Oesophageal manometry

Oesophageal manometry provides information on oesophageal muscle activity and can be useful in diagnosing oesophageal motility disorders. The oesophageal peristaltic wave pressure rises slowly to approximately 50 mmHg, and falls rapidly. Secondary peristaltic waves arise locally in response to distension, needed for more solid bolus transportation. Tertiary oesophageal contractions are irregular, non-propulsive contractions involving long segments of the oesophagus.[37]

The 3 cm long lower oesophageal sphincter (LOS) behaves like the UOS, but with a lower tonic (resting) contraction pressure of 10–30 mmHg relative to intragastric pressure. It remains closed except for relaxation when the bolus and peristaltic wave arrive, as swallowing induces inhibition of LOS tone activity. The barrier formed by LOS tonic pressure is lower after meals and tighter at night. Similar to the UOS, measurement of the LOS tonic pressure is complicated by radial asymmetry and a respiratory pressure fluctuation.

HIGH-RESOLUTION MANOMETRY (HRM)

Conventional pharyngeal or oesophageal manometry utilizes a solid-state catheter with sensors spaced at intervals along the catheter. Sensors are unidirectional and record pressure changes shown as pressure waveforms. The enhanced technology of HRM offers several advantages over conventional manometry. The catheter has 36 circumferential pressure sensors, at 1 cm apart, thus providing greater specificity and accuracy. Output is interpreted from a spatiotemporal plot, requiring manual analysis.

PATIENT SELECTION

Manometry is not frequently used as part of a routine clinical assessment in the UK. Robust guidance on who to select for this procedure is still in its infancy. However, the information derived can help to form a more detailed understanding of swallow breakdown. A small number of patients may not be able to tolerate the passage of a nasopharyngeal catheter and this may be contraindicated in those with recent nasopharyngeal surgery. Patients with suspected Zenker's diverticulum will require X-ray guidance, to ensure correct catheter placement into the upper oesophagus. The range of manometric findings for different pathological processes is dealt with in Chapter 49, Causes and assessment of dysphagia and aspiration, and Chapter 53, Oesophageal diseases.

OTHER INVESTIGATIONS

Respiration

Respiratory recordings measure the duration and timing of deglutition apnoea, and direction and rate of airflow and thus a more complete picture of the physiology of swallowing.[58, 59] Several assessment tools have been used and reported in the literature, including intranasal pressure measurements, resistive chest belt, nasal thermistor and respiratory inductive plethysmography.[60–63] Continuous recordings of oxygen saturation by pulse oximetry have also been investigated as a possible marker of aspiration, with conflicting results.[64–67]

Ultrasound

Ultrasonography is a non-invasive technique for soft-tissue imaging during swallow events. The ultrasound transducer with high-frequency sounds (>2 MHz) is placed submentally to produce dynamic images of the soft tissue in the oral cavity and parts of the oropharynx, hyoid motion and changes to hyoid–thyroid distance. The quality of the tongue image for measuring movements is not easy to interpret.[37, 68] It cannot visualize episodes of penetration or aspiration. Patients need to maintain sufficient head control during this examination. There are further methodological issues such as accuracy of transducer placement and reliability of measurements.[69]

Pharyngeal and oesophageal pH monitoring

Prolonged (24-hour ambulatory) pH monitoring is the most reliable method of diagnosing gastro-oesophageal reflux disease (GORD). Recently, the introduction of pharyngeal probes has resulted in the technique being used to diagnose laryngopharyngeal reflux (LPR). Technological advances have led to the, single, dual and even triple lumen sensors that can detect liquid reflux events as well as purported aerosolized acid exposure at various points along the upper digestive tract.[70, 71]

In oesophageal pH monitoring the distal oesophageal pH probe is placed 5 cm above the LOS (position determined by manometry) and the proximal one below the UOS, thus any reflux is measured along the entire length of the oesophagus. The pharyngeal probe is typically placed at the level of the uvula; there is, however, inconsistency in the methodology of pH monitoring in much of the published literature, in particular location of the pharyngeal probe.[72] Further limitations identified in pH monitoring include the impact of diet[73] and the role of non-acidic factors, particularly in LPR.[74] A recent meta-analysis of pH manometry showed that, when techniques were tightly controlled, consistent differentiation of LPR patients from healthy controls was possible.[72] Nevertheless, oesophageal and pharyngeal pH manometry does require specific invasive equipment. This invasive technique prevents some patients from undertaking activities that provoke reflux during the investigation, so it can lead to underestimating their problems.[75]

Scintigraphy

This procedure tracks movement of the bolus over time and quantifies the residual bolus in the oropharynx, larynx and trachea, using radionuclide material with liquid or food, and a gamma camera. It can offer information regarding oesophageal transit.[76] Although it can detect aspiration and reflux, it has poor anatomical definition in comparison to VFSS or barium swallow, and it does not image the biomechanics of swallowing, thus the cause of aspiration cannot be determined.

Lingual pressure recording

Tongue strength and endurance are important components for bolus pressure drive. Three-bulb linear manometric sensor arrays have been used to evaluate the timing and pressure patterns of the anterior, middle and posterior tongue during the oral phase of swallowing. Small pressure sensors are attached to the palate. Most work to date has been experimental.[77]

Electromyography

Surface electromyography (sEMG) measures the amplitude of submental muscle activity from electrodes placed under the chin, in combination with a laryngeal sensor. Activity is recorded from any or all of the submental muscles during swallowing. They are variable in their order of activation both within and between subjects. Preliminary evidence suggests that it may be an important adjunct in identifying aspiration risk in acute stroke patients.[78]

CONCLUSION

Manometry, nasendoscopy and videofluoroscopy are complementary procedures which enhance our understanding of the pathophysiological processes causing symptoms and inform management decisions. Other techniques mentioned are either at experimental stages requiring more research-based data, or are for specific conditions related to dysphagia.

BEST CLINICAL PRACTICE

- ✓ After careful history-taking, evaluation of symptomatology and a clinical swallow evaluation, choosing the most appropriate investigation for any one patient depends on many factors:
  - ✓ specific symptoms of dysphagia
  - ✓ medical condition, cognitive functioning, fatigue level and mobility of patient
  - ✓ invasive nature of investigations and the likely effect(s) this may have
  - ✓ availability and cost of both equipment and trained/experienced professionals.
- ✓ Each investigation has different advantages and limitations, as listed in detail in the chapter.
- ✓ Some patients may require several investigations for a more complete picture but, in general, FEES and/or videofluoroscopy are the first choices for oropharyngeal dysphagia, followed by manometry for motility disorders and to identify candidates for myotomy or dilatation. Barium contrast identifies anatomical and some motor disorders; endoscopy of the oesophagus is the approach of choice for obstructions, taking biopsies for pathologic identification, therapeutic dilatation of a stricture or removal of foreign bodies.
- ✓ The two techniques of videofluoroscopy and FEES are equally effective in discrimination between penetration and aspiration and in guiding management with respect to the outcome of pneumonia.

KEY POINTS

- Functional investigations of the upper GI tract to explore oropharyngeal dysphagia provide information about anatomy, muscular function, mucosal sensation, bolus direction and flow, and the relationships between them. This information is important for devising management recommendations, shared decision-making and evaluating treatment over time.
- Oropharyngeal dysphagia is caused by many underlying aetiologies, producing a wide range of symptoms. The selection of functional assessments will depend on the clinical question needing to be answered.
- Non-instrumental and screening tests are useful to detect the presence of dysphagia. However, functional investigations using instrumentation are more sensitive and specific in accurately detecting aspiration or penetration.
- Instrumental tests, such as videofluoroscopy and FEES, are diagnostic assessments as they can define the swallow disorder in terms of anatomy and physiology causing the problem, and the symptoms in terms of aspiration, penetration, reflux and residue. Such information enables treatment to be directed at the physiological disorder(s) while symptoms are managed by compensatory strategies.
- Technological advancements are allowing for a multitude of further advanced assessments of the upper GI tract and are useful for specific clinical scenarios.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: acute pharyngitis, sore throat, acute tonsillitis, streptococcal pharyngitis/sore throat, bacterial pharyngitis/sore throat, viral pharyngitis/sore throat; peritonsillar abscess alone and with epidemiology, bacteriology, clinical features, differential diagnosis, investigation, treatment and complications; infectious mononucleosis, glandular fever and Epstein–Barr virus, both in isolation and in conjunction with, epidemiology, clinical features, systemic manifestations, associated tumours, serological diagnosis and treatment; chronic pharyngitis/ nonspecific chronic pharyngitis or non-infectious chronic pharyngitis.

In addition, the Cochrane Database of Systematic Reviews and the references in the Scottish Intercollegiate Guidelines Network (SIGN) were reviewed.

DEFINITION

Pharyngitis is defined as inflammation of the pharynx. It can be generalized inflammation of the whole pharynx (**Figure 51.1**) or localized to a specific area of the pharynx (tonsillitis, **Figure 51.2**). The presenting symptom of pharyngitis is usually a sore throat, which is one of the most common presentations for outpatient consultations in primary care.

EPIDEMIOLOGY

Pharyngitis affects both sexes and all age groups, but it is more common in children in late autumn and early winter. The overall incidence of sore throat in all age groups varies widely and different definitions make comparisons between figures difficult. Moreover, most patients with sore throat never or only rarely see their GP. A study demonstrated that only 1 in 18 sore throat episodes led to a GP consultation.[1]

In 2007, the age-standardized patient prevalence rate for acute pharyngitis for all ages in UK was 182 per 10 000.[2]

The cost to the UK National Health Service (NHS) of GP consultations for sore throat, before any treatment or investigation, has been estimated at approximately £60 million per annum.

AETIOLOGY

Most cases of pharyngitis are due to infectious causes (**Box 51.1**). Viruses are isolated in approximately 40–60% of cases and bacterial pathogens in approximately 5–30% of cases. In approximately 30% of cases no pathogen is isolated.

Non-infectious causes include dry air, allergy/post-nasal drip, chemical injury, gastro-oesophageal reflux disease (GORD), smoking, neoplasia and endotracheal intubation.

GABHS BACTERIAL PHARYNGITIS

Group A beta-haemolytic streptococci (GABHS) are the commonest cause of bacterial pharyngitis and are spread via respiratory secretions through close contact. There is

Figure 51.1 Acute pharyngitis with a mucopurulent secretion on the posterior pharyngeal wall.

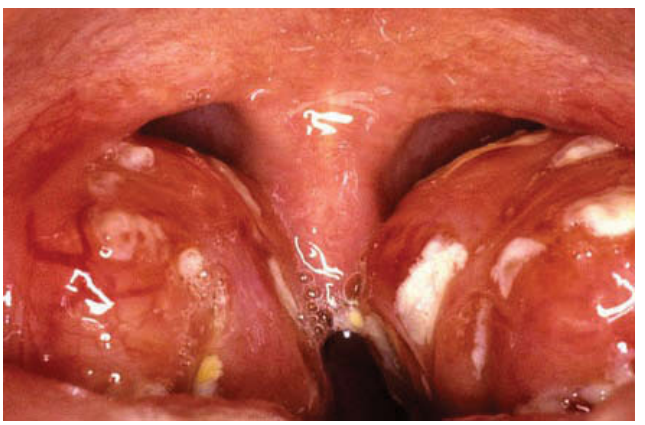

Figure 51.2 Clinical appearance of tonsillitis with pharyngeal erythema, enlarged tonsils and tonsillar crypts containing necrotic or purulent exudates.

an incubation period of 1–5 days. The risk of contagion most probably depends on inoculum size and the virulence of the infecting strain. Individuals are most infectious in the early stages of the disease. More than 120 M-protein types of GABHS have been isolated, with serotypes 1, 3, 5, 6, 18, 19 and 24 associated with rheumatic fever (i.e. rheumatogenic forms) and others, such as serotypes 49, 55 and 57 associated with pyoderma and acute post-streptococcal glomerulonephritis.

Clinical presentation

The classical history is that of sore throat, fever, chills, malaise, headaches, anorexia, abdominal pains as well as a history of exposure to known carriers. However, all these features are rarely present, but sore throat is present in all those old enough to recognize the symptom (see **Figure 51.1**).

The clinical picture in an individual sore throat is of limited assistance in distinguishing between a bacterial and a viral aetiology. There is no evidence that bacterial sore throats are more severe than viral ones or that the duration of the illness is significantly different in the two types.

BOX 51.1 Causes of pharyngitis

Bacterial	
Common	Group A-beta haemolytic *Streptococcus pyogenes (GABHS)*
Uncommon	*Neisseria gonorrhoeae* *Haemophilus influenza* *Corynebacterium diphtheria* *Moraxella (Branhamella) catarrhalis* Group C and G streptococci *Corynebacterium haemolyticum* *Chlamydia trachomatis* *Mycoplasma pneumonia* *Borrelia* species *Francisella tularensis* *Yersinia* species
Probable co-pathogens	*Staphylococcus aureus* *H. influenza* *Branhamella catarrhalis* *Bacteroides fragilis* *Bacteroides oralis* *Bacteroides melaninogenicus* *Fusobacterium* species *Peptostreptococcus* species
Viral	
	Rhinovirus *Adenovirus* *Parainfluenza* virus Coxsackievirus *Coronavirus echovirus* Herpes simplex virus Epstein–Barr virus (EBV) (mononucleosis) Cytomegalovirus (CMV) Human immunodeficiency virus (HIV) infection
Fungal	*Candida* species
Protozoa	*Toxoplasma gondii*
Non-infectious causes	Dry air Allergy/post-nasal drip Chemical injury Gastro-oesophageal reflux disease (GORD) Smoking Endotracheal intubation

Although no single or combination of physical findings is specific for distinguishing GABHS from viral aetiologies, several features are suggestive (**Box 51.2**).[3]

Specific viral infections have characteristic features: conjunctivitis more commonly with adenovirus infections, infectious mononucleosis (IM) typically is exudative and associated with extensive false membranes; finally, herpangina (usually coxsackievirus A or herpes virus) is associated with papulovesicular lesions. Concomitant vesicles on the hands and feet are associated with coxsackievirus A (hand, foot and mouth disease).

Several scoring systems have been described to provide a rational basis for differentiating GABHS from viral pharyngitis. SIGN guidelines[4] recommend that the Centor clinical prediction score should be used to assist the decision on whether to prescribe an antibiotic but cannot be relied upon for a precise diagnosis.

BOX 51.2 Features distinguishing GABHS pharyngitis from viral pharyngitis

Features suggestive of bacterial pharyngitis	Features suggestive of viral origin
Pharyngeal erythema Enlarged tonsils Tonsillar crypts containing necrotic or purulent exudates Fever Cervical lymphadenopathy Soft palate petechiae Scarlet fever rash (punctate erythematous macules with reddened flexor creases and circumoral pallor), also called 'sandpaper' rash History of exposure 5–15 years age group	Conjunctivitis Sneezing and rhinorrhea Cough Diarrhoea Exanthems or enanthems Papulovesicular lesions

The Centor score[5] gives 1 point each for:

- tonsillar exudate
- tender anterior cervical lymph nodes
- history of fever
- absence of cough.

McIsaac et al[6] developed the modified Centor criteria, which add the age of the patient (+1 if age 3–14, 0 if age 15–44 and –1 if age ≥45), taking into account the fact that GABHS is more prevalent in the age group of 5–15 years.

The likelihood of GABHS infection increases with increasing score, and it is 25–86% with a score of 4 and 2–23% with a score of 1, depending upon age, local prevalence and seasonal variation.[4] The score is not validated for use in children under 3 years.

Studies on sensitivity and specificity suggest that reliance on clinical diagnosis will miss 25–50% of GABHS pharyngitis cases and that 20–40% of those with negative throat cultures will be labelled as having GABHS.

Investigation

Investigations are of limited practical value but may occasionally be of benefit when symptoms are severe or if they persist despite adequate conservative management. Full blood count may show leukocytosis, which is highly suggestive of bacterial infection.

Recommendation regarding routine use of tests for microbiological diagnosis of GABHS varies among national guidelines.

According to US[7,8] and French[9] guidelines, microbiological confirmation is required for the diagnosis of GABHS pharyngitis, and rapid antigen detection tests (RADTs) or throat culture should be routinely performed in suspected cases. However, according to UK guidelines, further studies are required to evaluate the cost-effectiveness and clinical benefit of RADTs and insufficient evidence was identified to support a recommendation (SIGN).

RADTs involve extraction of the group-specific carbohydrate antigen from the GABHS cell wall and identification of the antigen by an immunological reaction. A recent meta-analysis of these tests[10] determined an overall sensitivity of 0.85 [95% CI, 0.84–0.87], specificity was 0.96 [95% CI, 0.96–0.97], likelihood ratio (+) 22.21 [95% CI, 15.12–32.63], and likelihood ratio (–) 0.15 [95% CI, 0.13–0.18].

A well-conducted prospective study showed that the RADT can be a valid diagnostic test for the diagnosis of GABHS in adults with pharyngitis, particularly when combined with the Centor clinical score and should be used in patients with at least two clinical findings suggestive of GABHS.[11]

It has been suggested that a strategy based on clinical scores alone may be associated with higher antibiotic usage as compared with either (i) a combination of clinical score and rapid tests use or (ii) use of rapid tests alone.[12] Rapid antigen detection, however, is not sensitive for group C and G streptococci or other bacterial pathogens.

Throat culture is described as the criterion (gold-standard) diagnostic test for GABHS in the North American literature. Results can take up to 24 hours. Throat culture results are highly sensitive and specific for GABHS but can vary, depending on technique, sampling and media. A positive throat culture for GABHS makes the diagnosis of streptococcal sore throat likely but a negative culture does not rule out such a diagnosis. There are cases where *Streptococcus* is isolated from sore throats but there is no serological evidence of infection.[13] There is also a high asymptomatic carrier rate of up to 40% for GABHS.[14] The flora of bacteria recovered from the surface of the tonsil correlates poorly with that deep in the tonsillar crypts, which is the most likely cause of infection.[15,16] Symptoms also correlate poorly with results of throat swab culture.[17] Throat swabs are neither sensitive nor specific for serologically confirmed infection, increase costs considerably, may medicalize illness and alter few management decisions. **Throat swabs should not routinely be carried out in sore throat.**[18]

Antistreptococcal antibody titres reflect past and not present immunologic events and therefore cannot be used to determine whether an individual with pharyngitis and Group A streptococcus (GAS) in the pharynx is truly infected or merely a streptococcal carrier.

Treatment

Streptococcal pharyngitis usually has a 5–7-day self-limiting course. Non-steroidal anti-inflammatory drugs (NSAIDs) and paracetamol are more effective than placebo for relief of symptoms.[19] Paracetamol will suffice for mild cases, but in adults NSAIDs such as ibuprofen and diclofenac are considered superior to paracetamol for pain relief.[12]

Although concerns about risks of NSAIDs have been raised, a large double-blinded randomized controlled trial (RCT) showed that ibuprofen is as well tolerated as paracetamol,[20] hence the SIGN guidelines recommend use of ibuprofen 400 mg thrice daily for symptomatic relief of sore throat, fever and headache, in accordance with the

usual contraindications. Ibuprofen should not be given to patients with or at risk of dehydration due to concerns regarding renal toxicity. In patients who have contraindications for ibuprofen, paracetamol 1 g q.i.d. is recommended. However, in children paracetamol should be used as the first choice, with ibuprofen being used as an alternative.

TOPICAL ANALGESIA

A recent placebo-controlled study suggested that chlorhexidine gluconate and benzydamine hydrochloride mouth spray, added to standard antibiotic treatment, significantly alleviate the intensity of clinical signs in patients with streptococcal pharyngitis.[21]

Based on *in vitro* studies, amylmetacresol and 2,4-dichlorobenzyl alcohol (AMC/DCBA)-containing throat lozenges have been thought to produce an analgesic effect by means of its antiseptic action on bacteria and viruses and partly due to sodium channel blocking, i.e. direct local anaesthetic-like effects.[2] However, in the absence of good quality evidence confirming their efficacy or lasting benefit, there is insufficient evidence to support a recommendation of use of topical analgesia.

CORTICOSTEROIDS

According to a recent Cochrane review, in adult patients with sore throat, pain can be reduced and resolution hastened by use of a single dose of oral or intramuscular corticosteroids in conjunction with antibiotic therapy.[22] Two studies which directly compared intramuscular and oral routes found no differences and it is suggested that the oral route is used. Patients taking corticosteroids were three times more likely to experience complete resolution of their sore throat symptoms by 24 hours compared to those taking placebo. The mean time to onset of pain relief was 6.3 hours earlier in participants taking corticosteroids compared to placebo. However, these modest benefits have to be balanced with possible adverse drug effects of steroids,[23] although it is suggested that a short course is unlikely to be harmful.

There was insufficient evidence to recommend steroids in children with sore throat or as stand-alone treatment without the use of concurrent antibiotics.

ANTIBIOTICS

Bacterial pathogens are responsible for only 5–30% of cases of acute pharyngitis.[24] It is therefore illogical to treat all sore throats with antibiotics, and there is a favourable outcome in the majority of cases even when antibiotics are withheld. An open study of prescribing strategy in over 700 patients randomized to antibiotic versus no prescription versus delayed prescription for 3 days showed no difference in the main outcomes.[25]

A recent assessment of Cochrane reviews suggests that, for streptococcal tonsillitis, the use of antibiotics seems to be discretionary rather than prohibited or mandatory. This is because the benefit in terms of symptoms is only about 16 hours compared with placebo.[26] Estimates of the number of people with sore throat who must be treated to resolve the symptoms of one of them by day 3 (i.e. the number needed to treat to benefit (NNTB)) varied between 3.7 and 14.4, with benefit being more pronounced in patients with a positive throat swab for *Streptococcus*.

Role of antibiotics in preventing complications

Although the Cochrane review on the role of antibiotics found that antibiotics reduced the rate of non-suppurative complications such as rheumatic fever to about one-quarter of that in the placebo group and the rate of suppurative complications to about one-third, most of the beneficial effects were seen in studies conducted before 1975. The incidence of rheumatic fever in the UK is extremely low and there is no support in the literature for the routine treatment of sore throat with penicillin to prevent the development of rheumatic fever.[17] Protecting sore throat sufferers against suppurative and non-suppurative complications in high-income countries requires treating many with antibiotics for one sufferer to benefit. This NNTB may be lower in low-income countries as acute rheumatic fever remains a major problem in tropical regions, resource-poor countries and minority indigenous communities, with Aborigines in central and northern Australia showing some of the highest rates of both acute rheumatic fever and rheumatic heart disease in the world. Study of this latter group suggests that group C and G streptococcal organisms as well as the usual group A streptococcal infections may also have rheumatogenic strains.[18] Similar considerations apply to the prevention of glomerulonephritis.[19]

Recommendation regarding role of antibiotics

Most guidelines[4, 12, 27] recommend that antibiotics should not be prescribed for symptomatic management of pharyngitis, especially in patients with less severe presentation (e.g. 0–2 Centor criteria). Antibiotics should be considered in patients with more severe presentations (when three or more Centor criteria are present), but the modest benefit in symptoms from antibiotics should be weighed against increased antibacterial resistance, costs and possible side effects.

Antibiotics need not be started immediately. A Cochrane review evaluated the use of delayed antibiotics (more than 48 hours after presentation) compared to immediate or no antibiotics as a prescribing strategy for acute upper respiratory tract (URT) infections.[28] No significant differences in outcome were observed among the three groups, which led the authors to conclude that, in patients with respiratory infections where clinicians feel it is safe not to prescribe antibiotics immediately, no antibiotics with advice to return if symptoms do not resolve is likely to result in the least antibiotic use, while maintaining similar patient satisfaction and clinical outcomes to delayed antibiotics.

Patient and doctor education on the lack of benefit of antibiotics in routine management of sore throat can have a significant impact on the amount of antibiotics prescribed.[29]

Choice of antibiotics

Penicillin has been the antimicrobial agent of choice for GABHS and is recommended by most guidelines, if an antibiotic is deemed necessary for the management of pharyngitis. The minimal inhibitory concentration of penicillin for GABHS has not shown an increase over at least five decades.[30]

Most trials have compared penicillin with a variety of other antibiotics, notably cephalosporins. Although optimum elimination of GABHS is secured with intramuscular long-acting penicillin, oral penicillin V, 500 mg, four times daily for 10 days (adults) is the recommended dosage[4] and is widely regarded as the gold-standard treatment, with the advantages of being cost-effective and well-tolerated. A 10-day course of penicillin appears to be more effective than a 5-day course in reducing the incidence of bacteriological treatment failure, characterized by the presence of the same seroptype of GABHS in follow-up throat cultures.

Other more expensive antibiotics, mainly cephalosporins, have been shown to be statistically significantly more successful in eradicating the organism although the clinical advantage is much less clear. Some cephalosporins offer a more convenient dosage regimen, but twice and three times daily dosage of oral penicillin V has also been shown to be effective in eliminating GABHS. A 2010 Cochrane review[31] noted that, although there seem to be indications that carbacephems and cephalosporins might have some benefit over penicillin in terms of resolution of symptoms and incidence of relapse, the findings were inconsistent across analysis methods and the NNTBs were substantial. Therefore there is insufficient convincing evidence to alter current guideline recommendations for the treatment of patients with GABHS tonsillopharyngitis.

In patients allergic to penicillin, the alternatives include narrow-spectrum cephalosporins (cephalexin, cefadroxil) or macrolides (azithromycin, clarithromycin).

Doctors need to be aware that IM may present with severe sore throat with exudate and anterior cervical lymphadenopathy, and therefore should avoid prescription of ampicillin-based antibiotics, including co-amoxiclav, as first-line treatment.

When sore throat recurs in patients who have received antibiotic treatment, the reasons may include inappropriate antibiotic therapy, inadequate dose or duration of previous therapy, patient non-compliance/non-concordance, reinfection and local breakdown of penicillin by beta-lactamase producing commensals. Benzathine penicillin, cefuroxime and clindamycin have been shown to be superior to penicillin V in the management of children with this problem, and they may reduce the frequency of episodes.

ROLE OF TONSILLECTOMY IN THE MANAGEMENT OF PHARYNGITIS/TONSILLITIS

Although the non-inflammatory indications for tonsillectomy are reasonably defined with further trials in progress, the indication for tonsillectomy in the setting of recurrent/chronic tonsillitis/pharyngitis is controversial, with varied opinions regarding the relative risks and benefits. The controversy stems from the fact that palatine tonsils are only one constituent of the Waldeyer's ring of lymphoid tissue within the pharynx. Therefore, a patient who has had the tonsils removed can still have inflammation of the surrounding lymphoid tissue leading to recurrent sore throat. Hence, the important clinical question is to differentiate patients with recurrent tonsillitis from those with recurrent generalized pharyngitis presenting with sore throat. The natural history of tonsillitis is for the episodes to become less frequent with time, but there are insufficient epidemiological data for all age groups to allow predictions of this to be made in individual patients.

Various criteria have been proposed to select patients who are most likely to benefit from tonsillectomy. The referral criteria for tonsillectomy in the presence of recurrent sore throat that are used currently in the UK are based on the SIGN guidelines,[4] which are adapted from Paradise et al:[32]

- Sore throats are due to acute tonsillitis
- The episodes of sore throat are disabling and prevent normal functioning
- Seven or more well-documented, clinically significant, adequately treated sore throats in the preceding year *or*
- five or more such episodes in each of the preceding 2 years *or*
- three or more such episodes in each of the preceding 3 years.

Cognisance should also be taken of whether the frequency of episodes is increasing or decreasing.

A 2009 Cochrane review looked at the benefits of tonsillectomy compared with non-surgical treatment in the management of chronic or recurrent acute tonsillitis.[33] In this review, Burton et al observed that good information about the effects of tonsillectomy was only available for children and for effects in the first year following surgery. Children were divided into two subgroups: those who are severely affected (based on specific criteria which are often referred to as the 'Paradise criteria') and those less severely affected. Severely affected children will on average have one rather than three unpredictable episodes of any type of sore throat in the first year post-surgery, at the cost of one additional episode of post-operative pain. In the less severely affected group, surgery will mean having an average of two rather than three unpredictable episodes of any type of sore throat. Although the size of the effect is modest, the authors concluded there may be a benefit to knowing the precise timing of one episode of pain lasting several days; it occurs immediately after surgery as a direct consequence of it.

Several non-controlled studies suggest that tonsillectomy in children leads to an improvement in their general health and well-being.[34, 35]

The Cochrane review cited above found limited evidence of benefit of tonsillectomy in adults. One small well-conducted RCT[36] which looked at the effects of tonsillectomy in adults with proven recurrent group A streptococcal pharyngitis over a very short period

demonstrated a modest benefit; one episode of post-operative pain led to 1.5 fewer episodes of sore throat in the first 6 months.

These benefits have to be assessed keeping in mind that tonsillectomy is associated with a small but significant degree of morbidity in the form of primary and secondary haemorrhage. Patients who choose surgery for themselves or parents who choose it for their child must therefore be fully informed of the benefits and risks of the procedure.

THE CARRIER STATE

Patients exposed to GABHS may continue to carry the organism asymptomatically even after adequate antibiotic therapy. Carriers are recognized as those who demonstrate a positive culture but no rise in antistreptolysin O convalescent titre, and rates reported in the literature vary between 3% and 40% depending on the population studied. Carriers are at little risk of transmitting the disease: only 3.5% produce disease within their families.

Complications

Complications of GABHS pharyngitis can be classified as suppurative and non-suppurative (**Box 51.3**).

SUPPURATIVE COMPLICATIONS

Peritonsillar abscess (quinsy)

Peritonsillar abscess (PTA) is a collection of pus between the fibrous capsule of the tonsil, usually at the upper pole, and the superior constrictor muscles of the pharynx.

Epidemiology

Data from England have suggested that there was an 18% increase in the incidence of PTA in the 10 years to 2012, with 7589 episodes seen in 2009–2010.[37] It has been hypothesized that it could be because of fewer tonsillectomy operations being performed during that same period.

It may happen at any age but the majority of abscesses are seen in young adults between 20 and 39 years of age, which is surprising in view of the fact that the incidence of tonsillitis peaks in childhood, suggesting the aetiology must be more complex.

Several factors are known to increase the predisposition to form PTA. They include age, male gender, smoking, poor dental hygiene and immunodeficiency.

Pathogenesis

Two mechanisms have been proposed to describe the pathogenesis of PTA:[38]

- **A complication of acute tonsillitis.** This has been the most accepted theory, but recently questions have been raised about this hypothesis. This is because of certain studies which demonstrated up to 68% of patients with PTA had no preceding history of tonsillitis.[39, 40] The other factor which goes against this theory is the fact that the incidence of PTA is highest in the 20–39 age group whereas acute tonsillitis has the highest incidence in the 5–15 age group.
- **Weber gland blockage.** Passy[41] introduced the theory that a PTA may also represent a sequela of damage to Weber's glands, which are minor salivary glands located in the supratonsillar space. It has been suggested that the production of saliva by these glands helps to keep the tonsillar crypyts and peritonsillar areas clean. Poor dental hygiene and localized Weber gland infection could lead to blockage of the gland or the draining duct, predisposing this area to abscess formation.[41, 42] The reduction of innate immunity provided by saliva could be a contributing factor.[43]

Bacteriology

Group A beta-haemolytic streptococci and anaerobes such as *Fusobacterium necrophorum* and *Streptococcus milleri* have been clearly identified as causative organisms in PTA.[38]

Powell et al[38] suggested that there seem to be predominantly two pathogenically different PTA subtypes. Type 1 contains a pure culture of a single organism, most often GABHS. Type 2 displays heavy polymicrobial growth, often containing a variety of facultative and obligate anaerobes. Clinically, type 2 PTA often appears to be more severe, probably due to synergistic microbial interactions.

Clinical features

The main feature of the history is the progressive, usually unilateral, sore throat over 3–4 days, odynophagia, dysphagia for solids and eventually liquids, drooling of saliva, trismus, ipsilateral otalgia and headache associated with fever, lethargy and ipsilateral lymphadenopathy. The patient often develops a 'plummy' voice secondary to the oropharyngeal swelling and, on examination, limited mouth opening is virtually pathognomonic.[44] The tonsil is displaced medially by the hyperaemic, bulging mucosa of the anterior pillar over the peritonsillar space (**Figure 51.3**) and, in addition, the jugulodigastric nodes are tender and enlarged. Bilateral quinsies have been reported[45, 46] and in association with IM.[47] PTA arising in patients with IM is not linked to steroids prescribed to relieve upper airways obstruction in these circumstances.[48]

Investigation

Investigation is not mandatory in clear-cut cases but may be helpful in less straightforward cases.

Needle aspiration of pus is often curative and may also provide useful bacteriology in recurrent or non-responsive quinsies and help clarify the difference between peritonsillar cellulitis and PTA. Bacteriological specimens do not need to be sent to the laboratory routinely after needle aspiration; this should be reserved for patients with a high likelihood of infection by resistant organisms, such as diabetics, immunocompromised patients or patients with recurrent PTAs.[49]

Although traditionally routine screening for IM in all patients presenting with PTA had been recommended,[50] a recent evidence-based review suggests that tests for infective mononucleosis should be reserved for cases were clinical suspicion is high, such as in teenagers and young adults and those with general features that are suggestive of infective mononucleosis.[37]

Transoral ultrasound is used in some countries[51] as an effective non-invasive method of differentiating pus from cellulitis (sensitivity 92.3%, specificity 62.3%).

Dental radiographs or an orthopantomogram may be helpful in the presence of coincidental dental disease or uncertainty as to whether a dental abscess may be involved.

Computed tomography (CT) has been used in the presence of suspected complications such as spread to the parapharynx, retropharynx and mediastinum. If descending necrotizing mediastinitis is suspected, CT of the neck and chest is the investigation of choice, rather than chest radiograph, as it will pick up signs when the chest radiograph is still normal.[52]

Magnetic resonance imaging (MRI) allows better soft-tissue detail and MR angiography may be suitable for suspected vascular anomalies. However, it takes longer and is more expensive and hence used sparingly.

Treatment

Surgical drainage is the mainstay of treatment for PTA. Drainage of the abscess can be performed by either needle aspiration or an incision and drainage. Needle aspiration is the most common treatment in the UK.[53] It is relatively pain-free, significantly contributes to pain relief compared with no aspiration[54] and is not associated with any significant complications. However, complete pus drainage may be less reliable than with a quinsy knife thus potentially predisposing to greater recurrence risks and delayed complications. Quinsy knife drainage is mainly used when needle aspiration has failed but it is more painful than needle aspiration and has, historically, been associated with some disastrous complications. Incision and drainage are less painful if carried out with proper infiltration of local anaesthetic at the site of drainage rather than local anaesthetic spray.[54]

Meta-analysis of success rates for needle aspiration gives a rate of 94 with recurrence rates ranging between 10% and 15%.[55] Since recurrence rates with incision and drainage (~10%)[56] are comparable to those with needle aspiration, clinician experience and patient choice should prevail in decision-making regarding the choice of approach.[37]

Medical management

Although surgical drainage is the mainstay of treatment, antibiotics are recommended for resolution of infection. A combination of benzyl penicillin and metronidazole is the preferred choice of antibiotics.[57] In patients with penicillin allergy, erythromycin/clarithromycin should be used. There is some evidence that benzyl penicillin alone is effective,[58] but, in view of the polymicrobial nature of these infections and variable rates of penicillin resistance, a combination of antibiotics is preferred.[37]

The use of steroids as an adjunctive treatment has been increasing, with one RCT reporting a range of favourable outcomes with steroids with no increase in complications.[59] A single dose of intravenous steroid in addition to antibiotic therapy significantly reduces throat pain, time in hospital, fever and trismus.

Supportive management

Attention should be paid towards adequate analgesia for symptomatic relief in this painful condition. Intravenous fluid resuscitation is important in patients who are unable to maintain adequate oral intake.

Inpatient admission for the above measures is the routinely followed practice in UK in the management of PTA. In the US, most patients are managed as outpatients. Multiple studies[56, 60] have shown that patients can be successfully managed in an outpatient setting with high levels of patient satisfaction. Outpatient management of PTA can be recommended if systems are in place for recognition of patients with risk of airway compromise/dehydration, short-term monitoring, good follow-up protocols and easy access for admission if the condition worsens.

Role of tonsillectomy

Abscess tonsillectomy is a technique with a poor reputation in the UK but it is practised in other countries[61, 62] with good results and minimal morbidity, with the additional advantage of avoiding recurrence and the need for

elective delayed tonsillectomy admission.[63] Moreover, the dissection plane is already created by the pus and prevents fibrosis, which makes interval tonsillectomy difficult. In a paediatric population in which needle aspiration or abscess drainage requires general anaesthesia, abscess tonsillectomy under general anaesthesia may be the treatment of choice.[64] Although concerns have been raised about the incidence of post-operative haemorrhage, comparison of the post-tonsillectomy haemorrhage rates of abscess tonsillectomy versus elective tonsillectomy in age- and gender-matched groups shows no statistically significant difference.[62, 65] However, the presence of trismus and associated intubation issues can increase the risk of GA, which has to be weighed against the advantages of the procedure.

Interval tonsillectomy Elective tonsillectomy after recurrent PTA is recommended. Most surgeons do not recommend surgery after one episode alone, as after tonsil-conserving treatments approximately 11% of cases recur by 5 years and 22% by 17–35 years and the number needed to treat would be 5–10 patients. In this group of patients, a subset with a higher risk (20–39 years, recurrent tonsillitis) may be considered for interval tonsillectomy.

Recurrence is rare after the age of 40 and therefore elective tonsillectomy is not warranted.[66]

Deep neck space infections and mediastinitis have been described in 1.8% of cases.[67] Mediastinitis is a condition with significant mortality (23%) [68] even with aggressive management, i.e. combined neck and mediastinal drainage as well as appropriate antibiotic therapy. If initial mediastinal drainage does not lead to resolution, reoperation including contralateral thoracotomy may be required.

Necrotizing fasciitis following PTAs has rarely been described. Treatments advocated include broad-spectrum antibiotics, abscess tonsillectomy and large-scale debridement of necrotic tissue.[69]

Parapharyngeal abscess and retropharyngeal abscess

Parapharyngeal abscess and retropharyngeal abscess are discussed in Chapter 40, Neck space infections.

NON-SUPPURATIVE COMPLICATIONS

Rheumatic fever

Rheumatic fever results from antibodies to streptococcal M protein cross-reacting with heart muscle leading to pancarditis. It may be associated with migratory arthritis involving the large joints, the erythema marginatum rash, subcutaneous nodules, and choreoathetotic movements of Sydenham's chorea. It typically occurs about 1–4 weeks after the GABHS infection.

Elevated or rising antistreptococcal antibody titres provide reliable confirmation of a recent group A streptococcus (GAS) infection and are of value in identifying a preceding GAS infection in a patient suspected of having rheumatic fever.

Although the incidence of rheumatic fever has decreased significantly in the developing world, it is still a major cause of morbidity, with the global prevalence estimated to be at least 15.6 million cases, with 282 000 new cases and 233 000 deaths each year.[70]

POST-STREPTOCOCCAL REACTIVE ARTHRITIS

Post-streptococcal reactive arthritis (PSRA) is a distinct clinical entity following streptococcal infection, with patients presenting with arthritis but lacking other major criteria for diagnosis of rheumatic fever. While the arthritis of rheumatic fever occurs 14–21 days after an episode of GAS pharyngitis and responds rapidly to acetylsalicylic acid, PSRA occurs about 10 days after the GAS pharyngitis and does not respond readily to acetylsalicylic acid.[7]

Post-streptococcal glomerulonephritis

Post-streptococcal glomerulonephritis (PSGN) is a type 3 hypersensitivity reaction and deposition of immune complexes in the glomerulus leading to an acute nephritic syndrome. It usually occurs 1–2 weeks after the infection. Although the incidence of this condition is also decreasing rapidly, it has been estimated that there are more than 470 000 cases of acute PSGN worldwide annually with around 5000 deaths, 97% of them occurring in less-developed countries.[70] Moreover, the majority of acute PSGN in tropical regions occurs predominantly as a result of skin infections, with the burden of PSGN attributable to pharyngitis being much lower. The prognosis for children with acute PSGN is generally favourable with a mortality of <0.5% and fewer than 2% progressing to end-stage renal failure.[71]

Scarlet fever

Scarlet fever is due to exotoxin production (erythemogenic or erythrogenic toxin) and leads to an erythematous rash and the tonsils and pharynx being covered by a yellow membranous film. Desquamation of the papillae of the tongue leads to a 'strawberry tongue' appearance, which is pathognomonic of this condition.

Paediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS)

Paediatric autoimmune neuropsychiatric disorder and acute disseminated encephalomyelitis, which can affect children and adults, have quite recently been recognized as immune-mediated illnesses associated with GABHS infection. Similar to Sydenham's chorea, it is believed to be due to an autoimmune response that cross-reacts with brain tissues and presents as an abrupt onset obsessive-compulsive disorder including hand washing, tic disorders and daytime urinary urgency.

The PANDAS hypothesis has stimulated considerable research, and controversy, but the American Heart Association guidelines state that, based on the current state of knowledge, the concept of PANDAS should be considered only as a yet-unproven hypothesis.[7]

NON-GABHS BACTERIAL PHARYNGITIS

Group C and G streptococci have been noted to be responsible for food-borne and waterborne outbreaks of pharyngitis.[72, 73] Some of these organisms are normal commensals, so differentiating colonization from infection is difficult. They can be cultured in patients with acute pharyngitis with clinical symptoms and examination findings indistinguishable from those of GABHS but generally less severe.[73] Pharyngeal infection with group C and G streptococci can cause acute glomerulonephritis but has never been shown to cause acute rheumatic fever.[74] Penicillin and clindamycin both provide effective eradication when necessary.

Sexually transmitted bacterial infections such as *Neisseria gonorrhoeae* and *Treponema pallidum* can lead to tonsillopharyngeal infections. Anaerobic bacteria can also be copathogens in GABHS infections, with a synergistic effect leading to suppurative complications.

Diphtheria

Diphtheria is a disease which was thought to be almost eradicated in most countries with high levels of vaccination. However, the level of immunity is believed to decline in late childhood and adolescence, depending on the schedule of immunization and the remaining reservoir of the causative organism *Corynebacterium diphtheria* in the population. This fact may lead to gaps in the immunity of the adults and diphtheria outbreaks may occur in subgroups of susceptible individuals despite widespread childhood vaccination.[74]

Diphtheria is caused by *Corynebacterium diphtheriae*, a non-motile, gram-positive pleomorphic bacillus. The characteristic feature is the presence of a fibrinous gray pseudomembrane on the tonsils, sometimes spreading to other areas of the pharynx and larynx, which is usually preceded by sore throat and fever. Attempts to remove the pseudomembrane cause bleeding from the pharyngeal mucosa. Marked cervical lymphadenopathy may lead to the 'bull neck' appearance. Since this condition can rapidly lead to significant airway obstruction or delayed exotoxin-induced myocarditis and neuritis, a high index of suspicion is to be maintained for diagnosis.

DIAGNOSIS

Definitive diagnosis is based on microbiological tests. Culture of swabs is performed on special culture media such as Loeffler medium. Smear morphology shows the classical 'Chinese character' appearance. Confirmation of toxigenicity of the organism was traditionally undertaken by the Elek test, but this test can lead to a delay in diagnosis of more than 48 hours. A rapid immunochromatographic strip (ICS) method for detection of diphtheria toxin has recently been developed.[75] The use of polymerase chain reaction (PCR) for rapid screening of toxigenic *C. diphtheriae* has also been described.[74]

TREATMENT

Treatment consists of rapid administration of antitoxin which can inactivate toxin that has not entered cells. The recommended dose is dependent on the location of the disease and duration of the illness.[51] Antibiotics are also needed to eradicate the organism. Penicillin is the drug of choice and erythromycin can be used as an alternative.

Airway monitoring is important and occasionally intubation/tracheostomy may be necessary to secure the airway. Patients need to be monitored for impending cardiac and neurological complications for up to 3 weeks.

VIRAL PHARYNGITIS

Viral pharyngitis is more common than bacterial and is usually a sequela of the common cold. The viruses that cause common cold (*Rhinovirus, Parainfluenza, Corona*) are the most common etiological agents. Symptoms are similar to those of GABHS pharyngitis, although usually milder, but certain features such as coryza, exanthema and cough are indicative of a viral infection. Treatment is usually symptomatic but can predispose to secondary bacterial infection.

EBV is responsible for the most clinically relevant form of viral pharyngitis, leading to the characteristic picture of IM.

Infectious mononucleosis (glandular fever)

Glandular fever is a common, acute, systemic viral infection presenting typically with the classical triad of sore throat, fever and lymphadenopathy, hence the name glandular fever. The causative agent is the EBV, one of six human herpes viruses isolated from blood, lymph nodes and saliva.

EPIDEMIOLOGY

IM is primarily a disease of young adults but can present in early childhood and older age groups. The current incidence of this condition is estimated at approximately 500 cases/100 000 persons/year with the highest incidence in the age group 15–24 years.[76] Transmission is via saliva, and it has thus been described as the kissing disease. Individuals with the antibody to the viral capsid antigen will not usually develop the disease. The incubation period is normally 5–7 weeks.

CLINICAL FEATURES

There is a prodrome of 4–5 days with malaise, fatigue and headache. The most common symptom is tender cervical adenopathy, usually accompanied by sore throat. Pharyngeal signs range from acute follicular tonsillitis indistinguishable from follicular tonsillitis to a grey membrane lining the oropharynx, petechiae on the soft palate and sometimes a PTA, which can be bilateral (**Figure 51.4**).

Figure 51.4 Infectious mononucleosis (IM) with features of exudative tonsillitis and false membrane.

Occasionally, all the lymphoid tissue of Waldeyer's ring may enlarge and become covered with a membranous slough, with significant risk of respiratory obstruction. Airway obstruction in IM may be aggravated by herpes infection. Rare, head and neck manifestations include periorbital oedema, especially of the lower lids (Hoagland sign)[77] and cranial nerve mono- and polyneuropathies of which facial nerve weakness is the most common. Other cranial nerves including the hypoglossal nerve, oculomotor nerve and vagus have been reported to be involved either in isolation or as a polyneuropathy.

SYSTEMIC MANIFESTATIONS OF EPSTEIN–BARR INFECTION

The systemic manifestations of EBV infection are summarized in **Box 51.4**.

The oncological risks following EBV-related IM include the following:

- Hodgkin disease
- genome-positive Burkitt lymphoma
- lymphoproliferative disorders in immunocompromised patients
- EBV is a cofactor for the development of nasopharyngeal carcinoma.

Recent developments in molecular and immunological diagnostic approaches have suggested that EBV has a causative role in chronic active EBV infection syndrome, EBV-related haemophagocytic lymphohistiocytosis, EBV genome-positive T-cell lymphoma, natural killer cell leukaemia/lymphoma, Hodgkin disease and gastric carcinoma.

A recent study showed that a history of IM significantly increases the risk of multiple sclerosis.[78]

DIAGNOSIS

The diagnosis is made from the clinical picture, together with the finding of mononucleosis on the peripheral blood film. The two clinical conditions with a similar picture are CMV infection and toxoplasmosis. The differential diagnosis of acute pharyngotonsillitis from IM can be aided by flexible nasendoscopy. Lymphoid tissue is present in the nasopharynx of 92% of patients with IM, unlike in patients with acute tonsillitis. The white cell count may be normal in the first week but is usually raised in the second.

Traditionally, the Hoagland criteria have been used to confirm the diagnosis of IM:[79] at least 50% lymphocytes and at least 10% atypical lymphocytes in the presence of fever, pharyngitis and adenopathy, and confirmed by a positive serological test.

It has recently been suggested that a lymphocyte/WBC ratio could be a quick screening tool to differentiate acute tonsillitis from glandular fever.[80] This study concluded that a ratio higher than 0.35 could indicate glandular fever. However, a review of this hypothesis by a large retrospective study involving 1000 individuals who underwent a monospot test revealed that this ratio had a sensitivity and specificity of only 72% and 84% respectively for the detection of this condition.[81] The authors concluded that, although it is a good indicator of IM, using this ratio alone would lead to one in seven of the patients with IM being missed. It has therefore been proposed that the L/WCC ratio should only be used in conjunction with the Hoagland criteria.

BOX 51.4 The systemic manifestations of EBV infection

Common	Rare
Pyrexia usually accompanies the severe form of the disease	Gastrointestinal: acute appendicitis, mesenteric adenitis, pseudoappendicitis
Generalized lymphadenopathy	Genitourinary: genital ulceration, interstitial nephritis
Splenomegaly occurs in 50% of patients with occasional reports of rupture following blunt soft-tissue trauma or splenic infarcts	NS: Guillain–Barré syndrome, meningoencephalitis, myelitis
Hepatomegaly and jaundice occur in 10% of patients and liver function tests are frequently abnormal	CVS: myocarditis, infective endocarditis, pericarditis
Ascites	RS: pneumonitis, bilateral empyema and mediastinitis
Rubelliform skin rash sometimes occurs and almost invariably if ampicillin is prescribed	Haem: severe autoimmune haemolytic anaemia, haemophagocytic syndrome aplastic anaemia and thrombocytopenia and common variable immune deficiency
	Chronic fatigue syndrome following IM with a premorbid history of poor physical functioning being the main predictive factor. The risk of chronic fatigue syndrome postglandular fever has been estimated to be 9–22% 6 months after glandular fever compared with 0–6% following an ordinary URT infection. EBV virus infection may have a role in initiating multiple sclerosis
	Unexpected deaths possibly related to upper airway obstruction

The heterophil antibody test has remained the basis for serological diagnosis since 1932 when Paul and Bunnell discovered that serum from IM patients caused sheep erythrocytes to agglutinate. The monospot test, which uses bovine erythrocyte-extracted antigen to detect heterophil antibodies, is the most commonly performed serological test today. Both of these are screening tests. The sensitivity of this test varies from 63% to 95% whereas the specificity varies from 84% to 100%, based on the various commercial kits available.[82] False positive monospots can occur in healthy controls as well as in a variety of conditions including mumps, systemic lupus erythematosus, Mediterranean spotted fever and diabetes sarcoidosis. These tests are usually positive in the first week of the disease, although approximately 10% never develop a positive test and this figure may be higher in children. Serological tests cannot distinguish between typical and atypical severe forms of IM.

The gold standard includes serological evidence of EBV-specific antibodies, the most useful being immunoglobulin M (IgM) antibody to EBV viral capsid antigen found during acute primary EBV infection. A recent review of new diagnostic modalities suggested that real-time PCR and measurement of EBV viral load may aid in the early diagnosis of IM in cases of inconclusive serological results.[82]

Female patients without tonsillitis and a WCC of less than 10 and an aspartate aminotransferase over 150 are at significant risk of complications and should be carefully monitored.

TREATMENT

Treatment is symptomatic for mild to moderate cases.

Role of antivirals

A lot of interest has been generated in the role of antivirals in treating this condition. Acyclovir (ACV) is the most commonly prescribed antiviral agent. A meta-analysis of five RCTs involving 339 patients with IM treated with ACV concluded that clinical data did not justify use of ACV for the treatment of mild to moderate IM.[85]

On the other hand, there is evidence to suggest that antiviral agents may benefit patients with severe manifestations of IM, especially when used as an adjunct to corticosteroids.[86] This may be increasingly justified for some of the high-risk complications and prolonged fatigue syndromes.

Ampicillin-based antibiotics should be avoided because of the certainty of producing a rubelliform rash.

Role of steroids

The role of steroids is similar to that of antivirals. A Cochrane review concluded that there was insufficient evidence to recommend steroids for routine symptom control in IM.[87]

However, steroids have been indicated in the setting of acute upper airway obstruction secondary to this condition. The role of corticosteroids in managing complications other than upper airway obstruction is less clearly defined but there may be a role in immune-mediated anaemia, thrombocytopenia and interstitial nephritis.

Patients who develop upper airway obstruction seem to be more prone to developing later recurrent tonsillitis, and acute tonsillectomy has the incidental benefit of avoiding this complication. Rarely, tracheostomy may be required if tonsillectomy fails to relieve airway obstruction.

Contact sports should be avoided for 4–6 weeks even in the absence of splenic enlargement because of the risks of splenic rupture.

There is ongoing research regarding the role of novel therapeutic agents including 5-substituted uracyle, azacytosine derivatives, and peptides inhibiting EBV-mediated membrane fusion in the management of IM.[82]

Cytomegalovirus

Cytomegalovirus (CMV; herpes virus 5) is ubiquitous, and most individuals develop antibodies to it due to infection in childhood. Infection in the immunocompetent host rarely results in clinically apparent disease. Infrequently, immunocompetent hosts exhibit a mononucleosis-like syndrome with mild pharyngitis. About two-thirds of adults with heterophil-negative mononucleosis have CMV-induced mononucleosis. Patients with this illness are usually older than those with EBV IM. Symptoms are similar to IM but lymphadenopathy is less common. The diagnosis is made by isolating CMV from the blood or showing a fourfold rise or greater in antibody titre to CMV.

The virus can lead to a significantly more severe infection in immunocompromised hosts, especially in those with HIV infection.

Herpes simplex 1

Type 1 herpes simplex infection primarily involves the oral cavity and oropharynx and usually affects young children, being less frequently found in the late teens and early twenties. It causes severe vesicular and ulcerative stomatitis of the lips, tongue, gums, buccal mucosa and, occasionally, oropharynx. The oropharyngeal involvement may be an isolated pharyngitis without ulceration or vesicles. Children are systemically unwell with pyrexia, tachycardia and cervical adenopathy.

Diagnosis is usually clinically obvious, although it may be confused with Stevens–Johnson syndrome. The condition is infective and may be transmitted to staff. Occasionally, severe ulcerative pharyngitis may be due to type 2 herpes simplex infection contracted by heterosexual orogenital contact. In the virology laboratory virus from an unruptured vesicle can be identified using fluorescent antibody or be seen as intranuclear inclusions on scrapings. Secondary herpetic infection takes place when the herpes virus resides within the posterior root ganglion. Intercurrent illness then results in the appearance of herpetic vesicles, usually in the lips or the angle of the mouth, as a typical cold sore.

The treatment is usually supportive with appropriate analgesics and fluids. Acyclovir is active against herpes virus but does not eradicate it. It is effective only if started at the onset of infection.

Herpes zoster

Herpes zoster pharyngitis probably arises from the reactivation of virus particles in the cranial nerve nuclei after a previous attack of chickenpox, thus it is analogous to shingles or cold sores. It can, though, also appear during an epidemic of chickenpox. In the pharynx, herpes zoster can materialize in the distribution of the Vth, IXth and Xth cranial nerves. It often occurs with herpes zoster oticus (Ramsey–Hunt syndrome). The pharyngeal features may be transient and can easily be overlooked. They may give rise to pain on swallowing, vesicles and shallow ulcers, which heal rapidly, may be seen on the soft and hard palate, tonsil or posterior pharyngeal wall.

Treatment with antivirals should be started within 72 hours of onset of the lesions. Acyclovir has been the drug of choice in the past, but newer drugs such as valacyclovir and famciclovir are equally effective and have more convenient dosing regimens and decreased incidence of post-herpetic neuralgia. A single dose of gabapentin reduces acute pain associated with herpes zoster infection. Herpes zoster vaccination markedly reduces the incidence and morbidity of this condition as well as the likelihood of developing post-herpetic neuralgia.

Hand, foot and mouth disease

This is usually caused by enterovirus 71 or coxsackieviruses, but untypable enteroviruses and mixed cultures may also be responsible. It is characterized by a vesicular eruption in the oral cavity and oropharynx causing dysphagia and dehydration, accompanied by vesicles on the hands and feet. It is normally accompanied by pyrexia, malaise and vomiting. The illness is short-lived and mainly affects young children but has been associated with mortality, for example in the 1998 epidemic in Taiwan. Fulminant enterovirus 71 infection may lead to severe neurological complications, acute pulmonary embolus and cardiopulmonary decompensation. Age younger than 3 years has been associated with higher mortality as have larger families and kindergarten attendance. Hospital admission, careful staging and stage-based management reduce the fatality rate in those with cardiac complications. Initial investigations include stool cultures and a white blood cell count. Currently, hand, foot and mouth disease is not susceptible to antiviral agents or vaccination, and prevention of outbreaks in high-risk areas requires high-level surveillance and public health interventions.

Herpangina

This is a self-limiting vesicular eruption that occurs in the oropharynx and a number of enteroviruses (30 and 71) and coxsackievirus group A have been implicated. Its regular spread to the oropharynx distinguishes it from herpes simplex type 1 infection.

NON-SPECIFIC CHRONIC PHARYNGITIS

Non-specific chronic pharyngitis is a common clinical diagnosis and relies on a history of long-standing throat discomfort of variable severity without any evidence of specific aetiological factors, with often little to find on clinical examination apart from prominent lymphoid tissue, especially lateral pharyngeal bands. Possible aetiological factors include:

- heavy smoking, including passive smoking
- industrial/occupational irritants
- chronic sinusitis with post-nasal drip
- acid reflux
- poor dental hygiene
- psychological stress
- *Chlamydia pneumoniae* infection
- indoor secondary heating sources (which emit NO_2 and SO_2).

Exclusion of malignancy is the most important aspect of managing these patients. This requires a careful history, in particular enquiring about localized pain to one side and earache, progressive dysphagia or weight loss, and careful physical examination of the whole upper aerodigestive tract with a nasendoscope and otoscopy. Direct examination of the oral cavity and oropharynx, paying special attention to the tongue, floor of the mouth, buccoalveolar sulcus region and manual palpation of the tongue, including its base, is required. Finally, the neck must be carefully palpated to exclude lymph node metastases. Usually this is sufficient to exclude malignancy in the absence of unexplained otalgia or progressive dysphagia but, occasionally, further investigations, mainly rigid panendoscopy under general anaesthetic to take biopsies, may be required.

If physical examination bears out evidence of post-nasal drip or significant acid reflux, both should be treated appropriately with intranasal steroids and proton pump inhibitors, although there is little documentation to support this practice.

Strong advice is given about cutting out smoking and alcohol if these are involved and an appropriate dental referral may need to be initiated. In those patients where stress is deemed to be a significant factor, neck and throat muscle relaxation therapies are deemed to be beneficial.

A large variety of non-specific remedies has been used, such as gargles, antiseptic and analgesic throat spray, with no well-defined benefits. Surgery is of no demonstrable help in this situation and operations to remove excess extratonsillar lymphoid tissue are of no proven benefit.

SPECIFIC CHRONIC PHARYNGITIS

Syphilis

This is an infection by the spirochaete *Treponema pallidum* and, apart from the congenital form, is acquired

through sexual intercourse. The disease progresses through primary, secondary and tertiary stages with the secondary stage being most likely to give rise to pharyngeal symptoms. The condition may present with almost any symptom in any organ system and hence is termed the 'the great pretender'. The lesion of primary syphilis is at the site of initial inoculation and the organism can penetrate both normal and mucosal abrasions. After a decade of unprecedented decline in the 1990s, the worldwide incidence of syphilis has been rising since 2000, mainly among HIV-positive men. This has been well-documented in the UK.[88] Patients immunocompromised by HIV have a higher likelihood of developing neurosyphilis.

In primary syphilis, the lesion is the chancre, which develops after an incubation period of 21 days. The most frequent extragenital sites for the chancre are the lips, tongue, buccal mucosa and tonsil. The lesion begins as a papule that breaks down to form a painless ulcer with indurated margins. At the same time there may be non-tender uni- or bilateral cervical lymphadenopathy. Secondary infection of the classically painless ulcer can result in pain. The ulcer usually persists for 2–6 weeks and then heals spontaneously, often despite inappropriate treatment. While the primary lesion is present the patient is highly contagious. It is therefore very important to consider the possibility of primary syphilis in atypical oral or oropharyngeal ulceration.

Secondary syphilis usually occurs several weeks (commonly 4–6 weeks) after the primary lesion and about 30% of patients at this stage will have a healing chancre. The features of the second stage are fever, headache, malaise, generalized lymphadenopathy, mucocutaneous rash and sore throat. The pharynx and soft palate display hyperaemia and inflammation and there may be lesions, which have been described as mucous patches or 'snail track' ulcers. The lesions are more commonly seen in the oral cavity than the oropharynx and are ulcerated and covered with a greyish white membrane, which when scraped off has a pink base with no bleeding. The secondary stage of the disease lasts a few weeks and, again, the lesions in the mouth and pharynx are infectious. About 30% of cases will go on to develop the tertiary stage.

Tertiary syphilis develops 5–25 years after the initial infection and is characterized by lesions that may be widespread throughout the body or restricted to one or two organ systems. In the URT they are due to gumma. This is a granulomatous necrotic lesion that begins as a nodule and then breaks down to form an ulcer. It can arise in the hard palate, nasal septum, tonsil, posterior pharyngeal wall or larynx. The gumma, whether ulcerated or not, is typically painless. There is usually no lymphadenopathy unless the lesions are secondarily infected. When treated with penicillin, the gumma will heal rapidly.

DIAGNOSIS

In the primary or secondary stage of the disease, spirochaetes can be identified by darkfield illumination microscopy in smears taken directly from the lesion. PCR may be used on oral or other lesions where contamination with commensal treponemes is likely. The spirochaetes can also be identified in biopsy specimens using silver stains or fluorescent-labelled antibody. Biopsy of a tertiary lesion provides a typical histopathological picture.

Serological tests for syphilis fall into two main groups: those used to identify non-specific antibodies to cardiolipin (i.e. Venereal Disease Research Laboratory (VDRL)/rapid plasma reagin (RPR) tests) and those to detect specific treponemal antibodies.

There are several tests to detect specific treponemal antibodies. The UK national guidelines[89] recommend using treponemal enzyme immunoassay (EIA) to detect immunoglobulin M and immunoglobulin G (IgG), if primary syphilis is suspected. IgM is detectable towards the end of the second week of infection while IgG is detectable usually in the fourth or fifth week. A positive screening test should be confirmed with a different treponemal test. The other tests include *T. pallidum* haemagglutination assay (TPHA), *T. pallidum* particle agglutination assay (TPPA), fluorescent treponemal antibody absorbed test (FTA-ABS) and *T. pallidum* recombinant antigen line immunoassay. All the specific tests are almost invariably positive in secondary and early latent syphilis.

The guidelines recommend that a quantitative VDRL/RPR test should be performed when treponemal tests indicate syphilis, as this helps stage the disease and indicates the need for treatment. The VDRL tests use an antigen extracted from beef heart in a slide flocculation test. The VDRL reaction starts to become positive during the first or second week after the development of the chancre and 99% of patients with secondary syphilis have a positive reaction.

An immunoblot (*T. pallidum* recombinant antigen line immunoassay) is recommended when the standard confirmatory test does not confirm the positive treponemal screening test result.[90]

TREATMENT

Penicillin is the treatment of choice, with 2.4 mega units i.m. in single or divided doses, being the standard for primary and secondary syphilis. In tertiary syphilis, 7.2 mega units in divided doses of 2.4 mega units at 7- to 14-day intervals are recommended. Azithromycin is recommended as a second-line alternative in primary syphilis.

Full details of treatment regimens can be obtained from the detailed guidelines on the management of early and late syphilis.[89]

Tuberculosis

The pharynx is not a common site for clinically manifest tuberculosis (TB); however, it is the site of primary infection almost always in children and results in an asymptomatic primary focus in the pharynx (usually tonsil or adenoid) with cervical lymphadenopathy.

Secondary TB affects the pharynx, but only in patients with massive positive and usually cavitating pulmonary TB. This is in contrast to laryngeal TB in which lesions do

occur with low-grade or inactive pulmonary disease. The pharyngeal lesions are secondary to coughing up heavily infected sputum and consist of multiple, painful shallow ulcers in the pharynx or oral cavity. Occasionally, the pharynx is involved in patients with widespread military TB and here the lesions may be from blood-borne as well as sputum-borne dissemination of disease. Lupus vulgaris is a low-grade cutaneous form of TB and has been described in the nasal cavities and in the pharynx. Tuberculous otitis media is probably a blood-borne dissemination of the disease but, on occasion, can result from pharyngeal disease by spread from the Eustachian tube.

The resurgence of TB has closely paralleled the epidemic caused by HIV. In both the US and Africa, the areas with the highest rates of HIV infection and high-risk groups, such as intravenous drug abusers, are those that have sustained the highest increase in TB. Poverty, overcrowding and homelessness are the socioeconomic factors common to coinfection with both. HIV-infected individuals are at risk of reactivation of previous TB and to rapid progression of acquired infection. The presentation is often atypical and an increase in extrapulmonary TB has been demonstrated.

DIAGNOSIS

The diagnosis is usually clear because of the association with pulmonary disease, both clinically and radiologically, although pharyngeal squamous cell carcinoma with pulmonary metastases is the obvious differential. Microscopic examination of stained smears for acid-fast bacilli is still one of the most useful tests for the initial diagnosis of TB. Although less sensitive and specific than culture, the sensitivity can be greatly improved by using phenol auramine stain as compared with the older Ziehl–Neelsen technique. Semi-automated and continuous monitoring systems developed specifically for the isolation of mycobacteria include enzyme-linked immunosorbent assay (ELISA) tests to detect antigens and PCR to detect genetic elements.

TREATMENT

Pharyngeal TB requires no special treatment. It will, in principle, be treated at the same time as the pulmonary disease with triple therapy, usually isoniazid, rifampicin and pyrizinamide as first-line drugs. All cases should be treated in association with an interested specialist. Drug resistance (DR) worsens outcomes and may have significant cost implications. Multiple drug resistance (MDR) is found globally. Management relies upon treatment with at least three drugs to which the isolate is susceptible. Directly observed treatment strategy should be used in adults and children where there is a significant risk of non-compliance and is vital to cut down transmission of disease in the community. TB can be controlled if appropriate policies are followed, effective clinical and public health management is ensured, and there are committed and coordinated efforts from within and outside the health sector. Rapid expansion of effective TB control services is urgently required to avert the continued high burden of morbidity and mortality from TB and its effects on the HIV pandemic.

Toxoplasmosis

Toxoplasmosis is a common disease of birds and mammals caused by the protozoan *Toxoplasma gondii*, which was first described in 1908. The parasite has three stages in its life cycle: tachyzoite, oocyst and tissue cyst. The infection can be transmitted to humans (zoonosis) by the ingestion of cysts or food contamination with animal faeces, the incorporation of tissue cysts or tachyzoites from transplanted organs or blood products from other humans with acute or latent toxoplasmosis, and transplacental transmission from a mother who is acutely infected. About 750 cases of toxoplasmosis occur annually in the UK with a mean age of 30 years. The number of cases rises evenly from adolescence with males predominating up to the age of 20 but after this age females prevail. The age distribution has rose over the 1980s. There is no longer any seasonal or geographical distribution.

In immunocompetent humans, acquired toxoplasmosis usually gives rise to no symptoms. Some patients have a sore throat with malaise, fever and cervical adenopathy and, on occasion, a patient will present with cervical lymphadenopathy only. The fever and malaise may last for several weeks and many organ systems, such as lungs, skin, liver, spleen, myocardium, pericardium, liver, brain, eyes and skeletal muscles, may be involved. The disease is usually self-limiting; rarely, symptoms persist for many years due to chronic active infection, but death is most unusual. The differential diagnosis is usually from other glandular fever-type syndromes. Eye disease presents as isolated retinochoroiditis with little systemic or immunological response. Transplacental infection occurs in approximately 45% of women who acquire toxoplasmosis during pregnancy. The effects range from subclinical infection to intrauterine death. Damage to the central nervous system and retinochoroiditis are the most common nonfatal affections. Only 10–20% of congenitally infected infants have clinically apparent disease at birth but most will develop some sequelae in later life, most commonly retinochoroiditis.

Toxoplasmosis in people with impaired immunity has been documented in association with cancer, organ transplantation, connective tissue disorders and HIV infection. Patients with such conditions are more likely to experience reactivation of latent disease than to acquire new infections. Encephalitis and space-occupying lesions in the brain may develop and, if untreated, rapidly progress to disseminated infection.

DIAGNOSIS

The differential diagnosis is usually from other glandular fever-type syndromes. A dye test for the serological diagnosis of toxoplasmosis was described in 1948. This test, in modified form, remains the gold standard although for diagnostic purposes it is restricted on grounds of cost to

reference laboratories. Several tests for specific antibody classes have been developed and used for diagnostic as well as epidemiological purposes. Lymph node biopsy, which reveals follicular hyperplasia and typical epithelioid cells, is sometimes carried out to confirm the diagnosis.

TREATMENT

Treatment is usually unnecessary but in those individuals with severe systemic upset or immunodeficiency a combination of pyrimethamine and sulphadiazine is indicated, although these are associated with significant side effects. A combination of primethamine and azithrimycin with similar efficacy but fewer side effects has been used for sight-threatening ocular toxoplasmosis. A twice weekly, 25 mg pyrimethamine/500 mg sulphadoxine combination is used as effective prophylaxis against toxoplasmosis encephalitis and *Pneumocystis carinii* pneumonia in patients with advanced HIV infection. In an effort to minimize side effects, considerable work is ongoing to develop new drugs or drug combinations for the treatment of severe symptomatic toxoplasmosis. Early studies suggest that macrolides and fluoroquinolones are possibly effective. A Cochrane review demonstrated a lack of evidence for routine treatment of the acute form of toxoplasma retinochoroiditis but weak evidence for treating chronic disease.

Leprosy

Leprosy is a rare condition in the UK, a dozen or so cases per year notified since the 1990s. No definite cases of indigenously acquired leprosy have been reported since the disease became notifiable. Globally, of the 122 countries considered endemic for leprosy, WHO states that 119 have eliminated the disease as a public health problem (defined as 1 case per 10 000).[90] It is a curable, chronic infectious disease caused by the bacillus *Mycobacterium leprae* that mainly affects the skin and peripheral nerves but also the respiratory mucosa and eyes. Leprosy affects all ages and both sexes. It is still a stigmatizing disease and yet, despite its reputation, is not a highly infectious one. Prolonged contact with an untreated person suffering from an infectious form and an inherent immunological susceptibility in the exposed person are normally required for transmission to take place.

Leprosy usually begins as an anaesthetized area in a hypopigmented skin lesion that can arise anywhere within the body. The spectrum of disease that then develops depends upon the degree of cell-mediated immune response mounted by the host. If there is a vigorous host response, tuberculoid leprosy, which is not infectious and clinically must contain fewer than five skin lesions, results. Borderline leprosy can progress to lepromatous leprosy with numerous skin lesions and this is infectious.

Isolated leprosy of the pharynx does not occur. It spreads to the naso- and occasionally oropharynx from the nasal cavities. Lepromatous leprosy can affect the pharynx and gives rise to a combination of granulomatous lesions ulcerating and healing with fibrosis.

DIAGNOSIS

The diagnosis is usually made by biopsy.

TREATMENT

Treatment is with multidrug chemotherapy, which was introduced by WHO in 1982.[91] Under this programme, patients are classified as having one of two types – paucibacillary (PB) or multibacillary (MB) – and receive either the combination of rifampicin and dapsone (known as paucibacillary multidrug therapy or PB-MDT) or the triple drug combination of rifampicin, dapsone and clofazimine (known as multibacillary multidrug therapy or MB-MDT). The rifampicin and part of the clofazimine component are taken monthly under supervision. PB-MDT is given for 6 months and MB-MDT for 1–2 years.[92] Chemoprophylaxis with dapsone and Bacille Calmette-Guérin (BCG) vaccine provide protection for household contacts.

Scleroma

Scleroma is a chronic infective condition caused by *Klebsiella rhinoscleromatosis*. The disease begins in the nose and only secondarily spreads to the pharynx where it produces granulomatous lesions and scarring.

Candidiasis

Oropharyngeal candidiasis (OPC), or thrush, is a common infection typically caused by the yeast *Candida albicans*, which is part of the flora of the oral cavity and oropharynx in 30% of normal individuals. Other *Candida* species such as *C. glabrata*, *C. krusei*, *C. tropicalis*, *C. parapsilosis* and *C. dublinensis* have also often been implicated, especially in immunosuppressed individuals.

In order for these organisms to become pathogenic and symptomatic there must be some local or systemic change in the host. The predisposing factors are listed in **Box 51.5**.

CLINICAL FEATURES

Clinically, candidiasis may be asymptomatic or present with pain and dysphagia. Examination reveals small

BOX 51.4 Predisposing factors for candidiasis

Local	Systemic disease and or immune compromise
Local disease: lichen planus, leukoplakia	Diabetes mellitus
Systemic antibiotics may change local oral flora sufficiently to allow overgrowth of *Candida*	Lymphoma
Radiotherapy to the oral cavity and oropharynx	Immunosuppressive drugs
	AIDS
	Usually *C. albicans*, but increasingly *C. dubliniensis* is becoming the opportunistic infective agent

Figure 51.5 White membranous lesions of the soft palate in a man who uses steroid inhalers. This appearance is typical of pseudomembranous candidiasis.

white/creamy-white plaque-like lesions on the tongue, palate, buccal mucosa or oropharynx (pseudomembranous lesions). These can typically be 'wiped' away from the underlying mucosa to leave an erythematous ulcer or an erythematous lesion (**Figure 51.5**). The presentation could also be in the form of chronic hyperplastic candidiasis (i.e. hyperkeratotic white patch), which cannot be removed by scraping or chronic atrophic candidiasis (i.e. erythema without plaque formation).

TREATMENT

Mild disease responds well to local therapy, such as nyastatin drops or lozenges 100 000 units 6-hourly, or clotrimazole troches at a dosage of 10 mg five times daily and there is little risk of developing resistance. For moderate to severe disease, oral fluconazole at a dosage of 100–200 mg (3 mg/kg) daily for 7–14 days is recommended.[93]

Increasing resistance of *Candida* species to fluconazole is becoming a problem, especially in the HIV population. For fluconazole-refractory disease, either itraconazole solution or posaconazole suspension can be used.[93] In severe cases not responding to triazoles, a new class of agents called echinocandins or amphotericin may rarely be required.

Neither primary nor secondary prophylaxis is recommended for most patients exhibiting OPC because of the potential for resistant *Candida* species to develop over time with continued antifungal pressure.[94] Moreover, mucosal disease is associated with very low attributable morbidity and mortality, and acute therapy is highly effective.[95]

HIV and AIDS

Although great progress has been made in the global response to the AIDS epidemic in 30 years, more than 34 million people are still living with HIV infection worldwide.[96] Sub-Saharan Africa continues to be the most affected continent, followed by Eastern Europe and the Caribbean.

Pharyngeal presentation of HIV disease includes the following:

- acute seroconversion illness
- opportunistic infections, especially with *Candida*, but also TB, syphilis, CMV and *Cryptococcus*
- oral hairy leukoplakia (OHL) and Kaposi's sarcoma (KS), both AIDS-defining illnesses, and oral aphthous ulceration
- lymphoid tissue hyperplasia
- neoplastic lesions including non-Hodgkin lymphoma (NHL), KS, SCC of the head and neck, Hodgkin disease, myeloma and leiomyosarcoma in children.

PRIMARY HIV INFECTION/ACUTE SEROCONVERSION ILLNESS

Primary HIV can be asymptomatic or result in severe symptomatic illness. Common symptoms are pyrexia, pharyngitis, malaise, lethargy, maculopapular rash, mucous membrane ulceration, cervical lymphadenopathy and headache. Non-head and neck manifestations of primary HIV infection might include gastrointestinal tract transit disturbances, weight loss, anorexia, abdominal pain, myalgia, arthralgia and neurological features. The differential diagnosis is with glandular fever-type syndromes. A careful sexual history may provide a clue. It can be diagnosed by virology testing (HIV-1 RNA level >50 000 copies/mL) in the absence of HIV-specific antibodies (ELISA and confirmatory Western blot antibody testing). Progression to late-stage disease is influenced by the severity of the symptoms in primary HIV infection, the duration of illness, and the presence of neurological symptoms and oral candidiasis. Currently, the experimental evidence is insufficient to recommend whether those diagnosed with primary HIV infection should routinely receive antiretroviral therapy although it is routinely given in the US. Treatment of primary infection with highly active antiretroviral therapy (HAART) does not prevent establishment of chronic infection. Very early therapy could, potentially, decrease the viral set point, prevent viral diversification, preserve immune function, improve clinical outcome and decrease secondary transmission.

ORAL AND OROPHARYNGEAL LESIONS DUE TO OPPORTUNISTIC INFECTION

Oral candidiasis has been reported as the most prevalent oral lesion. *Candida* species other than *Candida albicans* are more prevalent in HIV disease, including *C. glabrata, C. krusei* and *C. dubliniensis*. Fluconazole is the mainstay of therapy, although resistance is developing. *Penicillium marneffei*, a newly described fungal infection, has been identified in South East Asia.

Oral lesions common in the early years of the AIDS epidemic including KS, oral aphthous ulceration, AIDS-associated oral lymphoma (Figure 51.6) and OHL all contain EBV DNA. Abundant viral replication only occurs in OHL and is due to a previously unknown mechanism involving concurrent expression of prolific, replicative

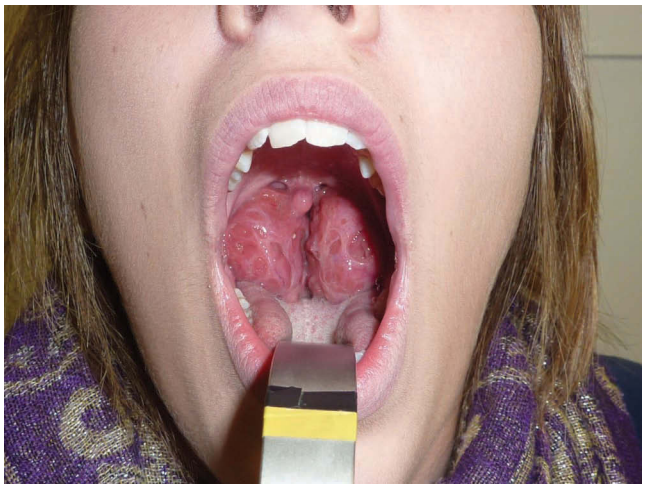

Figure 51.6 Tonsil hypertrophy presenting as lymphoma in an immunocompromised patient.

Figure 51.7 Papilloma on the uvula seen as a discrete papillary, cauliflower-like lesion.

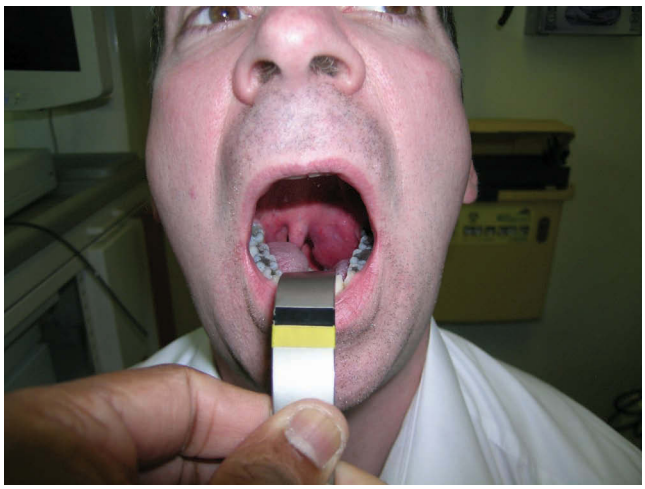

Figure 51.8 Lymphoid tissue hyperplasia.

and transforming proteins of the gamma herpes virus EBV. KS has also been shown to contain a different herpes virus specific to this lesion, which is now known as KS-associated virus.

Oral lesions, especially pseudomembranous and/or erythematous candidiasis and OHL, which are highly suggestive of HIV infection in individuals of unknown HIV status and those known to be HIV infected, indicate that the battle lines between HIV virion production and destruction of immunologically important cells have been drawn. These observations have led to the almost universal inclusion of oral lesions in HIV staging. Recently, lower frequencies of oral disease due to HAART have been noted, except that oral warts may become more common as the viral load falls and the CD4 count rises. Human papillomaviruses (HPV) are associated with oral warts in HIV-positive individuals (**Figure 51.7**), a diagnosis that is increasing. Types include verruca vulgaris, condyloma acuminatum and focal epithelial hyperplasia. In addition to HPV, herpes simplex virus infection is increasing in this group and may run an atypical course including presentation as an exudative erythema multiforme. In children with HIV infection, additional oral lesions include angular cheilitis, ulcerative gingivitis/periodontitis and enamel hypoplasia, salivary gland disease, linear gingival erythema over-retention and delayed primary eruption of teeth. OHL is much less common in children than adults.

LYMPHOID TISSUE HYPERPLASIA IN THE PHARYNX

Lymphoid tissue hyperplasia (**Figure 51.8**) in the pharynx commonly involves all the tissues of Waldeyer's ring including adenoidal, palatine and lingual tonsils. Adenoidal hyperplasia and hypertrophy may cause Eustachian tube obstruction and otitis media with effusion. Biopsy of this tissue to exclude nasopharyngeal carcinoma and lymphoma is mandatory but radical adenotonsillectomy is to be avoided because of the bleeding risks. HIV viral RNA but no other microorganisms can be identified in this tissue. The complex immunological changes suggest that HIV may be disseminated through the upper aerodigestive tract via target cells. Subsequent presentation of viral antigens to the tonsillar and adenoidal lymphoid tissue results in simulated neoplastic proliferation of these structures, which are highly suspicious of HIV, even in asymptomatic HIV-positive patients.

PHARYNGEAL NEOPLASMS

Pharyngeal neoplasms include KS, NHL and SCC. The outlook for patients with these malignancies has improved significantly with the use of HAART and more aggressive cytotoxic therapies. The relative risk of acquiring these conditions compared with non-HIV-infected individuals is for KS greater than 10 000, B-cell NHL greater than 100, NHL eight and multiple myeloma five. Children also have a high risk of leiomyosarcoma (RR = 10 000). KS appears to result from an uncontrolled expression of latency genes of human herpes virus-8. It is exquisitely sensitive to immune deficiency and its incidence has declined rapidly with the use of HAART while

that of NHL has declined much less so. Patients with head and neck SCC who are HIV-positive in the absence of AIDS, presented at a younger age, more frequently experienced treatment-related complications and had a poorer outcome, suggesting that head and neck SCC may be an AIDS-defining diagnosis. Oral cavity and oropharyngeal tumours in HIV-positive patients respond to radiation therapy but there is a marked difference in the degree of acute reactions to treatment between patients with and without KS.

BEST CLINICAL PRACTICE

- ✓ A combination of Centor Clinical prediction score and Rapid Antigen Detecton test (RADT) should be used to diagnose GABHS pharyngitis.
- ✓ Supportive care with NSAIDs/Paracetamol with delayed antibiotics (48 hours after presentation) or no antibiotics for most patients with GABHS pharyngitis.
- ✓ SIGN guidelines[4] as a criterion for tonsillectomy.
- ✓ Serum Monospot test for patients with suspicion of Infectious mononucleosis.
- ✓ HIV infection to be considered in unusual pharyngeal presentation.

FUTURE RESEARCH

- ➤ Quality-of-Life studies to further ascertain the role of tonsillectomy in adults.
- ➤ Selective vs. Universal use of RADT in patients with pharyngitis.
- ➤ Role of novel therapeutic agents in the management of infectious mononucleosis.

KEY POINTS

- Viruses and not bacteria are the most common cause of acute sore throat, but GABHS is still the most frequent bacterial pathogen.
- Despite some forms of acute pharyngitis being associated with classical presentations, one cannot reliably distinguish between viral and bacterial aetiologies on clinical grounds alone.
- In UK practice there is insufficient evidence to support the use of antibiotics in the management of acute sore throat for symptom relief and prevention of spread, recurrent sore throat or to prevent rheumatic fever, glomerulonephritis or suppurative complications.
- The indications for tonsillectomy in the setting of recurrent/chronic tonsillitis/pharyngitis are controversial with varied opinions regarding the relative risks and benefits. The referral criteria currently used in the UK are based on the SIGN guidelines.
- There has been a steady increase in the incidence of peritonsillar abscess over the past 10 years. Drainage of abscess can be performed either by needle aspiration or an incision and drainage.
- Pharyngeal signs of EBV infection are clinically indistinguishable from follicular tonsillitis and even PTAs may occur as a complication. Screening tests include the monospot and Paul Bunnell tests, but both have false-positives rates. EBV IgM to viral capsid antigens is the gold standard for accurate diagnosis. Treatment is symptomatic in most cases but antiviral agents may be justified in the presence of systemic complications.

ACKNOWLEDGEMENT

We would like to acknowledge the contribution of the late Mrs Marcelle MacNamara who wrote the chapter on acute and chronic pharyngeal infection in the previous edition of this textbook.

SEARCH STRATEGY

Data in this chapter are based on a Medline search using the keywords: upper oesophageal sphincter, oropharyngeal, dysphagia, cricopharyngeus/cricopharyngeal, pharyngeal pouch, hypopharyngeal diverticulum and Zenker's diverticulum.

INTRODUCTION

This chapter is about difficulty swallowing due to dysfunction of the upper oesophageal sphincter or cricopharyngeus. The applied anatomy and physiology of the upper oesophageal sphincter are first described. The chapter then details the management of cricopharyngeal dysphagia, with and without a pharyngeal pouch. Management of the conditions requires consideration of medical, endoscopic and open surgical approaches. All of these are discussed.

DEFINITION

The terms cricopharyngeus and upper oesophageal sphincter are often used interchangeably. The cricopharyngeus is the most inferior part of the constrictors of pharynx. The upper oesophageal sphincter is the term used to describe the area of the digestive tract at the junction of the pharynx and oesophagus. This term perhaps oversimplifies the functional zone of the lower pharynx and upper oesophagus. Rather than being a simple sphincter made up of a circular muscle lying at the lower border of the pharynx, the functional area is most likely an inverted cone shape with the cricopharyngeus at the lower end of the confluence of the piriform fossae and indented anteriorly by the cricoid cartilage. Opening and closing is a complex function influenced by this circular muscle as well as the position of the cricoid cartilage in relation to the lumen of the upper oesophagus.

Cricopharyngeal dysphagia is difficulty swallowing due to dysfunction of the cricopharyngeal muscle. Dysfunction is failed relaxation due to fibrosis or muscle spasm. This can occur either with or without the formation of a pharyngeal pouch.

A pharyngeal pouch is a herniation of pharyngeal mucosa through a defect (usually posterior) in the pharyngeal wall. The terms Zenker's diverticulum and hypopharyngeal diverticulum are also used.

The most frequent location of the herniation is the posterior wall of the pharynx through an area of natural weakness between the two parts of the inferior constrictor muscle. This area was described by Killian in 1908 and is referred to as Killian's dehiscence.[1]

INCIDENCE

It is difficult to quantify the incidence of pharyngeal pouch in the general population because not all patients present to a specialist. The incidence of presentation to an ear, nose and throat (ENT) specialist has been estimated as

0.47–1 cases per 100 000 per year.[2,3] Pharyngeal pouch is more common in men, with a ratio of approximately 2 : 1. Patients are usually over the age of 50 years with the most common presentation being between the sixth and ninth decades. In an ageing population, it might be expected that prevalence will increase. The condition of pharyngeal pouch affects Caucasians and is rare in Asian and Afro-Caribbean races.

DIAGNOSIS

Patients present with symptoms of variable severity, not necessarily related to the size of the pouch. Most patients present with long-standing symptoms; indeed, it is the insidious onset and slow progression of the symptoms that cause many patients to present with a well-developed pouch and sometimes severe weight loss.

Dysphagia is the most common symptom and is present in virtually all patients. Dysphagia means that the patient must have either a mechanical blockage or neuromuscular incoordination or both. Dysphagia should be distinguished from the sensation of a lump in the throat that typifies the globus syndrome. In a patient with a pharyngeal pouch the early symptoms are of solids sticking in the throat with the need to swallow several times to clear the food. Frequently, the patient attempts to chew every mouthful of food down to small fragments. As the condition progresses, it becomes impossible to enjoy a meal with friends, owing to the excessive length of time taken to eat the meal and the fact that regurgitation sometimes occurs. Eventually, dysphagia with semi-solid foods and then liquids develops. Occasionally, patients present with total dysphagia, unable to swallow their own saliva. Severe weight loss and malnutrition accompany this final state. Painful swallowing in very unusual and should raise suspicion of a malignancy.

Regurgitation of undigested food is a very common presenting symptom. Undigested food may regurgitate into the mouth during a meal, although more often it is after the meal. The regurgitation is more likely to happen when the patient is lying down, and sleep may be disturbed by it. A few patients solve this problem by evacuating the pouch before going to bed by pressing on the side of their neck. Frequently, there is stasis of food in the pouch and this leads to a 'foul taste' and friends or relatives may complain about the patient's halitosis.

Pulmonary complications may arise and result from aspiration of the pouch contents into the larynx. The patient may complain of a persistent cough or throat irritation. The aspiration may lead to chest infections, pneumonitis, lung abscess, bronchiectasis and lung collapse. Hoarseness occurs due to laryngitis caused either by aspiration or gastric reflux, which commonly coexist. The voice might also have a 'wet' quality due to stasis of fluid and soiling of the larynx.

The patient may complain of a lump in the neck that appears intermittently, and gurgling noises in the neck are sometimes noticed (cervical borborygmi). The patient is often aware that food is sticking in the upper throat and frequently will point to the region just below the cricoid cartilage.

Clinical examination may reveal a thin or malnourished patient. The endoscopic view of the larynx and pharynx may be normal although sometimes 'pooling of saliva' can be seen. Rarely, a soft compressible swelling may be found in the neck, usually on the left side in the anterior triangle. The 'rising tide' clinical sign has been described in this setting. During flexible endoscopic evaluation of swallowing using fluids (usually with water or milk with dye), small amounts of swallowed fluid can be seen to rise up from the postcricoid region after the bolus has disappeared from view.

The differential diagnosis includes all motility disorders of the pharynx and oesophagus (globus, scleroderma, achalasia) as well as structural oesophageal disease (neoplasm and strictures) and, finally, neuropathies and myopathies. Gastro-oesophageal reflux disease (GORD) is often present and virtually all motility disorders have been reported in association with GORD. The successful treatment of GORD usually improves the symptomatology of all motility disorders, and is certainly relevant in the treatment of patients with a pharyngeal pouch.

The investigation needed to confirm the diagnosis is either a barium swallow or a contrast video swallow (**Figure 52.1**). The latter provides considerably more

Figure 52.1 Barium swallow showing a pharyngeal pouch.

information about the function of the pharyngeal muscles as well as the presence or absence of gastric reflux.[3] It is essential that the contrast study includes the lower oesophagus and stomach because a lower oesophageal carcinoma can coexist with a pharyngeal pouch.

KEY POINTS

- Incidence is one per 100 000 per annum.
- The condition occurs almost exclusively in Caucasians.
- Dysphagia, regurgitation, hoarseness and pulmonary complications are the main symptoms.
- Differential diagnosis: globus, scleroderma, achalasia, neoplasm, stricture, neuropathies.
- There is a common association with gastro-oesophageal reflux.
- Contrast study is required and a dynamic video swallow is best.

AETIOLOGY

Over the years, many theories concerning the aetiology of pharyngeal pouch have been advanced but no one theory is accepted. There is agreement about the site at which a pouch forms: the posterior wall of the most caudal part of the hypopharynx between the oblique fibres of the thyropharyngeus muscle and the horizontal fibres of the cricopharyngeus muscle. The area between these two muscles is triangular and there are very few muscle fibres in this part of the pharyngeal wall (**Figure 52.2**). This triangular area is called Killian's dehiscence after the man who first described it in 1908. With the advent of more sophisticated and accurate manometric methods for measuring pharyngo-oesophageal sphincter function, one might have hoped for a common consensus on aetiology. On the contrary: even the most popular theories continue to be questioned.

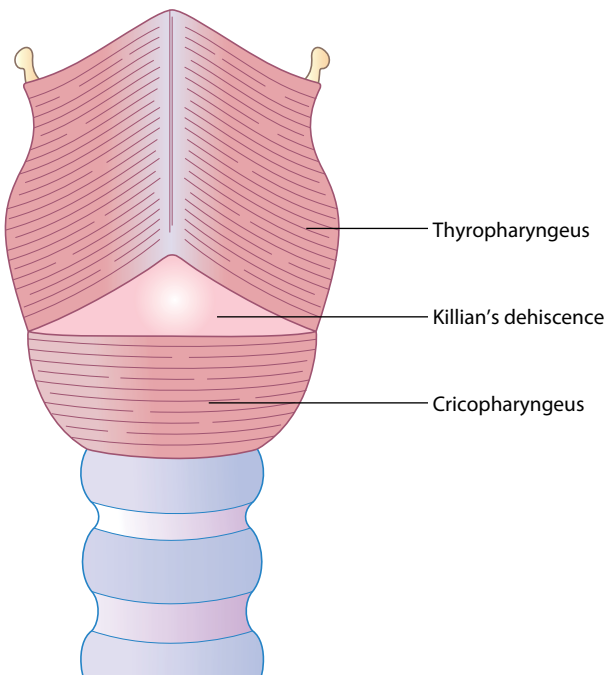

Figure 52.2 Killian's dehiscence.

The three main theories currently proposed to explain the formation of a pouch are:

- that it occurs mainly because of an anatomical weakness in the pharyngeal wall
- spasm of the cricopharyngeus muscle
- various theories that can be labelled as incoordination of the pharyngeal muscles.

Killian's dehiscence; an area of anatomical weakness

Van Overbeek has proposed that anatomical dehiscence is the major cause of pharyngeal pouches.[4] He reasons that, in humans, the larynx is an important structure generally larger than in other animals. In most mammals, the larynx is located just below the skull base, but in humans it has descended to the cervical region. Consequently, the pharyngeal constrictor muscle fibres in humans (with the exception of cricopharyngeus) have assumed an oblique course because the raphe in the dorsal midline is attached to the skull base. However, the cricopharyngeus muscle has horizontal muscle fibres which arise from either side of the cricoid cartilage and not the skull base. Therefore, the 'descent of the human larynx' gives rise to Killian's dehiscence. (It should be noted that pharyngeal pouches do occur in other animals.)

Van Overbeek further proposes that individual variations in anatomy are the cause of a predisposition for hypopharyngeal diverticulum; for instance, some individuals with longer necks might have a larger triangle of Killian.[4] Perrott studied the pharyngeal muscles in cadavers and found several different patterns of fibre arrangement in the gap between thyropharyngeus and cricopharyngeus, and in each individual muscle.[5] He suggested that in some individuals the arrangement of the cricopharyngeus muscle leaves denuded portions, and therefore these individuals were more liable to pouch formation.

To account for the fact that pharyngeal pouches develop after 40 years of age, Van Overbeek suggests that, with advancing age, there is loss of tissue elasticity and a decrease in muscle tone. The large size of the laryngeal skeleton may explain why pharyngeal pouches are more common in men.

That an anatomical predisposition may play a prominent role in pouch formation is also supported by the familial incidence seen with these relatively rare diverticula. In Van Overbeek's series of 545 patients with pharyngeal pouch, nine patients were from four families and three of the nine were brothers from the same family. All 545 patients were Caucasian.[4]

Van Overbeek's manometric studies showed that, in normal people as well as patients with a pouch, there is a high intraluminal pressure in the caudal hypopharynx that peaks during pharyngeal contraction. He proposes that, in individuals with an anatomical predisposition (large or weak Killian's dehiscence), a mucosal prolapse takes place

and over the years the intraluminal pressure produces a pulsion diverticulum that gradually increases in size. He found no significant differences in the maximal contraction pressure in the hypopharynx between patients with a pouch and normal individuals, and thus concluded that the problem is due to an anatomical weakness (Killian's dehiscence).

Failed relaxation of the cricopharyngeus muscle

The cricopharyngeus muscle normally is in a state of tonic contraction, but it relaxes at the end of the second stage of swallowing when the sequential contraction of the pharyngeal constrictors occurs from above downwards. Various functional abnormalities have been suggested to account for pouch formation.

Negus,[6] Sutherland[7] and Belsey[8] favoured the theory that persistent tonic spasm of the cricopharyngeus muscle prevents the downward passage of the bolus and creates a high pressure above the cricopharyngeus that eventually causes herniation through Killian's dehiscence.

Dohlman and Mattson[9] stressed the importance of an intact prevertebral fascial layer that normally supports the posterior wall of the larynx. They reasoned that, with increasing age, the fascia may weaken, allowing the larynx to fall forwards and thus decrease the circumference of the cricopharyngeus muscle, which is normally stretched open during the act of swallowing. A functional obstruction would be produced and, with elevation of intrapharyngeal pressure on swallowing, herniation of mucosa through the weakened posterior triangle, now unsupported by prevertebral fascia, would take place.

Cook[10] has more recently proposed that, rather than spasm of the muscle, the failure to relax is due to fibrosis. Laryngopharyngeal reflux is suggested as one possible cause of this.

Some patients with primary muscle disorders such as inclusion body myositis can have failed cricopharygeal relaxation, initially due to muscle failure and laterally due to fibrosis in the muscle. A pharyngeal pouch may then develop above the disease cricopharyngeal muscle.

Incoordination theories

Ardran, Kemp and Lund[11] used contrast cineradiography to examine 16 patients with pouches of differing sizes and 17 normal subjects. After the initial swallow, the main bolus descended into the pharynx to be moved on by the pharyngeal stripping wave. In patients with pouches they found this to be defective in two ways: the oropharyngeal contraction was weak, and the pharyngeal peristaltic wave was also weak together with early closure of the cricopharyngeus muscle. As a result of their studies they proposed a mechanism of pouch formation. The cricopharyngeus contracts prematurely and, as the stripping wave descends to the prematurely closed sphincter, it pushes the posterior pharyngeal wall down and forwards to meet the back of the cricopharyngeal sphincter. A dimple is produced which, in time, goes on to form a pouch.

Ellis et al[12] came to similar conclusions by measuring the intraluminal pressures in patients with pouches and comparing them with those of normal subjects. The resting tone of the cricopharyngeus was found to be normal in all subjects, but in patients with a pouch the cricopharyngeus was found to contract a fraction of a second before pharyngeal contraction was complete so that the pharyngeal–oesophageal peristaltic sequence was not coordinated.

Lichter et al[13] also supported the incoordination theory. His manometric study showed that, although the sphincter relaxes for the normal amount of time, relaxation begins prematurely and therefore ends prematurely. The effect is the same: high pharyngeal pressures conducive to herniation of mucosa through a muscle-deficient area. Lichter also noted the phenomenon of repetitive pharyngeal swallow, thought to be a result of obstruction to the swallow wave at the upper oesophageal sphincter, since it disappeared following sphincterotomy.

Hunt[14] proposed that gastro-oesophageal reflux may lead to cricopharyngeal spasm or incoordination. The reported incidence of gastric reflux in patients with pharyngeal pouches ranges from 5% to 100%, with the incidence in the normal population being put at 23%.[15] The wide variation in these series could easily be explained by how persistently the symptom of reflux was sought and interpreted. Resouly et al[16] studied 29 patients who underwent surgical correction of pharyngeal pouches. Of these, 19 were found to have reflux and 20 dysmotility. Their findings suggest that many patients with a pouch may have a generalized oesophageal muscle dysfunction and not purely a localized incoordination of the cricopharyngeal muscle.

Rarely, a pharyngeal pouch may form by traction as opposed to pulsion. The adhesions associated with surgery to fuse the anterior cervical spine following trauma can 'pull' a pouch out of the pharynx.[17, 18]

Similarly, pouches (or more correctly pseudopouches) may appear in the presence of large anterior cervical spinal osteophytes over which the pharynx moves, causing an apparent pouch. When examined, such sacs do not herniate through muscle and disappear on removal of the osteophytes.[19, 20]

In summary, opinion concerning the pathophysiology of pharyngeal pouches is divergent. Part of the disagreement may be ascribed to differences in measuring techniques.

CONCLUSION

It is unlikely that there is a single pathophysiological process causing pharyngeal pouch formation. However, in general terms, incoordination between the descending peristaltic wave and failed cricopharyngeal muscle relaxation creating an abnormally high intraluminal pressure subsequently leads to mucosal herniation through the weak area of Killian's dehiscence.

As most agree that failed cricopharyngeal muscle relaxation is involved in the aetiology of pouch formation, a cricopharyngeal myotomy is recommended. With endoscopic techniques this is always carried out because the

cricopharyngeus muscle lies within the bar that divides the pouch from the oesophagus. For operations involving pouch excision, a separate myotomy is required.

KEY POINTS

- Killian's dehiscence is an area of potential weakness between the thyropharyngeus and cricopharyngeus muscle.
- Dysfunction of the cricopharyngeus muscle (or failed cricopharyngeal relaxation) is involved in pouch formation.
- Gastro-oesophageal reflux may contribute.

PATHOLOGY

The histology of an excised pouch shows an epithelial lining of stratified squamous epithelium and submucosa, often surrounded by fibrous tissue. Nearer the neck of the pouch, scanty muscle fibres are found in the wall.

There is evidence of myositis either isolated or as part of a systemic disease (e.g. inclusion body myositis) in some patients.

Carcinoma occurring within a pouch

Carcinoma within a pouch was first described by Vinson in 1927; it is a rare problem with only 47 cases reported in the English literature.[21] Huang et al,[22] in a series of 1249 patients, found four patients with a malignancy arising within the pouch, an incidence of 0.32%. In Van Overbeek's series of 545 patients only two (0.4%) had a carcinoma.[4] However, Bradley et al, in a retrospective review, found that out of 50 pharyngeal pouch excisions, two had carcinoma *in situ* and two had invasive carcinoma.[23]

Carcinoma usually seems to occur in individuals who have had a very long-standing pouch, with the average duration of symptoms in Huang et al's four patients being greater than 7 years. The main predisposing factor is thought to be chronic irritation and inflammation of the pouch lining caused by food retention.

It has been stated that barium studies show a constant filling defect as opposed to the filling defect due to food debris, which may move or alter between films. Symptoms indicating a carcinoma are rapidly increasing dysphagia, pain and/or blood in the regurgitated food. Nodes or a mass in the neck may be found. Patients with a pouch do not normally complain of pain or bleeding and the dysphagia usually progresses slowly. An urgent endoscopy is required in any individual with these suspicious symptoms, whether or not they have had a pouch treated before.

The endoscopic management of a pharyngeal pouch should include a close inspection of the pouch lining with a biopsy of any areas that look suspicious. Close inspection with a Hopkins rod is recommended and it may be necessary to wash the food debris out of the pouch with saline in order to obtain a reliable view of the pouch mucosa.

Carcinoma arising after pouch surgery

At a meeting in 1951, Lodge was the first to question the possibility of a carcinoma arising in the pouch wall following Dohlman's procedure. To this Professor Dohlman replied: 'I suppose the operation, as soon as it relieves the retention in the sac, contributes to a more normal appearance and function in the mucous membrane, and consequently diminishes the danger of cancer.'[24] However, carcinoma certainly can arise in the pouch wall following endoscopic division of the cricopharyngeal bar and after pouch excision (at the junction of pouch and oesophagus). In all reported cases there has been a delay of several years before the carcinoma occurred and often the patient has had persistent symptoms and multiple procedures.[25]

KEY POINTS

- Carcinoma developing in a pouch is rare (0.4%).
- At operation, it is essential to examine the lining of the pouch.
- Carcinoma can rarely occur after pouch surgery.
- Rapid-onset dysphagia, pain or blood-stained secretions should raise suspicion for malignancy.

MANAGEMENT OPTIONS

The management options for patients with a pharyngeal pouch can be divided into three groups: conservative, endoscopic surgery and external approach surgery. Particularly for patients with a pharyngeal pouch, it is essential to consider the overall health of the patient carefully as well as assessing how much effect the pouch is having on the individual's quality of life. A small pouch may cause minimal symptoms, in which case the patient may or may not present to their general practitioner.

Careful consideration of the patient's general health and their specific symptoms needs to be undertaken. When weighing up the decision as to whether to operate or not it is important to consider that the symptoms associated with a pharyngeal pouch usually increase with time whereas the elderly patient's overall health tends to decline. In Zenker's original review, 13 of 22 patients died because of the complications associated with living with a pouch.

The majority of patients undergoing pharyngeal pouch surgery are elderly and frail. The mortality rates observed in some of the published series are a reflection of this frailty. Therefore, the ideal surgical method is one that requires a short anaesthetic and the minimum surgical intervention. The modern endoscopic technique employing stapling fulfils these criteria.

Pouch operations include:

- endoscopic:
  - fibre-optic (flexible) endoscopy and division of cricopharyngeus (diathermy)
  - rigid endoscopy and diathermy division of the cricopharyngeal bar

  - rigid endoscopy and laser division of the cricopharyngeal bar
  - rigid endoscopy and division of the cricopharyngeal bar by a cutting and stapling device
- open cricopharyngeal myotomy
- open excision of the pouch with/without cricopharyngeal myotomy
- inversion of the pouch and cricopharyngeal myotomy.

HISTORICAL COMMENT

Ludlow of Bristol was the first, in 1769, to identify a patient with a pharyngeal pouch.[26] In 1878 the clinical features were reported by Zenker,[27] who described a hypopharyngeal diverticulum as a pulsion diverticulum above the oesophageal inlet.[27]

In 1886, Wheeler[28] reported the first successful excision of a pharyngeal pouch, performed the year before, in 1885. It was an incidental finding while operating on an army officer who had acquired a lateral pharyngocoele from overexercising his voice on the parade ground. This patient recovered completely and his swallowing returned to normal. However, many of the early attempts at excision were unsuccessful, being complicated by sepsis and, in particular, mediastinitis. Other methods were therefore advocated including inversion of the sac and diverticulopexy, in which the fundus of the sac is secured high up in the neck. All types of pharyngeal pouch surgery had high mortality rates until the advent of antibiotics; Stetten,[29] in 1910, reported a 17% mortality rate for pouch excision.[29] Even when antibiotics were available, external excision of a pharyngeal pouch continued to carry significant morbidity and mortality. A high fistula rate meant that in most series of pouch excision the average length of hospital stay was in excess of 12 days.[30] The use of an autosuture stapling device to excise the pouch, while at the same time sealing the wound edges, improved the results for pouch excision considerably.[31, 32]

Inversion of a pharyngeal pouch was first described by Girard in 1895.[33] This technique was developed to avoid the risk of opening the sac, associated as it was with the serious problems of sepsis and fistula formation. Stell repopularized this technique, which, when compared with pouch excision, has a lower complication rate and the patient has a shorter hospital stay.[34, 35]

The principle of endoscopic treatment, in which the cricopharyngeal bar is divided to create a common cavity so that the bolus must pass into the oesophagus, was first described by Mosher in 1917.[36] The common wall between the oesophageal lumen and the pouch was divided with punch forceps. Mosher noted that 'a small cresenteric rim was to be left at the bottom of the pouch to wall off the mediastinum' and that 'should symptoms return, it should be an easy matter to cut the common wall still more'. Six patients were treated successfully until Mosher discontinued the procedure when his seventh patient developed mediastinitis and died.

The concept of creating a common cavity endoscopically was restored to favour by Dohlman and Mattson.[9] Dohlman introduced diathermy for coagulating the common wall prior to cutting it. He pointed out that division of the bar or septum, within which lay the cricopharyngeal muscle fibres, simultaneously produced a cricopharyngeal myotomy. Dohlman carried out 100 diathermy divisions in 39 patients, with no complications and a recurrence rate of 7%. It should be noted that many of his operations involved at least two stages. Other individuals could not achieve his results and this endoscopic procedure using diathermy did not gain universal acceptance because many patients complained of persistent dysphagia after the operation and required revision procedures.[37]

Most retrospective reviews showed that the results for pouch excision and endoscopic cricopharyngeal bar division were similar, with both groups having significant morbidity and a high recurrence rate. However, one individual surgeon's figures did stand out; Van Overbeek's series of patients, all treated endoscopically, is still the largest. The first 328 patients were treated by Dohlman's procedure using diathermy and, subsequently, 216 patients were treated with a microscope coupled with a carbon dioxide laser to divide the bar. Van Overbeek's success rate surpassed all other published series at the time and had the lowest complication rate.

In the early 1990s, developments in laparoscopic surgery produced stapling devices that allowed division and sealing of tissue simultaneously.[38] Collard was the first surgeon to use a cutting stapler to divide the common wall between the pouch and the oesophagus while at the same time sealing the opposing walls of the pouch and the oesophagus.[39] Independently, in 1993, Martin-Hirsch and Newbegin published a case report describing a similar endoscopic technique using a stapling gun.[40] Several centres then developed and refined the technique, so that by the time of a 1996 survey 28% of ENT surgeons in the UK were using a stapling device if they used an endoscopic technique. In the following year, the National Confidential Enquiry into Perioperative Deaths (NCEPOD) in the UK recommended that endoscopic stapling should become the treatment of choice.[41] This enquiry also recommended that there should be one or, at the most, two surgeons within each ENT department who are trained and competent in the surgery of pharyngeal pouches. Following this recommendation there has been a shift away from pouch excision.

Cricopharyngeal myotomy via an external incision still has a role, in particular for patients with a very small but symptomatic pouch.

The indications for excision include the presence of a carcinoma in a pouch and a large perforation if it happens during attempted endoscopic stapling.

Table 52.1 describe the authors' approach to surgery for symptomatic pharyngeal pouches.

CONSERVATIVE MANAGEMENT

There is no evidence that any drug therapies work for cricopharyngeal dysphagia.

Botulinum toxin has been injected both percutaneously and endoscopically. Success is variable, and there

TABLE 52.1 The authors' approach to surgery for symptomatic pharyngeal pouches

Size of pouch	First-line treatment	Recurrence/failure/poor access
Small (less than 2 cm)	Balloon dilation of cricopharyngeus *or* Endoscopic division of the cricopharyngeal bar (LASER)	Endoscopic division of the cricopharyngeal bar (LASER) *or* Open cricopharyngeal myotomy
Moderate (2–4 cm)	Endoscopic stapling	Revision stapling *or* Open excision of the pouch and cricopharyngeal myotomy
Large (greater than 4 cm)	Endoscopic stapling *or* Open excision of the pouch and cricopharyngeal myotomy;	Revision stapling *or* Open excision of the pouch and cricopharyngeal myotomy;

are reports of protracted dysphagia due to dysmotility and also of paralysis (temporary) of the larynx.

OPERATIVE DETAILS OF THE METHODS AVAILABLE FOR PHARYNGEAL POUCH SURGERY

Endoscopic stapling technique

In order to obtain informed consent, a thorough discussion with the patient is required. The following points need to be discussed.

- The possibility of not being able to complete the operation safely exists. During the pre-operative assessment it should be possible to identify the patients in whom access may be difficult. The biggest problem encountered is prominent teeth and this may be combined with retrognathia. These patients should be told that it may not be possible to staple the pouch safely, and an alternative strategy should be discussed prior to surgery.
- Patients should be told that there is a risk of damaging their teeth.
- There is a risk of perforating the pouch during attempted endoscopic stapling. Should this happen, a small tear can be sutured endoscopically or managed conservatively but, if it is a large perforation, it would be prudent to open the neck, find the perforation and excise the pouch. It follows that any surgeon undertaking pouch surgery should be competent in head and neck surgery and the patient should be warned pre-operatively that external surgery is a possibility.
- When quoting figures as part of the informed consent, the optimum arrangement is to quote personal figures if this is possible; if it is not, a conservative interpretation of the outcomes given at the end of this chapter could be used.

Technique: endoscopic

This is a modified version of the technique described by Bates.[42]

The procedure is performed under general anaesthesia with endotracheal intubation (preferably with a microlaryngscopy tube to afford more space). If present, the upper teeth are protected with a gum guard or wet swab; the latter allows a little more room for the scope.

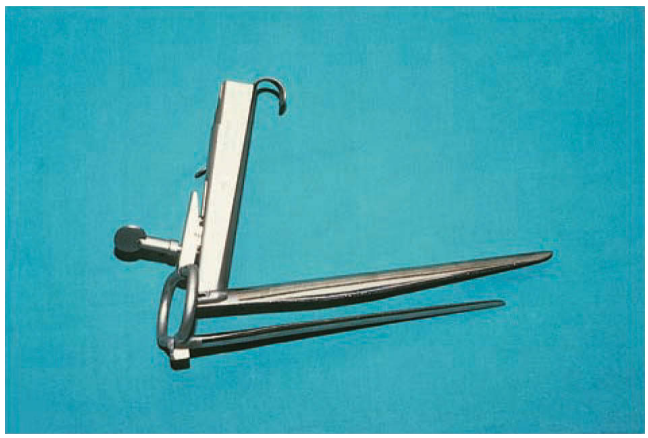

Figure 52.3 A Weerda diverticuloscope.

A rigid Negus pharyngoscope is introduced to identify the cricopharyngeus. At this point any stenosis due to scarring can be dilated with a balloon. A rigid oesophagoscope is then introduced to identify clearly and inspect the upper oesophagus. Then a Weerda distending diverticuloscope (Karl Storz Endoscopy (UK) Ltd, Slough, UK) is introduced (**Figure 52.3**) with confident knowledge of the anatomy of the pouch and any coexisting lesions. (As an alternative, an Oxford Roberts pharyngoscope may be used in a patient with a limited access.) The upper blade of the diverticuloscope is carefully inserted into the oesophagus, with the lower blade simultaneously entering the neck of the pouch. The blades of the diverticuloscope can be adjusted in two directions, and the necessary adjustments are made until a good view of the cricopharyngeal bar is obtained (**Figure 52.4**). The scope is then suspended with a laryngoscope holder. Food debris is gently cleared from the pouch using a sucker and adherent debris can be washed out with saline from a 50 mL syringe.

A Hopkins telescope is used to inspect the lining of the pouch. Any abnormality of the mucosa should be biopsied, although it is rare to have to do this. At times, the lining of the pouch will be inflamed and under these conditions it is important to take extra care, with gentle suction in order

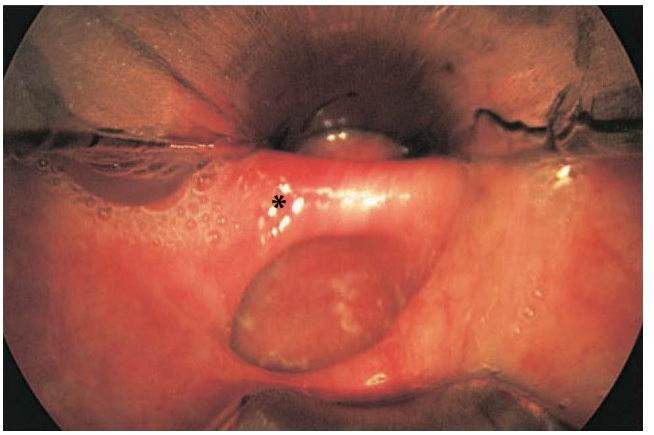

Figure 52.4 The cricopharyngeal bar*.

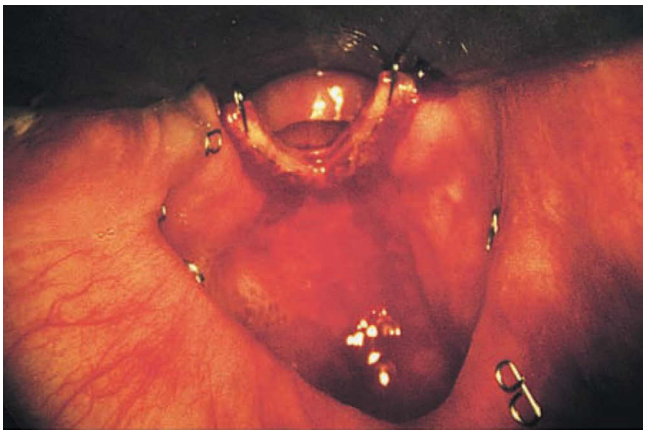

Figure 52.5 A divided and stapled cricopharyngeal bar.

to prevent any bleeding. The presence of blood impedes the view of the operator.

Once a satisfactory view of the cricopharyngeal bar is obtained, an endoscopic linear cutting stapling gun or similar device is removed from the packet and checked. At this stage, the end of the gun carrying the staples is rotated so that the staples are in the upper jaw, which will be inserted into the oesophagus, with the anvil (lower jaw) going into the pouch. Spare staples should be available. The gun is carefully introduced through the Weerda diverticuloscope until the cricopharyngeal bar lies between the two jaws of the gun. The jaws are closed and locked in place. Visual inspection and gentle traction ensure that there is adequate tissue between the jaws. The gun is fired and this divides the septum and simultaneously seals each of the cut edges with a triple staggered row of staples (**Figure 52.5**). The release button is then pressed to free the jaws and the gun is gently removed, making sure that the jaws are not snagged on any tissue.

Tips and tricks for pouch stapling

MAXIMIZING THE VIEW

It is most important to try to obtain the best view possible prior to placing the jaws of the stapling gun over the cricopharyngeal bar. In edentulous patients with a wide mouth, the Weerda scope affords an excellent stereoscopic view and should be used whenever possible. If a good view can be obtained, the operation is usually straightforward. However, difficult access, and a little trauma and possibly bleeding can convert the situation into one where the surgeon will really struggle. A few simple precautions can ensure the best view possible.

- Use a small endotracheal tube or microlaryngoscopy tube, with minimal cuff inflation.
- Ensure that the patient is totally paralyzed.
- Use the Weerda scope if it will fit.
- Use a wet swab to protect the teeth if the access is limited.
- Be prepared to alter the degree of neck extension.
- Use a sucker with great care to limit mucosal damage and bleeding.
- Wash out any debris with 50 mL of saline.
- Use the Hopkins rod.
- Be extremely gentle with the tissues.

DIFFICULT ACCESS

In about 20% of patients access will be difficult owing to a combination of prominent teeth and retrognathia. The anaesthetist will usually confirm that intubation has been difficult (grade 3 or 4). A stiff or arthritic neck needs care but does not often prevent access.

If it is not possible to obtain a view with the Weerda scope, the Oxford Roberts pharyngoscope, the Negus pharyngoscope or the Steiner pattern bivalved laryngopharyngoscope can be used. Each has advantages and disadvantages, but these unfortunately will probably offer poorer visualization than the Weeda diverticuloscope.

NO APPARENT OESOPHAGEAL OPENING

The oesophageal opening is obviously present, but at times it can be hard to find. The reason is that, as a pouch enlarges, the plane of the neck of the pouch rather that the oesophagus comes to lie directly in line with the hypopharynx so that food (and the endoscope) passes into the pouch preferentially. Finding the opening of the pouch is therefore relatively easy, and once found the oesophageal lumen must lie anterior and behind the larynx. The oesophageal opening may appear as a tiny slit or dimple, but when recognized it can be gently dilated using a balloon until the upper beak of the endoscope can be inserted. It can often be found more easily with the use of a Roberts–Jesberg oesophagoscope as this has a slightly upturned superior lip. Also, a fine bougie can be gently passed with its tip bent slightly upwards to cannulate the oesophagus.

DIVISION OF THE SEPTUM

Ideally, virtually all the cricopharyngeal bar should be divided with only a small rim of tissue remaining. Achieving this result is not always easy. The Hopkins telescope can be used to estimate the depth of the

pouch and, with the Weerda scope, it can also be used to check the placement of the jaws of the stapler. It has been suggested to use two endoscopically placed 'stay sutures' to pull the bar up into the jaws of the pouch.[43] It is not possible for the stapling device to cut completely to the end of the cricopharyngeal bar, because the anvil protrudes further than the cutting surface. It is possible to saw the end of the anvil and/or create a deeper pouch by pushing inwards with the jaws, but both these manoeuvres possibly increase the risk of perforation. Leaving an excessively long bar probably predisposes the patient to recurrence but, if in doubt, it is safer to underdivide rather than overdivide the septum and risk a perforation. It is interesting to note that Dohlman was cautious and most of his patients underwent two separate operations. Some surgeons advocate use of the CO_2 laser to divide this last bit of the bar. This does run a higher risk of perforation, as one would expect.

GUN JAMMING

Failure of the stapling gun is rare but the jaws of the gun can jam if too much tissue is placed between them. This occurs when there is a large pouch and the operator is overambitious in trying to do too much with one stapling. In most published series at least two sets of staples are used in the majority of patients. If the gun does jam, gentle manipulation of the release lever will eventually free the mechanism. Do not pull/withdraw a jammed gun; only withdraw when the jaws have been released.

PREVENTING A TEAR/PERFORATION AND SUBSEQUENT MANAGEMENT

It is relatively easy to create a perforation, especially in the pouch itself! The pouch mucosa may be chronically inflamed and, by definition, there is no protective muscle layer. It is possible to push the beak of the scope through the fundus of the pouch or inadvertently tear the pharynx when the stapling device is removed. Occasionally, the stapling device may fail and, if this happens, a diagonal defect in the tissues of the bar appears. Under these circumstances it is possible that the staples have simply not sealed the edges of the tissues properly.

If a small perforation is identified, it may be possible to suture via the endoscope;[44] several endoscopic needle holders are available, such as the 'Berci' needle holder (Stortz). A nasogastric tube should then be inserted and the patient observed carefully for signs of mediastinitis over the next few days.

If a large perforation is present, it is prudent to open the neck, excise the pouch and repair the oesophagus if necessary. Insertion of a large nasogastric tube and a large wound drain is recommended.

If the procedure is traumatic, it is wise to insert a nasogastric tube. In most large series one or more patients are noted to have had a small perforation in the post-operative period because of the presence of surgical emphysema. Conservative management with parenteral feeding and antibiotics is usually successful.

THE LARGE POUCH

Generally, the larger the pouch, the easier it is to deal with using the stapling technique. With a large pouch there is always a long cricopharyngeal bar and as many sets of staples as it takes to divide the bar are used. A huge pouch that extends into the mediastinum is not a contraindication to the stapling procedure, although there is some evidence that large pouches are more likely to recur.[45, 46] Very large pouches may be better treated by open excision; there is no clear evidence favouring either technique, so this has to be carefully discussed with the patient.

THE SMALL POUCH

A patient with a small pouch presents the biggest challenge whether an endoscopic or external approach is used. Unfortunately, small pouches can be symptomatic and some patients who simply have a prominent cricopharyngeal bar and not even a true pouch sometimes also have significant dysphagia. If there is a sufficient cricopharyngeal bar to fill half the jaws of the gun, then stapling is likely to work, but a bar smaller than this makes stapling impossible. Advocates of CO_2 laser division claim that the laser is able to deal with smaller pouches than the stapling device. While this may be true, the margin for error is small. The other options are to let the patient tolerate their symptoms until a more substantial pouch develops, perform an external cricopharyngeal myotomy or simply perform a balloon dilatation of the cricopharyngeus.

PREVIOUS POUCH SURGERY

If the patient has had a previous pouch excision or inversion and then develops a recurrence, it might be assumed that endoscopic stapling would be difficult; this is not the case. Occasionally, scarring twists the pouch to one side but usually the appearances are the same as a pouch presenting for the first time. Following diathermy, laser or stapling division recurrent surgery is usually straightforward.

RECURRENCE

A significant recurrence rate occurs with all endoscopic procedures but, given the minimal discomfort of the first procedure, most patients are usually willing to undergo a repeat stapling, which is not difficult. The same cannot be said for revision external surgery which is difficult and associated with an increased complication rate.

It is arguable whether contrast studies are helpful if a patient has recurrent symptoms after an endoscopic procedure.[47–49] The contrast coats the pouch wall before passing into the oesophagus and the radiologist invariably reports that there is a recurrent pouch. However, multiple pathologies (such as oesophageal dysmotility) can exist, so the authors would recommend a repeat contrast study if surgery is being entertained.

Post-operative care

The patient should not eat or drink for the first few hours after the operation, giving the surgeon time to check the

patient's general well-being and, in particular, confirm the absence of neck or back pain, tachycardia and surgical emphysema. A nasogastric tube is not routinely required but should be inserted if there is significant mucosal damage. Antibiotics are not routinely required and should be reserved for complications. A sensible approach is to allow the patient to drink water initially and then proceed to a soft diet on the evening of surgery if all is well. Many patients can be discharged on the day of surgery.

It is the authors' practice to recommend a soft diet for a week and then progress to a normal diet. The rationale behind this is that the discomfort that can be associated with swallowing can be minimized with a soft diet. Having been denied a good swallow for months, most patients need little encouragement to move on to a normal diet. It seems logical to treat patients with symptomatic gastric reflux with proton pump inhibitors although there is currently no evidence to suggest that this practice reduces the risk of recurrence.

DIVISION OF THE CRICOPHARYNGEAL BAR USING A CO_2 LASER

The Weerda scope is used and the cricopharyngeal bar identified in exactly the same way as for pouch stapling. Swabs soaked in saline are placed around the mouth. An operating microscope with a 400 mm objective lens and attached laser is used. The cricopharyngeal bar is then divided using a CO_2 laser. A nasogastric tube is not essential and the patient is monitored post-operatively in the same manner as for stapling.

Division of the septum using a laser requires experience because it is often difficult to judge the exact amount of septum that can be safely divided without causing a perforation. Inadequate division, on the other hand, results in recurrence of symptoms, requiring revision surgery.

A potential advantage of the laser over the stapling technique is when access is difficult, necessitating the use of a small scope; a better view is obtained because there is no stapling device in the way. The laser can also be used on a cricopharyngeal bar that is simply too small for the jaws of the stapler; however, division of such a small bar does carry with it an increased risk of perforation.

There has been a report of laser endoscopic myotomy with suture closure of the mucosal defect.[41, 50, 51] Although no high-level evidence exists that this represents a better procedure, with modern instrumentation is appears reasonable to close the mucosal defect routinely.

FIBRE-OPTIC ENDOSCOPIC CRICOPHARYNGEAL BAR DIVISION

Fibre-optic endoscopic cricopharyngeal bar division is a technique that uses monopolar cautery to divide the bar. Although approved by the National Institute for Health and Care Excellence (NICE), there are no comparative trials between this technique and established procedures. There are no long-term results available for its efficacy.

The cricopharyngeal myotomy: sole procedure

The approach through the neck tissues is the same as for pouch excision. The assistant passes an oesophagoscope down to just beyond the level of the cricopharyngeus and then withdraws it slightly and rotates the scope so that the light shines through and highlights the muscle fibres, which are divided with a knife. These fibres often do not look substantial and it is important to divide along a length of at least 4 cm. An alternative method is to use the microscope to identify the fibres although it is still helpful to have a solid object, such as a large nasogastric tube, within the lumen. The authors use a pledget to push the muscle fibres apart such that there is at least a 1 cm gap between them. A nasogastric tube is placed by the surgeon in case of any post-operative problems.

Pouch excision

The operation is performed under general anaesthesia with the patient intubated. A pharyngoscope is passed and the openings to the pouch and the oesophagus are identified. A nasogastric tube is passed down the oesophagus. A large bougie can also be passed down the oesophagus alongside the nasogastric tube and can be helpful in the dissection (see below). Food debris is very gently removed from the pouch. The lining of the pouch is carefully inspected with a Hopkins telescope in order to exclude a carcinoma. The pouch is then packed with ribbon gauze soaked in either proflavin or bismuth iodoform paraffin paste, and the proximal end of the strip of gauze brought out through the mouth. The patient is then finally positioned with a sandbag under the shoulders and the head extended and rotated away from the side of the incision.

Either a horizontal incision (usually left sided, level with the upper border of the cricoid), or a vertical incision (along the anterior border of the left sternomastoid muscle) is made. The authors favour a vertical incision for very large pouches. The deep cervical fascia is incised along the anterior border of the sternomastoid muscle, which is retracted laterally. The anterior belly of the omohyoid muscle is divided. The sternohyoid and sternothyroid are retracted towards the midline. The middle thyroid veins are then ligated and divided and this allows the ipsilateral lobe of the thyroid gland to be turned forwards. The contents of the carotid sheath are retracted laterally while the pharynx and larynx are gently rotated to the right. It is good practice to identify the left recurrent laryngeal nerve. It is in close proximity to the inferior thyroid artery, which may have to be ligated and divided. The recurrent laryngeal nerve enters the larynx just inferior to the cricothyroid joint. The dissection is then carried posteriorly along the anterior aspect of the prevertebral fascia so that the tracheoesophageal groove is identified. The pouch will lie immediately above this and can usually be palpated because of the packing within it. It should also be possible to feel the bougie within the oesophagus. This provides 'a base' on which dissection of the pouch can be carried out and it also helps prevent the excessive excision of oesophageal wall.

Sharp dissection of the connective tissue surrounding the pouch is necessary before forceps (Babcock) can be used to grasp the fundus of the pouch. The anaesthetist is then asked to remove the gauze packing. The pouch is carefully dissected free of the oesophagus and the neck of the pouch is carefully cleaned of muscle fibres at its junction with the pharynx.

The pouch should be completely mobilized so that it can be held at right angles to the long axis of the oesophagus, with its neck dissected down to the point where the mucosal sac protrudes through the muscular defect of the pharynx. Care must be taken not to pull normal mucosa out through the deficiency.

A cricopharyngeal myotomy is completed (see 'The cricopharyngeal myotomy: sole procedure' above), and then a large swab should be placed under the pouch to collect any spillage. The neck of the sac is clamped, the pouch excised and the wound edges sealed, preferably using an autosuture stapling gun. A continuous praline suture can be used to invert the suture line.

Recurrence following pouch excision is not uncommon. Contrast studies may be useful in patients who have recurrent symptoms following pouch excision, although a post-operative contrast study by Zeitoun et al[52] showed a multitude of abnormalities even among those patients who were asymptomatic. Their conclusion was that excision of a pharyngeal pouch does not appear to restore a normal swallow.

OUTCOMES

The result of the majority of published series involving ten or more patients is shown in **Table 52.2**. In some of the series, detailed data were collected at the time of surgery but in many of the publications the collection of data was retrospective and is therefore incomplete.

From the data, pouch excision with or without a cricopharyngeal myotomy is an operation that is usually 90% successful, has a recurrence rate of greater than 10% and is associated with major complications in at least 20% of patients. Lengthy anaesthesia is required and the duration of stay in hospital is usually more than 7 days.

Indications for pouch excision remain, including the patient in whom either the pouch or oesophagus is perforated during an attempted endoscopic procedure or the patient in whom a carcinoma is suspected. Some surgeons also advocate pouch excision for young patients and for those with large pouches.[46] The results are better for pouch excision if a stapling device is used to excise the pouch and seal the edges of the pharynx.[31, 32] Pouch inversion also appears to reduce the complication rate but the number of patients reported in the literature is small.[34, 35]

Endoscopic procedures involving division of the cricopharyngeal bar can be seen to produce good results, in particular when the larger series under the care of one surgeon are considered. Dohlman's figures for the period 1940–1960 remain most impressive, with 39 patients being treated with diathermy, a 90% success rate and no major complications.[9] The majority of Dohlman's patients did, however, require two-staged operations. Similarly, Van Overbeek's diathermy series of 328 patients recorded a success rate of 91.5%, a revision rate of 8% and a relatively small number of major complications.[4] **Table 52.3** shows that, when multiple surgeons, each doing a small number of operations, attempt Dohlman's procedure, the success rate drops to 70% with a revision rate of 19%, and the complication rate rises.

With the advent of the Weerda telescope and the CO_2 laser, Van Overbeek changed to laser division in 1981 and his next 216 consecutive patients showed the same success rate and recurrence rate as diathermy, but there was a reduction in the number of complications. When the results of several large studies using the laser technique are summated, it can be seen that the technique has a success rate of 90% and a recurrence rate of 7%. The complication rate is low but higher than for endoscopic stapling.

The results for endoscopic stapling are impressive, with a success rate of 90%, a revision rate of 12% and a very low complication rate.

Long-term recurrence/failure is possibly greater than with open resection, based on the often short follow-up data in endoscopic stapling papers. However, a big advantage of the endoscopic technique is that, when a recurrence occurs, revision is straightforward.

The criticism that a carcinoma may be missed at the time of endoscopic resection is not borne out by the results. There are no reports of this happening in the literature. Bradley's report[23] of a carcinoma *in situ* being found within the wall of a resected pouch of two patients is of concern, and the advice to inspect the mucosa of the pouch thoroughly with a Hopkins rod at the time of the operation seems entirely appropriate. The reported cases of a carcinoma developing some time after endoscopic resection and, indeed, after pouch excision, underline the fact that, if a patient presents with increasing dysphagia, pain or blood-stained regurgitated fluid, then early investigation is required whether they have had pouch surgery or not.

The NCEPOD enquiry noted that pharyngeal pouch surgery is an uncommon procedure associated with a significant mortality of 1–2%. In the year of the study (1995–1996), there were seven deaths following open surgery and one after endoscopic stapling.[41] The one death that followed endoscopic stapling has been published but the other seven have not. The 1996 survey of pouch surgery in the UK showed that 75% of surgeons were doing less than three operations a year. NCEPOD recommended that, because the majority of patients undergoing pharyngeal pouch surgery are elderly and represent a high risk, specialist head and neck surgeons should perform the surgery and, ideally, there should be one, or at most two, surgeons within an ENT department who are trained and competent in this type of surgery. The summated results from the main published series support this recommendation. NCEPOD further recommended that pouch stapling should be the procedure of choice; the summated results indicate that both stapling and laser division of the cricopharyngeal bar should be the operations of choice at the present time.

CONCLUSIONS

The short-term results with endoscopic procedures are superior to external operations. Endoscopic stapling and laser division are quick and bloodless, are associated with minimal discomfort and avoid the need for a nasogastric tube. Endoscopic techniques permit an early oral intake and early hospital discharge, thus reducing the morbidity and costs traditionally associated with pharyngeal pouch surgery. The long-term recurrence of endoscopic techniques is probably higher than pouch excision. However, revision surgery via the endoscope is relatively easy and successful.
