All these changes demand a change in the woman's lifestyle including her dietary habits, to cope up with the increased requirement of nutrients. The nutrient requirements during pregnancy and lactation are discussed here. A Table summarizing the same is also appended (Table - 1).

Nutrient Requirements During Pregnancy and Lactation

Energy requirements : The energy equivalent of the raised resting oxygen consumption is of the order of about 27,000 Kcal, over the entire duration of pregnancy. The diet also has to provide energy for the fat and proteins laid out in the foetus and maternal tissues. The maternal fat deposited is about 4 kg. The total energy cost of pregnancy could be put at about 73,000 Kcal. Most of this extra energy is needed in the latter two trimesters. An additional requirement of 300Kcal per day is to be met, throughout the pregnancy. The additional energy requirement during lactation has been worked out to 550 Kcal in the first 6 months and 400 Kcal thereafter.

Protein requirements : The rapid growth of foetus, development of placenta and other maternal tissues, the expanding fluids (blood volume, amniotic fluid) and other storage reserves demand extra proteins. It has been recommended that an additional 15 g of proteins per day must be catered for during pregnancy. During lactation, extra protein demand is incurred for the production of milk. Therefore an additional intake of 25 g proteins/day in the first six months and 18 g in the next 6 months (6 - 12 months) is recommended.

Fats & Essential Fatty Acids (EFA) : The linoleic acid requirement during pregnancy is put at 4.5% of total energy. This can be met by the normal intake of invisible fats along with an intake of 12.5% of total energy equivalent of visible fats. The EFA requirement goes up further during lactation

Table - 1: Nutrient requirements for a sedentary woman during Pregnancy and Lactation (2,4)

Nutrient	RDA (Sedentary woman)	Pregnancy		Lactation (1st 6 months)		Lactation (6-12 months)	
		Add	Total	Add	Total	Add	Total
Energy (Kcal)	1875	300	2175	550	2425	400	2275
Proteins (g)	50	15	65	25	75	18	68
Fat (g)	20	10	30	25	45	25	45
Iron (mg)	30	8	38	0	30	0	30
Vitamin A (RE)	600	0	600	350	950	350	950
Thiamin (mg)	0.9	0.2	1.1	0.3	1.2	0.2	1.1
Riboflavin (mg)	1.1	0.2	1.3	0.3	1.4	0.2	1.3
Niacin (mg)	12	2	14	4	16	3	15
Pyridoxine (mg)	2	0.5	2.5	0.5	2.5	0.5	2.5
Folic Acid (μ g)	100	300	400	50	150	50	150
Vitamin B ₁₂ (μ g)	1	0	1	0.5	1.5	0.5	1.5
Vitamin C (mg)	40	0	40	40	80	40	80

to 6% of total energy. This can be met by the normal intake of invisible fats along with an intake of 17.5% of total energy equivalent of visible fats. This would correspond to a total of about 45g of visible fats.

Iron : Additional iron is required to meet the augmented demand for foetal growth, expansion of maternal tissue including RBC mass, iron content in placenta and blood loss during parturition. These additional requirements should be added to the basal ones. Owing to these additional needs the iron requirements go up in the second and third trimester to 3.3 mg and 5 mg respectively (taken as RDA of 38mg during pregnancy). However due to amenorrhoea during pregnancy, the menstrual loss of iron is prevented saving some iron loss. Breast milk contains iron, so this iron need is to be catered for during lactation. But since there is lactational amenorrhea, there is no menstrual loss and the total daily iron requirement remains the same as that of a normal woman i.e. 1mg/day (or the RDA of 30mg).

Taking the poor absorption of iron (only 3 - 5%) from habitual Indian diets into consideration, the RDA of iron for pregnant women has been slated at 37.5mg, rounded off to 38mg per day and for lactating women at 30mg per day.

Vitamins

Vitamin A : The vitamin A requirements during pregnancy were calculated on the basis of vitamin A content of livers of the newborn. The additional intake required for this purpose is about 25 $\mu\text{g/day}$ throughout pregnancy. Since this constitutes a very small fraction of the RDA no additional dietary allowance was recommended for pregnancy. On the other hand, a substantial amount of vitamin A is secreted in human milk, hence an additional intake of 350 $\mu\text{g/day}$ is recommended for the lactational period.

Thiamine : The intake of thiamine is based on the energy intake and is normally recommended at 0.5 mg/1000Kcal. The calorie intake does go up during pregnancy and markedly so during lactation so would the thiamine intake. Hence when computed on the basis of energy allowance, it works out to an additional 0.2 mg for pregnancy and 0.3 mg and 0.2 mg for the first six months and latter six months of lactation respectively.

Riboflavin : The RDA of riboflavin is based on the total calorie requirement and is taken as 0.6 mg/1000 Kcal. The higher energy intake during pregnancy and lactation calls for this additional demand which corresponds to an additional 0.2 mg for pregnancy and 0.3 mg and 0.2 mg in the first six months and latter six months of lactation respectively. This increment is the same as that for thiamine.

Niacin : The niacin RDA is fixed at 6.6 mg per 1000 Kcal as is done for adult subjects. This corresponds to an additional 2 mg for pregnancy and 4 mg and 3 mg in the first six months and latter six months of lactation respectively.

Pyridoxine : The Pyridoxine requirement also goes up during pregnancy and lactation. It is recommended that an additional 0.5 mg/day of pyridoxine be catered for pregnancy as well as lactation.

Folic Acid : The additional requirement of folic acid during pregnancy is known to increase by 200 to 400 $\mu\text{g/day}$. The additional RDA is put at 300 $\mu\text{g/day}$ for the duration of pregnancy. It is however difficult to provide this amount through diet alone, so supplementation through medicinal folates have to be made. An amount of about 25 $\mu\text{g/day}$ is lost through lactation. An additional amount of 50 $\mu\text{g/day}$ is therefore recommended during lactation.

Vitamin B₁₂ : About 0.25 to 0.30 μg of this vitamin is lost per day during lactation. An additional intake of 0.5 μg per day is recommended.

Vitamin C : There is no data to indicate that vitamin C requirement is increased during pregnancy. The foetal requirement is too small to justify any additional requirement. Therefore no additional allowances are considered necessary. The additional requirement during lactation is about 20 mg per day. Taking into consideration the cooking losses of 50%, an additional allowance of 40 mg per day is recommended.

Effect of Micronutrient Deficiency During Pregnancy

The micronutrient demands of the rapidly growing fetus are mandatory and inevitable. It is extremely sensitive to the deficiency of micronutrients during the organogenesis and growth. Whenever there is micronutrient deficiency in the mother's diet, the high demand of the foetus is initially met by the maternal resources. But when these resources are exhausted, the maternal reserves are tapped and besides foetus, the mother's health is also compromised. The likely adverse effects of micronutrient deficiency on foetus and mother are shown in Box - 1.

Diet During Pregnancy

Various studies indicate that diet of pregnant ladies in India are generally deficient, esp. so in the rural areas and in the urban lower class (5). These two groups form a major proportion of our society. The diet is mainly a cereal based diet supplemented with little pulses and vegetables. Many a times only a chilly - salt mixture or onion is eaten with rice or chapati, with no pulses, vegetables, fat or fruits. Milk is used only to prepare tea. Usually only two main meals are taken. The nutrient value of such a diet is grossly limited even for a non pregnant woman.

This inadequate diet is not only limited in calories, but is poor in proteins, fats and micronutrients as well. The pregnant woman becomes malnourished. She is more prone to post-partum haemorrhage and death. This anaemic and malnourished woman delivers a physically and/or mentally retarded neonate. There may be bone deformities, mental deficiencies and due to low immunity and nutritional reserves such a child would be more prone to infections and malnutrition. In case it was a girl child, she grows into a nutritionally deficient teenaged girl and mother. The cycle continues and so perpetuates the malnutrition cycle. It is therefore important to offer and consume a balanced diet. The diet should be so modified that more of the protective foods (vitamins and minerals) and body building foods (proteins) are included rather than only excess of energy. A typical balanced diet (raw) is given in Table - 2. The general advise to be given is laid out in Box - 2.

Box - 1 : Adverse effects of micronutrient deficiency on foetus and mother		
Nutrient	Adverse effect on mother	Adverse effect on foetus/infant
Thiamin	-	Infantile Beriberi
Folic Acid	Anaemia	Iugr, Neural Tube Defects, Low Birth Weight, Abortion
Vitamin A	Anaemia	Low Birth Weight, Premature Birth
Vitamin D	Increased risk of osteomalacia	Impaired Bone Development, Hypocalcemia, Rickets
Vitamin E	-	Birth Defect, Spontaneous Abortion
Calcium	Higher risk of hypertension, eclampsia, osteoporosis	Impaired Bone Development, Hypocalcemia, Rickets
Magnesium	Higher risk of hypertension, eclampsia	Premature Birth
Iron	Anaemia	Low Birth Weight, Premature Birth, Higher Infant Mortality
Iodine	Hypothyroidism	Still Birth, Cretinism, Neonatal Hypothyroidism, Deaf Mutism
Zinc	-	Birth Defect, Premature Birth, Low Birth Weight, Hypogonadism

Table - 2 : Balanced diet for a pregnant woman* (3)		
Food Group	Food stuff	Amount per day
Cereals	Rice, wheat, millets	300 g
Fats	Oil, <i>ghee</i> , butter	30 g
Sugars	Sugar, <i>Jaggery</i>	20 g
Milk	Milk, curds, etc	500 ml
Pulses & Nuts	Pulses, legumes, dry beans, nuts	60 g
Fruits & vegetables	Fruits	200 g
	Vegetable	350 g
	Green Leafy Vegetables	150 g
	Other vegetables	120 g
	Roots and tubers	100 g

*The diet shown in the table is a vegetarian diet for a pregnant sedentary woman, for non vegetarians additional 30 g of flesh foods (meat, fish, chicken) or one egg is suggested in lieu of 30 g pulses..

The Meals : In the first trimester the woman suffers from gastritis and morning sickness. In the third trimester the abdomen feels too full and she may not be able to eat much food. Therefore it is advisable to eat small quantities of food more frequently, rather than large quantities in, say only two meals. This means that long inter - meal spans must be interrupted with snacks like the mid - morning snacks after breakfast and the evening snacks with tea.

Diet During Lactation

Just like the diet of a pregnant woman the diet consumed by a lactating woman is also poor in quality and quantity, particularly in the poor rural and urban slum areas, if particular attention is not paid to it. First, the woman might have been undernourished during pregnancy and such a person, when starts breastfeeding her child puts herself to great nutritional strain. Secondly her own demand of nutrients is very high as she has to breastfeed the child. Thirdly, women esp. in the rural, hilly and tribal areas breastfeed the child for a prolonged period. Lactational amenorrhoea serves as a contraceptive incentive for them, and the breast feeding continues till they become pregnant again. This cycle of pregnancy, lactation and repeated pregnancies continue, rendering the mother malnourished. The principles of diet during lactation are basically the same as during pregnancy (please refer

Box - 2 : Public Health Manager's Advise to Pregnant ladies
<ul style="list-style-type: none"> • Eat one extra meal a day, to ensure adequacy of all nutrients • Try and eat with the whole family and not alone • Prefer high fibre cereals and legumes - include sprouts • Include ample amounts of vegetables and fruits • Take meat, milk and eggs regularly • If vegetarian, insist on at least ½ lit of milk, and extra pulses • Prefer nutritious foods like groundnuts and soya beans • No fad diets • Take iron and folate supplements regularly • No un-prescribed medicines, alcohol and tobacco • Attend ANC clinic regularly and follow your doctor's advise

to the earlier paragraphs for nutritional requirements during lactation). A lactating mother must increase her diet by about 10% than what she was eating during pregnancy. A typical diet is outlined in Table - 3.

Food Group	Food stuff	Amount per day
Cereals	Rice, wheat, millets	330 g
Fats	Oil, <i>ghee</i> , butter	30 g
Sugars	Sugar, <i>jaggery</i>	20 g
Milk	Milk, curds, etc	500 ml
Pulses & Nuts	Pulses, legumes, dry beans, nuts	90 g
Fruits and vegetables	Fruits	200 g
	Vegetable	350 g
	Green Leafy Vegetables	150 g
	Other vegetables	130 g
	Roots and tubers	120 g

*The diet shown in the table is a vegetarian diet for a lactating sedentary woman, for non vegetarians additional 30 g of flesh foods (meat, fish, chicken) or one egg is suggested in lieu of 30 g pulses.

Nutrient Requirements for Infants and Children

Weight for weight, the infants and children require more food as compared to adults. This is because the children not only need food for maintaining the BMR, thermogenesis, repairing wear and tear, but also for the important function of continuous growth. Child therefore needs all kinds of extra nutrients, namely, proteins, fats carbohydrates, minerals and vitamins.

Energy Requirements of Infants and Children

Infants : The energy requirement for Indian infants are adapted from the FAO/WHO expert group and the same is summarized in the Table - 4.

Age	Kcal/kg	Average during 1st year
0 - 3 months	116	103 Kcal/kg
3 - 6 months	99	
6 - 9 months	95	
9 - 12 months	101	

Children : Based on the FAO/WHO recommendations the energy requirements are worked out for Indian children. These are given in Table - 5.

Protein Requirements

Infants : The protein requirements for infants are derived from the breast milk intake of normally growing infants (FAO/WHO expert consultation group, 1985) and the same is summarized in the Table - 6.

Children : The RDAs are given in Table - 7.

Age (years)	Boys (Kcal/kg)	Girls (Kcal/kg)
1-3	1287	1193
4-6	1752	1630
7-9	2075	1833
10-12	2194	1965
13 - 15	2447	2056
16 - 18	2642	2064

Age (months)	Proteins (g/kg body weight)
0 - 3	2.3
3-6	1.85
6-9	1.65
9-12	1.5

*In terms of milk proteins

Age (years)	Boys (g/kg body weight)	Girls (g/kg body weight)
1 - 2	1.81	1.81
2 - 3	1.67	1.67
3 - 4	1.61	1.61
4 - 6	1.52	1.52
7 - 9	1.48	1.48
10-12	1.46	1.45
13 - 15	1.4	1.33
16 - 18	1.31	1.21

*In terms of proteins present in routine Indian diets (cereals and pulses)

Fat Requirements

Children and Adolescents : The minimum visible fat intake would also be 5% of total energy. For their energy intake of 2400 Kcal, minimum visible fat intake works out to 12 g/day, but the desirable intake levels should be 20 g/day, which helps to reduce the bulk of diet.

Young Children (1 to 5 years) : For young children the linoleic acid requirement of 3% of the total energy can be satisfied by the minimum visible fat intake of 10 g/day (which would also be 5% of total energy intake). Hence visible fat intake of up to 25 g/day is desirable.

Infants : Breast milk meets the EFA needs of infants which is about 6% of total energy intake. It provides about 30g fat per day, of which about 10% is linoleic acid and 1% linolenic acid. Infants who are not taking breast milk for some reason should be given enough vegetable oils with high linoleic acid content (e.g. safflower, sunflower, corn, soyabean, cottonseed oils) to provide 6% energy equivalent.

Minerals Requirements

Calcium, Phosphorus and Magnesium : These minerals are extremely important for the infants and growing children. They help in bone formation, teeth development, neuro - muscular activities, impulse conduction and structural and metabolic integrity of cells. Suggested intakes of calcium and phosphorus are summarized in Table - 8.

Iron Requirements

Infancy and childhood : The demand of iron is not great during infancy as the infant is born with storage iron and a high haemoglobin count, which disintegrates to provide iron. Therefore as little as 0.3 mg iron per day is sufficient to meet his excretory losses. The demand of iron picks up in the second year of life when 0.4 mg iron is required every day. From second to the twelfth year in males and 10th in females, the mean increase in body weight is 2.5 - 2.7 kg/year, which corresponds to an iron demand of 0.3 mg/day. The daily requirement is further increased by a rise in the haemoglobin concentration by about 1 g/100ml during this period. The amount of iron required to replace the losses, also increases from 0.2 mg /day in infancy to 0.5 mg/day in the 12th year (a total requirement of 0.5 mg and 0.8 mg respectively).

Adolescence : During adolescence, there is an increase in iron demand owing to increase in body mass, growth, further increase in haemoglobin. The obligatory losses also increase with age. In young girls from 13 years onwards, the menstrual losses also become significant (about 0.45 mg daily).

Considering all these issues the iron requirement for Indians have been worked out which are summarized in Table - 9.

Vitamin Requirements

Vitamin A : The RDA of vitamin A for infants are recommended on the basis of its intake through breast milk and extrapolated for children. A summary of the recommendations is given in Table - 10.

Water Soluble Vitamins : The RDA of various B complex vitamins for infants & children are summarized in Table - 11.

Group (years)	Calcium (mg)	Phosphorus (mg)
Infants	500	750
Children 1 - 9 yrs	400	400
Children 10 - 15yrs	600	600
Children 16 - 18yrs	500	500

Group	Age	Retinol (μ g)
Infants	0 - 6 months	350
Infants	6 - 12 months	350
Preschool children	1 - 5 years	400
School children	7 - 12 years	600
Adolescents	13 - 18 years	600

Diet for the infants up to 6 months of age : The documented virtue of breast milk goes back to 2000 years to the *Charak Samhita*. There is no variation in the opinion of the scientists that breast milk is the best for the baby. It contains all the nutrients required by the baby in the correct proportion for at least the first 4 - 6 months. It is well balanced nutritionally and immunologically and is easily digestible.

Composition of Breast Milk : Breast milk is an astonishing emulsion that contains more than 200 known substances, including more than 30 types of sugars, 10 types of fats and many proteins and minerals. Its primary constituents are :

Nutrients : Milk contains almost all known nutrients : fats, proteins, sugars, minerals, vitamins, etc.

Enzymes : These are present to digest and absorb the nutrients.

Immune factors : Many antibodies, lysozymes, etc are present to protect the baby from infections.

Growth factors and hormones : These are present for adequate growth of child.

Breast feeding : The mother must begin breast feeding at the earliest. The milk that is secreted by the woman in the first week after birth is a thick yellowish mixture, called as colostrum. It is highly recommended that the colostrum must be fed to the child as it is not only rich in fats, proteins, minerals and vitamins but also has anti - infective properties (antibodies, immunoglobulins, etc). The carotene content of colostrum is 10 times higher than milk. Vitamin A and E along with other antioxidants play an important role in the growth and immunological defence of the neonate. The practice of pre - lacteal feeding with honey, glucose water or formula feeds must be discouraged. It is advisable to exclusively breast feed the child till about 4 to 6 months. Following this some liquid feeds/supplements may be started (e.g. orange / tomato juice).

Non availability of breast milk : Use of milk other than mother's must be avoided as far as possible. In case breast milk

Group	Age	Daily requirement (mg)	RDA (mg)	
<i>Infants</i>	0 - 6 months	0.32	-	
	<i>Children</i>	1 - 3 yrs	0.35	11.5
		4 - 6 yrs	0.55	18.4
	7 - 9 yrs	0.78	26	
<i>Adolescents</i>				
Boys	10 - 12 yrs	1.03	34.2	
Girls	10 - 12 yrs	0.95	18.9	
Boys	13 - 15 yrs	1.24	41.4	
Girls	13 - 15 yrs	1.4	28	
Boys	16 - 18 yrs	1.49	49.5	
Girls	16 - 18 yrs	1.5	29.9	

Group	Age	Pyridoxine (mg)	Folate (μ g)	Vitamin B ₁₂ (μ g)	Vitamin C (mg)
<i>Infants</i>	0-6months	0.3	25	0.2	25
	6-12 months	0.4	25	0.2	
<i>Preschool children</i>	1-3 years	0.9	40	0.2 to 1.0	40
	4-6 years	0.9	50		
<i>School children</i>	7-9 years	1.6	60		
	10-12 years	1.6	70		
<i>Adolescents</i>	13-15years	2	100		
	16-18 years	2	100		

is not available the best alternative is cow's or buffalo's milk. Whenever this milk is to be given in the first month one part of boiled clean water must be added to 2 parts of milk. With passing time the proportion of water must be reduced to 1 part water and 3 parts milk. By 8 weeks of age the infant gets whole milk without any dilution. Since this milk is poor in iron, iron supplementation is recommended from 2 to at least 8 months.

Diet for the infants from 6 months to 1 year : Breast milk is good enough to meet the nutritional requirements of infant till about 4 to 6 months of age, thereafter the requirements of the infant goes up and the milk yield also starts declining. As a result it is advisable to supplement feeding at six months of age to maintain good growth rate. Introduction of a dilute and nutritionally inadequate cereal gruel as a supplement to breast feeding is unpardonable. This is the time when the mother might become pregnant again and breast feeding is ceased abruptly. A child in such a situation is quite likely to end up as a malnourished child. The weaning has to be understood and practiced scientifically, if good growth of the child is to be maintained.

Weaning is the introduction of supplementary foods to augment the energy and nutrient intake of the infant. During this phase breast feeding is continued and maintained till about 1 year of age. Supplementary foods are gradually introduced and increased in quantity whilst breast feeding is slowly withdrawn. The process starts with omitting one breast feed and supplementing it with a chosen food in suitable quantity. Gradually the baby is given higher quantities of top - feeds and more frequently. This allows the mother to withdraw and eventually cease breast feeding smoothly. It is ideal to wean the child completely by 18 months of age. Some basic guidelines to weaning an infant through 4 to 12 months are given in

Table - 12.

Supplementary Feeding for infants aged 6 months to 1 year : Depending on the age of the baby the supplements could be :

a) Liquid supplements : Breast milk must be continued in this period of the 1st year of life. However supplementation and substitution with certain liquids is recommended. Foods that can be used could be fruit juices like orange, *mousambi* and grapes. These would cater for mineral and vitamin requirement of the growing infant. Green leafy vegetable soups can be used as alternatives. Cow/buffalo milk is also introduced in a graded manner as described in an earlier paragraph.

b) Mashed solid supplements :

(i) *Mashed solids* like boiled and mashed potatoes with salt and *ghee*, cereal gruels like sweet *dalia*, porridge, etc. must be introduced in the 7th month. These foods contribute to the energy required for the rapidly growing baby. Well boiled and if required mashed *dals* can also be added. These will add to the variety and protein content of diet.

(ii) *Vegetables* : Green leafy vegetables can be used as semisolid soups suitably garnished with salt and *ghee*.

(iii) Other vegetables can also be used. The skin and seeds of these boiled vegetables can be removed and only the pulp used for the baby. The mother should start feeding with small quantity and increase gradually.

(iv) *Boiled egg* : It is a very useful, nutritious and easy to cook foodstuff. One may start with egg yolk. Egg white can be introduced later. Initially a partially boiled egg can be given later on a boiled or poached egg is fed.

(v) *Meat* : Well cooked, finely minced or ground meat or mashed fish can also be introduced at this time.

Age	Supplementary foods	Frequency
4-6 months	Mashed banana, Wheat flour, porridge, Ground rice and/or <i>ragi</i> mixed with oil or <i>ghee</i>	Start with 1 feed/day. Gradually increase to 3 feeds/day by 6 months of age
6-9 months	Banana, mango, <i>chickoo</i> , Boiled egg yolk, <i>Khichri</i> , Mashed vegetables, <i>Chapati</i> softened in milk, Green leafy vegetables. Add little <i>ghee</i> /oil to all	4-5 times a day
9-12 months	Fruits, <i>Khichri</i> , <i>Upma</i> , <i>Idli</i> , <i>Chapati</i> , Curd-rice, Vegetables, Egg (boiled/scrambled), Minced meat/fish	4-5 times a day

(vi) **Fruits** : Mashed ripe banana, mango, *chickoo*, apple, etc can be given depending on the availability and taste.

c) **Unmashed solid supplements** : When the baby starts cutting his teeth it is time to introduce chopped and solid foods. Chopped vegetables and minced meat of a coarser consistency can be used. Bit of potato, well cooked rice or *dalia* can also be given. A piece of toast, biscuits, banana, carrots can also be given for healthy teeth and gums. Fruit slices should be preferred to fruit juices now.

Supplementary Feeds for children aged 1 to 2 years

Cereals : Cereals (wheat or rice) based preparations which the child could easily masticate and digest must be encouraged. Potato, sweet potato, tapioca and other starchy vegetables must be continued. These can be given at least three times a day.

Pulses : A pulse or legume preparation must be given at least once a day, to cater for the protein requirement.

Milk : While the breast milk quantity is being tapered off, the dairy milk must be supplemented, starting from about 200ml to 500 ml a day.

Vegetables and Fruits : Well cooked green leafy vegetables and other vegetables must be given twice a day to the child. Fruits must also be given at least once a day.

Eggs : One egg a day, prepared in any form is advisable to be given. As discussed earlier, it could be half boiled, boiled, poached or in any other acceptable form.

Meat : Meat, fish, chicken and their products can also be given as per dietary practices. Easily digestible forms are preferable. Minced meat, *keema*, mashed, shredded or meat soups can be used.

Diet for children aged 3 to 5 years : A three year old child might not be eating much more than a two year one, as the rate of growth in this period (2 - 4 years) is not as fast. So the mother need not be unnecessarily alarmed as long as it is following the height weight norms (Table - 13). The principles of diet are the same as those for a 1 to 2 year child. The only difference might be that a 3 to 5 years child is able to eat a variety of foods as he is capable of chewing and he likes to experiment with new foods. Hence the mother may try and feed him everything that is cooked for the family. Thus the child adapts to the adult diet. The frequency of feeding the child is however more as compared to adults. Children routinely need mid - meal snacks, couple of glasses of milk, variety of 'well presented' foods and an early dinner.

Table - 13 : Expected Height and weight for age (NCHS Standards)

Age (yrs)	Boys		Girls	
	Height (cm)	Weight (kg)	Height (cm)	Weight (kg)
2	85.6	12.3	84.5	11.8
3	99.1	15.7	93.9	14.1
4	102.9	16.7	101.6	16
5	109.9	18.7	108.4	17.7

The Nutritional Requirements for the Elderly

Provision of good nutrition for the elderly is not as easy as it appears. Many physiological, social, economic, medical and psychological alterations take place in the old age, which directly or indirectly affect the food intake, digestion and nutritional status. The BMR goes down with age and so does the physical activity. These factors dictate the reduction of diet. Just like every other system the efficiency of gastrointestinal system goes down, resulting in a lower appetite. The elderly may be lonely and socially aloof, so the zest to cook and enjoy food is lost, thereby compromising with availability of good food intake. The old man may be affected by many chronic illnesses that restrict his food intake, for example salt has to be restricted in hypertension, sugar in diabetes, fat in CVD and proteins in renal disease. The 'taste' of food is thus lost and so is the interest. Certain psycho - social factors like loneliness, lack of family support, feeling of worthlessness, stresses of daily living and possible economic constraints further limit the intake (6).

Nutritional Requirements

Energy : There has not been any conclusive word regarding energy requirement and recommendation for the elderly. Results of various studies have at best been highly variable. Therefore the expert groups have not come out with any special requirements for the elderly. But since it is known that BMR and physical activity go down in the elderly the energy requirement might have to be curtailed. Some authorities recommended energy requirement to be reduced by 11% in elderly men and 10% in women, as compared to young adults (7).

Proteins : Lean body mass protein, turnover and protein synthesis fall with age. WHO/FAO/UNU expert group has recommended a safe protein intake of 1 to 1.25g/kg per day.

Fats and Oils : Fats and oils are recommended at the same level as for the young. In case the person suffers from any chronic lifestyle disease e.g. CVD, hypertension, stroke, etc he might be advised to restrict fat.

Vitamins : It is felt that the vitamin requirement goes up in old age. However no special requirement has been slated for them.

Calcium : Calcium along with vitamin D is required for the integrity of bones. A deficiency of calcium may lead to osteoporosis in the elderly. Sufficient amount of calcium must therefore be taken every day. A slightly higher amount of calcium is recommended, about 0.8 - 1g per day.

Iron : The elderly may have lower iron requirements than the young. At the same time there might be a higher prevalence of disorders that might interfere either with iron absorption (atrophic gastritis etc.) or cause blood loss (hiatus hernia, peptic ulcer, haemorrhoids and cancer). Hence their iron requirement cannot be scaled down and it should be the same as for the young.

Diet for the Elderly : Except for a marginal reduction in energy requirement, the need for other nutrients almost remains the same. Besides the diet being nutritionally adequate the food preparations for the elderly should be tasty, soft and easily palatable. These basic principles are summarized in Box - 3

and some common preparations to be preferred are listed in Box - 4.

Box - 3 : Principles of Diet for the Elderly	Box - 4 : Foods to be preferred
Simple but nutritious food	<i>Dalia</i>
Include green leafy vegetables	<i>Khichdi</i>
Eat plenty of fruits	<i>Upma</i>
Include whole cereals	<i>Kheer</i>
Insist on frequent, small meals	<i>Pohe</i>
Drink plenty of fluids	Canned foods
Avoid fasting	Fruit juices
Avoid fried foods	Vegetable soups
Consume low salt and sugar	Meat stew
Food should be easy to cook	

With this background of nutritional requirements in mind, a typical balanced diet, along with the nutrients supplied with it is given in Table - 14.

Table - 14 : Balanced Diet for the Elderly		
Foodstuff	Quantity (raw in gm)	
	Males	Females
Cereals	350	225
Pulses	50	40
Vegetables	200	150
Green leafy vegetables	50	50
Roots and tubers	100	100
Fruits	200	200
Milk and milk products	300	300
Sugar	20	20
Fats and oil	25	20
Approximate nutrient contents of above food items		
Calories	2200	1700
Protein	65 g	50 g
Fat	50 g	40 g
Calcium	1 g	0.9 g
Iron	38 mg	30 mg
Vitamin A (Retinol)	1030 µg	930 µg
Thiamin	1.96 mg	1.45 mg
Riboflavin	1.78 mg	1.51 mg

Summary

Pregnancy and lactation : Many physiological changes take place during pregnancy and lactation. The nutritional requirement increases substantially during this time. The daily energy requirement increases by 300 Kcal, protein and fat requirement by 15 g and 10 g respectively. The iron requirement

also goes by about 8 mg. The demand during lactation is still higher. The energy requirement goes up by 550 Kcal and protein and fat requirement by 25 g each. Suitable modification in diet should to be made through addition of another meal, mid meal snacks and nutrient dense foods. Protein, iron and vitamin rich foods should be included in diet. It is wise to include fruits, vegetables, whole grains, milk products, meat, egg, legumes, nuts, etc. Also include vitamin C rich foods to improve iron absorption. Minimise coffee/tea during mealtime. It is advisable to take iron - folate supplement. Don't take any medicines without prescription and abstain from smoking and alcohol.

Infants and children : Weight for weight the infant and children require more food than adults. It is advisable to exclusively breast feed infants till about 6 months. Thereafter they should be gradually weaned through introduction of fruit juice, cow's milk, semisolid foods, boiled vegetables, potatoes, eggs and fat. As the children grow, so do their nutrient requirements. It is wise to keep an eye on the age - weight chart while the child is growing up.

Elderly : It is a challenge to meet the nutritional requirements of the elderly people for more than one reason. There is not enough research to base our recommendations for various nutrient requirements. Unlike adults where only the physical requirements govern the nutritional demand, in elderly the social, psychological, economic, emotional and physical needs are all important when it comes to eating food. Moreover the biological process of ageing differs in each individual. The challenges increase with increasing longevity. Illness, psychological voids, bereavements all pose varied impact. It is understood that the nutritional requirements for elderly are almost the same as that for adults. The food must be simple, easy to cook and more palatable.

Study Questions

Long Question : What are the nutritional requirements elderly age? Elaborate a plan to meet these requirements.

Short Notes : (1) Weaning (2) Meeting Iron demand of a pregnant woman (3) Diet during lactation

MCQs

- Which of the following is not true regarding diet for the elderly : (a) Their poor dentition restricts their food intake (b) The zeal to cook and eat goes down (c) Their food requirement is about half that of a robust young adult (d) There is not enough research to accurately predict RDA for elderly.
- Which of the following is not true regarding diet during lactation : (a) Energy requirement during lactation is higher than during pregnancy (b) Iron requirement during lactation is higher than during pregnancy (c) Vitamin C requirement during lactation is higher than during pregnancy (d) Vitamin A requirement during lactation is higher than during pregnancy
- Higher need of vitamin A during pregnancy can be met by all except : (a) Carrots (b) Cod liver oil capsules (c) Extra egg whites (d) Extra milk

4. Which of the following is true about diet during pregnancy: (a) Salt intake must be minimized to prevent edema (b) Diet before pregnancy has no bearing on health of neonate (c) Strict weight control helps minimize childbirth complications (d) One extra meal per day is recommended during pregnancy
5. Which of these is not true for weaning : (a) Weaning means gradually replacing breast milk with other foods (b) It should be started at 1 year of age (c) One must start weaning with fruit juices and cow's milk (d) Infant is more vulnerable to infections during this period

Answers : (1) c; (2) b; (3) c; (4) d; (5) b.

Nutritional Deficiency Diseases of Public Health Importance

Rajul K Gupta

A large part of our population particularly the poor suffer from serious deficiencies in their diet. This might be an actual deficiency or one due to lack of knowledge about food and nutrients. As a consequence of this, several nutritional deficiencies with clinical manifestations and disabilities are encountered in our country. Most important of them are Protein Energy Malnutrition (PEM), Anaemia, Vitamin A Deficiency and Iodine Deficiency Disorders (IDD) and have been the concern of health authorities in our country for a very long time. Anaemia is the most prevalent affecting all ages. In India an astounding three fourths of all females and more than half of all males suffer from anaemia. PEM and vitamin A deficiency occur mostly among preschool children. More than 85% of Indian children suffer from some degree of undernutrition (mild, moderate or severe), making it a national priority. Vitamin A deficiency is of grave concern as it causes blindness that is easily preventable. Thyroid insufficiency due to iodine deficiency, which affects all age groups results in many a serious condition including goitre, impaired metabolism, cretinism, mental retardation and deaths (still births).

Protein Energy Malnutrition (PEM)

Malnutrition is a range of conditions occurring when intake of one or more nutrients doesn't meet the requirements. Protein Energy Malnutrition (PEM) is a malnutrition resulting from the deficiency of protein and/or energy in diet. PEM is an important nutritional problem among preschool age children. This leads to various degrees of growth retardation. When growth retardation is severe, functional deficiencies, like resistance to infection and poor intellectual development may result. The main cause of PEM is food inadequacy i.e. the deficiency of

energy or proteins or both. In these cases deficiency in other nutrients like vitamin A, iron, calcium and riboflavin is also seen. It is also known that infections like measles and diarrhoea aggravate PEM. In 1959, Jelliffe introduced the term 'Protein Calorie Malnutrition' (PCM) as there was close association between the two poles of the syndrome namely, Kwashiorkor and Marasmus. The term PCM, was later rephrased as Protein Energy Malnutrition (PEM).

Undernutrition includes underweight (being underweight for one's age), stunted (being too short for one's age), wasted (being dangerously thin), and micronutrient malnutrition (being deficient in vitamins and minerals).

Magnitude of the Problem

World : The magnitude of the problem at a global level can be reckoned from the fact that malnutrition contributes to 60% of the total 10 million deaths of children under five years of age. Its contribution to child deaths is highest during first six months of life (1).

India : As per NFHS-2 (1998-99), 47% of children under three years are *underweight*, 45.5% *stunted* and 15.5% *wasted*. India fares poorly even among the South East Asian countries, occupying the third place from the bottom with only Nepal and Bangladesh faring worse than India. The prevalence of low birth weight continues to be about 30% for last three decades. *Low birth weight* babies are more likely to die because of neonatal infections and undernutrition (1). *Chronic Energy Deficiency* in adults is 39% in females and 37% in males (NNMB 2002) (2).

As per the NFHS report of the National Health Profile, 2007, considering various parameters, as many as one fourth to half of all Indian children are undernourished in various age groups (3). Even during the first six months of life, when most babies are breastfed, 20-30 percent of children are undernourished according to each of the three criteria, namely stunting (or too short a height for age), wasting (or too thin for height) and underweight. However, malnutrition peaks during the first two years of life. From 11.9% prevalence among 0-6 month old

infants, it reaches to 58.5% in one to two year old children. This steep rise in malnutrition during the first two years is mainly due to poor infant feeding practices (1). Among the children *under 3 years of age*, 38.4% are stunted, 19.1 are wasted and as many as 45.9% are underweight. The highest number of underweight children (under 3 years) is reported from Madhya Pradesh 60.3%. Other states reporting high percentage of underweight children are Jharkhand (59.2%), Bihar (58.4%) and Chattisgarh (52.1%). Mizoram reports the lowest number of underweight children at 21.6%. Other states reporting low percentage of underweight children are Sikkim (22.6%), Manipur (23.8%), Punjab (27%), Kerala (28.8%) and Goa (29.3%) (3). In the under-fives year age group, almost half of all children are stunted, which indicates that they have been undernourished for some time. Twenty percent are wasted, which may result from inadequate recent food intake or a recent illness. Forty-three percent are underweight, which takes into account both chronic and acute undernutrition.

Adults in India suffer from a dual burden of malnutrition; more than one-third of adults are too thin, and more than 10 percent are overweight or obese. Only 57 percent of men and 52 percent of women are at a healthy weight for their height.

Undernutrition is particularly serious in rural areas. The condition is worst in the lower wealth quintiles, among scheduled tribes and scheduled castes, and among those with no education. More than two out of five women are too thin in Bihar, Chhattisgarh, Jharkhand, Madhya Pradesh, and Orissa; similar proportions of men are too thin in Tripura, Madhya Pradesh, and Rajasthan.

Overweight or obesity is most common among adults in Punjab, Kerala, and Delhi. These conditions are most common in older adults, those in urban areas, the well-educated, and those in the highest wealth quintile (3).

Etiology and Epidemiology : PEM characteristically occurs in children less than 5 years of age, whenever the diet is poor in energy and proteins. PEM was earlier attributed to the concept of 'protein gap' (deficiency of proteins in diet), which has now given way to the new etiological theory of 'Food gap', wherein it is not only the deficiency of proteins but inappropriate food (low in energy density, protein and micronutrients - Vitamin A, Iron, Zinc) which is poor both quantitatively and qualitatively, is the chief cause of PEM (5).

Under-nutrition in fetal life, esp. last trimester, lactation failure, low energy dense weaning foods, incorrectly constituted formula, contaminated water and infections (diarrhoea, measles, acute respiratory infections, intestinal worms etc.) also play important role in the causation of PEM. The other associated *social factors* are poverty, poor environmental conditions, large families, poor MCH services and poor cooking practices. Ignorance and the inability to provide adequate food also seem to be important contributory factors.

Classification of PEM : Even though Marasmus and Kwashiorkor are the two main and polar forms of PEM, clinically it can be broadly classified into five forms (Table-1). These varied syndromes result from the types, severity and duration of dietary deficiency.

Type	Percent of standard body weight	Oedema	Deficit in weight for height
Kwashiorkor	80-60	+	+
Marasmic-kwashiorkor	<60	+	++
Marasmus	<60	0	++
Dwarfing	<60	0	Minimal
Underweight	80-60	0	+

Marasmus : Conditions conducive to the evolution of marasmus typically exist in the lower socio-economic classes of the urban community. A low birth weight neonate born to an economically and nutritionally deprived working woman in a setting of ignorance and poverty is most vulnerable to marasmus. The weaning is often early and abrupt. The mother stops breast feeding for various reasons. Most often she has to return to work early. She might be suffering from infections like mastitis, etc. which don't allow breastfeeding to continue. The infant might be having an illness (gastrointestinal or respiratory infections), during which it is not wise to feed the child, in the mother's opinion. Social influences in the form of peer pressure, advertisements of alternative feeds could also be major reasons for discontinuing breast feeding. Another quick pregnancy could change the priority and infant is neglected. Taboos restricting the use of colostrums and breast milk also limit its full utilization. The sheer inconvenience or non availability of a private place to breast feed the child at the work place could dissuade the mother.

A typical epidemiological case is illustrated as follows : Let us take a pregnant construction labourer in an urban setting as an example. Being economically deprived she is in a poor nutritional state. More often than not, she has rapid succession of pregnancies. She delivers low birth weight babies. She breastfeeds the infant for a short duration since she has to return to work at the earliest. The infant is handed over to the elder sibling. This is invariably followed by dirty and dilute formula for feeding. The infant is inadequately fed because of ignorance and to limit expenditure. The diet is low in both proteins and energy. Moreover poor housing/sanitation, lack of fuel, water and utensils makes it impossible to prepare a clean and healthy weaning food. Repeated infections develop (particularly gastroenteritis), which are treated by starvation for long periods. The child is fed with water, weak tea and rice water. This forced early, abrupt and faulty weaning takes its toll on the nutritional state of the infant. The infant ends up being Marasmic.

Clinical features of Marasmus : Marasmus is most commonly seen in children aged less than 5 years (most cases are less than 1 year of age in the urban areas). There is failure to thrive, irritability or apathy. Many infants are hungry and some anorexic. Diarrhoea and dehydration are frequent. The weight is grossly below standards and the child is 'skin and bones' owing to loss of subcutaneous tissue. The common clinical

features of marasmus are enumerated in Box - 1. A standard text on paediatrics could be consulted for more details on the clinical aspects.

Box - 1 : Clinical features of Marasmus	
Constant features	
<ul style="list-style-type: none"> • Growth retardation • Wasting of muscles and subcutaneous fat • 'Wisened old man's look' 	
Other features	
<ul style="list-style-type: none"> • Hair changes like easily pluckable hair • Infection • Vitamin deficiency • No psychomotor changes 	

Kwashiorkor : The term Kwashiorkor was introduced by Cicely Williams into modern medicine. It comes from language of 'Ga' tribe of Ghana, meaning "Sickness the older child gets when the next baby is born".

If the epidemiological events for the causation of PEM had to be greatly simplified, while marasmus is seen in an early and abruptly weaned baby in an urban setting, the other 'pole' of PEM, Kwashiorkor is typical in an older child who is breast fed for a rather prolonged period and weaned late in a rural setting. Poverty, insufficient food and land, poor agricultural practices, religious issues and taboos compromise the nutrient intake. Protein sources like milk, eggs and meat are costly so their supply tends to be inadequate. In some areas Kwashiorkor runs an endemic course, when food supply becomes scarce every year before the harvest season.

In such children the protein and energy supplies are almost always at brink. Frank Kwashiorkor may be precipitated by acute febrile infections like ARI, measles, whooping cough or diarrhoea as the nutritional demand shoots up.

Clinical features of Kwashiorkor : Kwashiorkor is most commonly seen in children aged 2 to 5 years of age. Many children of a given locality sharing the same socio-economic milieu may suffer from Kwashiorkor. The child may be brought to the doctor for an underlying infection. Failure of growth may be an early sign. There may be weight loss, anorexia or diarrhoea. Oedema is present, which is more marked on the lower limbs. Quite often it is grossly present all over the body including face. The common clinical features of Kwashiorkor are enumerated in Box - 2.

Prevention of PEM : "Prevention of PEM is the fight against poverty and ignorance" (7). As was discussed earlier it must be appreciated that there is no single shot solution to the treatment or prevention of PEM. It is a complex problem involving each of the social, economic, educational, political, administrative, medical and health dimensions. An integrated effort involving all these and also awareness and a positive attitude towards the condition might help to limit it. The most vital preventive measures that are executable through the classical health and medical infrastructure and classifiable under the traditional heads of the preventive strategy are enumerated here. Details on mitigation of poverty, improving the health infrastructure, provision of health care and hygiene-sanitation facilities, strengthening immunization facilities, making the PDS more efficient or provision of nutritional education though extremely important, are beyond the scope of this book. Hence these issues have not been elaborated.

Health promotion

- Good ante-natal care
- Education on food, hygiene and family planning
- Education on the importance of colostrum, diet during lactation
- Various measures under the ICDS initiative, like good nutrition, immunization, education, hygiene and sanitation etc.
- Promotion of breast feeding
- Good weaning practices, correct time of weaning, importance of low cost weaning foods
- Prevention and control of infections during weaning
- Improve family diet
- Correct knowledge on balanced diet
- Utilization of family planning practices
- Hygiene & sanitation

Specific protection

a) Diet : Protein and energy rich food should be consumed by children. Special attention must be paid to diet during weaning. Adequate quantities of fruits and vegetables must be included in the diet.

b) Immunization : The child must be immunized as per the national schedule.

Early Diagnosis & Treatment

a) Growth monitoring : Vulnerable children must be identified. Children must be monitored through growth charts. Early diagnosis of growth failure must be done and treated as appropriate.

Box - 2 : Clinical features of Kwashiorkor	
Constant features	Other features
<ul style="list-style-type: none"> • Oedema • Growth retardation • Muscular wasting • Retention of subcutaneous fat • Psychomotor changes 	<ul style="list-style-type: none"> • Hair changes - Flag sign • Diffuse pigmentation of skin and dermatoses-- Flaky paint dermatosis • Moon face • Anaemia • Hepatomegaly • Associated vitamin deficiencies (retinol, tocopherols, folate, pyridoxin, Vitamin K) • Associated mineral deficiencies (iron, potassium, zinc, copper, selenium, magnesium) • Associated acute infections

b) Early diagnosis and treatment : Early diagnosis and treatment of infections is also vital. To achieve this, health worker must be alert and mothers should be aware of the signs and symptoms of common infections. Preparation and use of ORS should be known to all mothers. The services available through the IMNCI initiative must be fully utilized.

c) Medical advice : In extreme and serious cases early medical advice and treatment facilities must be available. Hospitalization of the case remains the only choice in complicated cases.

Rehabilitation : Even if PEM patients are treated well in a hospital setting, many follow up studies have shown that they tend to die of the same disease and infections for which they were treated earlier. It is because the immediate disease in question was treated but the family and community milieu which was responsible for the problem remains largely unchanged. The poverty, hygiene, sanitation, dietary/ feeding knowledge and practices, taboos, predisposing factors for infection etc remain the same. While it may not be possible for the medical fraternity to improve the socio-economic condition of the family, but substantial changes can be brought to the knowledge, attitude and practice about the disease. After an intensive hospital resuscitation session, knowledge can be imparted to the mothers about the disease. Correct feeding practices and skills can be taught. Myths and taboos can be busted. These principles can be undertaken in three settings :

(a) Residential Units : Mothers are admitted with their sick children. The mother gets hands on experience in the practical learning of preparation and administration of a therapeutic diet for her child with an expert. This demonstration and involvement of the mother in her child's recovery goes a long way in understanding the problem and mitigating it.

(b) Day Care Centre : The mother attends the day care centre along with the child where cooking and feeding is taught to the mother. While the child attends every day, involvement of the mother is partial.

(c) Domiciliary Rehabilitation : The expert comes home and assesses the situation as a whole. The mother is then rendered suitable advice with regards not only to feeding but also about improving various domestic contributory factors to PEM.

Anaemia

Anaemia is a global menace affecting both developing and developed countries with major consequences for human health as well as social and economic development. It occurs at all stages of the life cycle, but is more prevalent in women esp pregnant women and young children. In 2002, iron deficiency anaemia (IDA) was considered to be among the most important contributing factors to the global burden of disease (8). The numbers are staggering; as many as 2 billion people or over 30% of the world's population is anaemic. This is frequently exacerbated by infectious diseases like malaria, tuberculosis, HIV/AIDS, hookworm infestation and schistosomiasis in some areas. It is a major public health problem. More subtle in its manifestations than, protein-energy malnutrition, iron deficiency exacts its heaviest overall toll in terms of ill-health, premature death and lost earnings. Iron deficiency and anaemia reduce the work capacity of individuals and populations, bringing serious economic consequences and obstacles to

national development. Overall, it is the most vulnerable, (poorest and the least educated) who are disproportionately affected by iron deficiency, and it is they who stand to gain the most by its reduction. See Box - 3 and 4.

Box - 3 : Facts about Anaemia (9)

In developing countries every second pregnant woman and about 70% of preschool children are estimated to be anaemic.

Anaemia is aggravated by infectious diseases like worm infestations, malaria, HIV and tuberculosis.

The major health consequences include poor pregnancy outcome, impaired physical and cognitive development, increased risk of morbidity in children and reduced work productivity.

Anaemia contributes to 20% of all maternal deaths

Box - 4 : Consequences of Anaemia

General : Weakness, easy fatigability, lethargy, Inhibition of lymphocyte proliferation lowered cell mediated immunity, reduced neutrophil bactericidal activity, vulnerability to infections, diminished physical and earning capacity, reduced work capacity reduced endurance

Pregnant and Lactating Women : Weakness, diminished physical and mental capacity, increased morbidity from infectious diseases, Increased risk of low birth baby, abortion, premature delivery, intra-uterine growth retardation, Congenital fetal malformations, PPH, maternal mortality

Children : Low birth weight, Perinatal mortality, impaired cognitive performance, motor development and scholastic achievement, Psychological and behavioural effects like inattention, fatigue and insecurity

Defining Anaemia : Anaemia is traditionally defined as the reduced oxygen carrying capacity of the blood due to a reduction in its haemoglobin content. The WHO defines anaemia as "a condition in which the haemoglobin content is lower than normal as a result of deficiency of essential nutrients, regardless of the cause of such deficiency". The WHO has further defined as to when should the haemoglobin content be considered as low. The level of 'low' haemoglobin levels vary with sex, age and physiological status. These are summarised in Table - 2 .

Table - 2 : Haemoglobin thresholds used to define Anaemia (10)

Age or gender group	Haemoglobin threshold (g/dl)
Children (0.50-4.99 yrs)	11.0
Children (5.00-11.99 yrs)	11.5
Children (12.00-14.99 yrs)	12.0
Non-pregnant women (≥ 15.00 yrs)	12.0
Pregnant women	11.0
Men (15 yrs and more)	13.0

Anaemia as a public health problem : Globally, anaemia is considered to be a problem of public health significance when the prevalence exceeds certain levels, as elaborated in Table-3.

World : Anaemia is a huge public health problem globally. As per the WHO (2008) estimates about half (48.8%) of the entire world population suffers from anaemia. More than 3/4th of all preschool children, 1/3rd of all school aged children, 69% of all pregnant women and 73% of the non pregnant women have anaemia. More than 40% men suffer from anaemia (8).

India : Anaemia is a major health problem in India, especially among women and children (See Table- 4). Specific groups are elaborated here. The WHO classifies India to be having a 'severe' level of public health problem in the form of anaemia (>40% prevalence in all groups - preschool children, pregnant women, non pregnant women) (8). Among the age group of 6 and 59 months, the great majority i.e. 70 percent of children are anaemic. This includes 26 percent who are mildly anaemic, 40 percent who are moderately anaemic and 3 percent who suffer from severe anaemia. Boys and girls are equally likely to have anaemia. Children of mothers who have anaemia are much more likely to be anaemic. Although anaemia levels do vary, by and large anaemia among children is widespread in every group and every state in India. Even when the mothers were Class XII educated and/or economically well off, the prevalence of anaemia amongst their children too was 50% (3).

More than half of women in India (55%) have anaemia. About 39 % have mild anaemia, 15 % moderate anaemia and 2 percent severe anaemia. Anaemia is particularly high amongst women with no education, women from scheduled tribes, and women in the lowest wealth quintiles. Pregnant and lactating women too have high prevalence of anaemia (3).

Among men, while globally the prevalence of anaemia is about 40%, only one-fourth of the Indian men are anaemic. Men under 20 and over 40 years of age are more likely to suffer from

anaemia. Men at higher risk of anaemia are the widowed men, scheduled-tribe men, and men belonging to the lowest wealth quintile. In these vulnerable groups the prevalence of anaemia goes up to 40% (3).

Etiology : Causation of anaemia is a maze of a multitude of social, cultural, religious, dietary and environmental factors. Poor economic condition, religious practices disallowing certain nutritious foods, dietary practices like vegetarianism limiting food choices, faulty cooking practices discarding nutrients from food, faulty child rearing practices (premature weaning) enabling predisposition of PEM and anaemia, large families limiting food intake and poor environmental sanitation and non availability of sanitary latrines and drinking water, all predispose to anaemia either directly or indirectly.

Anaemia is the result of a wide variety of causes that can be identified, but more often they coexist. Globally, the most significant contributor to the onset of nutritional anaemia is iron deficiency so the terms iron deficiency anaemia and anaemia are often used synonymously, and the prevalence of anaemia has often been used as a proxy for iron deficiency anaemia. It is generally assumed that most of the cases of anaemia are due to iron deficiency. Therefore the causes of iron deficiency are discussed in detail here. These can be enumerated in a simply manner as shown in the Box - 5.

a) Inadequate intake of iron : The sources of iron have been discussed in greater details in the chapter on minerals. Poor diet is an important cause of inadequate intake of iron. While economic constraints make one's diet poor, it is also the ignorance about the dietary sources of iron which also makes even a well to do man's diet poor in iron. For example it is generally believed that spinach is a 'very good' source of iron. But the fact is that it is a poor source as it contains only 1.1mg iron per 100g. On the other hand almost all other green leafy vegetables like radish leaves (18 mg), rape leaves (12.5mg),

Table - 3 : Classification of anaemia as public health problem (3,8)

Prevalence of anaemia	Health significance	Examples (Countries)	Examples (Indian states)
<4.9%	No public health problem	Chile (Non pregnant women), USA (Preschool children)	-
5.0-19.9%	Mild public health problem	Australia, Israel, UK, USA and most Western European countries	-
20.0-39.9%	Moderate public health problem	Japan, Malaysia, China, Pakistan and most of the middle east countries	Goa, Kerala (pregnant and non pregnant women), Mizoram, Manipur (Non pregnant women), Delhi (pregnant women)
> 40.0%	Severe public health problem	India, most of the SE Asian and African countries	All Indian states, except the categories mentioned in the row above

Table - 4 : India - WHO estimates of anaemia prevalence amongst preschool children and women (8)

Age	Cut off haemoglobin	Prevalence %	Estimated Number	Level of public health problem
Preschool children (6m-3yrs)	< 11g/dl	74.3%	8,90,90000	Severe
Pregnant women (15-49 yrs)	< 11g/dl	49.7%	1,27,99000	Severe
Non-pregnant women (15-49yrs)	< 12 g/dl	52.0%	13,44,95000	Severe

turnip greens (28.4mg), amaranth species (1.8 -38.5mg), methi leaves (1.9 mg) and lettuce (2.4) mg all contain high iron.

Box - 5 : Causes of Anaemia
<p>Inadequate intake of iron</p> <ul style="list-style-type: none"> • Poor diet • Poverty • Ignorance • Inadequate folate/vitamin C intake
<p>Poor absorption and bioavailability of iron</p> <ul style="list-style-type: none"> • Absorption -Only 5% • Poor absorption-Non haeme iron (Ferric iron) • Inhibitors: Phosphates, phytates, oxalates, fibre • Tea (tannin), Eggs (Phosphate), Milk (Calcium)
<p>Excessive loss of iron</p> <ul style="list-style-type: none"> • Normal man (1mg/day) • Menstruation (2mg/day) • IUDs • Intestinal worms • Malaria • Repeated / frequent pregnancies
<p>Increased demand of iron</p> <ul style="list-style-type: none"> • Pregnancy • Growth

b) Poor absorption and bioavailability of iron : It must also be appreciated that the non heme iron (as present in green leafy vegetables) is absorbed poorly. Moreover a poor intake of vitamin C also limits the absorption of non heme iron, as ascorbic acid acts as a dietary reducing agent converting the non absorbable Ferric (Fe³⁺) ions into Ferrous (Fe²⁺) ions. Similarly concomitant intake of folate also helps in haemopoiesis and thus preventing anaemia. There are certain inhibitors of iron absorption which are inherently present in our diet. For example phytates are present in fibres and cereals, phosphates in milk and eggs, oxalates in vegetables, tannins in tea, calcium in milk, etc. All these normal constituents of diet tend to retard the absorption of iron, contributing to anaemia.

c) Excessive loss of iron : The normal physiological loss of iron per day is about 1mg for men and 2mg for women. But there are certain conditions in which this loss becomes excessive and abnormal. Heavy blood loss may be a result of abnormal menstruation (menorrhagia, metrorrhagia), parasite infections such as hookworms, ascaris, and schistosomiasis. Acute and chronic infections, including malaria, tuberculosis, and HIV can also lower blood haemoglobin concentration. Other conditions like haemorrhoids, peptic ulcers and cancer may also result in blood loss causing anaemia. In our context IUD insertions and repeated pregnancies/deliveries are also frequent causes of anaemia.

d) Increased demand of iron and other micronutrients : There are certain periods in the life cycle when iron requirements are especially high. Commonly this happens during growth and pregnancy. This has already been deliberated in the previous chapter.

A neonate is born with sufficient iron resources, therefore the chances that it should get anaemia in the early infancy (6

months) are remote. Moreover breastfed infants are in a happy iron state as iron from breast milk is very well absorbed. It is the preterm and low birth weight babies that have poor iron stores. The requirement of folates is also high for the preterm babies. Preterm babies are thus more likely to develop anaemia at 2-3 months. Babies that are not allowed colostrum intake and are not breastfed are also likely to develop anaemia as iron from artificial feeds or animal milk is not well absorbed. A condition "Goat Milk Anaemia" is known in babies that are fed goat milk as it is deficient in folate.

Prevention and Control of Anaemia : Given the multifactorial nature of this disease, correcting anaemia often requires an integrated approach. The benefits of preventing and controlling anaemia are substantial. Timely intervention can restore personal health and raise national productivity levels by as much as 20%. In order to effectively combat it the contributing factors must be identified and addressed. Additional iron intake is usually provided through iron supplements to vulnerable groups, in particular pregnant women and young children. Food based approaches to increase iron intake through food fortification and dietary diversification are important sustainable strategies for preventing IDA in the general population.

Strategies should also include addressing other causes of anaemia and should be built into the primary health care system and existing programmes. These strategies should be tailored to local conditions, taking into account the specific etiology and prevalence of anaemia in a given setting and population group. The main strategies for prevention and control of anaemia are as follows :

1. Breastfeeding and appropriate weaning : While it is true that milk is not a very rich source of iron, but the bioavailability of iron from breast milk is exceptionally good. Breast milk thus is a source that in itself is adequate to suffice the iron requirement of the young infant, till about 6 months of age. Breast feeding is therefore the first step to the prevention of anaemia. The iron requirement of a growing infant increases by 1 year. It is important to wean the child with iron rich foods. Food stuffs like meat/chicken soups, vegetable soups, jaggery, etc must be included. Iron supplementation must be considered if necessary. Prevention and control of infections and deworming must also be carried out.

2. Dietary modification : The diet must be assessed and suitable dietary modification must be undertaken with a view to increase iron intake. Nutritious diet which includes rich sources of iron must be consumed. Use of green leafy vegetables, pulses, non vegetarian foods, *ragi*, jaggery and fruits like custard apple must be promoted. Foods with high contents of vitamin C (lime, lemons, guava, *amla*, orange, green vegetables, etc.) must be encouraged as vitamin C promotes iron absorption through reduction. Food stuffs that inhibit iron absorption like tea, tamarind and high fibre should be spaced out away from the main (iron containing) meal.

3. Deworming : Deworming as required, must be undertaken for all, esp. infants and children.

4. Control of infection : Prevention and control of infections through good health care, immunization, early diagnosis and treatment, hygiene and sanitation practices and potable

water provision facilities is an important indirect step towards anaemia control.

5. Supplementation : Iron supplementation is routinely recommended for the pregnant women and children, under the national programme. Details are available on the chapter on National Nutritional Programmes. Therapeutic iron supplementation may also be required in moderate to severe cases of anaemia.

6. Iron Fortification : Trials are already completed at the National Institute of Nutrition for fortification of certain food items with iron. Common salt can be fortified with Ferric-orthophosphate or Ferrous sulphate and Sodium bisulphate. Double fortification of salt with iron along with Iodine is also feasible. However these fortified foods are still awaiting induction at a public level.

7. Nutrition education : It can be well appreciated that anaemia is not caused solely due to poverty and lack of resources. Ignorance on various facets of dietary intake, hygiene, sanitation, immunization, dietary interactions is also important and must be dispelled. This could be achieved through health education. The health education can be carried out at all levels including children at schools, for housewives, men and pregnant women. Using the locally available foods that are fresh, nutritious and cheap is also an important part of the nutritional education.

8. Home gardening : Promoting and utilizing a kitchen garden and poultry can go a long way in having good nutrition and preventing anaemia.

9. Care of pregnant and lactating women : Adequate care of the pregnant and lactating women can go a long way in preventing anaemia in them as well as the infant.

Iodine Deficiency Disorders (IDD)

Iodine deficiency is a major public health problem throughout the world, particularly for pregnant women and young children. They are a threat to the social and economic development of community. IDD is the cause of cretinism and a substantially increased perinatal mortality. A large proportion of mental retardation in infants and young children is attributable to IDD. In fact, iodine deficiency is the greatest cause of preventable brain damage in childhood. Hence no effort must be spared to implement measures to eliminate it.

Etiology : The content of iodine in water, crops or food materials is a function of the soil content of iodine. Therefore populations living in areas where the soil has low iodine content suffer from iodine deficiency. Heavy rainfall, past glaciation and snow drain of iodine from the top soil layer. Crops grown in this iodine depleted soil are devoid of iodine leading to a low dietary supply of iodine (11). Although goitre is primarily due to iodine deficiency in some areas, certain chemicals, collectively known as goitrogens that are present in some of the habitual foods, may contribute to the precipitation of iodine deficiency when iodine intake is marginal. These are present in vegetables of Brassica family, e.g. mustard, cabbage, etc.

Magnitude of the problem

World : It is estimated by the WHO that Iodine nutrition is optimal in 43 countries (including India). Nevertheless, in 54

countries, located in all regions of the world, iodine intake of the population is insufficient and it is a public health problem (11) More than 7% of world population suffers from iodine deficiency. In the developing countries alone, 800 million people are at risk and 200 million suffer from Goitre. As many as 3 million cretins are born. In our neighbourhood other South East Asian countries like Bangladesh, Bhutan, Indonesia, Myanmar, Nepal, Sri Lanka and Thailand are also prone to iodine deficiency.

India : Even though WHO classifies India as a country with 'optimal iodine nutrition', about 1/3rd (31.3%) of Indian school age children have a urinary iodine excretion of less than 100µg/l. This indicates 'insufficient iodine intake' and 'mild iodine deficiency'. This might be true for the country as a whole, but the fact remains that the 'sub-Himalayan goitre belt' is the world's most intense Goitre endemic region affecting nearly 120 million people. More than 55 million people suffer from the condition in this region. The total Goitre prevalence amongst school age children in India is 17.9% (11). The prevalence of goitre in an iodine replete population should be 5% or less.

Lately it has been appreciated that it is not only the sub Himalayan regions that are endemic for IDD but some extra Himalayan foci close to low lying hills like Chota Nagpur region of Bihar, hilly regions of Madhya Pradesh and Chattisgarh, Aravali ranges of Rajasthan, Narmada valley in Gujarat, parts of Western Ghats (Maharashtra, Kerala and Karnataka), Eastern Ghats (Andhra Pradesh and Tamilnadu) and Nilgiris are also endemic for IDD.

It is estimated that the total population at risk in India is about 200 million and 70 million are estimated to suffer from IDD.

Clinical Features : IDD may present as a spectrum of disorders and illnesses throughout the life cycle (See Box-6) (12). Though goitre is the most visible manifestation of IDD, the spectrum ranges from abortions, stillbirths and congenital anomalies to frank cretinism and mental/physical underdevelopment. If iodine deficiency occurs during the most critical period of brain development (from the fetal stage up to the third month after birth), the resulting thyroid failure will lead to irreversible alterations in brain function. Iodine deficiency might be responsible for a mean IQ loss of up to 13.5 points in the population (13). Cretinism is the most extreme and well known manifestation of IDD. Numerically however, subtle degrees of mental impairment (leading to poor school performance), reduced intellectual ability and impaired work capacity are of considerably greater significance, in a large number of children (12).

Indicators for Assessment and Monitoring : Urinary Iodine Excretion (UI), Total Goitre Prevalence (TGP), radiology, ultrasonography, TSH, T3 and T4 level estimation are useful to *assess* and *monitor* the cases.

Urinary iodine (UI) excretion is a marker of recent dietary intake of iodine (over the past 48 hrs.) & therefore, is the index of choice for evaluating the degree of iodine deficiency & its correction. Iodine concentration in casual urine specimen provides an adequate assessment of the population iodine nutrition. Median urinary iodine is used to classify countries into different grades of public health significance. Median UI of

Box - 6 : Clinical Features of IDD through the Life Cycle

Foetus and neonate : Abortions, stillbirths, congenital anomalies, high unexplained perinatal and infant mortality, low birth weight, neonatal goitre, lethargy, poor feeding, prolonged physiological jaundice. Congenital anomalies like umbilical hernia and large anterior fontanella.

Infancy & early childhood : Signs of cretinism that include mental deficiency, squint, short stature, hoarseness of voice, deaf-mutism and motor spasticity characterized by proximal rigidity of both lower and upper extremities and trunk.

Child & adolescent : Poor scholastic performance, retarded mental and physical development. Goitre and/or signs of juvenile hypothyroidism (growth retardation, mental retardation, hoarse voice). In addition there may be features of puffiness, thickened and dry skin, dry and rare hair/eyelashes/eyebrows and much delayed sexual maturation.

Adult : Mental and physical underdevelopment. Patients appear to be slow and rather 'sleepy'. Impaired mental function and impaired decision making. On examination, an enlarged thyroid may be palpable in normal position of neck (goitre), equal to the size of terminal phalanx of patient's thumb or visible in addition to being palpable. There may be symptoms of hypothyroidism - intolerance to cold, weight gain, somnolence, hoarseness of voice, menorrhagia and non-pitting oedema.

<100 µg/l indicates insufficient iodine intake and hence mild to severe iodine deficiency. A very commonly used epidemiological parameter is TGP (Box-7).

Box - 7 : Total Goitre Prevalence (TGP) (12)

The size of thyroid gland changes inversely in response to alterations in iodine intake, with a lag interval that varies from a few months to several years. The prevalence of goitre is an index of the degree of longstanding iodine deficiency and therefore, is less sensitive than urinary iodine in the evaluation of a recent change in the status of iodine nutrition. Thyroid size is traditionally determined by inspection and palpation. However, the evaluation of the prevalence of goitre based on palpation has been questioned because the reproducibility of assessment by palpation is low, especially with the size estimation of smaller glands, particularly in children. But it is still employed as a useful field tool for assessing goitre prevalence. The prevalence of goitre in an iodine replete population is below 5%.

Table - 5 shows the revised and simplified classification of goitre.

Table - 5 : Classification of goitre (14)

Classification	Description
Grade 0	Not palpable or visible goitre
Grade 1	A goitre that is palpable but not visible when the neck is in the normal position (i.e. the thyroid is not visibly enlarged). Thyroid nodules in a thyroid which is otherwise not enlarged fall in this category
Grade 2	A swelling in the neck that is visible when the neck is in a normal position and is consistent with an enlarged thyroid when the neck is palpated

Determining presence of iodine in salt : Presence of iodine in salt can be qualitatively determined using rapid test kits (containing starch-based indicator e.g. MBI Kit by UNICEF). One drop of this solution placed on salt containing iodine (potassium iodate) produces a blue/purple color. Coverage of adequately iodised salt is an important indicator used for assessment of iodine status in a population besides urinary iodine excretion

and total goitre prevalence. To meet the WHO criteria for monitoring progress towards sustainable IDD elimination, salt iodization coverage or proportion of households consuming adequately iodized salt should be more than 90% (See Box-8).

Box - 8 : Present Status of Salt Iodization

Unfortunately the legal policy on mandatory iodization of salt has not been consistent. As a result only about half of all households in India (49% as per NFHS-2 report year 2000 and 51% as per NFHS-3 report) are using sufficiently iodized salt. Use of iodized salt varies greatly by region; it is highest in the northeast region and in some states in the north. However, now a nationwide ban on non-iodized salt is taking effect and the current figures could well be more encouraging.

Prevention and Control : The recommended strategy for IDD control is based on correcting the iodine deficiency by increasing iodine intake through supplementation or food fortification. Under the *National IDD Control Programme* four main components of the IDD control strategy are :

1. Use of Iodized salt or oil
2. Iodine monitoring
3. Manpower training
4. Mass communication

Using iodized Salt / Oil : This prevents iodine deficiency. Control and prevention of goitre has been principally based on providing extra iodine to the population through iodised salt distribution or iodised oil injection (in hyper-endemic areas). Commonest prophylactic public health measure against endemic goitre is iodization of salt. Various agents can be used. Potassium iodate is most commonly used. Sodium & Potassium iodide can also be used. Iodization of salt is undertaken in a dose of 30 ppm at source so as to render at least 15 ppm at the consumer end.

Iodized Oil : Injectable and oral iodized oil are available as oral drops (400 mg/ml) and intramuscular (IM) injections (480mg/ml). Single IM injection of iodized oil can protect a woman through pregnancy and one year post partum. Oral supplementation is to be repeated every 6 months to 1 year (See Table - 6). More details are available in standard recommendations (15).

Table - 6 : Iodized Oil - Recommended Doses and Duration of Action (15)

Age groups	Duration of effect of iodine			
	Oral iodine (mg)			Intramuscular (mg)
	3 months	6 months	12 months	> 1 year
Women of child bearing age	100-200	200-480	400-960	480
Pregnant women	50-100	100-300	300-480	480
0 - 1 year	20-40	50-100	100-300	240
1 - 5 years	40-100	100-300	300-480	480
6 - 15 years	100-200	200-480	400-960	480
Males 16 - 45 yrs	100-200	200-480	400-960	480

With the wide availability of iodized salt, iodized oil is now recommended only for populations living in severely endemic areas where a quick and definite outcome is required within a short period or where there is no access to iodized salt.

Nutritional Education : The importance of iodized salt in prevention of IDD has to be emphasized repeatedly to the community. It must be reiterated that only iodized salt must be consumed by all. It must be consumed within 6 months of iodization, as the concentration of iodine diminishes with time. The community must be made aware of the fact that selling of non-iodized salt may attract legal action. Suitable health education methods must be resorted to, for effective dissemination of this information e.g. through lectures, road shows, audiovisual aids, schools and women groups, etc. The experiences of IDD patients and their parents may help in making the community more aware of this malady.

The other strategies namely iodine monitoring, manpower training and mass communication are discussed in the chapter on national nutritional programmes.

Vitamin A deficiency

Vitamin A Deficiency (VAD) is the leading cause of preventable blindness in children. It also increases the risk of disease and death from severe infections. In pregnant women VAD causes night blindness and may increase the risk of maternal mortality.

Magnitude of the Problem

World : Vitamin A deficiency is a public health problem in more than half of all countries, especially in Africa and South-East Asia. Young children and the pregnant women bear the major brunt of Vitamin A deficiency in poorer developing countries. Millions of children (esp preschool children) are at risk of xerophthalmia. About 36 countries in South East Asia, Western Pacific and Africa are severely affected. World - over 256 million people suffer from preclinical xerophthalmia and 2.7 million from xerophthalmia. As many as 7,00,000 patients develop corneal lesions and 3,50,000 become blind of xerophthalmia.

India : In India it is commonest amongst preschool children particularly in Andhra Pradesh, Tamilnadu, Karnataka, West Bengal and Bihar. The prevalence of Bitot Spots in the 1 to 5 years age group is about 1 to 5%. Very few studies report corneal lesions in India (0.05-0.1 per 100 preschool children in South India) (17)

Etiological Factors : Vitamin A deficiency is most common in the age group of 1 to 3 years, the preschool children. It results from a very complex web of causation involving ignorance, poverty, infections, lack of food, malnutrition, environmental and social factors. A compromised state of any one of these factors could tip the balance leading to vitamin A deficiency.

Weaning and Infections : It is often seen to be associated with weaning. The mothers may not be conversant with the correct weaning practices. During weaning the child is offered low vitamin A diet in the form of dilute milk, poor starchy food with hardly any fruits, vegetables butter or other animal products. It is primarily because of ignorance and economic reasons. The vitamin A content of this poor diet cannot keep pace with the high demand of the growing child. Repeated infections during this crucial period of weaning, teething and increased exposure to the outside world further puts pressure of extra vitamin A and other micronutrients on the system. Concomitant protein energy malnutrition makes the situation worse making the child immunologically even more vulnerable to infections. Consequently attacks of measles, acute respiratory infections and diarrhoea further compromise the child's vitamin A status. This prepares a favourable ground for xerophthalmia to flourish.

Other Social Factors : These also play an important role in the causation of xerophthalmia. Cultural beliefs on breast feeding and weaning practices are vital. Discarding colostrums, early or late weaning, restriction of certain food items, excessive dilution of milk, vegetarianism, unscientific management of infections, belief in quacks and unsound indigenous 'medicine', all play an important role in the causation of this problem. While poverty and inability to manage nutritious food could be a genuine reason, ignorance about the disease and faulty food practices is also rampant and is largely preventable through nutritional education.

Poor Environment Sanitation Practices : Non availability of sanitary latrines, open air defecation, poor hygienic practices and lack of potable water invite infection and disease, which have a definite role to play in causation of the condition.

Clinical Features : The clinical features of vitamin A deficiency can be divided into two broad groups, namely those concerning the eyes (xerophthalmia) and the extra-ocular features.

Xerophthalmia : Xerophthalmia is the ocular manifestation of vitamin A deficiency in various clinical forms. Xerophthalmia

assumes extreme importance because of its seriousness may lead to blindness and is preventable. Public health problem of xerophthalmia can be ascertained by prevalence of the levels of its various stages amongst preschool children in the community (Table - 7).

WHO Classification	Clinical condition of xerophthalmia	Prevalence among preschool children
XN	Night blindness	>1%
X1A	Conjunctival xerosis	-
X1B	Bitot's spots	>0.5%
X2	Corneal xerosis	-
X3A	Corneal ulceration/keratomalacia (involving <1/3 of cornea)	>0.01%
X3B	Corneal ulceration/keratomalacia (involving >1/3 of cornea)	>0.01%
XS	Corneal scar	>0.05%
XF	Xerophthalmic fundus	-
Bio-chemical	Plasma retinol <0.35 $\mu\text{mol/l}$	>5%

Night Blindness : Night blindness is classically associated with vitamin A deficiency. The age group most commonly affected is the pre-school children. Mother of the child typically complains that in the evening child strikes against a stone while playing and falls down frequently. He is unable to see the contents of his food plate and gropes for food. In a dimly lit classroom he can't see what's written on the black-board. Night blindness usually responds rapidly to vitamin A tablets/oil or injections.

Conjunctival Xerosis : Conjunctival xerosis is one of the earliest detectable signs of vitamin A deficiency. It manifests as thick, wrinkled (vertically folded) conjunctiva with a tendency to dryness. It is restricted to 'exposed' bulbar conjunctiva. The dryness looks like "Waxy Paint" as there is loss of transparency and no shine in the affected conjunctiva. It is un-wettable, classically referred to as a "Receding tide" of the tear drop. The un-wettability is because of the affected epithelium leading to reduced goblet cells/mucin secretion from the lachrymal glands. The 'break-up time of tears' is also reduced.

Bitot's spots : Bitot's spots are white triangular patches present on the conjunctiva. They resemble flakes of foam or plaster on the surface of the conjunctivae. They are formed due to Vitamin A deficiency leading to hyper-keratinizing metaplasia of the epithelium and accumulation of seborrhoeic excretions.

Corneal xerosis : If the preceding condition (conjunctival xerosis) is not treated early, corneal xerosis results. The cornea becomes pale, lustreless and loses its sheen. This may progress to a state of *corneal ulceration* and subsequently *keratomalacia* may ensue. There may be an eventual perforation through which the contents of the eye may extrude out and the patient loses his sight.

Extra - ocular manifestations : Some extra-ocular manifestations of vitamin A deficiency are also known. Follicular hyperkeratosis, growth retardation and anorexia are some of them. They respond to vitamin A supplementation.

Treatment of Xerophthalmia (17) : An established case of xerophthalmia responds well to treatment with vitamin A. The following regime can be followed :

- 2,00,000 IU (110mg) of Retinol palmitate (oil miscible vitamin A) is administered orally for 2 days. In cases of persistent vomiting/diarrhoea, water miscible vitamin A 1,00,000 IU is administered as IM Injection, followed by 2,00,000 IU, 1 to 4 weeks later.
- For infants less than 1 year old or less than 8 Kg weight, half the dose is used.

Prevention

Dietary modifications should be achieved through promotion of growth, production and consumption of vitamin A / beta-carotene rich foods. Rich sources of vitamin A like dark green leafy vegetables, deep yellow/ orange fruits, eggs, milk and meat must be included in diet.

Nutrition education : Educate the community on the importance of vitamin rich diet, its regular intake and the harmful effects of its deficiency. Importance of home gardening, consumption of fresh seasonal fruits and vegetables must be reiterated. Healthy food preservation techniques must also be emphasized. Public meetings, schools and mass media can be used to the fullest to disseminate these messages.

Fortification of ghee, hydrogenated vegetable oil and butter are being done as a government policy to augment the vitamin A status of the community. Technology for the fortification of sugar, mono sodium glutamate, bread and milk also exists.

Periodic massive dosage (17) : Vitamin A administration is now integrated with immunization program. The first dose of 100,000 IU is given at 9 months of age along with measles vaccines. Thereafter, the second and subsequent doses of 200,000 IU are given at 6 monthly intervals till 3 years of age. In all, a total dose of 9,00,000 IU is administered.

Long term action : Constant nutritional education emphasizing good diet (including fruits and vegetables), importance of immunization, environmental sanitation, breast feeding, early treatment of infections and good maternal and child health care would go a long way in the prevention of this condition.

Diseases Due to Excess and Deficiency of Fluorine

Fluorine Excess (Fluorosis) : Ingestion of large amounts of fluorine occurs when the drinking water contains fluorine in excess of 3-5 ppm. Such a situation leads to endemic fluorosis. It is associated with dental and skeletal fluorosis. Fluorosis has been reported to be a health problem in rural districts of Andhra Pradesh (esp. Nellore, Nalgonda and Prakasham districts), Haryana, Karnataka, Kerala, Punjab, Rajasthan and Tamil Nadu.

Clinical Features : Fluorosis presents as dental or skeletal fluorosis, depending on the water content of fluorine, duration and level of exposure.

Dental fluorosis : For a patient to suffer from dental fluorosis, the fluorine intake through water has to be moderately in

excess (> 1.5 ppm). Moreover, if this exposure takes place during calcification of teeth (first 7 years of life), the teeth are more likely to get affected by fluorosis. The mottling of teeth is common. The enamel loses its lustre and the texture becomes rough. There could be brown bands alternating with white chalky patches. Mottling may progress to small pits. Upper incisors are affected the most, even though all the teeth are vulnerable. Dental fluorosis as such, is not usually associated with skeletal fluorosis or impairment of health.

Skeletal Fluorosis and Fluoride Poisoning : When the concentration of fluorine exceeds 10 ppm, a crippling skeletal fluorosis may ensue. This may occur as a result of high fluoride content of water (endemic) or as a result of an industrial poisoning. As a result there may be heavy deposition of fluorides in the bone (sclerosis). The condition may begin as anorexia. There may be sclerosis of spine, pelvis and limbs. The ligaments of spine may be calcified, producing a 'poker back'. The tendinous insertion of muscles may be ossified, producing the characteristic 'rose thorn' shadow in the X-Ray.

Genu valgum : Scientists working at the National Institute of Nutrition, Hyderabad found new form of fluorosis characterized by genu valgum and osteoporosis of the lower limbs in some districts of Andhra Pradesh and Tamilnadu. This was seen in people subsisting on sorghum (*Jowar*) as staple. It was concluded that *jowar* promoted a higher retention ingested fluoride in the body.

Prevention : In the endemic areas, fluoride is present in excess in water and if the community is dependent solely on that water, it is not easy to prevent the condition. It becomes even more difficult because there are no household methods to remove fluoride from water. However the following preventive measures are suggested :

1. **Changing water source** : Running surface water has lower fluoride content as compared to ground water. The community should shift from ground water (wells) to running water (rivers) if possible. Ideally the water should have a fluoride content of less than 0.5ppm.

2. **Defluoridation** : There is technology available that can be used to remove fluoride from water. An Indian technology called as the Nalgonda technique is an accepted defluoridation technique. It involves sequentially adding lime and alum to water. It is then followed up with flocculation, sedimentation and filtration of water.

3. **Avoiding additional fluoride** : Any additional fluoride intake must be avoided in endemic areas, as through fluoride tooth pastes for children up to 7 years of age.

Fluorine Deficiency - Dental Caries

Epidemiology : Communities subsisting almost exclusively on meat, like the Eskimos (raw walrus meat and fish), Masai tribes in Kenya (milk, raw blood and milk) have little caries. Caries occurs among people who adopted the British dietary habits throughout the world. Medieval records suggest that dental health was much better then. Altered dietary habits took a severe toll on dental hygiene in the past century or two. The dietary changes thought to be important are :

a) Decline in milk consumption.

b) General use of refined sugar that was earlier an aristocratic delicacy.

c) Introduction of roller milled fine flour.

Further lifestyle changes like introduction and wide use of sweetened soft drinks, refined wheat flour, excessive use of sugar, sweets and chocolates, sweetened milk and tea, made the teeth more vulnerable to caries.

Host factors : The buffering action of saliva and its ability to reduce acidity helps in preventing caries. Lysozymes present in saliva also help in caries prevention. Decreased saliva secretion due to less chewing, leads to caries.

Agent factors : *Streptococcus mutans* is notorious to cause caries. It flourishes in the mouth and teeth on sugars and refined carbohydrates.

Time : The frequency of consumption of refined carbohydrates and sugars and the duration for which they stay in the mouth is directly related to the chances of causation of caries.

Substrate and diet : The substrate for the bacteria is defined by the diet one eats. Refined carbohydrates and sugars are fermented by the bacteria and produce caries. Sucrose, fructose, glucose, xylitol and other sweeteners all cause caries. Strongly acidic drinks (sweetened, aerated drinks) consumed frequently can predispose to caries. A sharp increase in caries is seen in the developing countries with the increasing consumption of sugars. Firm fruits like apples have scouring action that reduces the chances of caries. Cheese increases pH and also saliva flow, inhibiting bacteria. Chewing betel increases saliva flow and lime content of pan also increases the pH thus preventing caries.

Fluoride : The water content of fluoride at a rate of 0.5 to 1 ppm prevents caries. In areas where fluoride content of water is low the prevalence of caries is high. Addition of fluoride to water can prevent caries in these situations.

Prevention

Reduction of sugar intake : Since sugar intake has a bearing on dental caries it is advisable to reduce sugar consumption. The following measures could be useful :

- Reduce sugar in diet. Avoid adding sugar to milk, tea and coffee. No added sugar to be made available. Reduce consumption of sweets, chocolates and cold drinks.
- No sugar should be added to infant/baby foods/pediatric medicine, fruit juices, vitamin preparations
- Sugar added to jams, jellies, cold drinks must be reduced to the minimum,
- Sugar free snacks and drinks must be made available

Promotion of dental hygiene : It is important to appreciate and promote dental hygiene. Regular brushing and dental checkups are important in prevention of dental caries.

Fluoridation of water supplies : In areas where fluoride levels are less than 0.7 ppm, it is advisable to add fluoride to raise its level optimally. This single measure is known to reduce the caries incidence by half.

Professional dental care : Besides regular dental examination, dentists help in prevention and deterioration of caries through filling cavities, cleaning, removing calculus, removing overcrowding of teeth through orthodontic treatment etc.

Application of topical fluoride solution and sealants is also effective. Good school dental hygiene services are also very useful.

Summary

Four important nutritional deficiency disorders are Protein Energy Malnutrition (PEM), Anaemia, Vitamin A Deficiency and Iodine Deficiency Disorders (IDD). Anaemia affects three fourths of all females and more than half of all males. PEM and vitamin A deficiency occur mostly among preschool children. Vitamin A deficiency is an easily preventable cause of blindness. Thyroid insufficiency due to iodine deficiency, results in many a serious condition including goitre, impaired metabolism, cretinism, mental retardation and deaths (still births).

PEM contributes to 60% of the total 10 million deaths of children under five years of age. The cause is diet poor in energy and proteins latest concept being of 'Food gap', wherein it is not only the deficiency of proteins but inappropriate food (low in energy density, protein and micronutrients - Vitamin A, Iron, Zinc) which is poor both quantitatively and qualitatively. PEM is classified into Kwashiorkor, Marasmic- kwashiorkor, Marasmus, Dwarfing and Underweight. Marasmus is characterised by Growth retardation, wasting of muscles and subcutaneous fat. Clinical features of Kwashiorkor include oedema, growth retardation, muscular wasting, retention of subcutaneous fat and psychomotor changes. Prevention of PEM includes Health promotion (Good ante-natal care, education on food, hygiene and family planning, good weaning practices). Specific protection measures are adequate Diet and Immunization. Growth monitoring, early diagnosis and treatment of infections and Hospitalization of the case are measures of Early Diagnosis & Treatment. Rehabilitation of a PEM case requires substantial changes in the knowledge, attitude and practice about the disease.

Anaemia is a global public health menace affecting over 30% of world population. The health implications range from General symptoms like : weakness, easy fatigability, lethargy, reduced work capacity, reduced endurance to pregnant and lactating women suffering increased risk of low birth baby, abortion, premature delivery, intra-uterine growth retardation, and in children suffering from low birth weight, impaired cognitive performance, motor development and scholastic achievement, inattention, fatigue and insecurity. Anaemia threshold is 11.0 for young children and pregnant women, 12.0 in Non pregnant women and 13.0 in men over 15 yrs.

Anaemia can be due to inadequate intake of iron, poor absorption and bioavailability of iron, excessive loss of iron and increased demand of iron. Measures for prevention and control of anaemia are Breastfeeding and appropriate weaning, Dietary modification (Use of green leafy vegetables, pulses, non vegetarian foods, *ragi*, jaggery and fruits like custard apple to be promoted), deworming & control of infection, iron supplementation, iron fortification and nutrition education.

Iodine deficiency is a major public health problem throughout the world, particularly for pregnant women and young children causing avoidable pregnancy losses and mental retardation/cretinism. Iodine deficiency in soil is main cause in addition to certain chemicals (goitrogens) that are present in some of

the habitual foods, like vegetables of Brassica family (mustard, cabbage etc.). The 'sub-Himalayan goitre belt' is the world's most intense goitre endemic region affecting nearly 120 million people. The total population at risk in India is about 200 million and 70 million are estimated to suffer from IDD. Clinical Features of IDD through the Life Cycle can be divided into Foetus and neonate (Abortions, stillbirths, congenital anomalies, high unexplained perinatal and infant mortality, low birth weight); Infancy & early childhood (mental deficiency, squint, short stature, hoarseness of voice, deaf-mutism and motor spasticity); Child & adolescent (Poor scholastic performance, retarded mental and physical development, Goitre) and in Adult (mental and physical underdevelopment, goitre, intolerance to cold, weight gain, menorrhagia). Urinary Iodine Excretion (UI), Total Goitre Prevalence (TGP), radiology, ultrasonography, TSH, T3 and T4 level estimation are useful to assess and monitor the cases. National IDD Control Programme has four main components : Use of Iodized salt or oil, Iodine monitoring, Manpower training and Mass communication.

Vitamin A deficiency (VAD) is the leading cause of preventable blindness in children. It also increases the risk of disease and death from severe infections. It is commonest amongst preschool children particularly in Andhra Pradesh, Tamilnadu, Karnataka, West Bengal and Bihar. The causes include weaning infections and poor environmental sanitation. The clinical features of vitamin A deficiency include those concerning the eyes (xerophthalmia, night blindness, conjunctival xerosis, Bitot's spots, corneal xerosis, corneal ulceration and keratomalacia) and the extra-ocular features. Prevention measures are dietary modifications (dark green leafy vegetables, deep yellow/ orange fruits, eggs, milk and meat), nutrition education of community, fortification (of ghee, hydrogenated vegetable oil and butter) and periodic massive dosage.

Fluorosis is a condition resulting due to Ingestion of large amounts of fluorine when the drinking water contains fluorine in excess of 3-5 ppm. Dental and skeletal fluorosis are two forms known. Preventive measures are changing water source, defluoridation and avoiding additional fluoride for at least next seven years.

Fluoride deficiency leads to dental caries. The water content of fluoride at a rate of 0.5 to 1 ppm prevents caries. Other measures are reduction of sugar intake (reduce sugar in diet, avoid adding sugar to milk, tea and coffee, reduce consumption of sweets, chocolates and cold drinks, no sugar should be added to infant/baby foods/pediatric medicine, lowering sugar added to jams, jellies, cold drinks to the minimum); Promotion of dental hygiene (regular brushing and dental checkups); Fluoridation of water supplies (where fluoride levels are less than 0.7 ppm) and professional dental care.

Study Exercises

Long Questions : (1) Define PEM (Protein Energy Malnutrition). Explain in detail etiology, classification, management and prevention of PEM (2) Describe in detail epidemiology of Anaemia in India. Elaborate on community measures for prevention of Anaemia in Pregnant and lactating women (3) Explain the process of assessing level of Iodine in salt. Describe various control and prevention measures undertaken

by National Iodine deficiency Disorder Control Programme (4) What are various grades of Xerophthalmia used to assess Vitamin A deficiency? Explain the preventive measures against Vitamin A deficiency in Pre-school children (5) Describe in detail the Epidemiology of Fluorosis.

Short Notes : (1) PEM (2) Kwashiorkar (3) Marasmus (4) Food Gap (5) Prevention of PEM (6) Classification of anaemia as public health problem (7) Prevention & Control of anaemia (8) sub-Himalayan goitre belt (9) Goitrogens (10) Urinary Iodine Excretion (11) Treatment of Xerophthalmia (12) Dental Fluorosis (13) Prevention of Dental Caries

MCQs

- (1) Jelliffe gave the _____ term in year 1959 (a) PEM (b) PCM (c) Food Gap (d) Marasmus.
- (2) The highest number (60.3%) of underweight children (under 3 years) is reported from (a) Bihar (b) Madhya Pradesh (c) Uttar Pradesh (d) Jharkhand
- (3) In _____ child is 'skin and bones' owing to loss of subcutaneous tissue (a) Kwashiorkar (b) Stunting (c) Nephrotic Syndrome (d) Marasmus
- (4) Term 'Kwashiorkor' was introduced by _____ into modern medicine (a) Cicely Williams (b) Jelliffe (c) Ghai (d) Barbar Mc Clintok
- (5) Anaemia contributes to _____ % of all maternal deaths (a) 10% (b) 20 % (c) 5% (d) 30%
- (6) It is generally believed that spinach is a 'very good' source of iron. But the fact is that it is a poor source as it contains only _____ mg iron per 100g (a) 5.5 (b) 6.0 (c) 1.1 (d) 10.0
- (7) Apart from India, other South East Asian country/ies prone to iodine deficiency is/are _____ (a) Myanmar (b) Thailand (c) Sri Lanka (d) All of these.
- (8) It is estimated that the total population at risk in India is about _____ million and _____ million are estimated to suffer from IDD (a) 20 & 7 (b) 100 & 35 (c) 40 & 14 (d) 200 & 70.
- (9) For infants less than 1 year old or less than 8 Kg weight, the dose of Vit A used is _____ (a) 4,00,000 IU (110mg) of Retinol palmitate (oil miscible vitamin A) administered orally for 2 days (b) 2,00,000 IU (110mg) of Retinol palmitate (oil miscible vitamin A) administered orally for 2 days (c) 1,00,000 IU (110mg) of Retinol palmitate (oil miscible vitamin A) administered orally for 2 days (d) 2,00,000 IU (110mg) of Retinol palmitate (oil miscible vitamin A) administered orally for 1 day

(10) Hb Threshold (mg%) to label Anaemia in Non-pregnant women (≥ 15.00 yrs) is _____ (a) 13.0 (b) 12.0 (c) 10.5 (d) 11.0

(11) For a patient to suffer from dental fluorosis, the fluorine intake through water has to be at least (a) > 1.5 ppm (b) 1.0 ppm (c) 0.5 ppm (d) 5.0 ppm.

(12) Poker Back, Rose Thorn appearance on Chest X-Ray and Genu Valgum are features of _____. (a) Hypervitaminosis D (b) Hypervitaminosis A (c) Skeletal fluorosis (d) Congenital Hypercalcemia.

Answers : (1) b; (2) b; (3) d; (4) a; (5) b; (6) c; (7) d; (8) d; (9) c; (10) b; (11) a; (12) c.

While food is the most important item to sustain life on this planet, next only to oxygen, it is a potent source of pathogens, toxins and disease. A food borne disease is one where the agent is toxic or infectious, and is transmitted to the body through food. Detailed discussions on the epidemiology and prevention/control of specific food and water borne diseases have been made in the section on communicable diseases of this book and readers are advised to refer to the same. In this chapter, we would discuss the details of prevention and control of food borne infections.

General Principles

Procurement and Storage

Procurement : Food should be procured from a reliable supplier. The hygiene standards maintained by the supplier should be noted, such as cold and chilled storage, separation of raw and cooked foods, handling of raw and cooked foods, cleanliness of premises and equipment. No more food should be purchased than the amount which can be stored in the available deep freeze cabinet or refrigerator (4°C).

Non-vegetarian foods : Raw and cooked meat and poultry, milk, cream, and fish should be bought in quantities sufficient for one day only. Meat and fish should not be refrigerated for more than three days.

Dry and canned foods : Dry foods and canned foods should be bought in reasonable quantities. Avoid overstocking; there is danger from vermin and deterioration where storage facilities are poor. These products should be stored in a dry, well ventilated storeroom.

Refrigerate perishable foods : Meat, poultry, dairy products, fish, and cooked rice must be refrigerated. Store raw and cooked meat and poultry separately to prevent cross-contamination. The temperature of the refrigerator should be 1-4°C.

Storing non-perishable food : Non-perishable food must be stored in a storeroom. It should be kept cool, well ventilated, and dry. Adequate precautions must be taken for rodents, flies and cockroaches. Surfaces of shelves, walls and floors should be easy to clean.

Deep freeze unit : For longer storage Deep freezer is used. A temperature of -18°C is desirable.

Vegetables : Vegetables should also be procured on a daily basis. They must be kept in a cool dry storage place away from direct sunlight. Most vegetables can be refrigerated.

Food Handlers' Hygiene : Cooks should be provided with special clothing consisting of 4 aprons, 4 caps (or pugrees), 4 shirts, 2 shorts, 2 trousers to wear while on duty. A clean set of jharons (mops) should be available to the cooks every morning. Facilities for scrubbing hands with brush and washing with soap and running water should always be available.

Immaculate personal hygiene of the cooks is of prime importance in the prevention of food borne infections. Infective organisms from all sources can be passed to food by hands. All cooks should take a thorough bath before starting daily work, keep their hair and nails clipped short and invariably scrub and wash their hands with brush, soap and water after every visit to the latrine or urinal and before handling food or raw rations. As far as possible, touching food with bare hands must be avoided. There should be access to toilets, hand washing facilities and wash rooms for the kitchen staff. The cooks must be subjected to regular medical examinations for communicable diseases that have a potential to be transmitted through food (e.g. wounds, boils, diarrhoea). Those found positive must be immediately excluded from kitchen duties and treated. Since it is not possible to detect carriers from a medical examination, it is worthwhile doing a stool examination as well. They should also be vaccinated against the enteric group of fevers.

Kitchen hygiene and sanitation : Besides personal hygiene, it is vital to have an immaculate kitchen hygiene as well. The storing, cooking and all working surfaces must be cleaned after each session of cooking. Utensils, equipment and mops, etc should also be in a good shape. More details are discussed in another section of this chapter.

Cooking Practices : The following healthy cooking practices must be adhered to :

1. Food must be 'fully' cooked and not merely cooked partially.
2. Food must be cooked rapidly and consumed quickly. Otherwise refrigerate at the earliest (store cooked food below 4°C).
3. Reheating of food must be avoided. If it is essential to reheat, the food must be heated to beyond 60°C for at least 5 minutes, ensuring that heat penetrates to the core of food. A mere warming of food is not good enough.
4. Insist on consuming fresh and hot food.
5. Use of pressure cookers, microwave, frying and grilling are safer cooking methods as compared to inadequate boiling, roasting or warming.

Serving of food

1. Avoid prolonged exposure of susceptible foods to warm environment. This will encourage rapid bacterial growth and deterioration of food. Keep cold food cold, below 5°C.
2. Avoid warm storage of cooked food. Keep hot food hot, above 63°C or else below 4°C.
3. Do not reheat cold food to store in a warm holding apparatus (hot cupboard, hot case, casserole). Place only hot food in such equipment, that too for a short while before consumption.
4. Minimize handling of cooked foods with bare hands. Use suitable kitchen tools.
5. Use new clean paper/cloth for wrapping and covering food.
6. Keep animals and insects out of the kitchen.

Sanitation of Some Specific Foods

Some foods require special attention. These are mainly the non vegetarian foods and fresh salads.

Poultry : Poultry may harbour food-poisoning organisms on the skin, offal and inside the carcass. Thus care should be taken where and how birds are dressed. Surfaces and utensils should be well cleaned after use, and hands should be washed well after handling the raw materials. Clothes should not be used to wipe carcasses either inside or outside, or to cover them. Frozen meat and poultry should be thawed properly before cooking

Sausages : Sausages, raw scraps, and minced meat may be contaminated with salmonellae. Great care should be taken when preparing sausages for cooking. If they are pricked the fork should be washed immediately with hot water. Sausages should be well cooked.

Meat : Dishes should be prepared fresh from raw meat. If there is likely to be any delay in using cooked meat, steaming under pressure is the best way to ensure the destruction heat-resistant organisms; it is a safe method of cooking. If left-overs are used after warming, they must be cooked thoroughly to boiling point to destroy contaminants and toxins which may have been formed. Spores on the outer surfaces of meat are more likely to survive if not well cooked. So it must be cooked thoroughly and eaten freshly cooked. It must not be allowed to cool slowly and stored at atmospheric temperature, as that promotes rapid multiplication of bacteria.

Salads and fruits : Salad vegetables including spinach, cabbage and lettuce could have been grown in sewage farming. Salads and cut fruits (which cannot be peeled), should be scrubbed and washed well, preferably with water containing hypochlorite.

Cooked rice : Cooked rice should not be stored without refrigeration.

Milk/eggs : Milk should be consumed after pasteurization or boiling. The most hygienic way to consume eggs is to boil them and eat.

Health education : There should be a continuous endeavor to educate the kitchen staff and public at large regarding food hygiene and its practice.

Milk Hygiene

There is a potential of disease causation through milk when it is not handled hygienically and therefore it is important to care for milk hygiene. The milk hygiene begins at its source of production namely the dairy farm. Milk can become a good nidus for many organisms (2). Some common diseases conveyed through milk are summarized in Table - 1.

Sanitation of Dairy Farms : Dairy farms should ensure a pure, wholesome and protected milk supply. A dairy consists of the farm, the milk depot and the pasteurization and bottling/ packing plant, staff changing rooms, and a manure disposal yard. The dairy proper has milk receiving, pooling, cooling and blending room. A pasteurization plant should also be integrated. All these are housed in permanent, solid, fly and dust

proof structures.

To prevent outbreaks of milk borne diseases hygiene of cattle, personnel, equipment, process (of milching and pasteurization), as well as sanitary packing and delivery should be ensured. A periodical medical examination of personnel, inspection of premises and equipments, veterinary inspection of cattle, scrutiny of the process in the dairy, inspection of functional efficiency of the farm, depot and plant, and laboratory tests for purity and quality of pasteurization are required to be carried out. These measures should ensure the following :

Care of Cattle : The quality and the quantity of milk not only depends upon the particular breed but also on the care that is devoted to the cattle. The milk yield also depends on comfort, feeding, watering, and cleanliness; hence a clean, airy, cool and spacious cattle shed is of prime importance. Ample water supply for drinking, to wash the cattle sheds and bathe the cattle should be available. Fodder, cottonseed, oilcake, bran and meal consisting of a coarsely crushed mixture of grains must be given to each animal. Stores should be rat proof. Sick animals must be immediately isolated and contacts segregated. Cattle should be inspected by a veterinary surgeon at least once a month. Preventive inoculation against common diseases must be ensured.

Cow Sheds : The cow shed should be well drained and higher than the surrounding ground. The floor area per cattle head should be minimum 6 m². The walls should be of reinforced concrete and whitewashed inside. Good cross ventilation is essential. The shed should be well lit. The whole flooring should be of impervious concrete. The sheds should be washed every day and cleaned twice a day. They should be sprayed with insecticide once a week.

Disposal of Cattle Dung and Sullage : All channels carrying sullage and liquid cattle dung should always be made of concrete. Semisolid cattle dung, a potent source of fly breeding, should be removed daily to a cow dung depot made of concrete and situated at least 200 m away from the cattle sheds. Anti-fly measures must be ensured.

Health of Workers : Medical inspection of the employees should be carried out very regularly and frequently, strict attention being paid to personal cleanliness. A regular immunization

Disease	Organism	Reservoir/Source
Tuberculosis	<i>M tuberculosis</i> (bovine)	Cattle
Brucellosis	<i>B abortus / melitensis</i>	Cattle, Goat
Q Fever	<i>Coxiella burnetti</i>	Cattle
Septic Sore throat	<i>Streptococcus pyogenes</i>	Cattle, milk handlers
Food Poisoning	<i>Staphylococcus aureus</i>	Cattle, milk handlers
Diarrhoea and dysenteries	<i>Shigella, E histolytica</i>	Milk handlers
Cholera	<i>Vibrio cholerae</i>	Water, milk
Enteric fever	<i>Salmonella</i> species	Milk
Viral hepatitis, polio	Hepatitis A, Polio viruses	Milk
Diphtheria	<i>Corynebacterium diphtheriae</i>	Milk

against enteric group of fevers must be ensured. All cases of illnesses, especially diarrhoea, dysentery, enteric fever, infected fingers or boils, running nose or ears, sore throat, or cough must be attended to. Exclusion of carriers of communicable diseases should also be rigidly enforced.

All indoor workers should scrub their hands thoroughly with soap, hot water and a nail brush and change into their working clothes including cotton masks. All workers should have adequate sanitary and bathing facilities. They should wash their hands with soap and water before entering the processing premises or milking.

Pasteurization

Boiling kills the microorganisms but is likely to adversely affect the quality, taste and flavour of milk, as milk constituents are heat-labile. Pasteurization involves rapidly heating milk (to less than the boiling point), maintaining it uniformly over a definite period and rapidly cooling it. This destroys most of the pathogenic microorganisms, reduces the total quantity of all the microorganisms without affecting its inherent qualities (taste and flavour). It may not sterilize milk but makes it non-infective, retains its nutritive and aesthetic qualities and improves its keeping quality. The important pathogens that are destroyed by pasteurization of milk are *M tuberculosis*, *B abortus*, *Streptococci* and *Staphylococci* and the non-lactose fermenting pathogenic organisms of the *Salmonella-Shigella* group. The subsequent rapid cooling of the heated milk inhibits the multiplication of any viable residual microorganisms or of the ones subsequently gaining access to the liquid. The low temperature must be maintained till the milk is consumed.

The nutritive value of pasteurized milk remains reasonably satisfactory. Its fat, protein, calcium, phosphorus, and vitamins A and D contents are not affected. There is a 10% loss of vitamins B and 20% loss of vitamin C. Pasteurization improves the keeping quality of milk, reduces the number of bacteria, and destroys tuberculosis bacilli and other pathogenic organisms except spores and thermoduric bacteria. However, milk with a high bacterial count in a raw state will not pasteurize so efficiently as clean milk. Pasteurized milk can be preserved for 8 to 12 hours at 18°C.

Methods of Pasteurization : The methods of pasteurizing milk are as follows :

(a) Holder (Vat) method : This method consists of heating the milk to the temperatures between 63°C and 65.5°C and holding it in large tanks at that temperature for 30 min before cooling it rapidly to 5°C. Milk gets heated efficiently and pathogenic bacteria are killed with certainty. From these holding tanks the milk runs directly to the cooler and then to the packing / bottling machine through a closed system.

(b) Continuous Flow Method : This method is the modification of the Holder method. The milk is first heated to 63°C or more and then led through a series of heated metal coils so that the milk remains at that temperature in the apparatus for 30 minutes.

(c) High Temperature Short Time (HTST) Method : In this method milk is heated to 72°C for 15 seconds and then rapidly cooled to 4°C.

(d) Ultra high temperature (UHT) Method : Milk is rapidly heated usually in two stages, the second stage being under pressure, between 125° to 150° C for a few seconds only. It is then rapidly cooled and packed / bottled as quickly as possible.

(e) Pasteurization in Bottles : The filled bottles can also be pasteurized. They are well sealed and heated by a shower of hot water or steam. The simplest method is to place the milk bottles in water-bath brought to 63°C held there for 30 min and then chilled. The theoretical risk of contamination after pasteurization is entirely eliminated.

Supervision of Pasteurization Process : The pasteurization process needs constant supervision and the following are the most important factors to ensure efficient pasteurization :

- (a) Raw milk must be clean and free from extraneous matter.
- (b) A pasteurization chart should show the range of and the period for which the temperature, as specified for the method, was maintained.
- (c) Milk must be protected from contamination during cooling and bottling / packing; unprotected open coolers are undesirable.
- (d) Excessive foaming of milk must be avoided as the temperature of the foam is too low to kill pathogens and may even encourage the growth of thermophilic organisms.
- (e) The apparatus must be efficiently cleaned and sterilized after each day's work.
- (f) Besides ensuring efficient supervision, the process of pasteurization should be checked from time to time by the colorimetric phosphatase test as described earlier.
- (g) If there is any doubt, about the effectiveness of pasteurization, the issue of such milk must be reconsidered. It is much safer for the consumer to assume that the milk he receives is untreated and is therefore boiled rather than to enjoy a false security.

Inspection of Milk : Inspection of milk involves physical and laboratory tests. Objectives of inspecting fresh milk are to detect visible dirt, deterioration, adulteration, nutritive quality, keeping quality, and to ascertain efficiency of pasteurization. The physical tests involve the inspection and taste of milk. The interpretation is given in Table - 2.

Laboratory Tests

Specific Gravity : The specific gravity of milk should be 1.029 to 1.033 but milk diluted with water can be readily restored to its normal specific gravity by adding sugar or cornflour.

Chemical Tests : A further chemical analysis is necessary to detect adulteration.

(i) Gerber's Test : Gerber's Test is carried out for estimation of fat.

(ii) Total Solids : These are estimated by the evaporation of whole milk in a water bath and then weighing the dried residue Solids Not Fat (SNF) are estimated by deducting the fat value from the total solids.

(iii) Methylene Blue Test : It is carried out for testing the keeping quality and bacterial contamination in the milk. The basis of the test is that the dye is reduced and decolourised

Table - 2 : Interpreting Physical Tests of Milk Inspection		
Visual Inspection	Likely Cause	Interpretation
Ropy milk or slimy milk	Disease of the udder or contamination with <i>Lactis vascosus</i> .	Not acceptable
Blue milk	Infection of animal due to tuberculosis or <i>Ps cyanogena</i> .	Not acceptable
Red milk	Crushed udder	Not acceptable
Highly coloured	Presence of colostrum.	Acceptable
Dirty milk	Manurial dust from the flanks and tail of the cow, or dirt in the container	Not acceptable
Taste	Likely Cause	Interpretation
Altered taste	Feeding of the cow (e.g. with turnips).	Acceptable
Medicinal taste	Cow is being administered some drugs	Not acceptable
Souring of milk	Likely bacterial fermentation	Not harmful, but not acceptable either

by the bacterial enzymes. The rate of reduction is an index of the extent of bacterial contamination. One ml of methylene blue solution of 1 : 300,000 strength is added to 10 ml of milk sample in a test tube and then incubated at 37 °C in a water bath or incubator. The mixture should not decolourise within 5½ hours. If kept at room temperature above 37 °C it should not decolourise within 4½ hours.

(iv) **Phosphatase Test** : This test is meant for ascertaining the efficiency of pasteurization and depends on the fact that the enzyme phosphatase is destroyed by the pasteurization temperatures; but not completely destroyed at a lower temperature, or in a shorter period than that required for pasteurization. Milk containing as little as 0.25 percent of raw milk in the properly pasteurized milk still contains detectable quantities of enzyme. The test is performed by addition of disodium phenyl-phosphate to pasteurized milk. The enzyme phosphatase, if present, splits up the phenol by means of a phenol test reagent which gives different shades of blue colour depending upon the amount of phosphatase enzyme present. The colour is matched against the standard colours in a Lovibond colorimeter. Pasteurized milk must not contain more than 2.3 Lovibond units.

(v) **Bacteriological Tests** : These are rarely carried out as a routine but when indicated, are used for detection of *M tuberculosis*, *B abortus* or some other bacteria. Under such circumstances 100 ml of milk is centrifuged at 3000 rpm for half an hour. Deposits of centrifuged milk also can be cultured for other organisms in appropriate media such as the Wilson Blair medium for the enteric group of organisms and the tellurite medium for *C diphtheriae*.

Inspection of Dairies and Milk Depots : The dairy should be inspected in a definite sequence and with a view to scrutinize all details in the process of production of milk / milk products, their wholesomeness, quality and safety for consumers. All the concerns described above should be covered. Sampling of milk may be carried out periodically at the dairy farm, milk depot and also at various points on the consumer line. The tests for nutritional ingredients, adulteration, pasteurization, bacterial contamination and keeping may be specifically requested as indicated.

Meat hygiene

Meat has got high nutritive value but it deteriorates fast. That is why it is notorious for severe bacterial infections and food poisonings. Meat hygiene is therefore extremely important at all levels of food processing.

Inspection of Meat

Fresh Meat : The common signs of deterioration can be elicited by the following methods (3).

(a) **Smell** : The outside of the carcass should be smelt. A foul smell is a reliable indication of decomposition.

(b) **Appearance and Firmness** : Fresh meat is firm and elastic. Decomposed meat loses its firm elastic consistency and tends to become soft and slimy.

(c) **Colour** : It should be uniform. On decomposition the fat becomes pale and the muscle appears dark brown to black. Discoloured patches may emerge with time.

(d) **Skewer Thrust Test** : A skewer must be thrust into the substance of the meat and should be smelt. Meat with an unpleasant smell is unfit for consumption.

Fresh Fish : The common signs of deterioration are as follows:

(a) **Smell** : It is probably the most important test of soundness. Fish with an unpleasant smell should be rejected, even if all other tests are in its favour.

(b) **Appearance** : When freshly caught the gills are bright pink, but after death they rapidly become darker and in a matter of an hour or so assume a liver colour. The longer the fish is kept, the darker are the gills.

(c) **Firmness** : The flesh should be firm to touch, not rapidly separated from the bones, and should not tear easily. If flesh pits readily under pressure, decomposition must be suspected.

(d) **Colour** : It should be uniform. There should be no evidence of discoloured patches on the skin. These are usually seen first along the line of the backbone.

(e) **Eyes** : These should be prominent and not sunken, collapsed or dull.

(f) **Floatation Test** : If not eviscerated, a sound dead fish sinks in water while a decomposed one floats, belly up.

Tinned Meat and Fish

During canning the interior of the tin and its contents are subjected to heat, though an absolute sterility is not achieved, but the growth of remaining live organisms and spores is so inhibited that hermetically sealed cans should normally remain sound for several years. Under tropical conditions, the rate of deterioration is somewhat accelerated and spoilage may result even in an intact tin. The date of packing and the recommended last date for usage, must therefore always be kept in mind. The acidity of preservative sauce may cause erosion of the tin and eventually results in pin point leaks. This may lead to bacterial infection.

Tins / Cans to be Viewed with Suspicion

- Damaged, dented or rusted tins
- Leaking tins
- Excessively convex tins
- 'Blown' tin (owing to the formation of gas from decomposition)
- A bulging tin under pressure ('Springer')
- Tainted, foul smelling or bad taste of contents
- If in doubt, subject to laboratory analysis

Poultry : Although it is the custom in temperate climates to allow poultry and game to hang for some days in order to improve flavour and tenderness, this is usually not practicable in India. Fresh poultry have bright prominent eyes, the feet are limp and pliable, the flesh moderately firm and the skin pale. Staleness is shown by stiff and dry feet, dull and collapsed eyes, soft and flabby flesh and probably a greenish discolouration around the crop.

Slaughter House Sanitation

Filthy slaughter houses are always a menace to the public health due to large collection of offal undergoing putrefaction and the continuous flow of blood, urine and faecal matter in the surrounding areas. A poorly managed slaughter house emanates rotten smell and it becomes a source of disease and nuisance to the public. Fly breeding and contamination of meat are the two major health hazards. Thus, for proper sanitary control, all slaughtering should be carried out in well maintained, licensed public slaughter houses (abattoirs) wherein hygiene rules must be followed strictly. A good slaughter house should conform to these basic standards (3) :

Design : The slaughter house should be well ventilated and totally fly proof. It should have sufficient running water supply. Adequate provision should be there to deal with blood, offal and waste animal products. It should be fitted with scaffolding having chrome plated hooks for dressing of animals.

Building : The slaughter house should be built with brick and concrete and well protected against rodents, cats and dogs. A concrete boundary wall is desirable. Adequate toilet/wash and hand-washing facilities (with soap and water) must be available.

Floor and walls : Special notice should be taken of the floor and general cleanliness of the place where the carcasses are dressed. Floor should be made of impervious concrete. The interior walls should also be of smooth concrete, which should be lime washed frequently.

Drains : Concrete channels should drain all liquid waste from the lairs and the slaughter room to a place of disposal outside, through covered drains. All the drains must be cleaned frequently. The manholes must also be frequently checked. Drains must be in a good state of repairs as damaged/broken drains are unhygienic.

Waste disposal : The liquid waste should be run into a water carriage sewer. All solid refuse should be burnt in the incinerator.

Employees : The employees must preferably be permanent. They must wear clean clothing and be free from communicable diseases. They must undergo initial and periodical examination. They must also take routine immunization.

Inspection of Slaughter House : A regular inspection of slaughterhouses is essential to ensure that it does not become a focus for the spread of infections. The abattoir must be inspected regularly and thoroughly. The most important points to note are :

- (a) The structural soundness of the building. The construction of the floor which should be made of cement concrete.
- (b) The fly proofing, rat proofing and dog proofing of the premises.
- (c) The method of disposal of offal, blood, animal excreta and discarded animal tissues.
- (d) The sanitation of the lair.
- (e) The spaciousness of the separate slaughtering, skinning and hanging rooms and their ventilation.
- (f) Availability of water for maintaining the sanitation.
- (g) The maintenance of equipment of slaughtering, skinning and handling and finally the personal hygiene of the workers.

Sanitary Inspections & Suggested Standards for Food Catering & Eating Establishments

A high standard of tidiness and cleanliness of all premises of the catering and eating establishments should be ensured. The following important aspects must be monitored :

(a) Kitchen premises - General Principles : The entire kitchen premises should be spacious, lighted, fly proof, rat proof, airy and spotlessly clean at all times. The kitchen complex should have a separate cooking room (actual kitchen), a storeroom for fresh provisions, a preparation room, a scullery and a room for the cooks' clothing. The design of a kitchen must be planned with the principles of hygiene in mind with regard to the sources of food-poisoning bacteria, importance of hot and cold storage and prevention of cross-contamination. So far as possible there should be separate work areas for raw and cooked food.

Floors : Floors must have non-slip surfaces, should be impervious to moisture and easy to clean. There should be a provision to raised or move the equipment to allow floor to be cleaned underneath.

Walls : Walls should also be impervious walls that reduces condensation and is easy to clean. The wall and floor junctions should be covered for easy cleaning, and equipment should be fixed away from the wall to allow for cleaning.

Ceiling : Ceiling should be smooth, should resist condensation, and easy to clean. Provision for exhaust/chimney-vents must be made.

Lighting : Lighting must be good, both natural and artificial, particularly over the work and preparation areas, sinks and cooking equipment. Shadows must be avoided.

Ventilation : Natural and mechanical ventilation is necessary to prevent a rise in temperature, smoke and humidity.

Conveniences : Toilets should not open directly into food-preparation rooms. Foot-operated flushes are desirable. Wash basins should be available in or adjacent to the toilet.

(b) Kitchen proper : The kitchen should be sufficiently large. A properly constructed cooking range is recommended. This will not only economize the consumption of fuel but also keep the kitchen clear of smoke. The kitchen should be fly proof and well ventilated. It should be meticulously clean and tidy. The floor should be well cemented and free from cracks and crevices. The cooking range should be flanked with platforms for cooks to sit and for prepared food to be kept, awaiting removal to a food serving hatch, racks or hot-plates. Chapati baskets must be lined with clean cloth which is washed daily. All food should be kept covered.

Kitchen equipment : Ease of cleaning is an important factor in selecting all surfaces, equipment, and utensils. The following facts must be kept in mind :

- (1) Keep surfaces, equipment and utensils clean and in good repair; they should not be old or worn.
- (2) Slicing machines, mincing machines, and can openers require frequent and thorough cleaning; they must be easy to dismantle and reassemble. In-plant cleaning may be necessary for fixed parts of equipment.
- (3) Use separate boards for raw meat, cooked meat, and vegetables.

Choose appropriate materials for ease of cleaning; for example, synthetic and/or natural rubber hardened with plastic fillers, high molecular weight, medium-density polyethylene, or phenolic fibre laminates. For cleaning, use hot water and a detergent combined with or followed by a disinfecting agent such as hypochlorite; avoiding cloths and using disposable paper instead.

(c) Preparation Room : Preparation room is meant for the preliminaries of cooking such as peeling, cutting and washing of food. Provision of fly proofing and good ventilation is necessary. The preparation of vegetables should always be done on a zinc-topped table or granite slabs fitted with a chopping board on it rather than on the floor. The peeling and refuse should be deposited directly in a covered refuse bin. A meat chopping block preferably of a special hardened plastic (high density polypropylene) must be provisioned that is thoroughly washed and cleaned after use. It must be disinfected with a suitable agent (e.g. hypochlorite) and covered with a layer of powdered salt and dried in the sun.

Preparation room should be supplied with hot and cold water for which foot operation is preferable. A soap dispenser, kept in a hygienic condition is also a must. A nail brush with plastic or nylon back and bristle should be available. Hand drying should be done using individual methods such as paper towels. Common towels may cause cross infection.

(d) Store Room : A separate fly proof and airy store-room for raw fresh food stuffs should be provided. Raw foodstuffs should be kept in baskets/ crates ensuring free circulation of air and stacked on shelves. A cool room or refrigerator must be available where fresh fruits, vegetables, milk and curd can be stored. Meat, fish and poultry should be kept refrigerated or frozen. Grains, pulses, flour and other dry stuff should be kept in racks, away from the walls, either in neatly tied bags or in boxes in a separate well ventilated store-room. Equipment and utensils should be stored separately. A room for the cooks clothing and other necessities should be provided separately.

(e) Scullery : The scullery should be dry, clean and tidy. Sinks should be adequate, and draining boards should be sufficient and clean. All utensils after use should be thoroughly cleaned, washed, dried and kept in clean places. Tables should be scrubbed with washing soda and water twice a day using a hard brush.

(f) Dining Room : The dining room should be clean, fly proof, well lit and ventilated. While serving food, it should not be exposed to flies or dust. It should be presented in a manner that will enhance the acceptability or appeal, and reduce wastage. An effort should be made to supply hot food. A hot plate should be incorporated in the serving hatch or platform.

(g) Washing Arrangements : Efficient washing-up arrangements are necessary to clean and remove bacteria from all dining room and kitchen equipment. The essential provisions are :

- (1) Good layout of washing-up area.
- (2) Correct temperature of wash and rinse water.
- (3) A good detergent suited to the type of water.
- (4) Orderly methods of work in rinsing, stacking, racking, and storage.

Methods of Washing the Crockery, Cutlery and Utensils

- **One Sink Method** : This is commonly used but is an inefficient method since crockery and cutlery may still be contaminated with bacteria.
- **Two Sink Method** : It is suitable for domestic as well as for large scale use. The dishes are rinsed, scraped, and wiped off, with paper. Food particles are removed. Utensils are then washed in hot water, (46-50°C) with measured detergent. They are rinsed in racks in hot water at 77-82°C. Both wash and rinse waters should be changed as soon as they become soiled or cold. They must be dried before storage.
- **Dish washing machine** could also be used.
- **Mops and cloths** : They harbour bacteria and can contaminate hands, equipment and cutlery. They require daily washing and disinfection preferably by heat. Paper should be used in place of dish cloths and towels.

(h) Waste disposal

Within the kitchen : Scraps of food attract bacterial growth and vermin. It is therefore important to dispose off the waste correctly. Waste must be collected in pedal-operated bins which can be emptied regularly and washed out or in paper or plastic bags on pedal-operated stands. Bags can be sealed and put into dustbins, incinerated, or collected by the local refuse collection service.

Outside the kitchen : Sufficient waste bins or paper or plastic sacks must be provided to prevent over spilling. Bins with well-fitting lids should be placed in the shade on a stand (10 to 12 inches) high above a concrete area with drainage which can be easily cleaned. Plastic bags with lids should be wall-mounted to give good ground clearance for hosing down. Bins should be kept as dry as possible.

(j) Vermin and fly control : Rats, mice, flies, cockroaches and ants are the most common pests. If premises does not provide food and shelter infestation can be prevented. For details on extermination the chapter on entomology may be referred to.

Control of Flies

- (1) Do not provide a breeding ground such as uncovered refuse bins. Bins should be kept as dry as possible.
- (2) Destroy flies by insecticidal spraying of the refuse area in summers to prevent breeding.
- (3) Prevent access to kitchen and food by fly-proof windows, doors and ventilators. Food must be kept covered.
- (4) Electrical fly killers will kill flies without the hazards associated with aerosol sprays.

Cockroaches

These are active at night. They get attracted to warm places, such as heating pipes. The hiding places (cracks and crevices) which provide shelter must be sealed off. Close-fitting lids prevent access to food. The area should be treated with suitable insecticide.

Sprays and other insecticide formulations

These must be used with great care in the kitchen premises Pyrethrum spray is relatively safer to be used in this setting.

Hazard Analysis and Critical Control Points (HACCP)

HACCP is an approach to food safety focusing on identifying and controlling critical points in the food production and distribution chain that may lead to food hazard. HACCP incorporates a set of food safety strategies specific to the tasks and settings of the food chain. These strategies apply to farmers working in the field to those responsible for food handling and production before it reaches the consumers table. Food handlers at all levels are trained to implement key strategies to eliminate or control food borne infection triggers at critical points in the 'operation'.

Principles of HACCP : The standard approach to HACCP has been specified by the Codex Alimentarius, 1997, and follows the following seven basic principles :

1. Analyze hazards : In a setting of food hygiene the hazard could be biological, (microbes); chemical (toxin); or physical

(ground glass or metal fragments). These potential hazards and measures to control them are identified.

2. Identify critical control points. These are points in a food's production from its raw state through processing and transport to consumption at which the potential hazard can be controlled or eliminated. Examples are cooking, cooling, packaging, and metal detection.
3. Establish preventive measures with critical limits for each control point. For a cooked food, for example, this might include setting the minimum cooking temperature and time required to ensure the elimination of a harmful microbes.
4. Establish procedures to monitor the critical control points. Such procedures might include determining how and by whom cooking time and temperature should be monitored.
5. Establish corrective actions to be taken when monitoring shows that a critical limit has not been met--for example, reprocessing or disposing of food if the minimum cooking temperature is not met.
6. Establish procedures to verify that the system is working properly for example, testing time-and-temperature recording devices to verify that a cooking unit is working properly.
7. Establish effective record keeping : This would include records of hazards and their control methods, the monitoring of safety requirements and action taken to correct potential problems.

Summary

Prevention of food borne infections and food poisoning can be achieved through appropriate steps taken at the all levels of food processing i.e. production, supply, procurement, processing of raw food, transport, cooking, storage, distribution and finally serving and eating of food. Immaculate personal hygiene of cooks, design and hygiene of the kitchen premises, appropriate storage of food and healthy cooking practices are vital for prevention of food borne diseases.

Milk and meat are also potential sources of various food borne diseases. Adequate hygiene measures should be implemented through their entire course of procurement and processing. Sanitation of dairy and slaughter house is of paramount importance in achieving this aim. Pasteurization of milk is the process of rapidly heating, maintaining it uniformly over a definite period and rapidly cooling it thus destroying most of the pathogenic microorganisms. Various methods of pasteurizing milk are: Holder (Vat) method, Continuous Flow Method, High Temperature Short Time (HTST) Method, Ultra High Temperature (UHT) Method. Various methods and tests are used to monitor pasteurization.

Study Questions

Long Question : Enumerate the hazards of an unsanitary kitchen. What measures would ensure adequate kitchen hygiene of a large eating establishment?

Short Notes : (1) Botulism (2) HACCP (3) Golden principles of food hygiene (4) Pasteurization (5) Hygiene inspection of meat

MCQs

1. Which is true for mushrooms : (a) It is a nutritious food (b) Some mushrooms could cause food borne disease (c) Some mushrooms could cause food poisoning (d) All of the above
2. Which of the following is generally not a source of food borne diseases (a) Dust (b) Skin infection (c) Home preserved food (d) Fruits
3. Pasteurization destroys (a) All pathogenic organisms (b) Some pathogenic organism (c) Most pathogenic organisms (d) No pathogenic organisms
4. Which of these insecticides is relatively safe for kitchen use : (a) Abate (b) Sodium Hypochlorite (c) Baygon (d) Pyrethrum

5. Which of these is the ideal method of disposing off solid refuse from slaughter house : (a) Incineration (b) Land fill (c) Sell it off to a contractor and get some money (d) Chemical treatment

Answers : (1) d; (2) d; (3) c; (4) d; (5) a.

Rajul K Gupta

In the less fortunate parts of the world, immense food related problems are a painful reality. Every day 800 million people in the developing world, ie 18% of the total world population, have to sleep hungry. In South East Asia, one out of four persons go hungry. In Sub Saharan Africa the condition is still worse; one third of the population does not get enough food. World over, 175 m children (under five years of age) are underweight. As many as two billion women and children are anaemic, 250 million children suffer from xerophthalmia, two billion people are at risk of Iodine deficiency...; the magnitude of the problems related to nutritional inadequacies is colossal.

Interventions by India

Over the past five decades India has been able to achieve self sufficiency in food production, through various interventions. Green revolution brought about an exponential increase in agricultural production, laying the foundation of self sufficiency. The government of India launched and improved the Public Distribution System, thereby facilitating the easy accessibility of food grains to the common masses at an affordable price.

Research in the field of nutrition was strengthened with the augmentation of the ICMR governed National Institute of Nutrition (NIN) at Hyderabad and the CFTRI at Mysore. In this series of events, various direct interventions were introduced through National Nutritional Programmes in the late 1960s and early 1970s. In addition certain interventions were inherently built up within other (non nutritional) programmes to improve the nutritional status of community.

Current Nutritional Deficiency Status

The nutritional state of the country still remains much below the desirable levels. Even though the agricultural production may be good, it does not automatically ensure enough nutrition of masses, owing to various reasons. These could be as diverse as poverty, lack of food security and ignorance.

The figures speak for themselves. More than one fourth (26.1%) population is below poverty line. As many as half (49%) of rural and more than one third (36%) of rural Indian children are underweight. A staggering 2.2 million are afflicted with cretinism and 6.6 million are mildly retarded. Nutritional blindness affects 7 million children in India, mainly because of vitamin A deficiency.

Many a challenges remain before us as far as nutritional adequacies are concerned. National programmes reflect the concern of the government of India towards the problem and is a way to bridge this inadequacy. Various nutritional programmes have been conceived over the past five decades with an aim of improving the nutritional state of our country. These have met with reasonable degree of success. A brief outline of some of the more important programmes is given here.

Direct Interventions : The Nutritional Programmes

The various nutritional programmes are being run by different ministries. These programmes are listed below :

Ministry of Social Welfare

- ICDS programme
- Balwadi nutrition programme
- Special Nutrition programme

Ministry of Health and Family Welfare

- Prophylaxis against nutritional anaemia

- Vitamin A prophylaxis programme
- Iodine Deficiency Disorders Control programme

Ministry of Education

- Mid Day Meal programme

Balwadi Nutrition Programme

The Balwadi Nutrition Programme was initiated in 1970 by the Ministry of Social Welfare. It was meant for the children from rural areas, in the 3 to 6 years age group. It was run through Balwadis. Meals were provided to the children with an aim of catering for 300 Kcal and 10 to 12 g protein per day for each child. The Balwadis had also endeavored to provide pre-primary education to the children.

Special Nutrition Programme

Special Nutrition Programme was also started in 1970 by the Ministry of Social Welfare. This programme was operational in the urban slums and tribal areas in addition to the rural areas. It had a wider scope than the Balwadi Nutrition Programme as it not only benefited children from 1 to 6 years but also the pregnant women. It provided supplementary nutrition for 300 days in a year. Children obtained food, providing 300 Kcal and 10 to 12 g protein. Pregnant women were provided with food supplementing 500kcal and 25 g protein. This programme has slowly been merged with the ICDS in most of the states.

Applied Nutrition Programme

The Applied Nutrition Programme was introduced as a pilot project in Orissa in 1963, which was extended later to other states. It had focused on production of more vegetables and fruits and ensuring their consumption by children, pregnant and lactating women. Nutritional education was also a thrust area. Kitchen gardening, poultry, bee-keeping etc. were also encouraged.

National Nutritional Anaemia Prophylaxis Programme

The programme for Prophylaxis against nutritional anaemia was started in the year 1970, during the fourth 5-year plan (1969-74) by the Ministry of Health and Family Welfare to prevent nutritional anaemia in mothers and children. Distribution of the Iron-Folic Acid tablet (IFA tablets) to pregnant women and children under 12 years of age is an important component of this programme.

Doses and Formulations : Women (pregnant, lactating and family planning acceptors) are given one tablet of iron and folic acid containing 100mg elemental iron and 0.5mg folic acid. Children in the age group of 1 to 5 years are given one tablet iron containing 20 mg elemental iron (60 mg ferrous sulphate) and 0.1mg folic acid daily for a period of 100 days. Recently (2007) the government of India recommended that infants (6-12 months should also be included in the programme and a liquid formulation must be incorporated for children for easy dispensing for children between 6-60 months. Dispersible tablets must also be used, which are easy to use under the 'programme conditions'.

There is another recent recommendation to include school children (6 to 10 years of age) and adolescents (11 to 18 years of age) also in the programme. Children will be provided 30

mg elemental iron and 250 microgram folic acid for 100 days. Adolescents will be provided the same dose as that for adults. Adolescent girls will be given priority.

The distribution of the tablets is carried out through the Primary Health Centres, MCH Centers in Urban areas and the ICDS.

Critique : It is generally agreed that the programme has failed to make any impact on the anaemia scene in the country. The incidence of anaemia has hardly changed over the past decade, as is clear from the comparison of figures from NHFS II and III. Some of the important causes of the poor outcome of this programme are summarized in Box - 1.

Box - 1 : Causes of Poor Outcome of National Nutritional Anaemia Prophylaxis Programme
Poor perception of the problem (of anaemia) by the population.
Inadequate outreach of target population.
Poor compliance.
Medicine supply & stocks inadequate and poor quality.
Knowledge of functionaries and beneficiaries poor.
No attention given to educational and training components of programme.
Evaluation system not implemented.

Achieving Control of Iron Deficiency : The following actions are required to achieve control of iron deficiency :

1. Better appreciation of the problem by the community and care givers.
2. Better organisation of primary health services to effectively render iron supplementation.
3. Strengthening of the supplementation programme.
4. Nutrition education with respect to Do's and Dont's of iron natures.
5. Development of suitable fortificant and its effective implementation.
6. Active involvement of medical community especially the nutritionists, haematologists, internists, paediatricians, obstetricians and community medicine specialists to combat iron deficiency.
7. Joint action by the Government, NGOs, medical and biomedical scientists, agriculturists and planners.
8. Using biotechnology for enhancing iron and ferritin contents of foods like soyabean and other seeds.

The experience from other countries teaches that long term measures for control of anaemia are more effective. The most promising intervention is fortification of food items with iron over long periods. These food items can be as varied as salt, sugar, milk, cereals, etc. India has already perfected the technology of double fortification of salt with iodine and iron. Nutrition education is also another long term measure that is likely to change the face of anaemia if followed well.

National Programme for Prophylaxis against Blindness in Children due to Vitamin A Deficiency

The deficiency of Vitamin A continues to be a public health

problem in India. Many surveys indicate the prevalence of Bitots spots to be higher than 0.5% and night blindness in the range of 0.7-2%. The solution is to supplement oral vitamin A to children. Vitamin A Prophylaxis Programme was started by the Ministry of Health and Family Welfare in 1970 with this aim. National Institute of Nutrition (NIN), Hyderabad rendered the necessary technical assistance.

The aim of the programme was to decrease prevalence of Vitamin A deficiency from the current 0.7% to less than 0.3%. The 10th five year plan had set a target to eliminate vitamin A deficiency as a public health problem and decrease prevalence of night blindness to below 1% and Bitots spots to less than 0.5% in children of 6 months to 6 years of age.

Dosage : Under this programme a total of 9 lakh IU of Retinol palmitate is administered orally in 5 doses. The first dose of 1 lac IU is given at 9 months, starting along with the measles vaccine followed by the second dose at 15 months of 2 lakh IU. This is followed by another 3 doses of 2 lakh IU at 6 monthly intervals, till the age of 3 years (ie 1 lakh IU at 9 months and 2,00,000 IU each at 15 to 18, 24, 30 and 36 months of age).

Implementation : The vitamin A doses are being administered by Anganwadi workers under the supervision of ANM. The programme is being implemented through the RCH programme.

Critique : This programme has significantly contributed to our endeavour of elimination of Vitamin A deficiency in India. The morbidity has steadily declined. Integration of vitamin A administration with RCH and immunization programme has made it logistically much simpler and practical to implement. Some episodes of deaths of children following vitamin A intake has brought the programme to disrepute. There is however no scientific explanation of mortality even after administration of double the recommended dose of vitamin A. The media must refrain from sensationalizing these news stories without solid scientific evidence. The health community too, must counter it through health education campaigns.

Iodine Deficiency Disorders (IDD) Control Programme

National Goitre Control Programme was launched in 1962. In 1992 the programme was renamed as National Iodine Deficiency Disorders Control Programme. The components of the programme are :

- a) To conduct surveys to establish magnitude of the problem
- b) Provision of Iodized salt
- c) IDD monitoring
- d) Manpower training
- e) Health Education (IEC) activities

Surveys : Surveys have proved beyond doubt that it is not only the Sub Himalayan Goiter belt but almost all states of India are endemic for IDD. More than 200 million people are living at risk of IDD.

Provision of iodized salt : The orders on banning sale of non-iodized salt have not been consistent over the past few decades. The exact policy on ban has been fluctuating. Moreover it was at the convenience of the states to implement the order. As a result some states have been following a strict ban and others not. The Ministry of Health and Family Welfare again issued a notification banning the sale of non-iodized salt in November

2005 under the PFA Act, to be effective from mid 2006.

The quality control of iodized salt is also important. Testing kits for spot qualitative analysis of iodine in salt have been developed. The iodine content of salt at production and consumption levels should be 30 and 15 ppm respectively. Iodized salt has been introduced in the public distribution system of most of the states.

IDD Monitoring : Continuous monitoring of the IDD status is vital to observe the progression of the condition. This is carried out through various surveys. Iodine in salt and urinary iodine excretion are also monitored. IDD monitoring laboratories have been established at district levels in 17 states. A national reference laboratory has been set up at National Institute of Communicable Disease at New Delhi.

Manpower Training : Various institutions run courses for manpower training in various facets of IDD control. Workers are trained in goiter survey methodology and laboratory technology with respect to iodine level monitoring in urine and salt, etc.

Health Education and IEC Activities : Government provides fund to run IEC campaign to increase awareness on consumption of iodized salt intake. Endemic districts are under operation of IEC activities through 268 units of Directorate of Field Publicity. Doordarshan is also used for IEC campaigns. Global IDD day is celebrated on 21st Oct. The misconceptions regarding consumption of iodized salt are also managed through the IEC campaign.

Critique : It was conceived that universal iodization of salt will root out IDD. But that has not really happened, even after a decade of 'universal iodization'. It is primarily because of the fact that we have not been able to achieve universal immunization, which was the main pillar of the programme. The priorities and policies of the state governments have been varying, and in the bargain the iodization status of salt suffers, compromising the programme. There is a ban on the sale of un-iodized salt but the same has to be ensured through various administrative mechanisms of respective states.

The allocation of funds is very small in comparison to other national programmes, since the priority attributed to it is lower. There have been 'roadblocks' in the transportation of salt through the railways. These administrative problems have to be sorted to enable a smooth programme. Cost of iodized salt too is a constraint for poor society in India. Only a strong and committed political and bureaucratic will could help the programme succeed.

Midday Meal Programme

It was Madras Presidency in the year 1923 that started the concept of providing cooked meals to children studying in corporation schools of Madras city. It was expanded to a larger scale in 1961, thus India became one of the first countries to have started the Midday Meal Programme, then called as the School Lunch Programme. Other states also joined in and programmes run by Gujarat and Kerala are also widely acclaimed. In 2001, a landmark decision was given by the honourable Supreme Court of India, which made it mandatory for all government primary schools to provide cooked meals. The primary aim of the programme was to provide at least

one nourishing meal to the school going children per day. The objectives were :

- It served as an incentive for the children to attend school.
- To reduce dropouts from school.
- To improve the nutritional status of the child

There are certain additional advantages of the programme too. It also serves as an opportunity to impart basic health / nutritional education to children. Moreover some local women get employment to cook food for the mid day meal.

It must be remembered that the programme provides a supplement, and not a substitute to the food eaten at home. This meal provides one third the total daily energy requirement and half the need of proteins (300Kcal and 8-12 g of proteins). The central government (Ministry of Education) supplies the full quota of grains to the states. Food that could be cooked easily, available locally and at low cost is preferable. To avoid monotony it is desirable to change the menu frequently.

Critique : The mid day meal concept was a noble one as it primarily serves the underprivileged rural primary children. The sustainability of the programme however depends on the political will, community participation and prudent running of the programme. The programme has to be saved from ill-publicity which it sometimes attracts through news of food-poisonings associated with the programme. The standards can be improved through a sustained improvement of quality of service.

Integrated Child Development Services (ICDS)

The Integrated child development program (ICDS) was initiated by the government of India on 2nd October 1975 by the Ministry of Social Welfare. It is the world's largest early child development program. It was initially started in 33 blocks (1975) but now it encompasses 6500 blocks, employing more than 6 lakh Anganwadi Workers (AWW) and equal number of helpers. It is providing its outreach services to 33.2 million children and 6.2 million pregnant and lactating women. It is an inter-sectoral programme which seeks to directly reach out to children, below six years, especially from vulnerable and remote areas and provide early childhood education, health and nutrition along with the care of the women in the reproductive age group (women of 15-45 years, pregnant and lactating women). Currently, services under the scheme are being provided to about 562.18 lakh beneficiaries, comprising of about 467.18 lakh children (0-6 years) and about 95 lakh pregnant and lactating mothers through a network of about 7.48 lakh Anganwadi Centres.

Objectives of ICDS :

1. Lay the foundation for proper psychological development of the child
2. Improve nutritional & health status of children 0-6 years
3. Reduce incidence of mortality, morbidity, malnutrition and school drop-outs
4. Enhance the capability of the mother and family to look after the health, nutritional and development needs of the child
5. Achieve effective coordination of policy and implementation among various departments to promote child development

This programme has a major nutritional component :

- Supplementary nutrition to children below 06 years of age, nursing and pregnant mothers from low income families.
- Nutrition and health education to all women in age group of 15 - 45 years.
- Referral of serious cases of malnutrition or illness to hospitals.

Services : The Scheme provides many services in an integrated manner through community-based workers and helpers. The services are provided at a centre called the 'Anganwadi'. The Anganwadi, literally a courtyard play centre, is a childcare centre, located within the village. A package of following six services is provided under the ICDS Scheme :

1. Supplementary nutrition
2. Non-formal pre-school education
3. Immunization
4. Health Check-up
5. Referral services
6. Nutrition and Health Education

The three services namely immunization, health check-up and referral are delivered through public health infrastructure i.e. the Sub Centres, PHCs and CHCs under the MoHFW.

<i>Target Groups & Service Provider</i>		
Services	Target Group	Services Provider
Supplementary Nutrition	Children below 6 years; pregnant and lactating mothers	Anganwadi Workers (AWW) & Anganwadi Helper (AWH)
Immunization*	Children below 6 years; pregnant and lactating mothers	ANM/MO
Health Check-ups*	Children below 6 years; pregnant and lactating mothers	ANM/MO/AWW
Referral	Children below 6 years; pregnant and lactating mothers	AWW/ANM/MO
Pre-School Education	Children 3-6 years	AWW
Nutrition & Health Education	Women (15-45 years)	AWW/ANM/MO
* AWW assists ANM in identifying & mobilizing the target group to health-centres		

Supplementary Nutrition : This includes supplementary feeding and growth monitoring; and prophylaxis against vitamin A deficiency and control of nutritional anaemia. All families in the community are surveyed, to identify children below the age of six and pregnant and nursing mothers. They avail of supplementary feeding support for 300 days in a year. By providing supplementary feeding, the Anganwadi attempts to bridge the protein energy gap for the beneficiaries.

Growth Monitoring and nutrition surveillance are two important activities that are undertaken. Children below the age of three

years are weighed once a month and children 3-6 years of age are weighed every quarter. Weight-for-age growth cards are maintained for all children below six years. This helps to detect growth faltering and helps in assessing nutritional status. Besides, severely malnourished children are given special supplementary feeding and referred to health sub-centres, PHCs as and when required.

Supplementary Nutrition Norms : Nutritional supplements are provided to the extent indicated in Table - 1.

Table - 1		
Beneficiaries	Calories (cal)	Protein (g)
Children below 3 years	300	8-10
Children 3-6 years	300	8-10
Severely malnourished Children on medical advice after health check-up	600	16-20
Pregnant & Lactating (P&L) Mothers	500	20-25

Non Formal Pre-School Education : This component for the three-to six years old children in the Anganwadi is directed towards providing and ensuring a natural, joyful and stimulating environment, with emphasis on necessary inputs for optimal growth and development. The early learning component of the ICDS is a significant input for providing a sound foundation for cumulative lifelong learning and development. It also contributes to providing the child the necessary preparation for primary schooling and offering substitute care to younger siblings.

Immunization : Immunization services are delivered by the Ministry of Health and Family Welfare under its Reproductive Child Health (RCH) programme. The ICDS only tends to facilitate these services through a reiteration of the family to attend the immunization clinic at the relevant centre. In addition, the Iron and Vitamin "A" Supplementation to children and pregnant women is also facilitated.

Health Check-ups : This includes health care of children less than six years of age, antenatal care of expectant mothers and postnatal care of nursing mothers. These services are provided by the ANM/ Medical Officers from Sub-Centres and Primary Health Centres. The various health services include regular health check-ups, immunization, management of malnutrition, treatment of diarrhoea, de-worming and distribution of basic medicines etc.

Referral Services : During health check-ups and growth monitoring, sick or malnourished children, in need of prompt medical attention, are referred to the Primary Health Centre etc. The Anganwadi worker has also been oriented to detect disabilities in young children.

Nutrition and Health Education : Nutrition and Health Education is also an important element of the work of the Anganwadi worker. This enables women in the age group of 15-45 years to look after their own health, nutrition and development needs as well as that of their children and families in a better way.

ICDS Staff : Anganwadi Worker, a lady selected from the local community, is a community based frontline voluntary worker of the ICDS Programme. She is also an agent of social change, mobilizing community support for better care of young children, girls and women. She is assisted by Anganwadi helpers. She reports to the supervisor. Child Development Project Officers (CDPOs) and District Programme Officers (DPOs) are the officers directing the programme within a block. Besides the Medical Officers, the Lady Health Visitors (LHVs) and Auxiliary Nurse Midwife and Female Health Workers from nearby Primary Health Centres (PHCs) and Sub-Centres work in an integrated manner with the ICDS functionaries to provide health, medical, immunization and referral services.

Administration of the Scheme

Location : The administrative unit for the location of ICDS Project is the Community Development Blocks in rural areas, tribal blocks in tribal areas and ward(s) or slums in urban areas. For the purpose of working out the estimated number of beneficiaries, a rural/urban Project is assumed to have a population of 1 lakh and tribal project 35,000. One Anganwadi Centre normally caters to 1000 population in a rural/urban project and 700 population in a tribal project.

Sparsely populated hilly/desert areas : There is provision for setting up an Anganwadi in every village or hamlet having a population of 300 or more sparsely populated hilly/desert areas. Very small villages/ hamlets with a population of less than 300 are covered by the adjoining Anganwadi.

Finances : ICDS is a centrally-sponsored Scheme implemented through the State Governments/UT Administrations with 100% financial assistance for inputs other than supplementary nutrition which the States were to provide out of their own resources. From 2005-06, it has been decided to extend support to States up to 50% of the financial norms or 50% of expenditure incurred by them on supplementary nutrition, whichever is less.

Mini-AWCs : Mini-Anganwadis can be set up to cover the remote and low populated hamlets/ villages in tribal blocks having a population between 150 to 300.

Anganwadi Workers : Anganwadi Workers (AWWs) and Helpers (AWHs) are "honorary workers" from the local community who come forward to render their services, on part-time basis, in the area of child care and development. Anganwadi Workers & Helpers are the grass roots functionaries to implement the ICDS Scheme. AWWs & Helpers, being honorary workers, are paid a monthly honoraria as decided by the Government from time to time. At present the AWW get about Rs 938 to 1063 (depending on qualification and experience) and AWH gets Rs. 500 per month as honorarium.

Critique : The ICDS programme has largely been a successful endeavour of the government of India. Given the very large scope of the beneficiaries (about 6 crores) and about 15 lakh AWW and AWH working in extremely diverse environs of states with varied ideologies, diverse terrains and constraints, there has to be criticism of the scheme in some quarters. The aim of the scheme was to reduce the incidence of mortality, morbidity, malnutrition and school dropouts, which has been achieved to a great extent. There is a criticism that the beneficiaries only

visit the centre only during the meal timings. But provision of nutrition too has been an objective of the programme. Infant Mortality Rate (IMR) has declined from 110 in 1981 to 58 per thousand live birth in 2004. Similarly, under-5 mortality has declined from 161 in 1983 to 87 in 2003. Various surveys have revealed that there has been significant impact of the scheme. Many non-monetary benefits like insurance, incentives, preference in other jobs (teachers) have been given to the AWW and AWH. There is certainly a scope of enhancing the honorarium offered to these grass root workers.

Summary

After independence the government of India took many initiatives to ensure food security for the country. National nutritional programmes were a firm step in that direction. Ministry of Social Welfare runs the ICDS programme, Balwadi nutrition programme and special nutrition programme. Ministry of Health and Family Welfare runs the programmes for prophylaxis against nutritional anaemia, vitamin A prophylaxis programme and the iodine deficiency disorders control programme. The mid day meal programme is run by the Ministry of Education. The programmes have achieved improvement in the nutritional status of the children, pregnant and lactating women. More specifically the ICDS programme that has a strong nutritional component can be termed as a successful programme.

Study Exercises

Long Question : What are the objectives of the ICDS scheme? Discuss the benefits offered to various vulnerable groups under

the scheme.

Short Notes : (1) Mid day meal programme (2) Anganwadi worker (3) Iodized salt (4) Services under National Nutritional Anaemia Prophylaxis Programme (5) Supplementary Nutrition under ICDS

MCQs

- Mid day meal programme offers (a) Half of daily protein and one third of calorie requirement (b) Half of daily protein and half of calorie requirement (c) One third daily protein and half of calorie requirement (d) One third of daily protein and one third of calorie requirement.
- To a child under 3 years of age, ICDS provides : (a) 300 Kcal energy and 8-10 g protein (b) 300 Kcal energy and 16-20 g protein (c) 500 Kcal energy and 8-10 g protein (d) 500 Kcal energy and 16-20 g protein.
- In rural areas, the administrative unit for the location of ICDS Project is (a) Gram Panchayat (b) Community Development Blocks (c) District head quarter (d) Primary Health Centre.
- Which of the following is not run by the Ministry of Health and Family Welfare (a) Prophylaxis against nutritional anaemia (b) Vitamin A prophylaxis programme (c) Iodine Deficiency Disorders Control programme (d) ICDS Programme.
- Which of these is not carried out at the Anganwadi centre (a) Supplementary nutrition (b) Non-formal pre-school education (c) Immunization (d) Nutrition and Health Education.

Answers : (1) a; (2) a; (3) a; (4) b; (5) c.

Nutritional Assessment and Surveillance of a Community

Rajul K Gupta

Assessment of Nutritional Status of Individuals and Communities

Aims of Assessment of Nutritional Status

The assessment of nutritional status is carried out with the following aims :

- To map out distribution and geography of nutritional disorders
- To identify high risk groups with respect to nutritional vulnerability
- To assess various epidemiological factors for nutritional deficiencies
- Make recommendations to rectify shortcomings leading to nutritional deficiencies
- To project for financial allocations and budget for food

materials at a large administrative level e.g. at the national level.

Various methods are available for the assessment of nutritional status. These are enumerated in Box - 1. These can be further sub-classified into direct and indirect methods of nutritional status assessment.

Box - 1 : ABCD... of Nutritional Status Assessment
Anthropometry
Biochemical & lab methods
Clinical assessment
Diet survey
Ecological studies
Functional assessment
G - - Vital statistics

Direct Assessment of Nutritional Status

The term 'direct assessment' refers to methods in which individuals or communities are investigated directly. The various methods that are available for the direct assessment are summarized in Box - 2.

Box - 2 : Direct Assessment of Nutritional Status
Clinical signs
Laboratory Tests
<ul style="list-style-type: none"> Biochemical Haematological Parasitological
Biophysical Methods
Anthropometry

Assessment of Nutritional Status using Clinical Signs : Clinical examination is a widely practiced direct method to assess the nutritional status of individuals and communities. Assessment of clinical signs is based on the examination for changes believed to be related to inadequate or excessive nutritional intake, that can be observed in superficial tissues (skin, eyes, hair, mouth) or in organs close to the surface (thyroid, skull).

Caution with Clinical Examination : The cheapness and the relatively easy organization of clinical examination for nutritional assessment, might sometimes lead to the assumption that the method is simple, can be quickly mastered by a beginner, and yield results that are quick to interpret. But this is not the case. This method has got its own limitations, advantages and disadvantages. Expertise is required to select it as a valid method in a given situation, to conduct it and to interpret the results obtained.

Classification of Clinical Signs : Based on their importance with regard to suggesting a nutritional etiology the clinical signs can be classified into three groups (1) :

Group 1 - Potentially Nutritionally Significant (Signs 'strongly suggestive' of dietary deficiency or excess) : Some signs are strongly suggestive of a particular nutritional deficiency or excess e.g. Bitot's spots (Vitamin A), Flag sign (PEM). A list of these is summarized in Table - 1.

Group 2 - Signs that are of probable nutritional significance : There are some signs that are of uncertain nutritional significance. These have to be appreciated and interpreted in correlation with the case. e.g. Xanthomata eye might indicate high blood cholesterol, Corneal scar (previous infection, trauma, malnutrition, avitaminosis A), Fissure tongue, recession of gums, transverse ridging of nails, etc.

Group 3 - Signs that have no nutritional significance : These signs are not nutritionally significant but required to be differentiated from other nutritionally relevant signs. e.g. pterygium (an insignificant sign) is to be differentiated from Bitot's spots, geographic tongue, pyorrhea.

Assessment of Nutritional Status using Biochemical and Laboratory Methods : We have seen previously that clinical signs are often non specific and develop rather late in the

disease process. Biochemical changes, on the other hand can be expected to take place prior to clinical manifestations. Hence tests that can be conducted on easily accessible body fluids (blood and urine), can help to detect disease at a sub-clinical level even in a community setting.

Table - 1 : Signs 'strongly suggestive' of dietary deficiency or excess	
Deficiency Sign	Suggested nutrient abnormality
Pale conjunctiva	Iron
Bitot's spots	Vitamin A
Angular stomatitis	Riboflavin
Spongy, bleeding gums	Vitamin C
Bilateral edema (young children)	PEM
Thyroid enlargement	Iodine
Bilateral epiphyseal enlargement of wrists	Vitamin D
Sign of Excess	Suggested nutrient abnormality
Mottled enamel	Fluoride
Dental caries	Sugar

Available laboratory tests : Three groups of laboratory tests are available, namely, haematological tests, parasitological tests and biochemical tests. The haematological tests include the commonly done hemoglobin estimation, parasitological tests would include stool examination for intestinal parasites and biochemical tests include many tests like the urine examination for albumin, sugar, etc. Advanced biochemical test are taken up for vitamin, minerals and enzyme estimations as well, that indicate nutritional status. Normal range of some of these tests is given in Table - 2.

Assessment of Nutritional Status through Anthropometry : Nutritional anthropometry is the measurement of human body at various ages and levels of nutritional status. It is based on the principle that appropriate measurements should reflect any morphological variation occurring due to a significant functional physiological change. For example, a low Fat Fold Thickness reflects a shift in energy balance. The advantages of anthropometry are that it is simple, quick to do, easy to reproduce and objective. In some cases it identifies even subclinical changes resulting from nutritional variations.

Common Methods of Anthropometry : The common anthropometric methods should be quick, simple and easy to reproduce. Minimum training should be required to conduct the measurement. The commonly used methods are : Height; Crown-heel length and standing height; body weight, mid upper arm circumference; and fat fold thickness. Head and chest circumference are measured for children under five years of age.

Body Weight : Body weight is the commonest and simplest anthropometric measure used for the evaluation of nutritional status. It is a reflection of total body mass comprising of all

body constituents. It is measured for both children and adults. Definite body weight standards are available to us. Body weight is an indicator of 'current' nutritional status of the individual, as weight fluctuates with nutrition. Unlike height which is irreversible, it reflects the nutrition state of the present day. It is therefore a useful indicator for acute disorders. Small illnesses like childhood diarrhoea is also good enough to alter the weight, it is thus a sensitive indicator.

Measurement of Weight : The ideal weighing instrument is the lever actuated balance or a beam balance. The balance must have a least count of not more than 100g. Balances using a 'spring' are not advisable as the spring loses its tension due to prolonged use and an error is inevitable. Commonly used bathroom scales are based on the 'spring' principle, thus they must be best avoided for scientific work. The balance which is in use must be calibrated frequently for best results. The precautions to be taken while measuring weight are given in the Box - 3.

Height : Height is an indicator of the linear growth of the individual. It is widely accepted that height is determined genetically. Environmental factors, most importantly nutrition and morbidity determine the extent to which the genetic potential will be harnessed, to achieve the maximum possible height. Growth retardation resulting from any environmental factors like infections, malnutrition, etc. result in a retarded height, resulting in stunting (or short stature). Height is

affected by long standing nutritional deprivation. A short or retarded height is thus indicative of chronic food insufficiency over a longer duration, unlike a reduced weight which indicates a short term nutritional deprivation or infection.

Box - 3 : Precautions while measuring weight
Use the right balance. Avoid bathroom scales.
Weight must be taken in minimum clothing.
Remove shoes before weight is recorded.
The zero-error must be checked and corrected before using a machine.
It is advisable to record weight in the morning (in basal conditions)
These precautions must be applicable in a standardized manner for all subjects (within a study group)

Measurement of Height : In young children, height is referred to as length or Crown-heel length in young children who cannot stand with ease (say up to 2 years of age). An infantometer is use to measure their recumbent 'length' (in lying position). In adults and older children, the height is measured using a vertical measuring rod, the Anthropometric rod.

The subject should remove his shoes and stand erect. He must keep his heels together and toes apart. He must look straight.

Table - 2 : Normal range of some biochemical tests (2)

Nutrient	Test	Normal (Acceptable)	Low (Medium risk)	Deficient (high risk)
Albumin (g/100ml) for age 6-17 yrs	Serum levels	>3.5	2.8-3.4	<2.8
Vitamin A (µg/dl)	Serum levels	>30	20-30	<20
Vitamin D (ng/ml)	Serum levels of 25-Hydroxy cholecalciferol	>10	05-10	<5
Vitamin E	Ratio of serum vitamin/total lipids	>0.8		
Vitamin K	*PIVKAS accumulation			If PIVKAS accumulates
	Prothrombin time			Delayed **
Thiamin	Urinary thiamin	100µg/24 hrs or 65µg/g creatinine		
Riboflavin	Urinary Riboflavin	80µg/g creatinine		
Niacin	2-Pyridone to NI-methyl nicotinamide ratio	1 to 4		<1
Vitamin B ₆	Vitamin B ₆ urinary excretion			<20µg/g creatinine
	Pyridoxic acid excretion			<0.5mg/day
Folic Acid	Serum folate (ng/ml)	>6.0	3.0-5.9	<3
	RBC Folate (ng/ml)	>160	140-159	<140
Vitamin B ₁₂	Serum B ₁₂ (pg/ml)			<80
Ascorbic acid	Plasma (mg/dl)	>15	08/15/09	<8

* PIVKAS: Protein Induced by Vitamin K Absence. ** Prothrombin time is a functional test

He stands against the anthropometric rod kept at his back, placed perpendicular to the ground. The investigator standing to the left holds the subject's chin with his left hand and the occiput with the right little finger in the Frankfurt horizontal plane (an imaginary line joining the tragus of the ear to the eye). The moving head piece of the anthropometric rod is brought down and placed on the head with little pressure, in the sagittal plane. The reading is taken. Average of three readings is recorded. The disadvantage of height as a measure of nutritional status is that it doesn't indicate present nutritional status of the individual, but indicates only the past history of a chronic disease.

Mid-Upper Arm Circumference (MUAC) : Mid-upper arm circumference indicates the muscle development. Since poor muscle development is seen in PEM, the lower MUAC indicates poor nutrition. MUAC correlates well with weight, weight for height and clinical signs of malnutrition. It can be used to calculate the mid arm muscle circumference using a simple formula, if the value of fat fold at triceps is also estimated simultaneously. The mid calf circumference can also be used instead of MUAC.

The mid-upper arm circumference is measured on the non-dominant arm (left arm in case of right handed subjects and vice-versa) of the subject. The mid point between the tip of the acromion (of scapula) and olecranon process of ulna is located with the arm flexed at the elbow. It should be marked with a pen. The arm is now held hanging freely by the side of the subject and a fiberglass tape is placed gently but firmly embracing the arm without 'squeezing' the soft tissue, at the point marked in pen. The reading is taken to the nearest millimeter.

Interpretation : The usefulness of MUAC is based on the principle that MUAC remains almost constant between 1 to 5 years of age (increasing only approx 1.5 cm between 1 and 5 years of age). Thus fair degree of standardization can be achieved even if the age is not known in a preschool child. A cut off point of 12.5 cm is taken. MUAC of less than 12.5 cm is taken as low. To make the procedure of measurement even simpler and usable at the grassroot level, Shakir introduced a simple tricoloured tape in 1975, called as the Shakir's tape. The red colour in the tape (which fell in the less than 12.5 cm zone) marked Danger, yellow or white colour, fell in 12.5-14 cm zone marked Caution and green colour more than 14.0 cm is considered as OK or normal.

MUAC can be used as an efficient technique for screening large population of children for malnutrition. Children thus screened, can be subjected to further anthropometric measurements and other (Clinical/biochemical) tests for specific nutritional deficiencies.

The biggest advantage of using the MUAC is that it is easy to conduct and it is age independent till about 5 years of age. A modified tape (Shakir's Tape) can be used easily even by a village health worker.

Body Fat : Body Fat indicates reserve of energy in the body. The quantity of fat present subcutaneously at various sites indicates the gross nutritional status of the person. The thickness of fat can be correlated to the body content of fat. Fat distribution in and around the body varies with age, sex,

physiological, nutritional and health status of the individual.

Anthropometric Measurement of Body Fat : Fat fold thickness

Anthropometric measurement of body fat can be carried out at various subcutaneous sites. These sites are commonly undertaken : Two sites on the trunk namely sub scapular and supra-iliac and three sites on the extremities namely triceps, thighs and mid calf. Biceps fat fold is also done. The fat fold thickness at triceps is the most sensitive (to socioeconomic changes) and most reliable (indicator of obesity).

Fat fold at triceps is the commonest measure. It is carried out at the dorsal side at the same mid point where MUAC is measured. The skin fold is picked up between the thumb and the forefinger 1 cm above the midpoint, taking care not to include the underlying muscle. The tips of the skin fold calipers must be applied at the mid point at a depth equal to the skin fold. The skin fold is held gently in the left hand throughout the measurement. Average of two measurements must be taken.

Head and Chest Circumference : Head and chest circumferences are measures used in children. A neonate is born with a bigger head. The chest grows faster than the head in a normally nourished child in the 2nd and 3rd years of life. As a result, the chest circumference overtakes the head by about 1 year of age. In a child suffering from PEM, the chest grows at a lower rate and it remains smaller than the head even till 2 ½ to 3 years of age. This indicates a poor state of nutrition.

Head and chest circumferences are measured using a fiberglass tape. Head circumference is taken at the supraorbital ridges of the frontal bone (just above the eyes) in front and the most protruding point of the occiput in the back. The chest circumference is taken at the level of the nipples in mid inspiration.

Classification of Nutritional Status Based on Anthropometric Parameters

Weight for age : There are standard weights laid down for a particular age. Thus a given child's weight (for his particular age), is compared to the 'standard' weight of a 'normal' child. This standard is taken as per the 50th centile of the Boston standard. The Gomez classification is one of the commonest classifications used to classify malnourishment into various grades.

$$\text{Weight for age(\%)} = \frac{\text{Weight of child}}{\text{Weight of 'normal child' of same age}} \times 100$$

The grades as per Gomez classification are given in Table - 3.

Table - 3 : Gomez Classification	
Malnutrition grade	Weight/Age (%) of normal
Normal	>90%
Grade I (Mild)	75 – 89 %
Grade II (Moderate)	60 – 74 %
Grade III (Severe)	< 60 %

The Indian Academy of Paediatrics (IAP) classification on the other hand puts the degree of malnutrition into four grades (Table - 4). This classification is used by the ICDS in India.

Malnutrition grade	Weight/Age (%) of normal
Normal	> 80%
I Grade	70-80%
II Grade	60-70%
III Grade	50-60%
IV Grade	<50%

Weight for height : The weight for height classification doesn't take age into consideration. Weight is also related to height. Many a times age is not known. Weight for height is an age independent parameter. It is a good prognostic indicator of severe PEM and an index of current nutritional status. Weight for height of less than 80% of normal is considered to indicate wasting in preschool children.

Wasting and Stunting : In the Waterlow classification weight for height and height for age are used to classify children as normal, wasted, stunted and wasted and stunted. Children with low weight for height are considered as wasted and those with low height are 'stunted' (Table - 5).

Weight for height	Height for age	Nutritional status	Interpretation
Normal	Normal	Normal	Normal
Low	Normal	Wasted	Acute malnutrition
Normal	Low	Stunted	Nutritional dwarf
Low	Low	Wasted and stunted	Acute on Chronic malnutrition

Body Mass Index (BMI) : Body Mass Index (BMI) is the ratio of weight in Kg to square of height in metre.

$$BMI = \frac{\text{Mass (Kg)}}{\text{Height (m)}^2}$$

It gives an indication of the nutritional status, esp. obesity. Now-a-days in context of lifestyle diseases, BMI is taken as an indicator of risk of cardiovascular diseases as well.

BMI does not measure the body fat but relates well with the degree of obesity. The categories of obesity as pronounced by the WHO are depicted in Table - 6. A BMI of 25-30 is considered as a warning sign and may warrant intervention, especially in the presence of additional risk factors. A BMI of 30 or higher is generally considered the point at which some form of treatment is required. Obesity Class III i.e. BMI >40 or morbid obesity, is a medical condition that impairs a person's overall health and therefore requires medical attention.

Table-6: Grades of obesity based on BMI (WHO, 1998) (3)

BMI	Classification	Risk of co-morbidities
< 18.5	Underweight	Low
18.5-24.9	Healthy/normal weight	Average
25 – 29.9	Pre-obese (Overweight)	Mildly increased
30 – 34.9	Obesity Class I	Moderate
35 - 39.9	Obesity Class II	Severe
> 40	Obesity Class III	Very severe

The guidelines have been revised and made more stringent lately for Asians, considering the fact that Asians (esp. South East Asians including Indians) are more susceptible to metabolic syndrome. These are summarized in Table - 7.

Table - 7 : Grades of obesity for Asians (5)

BMI	Classification	Risk of co-morbidities
< 18.5	Underweight	Low
18.5-23	Normal weight	Increasing but acceptable
23 – 27.5	Pre-obese	Increased
>27.5	Obese	High

Dietary Assessment for Nutritional Status

A nutritional survey is never complete without a diet survey. We may be able to find out that there is a nutritional deficit through clinical, laboratory or anthropometric methods, but in order to find out if this nutritional deficiency is because of diet and which particular diet/nutrient, we have to invariably resort to a diet survey. It is thus an integral part of nutritional survey. A diet survey objectively defines importance of diet in various health state and disease (2). Diet survey is nothing but the scientific assessment of food consumption, and using this data for various purposes including assessment of nutritional status.

Methods : Various methods are there to undertake diet surveys. These are appropriate in different settings (6) and are summarized in the Box - 4.

Food balance sheet method
Inventory method
Weighment method
24 hr Recall method (Questionnaire method)
Dietary score method
Food Frequency Questionnaire method
Duplicate sample (chemical analysis) method

Diet Balance Sheet Method : This method is used when information regarding availability and consumption of food is required at a macro level like at the global, national, region or state levels. The total food supplies available and used up at a

given level are taken into account in this method. Effectively the difference between receipt (of food various sources) and expenditure over a given period of time gives the food consumed by population. The consumption per capita/day is worked out as :

$$\frac{\text{Food consumed by population}}{\text{Mid yr pop} \times 365}$$

These figures are used for various types of planning and budgeting, namely plans for agriculture, fertilizers, productions, imports and Public Distribution System (PDS). The method has got certain demerits. It is a gross method. Secondly the consumption of rich and poor is equated and averaged out when this method is used. It gives the consumption pattern but doesn't include purchasing power of the individual.

Inventory Method : As mentioned earlier the inventory method is carried out at an institutional level, on a homogenous group as present in a hostel, jail, mess, army barrack, orphanage etc. It is essentially done from books. Amounts of various food stuffs available as per records are taken into consideration. The balance of various food items is again checked after a reference point of say 7 days (one week).

$$\text{Individual consumption / day} =$$

$$\frac{\text{Stocks at beginning of week} - \text{Stocks at end of week}}{\text{No. of individuals} \times \text{No. of days}}$$

The Merits are that it is fast, much easier, less cumbersome and faster than the weighment methods. It is also fairly accurate. It may not indicate an accurate individual food consumption but is fairly satisfactory for the purposes of planning.

The Demerits are that it doesn't account for wastage. Secondly, it gives only the mean individual consumption but actual individual consumption is not reflected. Thirdly, the estimates are as good as the food records made available. Lastly, the results will be affected if the subjects are eating some food stuff obtained from any source other than the common kitchen under question.

Weighment Method : In this method the foods are actually weighed using a grocer's balance. Both raw and cooked food are weighed. In community surveys (at a family level), the raw food is weighed rather than the cooked food, since weighing cooked food is not acceptable to the families. In an institution however, the cooked food can also be weighed, since cooking is carried out at a central kitchen. While using weighment method at a family level the following points are important :

1. Convince the housewife of the need of the survey for the benefit of the family
2. Avoid holidays/fares/festivals/feasts as the dietary practice of these days does not reflect the actual dietary practices.
3. It should be carried out for 3 to 7 days consecutively.
4. At least two visits a day for lunch and dinner have to be made.
5. Two investigators should be available - one talks and weighs and the other records observations.
6. Any pets, breast fed children, guests etc. should be considered.

The method : Weigh the raw food before cooking. It is preferable to weigh the food again after cooking. A conversion factor is arrived at. For example let's assume that the weight of raw rice is 100 g. The weight of cooked rice becomes 400g. Thus a conversion factor of 100/400 or ¼ is arrived at. In other words 1 g cooked rice represents 1/4 g of raw rice. Or if a person eats 400g cooked rice it is equivalent to 100g of raw rice. The nutrient contents of raw rice are extracted from standard Food Composition Tables. The same process is employed to estimate the nutrient contents of all food preparations.

Ideally both, raw and cooked foods must be weighed. But if it is not possible to weigh the cooked foods an approximate conversion factor can be taken. Obviously this will lead to some degree of error. Another alternative is to measure the volumes of raw and cooked foods and subject them to weight conversions. In practice measuring volumes of cooked portions actually eaten by the individuals is easier than weighing the portions eaten. The volumes can be converted into weights and subsequently into nutrients, through standard tables. The merits of this method are that it accounts for the non edible parts of food as well. The wastage is also taken into account. This method is more accurate than the inventory method. The demerit is that it is a very cumbersome, time consuming and tedious process as it involves weighing of all foods.

24 hour Recall (or Questionnaire) Method : The 24 recall (questionnaire) method is a relatively easy method based on the recall capabilities of the individual over a period of the past 24 hours. Since it is a short term retrospective method it is more prone to errors.

A set of cups and ladles standardized for volume are used. The housewife is asked about the types of food items prepared at the time of breakfast, lunch and dinner. The raw ingredients used for cooking each meal are noted. The cups are exhibited to the housewife. The cooked food items are noted in terms of these cups. The intake of each food item by the specific individual in the family is also assessed by using these cups.

The method is fairly accurate. It take lesser time than the weighment method. However, the disadvantage is that the method is based on recall capability of the respondent so there is a likelihood of 'inaccurate recall' and error in derivation of nutrients. A fair degree of cooperation is to be sought from the respondent. The process is a cumbersome.

Food Frequency Questionnaire (FFQ) Method : Food frequency questionnaire (FFQ) method is based on the principle as to how frequently an item is consumed over a period of time. It is an epidemiological technique used to study the meal patterns and dietary habits of people. It can be used to assess the specific dietary intakes during pregnancy, lactation, etc. It can even be conducted through post. For example a FFQ may read "In one week how often do you consume the following items...."

Item	Frequency (Consumption Per Week)			
Meat	1	2	3	4.....
GLV	1	2	3	4.....
Sprouts	1	2	3	4.....

This filled up questionnaire is then analysed, using pre-decided values of for nutrients for different food items.

Nutritional Surveillance

It is clear from the earlier chapters that the state of nutrition of an individual or a community depends on a variety of (unrelated) factors. These could be as diverse as the 'health' of the crops, state of rainfall, GDP per capita income, efficiency of the public distribution system, availability of food and the health state of the community.

Given this dynamic and ever changing state of availability and use of food, it is vital to keeping a constant watch over all these factors concerning nutrition, in order to continuously assess the situation, give an early warning and take appropriate decisions that will lead to improvement in the nutritional status of population. This on-going process of constant scrutiny of the nutritional situation and factors influencing them and its application in the public health interest is termed as nutritional surveillance. The word was used first in 1974 with respect to drought relief, during a World conference in nutrition. A nutrition surveillance programme was developed for the developing countries 1976. The term has been used extensively by the UNO since 1980. The process of nutritional surveillance finds the following applications :

- It provides inputs for health and development planning
- It is useful for programme management and evaluation
- It provides timely warning and intervention to prevent (short term) food consumption crisis and plan for long term action

Steps : The various steps of nutritional surveillance are :

- Identify community/population
- Data collection
- Data transit
- Data processing
- Interpretation
- Responses and Planning
- Improvement
- Further implementation

Methodology of Nutritional Surveillance : The methodology of the nutritional surveillance can be outlined through answering the following basic questions :

- What is the problem? → Define & describe the type of nutritional problem e.g. malnutrition (acute or chronic), micronutrient deficiency, etc.
- Who is at risk? → Describe the population groups affected by area, socioeconomic status, biological/physiological status, etc.
- Why is this population at risk? → Identify the causal factors. These causes could be immediate (non availability of food, poor health, etc) or of long standing nature like unequal resource distribution, poor sanitation and infections.
- Where to get the data from? → Identify the data sources. These will depend on the purpose for which surveillance has been undertaken.

Purpose of surveillance	Data source
Health and development planning	Household survey
Data from records	Programme management and evaluation
Interviews and records	Timely warning and intervention programme
Rainfall, prices, employment	Health system surveys

- Define food supply system. The food can be obtained mobilizing the existing stores, through national and international aid, improving the agricultural production, etc.
- Obtain the data, analyse and provide feedback to decision makers. Finally, evaluate the nutritional surveillance system.

Nutritional Rehabilitation

The cases of severe malnutrition are treated in a hospital setting. Such a treatment no doubt, does make the child survive; it doesn't guarantee that he will live a life free of malnutrition and disease in future. Besides only medical, additional inputs like those of social, physical, psychological and emotional rehabilitation have to go in, if the child is to live a life of positive health.

Principle : More often than not it is seen that after a short spell in the hospital, once the child returns back to the original social milieu, the condition recurs. The child either dies or becomes extremely vulnerable to subsequent infections, malnutrition, disease and death. The basic principle of nutritionally rehabilitating a child is not only to treat his malnutrition and related acute complications, but to prevent a recurrence of the condition.

Methods : The process of rehabilitation is to be dove-tailed with treatment. It can be undertaken at three levels, depending on the severity of the condition and the facilities available.

(a) Hospital : The child is hospitalized in severe cases or when he has concomitant complications. Special standardized dietary regimes (intensive feeding with high proteins and energy dense diets) are required to be instituted and continued for a long time to come. Systematic education of parents in food selection and cooking has also to be imparted. The standardized dietary regimes and specific nutritional education It is initiated in the hospital but is required to be followed up either at the day care centre or at home.

(b) Day Care Centre : A day care facility is an intermediate arrangement between the hospital and home. Children who are not required to be admitted to a hospital or those who have been discharged from the hospital are expected to visit the day care centre. This centre may be run by a health worker who is trained in preparation of special feeds for malnourished children and who could educate the mothers on preparation of special feeds suitable to the particular child (as discussed in last paragraph). Any health facility like an anganwadi centre, sub-centre or a PHC can be used as a day care centre. The advantage of a day care centre (over hospital) is that it

is cheaper; the mother can spend the day at the centre under supervision of a trained health worker, learn sufficient skills in specialized feeding and child-care, in an informal setting, closest to her home environment and really imbibe it.

(c) **Domiciliary** : In case the child is not severely affected, after medical consultation, he can be treated at home. He could also be one who has been weaned off a hospital or a day care set-up. To maintain health of child it is important that the mother is trained in handling the 'special' nutritional needs of this child.

Summary

The condition of the body resulting from intake, absorption and utilization of food and the effect of pathological factors is termed as nutritional status.

Nutritional status is assessed to map out distribution and geography of nutritional disorders, identify high risk groups and to assess various epidemiological factors for responsible for nutritional deficiencies. It is also an administrative tool used to allocate budget for food materials at a large scale. The important methods are anthropometry, biochemical and laboratory methods, clinical assessment, diet survey, ecological studies, functional assessment and indirect assessment from vital statistics data.

There are clinical signs that may be 'strongly suggestive' of dietary deficiency or excess (e.g. Bitot's spots), of probable significance (e.g. corneal scar) and those that are of no nutritional significance (e.g. pterygium). Clinical signs might develop rather late and are subjective and non specific.

Biochemical tests on the other hand give objective and quantitative indication of nutritional status, but these are costly and instrument intensive.

Anthropometry remains the sheet anchor of nutritional assessment. Weight, height, head and chest circumference, MUAC and fat fold thickness are the common anthropometric parameters used. Many derived parameters like the BMI, weight for age, weight for height, etc are also used in different situations.

Various methods of diet survey are used to ascertain as to what an individual or a group of people are eating. This indicates the deficiency of nutrients in the diet and thus appropriate measures can be suggested to improve it. The main methods Food balance sheet method are inventory method, weighment method, 24 hour recall method (Questionnaire method), dietary score method, food frequency questionnaire method and duplicate sample (chemical analysis) method. The inventory method, weighment method and 24 hour recall method are the most commonly used dietary survey methods.

Nutritional Surveillance is an on-going process to keep a constant watch over all the nutrition related factors, in order to continuously assess the situation, give an early warning and take appropriate actions.

Nutritional Rehabilitation aims at re-establishing the severely malnourished child medically, nutritionally and psychologically into the family and society. The aim is to prevent a recurrence

of acute malnourishment. This can be achieved through appropriate measures begun at the hospital. Subsequently the child may be managed at a day care centre or at home.

Study Exercises

Long Questions : (1) Enumerate the various methods for nutritional assessment. Describe any one in detail. (2) What is nutritional surveillance? Outline the methodology of nutritional surveillance. (3) What are the various anthropometric techniques available to assess nutritional status of a 5 year old child? How can weight for age be useful to ascertain malnutrition in this child?

Short Notes : (1) Mid Upper Arm Circumference (2) 24 hour recall method (3) FFQ (4) Using BMI to assess CED in adults (5) Disadvantages of using clinical signs for nutritional status assessment

MCQs

- All can indicate nutritional status except : (a) Fall in weight (b) Falling hair (c) Failure to gain height (d) Flag sign
- All are signs of PEM except (a) Flag sign (b) Unilateral pedal edema (c) Low weight for age (d) Dermatoses
- Stunting is _____ weight for height but _____ height for age : (a) Normal; Low (b) Low; Normal (c) Low; Low (d) High; low
- Acute malnutrition may be indicated by : (a) Stunting (b) Wasting (c) Stunting and wasting (d) All of the above
- Which of these is not true for nutritional surveillance : (a) It is an ongoing process (b) It can be used as a nutritional survey technique (c) It is a close scrutiny of events related to nutritional changes (d) It provides timely warning for action

Match the following

	Age		Suitable anthropometric measure
6.	New born	(a)	MUAC
7.	3 years	(b)	Weight
8.	42 years	(c)	BMI
9.	8 years	(d)	Head & chest circumference
10.	1 ½ years	(e)	Weight for age

Answers : (1) b; (2) b; (3) a; (4) b; (5) b; (6) b; (7) a; (8) c; (9) e; (10) d.

Food Processing

Food processing is the technique used to transform raw ingredients into food or to transform food into other forms for consumption. It can be done either at home or by the food processing industry.

Aim of Food Processing : Food processing is aimed at improving the colour, appearance, palatability, taste, texture, keeping quality and marketability of food. Food processing makes the food attractive and many a times makes it a long-life food product. Foods used in certain special situations can not be used without processing. Some of these situations can be space travel, high altitude expeditions, disaster aid situations, combat missions by soldiers, etc. Some common food processing techniques are enumerated in Box-1.

Processing helps to remove toxins, eases marketing and distribution of foods. In addition, it increases seasonal availability of many foods, enables transportation of delicate perishable foods across long distances and makes many kinds of foods safe to eat by de-activating spoilage and pathogenic micro-organisms. Food processing techniques are also used to add extra nutrients such as minerals and vitamins to food preparations.

Disadvantages of Food Processing : Food processing can sometimes lower the nutritional value of foods. Some vitamins are very sensitive to heat and are lost on cooking (e.g. vitamin C). Some water soluble vitamins can be lost on washing with water. Food additives such as colours, flavouring agents and preservatives, used while processing the foods, may be unhealthy. Some are known to be allergic or even carcinogenic. Processed foods (like junk foods) often have a higher ratio of calories to other essential nutrients than unprocessed foods, and may provide empty calories. Processing also increases the prices of food products.

Food Additives

The concept of adding “non-food” substances to food products is not new. Pickling preserves the food articles such as mango, lime etc. for fairly long periods by the addition of salt and spices. Salt and spices were the traditionally used food additives. These can be considered as natural additives.

With industrialization, increasing demand of ‘ready to eat food’ and use of modern techniques, the food processing industry is relying heavily on chemical additives. The food additives improve taste, flavour, texture and colour. They also help increase the shelf-life of food. Now a days majority of the processed foods contain some food additive or the other. Some commonly used food additives are enumerated in Box - 2.

Box - 1: Some Common Food Processing Techniques

Peeling and skinning (fruits and vegetables)
Mincing (meat)
Liquefaction (fruit juice)
Fermentation (Soy, beer, cocoa)
Baking (cakes, pastries, bread)
Sprouting (cereals, pulses)
Steaming (rice)
Boiling (vegetables)
Carbonation (beer, soft drinks)
Packaging (most commercial foods)
Canning (juices, fruits, fish)
Sauce and ketchups (tomato)
Brewing (tea)
Chopping or slicing (vegetables)
Pureeing (vegetables and fruits)
Pickling (vegetables)
Emulsification
Cooking (most foods)
Frying (French fries, <i>pakorries</i>)
Grilling (chicken)
Pasteurization (milk)
Spray drying (milk powder)
Dehydration (fish, vegetables, soup powders)
Jam and jelly (fruit, vegetables)
Wines and ciders
Freeze drying (meat)

Box - 2 : Some Commonly Used Food Additives (Emulsifiers, Stabilizers, Thickeners and Gelling Agents) * (1)

Name	Food
Lecithins	Chocolates, margarine, potato snacks
Citric Acid	Pickles, dairy products, baked products
Tartaric Acids	Baking powder
Alginic Acid	Ice creams, desserts
Agar	Ice cream, soups, tinned ham
Gums	Ice creams, soups, confectionery
Pectin	Jellies

* A list of antioxidants and preservatives is given in the next section

Definition : Food additives are the non-nutritious substances added intentionally to food, generally in small quantity, to improve the basic properties of food like its appearance, flavour, texture etc.

Food additives can be classified into the following two broad categories :

1. Additives deliberately added to food

- a) Colouring agents e.g. saffron, turmeric.
- b) Flavouring agents e.g. vanilla essence
- c) Sweeteners e.g. saccharin, cyclamate
- d) Preservatives e.g. sorbic acid, sodium benzoate (details given in next section)
- e) Acidity imparting agents e.g. acetic acid etc.
- f) Thickening Agents e.g. alginate (from seaweed) and casein used in ice creams, cheese, yogurt etc.
- g) Emulsifiers: Keep water and oil mixed together. e.g. lecithin, monoglycerides and diglycerides are used in margarine, baked goods and ice cream.
- h) Anti-Oxidants : Prevent spoilage, flavor changes, and loss of color caused by exposure to air e.g. Vitamin C and Vitamin E.

These are generally considered safe for human consumption. However, certain preservatives such as nitrites and nitrates can lead to the production of toxic substances, e.g. nitrosamines that have been implicated in cancer etiology.

2. Contaminants : They get incorporated incidentally through packing, processing, farming practices (insecticides) or other environmental contaminants.

Provisions of Law Applicable to Food Additives : The use of food additives is subjected to government regulations throughout the world. In India two regulations viz. the Prevention of Food Adulteration Act (PFA Act) and the Food Products Order are in vogue. The PFA Act has been discussed separately. Use of food additives that are not permitted by law is considered to be an adulterant. In case the quantity of the food additive exceeds the permissible limit then also the food is considered adulterated. It is also required by law that the nature and quantity of the additive shall be clearly printed on the label that is affixed to the container. Whenever any extraneous colouring agent is added to a food article, the words 'Artificially Coloured' shall be printed on the label.

At the international level, FAO/WHO have established the Codex Alimentarius Commission as its principal organ. Protection of the health of consumers is the primary aim of this commission.

Food Preservatives

It is not possible to consume food immediately on production as we don't have access to farm fresh food all the time. If we can't consume the food quick enough, the food tends to get spoilt. As soon as a food is harvested or cooked, the process of food spoilage sets in. The enzymes and other chemicals (e.g. acids and alcohols) present in foods initiate the process of deterioration. Micro-organisms (bacteria and fungi) are the prime agents that cause spoilage under suitable conditions. Environmental factors like heat and humidity enhance the process of spoilage. Once spoilt the food no more remains fit for consumption and may lose its original nutritive properties as well. Preserving food therefore becomes imperative. Preservation is undertaken with the following aims:

- a) Increasing the keeping quality of food
- b) Preserving its nutritional characteristics

c) Preserving the appearance, colour and texture of food

Methods of Food Preservation : Preservatives are centuries old. Since ancient times, salt has been used to make pickles, cure meats and fish. Sugar has also been added to fruits to conserve them. Herbs, spices and vinegar have also served as preservatives for centuries. These early preservatives (sugar and salt) produce food environments of high osmotic pressure that deny bacteria the conditions needed by them to propagate. Jams and jellies are preserved as solutions of high sugar content.

The Modern Day Preservatives could either be natural or synthetic.

Natural Food Preservation : As discussed earlier salt and sugar are the commonest natural preservatives. Another group of natural preservatives target enzymes in fruits and vegetables that continue to metabolize even after they are cut. For instance lemon juice contains citric and ascorbic acids which inhibit the action of enzyme phenolase that turns cut surfaces of apples and potatoes brown.

Anti-Oxidants : Anti-Oxidants not only preserve foods through preventing spoilage but also limit flavour changes and loss of colour caused by exposure to air. Vitamin C and Vitamin E are used as antioxidants. Other antioxidant preservatives are compounds like BHA (Butylated Hydroxyanisole).

Anti-microbial Preservatives : Anti-microbial preservatives inhibit the growth of microbes. Benzoic acid, sulfur dioxide and ethanol have long been used as preservatives. Other common anti-microbial preservatives are calcium propionate, sodium nitrate, sodium nitrite, sulphites, sulphur di-oxide, sodium bisulphite, potassium hydrogen sulphite, disodium EDTA.

Microbes as preservatives : All microorganisms are not harmful. Some microbes are responsible for the production and preservation of certain foods. Microbial action is a part of the production of cheese and flavouring agents. Sauerkraut is both processed and preserved by lactobacilli. Yeast cells ferment sugars, producing alcohol and help to preserve them.

Irradiation: Food irradiation using radioactive rays or high-intensity X-rays or streams of electrons is a modern method of food preservation. It has the advantage of preserving food while in their packets. There is minimal person-to-food contact reducing the possibility of contamination. Food is not required to be exposed to chemical preservatives which may be harmful. Irradiation extends the shelf lives of foods such as strawberries, potatoes, onions, grains, etc. Irradiation does not make foods radioactive, but may cause changes in food colour or texture.

Some commonly used food chemical preservatives are enumerated in Box - 3.

Health Concerns on Food Preservatives : There have been health concerns with many chemical additives like colouring and flavouring agents. Preservatives are also not untouched with these fears. Some modern synthetic preservatives have become controversial because they have been shown to cause respiratory or other health problems. Sulfur dioxide (often used to preserve wines) is irritating to the bronchial tubes of persons who have asthma, and nitrites have been implicated as carcinogens. Some preservatives are known to cause allergic reactions including anaphylactoid reactions.

Box - 3 : Commonly Used Food Preservatives (1)	
Preservative	Food
<i>Antioxidants</i>	
Ascorbic acid	Beer, soft drinks, fruits, meat, powdered milk
Tocopherols	Vegetable oils
Gallates	Vegetable oils, fats, margarine
BHA and BHT	Fats, margarine in baked products
<i>Other Preservatives</i>	
Sorbic Acid	Cheese, yogurt, soft drinks
Acetic Acid	Pickles, sauce
Lactic Acid	Sauce, confectionery
Propionic acid	Bread, cakes, flour
Benzoic Acid	Soft drink, pickles, fruit products, jams
Sulphur dioxide	Soft drinks, fruit products, beer, cider, wine
Nitrites	Cured meats, cooked meats and meat products
Nitrates	Meat products, cheese

Food Fortification

Food Fortification is the process by which a nutrient is added to commonly eaten foods to improve the quality of the food. WHO has defined food fortification as “the process whereby nutrients are added to foods in relatively small quantities to maintain or improve the quality of diet of a group, a community, or a population.” Fortification is the addition of nutrients at levels higher than those found in the original or in comparable foods. The food that carries the nutrient is referred to as the *food vehicle*; and the nutrient added is the *fortificant*.

Fortification of food is a public health measure aimed at reinforcing the usual dietary intake of nutrients with additional supplies to prevent/control some nutritional disorders. A food fortification program is usually undertaken when there is a widespread and consistent nutritional deficit in the population's diet. Food fortification has been commonly used as a method to control micronutrient deficiencies.

The term *food enrichment* is used for replacing nutrients lost in processing. It occurs with grains, as some vitamins and minerals are lost in the milling process.

The Need for Fortification : One of every four people in the world suffers from micronutrient deficiencies. Globally, the key micronutrient deficiencies are that of iodine, vitamin A and iron. These vitamins and minerals are referred to as micronutrients because the body needs them in minute quantities for normal growth and development. All these major micronutrient deficiencies can be overcome at a community level by the simple process of fortification. Some of the fortification programmes of demonstrated effectiveness are: iodization of salt for combating endemic goitre, fortification of vanaspati ghee, butter and milk with vitamins A and D and fluoridation of water to prevent dental caries. Recently, technology has

been developed at the National Institute of India, Hyderabad in India for the twin fortification of salt with iodine and iron. Some initiatives taken by the Government of India on food fortification are given in Box - 4.

Box - 4 : Some Facts on Fortification - Initiatives by the Government of India
Wheat flour (atta) : In February 1970, the Government of India launched a programme in Bombay for fortification of atta with vitamins and minerals, and for increasing the protein content by admixture with edible groundnut flour.
Edible oils : Fortification of Vanaspati (hydrogenated oil) with vitamin A has been made compulsory (2,500 IU of vitamin A and 175 IU, vitamin D per 100 g of Vanaspati) by the Government of India.
Common salt : Under the PFA act common salt has to be fortified with iodine (commonly potassium iodate) in a dose of 30 ppm at production site and 15 ppm at consumer end.

Choosing a Food Vehicle and a Fortificant : While choosing an ideal food vehicle the following aspects are considered:

- The food should be consumed by all population groups that is at risk of the particular nutritional deficiency.
- The food should be used regularly and in consistent amounts by the entire population at risk.
- Taste, appearance and smell of the food should not change after fortification.
- The fortificant should remain stable under extreme conditions such as cooking, food processing, delivery and storage.
- The food should not be consumed in amounts that would present a risk of consumption at toxic levels of the fortificant.
- The food should not increase the cost of food.

Benefits of Food Fortification

- It effectively prevents major micronutrient deficiencies at a small cost.
- Fortification does not require change in the dietary habits of the population.
- It can be implemented relatively quickly and can be sustained over a long period of time.
- It being a population based approach, benefits all.
- It is a very cost-effective approach.

Food Adulteration and the Prevention of Food Adulteration Act (PFA)

Food is a substance consumed for eating or drinking (except for water and drugs). Unscrupulous traders use the practice of adulteration for their ulterior motives. Any material which could be used for adulteration is called as an adulterant. Commonly it is believed that adding a substandard stuff to food (e.g. water to milk) is adulteration, but as per the law the word adulteration has a much wider connotation.

The Prevention of Food Adulteration (PFA) Act was enacted by the parliament in 1954. The PFA Rules were framed by an expert body called the ‘Central Committee for Food Standards’ in 1955. Various amendments have been made in the act since then.

Objective : The PFA Act was enacted with the main objectives of :

- Ensuring pure & wholesome food
- Protecting against fraudulent & deceptive trade practices

Adulteration

An article is deemed adulterated if 'it is not of the nature, substance or quality as demanded by the purchaser; if the food contains other substances that affect injuriously the nature, substance or quality of food; if the food is substituted by an inferior or cheaper substance; or if any constituent of the food has been abstracted; or if it contains any poisonous ingredient, the food is said to be adulterated' (PFA Act). Some common food adulterants are enumerated in Box - 5.

Box - 5 : Some Common Food Adulterants	
Food Item	Adulterant
Cereals	Mud, grit
Dal	Kesari dal, dyes
Dhania	Horse dung
Black pepper	Papaya seeds
Chilli	Brick powder
Tea	Gram husk
Milk	Water
Mustard seeds	Prickly poppy seeds
Sweets	Non permitted colours
Ghee	Vanaspati

As per the PFA Act the following acts amount to adulteration of food:

- If any article has been prepared, packed or kept under unsanitary conditions whereby it has become contaminated or injurious.
- If the article is filthy, putrid, rotten, decomposed or from a diseased animal or vegetables; or is insect infested or is otherwise unfit for human consumption.
- It is obtained from a diseased animal.
- Contains a non prescribed colouring matter or preservative.
- The mal-practices like mixing, substitution, concealing the quality, misbranding, selling decomposed food, adding toxicants, extracting food material or giving false labels also amount to adulteration.

Process : Whenever an instance of food adulteration comes to the notice, a food sample is collected from the site. The sample can be collected by a government functionary like the food inspector or even by the consumer (1986 amendment). The consumer/purchaser can get food analyzed, provided the vendor is informed of this intent and the purchaser pays fees to the designated laboratory to carry out the analysis.

Sample collection, disposal and analysis : The food inspector expresses his intent of collecting the sample and getting it analyzed under the PFA Act to the vendor in advance. The cost of food item (sample) is paid to the vendor. The signatures of

the shopkeeper / vendor are taken. In case the shopkeeper/ vendor refuses to put his signature, an independent witness is made to sign. In case the witness also refuses to sign, the food inspector endorses a certificate to this effect. The sample is divided into three parts, they are packed and sealed. The sample number one is submitted to public analyst under intimation to the local health authority (The local health authority is an officer appointed by the government through a gazette notification to be the in charge of health administration, in a given area. Generally this responsibility lies with the municipal/cantonment health administrators). The 2nd and 3rd samples are kept as reserve samples and are deposited with the local health authority for safe custody. Sample analysis is carried out by the local government public analyst. The report is submitted to the local health authority. In case the sample is found to be adulterated suitable action is taken by the court of law. The vendor can apply to the court, within 10 days to get the reserve sample, kept in the custody of the local health authority, analyzed at the relevant Central Food Laboratory, for confirmation. For the purpose of this reconfirmation four reference laboratories have been established and notified by the government of India. These labs have been allocated a zone of responsibility and certain predefined regions/states/ union territories are dependent on them. These laboratories are located at Mysore, Kolkata, Pune and Ghaziabad (Box - 6).

Box - 6 : Central Food Laboratories (CFL) and States Dependent on them	
Central Food Laboratory	Dependent states
Mysore	Gujarat, Himachal Pradesh, Haryana, Punjab, UP, Maharashtra
Kolkata	North Eastern states, Orissa, Andaman & Nicobar
Pune	AP, Delhi, J&K, Karnataka, Kerala, Rajasthan, Tamil Nadu
Ghaziabad	Bihar, Goa, MP, West Bengal

Punishment : Following the hearing, the court awards a sentence to the guilty. A minimum imprisonment of 6 month to a maximum of life imprisonment (in cases of grievous hurt or death) can be awarded. The court may also impose a fine of Rs 1000 to Rs 5000.

Food Toxicants

Even today there is always a lurking fear that some antisocial elements might poison a source of water. While such acts are deliberate, a toxic or poisonous substance might be present as an integral component of a foodstuff. In a small dose it may not have any significant toxic effect, but in a larger dose or when consumed over a prolonged period it may even be fatal. Many possible toxic effects of foods are known. Table - 1 indicates the great variety of ill effects that natural food poisons might have.

Table - 1 : Some Possible Toxic Effects of Common Foods (2)

Food stuff	Active toxic ingredient	Effects on
Some bananas	5-Hydroxytryptamine, adrenaline, noradrenalin	Central or and Peripheral nervous systems
Some types of cheese	Tyramine	Blood Pressure
Almond, cassava	Cyanide	Tissue respiration
Some fish/meat	Nitrosamines	Cancers
Mustard oil adulterated with argemone oil	Sanguinarine	Epidemic dropsy
<i>Kesari dal</i> (Lathyrus)	Beta Oxayl Amino Alanine and others	Neurolathyrism
<i>Brassica</i> species (seeds)	Glucosinolates, thiocyanate	Goitre
Green potato	Solanine	Gastrointestinal upset
Mushrooms (<i>A muscaria</i> , <i>A phalloides</i>)	Various toxins	CNS effects
Groundnuts	Aflatoxin	Aflatoxicosis

Lathyrus Toxin

The ancient Indian text '*Bhava Prakasham*' describes the *Kesari dal* and neurolathyrism. Hippocrates has also described it in the pre-Christian era. Lathyrus and related pulses ('tares') were poorly regarded even in the Biblical times, as is clear from a quote from the Bible.

Cantani coined the term lathyrism in Italy. In India too *Lathyrus sativus* is deliberately sown with wheat in the dry districts. If the rains are good, wheat overgrows the lathyrus (and it is not harvested), but if rain fails and there is poor crop of wheat, a reasonable crop of lathyrus is reaped. Lathyrus is a tasty and high protein pulse. If eaten in small quantities it probably does not cause toxicity. If consumed in larger amounts (providing more than 50% of energy) a severe disease of the nervous system may result, leading to spastic paralysis. Some landlords (*zamindars*) used to pay their labourers in kind, the form of *Kesari dal* and not in cash. In this situation *Kesari dal* used to become the staple diet for these poor people and a cause of neurolathyrism. Neurolathyrism is a crippling disease of the nervous system characterized by gradually developing spastic paralysis in lower limbs, occurring mostly in those consuming a pulse, *Lathyrus sativus* in large quantities. In animals a variant of the disease i.e. osteolathyrism affecting skeletal system is seen.

The disease is seen in some European, African and Asian countries. Cases are reported from Spain, Algeria, Ethiopia, Mexico, Afghanistan and India. In India it is seen in some districts of Madhya Pradesh, Maharashtra, UP, Bihar, Rajasthan, Assam and Gujarat. Old literature reports thousands of cases

of Neurolathyrism occurring in epidemic proportions in some given regions, but now no outbreaks are reported, only sporadic cases occur in certain areas.

Lathyrus Sativus (Kesari dal) : *Lathyrus sativus* is also referred to as *Teora dal*, *Lak dal*, *Batra*, *Matra*, etc. It looks like *Arhar dal* (*toor dal*) red gram or bengal gram. However its seeds are triangular in shape and greyish in colour. It is cheaper and a rich source of protein.

In 1962 a neurotoxin, β -N-Oxayl Amino-L-Alanine (BOAA) was isolated from the common vetch (*Vicia Sativa*), which frequently grows as a weed in *Lathyrus sativus*. In 1963, another toxin β -N-oxayl-L- α , β di-aminopropionic acid was isolated from the seeds of *Lathyrus sativus*. Both of these can cause neurological lesions in primates. These toxins are neuro-exitants and can be removed by soaking in hot water and rejecting it.

Clinical Features : If more than 30% energy is obtained from *Kesari dal* for more than six months, the signs and symptoms may appear in the form of spastic paralysis. The condition is known as Lathyrism. It is most commonly seen in men in the age group 15-45 years. The onset of Lathyrism is sudden, often preceded by exertion or exposure to cold. A patient may find himself paralyzed on getting up in the morning. Sometimes backache and stiffness of legs precede the paralysis of legs. The condition is spastic paralysis of lower limb.

The underlying pathology is the toxin induced degeneration of spinal motor tracts (pyramidal tracts) and sclerosis. The motor nerves to muscles of trunk, upper limbs and sphincter are spared. The sensory system is also not involved.

The patient may pass through progressive stages of severity. In the latent stage the patient may be apparently healthy. In the mild stage there is stiffness and weakness of legs, exaggerated knee and ankle jerks and clonus may follow. As the disease progresses the gait may be affected and the patient walks with bent knees on tiptoe. The legs may become crossed and patient may develop scissor gait. The patient may be able to walk only with one stick and later with two sticks. Later on when paraplegia develops, walking may become impossible. Later the patient has to support his body on his hands, buttocks and heels for moving about (crawling stage). In the most severe stage patient can only move on 'all fours', supported by his hands. Many patients might be left with no other alternative but to resort to beggary.

Detection of Toxin : The toxin can be detected through laboratory methods using the ninhydrin reaction, which gives a purple colour. Electrophoresis and biological methods (bioassay in animals) can also be used.

Prevention : The condition is preventable if pulse is removed from diet, at the earliest. Use of the legislation of Prevention of Food Adulteration act to limit the consumption of crop must be encouraged. In case the crop has to be consumed, the toxin can be removed by steeping. At the household level, steeping can be done by soaking the pulse in hot water for 2 hours. Water is then drained and pulse is dried in sun. The disadvantage of using this method is that the taste and nutrients are lost to an extent. At a large scale, parboiling can be done. The process is the same as used for parboiling rice. Soaking the pulse overnight in lime water and subsequently boiling or cooking it

also helps in removing the toxin.

High dose vitamin C (1000 mg/day) prophylaxis for few weeks is also found to be useful. Nutritional education in the form of abstaining from the use of crop or using it in the manner prescribed above would be useful in preventing the consumption of toxic crops. Bringing about social changes in the form of improving the socioeconomic status would also help people not to fall prey to the toxic dal.

Aflatoxicosis

The first known outbreak of Aflatoxicosis probably occurred in England in 1960, among young turkeys. Turkeys fed on infested groundnut meal had hepatitis and enteritis. The groundnuts concerned were harvested, stored and processed in high humidity conditions. The toxic effects were produced by a fungus *Aspergillus flavus*, a mould contaminating the nuts. Human cases have not been rare since then.

Causative Agent : *Aspergillus flavus* or another species *Aspergillus parasiticus* are storage fungi that affects foods in poor storage conditions of high temperature (30-37°C) and high humidity, as is common in the rainy season and during floods and cyclones.

Foods Infested : The fungus infests improperly stored foods like maize, groundnut, soya, sorghum, rice, wheat, sunflower, tree nuts, spices and even milk and cheese.

Toxins : Brightly fluorescing furanocoumarin compounds known as the 'aflatoxins' are known to be responsible for the condition. *Aflatoxin B1* is the most potent known natural hepatocarcinogen. Another toxin *Aflatoxin G1* is also known. They are known to cause hepatitis (jaundice), ascitis, portal hypertension, liver cirrhosis and hepatocellular carcinoma.

Ergotism

While aflatoxicosis is a storage fungus, *Claviceps fusiformis* and *Claviceps purpura* are field fungi. Crops get infested in flowering or seeding stages. *Bajra*, rice, sorghum, wheat and *rye* get commonly affected. Ergotamine is the toxin responsible for the clinical symptoms of nausea, vomiting, abdominal cramps, muscular cramps, giddiness, burning, itching and gangrene of digits and limbs.

Epidemics of aflatoxicosis were known as St. Anthony's fire in France in the 11th century. The disease was referred to as 'fire' because of the intolerable burning pain in the limbs, which became black and shriveled (gangrenous) and eventually dropped off. The legend also goes to say that the condition used to improve when the patients visited the St Anthony's shrine located a distance away. The patients probably improved because of the discontinuation of consumption of ergot affected cereals, as they shifted to the new location (of the shrine).

Epidemics were common in many European countries like Germany, Poland, England and Russia till the late eighteenth century, when it was related to the consumption of fungus (*Claviceps purpura*) infested rye. Besides the symptoms enumerated above, convulsions, palsies and discordant movements were also known, indicating the affliction of the nervous system. The *Claviceps fusiformis* infestation of *bajra* in India is a milder clinical entity as compared to the more severe classical European variant described above. This fungus

produces alkaloids of the clavine group that has milder toxicity than ergotamine. *Claviceps fusiformis* infestation leads to nausea, vomiting, abdominal cramps and drowsiness. The recovery is usually complete.

Fusarium

Fusarium incarnantum is another field fungus affecting crops like sorghum, rice and maize. It is seen in the subtropical and temperate regions. The fungus produces toxins like deoxynivalenol and fumonisin which are responsible for certain clinical symptoms like vomiting and diarrhoea. The episodes of mouldy ragi poisoning in India (1929) and Alimentary Toxic Aleukia (haemorrhagic rash, bleeding nose, leucopenia) seen in Russia during the Second World War were due to fusarium.

Detection of Mycotoxins : Many sophisticated methods are available for the detection of Mycotoxins. Thin Layer Chromatography (TLC), Radio-immuno Assay (RIA) and ELISA tests are available. Several rapid kits are also available for detection of aflatoxicosis, etc.

Prevention : Four broad groups of steps should be taken (3):

1. **Plant Breeding** : Cultivating varieties of *rye*, *bajra*, millets, and wheat resistant to disease (ergotism) can radically minimize the problem.

2. **Good agricultural practices during pre and post harvest period** : Good pre-harvest agricultural practices like avoiding water stress, minimizing insect infestation, are effective in reducing aflatoxin contamination in groundnuts and maize. Good post harvest and storage conditions for grains and nuts are also of paramount importance. These foods must be stored under ideal humidity and temperature conditions. Appropriate drying, storage and reducing the chances of moisture entry in the stores also limit the probability of contamination with storage fungi. If contamination does occur the infested grains can be removed using the floatation method in which the grain is allowed to float in 20% salt water. The infested grains floats and can be easily removed. Air floatation and hand picking techniques can also be used.

3. **Detoxification** : Ammonia process is being used to detoxify aflatoxin affected groundnuts and remove the mycotoxin. The detoxified product is available only for animal feeds and is not suitable for human consumption.

4. **Health Education**: The community must be educated about the ill effects of the conditions and the importance of the preventive measures described above.

Epidemic Dropsy

Several cases of epidemic dropsy were reported from many states of India as recently as in the year 1996. Similar outbreaks have been occurring off and on in the past as well. It was discovered by Indian scientists in the early twentieth century that the condition is attributable to contamination of mustard oil with argemone oil. Subsequently the toxic alkaloid sanguinarine was isolated from argemone oil and was chemically analysed. It was also determined that sanguinarine interferes with the oxidation of pyruvic acid, which is responsible for the dropsy.

The Prickly poppy plant grows indiscriminately and wild in India. It has large prickly leaves and bright yellow flowers (some species have white flowers as well). *Argemone mexicana*

is the species most commonly incriminated. The argemone seeds closely resemble mustard seeds. They mature with the mustard crop and may be harvested together. Argemone seeds (or oil) can be mixed with mustard to deliberately adulterate it. The contamination may sometimes be accidental.

Clinical Features : As the name suggests, the patient gets generalized swelling manifested as bilateral pedal edema of sudden onset. Patient may get diarrhoea. In advanced stage patient gets dyspnoea and signs of congestive cardiac failure (CCF). If not treated death may ensue. A mortality rate of 5 to 50% has been reported.

Detection of Toxin :

(a) Nitric Acid test: When nitric acid is added to a sample of oil, a brown orange colour emerges, indicating the presence of argemone oil. The sensitivity of this test is low. It is positive only if at least 0.25% of argemone oil is present in the sample.

(b) Paper chromatography: Paper chromatography is a test with much higher sensitivity, detecting argemone oil even at 0.0001%.

Prevention : The growth of argemone plant must be discouraged and the plants must be weeded out. Unscrupulous traders deliberately adulterating argemone oil to mustard oil must be tried under the PFA Act. Early detection and institution of control measures must be encouraged to limit the severity and further spread of morbidity. Educating and making the public aware of the problem and likely solutions will also go a long way in preventing the condition.

Summary

Food processing is the technique used to transform raw ingredients into food or to transform food into other forms for consumption. The basic aims of food processing are to improve the colour, appearance, palatability, taste, texture and keeping quality of food. Food processing includes various techniques like pickling, fermentation, baking, Pasteurization and canning. Loss of nutrients (in some cases) could be a major disadvantage of food poisoning.

Food additives are the non-nutritious substances added intentionally to food, generally in small quantity, to improve the basic properties of food like its appearance, flavour, texture, etc. Almost all processed foods contain food additives.

Food preservatives are used to increasing the keeping quality, preserving the nutritional characteristics, appearance, colour and texture of food. There are few natural food preservatives known. The synthetic ones include certain preservatives like antioxidants and other chemicals.

Food Fortification is the process whereby nutrients are added to foods in relatively small quantities to maintain or improve the quality of diet of a group, a community, or a population. Addition of iodine to salt is the most well known example of fortification.

Study Exercises

Long Question : What is the role of the PFA Act? Describe as to how a food sample can be obtained from a shop and how is it dispatched.

Short Notes : (1) Fortificant (2) Neurotoxicity (3) Common mycotoxins (4) Epidemic dropsy (5) Aims of food processing

MCQs

1. Vanilla essence is a food : (a) Additive (b) Fortificant (c) Supplement (d) Toxicant
2. Which of the following is not a mycotoxin : (a) Aflatoxin (b) Sanguinarine (c) Deoxynivalenol (d) Fumonisin
3. PFA Act was enacted in the year : (a) 1950 (b) 1954 (c) 1962 (d) 1986
4. _____ can take a food sample under the PFA act : (a) Consumer (b) Health inspector (c) Anyone authorized under the gazette (d) Any of the above
5. _____ are not to be used for preservation of foods : (a) Irradiation (b) Bacteria (c) Antibiotics (d) Antioxidants

Match the following

Food item	Role
6. Papaya seeds	(a) Flavouring agent
7. Sanguinarine	(b) Adulterant
8. MSG	(c) Fortificant
9. Salt	(d) Toxicant
10. Iodine	(e) Vehicle

Answers : (1) a; (2) b; (3) b; (4) d; (5) c; (6) b; (7) d; (8) a; (9) e; (10) c.

Rajul K Gupta

There might be certain situations wherein nutrition assumes special importance and has to be catered for in a different manner. The resources required may be different and those available may be limited, in that given situation. There may be many such states; few selected important situations are discussed in this chapter.

Nutrition during Disaster Situations

History is replete with the instances of disasters and their inevitable implications on human nutrition. May it be the Bengal or the Irish famines (in which millions died of starvation) or even a prolonged military conflict, it is the common population that suffers the most and starves in extreme cases.

Unfortunately the epidemiology of the nutritional consequences of a disaster unfolds in a pathetic manner. Irish famine can be taken as a typical example (See Box - 1).

Box - 1: A Peep into the Genesis of Nutritional Problems in a Disaster through the Irish Famine

It was an unassuming fungal disease, the potato blight, which initiated the Irish famine, as "potato rotted in the ground, there was horrible stench all over", the poor farmers lost all and they had no money to buy food. They became idle and unemployed and out of work, since they subsisted only on the potato crop! Sanitation suffered and diseases like dysentery, diarrhoea and Scurvy took on. Cholera epidemics were a common place. Due to extreme cold and wet winter of 1846, and hardly any money to buy warm clothing, typhus and relapsing fever ("Famine fever"), compounded the problems. Starvation followed and millions died. They tried to migrate to the New World - America, but many died enroute in the ships, some overloaded ships sank killing scores of people on board. Those who reached were too rickety and miserable to work even in America...

Any disaster as such, leads to scarcity of food but other inevitable consequences of disaster lead to disease prone conditions like overcrowding, poor sanitation, natural vagaries, lack of water, and lack of health care. These multiple factors in turn, worsen the scarcity of food and malnutrition. Starvation and epidemics force people out of the town displacing them. There is panic and social disruption. People become helpless and may die in large numbers. They might have to be moved to relief camps, which too are not problem free.

Importance of Nutrition in Disaster

Nutrition assumes extreme importance in a disaster situation as food is a primary requirement for sustenance of life. Nothing depletes human morale more than the non availability of food. Micronutrient deficiency is a reality in the absence of food,

and so is death. Starvation and malnourishment are common. Malnutrition leads to infection esp. in children and this vicious cycle is deadly.

The effect of disaster is not the same on everyone. Vulnerability of people to disaster depend on the severity and duration of disaster, degree of preexisting poverty, failure of the population to get timely food, aid, work and wages. In case the prevailing disaster conditions like conflicts continue, the recovery can not be expected to occur. The physiological groups most vulnerable to the consequences of disaster in general and poor nutrition in particular are the young children, pregnant and lactating women, the sick, disabled, and the elderly.

The requirement of food during disaster depends on the number and age distribution of people, their mean heights and weights, physical activity levels, environmental temperatures and the malnutrition and (ill) health status (1,2). The energy requirements for disaster situation is summarised in Table - 1.

Group	Age	Male (Kcal)	Female (Kcal)	Combined (Kcal)
Under 5s	0-4	1320	1250	1290
Children	5-9	1980	1730	1860
Adolescents	10-14	2370	2040	2210
Adolescents	15-19	2700	2120	2420
Adults	20-59	2460	1990	2230
Elderly	> 60	2010	1780	1890
Pregnant/lactating			285/500 (extra)	285/500 (extra)
Whole population		2250	1910	2080 (say 2100)

There is a general consensus that about 2100 Kcal per head should be catered for planning the energy requirements for a disaster situation. Proteins must contribute to 10-12% of the energy (about 52g of proteins per day). Fats must provide 17-20% of energy (46g of fat); half from invisible sources and half from visible fats (23g each). Critical micronutrients like iron, iodine, vitamin A and other vitamins (thiamine, niacin, vitamin C) must also be provisioned for, systematically. Ensuring the provision of locally available foods and maintaining their continuous supply would go a long way in disaster relief. At times, fortified foods and pharmaceutical supplements are also called for. A typical food survival ration is outlined in Table-2.

Meeting Nutritional Requirements in a Disaster Situation

Nutritional requirements in a disaster situation can be effectively met through being prepared all the time for a disaster and instituting sound interventions in the event of disaster.

1. Be Prepared ... Disaster may Strike

The community has to be taught to be always prepared for a disaster. Such preparations not only keeps the community confident that they can meet the 'unknown challenge effectively' but such a preparation can make the difference

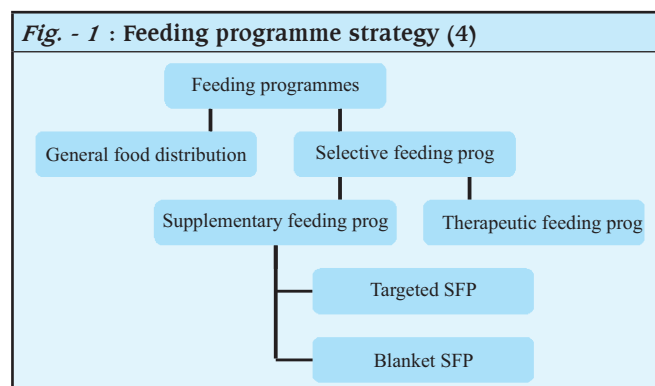

Item	Ration Option 1 (g)	Ration Option 2 (g)
Rice/Wheat flour	415	430
Pulses	45	0
Vegetable oil	25	25
Groundnuts	35	35
Canned fish	0	30
Sugar	15	15
Salt	5	5
Total	540	540

between life and death. Simple steps of storing food and water at vantage points and regularly replenishing them are some basic 'preparation' measures. The basic tips for storing water and food are summarised in Box - 2.

Store Water <ul style="list-style-type: none"> For drinking - @ 2 lit / person / day For cooking - @ 2 lit /person /day At least for 3 days (2 weeks) If supplies run low, don't ration water Don't risk dehydration Store in a cool, dark place at home, office, vehicle Preferably in store-bought, factory-sealed water container Or in washed, rinsed food-grade containers Change every six months
Store Food <ul style="list-style-type: none"> That is eaten regularly Requires no refrigeration, preparation, cooking Include vitamin, mineral, protein supplements Store two weeks supply Canned food can be stocked Stock for infants – formula feed, pacifiers, medicines Wrap perishables and keep sealed Empty opened packages into screw-top / airtight jars Avoid fatty, high protein, salty foods
Don't forget <ul style="list-style-type: none"> Can opener, disposable cups, plates, knife, sugar, salt, plastic bags To replace water/foods at regular intervals
Replace at six monthly intervals <ul style="list-style-type: none"> Dry fruits, biscuits, infant formula
Replace at yearly intervals <ul style="list-style-type: none"> Canned meat Vegetable soups, fruit juices Jelly, butter, instant cereals, vitamins
Store indefinitely <ul style="list-style-type: none"> Some foods like dried corn, dry noodles instant coffee, tea, soft drinks, vegetable oils, salt, soybean, wheat and rice can be stored almost indefinitely.

2. Interventions in the event of disaster

Rapid initial assessment will have to be undertaken to ascertain the origin of nutritional problem (failure of crops, war, drought, etc.), demographic profile of the affected population, baseline health data, factors affecting interventions like security, water, food and potential logistics constraints e.g. transport, roads, food supply, etc. Based on the above data the strategy for a particular feeding programme is chalked out. Many types of feeding programmes are available, depending on the situation. These are outlined in Fig. - 1. Various feeding programme strategies are described here in brief.

General Food Distribution (GFD) :The aim of the general food distribution strategy is to provide food to all for a basic level of survival. The limitations in this strategy are that the food might be insufficient to meet needs of all the people and the most vulnerable groups might be ignored. In any case it is a useful strategy esp. in the beginning of the disaster aid. It is done either through supplying cooked meal as an emergency measure or distributing dry ration when the situation has stabilized and people can cook in makeshift camps/shelters. The third option could be mass feeding the population with cooked meal. The principle is to provide energy dense foods on an immediate and urgent basis. 1 metric ton cereals can cater for the energy requirement of 1850 males for 1 day (5).

Presuming the individual consumption at a rate of 540g/person/day, the planning figures to determine food needs (in metric tons) has been worked out in Table - 3.

Popu-lation	1 day	1 month	3 months	6 months	1 year
1,000	0.54	16.20	48.60	97.2	197.10
5,000	2.70	81.00	243.00	486.0	985.0
10,000	5.40	162.00	486.00	972.0	1971.0
50,000	27.0	810.00	2430.00	4860.0	9855.0
1 lakh	54.0	1620.0	4860.00	9720.0	19710.0

(Basis of calculation: Requirement in metric tons = No. of persons per day x 0.540/1000 Kg)

It must be remembered that any food that is offered should be culturally acceptable, as close to routine food, available for consumption in a digestible form, suitable to vulnerable groups and must contain adequate quantity of micronutrients.

Organizing Mass Feeding : Mass feeding can be undertaken in institutions and refugee camps. Local foods should be used as far as possible. The calculations for mass feeding are similar to the one shown above. Mass feeding must be undertaken in enclosed areas. Public kitchens have to be established under supervision of administrators. Timings must be fixed for meals. Distribution of cooked food can also be done through families. Some special feeding regimes have to be thought of, for the elderly, infants and pregnant women (6).

Selective Feeding Programme : Selective feeding programme have to be undertaken for vulnerable groups. It could be a supplementary feeding programme or therapeutic feeding programme. The aim of the supplementary feeding programme is to provide necessary nutrient supplements to the vulnerable groups like under fives children with malnutrition, pregnant and lactating women. This helps prevent deterioration of nutritional situation through correction of moderate malnutrition, prevention of severe malnourishment, infections like measles, pertusis, ARI, diarrhoea and chances of epidemics and mortality (7) The planning figures for supplementary feeding for typical daily rations (with monthly totals) providing 350 Kcal, 15 g protein/person/day) are given in Table - 4.

Table - 4 : Planning figures: Supplementary Feeding (3)					
<i>(Typical daily rations (with monthly totals) providing 350 Kcal, 15 g protein/person/day)</i>					
Item (daily)	Amount (g)	Energy (Kcal)	Fat (g)	Protein (g)	Monthly (metric ton)
Cereal	50	180	-	4	1.50
Veg oil	10	89	10	0	0.30
Wheat-soya	55	204	3	11	1.65
Salt	5	0	0	0	0.15
Total	120	473	13	15	3.60

Therapeutic Feeding : The aim of a therapeutic feeding programme is to help in medical and nutritional treatment of severely malnourished children (8) This is aimed to reduce infant and child deaths esp. because of severe PEM. Therapeutic feeding provides an intensively managed, carefully balanced medical regimen. It helps in the rehabilitation of severely malnourished children. It can be undertaken at a residential level wherein the mothers (along with the sick malnourished children) are admitted and treated with special focus on nutrition. An alternative approach is to take care of the children in the day care centres established for this purpose. The mothers visit such centres for day long period, get medical attention and learn the basic skills in child nutrition, care and disease prevention. Besides the severely malnourished young vulnerable children and adolescents, the low-birth-weight babies, orphan infants who lack inadequate traditional care are

also the prime focus of therapeutic feeding. Mothers of infants with lactational failure are also given such care.

Conclusion : It can be well appreciated that nutrition during a disaster situation is not merely providing a 'feed'. But it involves anticipating, preparing and training for disaster beforehand; assessing the disaster situation in terms of impact, demography and resources; making an immaculate plan; implementing the plan and learn from the mistakes. Infant feeding, nutrition for the elderly and nutrition for pregnant and lactating women remain special situations and need expert attention.

Fairs and Festivals

India is a country of fairs and festivals. There is no month that doesn't have a festival or two. People tend to enjoy themselves during various festivals. Fairs and community feeding are integral to festivals. Fairs and festivals pose threat to public health as well, as people tend to congregate in large numbers in restricted spaces. The community is put to numerous risks; these could be as diverse as stampede, heat exhaustion, heat stroke, dehydration, infections, outbreaks, violence, terrorist threats, building collapse, fire, etc. The public health aspects pertaining to food in fairs and festivals are dealt with in brief, in the subsequent paragraphs. Mass feeding (during a festival) whether at the level of household or a community, poses threat to the people. The factors that make the community more vulnerable to food borne disease during mass feeding are:

- Large congregation of people
- Compromised food hygiene
- Scarcity of water
- Business interest of people that compromises basic hygiene
- Flies and other pests
- Indiscriminate littering of waste and poor waste disposal Facilities
- Inadequate (hand, raw foods, utensils) washing facilities
- Inadequate toilets and wash rooms
- Participation of unspecified food handlers

Responsibilities of Local Health Authority

It must be appreciated that the local health authority has a major role to play in managing health during fairs and festivals and ensuring proper measures to prevent disease. The local health authority is responsible for:

- a) Selecting the correct site for establishing the 'food centre'
- b) Selecting right agents/contactors providing food material (raw and cooked)
- c) Ensuring appropriate source of food
- d) Provision of safe drinking water
- e) Licensing the food shops and eateries
- f) Food hygiene and inspections
- g) Attending to complaints
- h) Food sampling as per the PFA act and follow up action
- i) Food and workplace safety
- j) Control of infectious disease and prevention of food poisoning
- k) Fly and pest control
- l) Educating the community on various aspects of food hygiene

The most common issues that must be ensured by the

administrators are :

- Adequate contingency planning and consistent procedures
- Communication between management and food handlers
- Adequate training, information, instruction and supervision for all
- Hazard analysis pertaining to feeding
- Recognition of potentially hazardous procedures.

Responsibilities of the Community

The local health authority might make rules and try to enforce them, but it is the community that has to ensure their implementation in the right earnest, for its own benefit. The community must take the responsibility of adhering to the rules laid down by the health authority. The community must be aware of various aspects of food hygiene, food safety, foods to be consumed and foods to be avoided during mass gatherings. The importance of flies and pests, safe drinking water and basic procedures like hand washing and proper garbage disposal must be appreciated by the community. Unhygienic and unlicensed food vendors must be shunned and reported against. The community must co-operate in the efforts of the authorities in maintaining food hygiene.

Role of Food Handlers

The responsibility of food handlers becomes even more important in the situation of fairs and festivals as they can transmit infection to numerous people. Their responsibilities have been discussed in detail in the chapter on food borne infections. Only the most salient points are repeated here. To prevent food borne infections hand-washing is of utmost importance. Hands must be washed with soap and water after visiting the toilet, handling rubbish, handling raw foods, putting hand over your nose or mouth and before starting work or after taking a break. Hands must be dried with clean towels. The nails must be clipped short; food handlers must be vaccinated against common diseases esp. typhoid. If the food handler is sick or has diarrhoea, it is best to refrain from kitchen duties.

Taking Care of Food

Whenever a communal feeding is planned either at home or at a community centre the following simple points must be ensured:

- Once procured, the food must be cooked at the earliest but closest to the time of consumption
- Prepare and store raw and cooked food separately
- Expiry date must be checked for all packed foods
- Keep pets and pests away from food and food preparation surfaces
- Wash hands thoroughly before preparing food, and after going to the toilet
- Wash worktops and utensils
- Avoid food containing uncooked eggs
- Ensure food is piping hot
- Keep hot food hot and cold food cold
- Food handlers with diarrhoea / vomiting must be excluded
- Food freshly cooked is usually safe. Eating stale food (more than couple of hours old) constitutes greater risks of food borne disease
- Food has to be thoroughly cooked and must be hot when

served

- Uncooked food apart from fruits and vegetables that can be peeled must be avoided
- Foods exposed to flies and pests must be shunned

Taking Care of Cleaning and Waste Management

Clean premises will reduce the risk of contamination, avoid pest infestations, provide a safe and pleasant environment to work. These simple guidelines must be observed:

- Always keep the premises clean
- A cleaning schedule must be followed. Staff must be nominated to clean a particular equipment or area, on a given day
- Keep all chemicals locked away from food
- Provide suitable dustbins with lids. Ensure their regular evacuation.
- Regularly clean refuse areas

Taking Care of Drinking Water, Ice and Beverages

It must be ensured that only clean and safe drinking water is used. The source of water must be ascertained and safety ensured. If in doubt do not drink that water. Bottled or carbonated water might be safer! Water used for recreational purposes (such as swimming) is often contaminated and must not be consumed.

Commercial ice must be avoided unless one is sure that it is made from safe water and has not been contaminated by dirty hands, pests, or equipment. Ice-cream from unreliable sources may be contaminated and cause illness. If in doubt avoid it.

Beverages such as hot tea, coffee, beer, carbonated soft drinks or fruit juices are usually safe to drink. Expiry dates and seals must be checked. Avoid unpasteurised milk, cheese, paneer and other products.

Specific Foods

Some food stuff must be viewed with suspicion and consumed only if one is sure of their safety, as there is a higher potential of food poisoning with them. Some of these are enumerated in the Box - 3.

To keep these foods safe ensure strict temperature control during the entire course of food processing: delivery, correct freezing, thawing, refrigeration, cooking and serving. They must be protected from contamination (bacterial and chemical). The entire supply line of the food product must be traced for hygiene.

Box - 3 : Suspicious foods - Consume with care!
Cooked meats and poultry
Milk, cream, artificial cream, cottage cheese (<i>paneer</i>) custards and dairy produce
Cooked eggs and products made with fresh shelled eggs (mayonnaise)
Fish and sea foods
Cooked rice
Ice
Salads, vegetables and fruit eaten raw
Sandwiches and filled rolls

Duties of Health Officers

Health officers have the responsibility to ensure implementation of laid down health policies. They inspect premises for ensuring hygiene, correct cooking practices, storage and distribution of food, etc. They undertake surveillance to keep an eye on the cases reported as diarrhoea, vomiting and dysentery and rule out if they were food poisoning. They would also ensure taking samples from suspicious locations. Health officers can arrange to collect samples and have them examined at the Public Health Laboratory.

If a restaurant or food shop is implicated, the officer will carry out an inspection of the premises and take food samples for examination (if required). Mainly the officer looks for the bacterial risks arising from the type of food handled in the business and how food is stored, prepared, cooked and served. They investigate incidences of outbreaks of food poisoning in detail; recommend and take appropriate prevention and control measures.

Community Feeding of Children

There are many instances when the community feeding of children has to be resorted to. It is commonly seen as part of certain national nutritional programmes. The Mid Day Meal Programme, Balwadi Programme and under the ICDS programme (Anganwadi), children are fed in groups ranging from a few dozens to thousands. While running such a programme is essential for the up-liftment of the nutritional status of children, such a mass feeding entails tremendous risk as well, given the large numbers involved. There have been occasional reports indicating food poisoning episodes in such congregations of children. This not only puts the lives of children at risk but also puts the very programme at stake of disrepute and rejection by the community. It is therefore imperative to take adequate measures to prevent such situations.

Infants and children are more vulnerable to infections owing to a poorly developed immune system and higher vulnerability to infections. For this reason it is important to take extra care when preparing food for infants and young children.

Preparing food for infants and children

Some precautions that must be taken for preparing foods for infants and children are enumerated in Box - 4.

Summary

Nutrition assumes extreme importance in a disaster situation as food is a primary requirement for sustenance of life. At an average energy requirement is 2100Kcal/person/day. It is best to be prepared for a disaster. Food and water must be stored at vantage points. After a disaster various feeding programmes namely a) General food distribution b) Selective food distribution can be resorted to. The latter can be applied either as a supplementary or a therapeutic feeding programme depending on the situation and the distribution of beneficiaries. Organizing a mass feeding programme for the disaster struck and refugees might pose a challenge to the authorities, so, sound administrative acumen is needed to make it a success, besides merely providing the relief material.

Mass feeding during fairs and festivals is a common and frequent feature in India. Large scale food preparation and distribution poses a serious public health threat if the same is not organized as per basic principles of hygiene. The local health authorities have to ensure implementation of relevant rules. Close monitoring and effective surveillance of health and hygiene during the feeding is indispensable. The community has a major role to play in maintaining health through following the rules laid down. Community must make effort to be aware of the basics of food hygiene and the dos and don'ts of eating in a large communal gathering. Cooks and food handlers must also realize their responsibilities to stop spread of infection.

Community feeding of children is often resorted to through various feeding programmes organized by the government, under the national programmes (Mid Day Meal, ICDS, etc). Special care in procurement, processing and distribution of food must be taken to prevent instances related to food poisoning. This can be achieved through immaculate kitchen hygiene, healthy food handlers and an aware community. We must strive to achieve these.

Box - 4 : Guidelines for Preparing Food for Infants and Children

Raw food must be procured from authentic sources

Immaculate personal hygiene of cooks must be ensured

Dining area, tables, chairs, bibs must be thoroughly cleaned before and after every meal

Kitchen surfaces, floors, platforms, etc. must be immaculately clean

Avoid foods that are more likely to cause food poisoning e.g. cream, raw eggs, paneer, meat dishes, salad, etc.

Kitchen towels and cloths must be changed daily or more often

'Cook fresh and consume fresh' should be the rule

Avoid storing cooked food for another day

Discard left-overs

Children must wash their hands after visiting the toilet or touching pets.

Study Exercises

Long Question : Discuss the nutritional interventions that could be undertaken in the event of an earthquake.

Short Notes : (1) Storing food for disaster (2) Therapeutic feeding programme (3) Community feeding of children (4) Post exercise feeding of athletes (5) Precautions with drinking water during fairs

MCQs

1. At an average _____ Kcal/person should be catered for planning food aid during disaster: (a) 2100 (b) 1850 (c) 2400 (d) 2800
2. Water must be stored @ _____ lit for drinking and _____ lit for cooking (per day): (a) 1,1 (b) 2,2 (c) 2,3 (d) 3,2
3. Onemetricktonnegrainsaresufficienttofeed _____ males/day in a disaster situation : (a) 2100 (b) 1850 (c) 1000 (d) 1500
4. In a disaster situation the aims of therapeutic feeding includes all except (a) Medical treatment of severely malnourished (b) Nutritional treatment of severely malnourished (c) Reduce infant/child deaths (d) Treat cases of infections
5. Community feeding of children is undertaken in all except (a) ICDS programme (b) Mid day meal programme (c) Balwadi programme (d) School health programme

Match the following

Act	Responsibility of
6. Take food samples	(a) Community
7. Lay down policy	(b) Local health authority
8. Report diarrhoea cases	(c) Food handler
9. Report own illness	(d) Local doctors
10. Maintain food hygiene	(e) Health officers

Answers : (1) a; (2) b; (3) b; (4) d (5) d; (6) e (7) b; (8) d; (9) c; (10) a.

A S Kushwaha

The health of women and children has always been an important social goal of all societies. Over the years, maternal and child health has evolved through various stages of conceptual approach, technological advances and social prioritization. The realization that, improved maternal and child health is the key to the ultimate objective of lifelong health in any society, has led to renewed interest and global focus towards this very important social health issue.

Mother and Child: A Single Entity

Mother and child are often spoken of in one breath for a number of reasons. Health of the child and the mother are so closely linked that each has the capacity to influence the other. The outcome of pregnancy in terms of a healthy newborn is dependent on the physical, physiological, mental and nutritional state of the mother during pregnancy. Some specific health interventions jointly protect pregnant women and their babies e.g. tetanus toxoid immunization and nutrition supplementation. At childbirth, both mother and child are at risk for complications which can endanger their lives. The postpartum care of the mother is inseparable from newborn care, immunization and family planning advice, and this provides not only operational convenience but offers continuity of care as well.

Important Sub Disciplines Related to MCH

There are a number of sub disciplines that have developed over the years in the field of maternal and child health. It is in this endeavour that disciplines like *social obstetrics, preventive pediatrics, community obstetrics, family health and family medicine* have originated. Various initiatives in child health include *essential newborn care, well baby clinics, under five clinics, Child guidance clinics and school health services*.

Why So Much Attention to This Issue?

Firstly, together, mothers (women 15-45 years of age) and children (under 15 years of age) constitute 70-80% of the population. They also belong to the most vulnerable section of society in terms of death, disease, disability and discrimination. Women and Children represent economically dependent and least empowered section of the society. The falling sex ratio (from 972 in 1901 to 933 in 2001) is a grim reminder of the social disadvantage faced by women in India⁽¹⁾. The issue also merits attention because of high morbidity and mortality faced by this group. Most of the deaths and illnesses in these groups are avoidable by cost effective interventions which are available to tackle them.

Scenario of Maternal and Child Health

Global Picture : Of the estimated 211 million pregnancies that occur each year, about 46 million end in induced abortion. Attending to all of the 136 million births every year is one of the major challenges that is now faced by the world's health systems. Globally, huge toll on account of maternal deaths continues unabated. Often sudden, unpredicted deaths occur during pregnancy itself (as a consequence of unsafe abortion),

during childbirth, or after the baby has been born due to blood loss and infections. The 5,29,000 annual maternal deaths, including 68,000 deaths attributable to unsafe abortion, almost all of these are occurring in poor countries with only 1% in rich countries. Each year 3.3 million babies are stillborn, more than 4 million (neonatal deaths) are dying within 28 days of coming into the world, and a further 6.6 million young children die before their fifth birthday. Although an increasing number of countries have succeeded in improving the health and well-being of mothers, babies and children in recent years, in some countries the situation has actually worsened. Slow progress, stagnation and reversal are closely related to poverty, to humanitarian crises, and, particularly in sub-Saharan Africa, to the direct and indirect effects of HIV/AIDS. Over 300 million women in the world currently suffer from long-term or short-term illness brought about by pregnancy or childbirth. Programmes to tackle vaccine preventable diseases, malnutrition, diarrhoea, or respiratory infections still have a large unfinished agenda.

India

Health of Women : The country has a falling low sex ratio of 933 female per thousand male. Early marriage in women and universality of marriage are important social issues. The median age at first marriage among women is 17.2 years. Almost half (46%) of women age 18-29 years got married before the legal minimum age of 18. Among young women age 15-19, 16 percent have already begun childbearing. Indians have poor knowledge about temporary contraceptive methods and this coupled with poor availability affects 'delaying the first and spacing the second child' doctrine adversely. Among the married women, 13 percent have unmet need for family planning. Less than half of women receive antenatal care during the first trimester of pregnancy, as is recommended. Three out of every five births in India take place at home; only two in five births take place in a health facility. Less than half of births took place with assistance from a health professional, and more than one third were delivered by a Traditional Birth Attendant. The remaining 16 percent were delivered by a relative or other untrained person. A Disposable Delivery Kit (DDK) is being used only in 20% of births taking place at home. Most women receive no postnatal care at all. Only 37 percent of mothers had a postnatal checkup within 2 days of birth. Every seven minutes an Indian woman dies from complications related to pregnancy and childbirth. The maternal mortality ratio in India stands at 300 per 100,000 live births. (Table - 1).

Child Health : Infant mortality is 77 per 1,000 for teenage mothers, compared with 50 for mothers age 20-29. Infant mortality in rural areas is 50 percent higher than in urban areas. Perinatal mortality, which includes stillbirths and very early infant deaths (in the first week of life), is estimated at 49 deaths per 1,000 pregnancies, that lasted 7 months or more. Less than half (44%) of children 12-23 months are fully vaccinated against the six major childhood illnesses: tuberculosis, diphtheria, pertussis, tetanus, polio, and measles. Although breast feeding is almost universal in India, only 46 percent of children under 6 months are exclusively breastfed. Many infants are deprived of the highly nutritious first milk (colostrum) as only 55 percent are put to the breast within the first day of life. Almost half

of children under age five are stunted or too short for their age. Anaemia is a major health problem in India, especially among women and children. Among children between the ages of 6 and 59 months, about 70 percent are anaemic including three percent who suffer from severe anaemia. More than half of women in India (55 percent) have anaemia with 17 percent of these have moderate to severe anaemia.

Indicator	1994	2000	2001	2002	2003	2004	2005

MMR	Maternal Mortality Ratio

Challenges in MCH

The look at statistics in Table - 1 gives a picture of many unfulfilled promises in the field of maternal and child health despite a family welfare programme running since 1950s. The challenges include lack of universalisation of services, rural urban differential, poor status of women in society and lack of political will and acceptance of the issue as a social priority. The main challenge to child survival no longer lies in determining the proximate causes of or solutions to child mortality but in ensuring that the services and education required for these solutions reach the most marginalized countries and communities.

Opportunities in MCH

A new paradigm in MCH - Continuum of Care : The continuum consists of a focus on two dimensions in the provision of packages of essential primary-health-care services:

Time: There is a need to ensure essential services for mothers and children during pregnancy, childbirth, the postpartum period, infancy and early childhood. The focus on this element was engendered by the recognition that the birth period – before, during and after – is the time when mortality and morbidity

risks are highest for both mother and child.

Place: Linking the delivery of essential services in a dynamic primary-health-care system that integrates home, community, outreach and facility-based care. The impetus for this focus is the recognition that gaps in care are often most prevalent at the locations – the household and community – where care is most required.

The continuum of care concept has emerged in recognition of the fact that maternal, newborn and child deaths share a number of similar and interrelated structural causes with undernutrition. The continuum of care also reflects lessons learned from evidence and experience in maternal, newborn and child health during recent decades. In the past, safe motherhood and child survival programmes often operated separately, leaving disconnections in care that affected both mothers and newborns. It is now recognized that delivering specific interventions at pivotal points in the continuum has multiple benefits. Linking interventions in packages can also increase their efficiency and cost-effectiveness. The primary focus is on providing universal coverage of essential interventions throughout the life cycle in an integrated primary-health-care system.

Road Ahead

The NRHM and RCH are aimed at meeting this challenge and have set out their targets as envisaged under various policies and MDGs. (See Table - 2)

Indicator	10th Plan goals (2002-07)	RCH -2 (2004-09)	National Population Policy 2000 (by 2010)	MDGs (by 2015)
Infant mortality rate	45 per 1000 live births	35 per 1000 live births	30 per 1000 live births	-
Under 5 mortality rate	-	-	-	Reduce by 2/3rd
Maternal mortality ratio	200 per 1 lakh live births	150 per 1 lakh live births	100 per 1 lakh live births	Reduce by 3/4th

A S Kushwaha

Risk as a Proxy for Need

In every society there are communities, families and individuals whose chances of future illness, accident and untimely death are greater than others; they are said to be vulnerable owing to peculiar set of characteristics they share. These characteristics could be biological, genetic, environmental, psychosocial or economic. Similarly there are others who have a chance to enjoy better health. Thus as an example we can see that pregnant, poor, very young children and elderly are vulnerable and young and affluent are not. Risk however has come to be associated with the vulnerability to disease or illness or death. A pregnant woman with high blood pressure is at risk of complications like eclampsia and this measured risk to her and the child is an expression of her need for medical help and intervention. The risk strategy utilizes these risk estimates as guide for action, resource allocation, coverage and referral care. The hypothesis, on which risk strategy rests, therefore, is that more accurately the risk is measured, the better is the understanding of the need.

The risk approach is a managerial tool based on the strategy for efficient utilization of scarce resources with more care for those in need and proportionate to the need.

Tools of the Risk Approach

The characters shared by a cohort making them vulnerable are referred to as risk factors. The measure of association with the outcome is known as the relative risk and estimation of the adverse outcome if these risk factors are present and calculation of effect if these risk factors are removed have made our decisions in public health prioritization. *Risks, predictions and possible effects* are therefore the tools of the risk approach. By quantifying the risks to the health of a population group and their associated risk factors, it focuses attention on the need for prevention.

Risk Approach Applied to MCH

The mothers and children are most susceptible to good or harmful influences that will permanently affect their health. The harm can be inflicted or the good can be promoted in a very short time. The preventive and promotive elements of primary health care will have greatest yield if applied by using risk approach in MCH.

Definitions

Risk : It implies that the probability of adverse consequences is increased by the presence of one or more characteristics or factors. It is a measure of statistical chance of a future occurrence.

Relative Risk : It measures the strength of the association between risk factor and the outcome e.g. RR of an outcome due to a risk factor is 1.3, means a 30% excess risk in those with the risk factor.

Attributable Risk : This brings together three ideas - the frequency of the unwanted outcome when risk factor is present, frequency of the unwanted outcome when risk factor is absent, frequency of the occurrence of risk factor in the community. It indicates what might be expected to happen to the overall outcome in the community if the risk factor was removed.

Risk Factors : Risk factor is defined as any ascertainable characteristic or circumstance of a person or group of persons that is known to be associated with an abnormal risk of developing or being especially adversely affected by a morbid process. Risk factor is one link in a chain of association leading to an illness or an indicator of a link.

Risk factors can therefore be causes or signals but they are observable and identifiable. Risk factor could be related to individual, family, community or the environment. Examples include - first pregnancy, high parity, teenage pregnancies, malnutrition, rural area, birth attendance etc.

The significance of risk factors from the point of application and utility in practice of preventive community medicine can be judged by -

- (a) Degree of association with the outcome.
- (b) Frequency of the risk factor in the community.

Combination of Risk Factors

The combination of two or more risk factors increases the probability of the outcome. For example in a pregnancy, the hypertensive disease and poor antenatal care are independent risk factors for perinatal mortality but when both factors are present, the probability of perinatal mortality is much higher than expected. This is because the risk factors may have an additive or multiplicative effect.

Risk Factors and Causes

Not all significant associations between the risk factor and the outcome are part of a chain of causality. Associations are usually described as 'causal' if they can be seen to be directly related to pathological processes, even if the pathways are not fully understood. e.g. Maternal malnutrition and low birth weight, placenta praevia and foetal death from anoxia, rubella in first trimester and congenital malformation. The important attributes in such association are 'dose response relationship, specificity, consistency of association, time relationship and biological plausibility. The complex relationship between risk factor and outcome can be explained by an example of gastroenteritis in a child belonging to a poor family where the complex of poverty may include contributions to risk from large family size, crowding, early weaning, poor nutrition with infection of infant and neglect of early Diarrhoea for a variety of reasons. Thus it is more than clear that family poverty is a risk factor for gastroenteritis and death from gastroenteritis. The advantage of risk approach is the attention being given to all causes regardless of their medical, intersectoral, economic, political or social origins.

Methodology in Risk Approach

The risk approach involves, first, decisions as to priority 'targets' or unwanted outcomes, measurement of association between risk factors and the outcome, and then intervention

planned. The risk approach has to be studied by research and then only applied over a wide population.

Outcome, Risk and Measurement : The risk approach seeks to use information about risk to prevent a variety of adverse outcome (illness, injury and death) through the application of a strategy at many levels of care.

Outcomes : This is the first information required. Collect details of morbidity and mortality rates which are our targets or priorities (prevalence and incidence, trends, distribution in geographical area and different groups).

Risk Factors : Collect information on the following :

- Risk factors for each unwanted outcome.
- Risk factors or combinations of risk factors for each group of unwanted outcome.
- For all risk factors -
 - Prevalence and incidence and trends in the population
 - Relative risk of unwanted outcomes associated with each risk factors or combinations
 - Attributable risk associated with each risk factors
 - Predictive power of each risk factor
 - The ease, accuracy and acceptability of screening for the presence of risk factor in communities and individuals.

Priorities among Outcomes : This will depend upon many variables like -

- Community priority and preference
- Prevalence or frequency of occurrence
- The seriousness of the problem (fatality rate)
- Degree of preventability
- Rising frequency or upward trend of the problem (emerging issues)

Steps

- Identifying the risk factors and the populations and the individuals at risk
- Selection of risk factors
 - Optimum grouping
 - Usefulness in terms of proposed intervention
 - Strength of association / cause - effect relationship
 - Ease of modification (intervention)
 - Ease and accuracy of identification (test)
- Who should do the screening? (Fig - 1)

To give an example, if it was the Perinatal and maternal mortality (Outcome) then the identification of risk factors will involve screening at various levels for different risk factors depending upon the complexity of identification and infrastructure available and training of the health worker.

These decisions to refer or to keep are based on some form of risk scoring system. For example, while doing above exercise, suppose there is a risk scoring from 0 - 5, the scheme would look like (See Table - 1).

Table - 1 : Risk Scoring System

Health level	Func - tionary	Exam - ines	Keeps	Refers	Returns
I	TBA	0, 1, 2, 3, 4, 5	0	1, 2, 3, 4, 5	-
II	ANM	1, 2, 3, 4, 5	2	3, 4, 5	1
III	Senior Nurse	3, 4, 5	3	4, 5	2
IV	Doctor	4, 5	4	5	3
V	Specialist	5	5	-	4

Issue of False Positives and False Negatives

When screening populations, some of the difficulties faced are related to the issues of false positive and false negatives. The value of risk factors at predicting outcomes is gauged by proportion of the true association. There are examples where the cases of gastroenteritis deaths may be seen in breastfed infants (though less likely) while some of the bottle fed infants may not suffer from gastroenteritis (less likely). The issue of false positives and false negatives may make decisions for interpreting and introducing screening tests difficult.

Risk Scoring

Scores must accurately reflect the risk to the mother and children which in itself is a proxy for the need for care. Scoring attempts to provide simple, easy to use index of the urgency, seriousness and complexity, of the future threat to health. The risk scores are a good managerial tool. Sources of scores are -

- Ad hoc - e.g. tall or short, poor or not poor, well fed or malnourished
- Points or score based on experience - For example, while scoring for poor outcome of pregnancy, 3 points for poor obstetric history, 3 for high parity, 2 for maternal age, 1 for birth interval, family income, poor education etc.
- Absolute risk
- Relative risk
- Attributable risk

Most scoring systems use the relative risk.

Trade off : While deciding the cut off for continuous risk factor there is a compromise between yield and resources by trade off between false positive and false negatives. This decision is arrived at by weighing how many more false positive can be afforded by the community for the desired reduction in the false negatives.

Basic information needed for planning the use of Risk Approach

1. Age and sex distribution and geographical distribution by community and household
2. Mortality by age, sex and cause
3. Local cultural factors, occupations, religion and attitude to health and disease
4. Services likely to have most impact from risk approach
5. Information on environmental risk factors
6. Local community organizations, groups
7. Local health care services including personnel and infrastructure
8. Present way to deal with the MCH problems
9. Information about traditional systems of medicine and their acceptance

Intervention at different levels of care : This is used to define the main point of impact of an intervention within the health care system. Risk approach can be applied at all levels from self and home to intersectoral policy.

Uses of the Risk Approach

1. Self & Family
 - (a) Improved ability to recognize health priorities and health lifestyle and behavior.
 - (b) Informed surveillance of self and family.
 - (c) Earlier self and family referral.
2. Local community - village groups, self help groups, women's group.
3. Application within the health care system - resource allocation.
4. Increasing coverage - e.g. Universal immunization, essential maternal and newborn care.
5. Improved referral - better facilities, technology and skills.
6. Regional and National level - for defining and planning priorities, capacity and staffing, design referral chain, resource allocation and evaluation.
7. Intersectoral collaboration is the key to planning, designing and executing any health intervention.

Selecting Interventions : Steps involved are -

- (a) Potential for change in health care - managerial, avoid authoritarian approach, no conflict with local, regional and national interest, local values and religious customs (MTP, Contraception).
- (b) Criteria for selection - importance, feasibility, acceptability.
- (c) Local priorities for action - Maternal mortality, Infant deaths, Perinatal mortality. Local priorities to be specific and well defined for application of risk approach.
- (d) Local resources - people (trained and trainable), institutions, facilities and technology, managerial skills, health information systems, funds. Most important resources are time, commitment, enthusiasm and cooperation.
- (e) National priorities
- (f) Decision pathway

Modifying Risk Factors : Individual risk factors capable of modification are exemplified by some taboos and cultural practices (difficult to change), malnutrition, dwarfing, inadequate family planning services, lack of concern for environmental hazards, unsatisfactory personal hygiene,

negligent or dangerous work pattern and numerous intercurrent illnesses. Some can be modified without delay, some will have to wait till next pregnancy while yet others will only be changed in the next generation. Modification of the community risk factors is probably the most important potential achievement of the risk approach.

Selecting Target Health Problems : Among many health problems of mothers and children, it is usually a simple matter to choose the most important. This choice is often coloured by opinions. Most important health problems are not always the best targets for prevention. A method of rating scale which balances the factors like prevalence, seriousness, preventability, trends in time and local concern (Table - 2) is shown as an example.

Health Problem	Criterion	Max rating	Rating accorded
Maternal mortality	Extent	10	3
	Seriousness	10	10
	Preventability	10	8
	Local concern	10	10
	Time trend	10	2
Neonatal tetanus	Extent	10	8
	Seriousness	10	10
	Preventability	10	10
	Local concern	10	4
	Time trend	10	5
Childhood RTAs	Extent	10	3
	Seriousness	10	10
	Preventability	10	5
	Local concern	10	7
	Time trend	10	8

The relative importance of each criterion is also given its weight e.g. say on a five point scale, if we rate, extent and seriousness are given 5/5, preventability and local concern is given 3/5, time trend is given 2 out of 5. A simple matrix will set the health problems in the order of priority as seen in the Table - 3.

The order of priority in the above example is: first neonatal tetanus, second maternal mortality and third childhood RTAs.

Lessons from the Risk Approach -

1. Application to the whole field of Primary Health care is limited due to shortage of support from evaluative research. Need to develop health system research.
2. Impediments and Barriers are related to Ethical (No research without service), Sociological (not in sync with local culture), Problems of human motivation, Political, managerial and technical problems and Shortage of skilled human resources.

The risk approach in MCH is a very useful tool and can help

in maximizing the output from the limited resources available especially in the developing countries. The risk approach helps to ease the pressure on the limited beds and facilities at the hospital level and also saving the expert human resources and sophisticated equipment for those who need it most. The risk approach also helps in developing health auxiliaries at the periphery providing the basic care in MCH close to home to the clientele within acceptable socio - cultural milieu. The policies and principles of care under NRHM using ASHA are an example of this approach.

Table - 3 : Selecting a problem by rating/scoring

Criteria and Relative weightage						
Health problem	Extent (weight 5)	Seriousness (weight 5)	Preventability (weight 3)	Local concern (weight 3)	Time trend (weight 2)	Total score
Maternal mortality	3x5	10x5	8x3	10x3	2x2	123
Neonatal tetanus	8x5	10x5	10x3	4x3	5x2	142
Childhood RTAs	3x5	10x5	5x3	7x3	8x2	117

Summary

The risk strategy utilizes the risk estimates as guide for action, resource allocation, coverage, referral and care. Therefore the more accurately the risk is measured the better is the understanding of the need for efficient utilization of scarce resources with more care for those in need and proportionate to the need. Risk, predictions and possible effects are the tools

of the risk approach. The preventive and promotive elements of primary health care will have greatest yield if applied by using risk approach in MCH. Risk factors could be related to the individual, family, community and environment and their significance can be judged by their frequency and the degree of their association with the outcome. The risk approach involves prioritizing targets, measuring associations and the interventions to be applied. Info about the risk factors can be obtained through prevalence, incidence, trends, relative risk of unwanted outcomes and attributable risk associated with each risk factors and predictive power of risk factors. Prioritization will depend upon community priority, prevalence, fatality rates, degree of preventability and rising trend. Risk scoring (most of them use relative risk) if used must reflect the risk to the mother and the child.

Increased coverage, improved referral, risk factor modification, local, national and regional reorganization and training are the some of the uses of risk approach. The risk approach in MCH is a very useful tool maximizing the output with the limited number of tools available in addition to developing the health auxiliaries at the periphery.

Study Exercises

Long Question : Risk approach in MCH

Short Notes : (1) Basic information needed for planning the use of risk approach (2) Risk scoring (3) Uses of risk approach within and outside the health care system (4) Steps for selecting interventions.

AS Kushwaha

All mothers and newborns, not just those considered to be at particular risk of developing complications, need skilled maternal and neonatal care. Maternal health care includes Antenatal, Intranatal care and Postnatal care. Quality intranatal care is critical to achieve the aim of a healthy mother and a healthy baby at the end of a pregnancy. This particular period (perinatal) though constitutes, only a small fraction in terms of its share (0.5 %) in the maternity cycle, but is probably, the most crucial.

Definitions

Maternal Death : Maternal death is defined as death of a woman, while pregnant or within 42 days of termination of pregnancy, irrespective of the duration and site of pregnancy, from any cause related to or aggravated by pregnancy or its management but not from accidental or incidental causes. (ICD-10)

Direct Obstetric Deaths : The deaths resulting from obstetric complications of the pregnant state (pregnancy, labour and the puerperium), from interventions, omissions, or incorrect treatment, or from a chain of events resulting from any of the above are called direct obstetric deaths.

Indirect Obstetric Deaths : Those resulting from previous existing disease or disease that developed during pregnancy and

that was not due to direct obstetric causes but was aggravated by the physiological effects of pregnancy.

Late Maternal Death : Late maternal death is death of a woman from direct or indirect obstetric causes, more than 42 days but less than one year, after termination of pregnancy.

Pregnancy Related Death : To facilitate the identification of maternal death in circumstances in which cause of death attribution is inadequate, ICD-10 introduced a new category, that of “pregnancy-related death” which is defined as : the death of a woman while pregnant or within 42 days of termination of pregnancy, irrespective of the cause of death.

Skilled Birth Attendant : Skilled Birth Attendants are people with midwifery skills (e.g. doctors, midwives, nurses) who have been trained to proficiency in the skills necessary to manage a normal delivery and diagnose and refer obstetric complications. This includes capacity to initiate the management of complications and obstetric emergencies, including life-saving measures where needed. Ideally skilled attendants live in, and are part of the community they serve.

Measurement of Maternal Mortality

There are three main measures of maternal mortality- the maternal mortality ratio, the maternal mortality rate and the lifetime risk of maternal death.

Maternal Mortality Ratio : This represents the risk associated with each pregnancy, i.e. the obstetric risk. It is calculated as the number of maternal deaths during a given year per 100,000 live births during the same period. This is usually referred to as rate though it is a ratio.

The appropriate denominator for the Maternal Mortality Ratio would be the total number of pregnancies (live births, foetal deaths or stillbirths, induced and spontaneous abortions, ectopic and molar pregnancies). However, this figure is seldom available and thus number of live births is used as the denominator. In countries where maternal mortality is high denominator used is per 1000 live births but as this indicator is reduced with better services, the denominator used is per 1,00,000 live births to avoid figure in decimals.

Maternal Mortality Rate: It measures both the obstetric risk and the frequency with which women are exposed to this risk. It is calculated as the number of maternal deaths in a given period per 100,000 women of reproductive age (usually 15-49 years). From the year 2000, the SRS (Sample Registration System) has introduced this method of verbal autopsy called RHIME (Representative, Re-sampled, Routine Household Interview of Mortality with Medical Evaluation).

Lifetime Risk of Maternal Death

This parameter takes into account both the probability of becoming pregnant and the probability of dying as a result of the pregnancy cumulated across a woman's reproductive years. *Lifetime risk can be estimated by multiplying the maternal mortality rate by the length of the reproductive period (around 35 years). This is also approximated by the product of the Total Fertility Rate and the Maternal Mortality Ratio.*

Antenatal Care

The care of women during pregnancy is called antenatal care. This begins soon after conception. The ultimate objective is

to have a healthy mother and a healthy child at the end of pregnancy. *Antenatal care* includes visit to antenatal clinic, examination, investigations, immunization, supplements (Iron, Folic acid, Calcium, Nutritional) and interventions as required. This is a comprehensive approach to medical care and psychosocial support of the family that ideally begins prior to conception and ends with the onset of labour. *Preconception care* refers to physical and mental preparation of both parents for pregnancy and childbearing in order to improve the pregnancy outcome (Refer Box - 1). Antenatal (Prenatal) care formally begins with the diagnosis of pregnancy and includes ongoing assessment of risk, education and counselling and identifying and managing problems if they arise (Box - 2).

Box - 1 : Indications for Preconception Care
Advanced maternal (>35 years) or paternal (>55 years)age
History of neural tube defects in family or previous pregnancy
Congenital heart disease, hemophilia, thalassemia, sickle cell disease, Tay-sach's disease, cystic fibrosis, Huntington chorea, muscular dystrophy, Down's syndrome.
Maternal metabolic disorders
Recurrent pregnancy loss (>3)
Use of alcohol, recreational drugs or medications
Environmental or occupational exposures

Box - 2 : Objectives of Antenatal Care
To promote, protect and maintain health of the mother
To detect 'at risk' cases and provide necessary care
To provide advise on self care during pregnancy
To educate women on warning signals, child care, family planning
To prepare the woman for labour and lactation
To allay anxiety associated with pregnancy and childbirth
To provide early diagnosis and treatment of any medical condition/ complication of pregnancy
To plan for “Birth” and emergencies / complications (where, how, by whom, transport, blood)
To provide care to any child accompanying the mother

Frequency : Under optimal conditions a women should undergo regular antenatal health check once a month during first seven months, twice a month for 8th month and every week thereafter till delivery. However, a minimum of four visits are essential.

Essential Antenatal Care: Under CSSM program three antenatal visits have been recommended as minimum acceptable level of antenatal care. Early registration by 12-16 weeks followed by visits at 20, 32 and 36 weeks is recommended during any pregnancy. At least one home visit by health worker must be made. Essential Antenatal Care also includes immunization with tetanus toxoid and Iron Folic Acid supplements for 100 days. Deworming with mebendazole in areas endemic for hook

worm may be provided during 2nd/3rd trimester. Under RCH a minimum of three visits are to be made.

History Taking and Examination : During history taking important points to be covered are detailed medical, psychosocial and immunization history followed by careful physical examination and certain relevant laboratory tests.

Physical examination should include measurement of height, weight, pelvimetry (not very important). Important laboratory tests include hemoglobin, urinalysis, PAP smear, VDRL and any other test as warranted by the concerned physician. There is an opportunity for health promotion like cessation of tobacco, alcohol, manage pre-existing medical disorders, appropriate immunization and pregnancy planning.

First Visit : The patient is registered and antenatal card is initiated. First visit should be made at the earliest possible after pregnancy is suspected, ideally at 8 weeks of gestation but not later than 12-16 weeks. This is important for determining accurate EDD, evaluation of risk and to provide essential patient education. The functions of this visit are-

- (a) Confirmation of pregnancy
- (b) Screening for high risk pregnancy
- (c) Baseline investigations
- (d) Initiation of Iron and Folic Acid supplementation
- (e) Immunization with Tetanus toxoid (if visit in 2nd trimester)
- (f) Education of the mother on pregnancy and childbirth

Identification of “High Risk” Pregnancies

The identification of high risk pregnancies involves meticulous history taking, careful examination and relevant investigations. The identification of these high risk pregnancies should follow needful referral and care. History should cover all aspects as outlined for preconception care. The ‘at risk’ pregnancies can be identified as under-

Maternal Factors

- (i) Age- <18 years or > 35 years (especially in primigravida)
- (ii) Multiparity (> 4)
- (iii) Short stature (< 140 cms)
- (iv) Weight < 40 Kg / weight gain < 5 Kg
- (v) Rh negative

Bad Obstetric History

- (i) Recurrent abortions (2 x1st trimester or 1 mid-trimester)
- (ii) Intrauterine death or intrapartum death/ stillbirth
- (iii) Prolonged labour, birth asphyxia , early neonatal death
- (iv) Previous caesarean section / scar dehiscence
- (v) Postpartum haemorrhage, manual removal of placenta
- (vi) Baby which is LBW, SFD or large for date, congenitally malformed
- (vii) Malpresentation, instrumental delivery, ectopic pregnancy
- (viii) Twins, hydramnios, pre-eclampsia

Medical Disorders

- (i) Cardiac (RHD, CHD, Valve defects), Renal, Endocrine (Thyroid) or Gastrointestinal disease.
- (ii) Infections - TB, Leprosy, Malaria etc.
- (iii) Hypertension, Diabetes, IHD and Seizures
- (iv) Anaemia

Besides the above, the pregnancy at any stage can be classified as high risk if any of the following conditions/ complications

appear -

- (a) Bleeding PV at any point (Antepartum haemorrhage)
- (b) Excessive vomiting (Hyperemesis gravidarum)
- (c) Hypertension, proteinuria
- (d) Severe anaemia
- (e) Abnormal weight gain
- (f) Multiple pregnancy, hydramnios, oligohydramnios
- (g) Abnormal presentation in 9th month
- (h) Preterm Labour, PROM
- (i) Pre-eclampsia, eclampsia

Health Education

This is one of the most important and often neglected functions of antenatal care. This is also called prenatal advice. The communication between the mother and the service provider should be free and encompass the issues concerning not only pregnancy but should spillover to childbirth and childcare. The family planning issues like spacing and sterilization are better received at this time. Important issues that need to be deliberated are given below.

- (a) Diet & Rest
- (b) Personal Hygiene and Habits
- (c) Sexual intercourse
- (d) Drugs
- (e) Exercise
- (f) Travel
- (g) Care of Breasts
- (h) Weight Gain

Warning signs : Besides education on common symptoms and their management, the woman should be educated on warning signs during pregnancy which should not be ignored. She should report to health facility in case she has any of the warning signs. The warning signs are-

- (i) Swelling of feet
- (ii) Convulsions/ unconsciousness
- (iii) Severe headache
- (iv) Blurring of vision
- (v) Bleeding or discharge per vaginum
- (vi) Severe abdominal pain
- (vii) Other unusual symptom

Pregnancy & HIV Infection

This situation is likely to be encountered in states where HIV prevalence amongst antenatal cases is high. This will require special handling. The urgency of preventing mother-to-child transmission (PMTCT) of HIV is clear. Without treatment, half of the infants born with the virus will die before age two. Significant reductions in mother-to-child transmission, however, can occur through implementation of basic but critical actions, such as identifying HIV-infected pregnant women by offering routine HIV testing, enrolling them in PMTCT programmes, ensuring that health systems are fully able to deliver effective antiretroviral regimens both for prophylaxis and for treatment, and supporting women in adhering to optimal and safe infant feeding. The counselling of women early in pregnancy on risk of transmission to the baby and testing of spouse is mandatory. AZT 300 mg every 12 hours is given from 36 weeks of pregnancy till onset of labour and thereafter 300mg every 3 hours. Alternatively, Nevirapine 200 mg single dose as early

as possible in labour and 50 mg in oral solution form to the newborn within 72 hours is recommended to prevent mother to child transmission. After delivery, this also helps to make required adaptations in infant feeding. Replacement feeding using principles of AFASS (acceptable, feasible, affordable, safe and sustainable) is a viable solution to prevent transmission of infection through breast feeding.

Planning for Birth (Birth Plan)

This is an important function of the prenatal care. The planning for birth and emergencies is very important as it can take care of many unforeseen complications which may endanger life of both mother and the child and may arise at any point of time without any prior warning in an otherwise normal pregnancy. Plans made early for emergencies during pregnancy and labour will result in favourable outcomes. The birth plan helps to tide over the uncertain and sudden nature of complications of labour. The delivery will take place at hospital or home must be decided (See Box - 3).

Box - 3 : Institutional delivery is a must if there is-
Mild pre-eclampsia
PPH in the previous pregnancy
More than 5 previous births or a primi
Previous assisted delivery
Maternal age less than 16 years
H/o third-degree tear in the previous pregnancy
Severe anaemia
Severe pre-eclampsia/eclampsia
APH
Transverse foetal lie or any other Malpresentation
Caesarean section in the previous pregnancy
Multiple pregnancies
Premature or pre-labour rupture of membranes (PROM)
Medical illnesses such as diabetes mellitus, heart disease, asthma, etc.

In case of delivery at home what arrangements are there to overcome any unanticipated complication? The arrangement

for vehicle, money and blood can be difficult to make if not already planned and can be crucial for the life of both mother and child. Institutional delivery should be encouraged. Institutional delivery should be advocated as it is the right of every pregnant woman.

Intranatal Care and Postnatal Care

Objectives of Intranatal Care - (AMC-N)

1. Thorough Asepsis ("The Five Cleans" - clean hands, surface, blade, cord, tie)
2. Minimum injury to mother and child
3. To deal with any Complications during labour
4. Care of the Newborn

The Postpartum Care

The Postpartum Care is aimed at achieving a Puerperium which is free of any complications and to ensure a healthy newborn. (Box - 4)

Box - 4 : Objectives of Postpartum care	
1.	Restoration of mother to optimum health
2.	To prevent complications of puerperium
3.	Provide basic postpartum care & services to mother and child
4.	Motivate, educate and provide family planning services
5.	To check adequacy of breast feeding

The Postpartum Visits : The first 48 hours following delivery are the most important. The next most critical period is the first week following delivery. The mother is asked to pay another visit on day 3rd and day 7th, or the ANM in charge of that area should pay a home visit during this period. The second postpartum visit should be planned within 7-10 days after delivery. A visit at 6 weeks is mandatory to see that involution of uterus is complete. Further visits can be once a month for 6 month and thereafter every 2-3 months till the end of one year. Efforts to organize 3 - 6 visits must be made. If the woman misses her postpartum visits, she should be informed regarding the danger signs which if appear she should report back (Box - 5).

Complications of the Puerperium : The postpartum period is often neglected after having a successful parturition. Sadly,

Box - 5 : Danger Signs in Puerperium			
Advise the woman and her family to go to an FRU immediately, day or night, WITHOUT WAITING		Advise the woman that she should visit the PHC as soon as possible, if . . .	
(i)	Excessive vaginal bleeding, i.e. soaking more than 2 or 3 pads in 20-30 minutes after delivery, or bleeding increases rather than decreases after the delivery	(i)	Fever
		(ii)	Abdominal pain
		(iii)	The woman feels ill
(ii)	Convulsions	(iv)	Swollen, red or tender breasts, or sore nipples
(iii)	Fast or difficult breathing	(v)	Dribbling of urine or painful micturition
(iv)	Fever and weakness; inability to get out of bed	(vi)	Pain in the perineum or pus draining from the perineal area
(v)	Severe abdominal pain	(vii)	Foul-smelling lochia

neglected postnatal period can be the cause of significant mortality in mother and the newborn. The infections and haemorrhage are two serious dangers of Puerperium. Besides these UTIs, thrombophlebitis and psychiatric disorders are also seen (Box - 6).

Box - 6 : Common Complications of the Puerperium	
1.	Puerperal sepsis
2.	Urinary tract infections
3.	Breast infections
4.	Venous thrombosis
5.	Pulmonary thromboembolism
6.	Puerperal haemorrhage
7.	Incontinence of urine
8.	Psychiatric disorders

Maternal Mortality

Global Burden

Maternal mortality is currently estimated at 5,29,000 deaths per year, a global ratio of 400 maternal deaths per 100,000 live births (1). There are immense variations in maternal death rates in different parts of the world (See Table - 1). Only a small fraction (1%) of these deaths occurs in the developed world. Maternal mortality ratios range from as high as 830 per 100,000 births in some African countries to as low as 24 per 100,000 births in European countries. Of the 20 countries with the highest maternal mortality ratios, 19 are in sub-Saharan Africa. In sub-Saharan Africa, the lifetime risk of maternal death is 1 in 16, (See Table 1) compared with 1 in 2800 in rich countries (2). Rural populations suffer higher mortality than urban dwellers, rates can vary widely by ethnicity or by socio-economic status, and remote areas bear a heavy burden of deaths. Such deaths often occur suddenly and unpredictably. Between 11% and 17% of maternal deaths happen during childbirth itself and between 50% and 71% in the postpartum period (3-7). The fact that a high level of risk is concentrated during childbirth itself, and that many postpartum deaths are also a result of what happened during birth, focuses attention on the hours and sometimes days that are spent in labour and giving birth. The postpartum period - despite its heavy toll of deaths - is often neglected. Within this period, the first week is the most prone to risk. About 45% of postpartum maternal deaths occur during the first 24 hours, and more than two thirds during the first week (3).

Table - 1 : Life Time Risk of a Woman		
Continents	Losing a Neonate	Of dying due to Maternal cause
Africa	1 in 5	1 in 16
Asia	1 in 11	1 in 132
Latin America	1 in 21	1 in 188
Developed countries	1 in 125	1 in 2976

Breakdowns of access to skilled care due to war, strife and HIV may rapidly result in an increase of unfavourable outcomes, as in Malawi or Iraq. Malawi is one country that experienced a significant reversal in maternal mortality: from 752 maternal deaths per 100,000 live births in 1992 to 1120 in 2000 due to rise in HIV prevalence. Fewer mothers gave birth in health facilities: the proportion dropped from 55% to 43% between 2000 and 2001. The quality of care within health facilities deteriorated in Iraq as sanctions during the 1990s severely disrupted previously well-functioning health care services, and maternal mortality ratios increased from 50 per 100,000 in 1989 to 117 per 100,000 in 1997 (12).

Scenario in India

Every seven minutes an Indian woman dies from complications related to pregnancy and childbirth. The maternal mortality ratio in India stands at 300 per 100,000 live births. It has some high performing states like Kerala with MMR of 110 and poorly doing states like Uttar Pradesh with MMR of 517 (13). The highlight is that most of the states recording unfavourable maternal mortality rates are the ones with the highest number of birth rates and huge population bases with poor health infrastructure. There are a number of reasons India has such a high maternal mortality ratio. Marriage and childbirth at an early age, lack of adequate health care facilities, inadequate nutrition and absence of skilled personnel, all contribute to pregnancies proving fatal. The common causes of maternal mortality in India are anaemia, haemorrhage, sepsis, obstructed labour, abortion and toxemia. Maternal morbidities are the anaemias, chronic malnutrition, pelvic inflammations, liver and kidney diseases. In addition, the pathological processes of some preexisting diseases, such as chronic heart diseases, hypertension, kidney diseases and pulmonary tuberculosis are aggravated by pregnancy and childbirth.

'Delay' Model Leading to Maternal Death

The maternal deaths can be explained by this model of delay which is due to:

- Delay in seeking care
- Delay in transport to appropriate health facility
- Delay in provision of adequate care

Causes of Maternal Mortality

Maternal deaths result from a wide range of indirect and direct causes (See Fig. 1 & 2). Maternal deaths due to indirect causes represent 20% of the global total. They are caused by diseases (pre-existing or concurrent) that are not complications of pregnancy, but complicate pregnancy or are aggravated by it. These include malaria, anaemia, HIV/AIDS and cardiovascular disease. Their role in maternal mortality varies from country to country, according to the epidemiological context and the health system's effectiveness in responding.

The lion's share of maternal deaths is attributable to direct causes. Direct maternal deaths follow complications of pregnancy & childbirth or are caused by any interventions, omissions, incorrect treatment or events that result from these complications, including complications from unsafe abortion.

The four major direct causes of maternal loss are-

- Haemorrhage

- (b) Infection (sepsis)
- (c) Eclampsia
- (d) Obstructed Labour

Haemorrhage : The most common cause of maternal death is severe bleeding, a major cause of death in both developing and developed countries (14,15). Postpartum bleeding can kill even a healthy woman within two hours, if unattended. It is the quickest of maternal killers. An injection of oxytocin or ergometrine given immediately after childbirth is very effective in reducing the risk of bleeding. In some cases a fairly simple - but urgent - intervention such as massage of the uterus, removal of clot or manual removal of the placenta may solve the problem. Other women may need a surgical intervention or a blood transfusion, both of which require hospitalization with appropriate staff, equipment and supplies. The proportion

needing hospital care depends, to some extent, on the quality of the first-level care provided to women; for example, active management of the third stage of labour reduces postpartum bleeding. The proportion that dies depends on whether appropriate care is provided rapidly and with the degree of skill with which it is provided.

Infection : The second most frequent direct cause of death is sepsis, responsible for most late postpartum deaths. This is often a consequence of poor hygiene during delivery. The introduction of aseptic (clean delivery) techniques brought a spectacular reduction of its importance in the developed world. However, sepsis is still a significant threat in many developing countries.

Eclampsia : Classic complications of pregnancy include pre-eclampsia and eclampsia which affect 2.8% of pregnancies in developing countries and 0.4% in developed countries leading to many life-threatening cases and over 63 000 maternal deaths worldwide every year accounting for 12 % of the maternal deaths (17).

Obstructed Labour : The prolonged or obstructed labour accounts for about 8% of maternal deaths. This is often caused by fetopelvic disproportion or by malpresentation (transverse lie, mentoposterior, brow presentation). Disproportion is more common where malnutrition is endemic, especially among populations with various traditions and taboos regarding the diets of girls and women. It is worse where girls marry young and are expected to prove their fertility, often before they are fully grown.

Abortions : More than 18 million induced abortions each year are performed by people lacking the necessary skills or in an environment lacking the minimal medical standards, or both, and are therefore unsafe resulting in 68000 deaths (18, 19). Almost all take place in the developing world. With 34 unsafe abortions per 1000 women, South America has the highest ratio (19). Unsafe abortion is particularly an issue for younger women. Around 2.5 million, or almost 14% of all unsafe abortions in developing countries, are among women under 20 years of age. The proportion of women aged 15-19 years in Africa who have had an unsafe abortion is higher than in any other region.

Others : Haemorrhage following placental abruption or placenta praevia affects about 4% of pregnant women. Less common, but very serious complications include ectopic pregnancy and molar pregnancy. Maternal malnutrition is a huge global problem, both as protein-calorie deficiency and as micronutrient deficiency. Anaemia is an important indirect cause of maternal death due to cardiovascular deaths but also is an important underlying factor in many direct causes like haemorrhage and sepsis.

Factors underlying the medical causes

Socio-Economic : The factors underlying the direct causes of maternal deaths operate at several levels. The low social and economic status of girls and women is a fundamental determinant of maternal mortality in many developing countries including India. Low status limits the access of girls and women to education and good nutrition as well as to the economic resources to pay for health care or family planning services.

Lack of decision making power in terms of family planning puts them to repeated childbearing. Excessive physical work coupled with poor diet leads to poor maternal outcomes. Many deliveries in rural areas are either conducted by relatives or traditional birth attendant or at times none. In India three out of every five births take place at home; only two in five births take place in a health facility. However, the percentage of births in a health facility has increased steadily.

Nutritional : Poor nutrition before and during pregnancy contributes in a variety of ways to poor maternal health, obstetric problems and poor pregnancy outcomes. Stunting predisposes to cephalopelvic disproportion and obstructed labour. Anaemia may predispose to infection during pregnancy and childbirth, obstetric haemorrhage and are poor operative risks in the event if surgery is required. Severe vitamin A deficiency make women more vulnerable to obstetric complications. Iodine deficiency increases the risk of stillbirths and spontaneous abortions. Lack of dietary calcium appears to increase the risk of pre-eclampsia and eclampsia during pregnancy.

Impact of Maternal Deaths (India)

Maternal death has implications for the whole family and an impact that rebounds across generations. The complications that cause the deaths and disabilities of mothers also damage the infants they are carrying. The impact is summarized as under-

- (a) Children who lost their mothers are more likely to die within two years of maternal death.
- (b) 10 times the chance of death for the neonate.
- (c) 7 times the chance of death for infants older than one month.
- (d) 3 times the chance of death for children 1 to 5 years.
- (e) Enrolment in school for younger children is delayed and older children often leave school to support their family.

Significant reduction in infant mortality can be achieved by improving the access to care during labour, birth and the critical hours immediately afterwards.

Measures to Reduce Maternal Mortality

What is known about Reducing Maternal Mortality?

The countries that have successfully managed to make motherhood safer have three things in common.

- (a) First, policy-makers and managers were informed: they were aware that they had a problem, knew that it could be tackled, and decided to act upon that information.
- (b) Second, they chose a common-sense strategy that proved to be the right one: not just antenatal care, but also professional care at and after childbirth for all mothers, by skilled midwives, nurse-midwives or doctors, backed up by hospital care.
- (c) Third, they made sure that access to these services - financial and geographical - would be guaranteed for the entire population.

Where strategies other than that of professionalization of delivery care are chosen or where universal access is not achieved, positive results are delayed. This explains why many developing countries today still have high levels of maternal mortality. To provide skilled care at and after childbirth and to deal with complications is a matter of common sense - it is

also what mothers and their families ask for. Putting it into practice is a challenge that many countries have not yet been able to meet.

Training of Traditional Birth Attendant - A Failed Experiment! : In the 1970s, training of traditional birth attendants (TBAs) to improve obstetric services became widespread in settings where there was a lack of professional health personnel to provide maternity care, and where there were not enough beds or staff at hospital level to give all women access to hospital for their confinement. TBAs already existed and performed deliveries (for the most part in rural areas), they were accessible and culturally acceptable and they influenced women's decisions on using health services. While WHO continued to encourage this strategy until the mid-1980s but evidence emerged that training TBAs has had little impact on maternal mortality.

Actions for Safe Motherhood : Countries vary widely in terms of the situations and challenges they face and their capacity to address these. However, it is seen that to reduce maternal mortality requires coordinated, long term efforts. Actions are needed within families and communities, in society as a whole, in health systems, and at the level of national legislation and policy.

Legislative & Policy actions : Long term political commitment is an essential prerequisite. This leads to adequate resource allocation and policy decisions are taken. A supportive social, economic and legislative environment allows women to access the healthcare. (transport, money, social barriers limit the access)

(a) Family planning : To avoid pregnancies that are too early, too late or too frequent.

(b) Adolescents : To encourage late marriage and childbearing by increasing educational opportunities. To improve their nutritional status by supplementary nutrition (e.g. *ICDS-Kishori Shakti Yojna*). Education of adolescents on reproductive health and empowerment of women to control fertility and reproduction.

(c) Barriers to access : Provision of skilled health worker at village level health facility to overcome problems of distance and transport. These workers to be adequately trained in midwifery and paid adequately and to be provided with adequate supplies and at minimal cost.

(d) Develop protocols : Aimed at providing both routine maternal care and referral facilities for obstetric complications. (e.g. IMNCI, 2005-Guidelines on pregnancy by MCH Division of Ministry of Health & Family Welfare)

(e) Decentralization and delegation : Decentralized facilities available close to people's homes together with written policies and protocols to allow delegation of certain functions at lower levels.

(f) Abortion : Availability of safe abortion services and policy to discourage illegal and unsafe abortions.

Society and Community Interventions : The long term commitment of politicians, planners and decision makers to programmes on safe motherhood depends on popular support from community and religious leaders, women's groups, youth

groups etc. National, regional and district safe motherhood committees can be set up. Health facility and community committee can investigate maternal deaths and implement strategies for improvement in areas such as referral, emergency transport, deployment and support of health care providers and cost sharing.

Health Sector Actions : The role of health sector is to ensure availability of good quality essential services to all women during pregnancy and childbirth. It is clear that certain pregnancy complications can be prevented but large number of these which occur around the time of childbirth/labour can neither be prevented nor predicted. Therefore, presence of a skilled birth attendant is crucial for early detection and management of such complications.

First Level Maternal and Newborn Care : First-level care does save lives and manage emergencies. It does so by controlling conditions before they become life threatening (e.g. treating anaemia) by avoiding complications (e.g. active management of the third stage of labour). A midwife or other professional with midwifery skills also actually deals with a range of emergencies on the spot, such as by administering vacuum extraction in case of foetal distress or by arranging emergency referral for caesarean section or other back-up care.

First-level maternal and newborn care should preferably be organized in midwife led birthing centres, combining cultural proximity in a non-medicalized setting, with professional skilled care, the necessary equipment, and the potential for emergency evacuation. Decentralization for easy access obviously has to be balanced by the need to concentrate the staff and equipment necessary to be available 24 hours a day, something more easily done in birthing centres with a team of several skilled attendants than in solo practices.

Health workers who provide first-level care need back-up when a problem occurs that they are unable to deal with as it goes beyond their competence or beyond the means they have at their disposal.

Back-up maternal and newborn care encompasses emergencies (such as a LSCS, hysterectomy or treatment of neonatal tetanus or meningitis) as well as non-emergency interventions (such as treatment of congenital syphilis). Back-up is ideally provided in a hospital where doctors - specialists, skilled general practitioners or mid-level technicians with the appropriate skills - can deal with mothers whose problems are too complex for first-level providers. To make the difference between life and death, the required staff and equipment must be available 24 hours a day, and the links between the two levels of care should be strong.

Rolling out Services Simultaneously : First-level maternal and newborn care and the referral hospital services that should provide back-up have to be rolled out in parallel.. The challenge of simultaneous roll-out has striking similarities to the one that led the primary health care movement to opt for the health districts, with both health centres and a district hospital, linked by referral mechanisms, and organized to ensure a continuum of care.

Initiatives in India

India has a history of starting Family planning programme

since 1952 which focused mainly on limiting family size. This was later made more client oriented and allowed voluntary acceptance of these services and came to be called as family welfare from 1977 onwards. The focus on maternal and child services was program centric without involving client. It was in 1992, that a comprehensive approach to ensure survival of children and safe motherhood was implemented in the form of CSSM programme. It was later realized, that the overall improvement in the reproductive health was the key to achieve the overall aim of lifelong health and thus, the approach was changed and RCH program was launched. Various initiatives that have been taken are spelt out in the succeeding paragraph. The MDGs and launching of NRHM have provided the necessary impetus to the issue of safe motherhood which is the right of every woman.

All India Hospital Postpartum Programme : The Post Partum Programme, a maternity centered hospital based approach to Family Welfare Programme was begun in 1969 with 54 participating hospitals, the program had 122 hospitals by 1971-1972. 90% of these were attached to medical colleges. With a view to provide maternal, child health and family welfare services in semi-urban/ rural areas, the Post Partum Programme has been extended to sub-district level hospitals also by covering 50 institutions during 1980-81. Subsequently the programme was extended in a phased manner and by the end of 1988-89, 1075 Sub-district Level Hospitals were covered. The training of medical students and graduates in the techniques of birth control is an important aspect of the program. The major purpose of the program is to convince maternity and abortion patients to adopt birth control practices while they are in the hospital and also to interest others who hear about the program by word of mouth. Contraceptive services, including sterilization, are available to all friends, relatives, and neighbors of the confined women. Rural areas are reached through the medical colleges and attached hospitals which have responsibility for the area. Educational programs are a significant part of the program and are carried out in many parts of the hospitals and clinics.

Essential Obstetric Care (EOC) : This is the minimum obstetric care that must be made available to all pregnant women.

- (a) Registration of pregnancy in the first 12-16 wks of pregnancy.
- (b) At least 3 prenatal check ups by ANM or in dispensary.
- (c) Assistance during delivery. (Skilled Birth Attendant)
- (d) At least 3 postnatal check ups.

Emergency Obstetric Care (EmOC) : This is the service provided to cater for any unforeseen complication that may arise in any pregnancy at any stage. EmOC is an intervention for preventing maternal morbidity and mortality. Early detection and management of complications such as anaemia, haemorrhage, obstructed labour and sepsis can substantially reduce maternal mortality & morbidity. This requires competent supervision and check ups by ANM during antenatal, intranatal & post natal period. ANM should refer all cases having complications during pregnancy or at the time of delivery to PHCs / FRUs.

Inputs : A total of 1748 FRUs have been identified & equipped under CSSM programme. Some of the FRUs are lacking in manpower or infrastructure. Under RCH programme, a

provision has been kept for strengthening these FRUs through provisioning of drug kits, laparoscope, blood transfusion and employing contractual staff like PHN/ANM/Lab Asst and anaesthesiologist.

24 Hour Delivery Services at PHCs/CHCs : Under RCH program, arrangements have been made that a doctor on call duty, a nurse and cleaning staff are available beyond normal working hours to encourage people to seek deliveries in PHCs/CHCs. For this doctor could be paid Rs 200/- per delivery & other staff could be hired on contractual basis.

Referral Transport to Indigent Families through Panchayats : In category C districts of eight weakly performing states, communication infrastructure is weak and economic status of families in remote villages is poor. Because of this, even if there is a complication identified during pregnancy or delivery, the women have the delivery conducted in the village and frequently through untrained Dais. This is one of the causes of high maternal mortality and morbidity. This has been addressed by providing financial assistance to Panchayats through District Family Welfare Officers.

Blood Supply to FRUs/PHCs : Dept of family welfare will be taking up pilot projects with the assistance of European Commission under the RCH programme for setting up of regular and reliable supply of blood to PHCs/CHCs by linking them with the nearest blood bank

MTP services : MTP by untrained or experienced persons is responsible for high maternal mortality and morbidity. Therefore, increasing and improving facilities for MTP is an important component of the RCH programme at PHC level.

Inputs

- (a) Need based training in MTP by NIFHW.
- (b) Supply of MTP equipment to District Hospitals, CHCs & PHCs where trained staff is available.
- (c) Assistance for engaging doctors trained in MTP to the PHCs once a week on fixed days for performing MTP (Pay Rs 500/- day). These doctors will also provide ANC and PNC services to patients during their visit.
- (d) Supply of MTP equipment to Private clinics if they have OT & trained doctors.

Janani Suraksha Yojna (Maternal Safety Scheme)

Janani Suraksha Yojana (JSY) is a safe motherhood intervention under the National Rural Health Mission (NRHM) being implemented with the objective of reducing maternal and neo-natal mortality by promoting institutional delivery among the poor pregnant women. The Yojana, launched on 12th April 2005, is being implemented in all states and UTs with special focus on low performing states. JSY is a 100 % centrally sponsored scheme and it integrates cash assistance

with delivery and post-delivery care. The success of the scheme would be determined by the increase in institutional delivery among the poor families

The Yojana has identified ASHA, the accredited social health activist as an effective link between the Government and the poor pregnant women in 10 low performing states, namely the 8 EAG states and Assam and J&K and the remaining NE States. In other eligible states and UTs, wherever, AWW and TBAs or ASHA like activist has been engaged in this purpose, she can be associated with this Yojana for providing the services.

Role of ASHA or other link health worker associated with JSY would be to:

- (a) Identify pregnant woman as a beneficiary of the scheme and report or facilitate registration for ANC,
- (b) Assist the pregnant woman to obtain necessary certifications wherever necessary,
- (c) Provide and / or help the women in receiving at least three ANC checkups including TT injections, IFA tablets,
- (d) Identify a functional Government health centre or an accredited private health institution for referral and delivery,
- (e) Counsell for institutional delivery,
- (f) Escort the beneficiary women to the pre-determined health center and stay with her till the woman is discharged,
- (g) Arrange to immunize the newborn till the age of 14 weeks,
- (h) Inform about the birth or death of the child or mother to the ANM/MO,
- (i) Post natal visit within 7 days of delivery to track mother's health after delivery and facilitate in obtaining care, wherever necessary,
- (j) Counsell for initiation of breast feeding to the newborn within one-hour of delivery and its continuance till 3-6 months and promote family planning

The scheme focuses on the poor pregnant woman with special dispensation for states having low institutional delivery rates namely the states of Uttar Pradesh, Uttaranchal, Bihar, Jharkhand, Madhya Pradesh, Chhattisgarh, Assam, Rajasthan, Orissa and Jammu and Kashmir. While these states have been named as Low Performing States (LPS), the remaining states have been named as High performing States (HPS).

Tracking Each Pregnancy : Each beneficiary registered under this Yojana should have a JSY card along with a MCH card. ASHA/AWW/ any other identified link worker under the overall supervision of the ANM and the MO, PHC should mandatorily prepare a micro-birth plan. This will effectively help in monitoring Antenatal Check-up, and the post delivery care.

Disbursement of Cash Assistance : As the cash assistance to the mother is mainly to meet the cost of delivery, it should be

Eligibility for Cash Assistance	
LPS States	All pregnant women delivering in Government health centres like Sub-centre, PHC/CHC/ FRU / general wards of District and state Hospitals or accredited private institutions
HPS States	BPL pregnant women, aged 19 years and above
LPS & HPS	All SC and ST women delivering in a government health centre like Sub-centre, PHC/CHC/ FRU / general ward of District and state Hospitals or accredited private institutions

disbursed effectively at the institution itself.

<i>Scale of Cash Assistance for Institutional Delivery</i>						
Cate- gory	Rural Area		Total Rs.	Urban Area		Total Rs.
	Mother's Package	ASHA's Package		Mother's Package	ASHA's Package	
LPS	1400	600	2000	1000	200	1200
HPS	700		700	600		600

Cash assistance for Referral transport : This assistance is given to go to the nearest health centre for delivery. The state will determine the amount of assistance (should not less than Rs.250/- per delivery) depending on the topography and the infrastructure available in their state. It would, however, be the duty of the ASHA and the ANM to organize or facilitate in organizing referral the transport, in conjunction with gram pradhan, Gram Sabha etc.

Note : This assistance is over and above the Mother's package.

Cash Incentive to ASHA : This should not be less than Rs.200/- per delivery in lieu of her work relating to facilitating institutional delivery. Generally, ASHA should get this money after her postnatal visit to the beneficiary and that the child has been immunized for BCG.

Transactional cost (Balance out of Rs.600/-) : It is to be paid to ASHA in lieu of her stay with the pregnant woman in the health centre for delivery to meet her cost of boarding and lodging etc. Therefore, this payment should be made at the hospital/ health institution itself.

All payments to ASHA would be done by the ANM only. In this case too, a voucher scheme be introduced in such a manner that for every pregnant woman she registers under JSY, ANM would give two vouchers to ASHA, which she would be able to encash on certification by ANM.

Special Dispensation for LPS States

- Age restriction removed
- Restricting benefits of JSY up to 2 births removed
- No need for any marriage or BPL certification

Subsidizing cost of Caesarean Section or management of Obstetric complications : Generally PHCs/ FRUs / CHCs etc. would provide emergency obstetric services free of cost. Where Government specialists are not available in the Govt's health institution to manage complications or for Caesarean Section, assistance up to Rs. 1500/- per delivery could be utilized by the health institution for hiring services of specialists from the private sector. If a specialist is not available.

Assistance for Home Delivery: In LPS and HPS States, BPL pregnant women, aged 19 years and above, preferring to deliver at home is entitled to cash assistance of Rs. 500/- per delivery. Such cash assistance would be available only upto 2 live births and the disbursement would be done at the time of delivery or around 7 days before the delivery by ANM/ASHA/ any other link worker.

Strategy : While the scheme would create demand for institutional delivery, it would be necessary to have adequate number of 24x7 delivery services centre, doctors, mid-wives,

drugs etc. at appropriate places. Mainly, this will entail -

- (a) Linking each habitation (village or a ward in an urban area) to a functional health centre- public or accredited private institution where 24x7 delivery service would be available,
- (b) Associate an ASHA or a health link worker to each of these functional health centre,
- (c) It should be ensured that ASHA keeps track of all expectant mothers and newborn. All expectant mother and newborn should avail ANC and immunization services, if not in health centres, at least on the monthly health & nutrition day, to be organised in the Anganwadi or sub-centre:

Micro-Birth Plan for JSY Beneficiaries : Inform the mother and the family about 4 Is, namely

- (a) *Inform* dates of 3 ANC & TT Injection(s) & ensure these are provided
- (b) *Identify* the health centre for all referral
- (c) *Identify* the Place of Delivery
- (d) *Inform* expected date of delivery

Vande Mataram Scheme

The scheme is continuing under Public Private Partnership with the involvement of Federation of Obstetric and Gynaecological Society of India and Private Clinics. The aim of the scheme is to reduce the maternal mortality and morbidity of the pregnant and expectant mothers by involving and utilizing the vast resources of specialists/trained work force available in the private sector. The scheme intends to provide free antenatal and postnatal check, counselling on nutrition, breast feeding, spacing of birth etc. through public private partnership.

This is a voluntary scheme wherein any Obstetric and Gynaecologist, maternity home, nursing home can volunteer themselves in joining the scheme. Any lady doctor/MBBS doctor providing safe motherhood services can also volunteer to join this scheme. The enrolled 'Vandemataram' doctors will display 'Vandemataram' logo in their clinic. Iron and Folic Acid Tablets, oral pills, TT injections etc. will be provided by the respective District Medical Officers to the 'Vandemataram' doctors/clinics for free distributions to beneficiaries. The cases needing special care and treatment can be referred to the Government Hospitals and institutes, who have been advised to take due care to the patients coming with Vandemataram cards.

Challenges in Maternal Health

(a) Establishing data base on maternal mortality : The maternal mortality continues to be a problem in rural, remote, inaccessible and tribal areas where there is hardly any health service available and even if available it is inadequate and in this setting the deaths in childbirth are either not recorded or recorded incorrectly due to causes other than pregnancy or childbirth. There is a need to record each and every maternal death to ascertain the correct magnitude of this public health problem.

(b) High Risk Pregnancy Behaviour - Too Early, Too Many, Too Close : The social customs like universality of marriage, early marriage, social pressure for early childbearing, son preference, lack of education and poor social status of women in decision making, all lead to consequences of pregnancies that are early, repeated and frequent leading to maternal

depletion and debility and even death.

(c) Urban-Rural Divide : The rural urban divide is a major social issue and a challenge for the public health administrators as most of the women who need the most care continue to be deprived of the same. The rural urban divide is marked not only by unequal distribution of health services but all the social and cultural factors which add up to the negative milieu for maternal health and survival.

(d) Poor Rate of Institutional Deliveries : Even after the facilities are made available, the uptake of these services continue to be poor because of various factors like lack of adequate manpower, infrastructure and facilities in the PHC/CHC, preference to deliver at home due to cultural reasons and inability to afford the cost of maternity in a civil or private health care setting.

(e) Lack of Skilled Care at Birth : The care available to mothers at birth continues to be by TBAs or midwives who are neither trained nor adequately equipped to handle complicated situations and thus either there is delay in diagnosing, transportation and referral to a FRU.

(f) Lack of Women Empowerment : This social aspect of women empowerment for a lady to take decisions for her own safety and health is still lacking where her in laws are making these decisions for her. The women are still not having the right to decide their age at marriage, pregnancy, spacing and contraception and even their maternity care.

(g) Poor Implementation of Programs : There has been a family welfare programme running in the country since last six decades but the services available for maternal health and survival at primary level is still inadequate with poor results. The reasons are many. The core intervention of providing a skilled care at birth by a midwife and backed by a referral service has still not materialized. There is a proposal for such services under NRHM as part of RCH programme.

Ten Action Messages for Safe Motherhood

These ten action messages were identified at the Sri Lanka Technical Consultation on Safe Motherhood in 1999, which marked the tenth anniversary of the Safe Motherhood Initiative.

- (1) Advance Safe Motherhood Through Human Rights
- (2) Empower Women: Ensure Choices
- (3) Safe Motherhood is a Vital Economic and Social Investment
- (4) Delay Marriage and First Birth
- (5) Every Pregnancy Faces Risks
- (6) Ensure Skilled Attendance at Delivery
- (7) Improve Access to Quality Reproductive Health Services
- (8) Prevent Unwanted Pregnancy and Address Unsafe Abortion
- (9) Measure Progress
- (10) The Power of Partnership

To provide skilled care at and after childbirth and to deal with complications is a matter of common sense - it is also what mothers and their families ask for. Putting it into practice is a challenge that many countries have not yet been able to meet. It is time to ensure that each pregnancy receives its due care with a view to prevent loss of lives in the form of maternal

deaths which are preventable to a large extent. India has an enormous task ahead to make assured services available at its health institutions and universalize the coverage of all women including those marginalized & underserved sections of society to realize the goal of safe motherhood. RCH and NRHM provide the necessary direction and opportunity to achieve this goal.

Summary

Maternal health includes Antenatal care, Intranatal care and Postnatal care. The Intranatal period constitutes only 0.5% of maternal cycle and but it is probably the most crucial.

Maternal death is defined as death of a women while pregnant or within 42 days of termination of pregnancy, irrespective of the duration and site of pregnancy, from any cause related to or aggravated by pregnancy or its management but not from accidental or incidental cause. There are three main measures of Maternal mortality which are maternal mortality ratio, maternal mortality rate and life time risk of maternal death.

Antenatal care is the care of women during pregnancy. Its ultimate objective is to have a healthy mother and healthy child at the end of pregnancy. Antenatal care includes visit antenatal clinic, examination, investigations, immunization, supplements and interventions as required. Pre-conceptional care is indicated in some cases like maternal age more than 35 yrs and paternal age more than 55 years, history of congenital defects in family, recurrent pregnancy loss and use of alcohol.

Prenatal care should start as early as 8 weeks but not later than 12-16 weeks with registration of patient and initiation of antenatal card. This is important for determining exact EDD, evaluation of risk and essential health education of the patient. The at risk pregnancies are age less than 18 or more than 35, multiparity, short stature, Rh negative, bad obstetric history, medical disorders for eg IHD, Diabetes, seizures, hypertension, tuberculosis, anaemia etc. Health education or prenatal advice includes issues like diet, rest, personal hygiene, sexual intercourse, drugs, exercise, travel and care of breasts. Women should also be educated about the warning signs which should not be ignored like convulsions, severe headache, blurring of vision and bleeding or discharge per vaginum.

Birth planning is an important function of prenatal care. It takes care of complications which may arise suddenly and can be dangerous to the life of both mother and the child. Institutional delivery should be advocated but it is a must in many conditions which should be identified.

Objectives of Intanatal care are aseptis (The five cleans- clean hands, surface, blade, cord, tie), minimum injury to mother and child, to deal with complications during labour and the care of newborn.

The first 48 hours following delivery are the most important followed by first week following delivery. The mother should give postpartum visit at 3rd, 7th day and 6 weeks after delivery to see that involution of uterus is complete. Mother should be educated about danger signs and advised to report to hospital if they appear. Infections, haemorrhage, UTI, thrombophlebitis, and psychiatric disorders are common complications of puerperium.

The global burden of maternal mortality is 400 maternal deaths per 100000 live births. The burden is very high in developing countries as compared to developed countries where it is low.

Rural population, low socio-economic status and remote areas bear a heavy burden of deaths. About 45% of maternal deaths occur in occur during the first 24 hours and more than two-thirds during first week. The maternal mortality ratio in India is 300 per 100,000 live births. The common causes in India are Anaemia, Haemorrhage, Sepsis, Obstructed labour, Abortion and Toxaemia. The 4 major direct causes of Maternal mortality are Haemorrhage, Infection, Eclampsia & Obstructed labour.

Actions for safe motherhood include legislative and policy decisions, society and community interventions, and health sector actions. Initiatives in India started since 1952 as Family planning programme. This was made more client oriented and voluntary since 1977 and called as Family welfare. In 1992 comprehensive approach was started in the form of CSSM programme. It was later realized, that the overall improvement in the reproductive health was the key to achieve the overall aim of lifelong health and thus, the approach was changed and RCH program was launched. Other programmes are All-India Hospital post-partum programme, Janani Suraksha Yojana (Maternal Safety Scheme) and Vande Matram Scheme.

The main challenges in Maternal Health are establishing data base on maternal mortality, high risk behavior, urban-rural divide, poor rate of institutional deliveries, lack of skilled care at birth, lack of women empowerment and poor implementation of programmes.

Study Exercises

Long Question : Describe in details the Programmes in India directed towards Maternal Health Care.

Short Notes : (1) Causes of Maternal mortality (2) Maternal Mortality Rate (3) All India Hospital Post-Partum Programme (4) Janani Suraksha Yojana

MCQs :

- Which of the following is not included in 'Cleans' in conduct of delivery : (a) Clean hands (b) Clean Perineum (c) Clean cutting and care of the cord (d) Clean surface of delivery
- In India, majority of deliveries take place at: (a) Hospital (b) Primary Health Centre (c) Private clinics (d) Home
- Ante-natal care includes: (a) Genetic counselling for prospective parents (b) Spacing of births (c) Ensuring adequate maternal nutrition (d) All of the above
- Janani Suraksha Yojana has been started under: (a) CSSM (b) NRHM (c) MCH (d) ICDS
- Iron/Folic acid tablets are distributed to private doctors for free distribution under which scheme: (a) NRHM (b) CSSM (c) Janani Suraksha Yojana (d) Vande Mataram Scheme
- Following are high risk ante-natal cases except: (a) Elderly Primi (b) Pre-eclampsia (c) Twin pregnancy (d) None
- Minimum number of Antenatal visits during pregnancy is: (a) Two (b) Three (c) Five (d) Six
- MMR in India is: (a) 300 per lakh (b) 400 per lakh (c) 200 per lakh (d) 500 per lakh

Answers : (1) b; (2) d; (3) d; (4) b; (5) d; (6) d; (7) b; (8) a.

Infancy is the first year of life and this is marked by the greatest threat to survival and therefore is a good measure of the progress in the fields of socio-economic, medical and healthcare development in a country. It is customary to divide infancy into various time periods for convenience of planning service. The determinants of health are also different in these phases.

Infancy is sub-divided into following four distinct phases or periods

- Perinatal period
- Early neonatal period
- Late neonatal period
- Post-neonatal period

Definitions

Perinatal Period : Perinatal period extends from 28th weeks of gestation to less than 7 days of life, after birth.

Neonate : A child in 1st month [under 4 weeks of age (<28 days)]. Early Neonatal Period- First week of life (<7days or <168 hours). Late Neonatal period extends from 7th to 28th day.

Post-Neonatal period : Period of infancy from 28 days to under 365 days (<1 year)

Live born : A live born neonate is a product of conception, irrespective of weight or gestational age, that after separation from the mother, shows any evidence of life such as breathing, heart beat, pulsation of umbilical cord or definite movement of the voluntary muscle.

Still birth : A foetal death is a product of conception that after separation from the mother does not show any evidence of life. The WHO has recommended that within any country the term stillbirth be applied to a foetus born dead and weighing >500gm which is associated with a gestation of 22 weeks. For international comparisons a weight of 1000gm is to be used which frequently measures to 28 weeks of gestation. Still birth rate is the number of foetal deaths (>1000gm weight at birth) occurring in a year per 1000 total births (live births + stillbirths).

Pre-term Baby : Any neonate born before 37 completed weeks (<259 days) of gestation irrespective of the birth weight.

Term baby : A neonate born between 37 and 42 weeks of pregnancies (259-294 days) irrespective of the birth weight.

Low Birth Weight (LBW) : Any neonate weighing less than 2500 gm at birth irrespective of gestational age.

Very Low Birth Weight baby (VLBW) : Any neonate weighing less than 1500 gm at birth irrespective of gestational age.

Extremely Low Birth Weight baby (ELBW) : Any neonate weighing less than 1000 gm at birth irrespective of gestational age.

Perinatal Mortality Rate : This includes both late foetal deaths

(stillbirths) and early neonatal deaths. The important thing to consider is the weight 1000gm and more at birth or a gestation of 28 weeks if birth weight is not available and if both weight and gestation are not available, body length (Crown to heel) of at least 35 cm should be used.

The preferred criterion is birth weight. The denominator used in calculation of perinatal mortality is 1000 live births (suits nations with poor recording of still births) but for more precise comparison the denominator includes all live births weighing 1000 gm or more. Perinatal mortality is a sensitive indicator of essential maternal and newborn care provided at childbirth. The factors responsible for stillbirths and early neonatal deaths are often similar. This indicator also assumes importance in view of the fact that many of the early neonatal deaths are recorded as stillbirth in developing nations thereby inflating figures for stillbirths but showing figures for early neonatal deaths lower than the factual. This anomaly is taken care of by Perinatal Mortality Rate. The Perinatal period comprises just 0.5 % of the average lifespan but has more deaths in this period than next 30-40 years of life.

Babies continue to be very vulnerable throughout their first week of life, after which their chances of survival improve markedly. The conditions causing newborn deaths can also result in severe and lifelong disability in babies who survive.

Infant Mortality Rate : The ratio of infant deaths registered in a given year to the total number of live births registered in the same year, usually expressed per 1000 live births.

The infants who survive early neonatal period then face the dangers of Malnutrition, Diarrhoea and ARI and certain vaccine preventable diseases like measles.

Infant mortality has a special significance as -

- Single category with largest age specific mortality.
- Measure of health status and level of living of a community
- Deaths are due to specific causes different from those that affect adults.
- Indicates social measures directed towards mother and child in a country. The importance of IMR can be gauged from the fact that it is one of the parameters for calculating Physical Quality of Life Index (PQLI). Various programs and policies have included reduction of Infant mortality as an important objective in the progress towards health for all.

Global Scenario : Each year, about four million newborns die during neonatal period across the world. Almost all (98%) of these deaths occur in developing countries. Newborn deaths now contribute to about 40% of all deaths in children under five years of age globally, and more than half of infant mortality. Rates are highest in sub-Saharan Africa and Asia. Two thirds of newborn deaths occur in the two WHO Regions (Fig. - 1), Africa (28%) and South-East Asia (36%). The average IMR for world is 54 per 1000 live births (2004). The lowest infant mortality rates in developed nations are under 10 with Japan recording an IMR of 3 per 1000 live births. The figures of IMR in underdeveloped nations are as high as 90 and above. The highest rates of IMR are recorded in Sierra Leone (165), Afghanistan (165), Mali (121) and Mozambique (104).

Progress : Consecutive household surveys from developing countries show that most have experienced a decline in neonatal mortality in recent decades. Much of the progress in survival has been made in the late neonatal period, with little improvement in the first week of life. Reductions in infant and child mortality in many countries are at least partly driven by socioeconomic development: improvements in women's education and literacy, household income, environmental conditions (safe water supply, sanitation and housing), along with improvements in health services and child nutrition

Scenario in India : The infant mortality has been declining steadily over the years but the decline has been slower than desirable (Table - 1). The progress over the last decade is given in Fig. - 2.

Table-1 : Mortality indicators of infancy: India (1994-2006)

Indicator	1994	2000	2006
Infant Mortality Rate	74	68	57
Neonatal mortality rate	48	44	37
Post-neonatal mortality rate	26	23	22
Still birth rate	9	8	9

The deaths in the 1st year of life account for 18.7 % of total deaths in the country. Of these infant deaths, >60% occur during the 1st month of life (Neonatal deaths). Of this 40% of

neonatal deaths occur in the 1st week of life (Perinatal deaths). Risk of death is highest during first 24-48 hours of life.

Girls in India face a higher mortality risk than boys. Children born to mothers under age 20 or over age 40 are more likely to die in infancy than children born to mothers in the prime childbearing ages. Infant mortality is 77 per 1,000 for teenage mothers, compared with 50 for mothers aged 20-29 yrs. Infant mortality in rural areas is 50 percent higher than in urban areas. Children whose mothers have no education are more than twice as likely to die before their first birthday as children whose mothers have completed at least 10 years of school. In addition, children from scheduled castes and scheduled tribes are at greater risk of dying than other children. Infant mortality rates are highest in Uttar Pradesh, Chhattisgarh and Madhya Pradesh, where about 70 children in 1,000 die in their first year of life, and lowest in Kerala and Goa, with 15 infant deaths per 1,000 live births.

Causes

Infant mortality is due to combination of various factors operating at different stages and are related to issues which may range from maternal, foetal, environmental and social. The causes differ during the neonatal and post neonatal phases of infancy. The factors operating in perinatal period do not have much relative impact in late neonatal part of infancy. Low birth weight (57%), respiratory infections (17%), diarrhoeal diseases (4%), congenital malformations (5%), Birth injury (3%) are the major causes of infant mortality in India. A list of causes is given in the Table - 2.

Table - 2 : Causes of Infant Mortality

Neonatal Mortality	Post neonatal Mortality (1-12 months)
Low birth weight & prematurity	Diarrhoeal diseases
Birth injury & difficult labour	Acute respiratory infection
Sepsis	Other communicable diseases-measles, malaria
Congenital anomalies	Malnutrition
Haemolytic diseases of newborn	Congenital anomalies
Conditions of placenta & cord	Accidents
Diarrhoeal diseases	
Acute respiratory infections	
Neonatal tetanus	

Factors Underlying Infant Mortality : The factors as discussed earlier vary in the Perinatal, neonatal and post neonatal phases of infancy. Perinatal mortality and neonatal mortality in particular accounts for nearly half of the infant mortality. Perinatal mortality is linked to a gamut of factors operating in the prenatal, intranatal and postnatal period.

(a) Prenatal

- Maternal factors-age (teenage, elderly), diseases like hypertension (toxemia), cardiovascular, diabetes, anaemia etc.
- Anatomical - uterine and cervical defects
- Blood incompatibilities

- Malnutrition, anaemia
- Antepartum haemorrhage
- Foetal- congenital defects

(b) Intranatal

- Birth trauma
- Birth asphyxia
- Prolonged or difficult labour
- Obstetric complications

(c) Postnatal

- Preterm baby/ Low birth weight
- Respiratory distress syndrome
- Congenital anomalies
- Infections

The causes operating in perinatal period are related to the maternal, foetal factors and care during delivery to the mother and the newborn. Factors like birth trauma, sepsis, asphyxia, prolonged labour and obstructed labour arise and operate due to lack of skilled care during delivery. The factors in the neonatal period are mainly 'endogenous' like prematurity, low birth weight and gestational age and congenital anomalies. This part of the infant mortality is the most difficult to tackle. Factors causing Post neonatal mortality are mainly social and environmental related. In developed countries the congenital anomalies is the main cause.

Prevention

The preventive strategy will be based on some direct and indirect measures as under -

Direct : These measures if taken can modify the problem of Infant mortality pretty quickly. These measures act both at primary and secondary prevention levels.

- Safe and clean delivery with skilled birth attendant
- Essential Care of the newborn at birth
- Newborn resuscitation
- Infection control measures
- Exclusive Breast feeding
- Early diagnosis and management of complications
- Special care for the preterm and premature infants
- ORT and antibiotics for Diarrhoea and ARI respectively
- Immunization

Indirect : These factors though intangible but have a role of immense importance and operate at the level of family, community, health care and society at large. These factors are mostly acting at promotion and primary prevention levels.

- Family planning - timing, spacing births, limiting family size
- Prenatal nutrition of mothers
- Education of the mother on pregnancy and child care
- Antenatal care
- Growth monitoring of child
- Prevention of malnutrition- weaning practices
- Breast feeding
- Vit A prophylaxis
- Improved Sanitation and safe water
- Access to primary health care
- Overall socio-economic development

Essential Newborn Care

Care of the newborn at birth is primarily aimed at helping the newborn to adapt to the extra-uterine environment. Physiological adaptation includes initiation of respiration and oxygenation of the arterial blood, temperature adaptation and initiation of breast feeding. Box - 1 shows the actions at birth.

Box - 1 : Actions at birth
Note timing of birth
Note sex of the baby and show to mother
Cleaning the airway
Cleaning and drying the baby
Put a identification mark / tag
Transfer the baby
APGAR score at 1 and 5 minutes
Take birth weight, length
Rule out any major congenital anomaly, birth injury

Routine Care at Birth

Over 90% of newborns do not require any active resuscitation at birth. Efforts are directed to maintain asepsis, prevent infection and hypothermia, and to keep the airway patent.

Advise the mother to return immediately if the young Infant has any of these signs
Breast feeding or drinking poorly
Becomes sicker
Develops a fever or feels cold to touch
Fast breathing
Difficult breathing
Blood in stool

Examination of the Newborn

A complete physical examination is an important part of newborn care. Each body system is carefully examined for signs of health and normal function. The physician also looks for any signs of illness or birth defects. The newborn baby at birth is 50 cm long & weighs >2.5 kg with a head circumference of 34 cm.

Risk Identification in the Newborn

An important task of the attending MO in the labour room is the identification of newborns at high risk for morbidity and mortality. These newborns would need special care, either at the PHC where the delivery took place (if the facilities and trained personnel exist) or at the FRU where these babies should be referred to.

Guidelines to detect these newborns at risk :

Danger Signs in a Newborn

- Convulsions
- Fast breathing (60 breaths per minute or more)
- Severe chest indrawing

- Nasal flaring
- Grunting
- Bulging fontanelle
- 10 or more skin pustules or a big boil
- Severe Jaundice
- Axillary temperature 37.5°C or above (or feels hot to touch) or temperature less than 35.5°C (or feels cold to touch)
- Lethargic or unconscious
- Less than normal movements
- Blood in the stools
- Not able to feed
- Not sucking at all
- No attachment at all

Referring the Newborn to an FRU

Check on the arrangement for referral. A newborn will benefit from referral to a higher centre only if it is properly ventilated and kept warm during transport. Two people are needed to escort a newborn who requires ventilation: one person will continue to ventilate the baby while the other will assist with other tasks. If possible, transfer for the mother should also be arranged alongside.

Stopping Resuscitation

Despite complete and adequate resuscitation efforts, some newborns may undergo brain death if the heart rate is absent at 15 minutes. Therefore, an absent heart sound, even after 15 minutes, is an absolute indication to stop resuscitation. If there is no gasping or breathing at all even after 20 minutes of effective ventilation (and cardiac massage, if required), stop ventilation.

Jaundice

In mild or moderate levels of jaundice, by 5 to 7 days of age the baby will take care of the excess bilirubin on its own. If high levels of jaundice do not clear up, phototherapy may be prescribed. The other modalities like exchange transfusion and suspension of breast feeding temporarily may be used if required depending on the cause.

Common Birth Injuries

A difficult birth or injury to the baby can occur because of the baby's size or the position of the baby during labour and delivery.

Breast feeding

Feeding of the Newborn : After birth, breast feeding should be initiated as early as possible (within 1 hour) unless there is a contraindication. The benefits of early and exclusive breast feeding must be explained to the mother. The baby should be fed on demand, both day and night. The mother should be advised that she SHOULD NOT-

- Force the baby to feed.
- Interrupt a feed before the baby is done
- Use the artificial teats or pacifiers
- Give the baby any other food or drink for the 1st six months of life.

Colostrum : During the first few days after delivery a woman produces special milk that is thick, sticky and yellowish or clear in colour. This special milk is called colostrum.

- Colostrum contains large quantities of protective

substances and growth factors and has more protein and Vitamins A and K than mature milk.

- It enhances the development and maturation of the baby's gastro-intestinal tract.
- The anti-infective proteins and white cells provide the first immunization against the diseases that a baby encounters after delivery.
- Although colostrum is secreted in small quantities (30-90 ml), it is sufficient to meet the caloric needs of a normal newborn in the first few days of life.
- Colostrum also has a mild purgative effect, which helps to clear baby's gut of meconium (the first, very dark stools) and helps to prevent jaundice by clearing the bilirubin from the gut.
- It stimulates the baby's immature intestine to develop in order to digest and absorb milk and to prevent the absorption of undigested protein.

Initiate breast feeding as soon as the baby is ready to suckle or as soon as the mother's condition permits. If breast feeding has to be delayed due to maternal or newborn problems, teach the mother to express breast milk as soon as possible and ensure that this milk is given to the newborn. The BFHI promotes, protects, and supports breast feeding through The Ten Steps to Successful Breast feeding for Hospitals, as outlined by UNICEF/WHO are given in Box - 2.

Box - 2 : BFHI : Ten steps to successful breast feeding	
1	Maintain a written breast feeding policy that is routinely communicated to all health care staff
2	Train all health care staff in skills necessary to implement this policy.
3	Inform all pregnant women about the benefits and management of breast feeding
4	Help mothers initiate breast feeding within 1 hour of birth.
5	Show mothers how to breast feed and how to maintain lactation, even if they are separated from their infants.
6	Give infants no food or drink other than breast milk, unless medically indicated
7	Practice "rooming in"-- allow mothers and infants to remain together 24 hours a day.
8	Encourage unrestricted breast feeding
9	Give no pacifiers or artificial nipples to breast feeding infants
10	Foster the establishment of breast feeding support groups and refer mothers to them on discharge from the hospital or clinic

Objective of Breast feeding is "Exclusive breast feeding of the first six months of life" to be propagated as it has the following benefits:

- It is the ideal method of infant feeding.
- It is the single most cost effective intervention for reduction of infant mortality.
- Delays return to fertility in the mother and hence acts as a natural contraceptive.

The Infant Milk Substitute (IMS) Act is being implemented and following initiatives have been taken-

- (a) Baby Friendly Hospital Initiative
- (b) Lactation Clinics
- (c) Peer Counselling

Weaning (Complementary Feeding) : The complementary feeding means giving the child other nutritious foods in addition to breast milk. Weaning literally meant taking the child away from the breast and nourishment by other means. Breast feeding alone is sufficient to take care of the requirements in 1st six months. Thereafter, concentrated energy dense complementary foods are essential to maintain adequate velocity of growth for the infant. Weaning if not carried out properly, may lead to malnutrition and illness.

Small Babies (LBW)

Neonates weighing <2500 gm at birth are classified as low birth weight. One third of the births in India are estimated to be LBWs. These LBWs can be of two broad groups- Preterm and SFA (small for gestational age) term infants. Most of these LBWs are SFA in developing countries while they are mostly pre-term in developed world. These LBWs face many risks at birth and are prone to many conditions like infections, respiratory difficulty and metabolic disturbances. Problems of each category are summarized in the Table - 3.

Preterm (<37 weeks)	Small for Age (SFA)
Birth asphyxia	Birth asphyxia
Hypothermia	Hypothermia
Infections	Infections
Metabolic acidosis	Meconium aspiration
Hyperbilirubinemia	Hypoglycemia
Apneic spells	Polycythemia
Respiratory distress (Hyaline membrane disease)	

Health Risk of being LBW : The low birth weight child begins with a disadvantage at birth and this may even have long term implications. The hazards of being born low birth weight are-

Survival : The mortality in infancy is much higher amongst those born with weight <2500 gm. This is due to several factors like physiological immaturity of respiratory, CNS system, liver; predisposition to hypoglycemia, hypothermia and infections, malnutrition etc.

Growth and development : Since LBWs are starting poorly at birth, they are likely to lag behind those born with normal weight. They have delayed milestones and grow poorly. The so called 'catch up growth' is seen more in preterm babies who are otherwise appropriate for their age.

Syndrome X : This metabolic syndrome is more common amongst those born with a poor weight at birth. Due to genetic programming (thrifty gene hypothesis) they develop tendency for accumulation of fat when nutrition is adequate and suffer the ill effects of this condition with increased likelihood of IHD, hypertension and diabetes.

The Causes of LBW : The causes of the LBW have been studied and they have inter-related multiple factors acting simultaneously in the setting of poverty (Table - 4). The famous triad of 'Malnutrition, Infection and Unregulated fertility' operates to produce this unfavourable outcome.

Preterm infants		SFA Infants
Maternal	Incompetent cervix	Short stature
	Medical diseases	Undernutrition
	Infections	Primi, grand multipara Smoking, tobacco
Placental	Placenta previa, APH	Abruptio placentae, infarction, anomalies
Foetal	Multiple pregnancy	IUGR, multiple pregnancy
	Congenital malformation	congenital malformation, intrauterine infections
Medical Conditions / complications	Uncontrolled diabetes	Hypertension, toxemia
	Hypertension, toxemia	Cardiac illness
	Cardiac illness	Foetal distress
	Foetal distress	Rh isoimmunisation
	Rh isoimmunisation	Anaemia
	Severe IUGR	Malaria
Iatrogenic	Improper assessment of maturity	-

Principles of Management of LBWs

- Care at Birth - All 'at risk' pregnancies for LBW babies must take place at a place where optimal facilities exist. Being prone to hypothermia, adequate precautions must be taken by maintaining a 'Warm chain'. All arrangements for resuscitation of newborn should be available.
- Appropriate place of care - Depending on the birth weight the LBW can be cared for at home (>1800 gm) and if <1800, at the hospital till the child gains weight and if <1500 gm, these babies will need tertiary level care.
- Thermal protection - As outlined elsewhere by delaying bathing, maternal contact by Kangaroo mother care and external heat source if required.
- Fluids and feeds - Breast feeding, expressed breast milk, nasogastric feeding and IV fluids if required.
- Monitoring for early detection and management of complications like respiratory difficulty, metabolic disturbances, infections etc.
- Kangaroo Mother Care

Kangaroo Mother Care (KMC) : This concept was first presented by Rey and Martinez in Colombia. It has been particularly advised in small, preterm and LBW babies but applies well in all babies. In this the key features are as under :

- Early, continuous and prolonged skin-to-skin contact between the mother and the baby
- Exclusive breast feeding
- It is initiated in hospital and continued at home
- Small babies can be discharged early
- Mothers at home require adequate support and follow up

It was developed as an alternative to inadequate and insufficient incubator care for those preterm newborn infants who had overcome initial problems and required only to feed and grow. It has been shown to be effective for thermal control, breast feeding and bonding in all newborn infants. The support binder is the only special item required for KMC. The baby is placed between the mother's breasts in an upright position, chest to chest. The position allows mother with both hands free and ability to move around.

Preventive Strategies to Tackle the Problem of LBW

Direct

- Maternal nutrition- by improving the pre-pregnancy weight and maternal nutrition during pregnancy, birth weight of the infant can be improved.
- Good antenatal care
- Prevention of infection in the mother
- Early diagnosis and management of maternal factors like anaemia, malaria, hypertension etc.

Indirect

- Delayed marriage and childbearing
- Adequate spacing
- Family planning
- Improved socio-economic status
- Women empowerment

Infection Prevention in the Newborn : This is an important component of every sphere of newborn care. Newborns are more susceptible to infection because of immature immune system. This is still more relevant to preterm and low birth weight infants.

General Principles

- Consider every person (including staff and the baby) as potentially infectious
- Wash hands or use hand rub (alcohol based) before handling a baby and after
- Wear protective clothing like gown, mask, gloves
- Observe aseptic techniques in all procedures
- Routine cleaning of the ward and all equipment
- Isolation of babies with infections
- Routine care of newborn

Early Childhood

Children are more likely to survive, to grow in a healthy way, to have less disease and fewer illnesses, and to fully develop thinking, language, emotional and social skills when well nurtured and cared for in their earliest years. Frequent illness, unsanitary environments and poor nutrition steal a child's potential.

It is a child's right to have every chance to survive and thrive. Moreover, ensuring optimal conditions for a child's early years is one of the best investments that a country can make if it is to compete in a global economy based on the strength of its human capital. The growth monitoring, correct feeding practices, immunization, responsive health care system, legal provisions, sensitive society, management during sickness and providing protection to these children can help in improving the lot of this important group of vulnerable population. The concept of well baby clinic, under five clinic and mother and child clinics are steps in this direction. The growth and development (Growth and Development) and care of sick children (IMNCI) are described in different chapters.

Community Based Health Care Interventions

UNICEF and WHO, have agreed on 12 key household practices for neonates and infants that can help to promote child survival, health and nutrition in communities:

- (1) *Exclusive breast feeding* from birth to six months.
- (2) *Complementary feeding* : Starting at about six months old, feeding children energy - and nutrient-rich complementary foods while continuing to breast feed for at least two years could prevent more than 10 per cent of deaths from diarrhoea and acute respiratory infections, particularly pneumonia; and increase resistance to measles and other illnesses.
- (3) *Micronutrient Supplementation* : Improving the intake of vitamin A through diet or supplements in communities where it is deficient could reduce mortality among children aged 6 months to five years by 20 per cent.
- (4) *Hygiene* : Better hygiene practices, particularly hand washing with soap (or ashes) and the safe disposal of excreta could reduce the incidence of diarrhoea by 35%.
- (5) *Immunization* : Vaccination against measles for children under age one could prevent most of the measles - related deaths each year. Caregivers should make sure children complete a full course of immunization (Bacille Calmette-Guérin; diphtheria, pertussis and tetanus vaccine; oral polio vaccine; and measles vaccine) before their first birthday.
- (6) *Malaria prevention* : The use of insecticide-treated mosquito nets in households in malaria-endemic areas could lower malaria-related child deaths by as much as 23 per cent.
- (7) *Psychosocial care and development*: Promote mental and social development by responding to a child's need for care and by talking, playing and providing a stimulating environment.
- (8) *Feeding and fluids for sick children*: Continue to feed and offer more fluids, including breast milk, to children when they are sick.
- (9) *Home treatment*: Give sick children appropriate home treatment for infections.
- (10) *Care seeking*: Recognize when sick children need treatment outside the home, and seek care from appropriate providers.
- (11) *Appropriate practices*: Follow the health worker's advice about treatment, follow-up and referral.
- (12) *Antenatal care*: Every pregnant woman should have adequate antenatal care.

Further important practices that protect children include - providing appropriate care for those who are affected by HIV and AIDS, especially orphans and vulnerable children; protecting children from injury and accident, abuse and neglect; and involving fathers in the care of their children. Many of these practices can be undertaken by community health workers or by community members themselves, given the appropriate support and distribution of products and services. The direct involvement of the community is perhaps most appropriate for those aspects of health care and nutrition that most closely affect members on a daily basis. These include infant and young child feeding, other caring practices, and water and sanitation.

Special Child Survival Initiatives in India

CSSM : The Child Survival and Safe Motherhood Programme jointly funded by World Bank and UNICEF was started in 1992-93 for implementation up to 1997-98. The Child Survival and Safe Motherhood Programme was implemented in a phased manner covering all the districts of the country by the year 1996-97. The objectives of the programmes were to improve the health status of infants, child and maternal morbidity and mortality. The programmes seek to sustain high coverage levels achieved under the Universal Immunisation Programme (UIP) in good performance areas and strengthen the immunisation services of poor performing areas. The programme also provides for augmenting various activities under the Oral Rehydration Therapy (ORT) Programme, universalising prophylaxis schemes for control of anaemia in pregnant women & control of blindness in children and initiating a programme for control of Acute Respiratory Infection (ARI) in children. The Programme yielded notable success in improving the health status of pregnant women, infants and children & also making a dent in IMR, MMR and incidence of vaccine preventable diseases.

UIP : Universal Immunization Programme against six preventable diseases, namely, diphtheria, pertussis, childhood tuberculosis, poliomyelitis, measles and neonatal tetanus was introduced in the country in a phased manner in 1985, which covered the whole of India by 1990. Significant progress was made under the Programme in the initial period when more than 90% coverage for all the six antigens was achieved. The UIP was taken up in 1986 as National Technology Mission and became operational in all districts in the country during 1989-90. UIP became a part of the Child Survival and Safe Motherhood (CSSM) Programme in 1992 and Reproductive and Child Health (RCH) Programme in 1997. Under the Immunization Programme, infants are immunized against tuberculosis, diphtheria, pertussis, poliomyelitis, measles and tetanus.

ORT : The diarrhoeal disease control programme was started in the country in 1978. The main objective of the programme was to prevent death due to dehydration caused by diarrhoeal diseases among children under 5 years of age due to dehydration. Health education aimed at rapid recognition and appropriate management of Diarrhoea has been a major component of the CSSM. Under the RCH programme ORS is supplied in the kits to all sub-centres in the country every year.

RCH : The initiatives under RCH for newborn and infant care

are as under-

Infant & Child Health

- (a) Reduction of new-born deaths, infant deaths and child deaths by providing continuous health care and strengthening of new-born care infrastructure facilities.
- (b) Organizing counselling sessions for the mothers.
- (c) Implementing integrated management of neonatal and childhood illness as a pilot initiative in selected districts.
- (d) Operationalising infant death/stillbirth verbal autopsy.
- (e) Addressing the issue of female infanticide and foeticide

IMNCI : Integrated Management of Neonatal and Childhood Illness (IMNCI)

Integrated Management of Childhood Illness (IMCI) strategy, which has already been implemented in more than 100 countries all over the globe, encompasses a range of interventions to prevent and manage five major childhood illnesses i.e. Acute Respiratory Infections, Diarrhoea, Measles, Malaria and Malnutrition. It focuses on preventive, promotive and curative aspects, i.e. it gives a holistic outlook to the programme. The details on the care of sick children are given in the chapter on IMNCI.

Home Based Care of Newborns and Mothers - (SEARCH) A Project

In the Gadchiroli district of India, Drs. Abhay and Rani Bang and colleagues at the *Society for Education, Action & Research in Community Health* (SEARCH) have developed a remarkable approach to home-based health care that benefits both newborns and their mothers. It had to be home-based because 83 percent of births in rural India occur at home, and these villagers have virtually no access to health facilities. After two years of research, SEARCH introduced neonatal care through trained village health workers and trained birth attendants, who provide health education to new mothers, support breast feeding and maintenance of body temperature, and recognize danger signs in mothers and babies. By the third year of the program, which tracked results in 39 intervention villages and 47 control villages, SEARCH had recorded a 62 percent reduction in the neonatal mortality rate for the intervention areas as well as a significant reduction in various neonatal and maternal morbidities. This strategy has been recognized as a valuable option for the districts with high infant mortality.

Tackling infant mortality is largely an issue of addressing the perinatal mortality. Perinatal mortality improves by universal coverage of all deliveries with skilled attendance at birth and essential maternal and newborn care coupled with effective referral mechanism and back up FRU facilities. Post neonatal mortality is amenable to known interventions and is easiest to tackle by launching child survival methods like ORT, treating pneumonia, breast feeding, supplementary feeding, weaning practices and immunization. The infant survival is related largely to clean delivery practices, correct feeding practices, immunization and availability, adequacy and timely health care during sickness especially due to Diarrhoea, ARI and measles. The malnutrition is one single factor which touches all of these and determines the survival of the infant. The core interventions for child survival are given in Box - 3.

Box - 3 : Core Interventions to Improve Child Survival
Skilled attendance during pregnancy Child birth and the immediate postpartum period : Nurturing newborns and their mothers.
Infant feeding : Exclusive breast feeding during the first six months of a child's life, with appropriate complementary feeding from six months and continued breast feeding for two years or beyond, with supplementation with vitamin A and other micronutrients as needed.
Vital vaccines : Increased coverage of measles and tetanus vaccines, as well as immunization against common vaccine-preventable diseases.
Combating diarrhoea : Case management of diarrhoea, including therapeutic zinc supplementation and antibiotics for dysentery.
Combating pneumonia and sepsis : Case management of childhood pneumonia and neonatal sepsis with antibiotics.
Combating malaria : Use of insecticide-treated bednets, intermittent preventive malaria treatment in pregnancy, and prompt treatment of malaria.
Prevention and care for HIV : Treatment, care, infant feeding counselling and support for HIV-infected women and their infants.

Summary

Infancy is the first year of life and is marked by greatest threat to survival and therefore is a good measure of the progress of a country. It is sub-divided into Perinatal, Early neonatal, Late neonatal and Post neonatal period. Babies are very vulnerable during their first week of life and also when they are weaned. Infant Mortality Rate (IMR) has special significance because it is a single category with highest age-specific mortality, measure of PQLI. Deaths are due to causes different from adults and hence IMR indicates measures directed to mother and child in a country.

Each year, 4 million children die during neonatal period worldwide. Neonatal deaths contribute to 40% of deaths in Under-5 children and more than half of infant mortality worldwide. Rates are highest in Sub-saharan Africa and Asia. The average IMR is 54 per 1000 for the world (2004). The highest rates of IMR are in Sierra Leone and Afghanistan and lowest in Japan. Consecutive household surveys in developing countries have shown a reduction in neonatal mortality rates of which maximum reduction is in late neonatal period.

In India the infant mortality rate is declining steadily over the years but the decline has been slower than desirable. IMR in 2006 for India was 57. The deaths in the first year of life account for 18.7% of total deaths in the country. Of these Infant deaths more than 60% occur in neonatal period. Of these neonatal deaths 40% occur in first week of life (Early neonatal period). The greater mortality risk is associated with girl child, children of mothers aged less than 20 and more than 40, children born in rural areas, children of mothers with no formal education, children of scheduled castes and tribes. In India IMR is highest in Uttar Pradesh, Chattisgarh and Madhya Pradesh and lowest

in Kerala and Goa. Major causes of Infant mortality in India are Low birth weight(57%), Respiratory infections(17%), Congenital malformations(5%), Diarrhoeal diseases(4%) and Birth injury(3%).

Infant mortality can be due to prenatal, intranatal and postnatal causes. Prenatal causes are Maternal age (teenage and elderly), Maternal diseases like hypertension, cardiovascular, diabetes and anaemia, Uterine and cervical defects, Blood incompatibilities, Malnutrition, Ante-partum haemorrhage and Feto-congenital defects. Intranatal causes are Birth trauma, Birth asphyxia, Prolonged or difficult labour and Obstetric complications. Postnatal causes are Preterm or low birth weight baby, Respiratory distress syndrome, congenital anomalies and Infections.

Preventive strategies for reducing Infant mortality are divided into direct and indirect methods. Direct methods are Safe and clean delivery by skilled birth attendant, Essential care of newborn, Newborn resuscitation, Infection control measures, Exclusive breast feeding, Early diagnosis and management of complications, Special care for preterm and premature infants, ORT and antibiotics for Diarrhoea and ARI respectively and Immunization. Indirect methods are Family planning, Prenatal nutrition of mothers, Education, Antenatal care, Growth monitoring of child, Prevention of malnutrition, Vit A prophylaxis, Improved water and sanitation, Access to primary health care and overall socio-economic development.

Care of newborn at birth is primarily aimed at helping the newborn to adjust to extra-uterine environment. Physiological adaptations include initiation of respiration and oxygenation of the arterial blood, temperature adaptation and initiation of breast feeding. The Baby Friendly Hospital Initiative (BFHI) promotes, protects and supports breast feeding through the ten steps to successful breast feeding for hospitals as outlined by UNICEF/WHO. Objective of breast feeding is Exclusive breast feeding for the first six months of life. The Infant Milk Substitute (IMS) act is being implemented and the initiatives are Baby friendly hospital initiative, Lactation clinics and Peer counselling.

Over 90% of newborns do not require active resuscitation at birth. In these cases the mother is advised to return to hospital immediately if infant is breast feeding or drinking poorly, becomes sicker, develops fever or feels cold to touch, difficult breathing and blood in stools. In case of Jaundice the child is taken to hospital if Jaundice is noted during first 24 hours or baby develops a fever over 100°F or colour deepens after day 7 or Jaundice does not disappear after day 15 or baby is not gaining sufficient weight.

Complementary feeding or weaning means giving the child other nutritious foods in addition to breast milk and is done after 6 months. In this, complementary energy dense foods, which are locally available and are inexpensive, easily digestible and culturally acceptable are given.

Neonates weighing less than 2500 grams at birth are classified as low birth weight. They can be divided into Pre-term babies and Small for Gestational Age (SFA) babies. The health risks of being low birth weight are decreased survival, delayed milestones, poor growth and development and increased

chances of Syndrome X later in life. The famous triad causing LBW babies include Malnutrition, Infection and Unregulated fertility. Principles of management of LBW babies include care at birth, appropriate place of care, thermal protection, fluids and feed, monitoring for early detection and management of complications and Kangaroo Mother Care (KMC).

The preventive strategies to tackle the problem of LBW are improving maternal nutrition, good ante-natal care, prevention of infection of the mother, early diagnosis and treatment of anaemia or hypertension or malaria etc., delayed marriage or childbearing, adequate spacing, family planning, improved socio-economic status and women empowerment.

UNICEF and WHO has agreed on 12 key household practices for neonates and infants that can help promote child survival, health and nutrition in communities. These are Exclusive breast feeding for six months, complementary feeding, micronutrient supplementation, hygiene, immunization, malaria prevention, psychosocial care and development, feeding and fluids for sick children, home treatment, care seeking appropriate practices and ante-natal care.

The important special child survival initiatives in India include CSSM (Child Survival and Safe Motherhood Programme), UIP (Universal Immunization Programme), RCH, IMNCI (Integrated Management of Neonatal and Childhood Illness).

Initiatives under RCH for newborn and infant care include reduction of newborn deaths, infant deaths and child deaths by providing continuous health care and strengthening of newborn care infrastructure facilities, organizing counselling sessions for the mothers, implementing IMNCI as a pilot project in selected districts, operationalising infant death/still birth verbal autopsy and addressing the issue of female infanticide and foeticide.

IMNCI strategy encompasses a range of interventions to prevent and manage five childhood illnesses i.e. ARI, Diarrhoea, Measles, Malaria and Malnutrition. It promotes on preventive, promotive and curative aspects i.e. it gives a holistic attitude to the programme.

Study Exercises

Long question : Discuss various causes of high IMR in developing countries and strategies to prevent it.

Short notes : (1) BFHI (2) IMR and its trend in India (3) Causes of Infant mortality (4) Essential newborn care (5) Breast feeding (6) Weaning (7) LBW (8) Kangaroo mother care

MCQs :

- Premature infant is one which is born: (a) Before 40 weeks (b) Before 38 weeks (c) Between 28-37 weeks (d) Between 28-42 weeks
- All are true of colostrum except: (a) Rich in proteins and minerals (b) Rich in anti-infective factors (c) Rich in fats (d) Secreted for first few days
- Breast feeding should be started _____ hours after birth: (a) Within 1 hour (b) 2 hours (c) 24 hours (d) 48 hours
- LBW baby is one whose weight is below: (a) 2200 grams (b) 2000 grams (c) 1500 grams (d) 2500 grams
- Exclusive breast feeding is sufficient for _____ months after birth: (a) 1 month (b) 2 months (c) 6 months (d) 9 months
- Low birth weight child is due to all except: (a) Maternal malnutrition (b) Infections (c) Unregulated fertility (d) Previous caesarean section
- Single most important factor determining survival chances of newborn is: (a) Birth order (b) Multiple gestation (c) Intrauterine infection (d) Low birth weight
- Adverse factor for child health is : (a) Birth order 5 or more (b) Maternal malnutrition (c) Teenage mother (d) All of the above
- Perinatal period is: (a) 20-32 weeks of gestation (b) 37-42 weeks of gestation (c) 28 weeks of gestation to 1 week postnatal period (d) 28 weeks of gestation to 1 week postnatal period (d) 32 weeks of gestation to 2 week postnatal period
- Perinatal mortality includes: (a) Stillbirths (b) Neonatal deaths (c) Stillbirths and Early neonatal deaths (d) Stillbirths and Neonatal deaths
- Infant mortality rate in India in 2006 was: (a) 64 (b) 67 (c) 54 (d) 57
- The denominator in IMR is: (a) Total no of live births (b) Total no of live and still births (c) Total no of still births (d) Total population

Answers : (1) a; (2) c; (3) a; (4) d; (5) c; (6) d; (7) d; (8) d; (9) c; (10) c; (11) d; (12) a.

A S Kushwaha

Accumulated evidence has suggested that an integrated and syndromic approach is needed for efficient management of sick children to improve outcomes. On analysis of the major causes of mortality in childhood and evidence based data, an approach called IMCI (Integrated Management of Childhood Illnesses) was developed by WHO. This encompasses a range of interventions to prevent and manage *five* major childhood illnesses i.e. Acute Respiratory Infections, Diarrhoea, Measles, Malaria and Malnutrition. It focuses on the preventive, promotive and curative aspects of the disease management with participation of the mother also in the process, i.e. it gives a comprehensive and holistic outlook to the programme.

As part of Millennium Development Goals (MDGs), Goal 4 and Target 5 are to reduce by two third, the mortality in the children under five. India is a signatory to the MDGs adopted in 2000 as part of the Millennium Declaration. A Core Group was constituted which included representatives from Indian Academy of Pediatrics (IAP), National Neonatology Forum of India (NNF), National Anti Malaria Program (NAMPP), Department of Women

and Child Development (DWCD), Child-in-Need Institute (CINI), WHO, UNICEF, eminent Paediatricians and Neonatologists, and the representatives from Ministry of Health and Family Welfare, Government of India. The Adaptation Group developed Indian version of IMCI guidelines and renamed it as Integrated Management of Neonatal and Childhood Illness (IMNCI).

Approach

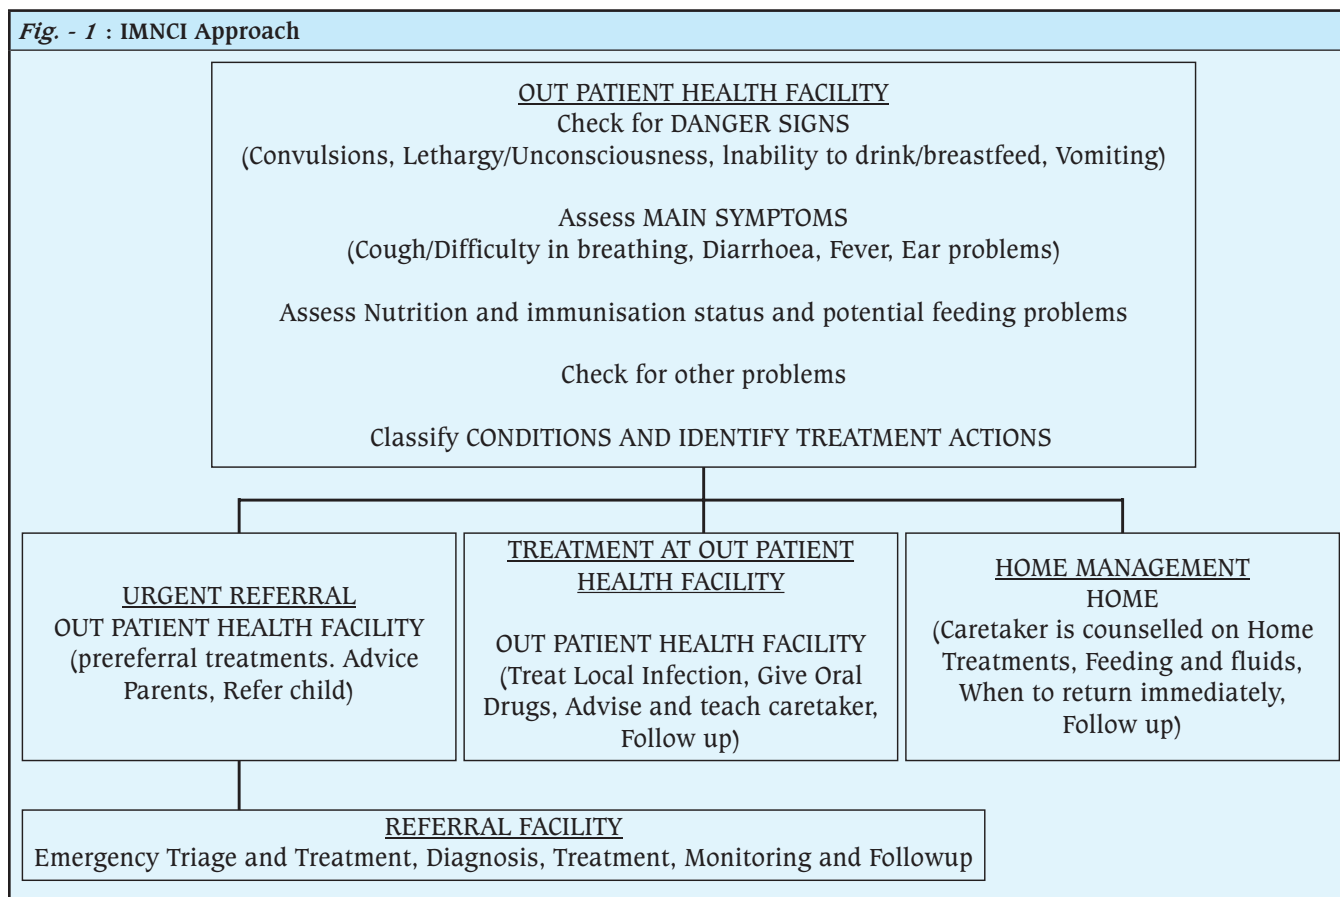

The IMNCI approach has some distinct features which are given as under-

(a) Syndromic Approach : Mostly the children suffer from a constellation of symptoms and need to be treated as a whole. Many sick children present with overlapping signs and symptoms of illnesses, and a single diagnosis may not be feasible or appropriate, especially in a primary care level with scarce resources. The Syndromic approach gives the advantage of not missing out on co-existing conditions while presenting with a particular condition.

(b) Holistic Approach : This means that taking care of all the factors that determine the health of the child. While treating for diarrhoea, the immunization and nutritional factors are also addressed.

(c) Triage : Management is planned after triage of the patient into those needing emergent, early treatment, referral or care at home.

Fig. - 1 : IMNCI Approach

(d) **Standardized Case Management** : Standardized case management based on the classification / severity of illness

(e) **Primary Health Care Model** : Based on primary health care model and referral to a facility when required.

(f) **Community Participation** : The IMNCI approach gives due importance to the role of the mother in the whole process of prevention, early diagnosis and management of the case at home by providing counselling to the caretaker.

Components of IMNCI

The major components of this strategy are:

- (a) Strengthening the skills of the health care workers
- (b) Strengthening the health care infrastructure
- (c) Involvement of the community

The first two components are the facility based IMNCI and the third is the community based IMNCI in which mother is actively involved in the care of child in health and disease.

Steps in Management

(ACT- assess, classify and treat) (See Fig. - 1)

The basic steps in the management of the sick children are as under-

- (a) Assess the child for group of symptoms
- (b) Classify the severity of disease
- (c) Treat as per the laid out plan
- (d) Counsell the mother
- (e) Follow up care

Age Categories

Depending on the age of the child, various clinical signs and symptoms differ in their degree of reliability, diagnostic value and importance and even the principles of management also differ. The IMNCI guidelines therefore recommend case management procedures based on two age categories:

- (a) Young infants (age up to 2 months)
- (b) Children (2 months up to 5 years)

Young Infants (Age Up to 2 Months) : Neonates and infants below 2 months of age are considered as a special group for several reasons. They become sick rapidly and can die quickly due to serious bacterial infections. Certain general signs in these infants such as low body temperature, fever or less body movements may be the only manifestation of illness. On the other hand, a finding such as mild chest in-drawing is normal in them due to a soft chest wall. Therefore the assessment and classification process is different from that in an older infant or child.

Assessment (Assess for BCD IF Hypothermic)

- (a) For serious **B**acterial infection or local infection
- (b) For jaundice (Colour of skin)
- (c) For **D**iarrhoea
- (d) Checking the **I**mmunization status
- (e) For **F**eeding problem or malnutrition and breast feeding
- (f) For low body temperature (**H**ypothermic)

1. Serious Bacterial Infection : Suspect possible serious bacterial infection if there is - (remember STING BALL CM)

- (a) **S**kin pustules (10 or more)
- (b) **T**achypnoea (60 breaths per minute or more)
- (c) Severe chest **I**n-drawing

(d) **N**asal flaring

(e) **G**runting

(f) **B**ulging Fontanelle

(g) **A**bnormal **A**xillary temperature (more than 37.5°C or less than 35.5°C)

(h) **L**arge Boil on the skin

(j) **L**ethargy or **U**nconsciousness

(k) History of **C**onvulsions

(l) Less than normal **M**ovements

If any one of these criteria is present, the infant is classified as having possible serious bacterial infection. Infant is to be *referred to hospital urgently* for admission. The pre-referral treatment consists of administering first dose of antibiotics (intramuscular ampicillin 100 mg/Kg and gentamicin 5mg/Kg) ; giving expressed breast milk (or appropriate animal milk orally or by nasogastric tube) to prevent hypoglycemia and providing warmth by skin to skin contact (kangaroo care) to avoid hypothermia.

2. Local Infection : The infant has local bacterial infection if there is redness of umbilicus, pus discharge from ear or less than 10 skin pustules. All such cases are given oral antibiotic - (cotrimoxazole 6 mg/kg/day of trimethoprim or amoxicillin 30 mg/kg/day) for 5 days. The mother is taught to apply gentian violet and dry the ear by wicking. Ear is dried at least 3 times daily. Clean absorbent cloth or soft, strong tissue paper is rolled into a wick and placed in the young infant's ear. It is removed when wet. Replace the wick with a clean one and repeat these steps until the ear is dry. To treat skin pustules or umbilical infection, gentian violet paint is applied twice daily. The mother should gently wash off pus and crusts with soap and water. Dry the area and paint with gentian violet 0.5%. To treat thrush (ulcers or white patches in mouth) the mother should wash hands and then wash mouth of the child with clean soft cloth wet with salt water wrapped around the finger. After cleaning, the mouth is painted with gentian violet 0.25%. The infant is followed up after 2 days.

3. Jaundice : (a) Jaundice in a neonate appearing at less than 24 hrs or after 14 days or associated with yellow discolouration of palms and soles is classified as severe jaundice. Infant requires urgent referral to the hospital after giving pre-referral treatment which includes oral expressed breast milk, skin to skin contact and advising mother to keep the infant warm en route to hospital.

(b) If the infant has jaundice but palms and soles are not yellow, mother is reassured and the infant is reviewed after 2 days. It is important to advise the mother to return immediately if the infant develops any signs of serious bacterial infection or jaundice on palms and soles.

4. Low Body Temperature : In every sick young infant, Axillary temperature should be recorded. If it is 35.5 - 36.4°C, the infant is said to have low body temperature. Such an infant is warmed by skin to skin contact for one hour and reassessed. If there is no improvement, he is referred to hospital, while feeding expressed breast milk to prevent hypoglycemia.

5. Diarrhoea : If the stools have changed from the usual pattern and have increased in number and watery (more water than fecal matter), infant is said to have Diarrhoea. The normally

frequent or loose stools of a breast fed baby are not considered as Diarrhoea. Duration of Diarrhoea and history of blood in the stool are important questions in the history. Assess for presence and severity of dehydration.

Severe dehydration : If the young infant has two of the following three signs, the dehydration is severe :

- (a) Lethargic or unconscious
- (b) Sunken eyes
- (c) Skin pinch goes back very slowly (> 2 seconds)

If such an infant has low weight or any other severe classification, he is referred urgently to hospital. The pre-referral treatment includes first dose of IM antibiotics (ampicillin and gentamicin), giving frequent sips of ORS on the way, continuing breast feeding and keeping the infant warm. If the infant does not have low weight or another severe classification, fluids are administered for severe dehydration as per *plan C* and he is then referred to hospital after rehydration. The ORS should be continued. If IV fluids cannot be given, fluids by nasogastric tube could be given. If none of this is feasible refer to a hospital.

Some dehydration : If the young infant has two of the following three signs he is classified to have some dehydration. Oral rehydration is the mainstay.

- (a) Restless, irritable
- (b) Sunken eyes
- (c) Skin pinch goes back slowly.

If the infant has low weight or another severe classification, first dose of IM antibiotics (ampicillin and gentamicin) are given and urgent referral to hospital is done, with mother giving frequent sips of ORS on the way, continuing breast feeding and keeping the infant warm. If the infant does not have low weight or another severe classification; fluids are administered for some dehydration as per *plan B*. The mother is told to give more if child asks. If the child vomits wait for 10 minutes and then resume. Reassess after 4 hours and re-classify. Breast feeding should be continued. The mother is counselled to return immediately if not improving, not accepting fluids and has blood in stools. Follow up visit in 2 days is recommended or earlier if danger signs develop.

No dehydration : If there are not enough signs to classify as some or severe dehydration, the infant has no dehydration and is given fluids to treat Diarrhoea at home as per *plan A*. The follow up is done in 5 days and mother is also advised when to return immediately.

Severe persistent diarrhoea : Severe persistent Diarrhoea is Diarrhoea lasting 14 days or more and the infant with this classification is referred to hospital. Give inj Ampicillin or gentamicin if the child has low weight, Diarrhoea or any other severe classification, keep the child warm and treat to prevent hypoglycemia as part of pre-referral treatment.

Severe Dysentery : If there is blood in the stool, the young infant has severe dysentery and is similarly referred to hospital. Administer same pre-referral treatment as above before sending to hospital in the presence of any criteria of severe classification.

6. Feeding Problems and Malnutrition

(a) Weight : The present weight and birth weight should be noted. Using the reference growth charts, the infant is classified as very low weight for age, low weight for age or not low weight for age.

(b) Feeding : Feeding should be assessed immediately if the infant feeds less than 8 times in 24 hours, receives no other foods or drinks, or is low weight for age and has no indications to refer urgently to hospital. The infant should be put to the breast and observed for attachment and effective suckling. Blocked nose, oral thrush and breast or nipple problems (flat or inverted nipples, sore nipples, engorged breasts or breast abscess) should be looked for. If the young infant is not able to feed, has no attachment at all, is not sucking at all or is very low weight for age, he has a life threatening problem and needs urgent admission to hospital after administering pre-referral treatment. If there are other feeding problems or the infant is low weight for age, counselling of the mother is done about correct position during breast feeding, increasing frequency of feeds, treatment of breast and nipple problems and treatment of thrush. The infant is followed up after 2 days for feeding problem and after 14 days for low weight for age.

7. Checking the Young Infant's Immunization Status : Check whether OPV, BCG, DPT-1 and Hep B-1 vaccines have been administered in every sick young infant. An infant who is not sick enough to be referred to hospital should be given the necessary immunization before being sent home.

2 Months to 5 Years

A sick child aged 2 months to 5 years may present to the primary health care facility with common ailments like pneumonia, Diarrhoea, fever or an ear infection. The child in addition may also have malnutrition and anaemia. Irrespective of the presenting complaints the child is assessed in a comprehensive manner as under-

Steps of Initial Assessment

- (a) Ask the mother about the child's problem.
- (b) Check for general danger signs.
- (c) Ask the mother about the four main symptoms: (**CDEF**)
 - (i) Cough or difficult breathing
 - (ii) Diarrhoea
 - (iii) Ear problem
 - (iv) Fever.
- (d) If one of the four above mentioned symptoms is present:
 - (i) Assess the child further for signs related to the main symptom
 - (ii) Classify the illness according to the signs which are present or absent.
- (e) Check for signs of malnutrition and anaemia
- (f) Check the child's immunization status
- (g) Assessing for any other problems.

Look for General Danger Signs : A sick child brought to the primary health care facility may have signs that point towards a specific problem. However, some children may present with serious, non-specific signs called "*General Danger Signs*" that may not point to a particular diagnosis. For example, a child who is having convulsions or is unconscious may be suffering from any of the diseases like meningitis, epilepsy or cerebral

malaria. It may be simply febrile convulsions. Presence of these general danger signs suggest that a child is severely ill and needs urgent attention. The following general danger signs are routinely checked in all children : (*VICU*)

- (a) Repeated Vomiting
- (b) Inability to drink or breast feed
- (c) Convulsions
- (d) Lethargy or Unconsciousness

If a child has any one or more of these signs, he is considered *seriously ill and should be referred*. In order to start treatment for severe illnesses without delay, the child should be quickly assessed for the most important causes of serious illness and death - acute respiratory infection (ARI), Diarrhoea, and fever (especially associated with malaria and measles). A rapid assessment of nutritional status is also essential.

Check for Four Major Symptoms (Remember CDEF) : After checking for general danger signs, the health care provider must check for the following main symptoms:

- (a) Cough or difficult breathing
- (b) Diarrhoea
- (c) Ear problems
- (d) Fever

Diagnosis & Management

(A) Cough or Difficult Breathing : Any child with cough or difficult breathing is assessed by respiratory rate, chest in-drawing and presence of stridor.

- (a) Respiratory rate: A child's age cut-off rate for fast breathing that suggests pneumonia is:
 - (i) 2 months up to 12 months: 50 breaths per minute or more
 - (ii) >12 months up to 5 years : 40 breaths per minute or more
- (b) Lower chest wall in-drawing
- (c) Stridor

Based on the above clinical signs, children presenting with cough or difficult breathing are classified in to one of the three categories:

- (a) Severe pneumonia or very severe disease
- (b) Pneumonia
- (c) No pneumonia (i.e. cough or cold).

Severe Pneumonia / Very severe disease : The child is classified as severe pneumonia /very severe disease if any general danger sign or chest in-drawing or stridor in an otherwise calm child is present. This child needs urgent attention and should be referred to a hospital by quickest means available, after administering the first dose of injectable antibiotic (IM Chloramphenicol 40mg/kg/dose) or if not possible, give oral amoxicillin 15mg/kg/dose.

Pneumonia : If only fast breathing is present without any stridor or chest in-drawing and there are no general danger signs, the child is classified as having pneumonia and is managed by oral antibiotics, cotrimoxazole (trimethoprim 8 mg/kg/day) for 5 days. Additional symptomatic treatment to soothe the throat and a safe cough remedy for children older than 6 months may be given. The mother is advised to return for follow up after 2 days. However if danger signs develop or the child becomes sicker, the mother should be asked to return

immediately.

No Pneumonia - Cough or Cold : If there are no signs of pneumonia, the classification is no pneumonia. The child is suffering from minor bout of cough or cold which can be managed symptomatically at home and does not warrant antibiotics. Such a child is followed up after 5 days if not improving, or immediately if any of the danger signs develop or the child deteriorates.

(B) Diarrhoea : A child presenting with Diarrhoea should first be assessed for general danger signs and the child's caretaker should also be asked if the child has cough or difficult breathing.

A child with Diarrhoea may have three *potentially lethal* conditions:

- (a) Acute watery Diarrhoea (including cholera)
- (b) Dysentery (bloody Diarrhoea)
- (c) Persistent Diarrhoea (Diarrhoea that lasts 14 days or more).

All children with Diarrhoea should be checked to determine the duration of Diarrhoea, if blood is present in the stool and if dehydration is present.

Check Dehydration : Based on a combination of the following clinical signs, children presenting with Diarrhoea are classified into the three categories of severe dehydration, some dehydration and no dehydration and appropriate treatment is to be given. Main clinical signs are used to determine the level of dehydration

Severe Dehydration (Plan C) : Presence of at least *two of the following signs* classifies the child as having severe dehydration.

- (a) Lethargic or unconscious
- (b) Sunken eyes
- (c) Not able to drink or drinking poorly
- (d) Skin pinch goes back very slowly

Child should be managed in the primary health care facility with fluids. Re-assess every 1-2 hours and if required, fluid can be repeated once. The ORS should be continued. If IV fluids cannot be given, fluids by nasogastric tube could be given. If none of this is feasible refer to a hospital. However if the child has any other severe classification, he should be urgently referred to hospital. Oral doxycycline (5 mg/kg/day) should be administered if cholera is prevalent in the area.

Some dehydration : Look for the signs of dehydration-

If two or more of the signs are present the, classification is some dehydration. The child should be treated as per *Plan B*.

Such a child is followed up after 5 days if not improving. Mother is counselled to return immediately if child has any of the following signs:

1. Not able to drink or breast feed
2. Becomes sicker
3. Develops fever
4. Passes blood in stool

No dehydration : The child is classified as if there are not enough signs to classify into some or severe dehydration. Treatment is given at home with fluids and feeds as per *Plan A*. The mother is advised to return after 5 days or immediately

if above danger signs develop like not able to drink or breast feed, becomes sicker, develops fever or passes blood in stool.

Dysentery : A child is classified as having dysentery if the mother or caretaker reports blood in the child's stool. This should be treated with oral cotrimoxazole (8mg/kg/day of trimethoprim in 2 divided doses) for 5 days. The child is followed up after 2 days.

Persistent Diarrhoea : All children with Diarrhoea lasting for 14 days or more are said to have persistent Diarrhoea. If dehydration is present, the child is classified as severe persistent Diarrhoea and should immediately be sent to hospital. If dehydration is not present, the child is given a single dose of vitamin A and oral zinc sulphate 20 mg daily for 14 days and the mother or caretaker is given counselling on feeding of the child. If still breast feeding, give more frequent, longer breast feeds, day and night. If taking other milk replace with increased breast feeding OR replace with fermented milk products, such as yoghurt OR replace half the milk with nutrient-rich semisolid food. Add cereals to milk (Rice, Wheat, Semolina). The child is followed up after 5 days.

(C) **Fever** : Children are considered to have fever if the body temperature is above 37.5°C axillary (38°C rectal). In the absence of a thermometer, children are considered to have fever if they feel hot or there is a history of fever. Body temperature should be checked in all sick children brought to an outpatient clinic. A child presenting with fever should be assessed for common serious causes like malaria, meningitis and measles. The following information is important:

- (a) Risk of malaria based on the geographic area endemic for it
- (b) Presence of bulging fontanelle or stiff neck suggesting very severe febrile illness such as meningitis
- (c) Presence of running nose, conjunctival congestion or generalized rash suggestive of measles

Serious Febrile Illness : A child with fever is classified as having serious febrile illness if there is any general danger sign or stiff neck or bulging fontanel. He requires urgent referral to hospital. Pre-referral required to be given to the child is a dose of IM quinine (10 mg/kg/dose) after making a blood smear; first dose of IV or IM chloramphenicol (40 mg/kg/dose or if not possible oral amoxicillin 15 mg/kg/dose), feeding to prevent hypoglycemia and one dose of paracetamol (15 mg/kg) for high fever (temp. 38.5°C or above).

High Malaria Risk area : Children with fever but without any danger sign or stiff neck or bulging fontanel are classified as Malaria and should be treated with antimalarials after making a blood smear. The antimalarials given are as follows:

Presumptive treatment -

- (i) Oral chloroquine 10 mg/kg single dose on Day 1, 10 mg/kg single dose on Day 2 and 5 mg/kg single dose on Day 3.
- (ii) In areas of high chloroquine resistance, give oral sulphadoxine (25 mg/kg) plus pyrimethamine (1.25 mg/kg) single dose.

Radical treatment : if *P. vivax* is positive on blood smear - Oral primaquine 0.25 mg/kg daily for 5 days.

Low Malaria Risk Area : Children with fever but without any danger sign / stiff neck / bulging fontanelle are classified as

Malaria there are no symptoms of runny nose, measles or any other cause of fever. The antimalarials given after making a blood smear are as follows:

Presumptive treatment

- (i) Oral chloroquine 10 mg/kg single dose on Day 1
- (ii) In areas of high chloroquine resistance, give oral sulphadoxine (25 mg/kg) plus pyrimethamine (1.25 mg/kg)

Radical treatment in Smear positive Pf case

- (i) Oral chloroquine 10 mg/kg single dose
- (ii) Oral primaquine 0.75 mg/kg single dose

Radical treatment in Smear positive Pv case

- (i) Oral chloroquin 10 mg/kg single dose
- (ii) Oral primaquine 0.25 mg/kg daily for 5 days

In a child being treated for malaria, the mother should be advised to return immediately if the child becomes sicker or is unable to drink or breast feed. The child should be followed up after 2 days if fever persists or recurs within 14 days. If fever persists every day for 7 days the child should be referred for assessment.

Measles : A child with fever is assessed for signs of measles such as generalized rash with cough, runny nose and red eyes.

- If the child has measles or has had measles within the last 3 months, and there is any general danger sign or clouding of cornea or deep / extensive mouth ulcers, the classification is Severe complicated measles. This child should be urgently referred to hospital after giving first dose of oral vitamin A, chloramphenicol IM and tetracycline eye ointment application.
- If the child has measles now or has had measles within the last 3 months, and there is pus draining from eye or mouth ulcers are present, he is classified to have measles with eye or mouth complications, and given first dose of vitamin A, tetracycline eye ointment and gentian violet for mouth ulcers. Follow up is done after 2 days.
- If the child has measles now or has had measles within the last 3 months, with none of the above signs, only first dose of vitamin A is given.

(D) **Ear Infections** : Any sick child should be assessed for ear problems such as ear pain or ear discharge. If there is a tender swelling behind the ear, the child has mastoiditis. He should be given first dose of IM chloramphenicol and urgently referred to hospital. If there is pus discharge or ear pain, the classification is acute ear infection and oral antibiotic (cotrimoxazole) should be given for 5 days. Dry the ear at least 3 times daily. Roll clean absorbent cloth or soft, strong tissue paper into a wick. Place the wick in the young infant's ear. Remove the wick when wet. Replace the wick with a clean one and repeat these steps until the ear is dry.

(E) **Malnutrition** : Every sick child should be weighed and assessed for visible severe wasting and oedema of both feet.

- If there is visible severe wasting or oedema, the child is said to have severe malnutrition and given a single dose of vitamin A, kept warm and urgently referred to hospital.
- If the child has very low weight (malnutrition grade II, III or IV), the mother is counselled for feeding. The child

is followed up in 5 days if there is a feeding problem or otherwise after 30 days.

(F) Anaemia : Palmar pallor is looked for in every sick child presenting to primary health care.

- If there is severe palmar pallor, the child has severe anaemia and should be urgently referred to hospital.
- If some palmar pallor is present, the child has anaemia and should be given iron and folic acid therapy in a single dose daily for 14 days (elemental iron 3-6 mg/kg/day and folic acid 100-200 mcg/day).
- All other sick children older than 6 months should be given prophylactic iron and folic acid (20 mg elemental iron + 100 mcg folic acid) for a total of 100 days in a year after the child has recovered from the acute illness.

Immunization

Immunization status of every sick child should be checked. Those being referred to hospital should not be immunized. All other children should be immunized as per schedule on the same day.

Assess Other Problems

Although the IMNCI guidelines focus on the main symptoms as enumerated above, every sick child should be assessed for other complaints, which can lead to severe or acute illness. In addition, the health of the caretaker should be also be addressed. Case recording form for management of the sick child age 2 months up to 5 years is given on subsequent pages.

Counselling of the Mother

- (a) Advise mother on home care for infant-The mother should be counselled on breast feeding the child and keeping the baby warm.
- (b) Advise mother when to return- To return immediately if the infant is
 - (i) Breast feeding or drinking poorly
 - (ii) Becomes sicker
 - (iii) Develops a fever or feels cold to touch
 - (iv) Fast breathing
 - (v) Difficult breathing
 - (vi) Yellow palms and soles (if infant has jaundice)
 - (vii) Diarrhoea with blood in stool
- (c) Counsell the Mother about her own health
 - If the mother is sick, provide care for her, or refer her for help.
 - If she has a breast problem (such as engorgement, sore nipples, breast infection), provide care for her or refer her for help.
 - Advise her to eat well to keep up her own strength and health.
 - Give iron folic acid tablets for a total of 100 days.
 - Make sure she has access to:
 - Family planning, Counselling on STD and AIDS prevention

Summary

WHO developed an approach called IMCI (Integrated Management of Childhood Illnesses) which encompasses a range of interventions to combat 5 major childhood illnesses i.e.

Acute Respiratory Infections, Diarrhoea, Measles, Malaria and Malnutrition. The Adaptation group developed Indian version of IMCI guidelines and renamed it as Integrated Management of Neonatal and Childhood Illnesses (IMNCI).

IMNCI approach has some distinct features i.e. It is based on syndromic and holistic approach, involves Triage and it works on Standardized case management and Primary health care model with community participation. The major components are strengthening the health care infrastructure, strengthening the skills of health care workers and community participation in which mother is actively involved. The basic steps in management are assess, classify, treat and follow up care of the child and counselling of the mother. The IMNCI guidelines recommend case management procedures separately for age up to 2 months and 2 months to 5 years.

For young infants aged up to 2 months the assessment and classification process is different from older infants and children. Assessment in young infants includes Serious bacterial infections or local infections, Jaundice, Diarrhoea, Low body temperature, Feeding problems or malnutrition and Immunization status. In case any sign of severe bacterial infection is present the child is given first dose of parenteral antibiotic and referred to hospital. If local infection present the infant is given oral antibiotics and advised home care. Jaundice in a neonate appearing in less than 24 hours or after 14 days or associated with yellow discolouration of palms and soles is classified as severe jaundice and urgent referral after initial treatment is done. Every sick young infant should be examined for low body temperature and managed accordingly. If Diarrhoea is present then assessment of dehydration should be done. If dehydration is present with low weight or any other severe classification, child is referred after giving first dose of IM antibiotics and frequent sips of ORS. If dehydration is present without low weight or any other severe classification, child is treated based on severity of dehydration. If Diarrhoea is present without signs of dehydration then child is treated at home with oral fluids. Weight and feeding of infant should also be assessed. Immunization status should also be checked and if feasible immunization should be carried out before discharging to home.

A sick child aged 2 months to 5 years may present with common ailments like Pneumonia, Diarrhoea, Fever, Ear infection, Malnutrition and Anaemia. Firstly the general danger signs should be looked for i.e. Lethargy or unconsciousness, Convulsions, Repeated vomiting and Inability to drink or breast feed. If a child has any one of these signs he is considered seriously ill and immediately referred. After examining for danger signs four major symptoms are looked for. These are Cough or difficult breathing, Diarrhoea, Fever and Ear problems. Any child with cough or difficult breathing is assessed by Respiratory rate, Chest-indrawing and Presence of stridor. Based on these signs children are classified into Severe pneumonia, Pneumonia and No pneumonia and treated accordingly. A child with severe pneumonia is referred to a hospital by quickest means after administering first dose of injectable antibiotics. A child classified as having pneumonia is treated with oral antibiotics at home for 5 days after giving necessary instructions to mother. A child with no pneumonia is treated

without antibiotics at home. A child presenting with Diarrhoea should be first assessed for danger signs and then assessed for dehydration. Based on dehydration status child is classified into Diarrhoea with severe dehydration, some dehydration or no dehydration. A child with severe dehydration is treated with intravenous fluids and reassessed every 1-2 hours. If signs of severe classification are present child is immediately referred to hospital. If a child has some dehydration treat with ORS and reassess after 4 hours. If a child has no dehydration treat at home with oral fluids. A sick child should be checked for fever and if present should be assessed for common serious causes like Malaria, Meningitis and Measles. A child with fever is classified as having serious febrile illness if there is any danger sign or stiff neck or bulging fontanellae and requires parenteral antibiotics and quinine and urgent referral to hospital. If a child is classified as having Malaria than appropriate treatment is given. A child with fever is also assessed for signs of Measles. Any sick child should also be assessed for Ear infections, Malnutrition and Anaemia. Immunization status of every sick child should be checked. Mother should also be counselled for child care and her own health.

Study Exercises

Long Question : Describe in detail the IMNCI guidelines for management of Neonatal and Childhood illnesses.

Short Notes: (1) Components of IMNCI (2) IMNCI guidelines for Management of Pneumonia (3) IMNCI guidelines for Management of Diarrhoea (4) General danger signs in a sick child

MCQs

1. General danger signs in a sick child include all except: (a) Convulsions (b) Unconsciousness (c) Inability to Breast feed (d) Vomiting

2. Which of the following is not true of dehydration: (a) Mild to moderate dehydration can be corrected at home by ORS (b) ORS Solution should be made fresh daily (c) Breast feeding should be delayed till dehydration is corrected (d) Patient should be given as much ORS as he wants
3. Young infants in IMNCI guidelines are up to the age of: (a) 6 months (b) 1 year (c) 2 months (d) 3 months
4. For young infants assessment is basically done for all except: (a) Jaundice (b) Hypothermia (c) Diarrhoea (d) Measles
5. IMNCI recommendations are up to the age of: (a) 10 years (b) 8 years (c) 7 years (d) 5 years
6. Severe Jaundice in a neonate are all except: (a) Less than 24 hours (b) More than 7 days (c) More than 14 days (d) Yellow discolouration of palms and soles
7. In a 6 month old child breathing rate _____ or more suggests pneumonia: (a) 40 per minute (b) 50 per minute (c) 60 per minute (d) 70 per minute
8. Signs for classifying a child as having severe dehydration are all except: (a) Dry tongue (b) Sunken eyes (c) Not able to drink (d) Lethargic or unconscious
9. A case of Simple Pneumonia is treated with: (a) Parenteral antibiotics (b) Oral antibiotics (c) Referred to hospital (d) Parenteral antibiotics and Referral
10. IMCI approach developed by WHO encompasses following childhood illnesses except: (a) Measles (b) Malaria (c) Diarrhoea (d) Chickenpox

Answers : (1) d; (2) c; (3) c; (4) d; (5) d; (6) b; (7) b; (8) a; (9) b; (10) d

CASE RECORDING FORM FOR MANAGEMENT OF THE SICK YOUNG INFANT AGE UP TO 2 MONTHS

Name: _____ Age: _____ Weight: _____ kg Temperature: _____ °C Date: _____

ASK: What are the infant's problems? _____ Initial visit? _____ Follow up Visit? _____

ASSESS (Circle all signs present)

CLASSIFY

CHECK FOR POSSIBLE BACTERIAL INFECTION / JAUNDICE

- Has the infant had convulsions?
 - Count the breaths in one minute. breaths per minute
 - Repeat if elevated _____ Fast breathing?
 - Look for severe chest indrawing.
 - Look for nasal flaring.
 - Look and listen for grunting.
 - Look and feel for bulging fontanelle.
 - Look for pus draining from the ear.
 - Look at the umbilicus. Is it red or draining pus?
 - Look for skin pustules. Are there 10 or more pustules or a big boil?
 - Measure axillary temperature (if not possible, feel for fever or low body temperature):
 - 37.5°C or more (or feels hot)?
 - Less than 35.5°C ?
 - Less than 36.5°C but above 35.4°C (or feels cold to touch)?
 - See if young infant is lethargic or unconscious
 - Look at young infant's movements. Less than normal?
 - Look for jaundice. Are the palms and soles yellow?

DOES THE YOUNG INFANT HAVE DIARRHEA?

Yes ___ No ___

- For how long? _____ Days?
- Is there blood in the stool?
- Look at the young infant's general condition. Is the infant:
 - Lethargic or unconscious?
 - Restless and irritable?
- Look for sunken eyes.
- Pinch the skin of the abdomen. Does it go back:
 - Very slowly (longer than 2 seconds)?
 - Slowly

THEN CHECK FOR FEEDING PROBLEM & MALNUTRITION

- Is there any difficulty feeding? Yes ___ No ___ . • Determine weight for age. Very low ___ Low ___ Not Low ___
- Is the infant breastfed? Yes ___ No ___
 - If Yes, how many times in 24 hours? _____ times
- Does the infant usually receive any other foods or drinks? Yes ___ No ___
 - If Yes, how often?
- What do you use to feed the infant?

If the infant has any difficulty feeding, is feeding less than 8 times in 24 hours, is taking any other food or drinks, or is low weight for age AND has no indications to refer urgently to hospital:

**CASE RECORDING FORM FOR MANAGEMENT OF THE SICK CHILD
AGE 2 MONTHS UP TO 5 YEARS**

Name: _____ Age: ____ Weight: _____ kg Temperature: _____ °C Date: _____

ASK: What are the child's problems? _____ Initial visit? ____ Follow-up Visit? ____

ASSESS (Circle all signs present) _____ CLASSIFY _____

CHECK FOR GENERAL DANGER SIGNS

NOT ABLE TO DRINK OR BREASTFEED LETHARGIC OR UNCONSCIOUS
VOMITS EVERYTHING
CONVULSIONS

General danger sign present?
Yes ____ No ____
Remember to use danger sign
when selecting classifications

DOES THE CHILD HAVE COUGH OR DIFFICULT BREATHING? Yes ____ No ____

- For how long? ____ Days
- Count the breaths in one minute
____ breaths per minute. Fast breathing?
- Look for chest indrawing.
- Look and listen for stridor. _____

DOES THE CHILD HAVE DIARRHEA? Yes ____ No ____

- For how long? ____ Days
- Is there blood in the stool?
- Look at the child's general condition. Is the child:
Lethargic or unconscious?
Restless and irritable
- Look for sunken eyes.
- Offer the child fluid. Is the child:
Not able to drink or drinking poorly?
Drinking eagerly, thirsty?
- Pinch the skin of the abdomen. Does it go back:
Very slowly (longer than 2 seconds)?
Slowly?

DOES THE CHILD HAVE FEVER? (by history/feels hot/ temperature 37.5oC or above) Yes ____ No ____

Decide Malaria Risk: High Low

- Fever for how long? _ Days
- If more than 7 days, has fever been present every day?
- Has the child had measles within the last 3 months?
- Look or feel for stiff neck.
- Look and feel for bulging fontanelle.
- Look for runny nose
- Look for signs of MEASLES:
- Generalized rash
- One of these: cough, runny nose, or red eyes

If the child has measles now or within the last 3 months: .

- Look for mouth ulcers
If Yes, are they deep and extensive
- Look for pus draining from the eye.
- Look for clouding of the cornea.

DOES THE CHILD HAVE AN EAR PROBLEM Yes ____ No ____

- Is there ear pain?
- Is there ear discharge?
If Yes, for how long? ____ Days
- Look for pus draining from the ear.
- Feel for tender swelling behind the ear.

THEN CHECK FOR MALNUTRITION

- Look for visible severe wasting.
- Look for oedema of both feet.
- Determine weight for age.
Very Low _____ Not Very Low _____

THEN CHECK FOR ANEMIA

- Look for palmar pallor.
Severe palmar pallor? Some palmar pallor? No pallor?

CHECK THE CHILD'S IMMUNIZATION, PROPHYLACTIC VITAMIN A & IRON-FOLIC ACID STATUS Return for next immunization or vitamin A or IFA supplement on: _____

Circle immunizations and Vitamin A or IFA supplements needed today.

BCG DPT 1 DPT 2 DPT 3 DPT(Booster)DT

OPV 0 OPV 1 OPV 2 OPV 3 OPV IFA

Plan A : Treat Diarrhoea at Home

Counsel the mother on the three rules of home treatment: Give extra fluids, continue feeding, return if child worsens

Give extra fluids (as much as the child will take)

Tell the mother :

- If exclusively breast fed, breast feed frequently and for longer at each feed. If passing frequent watery stools: For less than 6 months age, give ORS and clean water in addition to breast milk. If 6 months or older, give one or more of the home fluids in addition to breast milk.
- If the child is not exclusively breast fed: give one or more of the following home fluids: ORS solution, yoghurt drink, milk, lemon drink, rice or pulse based drink, vegetable soup, green coconut water or plain clean water.

It is especially important to give ORS at home when :

- The child has been treated with plan B or Plan C during the visit
- The child cannot return to a clinic if the diarrhea gets worse

Teach the mother how to mix and give ORS. Give the mother 2 packets of ORS to use at home.

Show the mother how much fluid to give in addition to the usual fluid intake:

- Up to 2 years: 50 to 100 ml after each loose stool
- 2 years or more: 100 to 200 ml after each loose stool

Tell the mother to :

- Give frequent small sips from a cup
- If the child vomits, wait for 10 minutes. Then continue, but more slowly.
- Continue giving extra fluids until the diarrhea stops

Plan B : Treat Some Dehydration with ORS

Give recommended amount of ORS over a 4 hour period

Determine the amount of ORS to give during next 4 hours as follows:

Age	Up to 4 months	4 months to 12 months	12 months up to 2years	2 years up top 5 years
Weight	< 6kg	6<10 kg	10 - <12 kg	12-19 kg
In ml	200-400	400-700	700-900	900-1400

- The approximate amount of ORS required (in ml) can also be calculated by multiplying the child's weight (in kg) times 75
- If a child wants more ORS than shown, give more.
- For infants who are not breast fed, also give 100-200 ml clean water during this period

Show the mother how to give ORS:

- Give frequent small sips from a cup
- If the child vomits, wait for 10 minutes. Then continue, but more slowly
- Continue breast feeding whenever the child wants

After 4 hours

- Reassess the child and classify for dehydration
- Select the appropriate plan and continue treatment
- Begin feeding the child in the clinic

If the mother must leave before completing the treatment

- Show her how to prepare ORS solution at home
- Show her how much ORS to give to finish 4 hour treatment at home
- Give her enough ORS packets to complete rehydration. Also give her two packets as recommended in plan A.

Explain the 3 rules of home treatment:

- Give extra fluids
- Continue feeding
- Return if child worsens, does not pass urine or refuses to drink

Plan C : Treatment of Severe Dehydration

If you can give IV fluid immediately

- If the child can drink, give ORS by mouth while drip is set up.
- Give 100 ml/kg Ringers lactate solution or Normal saline as follows

Age	First give 30 ml/kg in :	Then give 70 ml/kg in:
Infants(up to 12 months)	1 hour (repeat once if radial pulse is still very weak or not detectable)	5 hours
Children (12 months – 5 years)	30 minutes(repeat once if radial pulse is still very weak or not detectable)	2 ½ hours

- Reassess child every 1-2 hours. If hydration status is not improving, give the IV fluid more rapidly.
- Also give ORS (about 5 ml/kg/hour) as soon as the child can drink, usually after 3-4 hours(infants) or 1-2 hours(children)
- Reassess an infant after 6 hours and a child after 3 hours. Classify dehydration. Then choose the appropriate plan(A,B, or C) to continue

If you cannot give IV fluids immediately and IV treatment is available nearby (within 30 min)

- Refer urgently to hospital for IV treatment
- If the child can drink, provide the mother with ORS solution and show her how to give frequent sips during the trip \

If IV treatment is not available immediately and you are trained to use nasogastric tube for rehydration

- Start rehydration by tube (or mouth) with ORS solution: 20 ml/kg/hour for 6 hours (total of 120 ml/kg)
- Reassess the child every 1-2 hours
 - If there is repeated vomiting or increasing abdominal distension, give the fluid more slowly
 - If the hydration status is not improving after 3 hours, send the child for IV therapy
- After 6 hours, reassess the child. Classify dehydration. Then choose the appropriate plan (A, B, C) to continue treatment.

If IV treatment is not available immediately (within 30 min), you are not trained to use nasogastric tube and the child cannot drink

- Refer urgently to hospital for IV or Nasogastric tube treatment

Feeding recommendations during sickness and health

Up to 6 Months of Age	6 Months up to 12 Months	12 Months up to 2 Years	2 Years and Older
 <p>Breastfeed as often as the child wants, day and night, at least 8 times in 24 hours.</p> <ul style="list-style-type: none"> • Do not give any other foods or fluids not even water <p>Remember:</p> <ul style="list-style-type: none"> • Continue breastfeeding if the child is sick 	 <ul style="list-style-type: none"> • Breastfeed as often as the child wants. • Give at least <u>one katori serving*</u> at a time of : <ul style="list-style-type: none"> - Mashed rotl/ rice /bread/biscuit mixed in sweetened undiluted milk OR - Mashed rotl/rice/bread mixed in thick dal with added ghee/oil or khichri with added oil/ghee. Add cooked vegetables also in the servings OR - Sevian/dalia/halwa/kheer prepared in milk or any cereal porridge cooked in milk OR - Mashed boiled/fried potatoes - Offer banana/biscuit/ cheeko/ mango/ papaya <p>^a3 times per day if breastfed; 5 times per day if not breastfed.</p> <p>Remember:</p> <ul style="list-style-type: none"> • Keep the child in your lap and feed with your own hands • Wash your own and child's hands with soap and water every time before feeding 	 <ul style="list-style-type: none"> • Breastfeed as often as the child wants. • Offer food from the family pot • Give at least <u>1½ katori serving*</u> at a time of : <ul style="list-style-type: none"> - Mashed rotl/rice/bread mixed in thick dal with added ghee/oil or khichri with added oil/ghee. Add cooked vegetables also in the servings OR - Mashed rotl/ rice /bread/biscuit mixed in sweetened undiluted milk OR - Sevian/dalia/halwa/kheer prepared in milk or any cereal porridge cooked in milk OR - Mashed boiled/fried potatoes - Offer banana/biscuit/ cheeko/ mango/ papaya <p>^a 5 times per day.</p> <p>Remember:</p> <ul style="list-style-type: none"> • Sit by the side of child and help him to finish the serving • Wash your child's hands with soap and water every time before feeding 	 <ul style="list-style-type: none"> • Give family foods at 3 meals each day. • Also, twice daily, give nutritious food between meals, such as: banana/biscuit/ cheeko/ mango/ papaya as snacks <p>Remember:</p> <ul style="list-style-type: none"> • Ensure that the child finishes the serving • Teach your child wash his hands with soap and water every time before feeding

Feeding Recommendations For a Child who Has PERSISTENT DIARRHOEA

- If still breastfeeding, give more frequent, longer breastfeeds, day and night.
- If taking other milk:
 - replace with increased breastfeeding OR
 - replace with fermented milk products, such as yoghurt OR
 - replace half the milk with nutrient-rich semisolid food.
 - Add cereals to milk (Rice, Wheat, Semolina)
- For other foods, follow feeding recommendations for the child's age.

A S Kushwaha

Global Scenario

In 2006, for the first time since mortality data have been gathered, annual deaths among children under five dipped below 10 million to 9.7 million. This represents a 60 per cent drop in the rate of child mortality since 1960. Most deaths among children under five years are still attributable to just a handful of conditions and are avoidable through existing interventions (Fig. - 1). Six conditions account for 70% to over 90% of all these deaths. These are acute lower respiratory infections, mostly pneumonia (19%), diarrhoea (18%), malaria (8%), measles (4%), HIV/AIDS (3%), and neonatal conditions, mainly preterm birth, birth asphyxia, and infections (37%).

India

1	IMR	57 / 1000 live births
2	Under Five Mortality	74 / 1000 live births
3	Children <3 yrs who are underweight	42.5 %
4	Breast feeding initiation in 1 hour	24.5 %
5	ORS given to children with diarrhoea	26 %
6	Children (12-23 months) with completed immunization	43.5%
7	% of newborn babies LBW	30 %

Definitions

Child Death rate (1-4 Year Mortality Rate) : Child death rate is the number of deaths of children aged 1 to 4 years per 1000 children in the same age group in a given year. It therefore excludes infant mortality. This is a more refined indicator of the social situation in a country than infant mortality rate. It reflects the adverse environmental health hazards faced by the children including factors like malnutrition, poor hygiene and sanitation, infections and accidents caused due to social, economic, cultural characteristics of the community. This measure of child health excludes the perinatal and endogenous factors operating in the infancy. The second year of life is the one which poses greatest risk to life and accounts for nearly half of all deaths in the 1-4 years age children. The infectious diseases like measles, diphtheria, ARI, diarrhoea affect this age most. The 1-4 years child mortality rate in developed countries is negligible and quite high in the developing and underdeveloped nations. The countries also show a great interstate variation. The developed countries have home accidents as the leading cause in developed countries while infections predominate in the developing nations.

Under Five Mortality Rate (U5MR) (Child Mortality Rate): This is defined as the number of deaths in children under five

years of age expressed as rate per 1000 live births. This rate measures the probability of dying between birth and exactly five years of age. This indicator is considered as the single best indicator of social development and well being. The global figure stands at 72 while India has a rate of under five mortality at 74 per 1000 live births. There has been a declining trend in under five mortality but still continues to be very high in African countries especially Sub-Saharan countries. Child mortality is a sensitive indicator of a country's development and telling evidence of its priorities and values. It has several advantages as a barometer of child well-being in general and child health in particular. First, it measures an 'outcome' of the development process rather than an 'input', such as per capita calorie availability or the number of doctors per 1,000 population - all of which are means to an end. Second, the U5MR is known to be the result of a wide variety of inputs: the nutritional status and the health knowledge of mothers; the level of immunization and oral rehydration therapy; the availability of maternal and child health services (including prenatal care); income and food availability in the family; the availability of safe drinking water and basic sanitation; and the overall safety of the child's environment, among other factors. Third, the U5MR is less susceptible to the fallacy of the average than, for example, per capita gross national income (GNI per capita). This is because the natural scale does not allow the children of the rich to be 1,000 times as likely to survive, even if the human made scale does permit them to have 1,000 times as much income. In other words, it is much more difficult for a wealthy minority to affect a nation's U5MR, and it therefore presents a more accurate, if far from perfect, picture of the health status of the majority of children (and of society as a whole).

Child Survival Index : This indicator is calculated by subtracting the under five mortality rate from 1000 and dividing this figure by 10. The child survival is a measure of social development and the attention given to the care of under five children. The child survival index of developed countries is 99 and above approaching 100 and developing countries like India have a much lower survival index but it is improving steadily.

Evolution of Under Five Child Health Services

1. Primary Health Care Model : During the 1970s, socioeconomic development and improved basic living conditions like clean water, sanitation and nutrition were seen as the keys to improving child health. Primary health care stood for universal access to care and coverage on the basis of need. Along with intersectoral action for health, community involvement and self-reliance, much of the primary health care strategy was designed with the health of children as the priority of priorities.

2. Vertical Programmes-Model : At the end of the 1970s, the economic recession did not allow for such a development of primary health care system. Child health and particularly child survival was such an obvious emergency that by the early 1980s, many countries shifted their focus from primary health care systems to vertical, "single-issue", programmes that promised cheaper and faster results. Child health continued to constitute a 'silent' emergency, as close to 15 million children were still dying annually before their fifth birthday.

In the late 1970s, two scientists, Julia Walsh and Kenneth Warren, published '*Selective Primary Health Care* : An interim strategy for disease control in developing countries' - a milestone paper that proposed an alternative strategy for rapidly reducing infant and child mortality at a reasonable cost. After breaking down the relative role of each major cause of child mortality and listing the existing interventions proved to be effective in addressing them, they concluded that a small number of causes (diarrhoea, malaria, respiratory diseases and measles, among others) were responsible for the vast majority of under-five deaths and that these deaths could be easily prevented by immunization oral rehydration therapy, breast feeding and antimalarial drugs(1). The Child Survival Revolution of the 1980s, spearheaded by the United Nations Children's Fund (UNICEF), and built around a package of interventions grouped under the acronym GOBI (growth monitoring, oral rehydration therapy for diarrhoea, breast feeding, and immunization) soon gained currency.

3. Preventive Model (EPI) : Expanded Programme on Immunization of the mid-1970s, and programmes for Control of Diarrhoeal Disease and Acute Respiratory Infections became the successful strategy in which at country level, these vertical programmes successfully tackled a number of priority diseases. The Expanded Programme on Immunization started in 1974 and widened the range of vaccines routinely provided, from smallpox, BCG and DTP to include polio and measles. It set out to increase coverage in line with the international commitment to achieve the universal child immunization goal of 80% coverage in every country.

4. Breast feeding initiatives (BFHI) : Baby-Friendly Hospital initiative to support promotion of breast feeding in maternities was launched in 1992. In 1990, less than one fifth of mothers gave exclusive breast feeding for four months; by 2002 that figure had doubled to 38%.

5. Integrated and Syndromic Approach to a Sick Child (IMCI): A feverish and irritable child that has difficulty eating can be suffering from a single illness, such as dysentery, or from a combination of diseases, such as malaria and pneumonia. Single-issue programmes were not designed to provide guidance on how to deal with such situations. There was clearly a need for a more comprehensive view of the needs of the child, one that would correspond to problems as they were encountered in the field (4) and would offer a wider range of responses than the existing programmes. The response to this new situation was to package a set of simple, affordable and effective interventions for the combined management of the major childhood illnesses and malnutrition, under the label of "Integrated Management of Childhood Illness" (IMCI). Details are covered in chapter on IMNCI, the Indian adapted version of IMCI.

6. Child Health - An issue of Rights for the Children : The MDGs have made it binding on all countries to move forward on issues of child health focusing on survival, growth, development and protection. The children of the world are subjected to many violations of their rights like child labour, abuse and exploitation, neglect, early marriage and even sexual abuse and violence against them. The UNICEF with many NGOs are focusing on these issues.

Under Five's Clinic

History

Dr. Morley while working in rural areas of Nigeria developed the concept of growth chart popularly known as '*Road to Health*' chart (2-6). He highlighted the problem facing child health services throughout the developing world and especially malnutrition which was at the core of all other childhood problems. He emphasized the role of growth monitoring through under-fives 'clinic to quickly identify and combat malnutrition. These two measures have subsequently been adopted by many developing countries. Careful emphasis was placed on the social, economic, cultural and ethical considerations which were ignored by most doctors but also nurses and other health workers. Morley emphasized low-cost health services, within the means of the people involved, and the need to make extensive use of auxiliaries and villagers themselves. The concept of 'Well Baby clinics' is being practised with emphasis on preventive services mainly immunization and promotive growth monitoring.

Under Fives - A special group

1. They constitute about 15 % of the total population.
2. They suffer high rates of mortality and morbidity.
3. The effects of malnutrition and other diseases have a role in later life.
4. The majority of the deaths are preventable through available interventions.
5. This is a period of growth and development.
6. Brain growth is completed during 1st five years.
7. Most causes of morbidity are preventable by immunization.
8. Health of children under five years and family health are inter-related.
9. Likely to be neglected in the face of poverty and unregulated fertility.

Cause of Death in Children

The various causes of death in children are shown in Fig. - 1.

1. Pneumonia : Pneumonia kills more children than any other disease (19%), more than AIDS, malaria and measles combined. It is a major cause of child deaths in every region. Undernourished children, particularly those who are not exclusively breastfed or have inadequate zinc intake, or those with compromised immune systems, run a higher risk of developing pneumonia. Child suffering from other illnesses, such as measles, or those living with HIV, is more likely to develop pneumonia. Environmental factors, such as living in crowded homes and being exposed to parental smoking or indoor air pollution, may also play a role in increasing children's susceptibility to pneumonia and its consequences.

2. Diarrhoea : Diarrhoea is most common in children between 6 months and 2 years with highest incidence in the 6-11 months age when weaning occurs. The mortality is estimated at 4.9 children per 1000 per annum due to Diarrhoea in children under five in the developing regions. The ORS has reduced the burden of childhood mortality to a great extent.

3. Malaria : This is a major cause of death in Sub-Saharan Africa where it causes 25% of childhood mortality. It kills

about 1 million children accounting for 80% of all deaths due to malaria. It also contributes indirectly to deaths from ARI, anaemia, diarrhoea and malnutrition.

4. Measles : In India, measles is a major cause of morbidity and a major contributor to child mortality. It affects children between 6 months and 3 years. It tends to be severe in malnourished children. It weakens children's immunity to other life-threatening diseases and conditions, including pneumonia, diarrhoea and acute encephalitis, and remains one of the leading causes of vaccine preventable deaths among children.

5. HIV/AIDS : This is an emerging cause of childhood deaths especially in Sub-Saharan Africa. This accounts for 3% of all under five deaths.

Goal

The overall goal of the Under-Fives Clinic is to provide comprehensive health care to young children in a separate specialized facility.

The under five clinic is represented by traditional logo of a triangle with four internal triangles and an outer enveloping triangle as shown in the Fig. - 2.

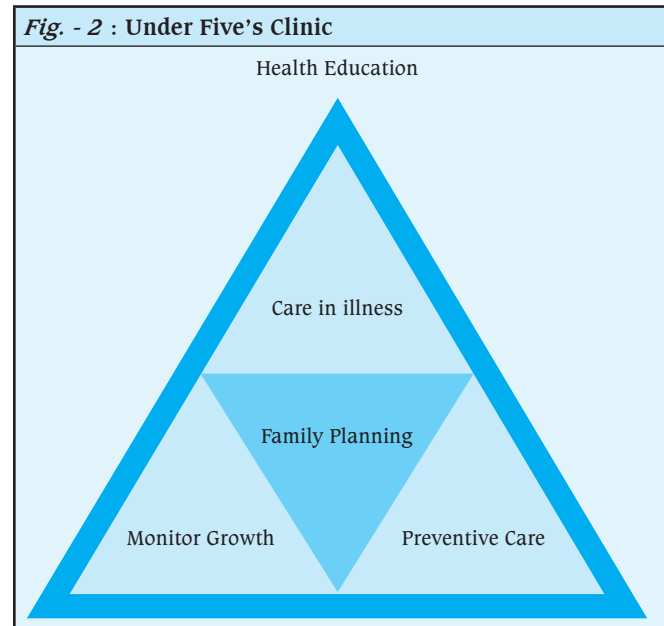

Objectives

1. Care in illness
2. Growth monitoring
3. Preventive care
4. Family Planning
5. Health education

Features

Under Five Clinics are specifically designed to serve children under the age of five in developing nations. It is important for the clinics to be as close to the residential areas as possible and for home visits to be a part of the services provided. Clinic visits also need to be kept as short as possible. The majority of the staff should be locally trained health care workers, nurses and auxiliary staff, who provide most of the care. The doctors on staff should be primarily responsible for training, diagnosis, and treatment of more complex conditions. When consultation with a senior staff person is necessary, the nurse

or auxiliary worker should be present and treated as an equal colleague. This procedure will encourage mothers to have more confidence in the skills of the locally trained worker. Mothers need education and support to institute practices that will minimize illness and promote health. Oral rehydration, breast feeding, and growth monitoring are all effective practices. Community health workers can also provide services, such as weighing, right in the residential areas. These workers should try to communicate with the key decision-makers in the child's family - mother, father and grandparents, to inform them of the child's nutritional needs.

Functions

(a) Care in illness : This is the felt need of the mother and child for which any child is brought to the clinic. The usual illnesses encountered in children under five are fever, diarrhoea, ARI, infections of the skin and helminthiasis. The facility should provide for essential laboratory investigations and X-ray facilities. The Clinic should be backed by an effective referral mechanism.

(b) Growth Monitoring : This is one of the most important functions of the clinic. The child is weighed periodically - every month during the first year, every 2 monthly from 1 to 3 years of age and every 3 monthly in 4th and 5th years. Besides weighing, measuring height, mid arm circumference can also be carried out depending upon the availability of trained manpower and equipments. The growth is plotted on the growth chart and any faltering in the growth is detected and suitable action initiated. The milestones are also recorded and any delay in achieving milestone is evaluated.

(c) Preventive Care : This involves primarily the immunization services during the 1st five years of life and vitamin A supplementation (1 lac IU at 18 months, 2 lac IU at 6 month interval thereafter upto 3 years of age) and administration of Iron supplementation and antihelminthic treatment to prevent anaemia. The preventive care also provides for regular health

check up, nutritional surveillance and use of ORS during Diarrhoea to prevent dehydration from developing.

(d) Family Planning : Family planning is central to any program directed towards women and children. The mothers are more receptive to family planning during early Puerperium and lactation. Mother is counselled on the various options available, their merits and de-merits so that she can make an informed choice.

(e) Health Education : The opportunity should be made use to educate the mother on issues of child care, breast feeding, nutrition, growth monitoring, immunization and hygiene of safe water and food preparation.

Child Health Programmes in India

In 1951, India was the first country in the world to launch a family planning programme. Since then approaches aimed at reducing population growth have taken a variety of forms. Till 1977, the major health activity was family planning which was changed into Family welfare programme with Maternal and Child Health becoming an integral part of family planning programme with the vision that reduction in birth rate has a direct relationship with reduction in infant and child mortality.

(a) The Diarrhoeal Disease Control Programme

This programme was started in the country in 1978. The main objective of the programme was to prevent death due to dehydration caused by diarrhoeal diseases among children under 5 years of age due to dehydration. Health education aimed at rapid recognition and appropriate management of Diarrhoea has been a major component of the CSSM. Under the RCH programme ORS is supplied in the kits to all sub-centres in the country every year.

(b) ICDS (Integrated Child Development Scheme)

The ICDS scheme was initiated by the then Ministry of Social and Women's Welfare on 02 Oct 1975, in pursuance of the National Policy for children. The Ninth Five Year Plan aimed to universalise ICDS, i.e. cover the whole country.

The beneficiaries of ICDS are -

- (i) Children below 6 years
- (ii) Pregnant and lactating women
- (iii) Women in the age group of 15-44 years
- (iv) Adolescent girls in selected blocks

The ICDS seeks to lay a solid foundation for the development of the nation's human resource by providing an integrated package of early childhood services. These consist of

- Supplementary nutrition
- Immunization
- Health check-up
- Medical referral services
- Nutrition and health education for women
- Non-formal education for children up to the age of 6 years
- Care of pregnant and nursing mothers

(c) Universal Immunization Programme

UIP against six preventable diseases, namely, diphtheria, pertussis, childhood tuberculosis, poliomyelitis, measles and neonatal tetanus was introduced in the country in a phased

manner in 1985, which covered the whole of India by 1990. Significant progress was made under the Programme in the initial period when more than 90% coverage for all the six antigens was achieved. The UIP was taken up in 1986 as National Technology Mission and became operational in all districts in the country during 1989-90. UIP became a part of the Child Survival and Safe Motherhood (CSSM) Programme in 1992 and Reproductive and Child Health (RCH) Programme in 1997. Under the Immunization Programme, infants are immunized against tuberculosis, diphtheria, pertussis, poliomyelitis, measles and tetanus. Universal immunisation against six Vaccine Preventable Diseases (VPD) by 2000 was one of the goals set in the National Health Policy (1983).

(d) The ARI Control Programme

ARI control programme was started in India in 1990. It sought to introduce scientific protocols for case management of pneumonia with co-trimoxazole. A review of the health facility done in 1992 revealed that although 87% of personnel were trained and the drug supply was regular yet there were problems in correct case classification and treatment. Since 1992 the Programme was implemented as part of CSSM and later with RCH. Cotrimoxazole tablets are supplied as part of drug kit for use by different category of workers for managing cases of Pneumonia. Under RCH-II activities are proposed to be implemented in an integrated way with other child health interventions.

(e) The Child Survival and Safe Motherhood (CSSM) Programme

This Programme jointly funded by World Bank and UNICEF, was started in 1992-93 for implementation up to 1997-98. The Child Survival and Safe Motherhood Programme was implemented in a phased manner covering all the districts of the country by the year 1996-97. The objectives of the programmes were to improve the health status of infants, child and maternal morbidity and mortality. The programme provided for augmenting various activities under the Oral Rehydration Therapy (ORT) Programme, universalising prophylaxis schemes for control of anaemia in pregnant women & control of blindness in children and initiating a programme for control of acute respiratory infection (ARI) in children. Under the safe motherhood component, training of traditional birth attendants (TBA), provision of aseptic delivery kits and strengthening of first referral units to deal with high risk and obstetric emergencies were taken up. Programme yielded notable success in improving the health status of pregnant women, infants and children & also making a dent in IMR, MMR and incidence of vaccine preventable diseases.

(f) Reproductive Child Health (RCH) Programme

Government of India during 1997-98 launched the RCH Programme for implementation during the 9th plan period by integrating Child Survival and Safe Motherhood (CSSM) Programme with other reproductive and child health (RCH) services. In addition, a new component for management of Reproductive Tract Infection (RTI) and Sexually Transmitted Infection (STI) has also been incorporated. The RCH Programme is partly funded by World Bank, UNICEF, UNFPA and European Commission. The program follows a differential strategy with

inputs under the program linked to the needs of the area coupled with the capacity for implementation. The details on the RCH are covered under separate chapter on RCH.

(g) IMNCI (Integrated Management of Neonatal and Childhood Illnesses)

This programme has been introduced on the principles of integrating all the services for management of sick children under 5 years of age. This is based on the fact that children have to be assessed as a whole for the entire important symptom complex and to be provided care and treatment involving the caregiver. Integration has different meanings at different levels. At the patient level it means case management. At the point of delivery it means that multiple interventions are provided through one delivery channel - for example where vaccination is used as an opportunity to provide vitamin A and insecticide-treated bednets during "EPI-plus" activities, boosting efficiency and coverage. At the system level integration means bringing together the management and support functions of different sub-programmes, and ensuring complementarity between different levels of care.

Childhood is the foundation of World's future. There has been a definite progress in improving the child survival, development and protection. The World must make more sustained, collective and focused efforts to realize the dream of 'World Fit for Children' and fulfill the promise of safe and healthy childhood for every child. The Millennium Development Goals, ratified by all UN member states, provide the world's governments with clear and tangible targets to combat poverty and raise the standard of living for the world's people by 2015. Early Childhood Development contributes to the achievement of the goals. Seven of the eight goals directly relate to child survival, growth and development. Research has shown that the most effective interventions to improve human development and break the cycle of poverty occur most in children's earliest years. Prevention is more cost-effective than treating a problem later. The important issues are ensuring positive gender socialization, supporting parents and families and developing standards and indicators for effective planning, monitoring and documentation of the progress in Early Childhood development.

Summary

Childhood is the foundation of world's future. Only six conditions account for 70% to over 90% of the total deaths in under 5 age group. Child death rate excludes infant mortality rate and is a better indicator of social situation in a country than the IMR where as under 5 mortality rate is considered to be the single best indicator of social development and well being. It measures the outcome of the development process and is a result of various inputs. Child survival index is calculated by subtracting under 5 mortality rate from 1000 and dividing this figure by 10. Its a measure of the social development and the attention given to the care of under 5 children. Evolution of the under 5 child health services passes through various models like primary health care model, vertical programmes model,

preventive model, breast feeding initiative, IMCI. Under fives is a special group with pneumonia, diarrhoea, malaria, measles and HIV/AIDS being attributed as the major killers in this age group. For this reason the under five clinics were established in developing nations with five major objectives of care in illness, growth monitoring, preventive care, family planning, health education. In 1951 India was the first country in the world to launch a family planning programme and in 1977 it was changed to family welfare programme with maternal and child health becoming an integral part of it. Various child health programmes have been launched namely the diarrhoeal disease control programme (1978), ICDS (2 Oct 1975), Universal Immunization Programme (1985), the ARI control programme(1990), the child survival and safe motherhood programme (1992-93), Reproductive child health programme(1997-98), IMNCI which has been incorporated in RCH programme. Seven of the eight Millennium Development Goals directly relate to child survival, growth and development.

Study Exercises

Long Question : Discuss various child health programmes.

Short Notes : (1) Child death rate (2) Under 5 mortality rate (3) Child survival index (4) Under 5 clinics

Fill in the blanks

- 1) Child death rate involves _____ age group
- 2) Child mortality rate involves _____ age group
- 3) CSSM was launched in year _____
- 4) Maximum number of children die because of _____ among the five major causes of mortality in under 5
- 5) IMR in India is _____ and Under 5 mortality in India is _____
- 6) The single best indicator of social development of a country is _____

Answers : (1) 1-4 yrs; (2) Less than equal to 5 yrs; (3) 1992; (4) Pneumonia; (5) 57/1000,74/1000 live births; (6) Under 5 mortality rate.

A S Kushwaha

School is a setting that plays an important role in the physical, emotional, social and mental development of children. Schools present an extraordinary opportunity to help millions of young people to acquire health supportive knowledge, values, attitudes and behavior. They can influence health behavior of other children, their families and community. School health services provide an opportunity to improve health of the students and promote healthful behavior through health education.

History

In India, the history of school health service can be traced back to 1909, when medical examination of school children was started in Baroda. This important issue of social value has been raised repeatedly in various forums but continues to be a neglected aspect of Community Health service till date. Bore committee in 1948 emphasized the need to put in place an organized system of school health service but this is still an unfulfilled dream. In 1953, Secondary Education Committee recommended medical examination and feeding of all school children to promote positive health early in the life as key to a healthy nation. The "National School Health Council" has been established since 1963 to plan and organize school children's health care. Provisions have been made in the municipal, cantonment and state regulations for organization and maintenance of a school health service.

The concept of school health service has undergone change from mere health check up to become a comprehensive service with elements of preventive, promotive, curative and rehabilitative services.

Global School Health Initiative (GSHI)

WHO's Global School Health Initiative was launched in 1995. The initiative is designed to improve the health of students, school personnel, families and other members of the community through schools.

Goal

The goal of GSHI is to increase the number of schools that can truly be called "Health-Promoting Schools".

Health Promoting School

WHO defines a health promoting school as one that is constantly strengthening its capacity as a healthy setting for living, learning and working.

Components of Comprehensive School Health Policy

- (a) School environment that is safe and promotes health
- (b) A sequential health education curriculum
- (c) A sequential physical education curriculum
- (d) Nutrition services programme
- (e) School Health Service programme
- (f) A counselling, psychological & social service programme
- (g) Integrated family and community involvement activities
- (h) Staff health promotion policy

School Health Service

The objectives of the school health care are as follows:

- (a) Help children in this critical period of their physical and mental growth.
- (b) Maintaining working efficiency at a high level and improving mental assimilating power by:
 - (i) Ensuring congenial working conditions.
 - (ii) Keeping them physically and mentally fit at all times.
 - (iii) Improving the general nutrition of the children.
 - (iv) Reducing absenteeism and thus increasing average study hours/days.
 - (v) Prevent spread of infections, reduce and detect minor ailments.
 - (vi) Imparting health education and physical training to children.
 - (vii) Providing special arrangement for the education of handicapped children.

Healthful School Environment

The environment at the school has an important influence on the health of the school children. The following points should be kept in mind as regards school premises.

1. School premises

- (a) The school should be located in areas free from crowded surroundings, away from market, butcheries, factories, disposal grounds for waste matters, public sanitary areas or enclaves, and such other places which may create a health nuisance.
- (b) There should be sufficient open space around the buildings.
- (c) Enough playgrounds should be provided. Free muscular activity reduces mental boredom and strain and provides a stimulus for growth.
- (d) There should not be any water collections for mosquito or fly breeding places around the school area.
- (e) Traffic should be restricted to the minimum so as to avoid noise, smoke and dust nuisance and mainly accidents.
- (f) Accidents should be prevented not only on roads around school but also on the playgrounds and in class rooms. First aid should be taught to all.

2. Seating Arrangement : These should be such as to allow adequate space, permitting freedom of movement for children on the bench so as to enable them to work without strain.

3. Drinking Water : It should be procured from an authorized clean source. Arrangements for central storage and safety must be provided. Ladles should be provided to take out water if taps are not possible.

4. Sanitary arrangements : A minimum of one urinal for 60 students and one latrine per 100 students should be provided. These should be maintained regularly and kept clean at all times. Adequate water supply should be arranged for sanitary block. Toilet facilities should be separate for boys and girls.

5. Nutrition services (Mid-day meal) : These should provide about one third of the total daily requirements of calories, proteins, vitamins 'A' and 'B' complex and calcium. They should provide about 20-30 g of fat, 20 g of protein of which one third should be of animal origin. Inclusion of milk in the

meals will ensure this requirement. The school meals not only aim at supplementing the nutritional requirement but also at inculcating healthy food and eating habits.

6. Canteen Facility : All schools have some facilities which provide eatables. This canteen must observe cleanliness and hygiene of food preparation. Selling of junk food items at canteen must be prohibited.

7. Vaccination : School settings provide suitable conditions for spread of communicable diseases droplet infections and gastrointestinal diseases. All diseases amenable to prevention by vaccination should be covered. Children should be immunized against typhoid group of fevers, diphtheria and tetanus as a routine. If and when facilities exist, immunization against poliomyelitis and tuberculosis by BCG should be carried out.

8. Health Check up : All children should be thoroughly examined at least once a year or three times during the curriculum in addition to the one carried out at the time of entry. Results are recorded in the health record card and parents should be advised regarding remedial action. There should be a permanent register and health cards with column for remarks against examination of each system. The card is meant to be transferred to the institution the child may go after leaving one institution. A monthly, quarterly and annual report must be sent to the coordinating authority and medical authorities. The special points, to look for during any check up, are given below:

- (a) Eyes for trachoma and vision (including tests for acuity of vision).
- (b) Ears for perforated drums, otitis media & hearing acuity.
- (c) Teeth for caries, non-alignment, mottling, gingivitis and so on.
- (d) Nose & throat for adenoids and enlarged/infected tonsils.
- (e) Chest for lungs, cardiac anomalies (congenital).
- (f) Abdomen for enlarged spleen, liver and any palpable lymph nodes.
- (g) Genitalia for phimosis, undescended testis or patent inguinal canal.
- (h) Lower limbs for skeletal & muscular defects/deformities.
- (i) Spine for any deformity.
- (j) Skin for ring worm, scabies & any de-pigmented patches.
- (k) Hair for pediculosis, dandruff.
- (l) Weight and height for age and sex and nutritional profile (anthropometry).
- (m) Any abnormal curvatures/postures, delicate health, nutrition etc.

9. Sick Reporting Facility : This should be provided and children are encouraged to report sick whenever they feel unwell. It not only helps to reduce minor ailments from developing into major ailments or disabilities but also helps to detect any other major ailments or disabilities undetected in the incipient or early stages. A trained staff is designated to provide necessary assistance whenever required. Availability of commonly required medications must be ensured at all times.

10. Referral Facilities : Facilities for reference of children to a specialist for investigation of ailments and their treatment/ hospitalization should be ensured. There should be arrangements for emergency transport and referral in case of

an emergency. The telephone number of the clinic or hospital should be known to the staff.

11. Physical Training : It is a major item of a school curriculum and should be insisted upon. Physical Training Instructors (PTI) should be appointed. Besides this if possible yoga trained teacher may also be appointed.

12. Health Education : This should be part of the curriculum. It can be imparted either as an integrated part of curriculum or otherwise. Health education is also incidentally acquired by children through the experiences and observation of healthy school life as described above.

13. School Health Committee : All schools must have a school health committee. It should consist of the Headmaster or Principal as the Chairman and class teacher, health educator, school nurse, physical training instructor and the school medical officer as its members. They should meet once a month or at least once in a quarter. A few parents should also be invited to attend these health committee meetings.

Management of Children with “Scholastic backwardness”

Once a child starts struggling with his studies, the school environment turns ‘hostile’ to him. He gets punished by the teachers and friends make fun of him. The young child is clueless as to why he cannot score like his classmates, in spite of effort. He reacts to all these the way children do - either, turn defiant and fight back, or swallow the insults and give up. A sensitive Teacher, sensitized to the various causes of poor school performance can turn out to be his saviour and guardian angel. She can identify the cause of this particular child’s failure and institute an appropriate remedial strategy. After ruling out visual impairment and hearing problems and mental and psychological deficiency, the child should be considered to be evaluated for learning disorders. It may first appear as behaviour problems : Attention deficit, Hyperactivity, naughtiness, defiance, aggression, addiction to TV or computer, forging progress reports, Tics, Obsessive disorders, Anxiety, Depression, School phobia etc. A Schematic algorithm for evaluation of a child with poor scholastic performance is given in Fig. - 1.

Notes :

1. Many normal children display some of these symptoms.
2. Not all LD children display all pointers.
3. Severe problems need multidisciplinary assessment.
4. LD - Learning Disorder; ADHD - Attention Deficit Hyperactive Disorder.

Educating ‘Special’ children

Categories of Disabilities

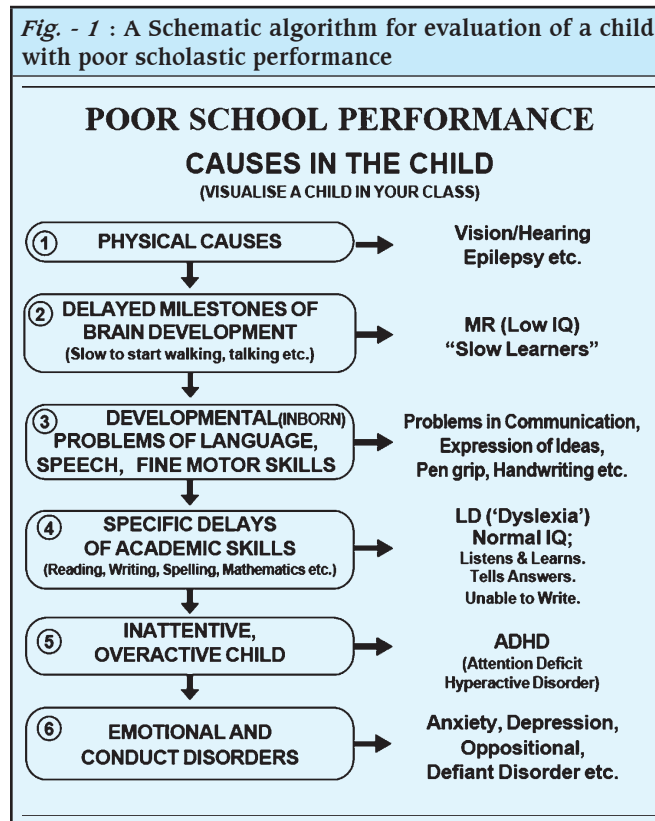

1. Physical Disability
2. Mental Disability
3. Developmental Disability
4. Learning Disability
5. Hearing Disability
6. Visual Impairment
7. Emotional Disability

Common disabilities

1. ADD/ADHD

2. Autism
3. Cerebral Palsy
4. Down Syndrome
5. Multiple Sclerosis
6. Muscular Dystrophy
7. Seizure Disorders

Fig. - 1 : A Schematic algorithm for evaluation of a child with poor scholastic performance

Special Schools in India : Along with other parts of the world, India too, witnessed the emergence of special schools for people with disabilities. The first school for the deaf was set up in Bombay in 1883, and the first school for the blind at Amritsar in 1887. There was rapid expansion in the number of such institutions. Today, there are more than 3200 special schools throughout India. However, these special schools have certain disadvantages which became evident as the number of these schools increased. These institutions reached out to a very limited number of children, largely urban, and they were not cost effective. But most important of all, these special schools segregated CWSN from the mainstream, thus developing a specific disability culture.

Integrated Education

The emergence of the concept of integrated education in India during the mid 1950s began by the Royal Commonwealth Society for the Blind, and the Christopher Blind Mission. The Ministry of Education, too, launched a comprehensive scholarship scheme in 1952, a rudimentary beginning of the integrated education initiative by the Government.

Integrated Education for Disabled Children (IEDC) : Consequent to the success of international experiments in

placing children with disabilities in regular schools, the Planning Commission, in 1971, included in its plan a programme for integrated education. The Government launched the IEDC scheme in December 1974.

The aim of IEDC is to :

- Provide educational opportunities to CWSN in regular schools.
- Facilitate their retention in the school system.
- Place children from special schools in common schools.

The scope of the scheme includes pre-school training, counselling for the parents, and special training in skills for all kinds of disabilities. The scheme provides facilities in the form of books, stationery, uniforms, and allowances for transport, reader, escort etc. Similar Scheme in US is known as 504 Plan, which is a legal document falling under the provisions of the Rehabilitation Act of 1973, designed to plan a program of instructional services to assist students with special needs who are in a regular education setting.

Project Integrated Education for the Disabled (PIED): Under PIED, there has been a significant increase in the number of not only mildly disabled, but also severely disabled children, with the number of orthopaedically handicapped children far outstripping other disabled children. All these perform at par with non - disabled children; in fact their retention rate is higher than that of non - disabled children and absenteeism is low. PIED has also had a positive impact on the attitudes of the teachers, the heads of schools, as well as parents and the community in general. Also, the interaction between the disabled and the non - disabled children is good.

DPEP estimates clearly showed that there were a large number of disabled children in the relevant age group. Gradually realization dawned that UPE could not be achieved unless children with special needs were also brought under the ambit of primary education. This led to more concrete planning and strategization of providing resource support and remedial assistance to children with special needs. As the programme progressed, many models of service delivery evolved with the sole aim of providing supportive learning environment to children with special needs. The thrust was on imparting quality education to all disabled children.

The steps needed for implementation of IED under SSA (*Sarva Shiksha Abhiyan*) are classified under three headings:

1. Direct Services to Children.
2. Support Services.
3. Monitoring and Evaluation.

This is an important aspect for assessing progress and providing improvement in the process.

Summary

School plays an important role in the physical, emotional, social and mental development of children. The medical examination of school children was started in Baroda in 1909. The "National School Health Council" has been established since 1963 to plan and organize school children's health care. WHO's Global School Health Initiative (GSHI) was launched in 1995. The goal of GSHI is to increase the number of schools that can truly be called "Health-Promoting Schools". The

concept of school health service has undergone change from mere health check up to become a comprehensive service with elements of preventive, promotive, curative and rehabilitative services that must include elements of safety, health education, physical education, nutrition and counselling and social service programme. A healthful school environment should be provided with due consideration to premises, seating arrangement, drinking water, sanitary arrangement, mid day meal, canteen, vaccination, sick reporting with referral facilities, physical education and health education which are to be monitored and supervised by a school health committee. Management of the children with scholastic backwardness should be proper as per algorithm for the evaluation of a child with poor scholastic performance. The Planning Commission, in 1971, included in its plan a programme for integrated education of disabled children in regular schools. The Government launched the IEDC scheme in December 1974. The steps needed for implementation of IED under SSA (Sarva Shiksha Abhiyan) are classified under three headings namely direct services to children, support services, monitoring and evaluation. School health services can influence health behaviour of other children, their families and community.

Study Exercises

Long Question : School health services in India

Short Notes: (1) GSHI (2) Healthful school environment (3) Causes of poor scholastic performance in school children (4) IEDC

MCQs & Fill in the blanks

- 1) National School Health Council was established in _____
- 2) Global School Health Initiative was launched in _____
- 3) The first school of deaf in India was setup in (a) Bombay (b) Calcutta (c) Delhi (d) Bangalore
- 4) The first school of blind in India was setup in (a) Bombay (b) Calcutta (c) Delhi (d) none
- 5) IEDC scheme was launched in India in the year _____
- 6) The medical examination of school children was started in _____ In the year _____

Answers : (1) 1963; (2) 1995; (3) a; (4) d; (5) December 1974; (6) Baroda, 1909.

A S Kushwaha

Adolescence is a critical period of life marked by biological, social and psychological changes for an individual. These are formative years for behaviour patterns and activities relevant to health. It is a period of major transition during which adolescents learn to become adults. They can benefit from guidance in respect of vital issues of human biology, health, disease and behavioural adaptation. Recent discoveries in biological, behavioural, clinical and epidemiological research have clarified the concepts of this transition. The lifestyle and behaviour developed during adolescence has an impact on the health not only during adolescence but even in later life. In fact, the bulk of morbidity and mortality in adulthood is due to the health related behaviours (smoking, alcohol, exercise and diet) developed during the adolescence. The major issues concerning adolescents are growth and development, STDs and RTIs, drug, alcohol and tobacco abuse, teenage pregnancy, abortion, RTAs, suicide, homicide and issues of behavioural problems. HIV is

the latest addition to the multiple dimensions of adolescent health with huge implications on their health. Unfortunately, the special needs of adolescents' have not been addressed by the educational, health, and family welfare programs in India so far.

Definition of Adolescence

The word 'Adolescent' has been derived from Latin word '*Adolescere*' which means 'to grow to maturity'. Adolescent is considered to be, no longer a child, and not yet an adult. The definitions vary as to the exact range of age for this period. Most cultures relate the beginning of adolescence to the onset of puberty, but differ on specifying the end of adolescence. Different cultures define the roles, responsibilities and prerogatives of adults differently and thus the above variation. Thus in certain societies, an individual may have attained biological maturity but may not have attained full adult status. The chronological definition of adolescence has been kept broad so that it can be used in a variety of socio-cultural and health settings. WHO defines Adolescence as 10-19 years old, 'Youth' as 15-24 years old and 'Young People' as 10-24 years old. The adolescence has been divided into two phases: 'early' (10-14 years) and 'late' (15-19 years).

The need to focus on Adolescent Health is because

- (a) Adolescents face serious health challenges
- (b) Adolescent health and development affect economic prosperity
- (c) Investing in youth helps to break cycle of poverty
- (d) Health is a key element of overall youth development
- (e) Young people have a right to health

Adolescents : A special group with special needs

The need to focus on adolescent health exists for a number of reasons. (See Box 1)

Box - 1 : Why Adolescents are a special group?
Because of their number: they constitute more than 22% of the population.
Adolescence is the period of rapid physical growth, sexual and psychological changes.
Habits and behaviour picked up during adolescence (risk taking behaviour, Substance abuse, eating habits, conflict resolution) have lifelong impact.
Adolescence is the last chance to correct the growth lag and malnutrition.
Many adolescent boys and girls are sexually active but lack information and skill for Self- protection.
They have simple but wide pervading crucial reproductive health needs - Menstrual hygiene, contraception (including emergency contraception) safety from STI and HIV.
Communication gap exists with parents and other adults.

Some Basic Physiological & Psychological Needs

1. Growth and Development : The early part of adolescence is characterized by rapid physical growth, changes in psychological functions and organ systems of the body and completion of sexual development. During adolescence marked morphological changes occur and hypothalamic-pituitary-gonadal system becomes mature. The ovaries and testes produce enough steroid hormones which result in the growth of genital organs and appearance of secondary sex characters. The body composition changes and there is increased strength and efficiency of body energy production. In adolescence these variations are exceedingly large within the same individual and between different individuals. This aspect needs to be understood by the adolescents, their families, health professionals in particular and society in general. The puberty in females is earlier as compared to males. Many adolescent boys and girls are sexually active but lack information and skills for self-protection (low level of information on Family Planning, low contraception use). They have simple but wide ranging crucial reproductive health needs- menstrual hygiene, contraception (including emergency contraception) safety from STI and HIV.

2. Nutritional and Psychosocial Needs : The adolescents in developing countries may suffer from malnutrition and dietary imbalance while those in developed countries may have problems of obesity. Adolescents have greater nutritional requirements because of rapid growth and physical activity

level. During this period that adolescents gain up to 50% of their adult weight, more than 20% of their adult height and 50% of their adult skeletal mass. In under-nourished children rapid growth during adolescence may increase the severity of under-nutrition. Iron is deficient in almost all age groups. Naturally the shortfalls create more vulnerability for adolescent girls. The factors that may interfere with nutrition are inadequate food supplies in quantity and quality, psychological factors affecting appetite, food fads and cultural attitudes and infections and parasitosis.

Adolescence is a period of change and, consequently, one of stress, characterized by uncertainties in regard to identity and position in the peer group, in the family, in the society at large and in the context of one's own responsibilities as an adult. The compulsions of parental approval often encounter the emerging aspirations for independence. Their behaviour is guided by an intense desire for independence and identity. In the process, adolescents undergo intense psychological stress and personality change.

3. Socio-Cultural Factors Affecting the Development : In most parts of the world, especially developing world, girls are deprived of nutrition, access to health care, and opportunities for education and employment. They are taken out of schools when they reach menarche. In most traditional societies, from the very beginning of life, girls are groomed to accommodate the male-dominated, patriarchal society. With the rising proportion of children attending school and ever increasing functions of education, opportunity to facilitate healthy development of adolescents has opened up in many developing countries. Increasing urbanization, globalization, cosmopolitan type of population, explosion of information technology, pervasive scientific attitude and changing social and cultural values in the evolving society affect the psychological development of an adolescent.

Health Problems of Adolescence

Though adolescence is a relatively healthy period in the life of an individual with lowest age specific mortality (NFHS-3); however, it has certain characteristics that put them at risk to health hazards specific to this age group. The health problems of the adolescents relate to a large extent to their growth and development, sexual maturation, psychological changes. These issues are not discussed with the parents and health professionals due to lack of privacy and confidentiality and thus remain either unresolved or attempts are made through peers and available media which may not always be helpful and appropriate. The adolescent, because of rapid biological-psychosocial changes, is prone to impulsivity, emotional and risk taking type of behaviour putting them at risk to problems like STDs/RTIs, accidents, drug and substance abuse and psychological and mental health disorders.

The health care system have provided for health of the children and adults but adolescents have been left out, without any specific health programmes directed towards them especially in developing nations where resources are scarce. However, of late this special group of population has been given some attention in the post HIV period as the adolescents constitute highly vulnerable group

Behaviour Related Health Problems

Alcohol, Smoking and Drugs : The adolescents tend to experiment with alcohol, smoking and other drugs. The use of tobacco and alcohol is widespread in both developing and developed nations. 30-50% of high school students in USA consider use of marijuana as an accepted way of life. In Sweden, drug dependence reaches its peak in the age group 12-20 years. The factors responsible for smoking in young people are peer pressure, following example of sibling and parents and employment outside the home.

Dietary Habits : Inappropriate dietary habits in adolescence are also commonplace. They tend to consume junk food and imbalanced diet more than any other age group. They may also develop habit of compulsive eating at one end and anorexia nervosa at the other end of spectrum.

Sexual Behaviour : Sexual indiscretion, lack of education on skills of responsible sexual behaviour and urge for experimentation can lead to myriad of problems ranging from unplanned pregnancy, STDs, HIV, unwed mothers, illegal abortions, psychological breakdowns and complex social problems.

Risk Taking Behaviour : Adolescent males tend to challenge difficulties without taking the danger into account to the extent that most adults would. This impulsive risk taking behaviour has implications for health of the adolescents, whether the activity is driving a vehicle, sports, any work or various health related behaviours like drugs, alcohol or sexual urge.

Adolescence - A Stressful Transition Period

The world in which adolescents of today live is marked by vastness as far as mobility is concerned and rapid technical and social changes. This demands a great degree of adjustments and adaptation by the adolescents who are undergoing rapid biological-social-psychological transition. The adolescents tend to explore actively in seeking information on new situations, new roles and future difficulties.

Adolescent Health : Global Scenario

The health of the adolescents can be measured by studying age specific morbidity, mortality, prevalence of behavioural disorders and DALYs. This relatively healthy phase of life must also be seen in the light of barriers to health seeking behaviour and under-reporting of adolescent related data in the developing countries. However, DALYs has been found to be most suitable indicator for the purpose of international comparison. More than 33 percent of the disease burden and almost 60 percent of premature deaths among adults can be associated with behaviours or conditions that began or occurred during adolescence - for example, tobacco and alcohol use, poor eating habits, sexual abuse and risky sexual behaviour (WHO 2002). Adolescence-related risk factors are a greater problem in wealthier countries, largely because of the relatively greater impact of smoking and diet-related risks in those countries, though the prevalence of these risks is expanding rapidly in many low - and middle-income countries.

Indian Scenario

Awareness on Common Health Issues : There is a lack of knowledge and awareness amongst adolescents about

important health issues and problems that affect them. An Indian Council of Medical Research (ICMR) study showed that knowledge and awareness about puberty, menstruation, physical changes in the body, reproduction, contraception, pregnancy, childbearing, reproductive tract infections, Sexually Transmitted Infections (STIs), and HIV was low among boys and girls, especially in younger adolescents (ages 10-14). The study reported, however, that older adolescents (ages 15-19) had better knowledge. About 80 percent had knowledge of STIs, including HIV.

Education : Only 83 percent of primary-school age children (6-10 years) attend school. School attendance drops to 75 percent for children aged 11-14 years and is only 41 percent for children age 15-17 years. Education is linked to delayed marriage and childbearing and better outcomes besides decreased fertility.

Marriage, Sex & Reproductive health : The importance of reproductive health of adolescents is receiving increased attention due to multiple factors- they are almost ¼ of the population, they are going to be parents of the next generation and HIV has provided the necessary impetus to this important issue. The fall in age at menarche and increased age at marriage coupled with changing social-cultural values and attitudes has increased the potential of pre-marital sexual activity. The effect of increased urbanization, migration, economic independence and declining family influence has provided suitable conditions for increased exposure of the young people to risky sexual behaviour.

High fertility rates, high rates of teenage pregnancy, high risk of STI/HIV and poor nutritional status are the main health problems among the adolescent population in India (4,5). The median age at first marriage among women is 17.2 years. Among young women aged 15-19 years, 16 percent have already begun childbearing. Of those who seek medical termination of pregnancy, 8-10% are teenage mothers and unmarried girls.

Public Health Implications

The public health implications of adolescent health are far reaching and have intergenerational effects as well. (See Box - 2)

Box - 2 : Public Health Implications of Adolescent Health
Mortality in Adulthood : The 70% of the mortality in adulthood is linked to habits picked up during adolescence (risk-taking behaviour, substance abuse, eating habit and conflict resolution.)
Intergenerational Effects : Prevailing malnutrition, anaemia, stunting and lack of immunization have adverse impact on MMR, IMR and morbidity.
Adolescent Sexuality : Leads to adolescent pregnancy, unsafe abortion, RTI, STI/HIV and social problems.
Adolescent Pregnancy : In this the risk of adverse outcome (IMR, MMR LBW babies) is higher.
Risk Taking Behaviour : Lack of "connectedness" with parents and other adults prevents transmission of health messages and crucial skills leading to adoption of risky behaviour, substance abuse, early sexual debut and STI, HIV etc.

Interventions

Improving the health of young people is a complex and difficult issue. Programs will have to seek multi-sectoral solutions that link health sector interventions with other types of interventions delivered through other sectors, either at the program level or at the policy level. Research has created international consensus over a multi-pronged intervention approach based on the following principles (Box - 3).

Box - 3 : Principles of Health Programming for Adolescents
Recognize the <i>diversity</i> of the youth age group.
<i>Involve</i> young people.
Design <i>comprehensive</i> programs
Make health services <i>Youth Friendly</i> .
<i>Address gender inequality</i> of Women.
<i>Address the needs of boys</i> .
Address <i>non-health factors</i> that influence health
Address underlying <i>risk and protective factors</i> .

(a) Life-Skills and Health & Sexuality Education in Schools: Well designed, well-implemented sexuality and reproductive health education can provide young people with a solid foundation of knowledge and skills to enable them to engage in safe and responsible sexual behaviour.

(b) Peer Education : Peer education programs are especially appropriate for young people who are not in school and for hard-to-reach, at-risk subsets of the youth population including, sex workers and street children.

(c) Mass Media and Community Mobilization : Mass media and community mobilization efforts that engage influential adults, such as parents, teachers, community and religious leaders, and music and sports stars, can help normalize positive adolescent behaviours and gender roles as well as direct young people to appropriate health services.

(d) Youth Development Programs : Youth development programs typically address a range of key adolescent needs, including life skills, education, jobs, and psychosocial needs. Programs with a voluntary community service component have successfully improved key reproductive health behaviours, but no evidence is available for developing countries.

(e) Clinical Health Services : Although some young people seek care through the formal health system, many others are deterred by the often judgmental attitudes of health workers, particularly when seeking care and advice on matters related to sexuality.

(f) Social Marketing : This approach involves the use of public health messages to promote healthy behaviours and the use of condoms and other health products and services. Effective programs bring products and services to places in the community that young people frequent, such as shops, kiosks and pharmacies.

(g) Workplace and Private Sector Programs : Programs that reach young people do so at their places of work and through

private channels, such as pharmacies and for-profit medical services, where many young people prefer to seek care.

Initiatives in India for Health and Development of Adolescents

The Government of India has identified “*Survival, Protection, and Development*” as a major theme, focusing on gender-specific needs. This was a conscious effort to ensure equitable rights, opportunities, benefits, and status to girl children as part of National Plan for the SAARC decade of the Girl child.

Realizing for the first time, the importance of this population sub group, the Planning Commission has set up a Working Group for the Welfare and Development of Adolescents, to provide inputs into the Tenth Five Year Plan. Most importantly, policies and programmes need to cover the entire range of health and related problems of adolescents and not confined to education and service delivery for reproductive health alone. The Working Group proposed an allocation of at least Rs.112 crore for the Tenth Five Year Plan for the schemes for adolescents to be implemented by the nodal Ministry (Ministry of Youth Affairs & Sports). The adolescents have been recognized as valuable human resource with certain rights.

The initiatives taken under inter-related issues concerning adolescents under various schemes are given as under-

1. National Policy on Education (1986 modified in 1992):

The main emphasis in the National Education Policy is on the eradication of illiteracy and universalization of primary education. Education helps to develop adolescent health by delaying marriage, childbearing while generating positive health behaviour.

2. National Population Policy : They are specifically referred to in the sections on information, nutrition, contraceptive use, STDs and other population-related issues. There is a special mention about developing a health package for adolescents and enforcing the legal age at marriage.

3. National AIDS Prevention and Control Policy : Since unprotected sex is a major source of AIDS and adolescents form a significant portion of the sexually active population, they should form a special focus group under the Policy. While the policy talks about programmes for adolescents like University Talk AIDS and NYKs, surprisingly, the policy does not specifically mention adolescents. One can say that even without specifically mentioning adolescents, the policy is crucially relevant to them and aims at addressing their needs.

4. National Nutrition Policy (1983) : The National Nutrition Policy has focused on adolescent girls and that too only in relation to the importance of their role as mothers and housewives. Adolescent boys do not find any mention in the policy. The need for the well being of adolescents, as a group has not been recognized. ICDS is providing supplementary nutrition to adolescent girls (Kishori Shakti yojna) but the coverage is abysmally low (3%). The 10th Five Year Plan and Nutritional Policy proposed a nutritional program for girls weighing less than 35 Kg and for pregnant women weighing less than 45 Kg and below poverty line, who would get ration of Rs 6/- per month in the form of wheat or rice, through the Public Distribution System. The adolescent girls need

appropriate nutrition, education, health education, training for adulthood, training for acquiring skills as the base for earning an independent livelihood, training for motherhood, etc. Similarly on the other side their potential to be a good community leader has to be realized. A scheme for adolescent girls in ICDS was launched by the department of Women and Child Development, Ministry of Human Resource Development in 1991.

All adolescent girls in the age group of 11-18 years receive the following common services:

- (a) Immunization
- (b) General health check up once in every six months
- (c) Training for minor ailments
- (d) Deworming
- (e) Prophylactic measures against anaemia, goiter, vitamin deficiency, etc.
- (f) Referral to PHC/District hospital in case of acute need
- (g) Watch over menarche

5. National Policy for the Empowerment of Women (2001) : The policy has recognized the girl child as a separate category and adolescent girls seem to be covered there under. The policy relates to their nutrition, education, holistic approach to health, violence against them, sexual abuse of them and the rights of the girl child.

6. Reproductive & Child Health : The special package of interventions for adolescents under RCH are-

- (a) One booster dose of TT at the age of 16 & immunization of girls against Rubella.
- (b) Sex education to promote responsible and healthy reproductive & sexual behaviour.
- (c) Prevention of STD/HIV and AIDS.
- (d) Adult Literacy especially among women.
- (e) Vocational training.
- (f) Pre marital counselling.
- (g) Gender equality.
- (h) Family life education.

It will be seen from the above that the present policies address specific sectors like education, health, family welfare, nutrition, HIV/AIDS, sports etc. or address certain population groups like women, children and youth. None of the policies however take an integrated and holistic view of adolescents. Adolescents in difficult circumstances like adolescents with disabilities, learning disorders, adolescent sex workers or children of sex workers and street children need much more visibility in policies.

Specific Programs on Adolescents

Brief of some specific programs initiated by governmental and non-governmental organization directed towards adolescents in India is given below-

1. Kishori Shakti Yojana : To improve the health and nutritional status of girls by supplementary nutrition, anaemia prophylaxis under ICDS. Poor coverage of the target population is the limitation of this programme.

2. Balika Samridhi Yojana, 1997: This scheme works to raise the status of girl children born in families below the poverty line by providing financial help to these families. Some specific

criteria have been laid down to provide financial assistance to the mother of a newborn girl child in the form of grants and investments through a postal financial instrument to be applied toward the education and economic independence of that child. The deposit will mature and be paid to the girl if she remains unmarried until she reaches 18 years of age. This helps to delay the age of marriage.

3. National Service Scheme (NSS) : NSS was launched in 1969 with a primary focus on students' personality development and community service. NSS involved more than 1.6 million student volunteers from more than 175 universities and 22 senior secondary councils. The scheme's programs include "regular activities" and "special campaign programs."

4. Bharat Scouts and Guides : It is the third largest youth organization in the world. Scouting and guiding movements aim to develop boys' and girls' characters with the goal of making them good citizens of India. It inculcates in them a spirit of patriotism and promotes balanced physical and mental development.

5. Child Labour Projects : The Ministry of Labour is running 76 national Child Labour Projects in the country.

6. Integrated Program for "Street Children" : The Ministry of Social Justice and Empowerment has been implementing this program since 1992-93. One of the important initiatives under the program's revision in 1998 was the establishment of the Child Help Line Services in a number of cities. The Child Help Line provides emergency assistance to children.

7. Population Council : The Population Council has supported initiatives on adolescent transition in different states in collaboration with several NGOs. The Population Council supported programs on adolescence run by Mahila Samakhya in Karnataka and Andhra Pradesh and in the state of Haryana, *Apni Beti Aapna Dhan* and services in the areas of personality development, education, health, reproductive health, economic participation, and life skills training.

8. International Centre for Research on Women (ICRW): ICRW is coordinating a multi-site intervention and research program to develop effective programs for adolescent sexual and reproductive health and development in India. The studies confirmed that a lack of power, decision making opportunity, autonomy, and access to resources underlie the reproductive health risks faced by adolescents, particularly adolescent females, and those who are unmarried.

9. Centre for Development and Population Activities (CEDPA) : CEDPA, An international NGO with operations in Delhi, in collaboration with local NGOs, UNFPA, UNESCO and USAID, has adapted "Choose a Future: Issues and Options for Adolescent Boys" to the Indian cultural context and is currently implementing programs in 11 states.

10. Planned Parenthood Federation : Planned Parenthood has promoted four major projects with the help of local NGOs:

(a) Improving the Reproductive Health of Young Women and Men : The goal of the project is to improve the lives of adolescents and youth by providing contraceptive services and sexuality education in 20 rural villages in a district in West Bengal with a local NGO.

(b) Couple to Couple : The project employs peer couples to work with groups of newlyweds and other young couples to motivate them to increase gender awareness, encourage supportive relationships, and plan for their new families together.

(c) Improving the Reproductive Health of Adolescents and Youth : Located in Jharkhand state, the project aims to increase young people's knowledge and understanding about sexuality and reproductive health and help them develop communication and decision-making skills so that they may lead healthy reproductive lives.

(d) Reproductive Health Through Advocacy and Services: The project is a part of a larger program to improve the reproductive health and rights of adolescents and youth in the Indian states of Bihar and West Bengal.

National Youth Policy, 2003

The National Youth Policy, 2003 reiterates the commitment of the entire nation to the composite and all-round development of the young sons and daughters of India. This Policy covers all the young people in the country in the age group of 13 to 35 years. The age group is, therefore divided into two broad sub-groups viz. 13-19 years and 20-35 years.

Strategy

1. Youth empowerment

- (a) Attainment of higher educational levels and expertise by the youth, as per their abilities and aptitudes, and access to employment opportunities accordingly.
- (b) Adequate nutrition for the full development of physical and mental potential and the creation of an environment which promotes good health.
- (c) Protection from disease agents and unwholesome habits.
- (d) Development of youth leadership.
- (e) Equality of opportunity.

2. Gender Justice : The Policy recognizes that prevailing gender bias is the main factor responsible for the poor status of health and economic well-being of women in our society. The Policy enunciates that:

- (a) Every girl child and young woman will have access to education and would also be a primary target of efforts to spread literacy.
- (b) Women will have access to adequate health services and will have full say in defining the size of the family.
- (c) Domestic violence will be viewed not only as violation of women's freedom but also as that of human rights.
- (d) All necessary steps should be taken for women's access to decision-making process, to professional positions and to productive resources and economic opportunities.
- (e) Young men, particularly the male adolescents shall be properly oriented, through education and counselling to respect the status and rights of women.

3. Inter-Sectoral Approach : The Policy recognizes that an inter-sectoral approach is a pre-requisite for dealing with youth-related issues.

4. Information & Research Network : The Rajiv Gandhi National Institute of Youth Development (RGNID) will serve as the apex Information and Research Centre on youth development issues. There is a crying need to have valid data

on health of adolescents in India. Priority Target Groups under the policy are given in Box - 4.

Box - 4 : Priority Target Groups
<ul style="list-style-type: none"> ● Rural and Tribal Youth ● Out-of-school Youth ● Adolescents particularly female ● Youth with disabilities ● Adolescents under special circumstances like victims of trafficking; orphans and street children.

Implementation Mechanism : The Union Ministry of Youth Affairs & Sports (with the guidance of this Committee) will be the Nodal Ministry for all such programmes and schemes and will oversee the implementation of the provisions of this Policy. A National Youth Development Fund will be created through contributions, including from Non-Governmental Organizations, which would be utilized for youth development activities.

Life Skills Education

Life skills have been defined by World Health Organization as *'the abilities for adaptive and positive behaviour that enable individuals to deal effectively with the demand and changes of everyday life'*. Life skills are abilities that help to promote mental well being and competency of young people to face the challenges of life. Effective acquisition of life skills can influence the way one feels about oneself and others and can enhance one's productivity, efficacy, self-esteem and self-confidence. Life skills can also provide the tools and techniques to improve interpersonal relations.

There are three kinds of life skills : *Thinking skills, social skills and negotiating skills*. Thinking Skills include problem solving, thinking critically, processing information and exercising choice, making informed decisions and setting goals. Social skills include appreciating/validating others; building positive relationship with peer groups and family; listening and communicating effectively; taking responsibility; and coping with stress. Negotiating skills include self realization that enables an individual to understand ones values, goals, strengths and weaknesses. Thus, negotiating skills need to be enhanced at two levels - within oneself and with others. *Adolescents need to learn to be assertive, including learning to say "no" to adopt risky and harmful behaviour like drug use or casual sex before marriage*. During adolescence, life skills development is an active process. Despite superior intellectual abilities, the adolescent's behaviour is occasionally influenced by emotions rather than by rational thinking. Frequently the adolescent is in an emotional dilemma of wanting to be guided by parents, yet wishing to be free from them, and more aligned to their peers. They also have the need to exercise skills to indicate and establish their individuality and independence. This becomes complex, as an adolescent has multiple situations to deal with. Many critical issues arise during adolescence like - puberty, dealing with sexuality and gender issues, tackling emotional upheaval, finishing education, need to make future career choices, facing responsibilities as an adult, etc. Hence, Life Skills Development is of immense value to the adolescents

in managing their lives. It is recommended that 30 to 45 day 'Life Skills Development Programmes' be organized by NGOs/NYKs/other community groups for both school going and out of school adolescents. Adolescents who go through such a training programmes could thereafter be used as peer educators. Education of adolescents on family life is an important exercise as they are the parents of tomorrow. It is defined as "an educational process designed to assist young people in their physical, social, emotional and moral development as they prepare for adulthood, marriage, parenthood, ageing as well as their social relationship in their socio cultural context of the family and society" (UNESCO).

Counselling

Counselling is a process of enabling and empowerment to help a person in problem solving and crisis management. This may be required at different stages of life. One of these stages is the period of adolescence when adolescents are usually either in school or college or out of school as 'drop-outs' and 'left-outs'), and therefore the need and importance of counselling is highest during this period and for these groups.

Adolescents in Difficult Circumstances

Adolescents in difficult circumstances are those who belong to special groups like drug addicts, adolescents with AIDS and adolescents with parents afflicted by AIDS, adolescent prostitutes and children of the same, juvenile delinquents and adolescent victims of crime, street adolescents, neglected juveniles and adolescents who are physically and mentally challenged. Any intervention to address adolescents must also keep in mind the environment in which adolescents live - their families and society. It is equally essential for any intervention aimed at adolescents in difficult circumstances, to address the parents and families of these adolescents. Needless to say a holistic and integrated approach has to be adopted.

Juvenile Delinquency

It refers to a large variety of behaviour of children and adolescents which the society does not approve of and for which some kind of admonishment, punishment or preventive and corrective measures are justified in public interest.

- Juvenile- '*Juvenis*'- young - boy who has not attained 16 yrs, girl aged less than 18
- Delinquent - "*delinquere*"
 - A child who has committed an offence
 - All deviations from normal youthful behaviour

This includes all children who are incorrigible, ungovernable and habitually disobedient and who desert their homes, with behavioural problems and anti-social practice. The term 'juvenile' has been defined in clause (h) of Section 2 of the Juvenile Justice Act, 1986, as a boy who has not attained the age of sixteen years or a girl who has not attained the age of eighteen years. Offence under clause (n) of Section 2 of the above Act means an offence punishable under any law for the time being in force which includes the Narcotics Drugs and Psychotropic Substances Act, 1985 and the Terrorist and Disruptive Activities (Prevention) Act, 1987.

A child becomes a criminal through the interaction of many causes, social and individual, familial, psychological and economic. In order to rehabilitate the juvenile delinquent as

a healthy member of society, it is necessary to understand all these causes and remove them through improving family life, proper schooling, reducing harmful peer influences, and social welfare services. Under the Juvenile Justice Act, 1986, separate provisions have been laid down for the neglected and uncontrollable juveniles. They are dealt with by the Juvenile Welfare Boards and not by Juvenile Courts.

Common Problems seen in Juvenile Delinquents

1. Behavioural problems e.g. lying, stealing, gambling aggressiveness, destructiveness, disobedience, over activity.
2. Learning disabilities.
3. Emotional problem e.g. depression, school refusal, fears, timidity, shyness.
4. Adjustment reactions e.g. school related problem, grief.
5. Development disorder e.g. autism, bedwetting & soiling.
6. Intellectual deficit.
7. Psychosomatic disorders.
8. Bizarre and abnormal behaviours.
9. Relationship (including parent-child, sibling and marital) problem.
10. Socio-legal issues and problem e.g. child custody assessment, sexual offences, child abuse and head injuries.
11. Other e.g. eating and sleep disorders, sexual problems in adolescence, tics (movement disorder) & stress reaction.

Prevention & Management of Juvenile Delinquency

- Improvement of family life
- Life Skills development
- Schooling
- Social welfare services - Child guidance clinics, juvenile court, Child placement (Orphanages, Foster homes, Borstals, Remand home)

Child Guidance Clinic (CGC)

The concept originated in USA when Child Guidance Clinic was started in 1909 in Chicago. These were originally intended to deal with juvenile delinquency. Now the concept has been widened to also deal with those children who are not adjusted with their environment. The basic objective of these clinics is to prevent children from becoming neurotics, psychotics, criminals in later life by offering a gamut of services provided by a team which may include-

- Psychiatrist
- Clinical psychologist
- Educational psychologist
- Psychiatric social worker
- Public health nurse
- Pediatrician
- Speech therapist
- Neurologist

The composition of the team is variable depending on the need and the resources available.

The clinic offers a number of services for these children. Psychotherapy is central to all other services provided.

Services

- Psychotherapy- core of services
- Physical health

- Children's One-Stop Psycho-Educational Services (COPES)

Treatment

- Medical treatment
- Individual psychotherapy
- Family and marital therapy
- Behavioural / Cognitive therapy
- Occupational therapy
- Group therapy
- Play therapy
- Social case work

Prevention : The preventive measures are based on the belief that juvenile delinquents are shaped by the socio-economic-cultural influences on a vulnerable child. A stable, emotionally fulfilling and healthy family environment is the best vaccine against this disorder. School plays an important role in shaping the behaviour of a child and healthy interaction with teachers and peers will result in a child who is emotionally balanced and mentally healthy. The role of developing life skills and family life education cannot be overemphasized.

Juvenile Justice (Care and Protection of Children) Act (2000)

Background

1. The constitution in Articles 15, 39, 45 & 47 has imposed on the state a primary responsibility of ensuring that all the needs of children are met and that their basic human rights are fully protected.
2. Convention on the rights of the Children adopted by UN general assembly in 1989.
3. Government of India ratified the convention in 1992.
4. United Nations Standard Minimum Rules for the administration of Juvenile Justice, 1985 (Beijing rules) and UN rules for the protection of Juveniles deprived of their liberty (1990).
5. Juvenile Justice Act 1986.

Earlier the Children Act, 1960 amended in 1977 laid down that delinquent children needed to be provided with care, education, maintenance, training and rehabilitation. This covered victimized, uncontrollable, ungovernable, destitute and delinquent children. The Juvenile justice Act 2000 has removed all the inadequacies of the children act and has made the care more comprehensive and encompassing. The Act has been published in "The Gazette of India" No.70: The Juvenile Justice (Care & Protection of Children) Act 2000 (No. 56 of 2000) published by the Legislative Department of Ministry of Law, Justice and Company Affairs after receiving the assent of the President of India on 30 December 2000.

The salient features of the Act are given below

(a) Child Welfare Committee : The State Government may, by notification in Official Gazette, constitute for every district or group of districts, specified in the notification, one or more Child Welfare Committees for exercising the powers and discharge the duties conferred on such Committees in relation to child in need of care and protection under this Act. The Committee shall consist of a Chairperson and four other members as the State Government may think fit to appoint, of whom at least one shall be a woman and another, an expert on matters concerning children. The Committee shall have

the final authority to dispose of cases for the care, protection, treatment, development and rehabilitation of the children as well as to provide for their basic needs and protection of human rights. Where a Committee has been constituted for any area, such Committee shall, notwithstanding anything contained in any other law for the time being in force but save as otherwise expressly provided in this Act, have the power to deal exclusively with all proceedings under this Act relating to children in need of care and protection.

(b) Juvenile Justice Board : State Government may, by notification in the Official Gazette, constitute for a district or a group of districts specified in the notification, one or more Juvenile Justice Boards for exercising the powers and discharging the duties conferred or imposed on such Boards in relation to juveniles in conflict with law under this act. A Board shall consist of a Metropolitan Magistrate or a Judicial Magistrate of the first class, as the case may be, and two social workers of whom at least one shall be a woman, forming a Bench and every such Bench shall have the powers conferred by the Code of Criminal Procedure, 1973 (2 of 1974), on a Metropolitan Magistrate or, as the case may be, a Judicial Magistrate of the first class and the Magistrate on the Board shall be designated as the principal Magistrate. No Magistrate shall be appointed as a member of the Board unless he has special knowledge or training in child psychology or child welfare and no social worker shall be appointed as a member of the Board unless he has been actively involved in health, education, or welfare activities pertaining to children for at least seven years.

(c) Children Homes : The State Government may establish and maintain either by itself or in association with voluntary organizations, children's homes, in every district or group of districts, as the case may be, for the reception of child in need of care and protection during the investigation of any pending inquiry and subsequently for their care, treatment, education, training, development and rehabilitation. The State Government may, by rules made under this Act, provide for the management of children's homes including the standards and the nature of services to be provided by them, and the circumstances under which, and the manner in which, the certification of a children's home or recognition to a voluntary organization may be granted or withdrawn.

(d) Rehabilitation : The rehabilitation and social reintegration of a child shall begin during the stay of the child in a children's home or special home and the rehabilitation and social reintegration of children shall be carried out alternatively by-

- (i) Adoption
- (ii) Foster care
- (iii) Sponsorship
- (iv) Sending the child to an aftercare organization

(e) Special Juvenile Police Unit : Special juvenile police unit, to handle juveniles or children may be created in every district and city to co-ordinate and to upgrade the police treatment of the juveniles and the children.

Child Placement

1. Orphanages : These are for the children who have no home, no parents or single parents or parents too poor to care for them. The concept is not very favourable to the overall wellbeing of

the child as it does not provide emotional and social warmth required for their development.

2. **Foster Home** : This is a setting which provides all that is available in a family setting but a home other than their original family.

3. **Borstals** : These are institutions somewhere between a certified school and an adult prison for the children 16 years and above who have some social adjustment pathology.

4. **Remand Homes** : This is for those children who have been arrested by the police in some situation which warrants them to be taken care of like immoral trafficking, prostitution etc.

Summary

WHO defines *Adolescence* as 10-19 years old, *Youth* as 15-24 years old and *Young people* as 10-24 years old. The adolescence has been divided into two phases: early (10-14 years) and late (15-19 years). The need to focus on adolescent health exists for many reasons. They constitute 23.1% of Indian population. It is the period of rapid physical growth, sexual maturation and psychological changes. Habits and behaviours picked up during this period (risk taking behaviour, substance abuse, eating habits and conflict resolution) have long lasting impact. Adolescence provides the last chance to correct the growth lag and malnutrition of childhood.

There are various health problems related to the period of adolescence. The adolescent because of rapid biological and psychosocial changes, is prone to impulsivity, emotional and risk taking type of behaviour putting them at risk to problems like STDs/RTIs, accidents, drug and substance abuse and psychological and mental health disorders. Inappropriate sexual behaviour may lead to unplanned pregnancy, STDs, HIV, unwed mothers, illegal abortions, psychological breakdowns and complex social problems. An unfavourable family environment in the form of poverty, marital discord between parents, and alcoholic parent puts the adolescent at risk of Delinquency and prone to psychological problems. Adolescence is also a stressful transitional period. The transitions include educational, occupational, marriage, pregnancy/parenthood and migration related to education and employment.

The health of the adolescents can be measured by studying age specific morbidity, mortality, prevalence of behavioural disorders and DALYs. DALYs have been found to be the most suitable indicator for international comparisons..

In India there is lack of knowledge and awareness among adolescents about important health issue problems that affect them according to an ICMR study. High fertility rates, high rates of teenage pregnancy, high risk of STI/HIV, and poor nutritional status are important problems in adolescents in India. The median age at first marriage in India is 17.2 years.

Improving the health of young people is a complex problem. A multi-pronged intervention approach which should include life-skills and health and sexuality education in schools, peer education, mass media and community mobilization, youth development programs, clinical health services, social marketing and work place and private health sector programs.

The Government of India has identified Survival, Protection and Development as a major theme, focusing on gender

specific needs. The initiatives have been taken under inter-related issues concerning adolescents under various schemes. The notable ones are National policy on education (1986 modified in 1992), National population policy, National AIDS prevention and control policy, National nutrition policy (1983), National policy for empowerment of women and Reproductive and child health policy. These policies address specific sectors like education, health, family welfare, nutrition, HIV/AIDS, sports etc. or address certain population groups like women, children and youth. There are specific programs initiated by governmental and non-governmental organization directed towards adolescents. National Youth Policy, 2003 reiterates the commitment of the entire nation to the composite and all-round development of the young sons and daughters of India. This policy covers all young people in the country in the age group of 13 to 35 years. The strategies are Youth empowerment, Gender Justice, Inter-sectoral approach and Information and research network. The areas of focus are General health, Mental health, Spiritual health, AIDS and STDs, Population education/Family life education/Reproductive health and Tobacco/Substance abuse. The implementation is by Union Ministry of Youth Affairs and Sports.

Life-skills has been defined by WHO as 'the abilities for adaptive and positive behaviour that enable individuals to deal effectively with the demands and changes of everyday life'. Effective acquisition of life skills can influence the way one feels about oneself and others and can enhance one's productivity, efficacy self esteem and self confidence. There are three kinds of life skills- Thinking skills, Social skills and negotiating skills. Adolescents need to be assertive, including learning to say "no" to adopt risky and harmful behaviour like drug use or casual sex before marriage.

Juvenile Delinquency refers to a large variety of behaviour of children and adolescents which the society does not approve of and for which some kind of admonishment, punishment or preventive and corrective measures are justified in public interest. Juvenile is a boy who has not attained the age of 16 years or a girl less than 18 years. The common problems seen in Juvenile delinquents are Behavioural problems like stealing or lying or gambling or aggressiveness or destructiveness or disobedience, Learning disabilities, Emotional problems, Adjustment problems, Development disorder, Intellectual deficit, Psychosomatic disorders, Bizarre and abnormal behaviours, Relationship problems and Socio-legal issues and problems. Prevention and management of Juvenile delinquency includes improvement in family life, life skill development, schooling and social welfare services (child guidance clinics, juvenile courts, orphanages, foster homes, borstals and remand homes).

Child Guidance Clinics (CGC) started in USA in 1909, deals with children who are delinquents and also those who are not adjusted to their environment. The Juvenile Justice (Care and Protection of Children) Act 2000 (No. 56 of 2000) was published by the Legislative Department of The Ministry of Law, Justice and Company Affairs on 30 December 2000. The salient features of the Act include Child welfare committee, Juvenile Justice Board, Children homes, Rehabilitation and Special Juvenile Police Unit. The various Child placement institutions are Orphanages, Foster homes, Borstals and Remand homes.

Study Exercises

Long Question: Describe various adolescent health problems in India and Programs directed against them.

Short Notes: (1) Specific programs on adolescents in India (2) National Youth Policy 2003 (3) Life skills education (4) Juvenile Delinquency (5) Child Guidance Clinic (6) Children Homes

MCQs

1. The concept of Child Guidance Clinic was started in (a) India (b) USA (c) Russia (d) France
2. Median age at first marriage among women in India is (a) 18.5 years (b) 17.2 years (c) 16.2 years (d) 19.5 years
3. The Population Council supported program on adolescents 'Apni Beti Aapna Dhan' is running in (a) Punjab (b) Haryana (c) Himachal Pradesh (d) Uttar Pradesh
4. A Juvenile boy is one who is under _____ years of age (a) 17 years (b) 18 years (c) 16 years (d) 15 years
5. Child Guidance Clinics deals with (a) Juvenile Delinquents (b) Children who are not adjusted to their environment (c) Both (d) None
6. A 13 year old with no father, runs from school and caught in a theft should be kept in (a) Foster home (b) Prison (c) Orphanage (d) Remand home
7. Which of the following closely resembles Juvenile Delinquency (a) Bedwetting (b) School failure (c) Speech problem (d) Destructiveness
8. The main service of Child guidance Clinic is (a) Career counselling (b) Management of Orphans (c) Psychotherapy (d) Recreation facilities
9. Children with parental disharmony are more prone to: (a) Mental retardation (b) Epilepsy (c) Delinquency (d) Accidents

10. All of the following are problems antisocial in nature except (a) Lying (b) Gambling (c) Unsociability (d) Destructiveness
11. The percentage of adolescents among total population in India is (a) 27.3% (b) 18.7% (c) 21.2% (d) 23.1%
12. According to WHO adolescents are _____ years of age (a) 10-19 (b) 11-18 (c) 10-17 (d) 12-21

Answers : (1) b; (2) b; (3) b; (4) c; (5) c; (6) d; (7) d; (8) c; (9) c; (10) c; (11) d; (12) a

A S Kushwaha

"We are guilty of many errors and many faults, but our worst crime is abandoning the children, neglecting the foundation of life. Many of the things we need, can wait. The child cannot. Right now is the time his bones are being formed, his blood is being made and his senses are being developed. To him we cannot answer "Tomorrow". His name is "Today"."

- Gabriela Mistral, 1948

The early years of life are crucial. When well nurtured and cared for in their earliest years, children are more likely to survive, to grow in a healthy way, to have less disease and fewer illnesses, and to develop thinking, language, emotional and social skills.

State of Children in India

UNICEF 2005 Report on the state of the world's children was published under the title "*Childhood under Threat*". Speaking about India, the report states that millions of Indian children are equally deprived of their rights to survival, health, nutrition, education and safe drinking water. A girl child is the worst victim as she is often neglected and is discriminated against because of the preference for a boy child. In India, children's vulnerabilities and exposure to violations of their protection rights remain spread and multiple in nature. The manifestations of these violations are various, ranging from child labour, child trafficking, to commercial sexual exploitation and many other forms of violence and abuse. With an estimated 12.6 million children engaged in hazardous occupations (2001 Census); for instance, India has the largest number of child labourers under the age of 14 in the world. The lack of available services, as well as the gaps persisting in law enforcement and in rehabilitation schemes also constitute a major cause of concern.

Child Protection Against Exploitation

An estimated 300 million children worldwide are subjected to violence, exploitation and abuse including the worst forms of child labour in communities, schools and institutions; during armed conflict; and to harmful practices such as female genital mutilation/cutting and child marriage. Millions more, not yet victims, also remain without adequate protection.

Protecting children from violence, exploitation and abuse is an integral component of protecting their rights to survival, growth and development. UNICEF advocates and supports the creation of a protective environment for children in partnership with governments, national and international partners including the private sector, and civil society. National child protection systems, protective social practices and children's own empowerment coupled with good oversight and monitoring are among the elements of a protective environment and enable countries, communities and families to prevent and respond to violence, exploitation and abuse.

The UN Convention on the Rights of the Child states that all children are entitled to the same rights, regardless of the child's, or their parent's or legal guardian's race, colour, sex, language, religion, political or other opinion, national, ethnic or social origin, property, disability, birth or other status. However, discrimination is a daily reality for millions of the world's children. There are numerous forms of discrimination. The most common include:

- (a) Gender
- (b) Disability
- (c) Ethnicity and race
- (d) Caste
- (e) HIV/AIDS
- (f) Birth status

Actions to Provide Protective Environment to Children

Building a protective environment for children that will help prevent and respond to violence, abuse and exploitation involves the following essential components as defined by UNICEF:

1. Strengthening government commitment and capacity to fulfill children's right to protection.
2. Promoting the establishment and enforcement of adequate legislation addressing harmful attitudes, customs and practices.
3. Encouraging open discussion of child protection issues that includes media and civil society partners.
4. Developing children's life skills, knowledge and participation.
5. Building capacity of families and communities.
6. Providing essential services for prevention, recovery and reintegration, including basic health, education and protection.
7. Establishing and implementing ongoing and effective monitoring, reporting and oversight.

UNGASS (UN General Assembly Special Session on Children): The UN held its 27th special session on children in May 2002. This was to review the progress made since 1990 when World Summit for Children (Convention on the Rights of

the Child) was held. The commitment to promote and protect rights of children was reaffirmed. The aim is to create a 'World Fit for Children' through following principles (See Box-1).

Box - 1 : World Fit for Children
Put children first
Eradicate poverty: Invest in children
Leave no child behind
Care for every child
Educate every child
Protect children from harm and exploitation
Protect children from war
Combat HIV/AIDS
Listen to children and ensure their participation
Protect the Earth for children

Initiatives on Child Rights

(a) National Policy on Children, 1974 : India is a party to the UN declaration on the Rights of the Child 1959. In 1974, the Government of India adopted a National Policy for Children, declaring the nation's children as 'supremely important assets'. The policy reaffirmed the constitutional provisions for adequate services to children, both before and after birth and through the period of growth to ensure their full physical, mental and social development. This policy lays down recommendations for a comprehensive health programme, supplementary nutrition for mothers and children, nutrition education for mothers, free and compulsory education for all children up to the age of 14, non-formal preschool education, promotion of physical education and recreational activities, special consideration for the children of weaker sections of the population like the scheduled castes and the schedule tribes, prevention of exploitation of children and special facilities for children with handicaps. The policy provided for a National Children's Board to act as a forum to plan, review and coordinate the various services directed toward children. The Board was first set up in 1974.

(b) The Department of Women and Child Development : This was set up in the Ministry of Human Resource Development in 1985. The Department, besides ICDS, implements several other programmes, undertakes advocacy and inter-sectoral monitoring catering to the needs of women and children.

(c) Convention on the Rights of the Child (CRC), 1990 : The Government of India ratified the CRC on 12 November 1992. By ratifying the Convention on the Rights of the Child, the Government is obliged "to review National and State legislation and bring it in line with provisions of the Convention". The Convention re-validates the rights guaranteed to children by the Constitution of India. The Ministry of Women and Child Development has the nodal responsibility of coordinating the implementation of the Convention. Since subjects covered under the Articles of the Convention fall within the purview of various departments/ ministries of the Government, the Inter-Ministerial Committee set up in the Ministry with representatives from the concerned sections monitor the implementation of the

Convention. In pursuance of this, the Department formulated a National Plan of Action for Children in 1992.

(d) National Plan of Action for Children, 1992 : India is a signatory to the World Declaration on the Survival, Protection and Development of Children. In pursuance of the commitment made at the World Summit, the Department of Women and Child Development under the Ministry of Human Resource Development has formulated a National Plan of Action for Children. Most of the recommendations of the World Summit Action Plan are reflected in India's National Plan of Action-keeping in mind the needs, rights and aspirations of children in the country. The priority areas in the Plan are health, nutrition, education, water, sanitation and environment. The Plan gives special consideration to children in difficult circumstances and aims at providing a framework, for actualization of the objectives of the Convention in the Indian context.

(e) Education - Right of every Child, 2002 : The Constitution (86th Amendment) Act was notified on 13th December 2002, making free and compulsory education a Fundamental Right for all children in the age group of 6-14 years.

(f) National Charter for Children, 2004 : The National Charter for Children, adopted on 9th February 2004, emphasizes Government's commitment to children's rights to survival, development and protection. It also stipulates the duties for the State and the community towards children and emphasizes the duties of children towards family, society and the Nation.

(g) National Action Plan for Children, 2005 : In recognition of the fact that 41% of India's population is below 18, constituting a significant national asset, The National Plan of Action for Children, 2005 re-affirms the Nation's commitment to wisely, effectively and efficiently invest its national resources to fulfill its commitments to children. This plan commits itself to ensure all rights to all children up to the age of 18 years. The guiding principles of the action plan are given in the Box - 2.

Box - 2 : The Guiding Principles of the National Plan of Action for Children, 2005

To regard the child as an asset and a person with human rights.
To address issues of discrimination emanating from biases of gender, class, caste, race, religion and legal status in order to ensure equality.
To accord utmost priority to the most disadvantaged, poorest of the poor and least served child in all policy and programmatic interventions.
To recognize the diverse stages and settings of childhood, and address the needs of each.

The National Plan of Action for Children, 2005 is divided into following four sections; and all categories of rights apply to all age groups, including before birth.

- (i) Child Survival
- (ii) Child Development
- (iii) Child Protection
- (iv) Child Participation

The Plan has identified twelve key areas keeping in mind

priorities and the intensity of the challenges that require utmost and sustained attention in terms of outreach, programme interventions and resource allocation, so as to achieve the necessary targets and ensure the rights and entitlements of children at each stage of childhood. Key result areas of the action plan are given in the Box - 3.

Box - 3 : Key Result Areas of the National Action Plan for Children 2005
Reducing Infant Mortality Rate.
Reducing Maternal Mortality Rate.
Reducing Malnutrition among children.
Achieving 100% civil registration of births.
Universalization of early childhood care and development and quality education.
Complete abolition of female feticide, female infanticide and child marriage.
Improving Water and Sanitation coverage both in rural and urban areas.
Addressing and upholding the rights of Children in Difficult Circumstances.
Legal and social protection from all kinds of abuse, exploitation and neglect.
Complete abolition of child labour
Monitoring, Review and Reform of policies, programmes and laws
Ensuring child participation and choice

(h) National Commission for Protection of Child Rights, 2006 : In order to ensure child rights practices and in response to India's commitment to UN declaration to this effect, the Government of India set up a National Commission for Protection of Child Rights. The Commission is a statutory body notified under an Act of the Parliament on December 29, 2006. Besides the chairperson, it will have six members from the fields of child health, education, childcare and development, juvenile justice, children with disabilities, elimination of child labour, child psychology or sociology and laws relating to children. The Commission has the power to inquire into complaints and take *suo motu* notice of matters relating to deprivation of child's rights and non-implementation of laws providing for protection and development of children among other things.

(j) Constitutional Provisions : India's commitment to children is clearly manifested in its Constitution wherein several articles are dedicated to children (See Box - 4).

National Plan of Action for Children, 2005 : GOALS

The National Plan of Action for Children 2005 has set out goals related to various fields of child welfare, exploitation, abuse and their right to health. The salient goals are laid out in Box - 5 to 9.

The ultimate objective of the entire international, regional, national and sub-national effort is to create a society where children will get the most favourable conditions to survive,

grow and develop into healthy adults. This in other words can happen only in a *Child Friendly Society* that promotes survival, protection, development of children ensuring their protection against all forms of exploitation with their participation.

There has been a lot of progress in the field of child health in terms of not only improved child health indices but also with respect to global focus towards this very vital social issue. The Convention on the Rights of Children to a healthy childhood is a milestone in this endeavor. However, it is disturbing to note uneven progress not only in different regions and countries but also country to country variation and rural urban differential not only continue to exist but widening as well. The global pledge to address these child health issues by adopting MDGs is a ray of hope for the children of the world. The society has a moral duty to give every child a right to survival, growth, development and protection so that they can achieve their full potential. The ultimate aim of all initiatives towards rights and protection of children is to develop a child friendly society.

Box - 4 : Constitutional Provisions to Children

Article 14 : Equality before the law or the equal protection of laws

Article 15 : The State shall not discriminate against any citizen. Nothing in this Article shall prevent the State from making any special provisions for women and children.

Article 21 A : The State shall provide free and compulsory education to all children of the age of 6-14 years in such manner as the State may, by law, determine.

Article 23 : Traffic in human beings and beggar and other forms of forced labour are prohibited and any contravention of this provision shall be an offence punishable in accordance with the law.

Article 24 : No child below the age of 14 years shall be employed to work in any factory or mine or engaged in any other hazardous employment.

Article 45 : The State shall endeavour to provide early childhood care and education for all children until they complete the age of six years.

Article 243 G read with Schedule 11 : Provide for institutionalization of child care by seeking to entrust programmes of Women and Child Development to Panchayat (Item 25 of Schedule 11)

Box - 5 : Child Health Goals (NAP 2005)

To reduce Infant Mortality Rate to below 30 per 1000 live births by 2010.

To reduce Child Mortality Rate to below 31 per 1000 live births by 2010.

To reduce Neonatal Mortality Rate to below 18 per 1000 live births by 2010.

To explore possibilities of covering all children with plan for health insurance.

Box - 6 : Care and Education Goals (NAP 2005)

To universalize early childhood services to ensure children's physical, social, emotional and cognitive development.

To ensure that care, protection and development opportunities are available to all children below 3 years.

To ensure integrated care and development and pre-school learning opportunities for all children aged 3 to 6 years.

To provide day care and crèche facilities to parents in rural and urban areas.

Box - 7 : Children in Difficult Circumstances Goals (NAP 2005)

To ensure that best interest of the child is upheld in all policies, plans, programmes, interventions and in strategies for children in difficult circumstances.

To create and uphold a safe, supportive and protective environment for all children within and outside the home.

Box - 8 : Protection Against Sexual Exploitation And Child Pornography Goal (NAP 2005)

To protect all children, both girls and boys, from all forms of sexual abuse and exploitation.

To prevent use of children for all forms of sexual exploitation, including child pornography.

To develop new and strengthen existing legal instruments to prevent sexual abuse and exploitation of children.

Box - 9 : Combating Child Labour Goals (NAP 2005)

To eliminate child labour from hazardous occupations by 2007, and progressively move towards complete eradication of all forms of child labour.

To protect children from all kinds of economic exploitation

Summary

The early years of life are the most crucial years. Violations of the basic rights of children ranging from child labour, child trafficking, to commercial sexual exploitation may lead to various problems in the future. An estimated 300 million children worldwide are subjected to violence and many others remain without adequate protection. The lack of available services with India having the largest number of under 14 child labourers in the world is a major cause of concern especially with India being a signatory to UN declaration on the Rights of the Child, 1959. UNGASS in its 27th special session in May 2002 aims to create a 'World Fit for Children' through certain laid out principles. As an initiative to child rights, India adopted National Policy on Children in 1974 and a number of conventions and departments were setup followed by National Action Plan for Children, 2005 as a recognition of the fact that 41% of India's population is below 18. It has set out various goals related to various fields of child welfare, exploitation, abuse and their right to health. India's commitment to children is clearly manifested in its several articles which are dedicated

to children. The ultimate aim is to develop a Child Friendly Society.

Study Exercises

Long Questions: India's initiatives on Child Rights.

Short Notes : (1) National Action Plan for Children, 2005
(2) Constitutional provisions relating to child's rights

MCQs and Fill in the blanks :

- 1) UNGASS stands for _____
- 2) India adopted the National Policy on Children in the year _____
- 3) Free and compulsory education is a fundamental right of the children in the age group (a) 7-12 yr (b) 6-8 yr (c) 6-12yr (d) 6-14 yr
- 4) National action plan for children was launched in _____
- 5) At present _____% of population is under 18 years of age
- 6) Free and compulsory education is a fundamental right of the children according to the article (a) 14 (b) 15 (c) 24 (d) 21A

- 7) No child will be employed in any factory or mines according to Article _____
- 8) Infant mortality rate should be brought down to below _____ by 2010 according to child health goals
- 9) Child labour from all hazardous occupations should be eliminated by _____ according to child health goals
- 10) The department of women and child development was set up under the Ministry of _____

Answers: (1) United Nations General Assembly Special Session; (2) 1974; (3) d; (4) 2005; (5) 41; (6) d; (7) 24; (8) 30/1000 live births; (9) 2007; (10) HRD

Growth and Development of Children

A S Kushwaha

Early Childhood

When well nurtured and cared for in their earliest years, children are more likely to survive, to grow in a healthy way, to have less disease and fewer illnesses, and to fully develop thinking, language, emotional and social skills. Although it is never too late to improve the quality of a child's life, the first three years are the most crucial for their survival and thriving. Frequent illness, unsanitary environments and poor nutrition steal a child's potential.

When they enter school, their prospects for performing well are improved, and as adolescents, they are likely to have greater self-esteem. Later in life, they have a greater chance of becoming creative and productive members of society. It is a child's right to have every chance to survive and thrive. Moreover, ensuring optimal conditions for a child's early years is one of the best investments that a country can make if it is to compete in a global economy based on the strength of its human capital. The growth monitoring, correct feeding practices, immunization, responsive health care system, legal

provisions, sensitive society, management during sickness and providing protection to these children can help in improving the lot of this important group of vulnerable population. The concept of well baby clinic, under five clinic and mother and child clinics are steps in this direction.

Definitions

Growth and Development : Growth is the progressive increase in the size of a child. Development is progressive acquisition of various skills (abilities) such as head support, speaking, learning, expressing the feelings and relating with other people. Growth and development go together but at different rates.

Importance : The assessment of growth and development is very helpful in finding out the state of health and nutrition of a child. Continuous normal growth and development indicate a good state of health and nutrition of a child. Abnormal growth or failure to thrive (growth failure) is a symptom of disease. Hence, measurement of growth is an essential component of the physical examination.

Factors affecting growth and development : Each child's pattern of growth and development is determined by its genetic and environmental influences. The genetic factors determine the potential and limitations of growth and development. If favourable, the environmental factors, such as adequate nutrition, facilitate the achievement of the genetic potential of growth and development. Unfavourable factors, acting singly or

in combination, slow down or stop the growth and development. Some of the unfavourable factors are malnutrition, infections (prenatal and postnatal), congenital malformations, hormonal disturbances, disability, lack of emotional support, lack of play, and lack of language training. To promote optimum growth, these environmental factors can be removed or minimized. Once they are removed, infant follows a period of catch up growth. During this period the growth rate is greater than normal. This growth rate continues until the previous growth pattern is reached. Then the growth rate is reduced to the normal rate determined by the individual's genetic factors.

A child genetically determined to be tall grows slightly more rapidly than a child genetically determined to be short. Socio-economic factors, emotional and cultural factors too exert their influence on the growth and development of children.

Laws of growth : Growth and development is a continuous and orderly process and follows a particular pattern over a period of time termed as sigmoid curve. There are periods of rapid growth and slower growth. Growth pattern of each child is unique. Each organ system and body part also has its characteristic pattern of growth. The body, brain and gonads grow in a different manner in different phases of childhood. The children grow in 3 different types of physical patterns of growth, ectomorphs, endomorphs and the mesomorphs.

1. Somatic growth (Body size) : This is rapid during foetal life, 1st 2 years of life and after onset of puberty. This follows a sigmoid curve pattern.

2. Brain growth : The brain enlarges rapidly during latter months of foetal life and early months of postnatal life. At birth head size is 65-70% of the expected head size of the adult. It reaches 90% by the age of two years.

3. Gonadal growth : Gonadal growth is dormant in childhood with rapid growth during puberty. The growth spurt during puberty is attributed to neuro-hormonal stimulation of the hypophysis by the hypothalamus.

4. Lymphoid growth : This is most notable in mid-childhood and may be even larger than in an adult.

Weight : Body weight represents the sum of protein, fat, water, and bone mineral mass, and does not provide any information on relative changes in these four chemical components.

Weight for age in children from 6 months to 7 years of age is an index of acute malnutrition, and is widely used to assess protein energy malnutrition and over nutrition, especially in infancy when the measurement of length is difficult. A major limitation of it as an index of PEM is that it does not take into account height differences. As a result children with low weight for age are not necessarily wasted. To interpret a single measurement of weight in relation to the reference data, the exact age of the child must be known. The average birth weight in Indian children is around 2.6 Kg and 3 kg in developed countries. After losing 10% weight in 1st week, the infants regain their weight by the second week. They gain weight at an approximate rate of 25-30 gm per day for 3 months. The gain in weight in next 9 months is @ 400 gm per month. An infant doubles weight by 5 months and triples by one year of age and becomes 4 times his birth weight by end of 2 years. At 3 years

the weight becomes 5 times the birth weight. On an average child gains 2 kg per year in 3-7 years age and 3 kg after that till puberty.

Head Circumference (HC) : HC is important because it is closely related to brain size. It can be used as an index of chronic protein energy nutritional status during the first two years of life. Chronic malnutrition during the first few months of life, or intrauterine growth retardation, may decrease the number of brain cells and result in an abnormally low head circumference.

Beyond the age of two years, growth in HC is slow and its measurement is no longer useful.

The head circumference is measured by encircling the head with an unstretchable tape measure, or a piece of string in the absence of a tape measure. This is passed over the most prominent part of the occiput posteriorly and just above the supra-orbital ridges anteriorly to obtain the greatest distance around the head. At birth HC is 35 cm, at 3 months 40 cm, 45 cm at 1 year and reaches 48 cm by second year and 52 by 3rd year. Crown rump length (CRL) is always <HC in 1st year of life.

Mid Upper Arm Circumference (MUAC) : Arm contains subcutaneous fat and muscle. A decrease in MUAC may therefore reflect a reduction in muscle mass, a reduction in subcutaneous tissue or both. In developing countries, where the amount of subcutaneous fat is frequently small, a change in MUAC tend to parallel changes in muscle mass and hence is particularly useful in the diagnosis of PEM or starvation. Changes in MUAC can also be used to see progress during nutritional therapy. MUAC changes are easy to detect and require a minimal amount of time and equipment. Some investigators claim that MUAC can differentiate normal children from those of PEM as reliably as weight for age. MUAC changes very little from 1-5 years of age and it can be used as an age-independent measurement.

Low MUAC has been shown to be a sensitive indicator of risk of death in children.

The mid upper arm circumference is measured using a tape or string in the absence of a tape. The tape or string is placed around the upper arm, midway between the olecranon and acromion processes. Care is taken not to pull the tape or string too tightly. The mid upper arm circumference increases fairly rapidly to about 16 cm by the age of one year. In the period 1 to 5 years, the mid upper arm circumference increases by only 1 cm. So, irrespective of age, the mid upper arm circumference of well nourished children ranges 16 -17 cm in the period 1-5 years. Conversely, if the mid upper arm circumference of a child of 1 to 5 years of age is less than 16 cm, that child has malnutrition and corrective intervention should be carried out.

Length / Height : The length of a child is measured in the first 3 years and the height is measured after 3 years of age. The length is measured using a horizontal measuring board put on the ground or on a table. The child is laid on his back with the head against the fixed head board. A helper holds the child's head so that the eye angle- external ear canal line is vertical and also keeps the body straight. With one hand of the health worker, the child's knees are pressed down to straighten the child's legs fully while, with the other hand, the sliding foot

board is placed to touch the child's heels firmly. With the foot board in place, the child's length is read on the metre scale. To measure the height, a bare foot child stands with the feet together. The heels, the buttocks and the occiput lightly touch the measuring device. The head is aligned so that the external eye angle- external ear canal plane is horizontal. The child is told to stand tall and is gently stretched upward by pressure on the mastoid processes with the shoulders relaxed. The sliding head piece is lowered to rest firmly on the head. The height is read and recorded. An average term baby is 50 cm long. The length increases by 50% in the first year. In the second year, the average height growth is about 12 cm. The birth length doubles by 4 years of age. After the second year of age, the annual height growth averages 5-6 cm until the beginning of the adolescent growth spurt. Height growth stops at about the age of 18 years in girls and at the age of about 20 years in boys. After plotting the child's height or length on a height chart, you should determine whether the growth pattern is normal. A normal growth pattern is parallel to the printed percentile lines.

Chest circumference : The chest circumference is 3 cm less than the head circumference at birth. They become equal by end of 1st year and thereafter chest circumference exceeds the head circumference.

Tooth eruption : Tooth eruption is an important part of growth. In general, teething in infants usually starts at about 6 months of age, but some start later than 6 months. A new tooth appears approximately every month so that by 2 - 2½ years of age the baby will have 20 primary teeth. This makes the number of teeth roughly equal to age in months minus 6.

A parent should only start to worry about tooth eruption if a child has not yet started teething by 13 months. This is because at this age the child should be eating solid foods. Teething may cause excessive salivation, irritability, disturbed sleep and some pain. Sometimes it also causes Diarrhoea. At the age of about 6 years, the shedding of the primary teeth starts and continues through to the age of 12 years. Eruption of permanent teeth starts at about 6 years of age.

Development

Development is defined as the progressive acquisition of various skills (abilities) such as head support, speaking, learning, expressing the feelings and relating with other people. Each child follows a unique path in growth and development that is laid down from the beginning of life by what he has inherited from both parents. Unfortunately, many factors may change the genetically determined path of growth and development. These things include, for example, infections, lack of care, psychological trauma, bad education, and malnutrition, to mention just a few. The normal well-fed infant who is protected from infections develops quickly, particularly during the first 3 months. It is very important to know the age ranges when most children acquire certain skills. The various skills the baby and a young child learn are called *milestones* (Table - 1). In monitoring development, we notice at what age the child achieves various milestones, such as smiling at the mother, sitting without support, grasping objects with his/her hands, standing, walking and talking. You should record at what

age the child has achieved the various milestones. Still, it is important to remember that every child develops at his/her own rate or pace. Some walk early, others late.

Infant development occurs in an orderly and predictable manner that is determined intrinsically. It proceeds from cephalic to caudal and proximal to distal as well as from generalized reactions to stimuli to specific, goal-directed reactions that become increasingly precise. Extrinsic forces can modulate the velocity and quality of developmental progress.

Table - 1 : Important Developmental Milestones		
Age range	Motor Development	Language and social development
Birth	When prone turns head to one side to avoid suffocation	Cries
3-6 Months	Good head control	Can follow an object with eyes, plays with hands
6-9 Months	Can sit unsupported	Grasps actively, makes loud noises
9-12 Months	Able to stand	Understands a few words, tries to use them
9-18 Months	Able to walk	Grasps small objects with thumb and index finger
15-30 Months	Able to run around as much as he wants	Can say several words or even some sentences
3 Years	Plays actively, is able to jump and climb	Starts talking a lot, is curious and asks many questions

Each developmental domain must be assessed during ongoing developmental surveillance within the context of health supervision. Generalizations about development cannot be based on the assessment of skills in a single developmental domain (i.e. one cannot describe infant cognition based on gross motor milestones). However, skills in one developmental domain do influence the acquisition and assessment of skills in other domains.

Speech delays are the most common developmental concern. A sound understanding of the distinction between an isolated speech delay (usually environmental and often can be alleviated) and a true language delay (a combined expressive and receptive problem that implies more significant pathology) will help the clinician refer appropriately for precise diagnosis and appropriate management.

It is essential to understand normal development and acceptable variations in normal developmental patterns to recognize early patterns that are pathologic and that may indicate a possible developmental disability. Assessment of the quality of skills and monitoring the attainment of developmental milestones are essential to early diagnosis of developmental disabilities and expedient referral to early intervention programs.

Theories of Development : Developmental theory has been shaped by the persistent debate of whether nature (intrinsic forces) or nurture (extrinsic forces) is the predominant

influence. Earlier theories centered on the role of nature. By mid 20th century, theories that stressed the importance of nurture began to prevail. Pavlov (1930s), Watson (1950s), and Skinner (1960s) promoted the view that development was a function of learning. Operant conditioning (positive and negative reinforcements through social interactions or environmental changes) promoted learning and shaped the child's development. During the second half of the century, the name of Piaget became almost synonymous with child development. Piaget was the first to describe the infant as having intelligence. Piaget revealed that infants were, indeed, capable of thinking, analyzing & assimilating. He viewed development as stage-like cognitive changes. The child actively explores objects in an effort to understand his or her environment.

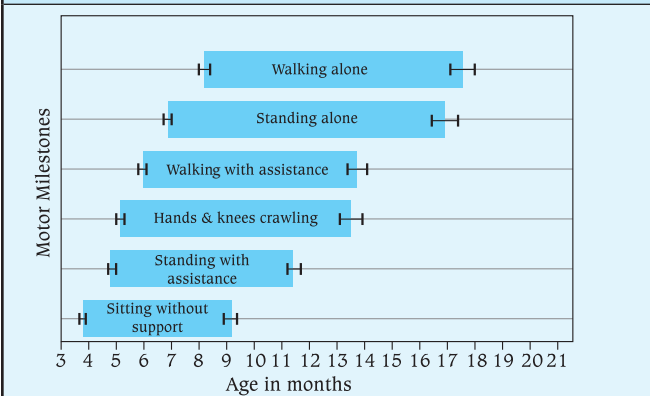

Fields of Development : Gross motor; Fine motor; Social; Cognitive; Psychological; Emotional; Problem solving; Adaptive; Language development.

Developmental Quotient : Developmental Quotient (DQ) is the developmental age divided by chronologic age times 100 (see Example in Box - 1). This provides a simple expression of deviation from the norm. A quotient above 85 in any domain is considered within normal limits; a quotient below 70 is considered abnormal. A quotient between 70 and 85 represents a gray area that warrants close follow-up. Values in the upper limit of normal do not particularly indicate supernormal abilities. The concept of windows of achieving milestones (Fig. - 1) becomes relevant as proposed by the WHO.

Box - 1 : Example - Motor Quotient

A 12-month-old boy is seen for health supervision. He is not walking alone, but he pulls up to stand (9 months), cruises around furniture (10 months), and walks fairly well when his mother holds both hands (10 months). This child has a gross motor age of 10 months at a chronologic age of 12 months. Should this 2-month discrepancy be a concern? To decide, one should calculate the DQ by using these gross motor milestones : $DQ = \text{motor age} / \text{chronologic age} \times 100 = 10 \times 100 / 12 \text{ months} = 83$

Fig. - 1 : Windows of Development

Source : WHO Child Growth Standards

The motor age and the developmental quotient are good summary descriptors of the child and have more meaning than plotting each milestone. Because the lower limit is 70, this boy's DQ falls within the "suspect" or gray zone. In reality, infants falling into the gray zone of motor domains usually do quite well and rarely require referral to an early intervention program. This is in contrast to those falling in the gray zones of the cognitive domains.

Factors in Development : The factors that promote development include good nutrition, emotional support, play and language training.

1. Good Nutrition : Good nutrition is essential for normal growth and development. Unlike most other organs in the body, the brain is not fully developed at birth. Good nutrition in the first 6 months of life is extremely important. Malnutrition in this period may impair the growth of the brain. As a result of impaired brain growth, the child may suffer for the rest of life. A malnourished child is often tired, apathetic and not interested in learning new things that will promote normal development. Nutrition is discussed in detail elsewhere.

2. Emotional Support : The first 5 years of life are critical for the foundation of the skills. A newborn starts with no knowledge and learns a great deal during his/her first year of life. It is very important to realize that a child is a growing and developing human being right from birth. He ought to be treated very carefully, with love and affection, so that he can develop normally. He needs full emotional support.

3. Play : Play is a source of information, stimulation for the brain, stimulation for the muscles and a lot of fun. All these activities are necessary for physical, mental and social development. All normal children like to play.

4. Language Training : Another factor that promotes development is language training. Children should be offered opportunities to meet, use, and play with words in conversation and in reading books.

Growth Monitoring

Growth Monitoring was popularized by David Morley in 1960s' and 70s' (1-5). This strategy proved that growth monitoring could improve nutritional status. His "road to health" chart was a tool which possessed a number of precise functions-

- (a) Provide a health record of the child which included weight but also relevant information on immunization, disease episodes, family planning, etc.
- (b) Emphasize integration of curative and preventive care.
- (c) Increase proportion of "care" as opposed to the prevailing "cure".
- (d) Help the family to take care of its own health.
- (e) Provide a support for the less qualified rural health worker.

In 1982, growth monitoring i.e. the regular weighing of children and charting their weight on a chart was taken up by UNICEF as part of the **GOBI** program. G= growth promotion, O= ORT (oral rehydration therapy), B = breast feeding, I= immunization. This programme was later extended with the three Fs of **Family Planning, Food and activities for Females to GOBIFFF**.

Growth monitoring is the process of maintaining regular

observation of a child's growth. It starts with measurements of weight daily, weekly, monthly, bimonthly etc. The successive weights are plotted on the growth chart of the child health card. A curve deviating downwards indicates a situation that the child is losing weight. The child needs extra care immediately. The baby may be suffering from malnutrition, tuberculosis, AIDS or other medical conditions. The mother is advised to take the baby to hospital for investigations and treatment. Any infant who does not gain weight for one month or a child who does not gain weight for two months should receive urgent attention. Such an infant or child is becoming malnourished.

Importance of Growth Monitoring : Health workers and parents should monitor the growth of children for the following reasons -

- (a) For early detection of abnormal growth and development.
- (b) To facilitate the early treatment or correction of any conditions that may be causing abnormal growth and development.
- (c) To provide an opportunity for giving health education and advice for the prevention of malnutrition.

Growth monitoring is one of the basic activities of the Under Five clinics where the child is weighed periodically at monthly intervals during the 1st year, every 2 months during the 2nd year and every 3 months thereafter up to the age of 5 to 6 years. The Anganwadi under ICDS is also based on Growth monitoring and supplementary feeding for children under six years of age.

IAP Guidelines on Growth Monitoring : Growth Monitoring Guidelines Consensus Meeting of the IAP recommended that-

(i) **Birth to 3 years** : Immunization contacts at birth, 6, 10 and 14 weeks, 9 months, 15-18 months may be conveniently used for growth monitoring. An additional monitoring visit at 6 months with opportunistic monitoring at other contacts (illness) is recommended. Normally growing babies should not be weighed more than once per fortnight under 6 months and no more than monthly thereafter, as this increases anxiety. After 18 months measurements are to be taken every 6 monthly. It is recommended that the height, weight and head circumference be measured up to 3 years of age.

(ii) **4 to 8 years** : It is recommended that height and weight be measured 6 monthly during this period and BMI should be assessed yearly from 6 years of age.

(iii) **9 to 18 years** : It is recommended that height, weight and BMI be assessed yearly during this period.

Anthropometry

Anthropometry means "body measurements". Anthropometry is very useful for measuring overall health status, not just nutritional status.

The advantages of anthropometry

1. Simple, safe, non-invasive procedure
2. Applicable to large sample sizes
3. Requires inexpensive, portable and durable equipment, which can be made or purchased locally
4. Methods are precise and accurate if standardized techniques are used
5. Information on past long term nutritional history can be obtained

6. Helps in identification of mild, moderate or severe degree of malnutrition
7. Helps in evaluation of nutritional status over time and from one generation to the next (secular trend)
8. May be used in nutritional screening to identify individuals at high risk of malnutrition

Limitations of anthropometric assessment

1. Relatively insensitive method and can not detect change of nutritional status over short period of time.
2. Anthropometric information is non-specific and does not identify the cause of growth failure.
3. In poor communities, dietary inadequacies and infection are often major environmental determinants of growth failure. While anthropometry may index the problem, it does not, by itself, identify the specific cause or indicate the specific solution.
4. Certain non-nutritional factors, viz. disease, genetics, diurnal variation, reduced energy expenditure, etc. can reduce specificity and sensitivity of anthropometric methods.
5. Appropriate sampling or experimental design can largely exclude such limitations.

Uses of Anthropometry

1. Population assessment
2. Identification of target groups
3. Nutritional surveillance
4. Monitoring of nutritional status
5. Evaluation of program impact
6. Growth monitoring of individuals

Reference Vs Standard : Height and weight measurements mean little unless compared to a growth reference.

Instead of the term "*standard*", which originated from the "Harvard Standard" that was developed in 1955, the preferred term today is "growth reference", which is used to compare measurements. The characteristics of a reference population as defined by WHO, include measurements taken from a well-nourished population with at least 200 children/age and sex group, and from a cross-sectional sample. There have been several growth references developed. The first was the "Harvard Standard", also known as the "Boston Standard," the "Stuart-Meredith Standard" or the "Jelliffe Standard". A "*Reference*" is defined as a tool for grouping and analyzing data and provides a common basis for comparing populations; no inferences should be drawn about the meaning of observed differences.

Deciding Cut-off Points : Environment plays a more important role than genetics in determining preschool age child nutritional status using anthropometry, given an adequate environment, preschool-age children around the world should have similar growth curves. There are three different types of cut-off points that can be used to identify stunting, wasting, and underweight. Percentiles are useful but are problematic in classifying children who fall outside the extreme centiles of the growth reference (i.e. below the 3rd and above the 97th percentiles) since they cannot be accurately classified. The percent of median is very useful since it provides a more precise estimate of the HFA, WFH and WFA of a population, particularly where stunting, wasting, and underweight are expected, which is common in developing countries. The median of the NCHS

growth reference is used since it is the best comparison point in distributions of HFA, WFH and WFA. For example, with HFA, in any population there will be a few tall children, a few short children, and the rest in-between. Since the few very tall or few very short children do not adequately represent the group, the median is selected as the comparison point. The cut-off points of <90%, <80% and <70% of reference median for HFA, WFH and WFA to define stunting, wasting and underweight respectively, were selected because studies have shown that significant increases occur approximately at these three cut-off points for various functional parameters, such as mortality. Therefore, these cut-off points are really not as arbitrary as it may appear. The preferred method of cutoff points is Z-score, which is the number of standard deviation units (SD) from the reference median, which is "0" Z-score. The Z-score gives a much more precise measurement of stunting, wasting, and underweight than percentiles or percent of median.

Measuring Growth

Measurements : There are various measurements that are used to measure growth.

1. Weight
2. Head circumference
3. Mid Upper Arm Circumference (MUAC)
4. Height / length
5. Chest circumference

Indices : Anthropometric indices are combinations of the measurements. They are important since mere measurements provide little useful information. For example, mere body weight has little utility unless it is related to age or height. An example of such combination of two measurements is BMI (weight in kg / height²). Ponderal index is weight/ height³. In children three common indices used are WFH (weight for height), HFA (height for age) and WFA (weight for age). These indices could be expressed in the form of Z-scores, percentiles and % of median which can then be used to compare a child to a reference population. To be useful, these measurements must be taken accurately using reliable equipment and correct measuring techniques.

(a) Z score : The deviation of the value for an individual from the median value of the reference population, divided by the standard deviation for the reference population.

$$Z \text{ score} = \frac{(\text{observed value}) - (\text{median reference value})}{\text{Standard deviation of the reference population}}$$

(b) Percentile : The rank position of an individual on a given reference distribution, stated in terms of what percentage of the group the individual equal or exceeds. For example, a child whose weight falls in the 10th percentile weighs the same or more than 10% of the reference population of children of the same age. Percentiles are easy to use and thus preferred in clinical settings. The percentile is interpreted by the percent of individuals above and below specified percentile value. For example 35th percentile is described by 35% of the individuals lying below the value and 65% above. However, the same interval of percentile values corresponds to different changes in absolute height or weight according to which part of the distribution is concerned. Another disadvantage being that

towards the extremes of the reference distribution there is little change in the percentile values for significant changes in height or weight.

For example : Consider a child of age 2 years having a weight of 10.5 kgs. When the child is tracked on the growth chart we first locate the age of 2 years i.e. 24 months on the Age axis and weight of 10.5 kgs on the weight axis. The intersection of these two is the point shown by coloured circle (Fig. - 2). We observe that the individual falls in between 50th percentile and 3rd percentile.

(c) Percent of Median : The ratio of a measured value in the individual, for example weight, to the median value of the reference data for the same age or height, expressed as percentage. The disadvantage is that this does not correspond to a fixed point of the distribution across age or height status.

For example consider a child who is 18 months of age and weighs around 7.5 kgs. Again while tracking the child on the growth chart we first locate the intersection point at the specified age and corresponding weight of the child. The coloured point denotes the intersection on the growth chart (Fig. - 3). We observe that the child falls in Grade II of malnutrition. Hence intervention is needed in this child.

Why use 'Z score'? : One of the problems with percent of median is that although 90% of reference median is the cut-off point for HFA where a child who has a HFA below the cut-off point is classified as stunted, each age group of children actually has a different cut-off point when using percent of median. For example, the cut-off point at -2 Z-score of boys 2 years 4 months is 92.2%; for boys 3 years 5 months, it is 91.1%; for boys 4 years 4 months, it is 91.7%. Therefore, using a cut-off point of 90% for all children may create problems in properly classifying children's nutritional status - using Z-score eliminates this problem.

Advantages of using Z score over percentage of median

1. Z-score cut-off point always at -2 Z-score
2. Different cut-off points for % of median for different ages of children
3. Z-score and percentage of median can yield different results - can cause misclassification
4. Clearer interpretation of Z-score
5. Misleading interpretation of % of median

Indicators

An indicator refers to the use or application of indices. Example, proportion of children below a certain level of weight for age (say -3SD) can be used as an indicator of undernourished children in a given community. These indicators could be used as indicators of body size, health or nutrition or a combination of these. The use of these indicators should be clearly defined as incorrect interpretation and its usage may lead to formation of unscientific interventions.

Growth Charts

In Haiti, in the mid sixties, Beghin with Fougère and King designed a growth chart based on Gomez classification of degrees of malnutrition, to select children for referral to nutritional rehabilitation centers (1). In Colombia, Rueda Williamson adapted a chart developed earlier by Tony, which

combined weight and height. As the Director of National Institute of Nutrition, he actively promoted his “auxogramme” which, interestingly enough, was also used for counselling the child’s mother. While working on malnourished children, Dr David Morley introduced the concept of growth monitoring and developed the earliest growth charts. These have come to be known as ‘Road to Health’ charts. The growth chart shows progressive changes in the height and weight of a child in a graphic form. They depict average and permissible range of variation for the particular age and attribute.

The Indian Council for Medical Research (ICMR) undertook a nationwide cross sectional study during 1956 and 1965 to establish Indian reference charts. The measurements were made on children of the lower socio-economic class and hence cannot be used as a reference standard. There are a number of different types of growth charts in use in India. The commonly used and approved by the Government had four reference curves depicting three different grades of malnutrition. The topmost curve represented 80 % of the median of WHO reference standards which is approximately equivalent to 2 SD below the median which is the conventional lower limit of normal range. The three lines below this curve represent 1st to 3rd degree of malnutrition. The prototype WHO chart (home based) had two reference curves. The upper curve represented the median for

boys (50th percentile) and the lower curve represented the 3rd percentile for girls. This chart had an advantage of application to both the sexes.

NCHS (National Center for Health Statistics) developed the growth charts in 1977 and were adopted by the WHO as a clinical tool to monitor growth of children. CDC (Center for Disease Control) in 2000 brought out growth charts and they represent the revised and improved version of NCHS charts. The CDC has introduced two BMI charts besides 16 (8 for boys and 8 for girls) charts. In 1993, the World Health Organization (WHO) undertook a comprehensive review of the uses and interpretation of anthropometric references. The review concluded that the NCHS/WHO growth reference, which had been recommended for international use since the late 1970s, did not adequately represent early childhood growth and that new growth curves were necessary. In response, WHO undertook the Multi-centre Growth Reference Study (MGRS) between 1997 and 2003 to generate new curves for assessing the growth and development of the children which could be applicable the world over.

WHO Multi-centre Growth Reference Study (MGRS) Charts: The MGRS combined a longitudinal follow-up from birth to 24 months and a cross-sectional survey of children aged 18 to 71 months. Primary growth data and related information were gathered from 8440 healthy breastfed infants and young

Fig. - 2

children from widely diverse ethnic backgrounds and cultural settings (Brazil, Ghana, India, Norway, Oman and USA). The MGRS is unique in that it was purposely designed to produce a standard by selecting

- (a) Healthy children living under conditions likely to favour the achievement of their full genetic growth potential.
- (b) The mothers of the children selected for the construction of the standards engaged in fundamental health-promoting practices, namely breast feeding and not smoking.

The growth standards provide a technically robust tool that represents the best description of physiological growth for children under five years of age. The standards depict normal early childhood growth under optimal environmental conditions and can be used to assess children everywhere, regardless of ethnicity, socioeconomic status and type of feeding. The new growth curves are expected to provide a single international standard that represents the best description of physiological growth for all children from birth to five years of age and to establish the breastfed infant as the normative model for growth and development.

Epidemiological Aspects of the Standards : As expected, there are notable differences with the NCHS/WHO reference that vary by age, sex, anthropometric measure and specific percentile or z-score curve.

1. Differences are particularly important in infancy.
2. Stunting will be greater throughout childhood when assessed using the new WHO standards compared to the NCHS/WHO reference.
3. The growth pattern of breastfed infants will result in a substantial increase in rates of underweight during the first half of infancy and a decrease thereafter.
4. For wasting, the main difference is during infancy when wasting rates will be substantially higher using the new WHO standards.
5. With respect to overweight, use of the new WHO standards will result in a greater prevalence that will vary by age, sex

and nutritional status of the index population.

Summary

Ensuring an optimal condition for a child's early years is one of the best investments that a country can make and it is a child's right to have every chance to survive and thrive. Environment plays a more important role than genetics in determining preschool age child nutritional status. Growth is the progressive increase in the size and development is progressive acquisition of various skills. Measurement of growth is an essential component of the physical examination in finding out the state of health and nutrition of a child. It follows a particular pattern over a period of time termed as *sigmoid curve* and the body, brain and gonads grow in a different manner in different phases of childhood. There are various measurements that are used to measure growth like Weight, Head circumference, Mid Upper Arm Circumference (MUAC), Height / length, Chest circumference. Weight for age in children from 6 months to 7 years of age is an index of acute malnutrition, and is widely used to assess protein energy malnutrition and over nutrition. HC is important because it is closely related to brain size. It can be used as an index of chronic protein energy nutritional status during the first two years of life. Arm contains subcutaneous fat and muscle. A decrease in MUAC may therefore reflect either a reduction in muscle mass, a reduction in subcutaneous issue, or both and it changes very little from 1-5 years of age and it can be used as an age-independent measurement. The length of a child is measured in the first 3 years and the height is measured after 3 years of age. On a height chart, you should determine whether the growth pattern is normal. A normal growth pattern is parallel to the printed percentile lines. The various skills the baby and a young child learn are called *milestones* and that's why we notice at what age the child achieves various milestones, such as smiling at the mother, sitting without support, grasping objects with his/her hands, standing, walking and talking. Infant development occurs in an orderly and predictable

Fig. - 3

manner that is determined intrinsically. Speech delays are the most common developmental concern. Piaget was the first to describe the infant as having intelligence. Developmental quotient (DQ) is the developmental age divided by chronologic age times 100. This provides a simple expression of deviation from the norm. A quotient above 85 in any domain is considered within normal limits. The factors that promote development include good nutrition, emotional support, play and language training. Growth Monitoring was popularized by David Morley in 1960s' and 70s' (1-5). This strategy proved that growth monitoring could improve nutritional status. In 1982 growth monitoring, i.e. the regular weighing of children and charting their weight on a chart was taken up by UNICEF as part of the *GOBI* program. Anthropometry is very useful for measuring overall health status, not just nutritional status. IAP has laid down various guidelines for growth monitoring according to different age groups. Height and weight measurements mean little unless compared to a growth reference. Anthropometric indices are combinations of the measurements. They are important since mere measurements provide little useful information; for example Ponderal index, WFH (weight for height), HFA (height for age) and WFA (weight for age). These indices could be expressed in the form of Z-scores, percentiles and % of median. The prototype WHO chart (home based) had two reference curves. The upper curve represented the median for boys (50th percentile) and the lower curve represented the 3rd percentile for girls. The growth standards provide a technically robust tool that represents the best description of physiological growth for children under five years of age.

Study Exercises

Long Question : "Growth and development is very helpful in finding out the state of health and nutrition of a child". Explain in detail.

Short Notes : (1) Mid upper arm circumference (2) Development quotient (3) Growth monitoring (4) Anthropometry (5) Growth charts (6) IAP guidelines for growth monitoring

MCQs and fill in the blanks

- 1) At birth head size is _____ % of the expected head size of the adult.
- 2) Weight for age in children from _____ years to _____ years of age is an index of acute malnutrition
- 3) Head circumference at birth is _____ cm
- 4) The length of a child is measured in the first _____ years.
- 5) By 2 - 2½ years of age the baby will have _____ primary teeth.
- 6) A developmental quotient below _____ is considered abnormal
- 7) Growth Monitoring was popularised by _____
- 8) Weight / height³ represents a) Brocas index b) Ponderal index, c) Quetelet index, d) none
- 9) Z score = _____

Answers: (1) 65 to 70; (2) 0.5 yrs to 7 yrs; (3) 35; (4) 3; (5) 20; (6) 70; (7) David Morley; (8) b;

$$(9) Z \text{ score} = \frac{(\text{observed value}) - (\text{median reference value})}{\text{Standard deviation of the reference population}}$$

Historical Aspects

Homo sapiens first appeared on this planet approximately 50,000 years ago. Early man seemed to be as curious as in the present day on matters of inheritance. Engravings in Chaldea in Babylonia (now Iraq) dating back at least 6000 years show pedigrees documenting the transmission of certain characteristics of the mane in horses. Early Greek philosophers and physicians such as Aristotle and Hippocrates concluded with typical masculine modesty that important human characteristics were determined by semen utilizing menstrual blood as a culture medium and the uterus as an incubator. Our present understanding of human genetics owes much to the work of the Austrian monk, Gregor Mendel, who in 1865 presented the results of his breeding experiments on garden peas. The importance of these findings were however only realized in 1900. It was a Danish botanist, Johannsen who coined the term “gene” for the hereditary factors postulated by Mendel. Credit for first recognition of a single gene trait is shared by William Bateson and Archibald Garrod who proposed that alkaptonuria was a rare recessive disorder. During the twentieth century, it gradually became clear that hereditary factors are implicated in many conditions and that different genetic mechanisms are involved. The study of genetics and its role in the causation of human disease has in modern times been at the forefront of medical research. Francis Crick, James Watson and Maurice Wilkins in 1962 gained acclaim for their elucidation of the structure of DNA. In the next 30 years or so the Nobel prize was awarded on twelve occasions to scientists working in the field of human and molecular genetics. Dramatic advances in technology lead to better and more complete understanding of the way we inherit different characteristics, why diseases occur and human biology. Increasing globalization and the internet enabled the gigantic “Human Genome Project” started in 1991, mainly with funding by United States Government, to map the complete human genome. Thus throwing up tremendous potential for diagnosis and management of human disease. Gene therapy, which till recently was considered in the realms of science fiction, suddenly became eminently possible although its routine use in the management of disease is still several years away.

Increasing control world wide on communicable diseases, ethical considerations of gene manipulation and better understanding of genetic basis of disease has pushed genetics into the realm of public health. A comprehensive knowledge of elementary genetics is now therefore inescapable for a potential public health specialist.

Cellular basis of Inheritance

The structure of a cell as evident on light microscopy is shown in Fig 1.

The transmission of hereditary characteristics is controlled by chromosomes located inside the nucleus and containing genes which are made up of DNA. The double helical structure of DNA

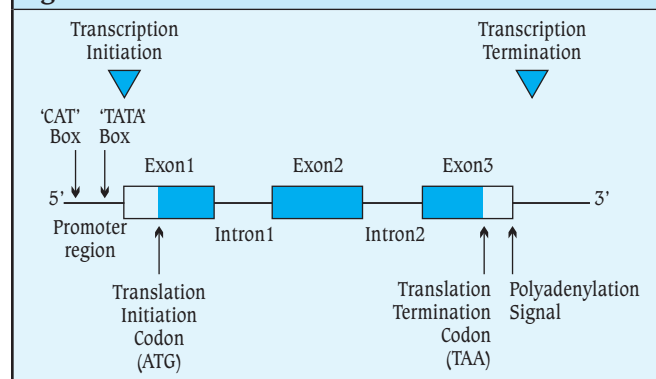

was proposed by Watson and Crick to explain the versatility of the transmission mechanism. The chromosome structure is however more complex. DNA sequences make up genes which code for different proteins necessary for life. It is estimated that there are upto 1,00,000 genes in the nuclear genome, which code for specific proteins in humans. Many human genes are single copy genes coding for polypeptides which carry out a variety of cellular functions. These include enzymes, hormones, receptors and structural and regulatory proteins.

Fig - 1 : Structure of Cell

The original concept of a gene as a contiguous sequence of DNA coding for a protein was turned on its head in the early 1970s by detailed analysis of the structure of the β -globin gene which revealed it to be much longer than the length necessary to code for the β -globin protein. The gene was found to be containing non-coding intervening sequences or “introns” separating the coding sequences or “exons”. The number and size of introns in various human genes is extremely variable although the general trend is that larger the gene, the greater the number of exons.

Fig - 2 : Structure of Gene

The process whereby genetic information is transmitted from DNA to RNA is called “transcription”. The information stored in the genetic code is transmitted from DNA to messenger RNA (mRNA) which is single stranded. The mRNA leaves the

nucleus after undergoing “post-transcription processing”. The transmission of the genetic information from mRNA to protein is called “translation”. mRNA migrates out of the nucleus into the cytoplasm where it becomes associated with the ribosomes, which are the site of protein synthesis. In the ribosomes, the mRNA forms the template for producing a particular sequence of amino acids (See Fig. - 3a & b).

Fig. - 3a : Process of Transcription

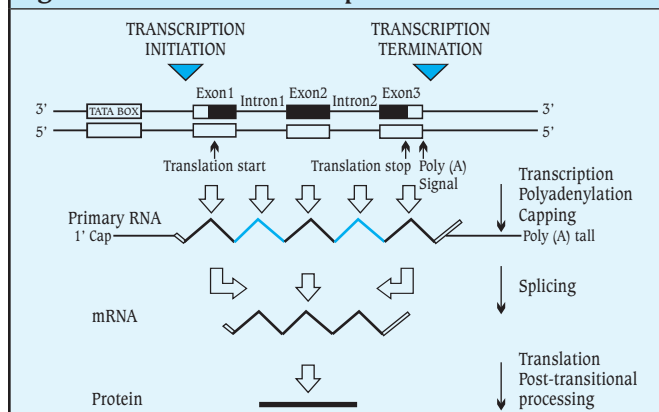

Fig. - 3b : Process of Translation

Genetic information is stored with the DNA molecule in the form of a triplet code, that is a sequence of three bases determines one amino acid. Only 20 different amino acids are found in proteins. By experimentation with various refinements, triplet codes have been assigned to all 20 amino acids. The triplet of nucleotide bases in mRNA which codes for a particular amino acid is called “codon”. In addition to “Structural genes” (which are concerned with the synthesis of specific proteins), there are “control genes” which regulate the activity of structural genes. It was initially believed that genetic information was transferred from DNA to RNA and thence translated into protein. However, at times genetic information can occasionally flow from RNA to DNA (as in the case of retro virus). This is referred to as “RNA directed DNA synthesis”.

Mutations

A mutation is defined as an alteration or change in the genetic material. Mutations are usually harmful and can arise due to exposure to mutagenic agents but may occur in a vast number of cases spontaneously through errors in DNA replication and repair. Although mutations can occur in “coding” or “non-

coding” sequences, it is only in the former that some disease or condition arises. A mutation occurring in a somatic cell cannot be transmitted to future generations. It is estimated that each individual carries upto six lethal or semi-lethal recessive mutant alleles which in the homozygous state would have very serious effects. Occurrence of mutations in DNA, if left unrepaired, would have serious consequences both for the individual and subsequent generations. The stability of DNA is dependent on “DNA repair”. Defects in this mechanism can lead to chromosomal breakage syndromes.

Chromosomes

Chromosomes are thread like structures and can be considered to be made up of genes. The centromere divides the chromosome into short and long arms designated ‘p’ = petit and ‘q’ = grand respectively. The tip of each end is referred as telomere, which plays an essential role in sealing the ends of the chromosome. In human cells, there are 22 pairs of autosomes and a pair of sex chromosomes - XX in female and XY in male. One member of each chromosome is derived from each parent. Somatic cells have a diploid component consisting of 46 chromosomes whereas gametes (ova or sperm) have haploid complement of 23 chromosomes. Recent developments have allowed the study of chromosomes to detect regions of allele loss and gene amplification. The process of cell division ensures that the human zygote which is a single cell at conception undergoes rapid division leading to approximately 10^{14} cells in an adult. In some organs and tissues, the process of cell division continues throughout life. In mitosis (somatic cell division) the chromosome divides longitudinally and after separation forms two daughter cells. In meiosis (gamete formation) the chromosome number is halved during Meiosis I while Meiosis II is like ordinary mitotic division. Meiosis facilitates halving of the diploid number of chromosomes so that each child receives half of its chromosome complement from each parent. It also provides an extraordinary potential for generating genetic diversity as DNA derived from both parents are present in each chromatid. The process of gametogenesis is different in male and female.

In oogenesis, oogonia derived from primordial germ cells start undergoing meiosis by 3 months of intra uterine life. At birth all the primary oocytes enter a phase of maturation arrest known as dictyotene in which they remain suspended until meiosis I is completed at the time of ovulation when a single secondary oocyte is formed. The lengthy interval between onset of meiosis and its eventual completion upto 50 years later has been suggested as the reason for the well documented increase in chromosomal abnormalities in offspring of older mothers.

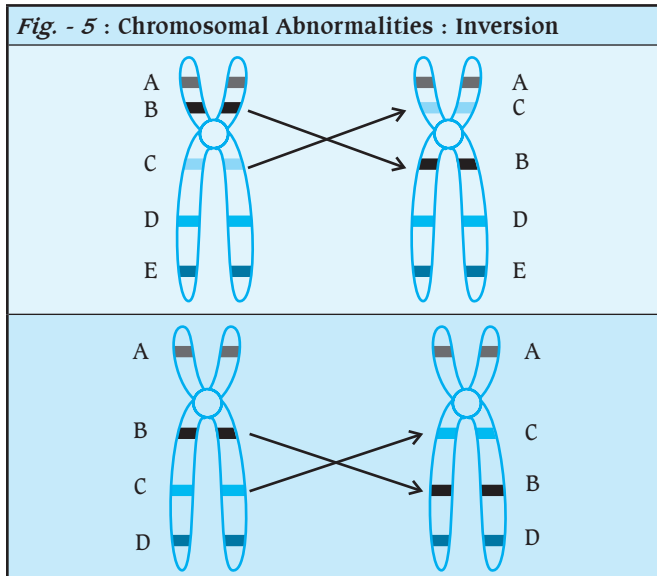

In spermatogenesis, spermatogonia mature into primary spermatocytes at puberty. Spermatogenesis is a continuous process involving many mitotic divisions so that spermatozoa produced by a man of 50 years or older could well have undergone several hundred mitotic divisions. DNA copy errors may lead to mutations in offspring of older parents.

Chromosomal Abnormalities

A large number of disorders are due to chromosomal abnormalities which can be due to either numerical or structural abnormality of chromosomes. Numerical abnormalities

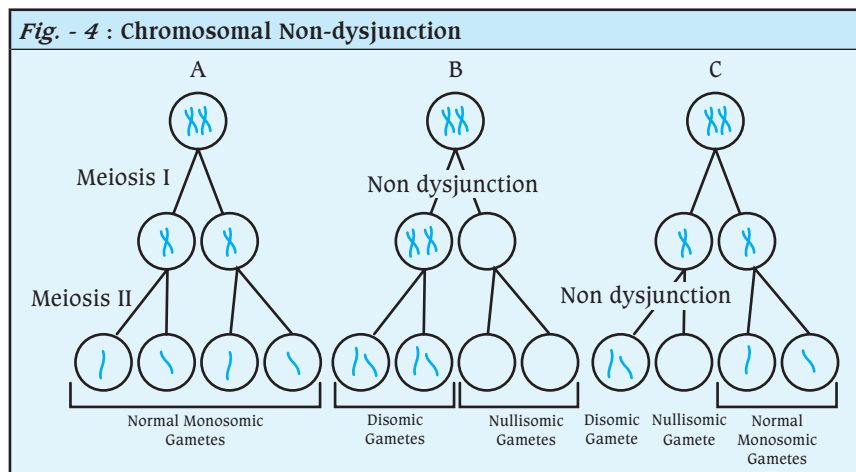

involve the gain or loss of one or more chromosomes- aneuploidy or addition of one or more complete haploid complement of chromosomes - polyploidy. The common examples are Trisomy 21 (Down's syndrome), Trisomy 13 (Patau's syndrome), Trisomy 18 (Edward's syndrome), Monosomy X (Turner's syndrome), Super males (XYY) or Super females (XXX). The commonest cause is non-disjunction during meiosis (Fig.-4). Polyploidy is found relatively often in spontaneous miscarriage and is usually not commensurate with life. It is usually due to failure of a maturation meiotic division in ovum or sperm or fertilization of an ovum by two sperms.

Structural chromosomal abnormalities result from chromosome breakage with subsequent reunion in a different configuration (Fig. - 5). This may be due to translocation (transfer of genetic material from one chromosome to another), deletions (loss of part of a chromosome), insertions (segment of one chromosome becomes inserted into another chromosome), inversions (two break rearrangement involving a single chromosome in which a segment is reversed in position), ring chromosome (break on each arm of a chromosome leaving two "sticky" ends which reunite as a ring) and Isochromosomes (loss of one arm of a chromosome with duplication of the other arm). In all the structural abnormalities, when there is loss or gain of genetic material called balanced rearrangement, the effect is mild. When there is incorrect amount of genetic material due to loss or gain, it is called unbalanced arrangement and the clinical effects are usually very severe.

Incidence and Prevalence of Genetic disease

Genetic disease may manifest at birth or may remain without manifesting till several decades later. Besides the disorders which are clearly genetic in origin, several disorders like

Diabetes mellitus, cancers etc. are multi- factorial in origin. The genetic predisposition with suitable environmental conditions can lead to the occurrence of these diseases. The very process of aging is now considered to be genetically determined as are some of the diseases which have a rising incidence with age - "acquired somatic genetic disease".

Certain predictions have been made based on the assumption that heritability of disease declines with increasing age :

- Persons with early onset of symptoms are more likely to have severe disease and also to have affected first degree relatives.
- Age specific age at onset should reach a peak and then decline.
- Multi-genic diseases do not require a specific environment for their occurrence.
- Migration, socio-economic status and other environmental change may affect the age of onset and the likelihood of the clustering of the disease in families.
- If one sex is less often affected, early onset, severity and increased incidence in affected relatives should characterize it.
- Concordance in monozygotic twins should be greatest when disease onset is early.
- Patients with late onset of the disease have milder forms of the disease which are more amenable to prevention and treatment.

Burden of Genetic Disease

The burden of diseases of genetic etiology in a community is determined by the "Gene pool", customs regarding marriage (breeding patterns) and migrations. The social and demographic structures of populations play a very significant role in the distribution patterns of specific inherited disorders. In countries with recent industrialization and urbanization, widespread population movement from the countryside (rural areas) to rapidly expanding towns and cities (urban areas) have resulted in dissolution of historical, local, regional and national boundaries. This has helped to exert a partial homogenizing effect on national gene pools. This is similar to the effect that large scale migration from Europe to Americas and Australia had in the previous centuries which resulted in significant mixing of previously distinct populations.

In most developing countries, local and regional clan, tribal and ethnic grouping have largely remained intact. In India, Pakistan and Bangladesh which collectively account for more than 20% of the world's population, marriage continues to be arranged within caste and *biraderi* boundaries that probably date back some 3000 years. In India, it is estimated that there are 50,000 to 60,000 separate endogamous communities. 25 percent of the population of more than 1 billion are members of the scheduled castes and scheduled tribes which number more than 1600. Muslims account for 130 million of India's population. Each of these groupings forms separate breeding pools - Hindus (divided into castes & regions), Muslims, Sikhs, Christians, Jains, Buddhists, Parsis etc.

Therefore diseases caused due to mutations of ancient origin are likely to be distributed throughout the population. However diseases due to mutation which have arisen more recently may be restricted or even unique to individual ethnic groups, sub-castes, tribes or clans.

Although adequate statistics are not available in India of the incidence and prevalence of genetic disorders, certain studies have attempted to estimate the burden due to genetic diseases in India. The large population, high birth rate and favouring of consanguineous marriage by significant numbers of communicants, should lead to high prevalence of genetic disorders in the country. According to a study it is estimated that every year 4,95,000 infants with congenital malformations, 3,90,000 with G-6 PD deficiency, 21,400 with Down's Syndrome, 9,000 with thalassaemia, 5,200 with sickle cell disease and 9,760 with amino acid disorders are born each year. Studies on haemoglobinopathies indicate that they represent a significant national health burden in India. Distribution of specific disorders varies geographically and by community. Heterozygote frequencies of thalassaemia range from 1 to 15 percent resulting in an estimated 20 million carriers. Sickle cell anaemia is mainly present in tribal communities with carrier presence as high as 40 percent in some cases. It is estimated that there are 50,000 affected Hemophilia patients nation wide with an additional 1,500 new cases born each year. The prevalence of late onset multifactorial disorders including coronary artery disease, hypertension and psychiatric disorders is also large. Genetic eye disorders have been reported in large numbers. Shankar Nethralaya, the premier institute for ophthalmology in South India has reported 2,335 patients with genetic eye disorders over a five year period. 673 (28.8 percent) of these patients reported a family history of consanguinity. Retinitis pigmentosa was detected in a large proportion (63.9 percent) of those reporting family history of consanguinity.

The seriousness of the burden of genetic disorders in India is thus clearly appreciable in spite of lack of population based studies. Determining the role of genetics in disease will require better methods of classifying disease and processing health data. Computerized record keeping will become very important not only to build longitudinal health histories on individuals but also to link these into sibships and family groupings. Administrative and other health data sets that already exist can be combined to evaluate if familial clustering occurs. If familial clustering is detected, then various methodologies may be used to untangle whether this is due to genetic or shared

environmental factors or more likely to be an interaction between the two.

Categories of Genetic Disease

The broad classification of various categories of genetic disease has evolved with the availability of sophisticated diagnostic tools which has enabled identification of genetic and molecular basis of these disorders.

Chromosomal Disorders

Since the demonstration in 1959 that the presence of an additional number 21 chromosome (Trisomy 21) results in Down's syndrome, more than 1,000 chromosomal syndromes have been reported. They have a major contribution to morbidity and mortality in infants and account for a large proportion of spontaneous abortions. Chromosomal abnormalities have been detected in 10 percent of spermatozoa and 25 percent of mature oocytes. It is estimated that 15-20 percent of pregnancies do not survive beyond a few weeks due to presence of chromosomal abnormalities and also that more than 50 percent of all spontaneous abortions are having chromosomal abnormalities. The common abnormalities are :

- Trisomy (50 percent)
- Monosomy X (20 percent)
- Triploidy (15 percent)
- Tetraploidy (5 percent)
- Others (10 percent)

The presence of chromosomal abnormality in newborns ranges up to 90 per 10,000 births. The common abnormalities are Autosomal (20 per 10,000) & Sex chromosome (30 per 10,000). The presence of chromosomal abnormality reduces from conception to birth. The presence in still births is about 5 percent. It is known that spontaneous pregnancy loss occurs commonly in the presence of chromosomal abnormalities, with as high as 80%-98% pregnancies being lost among foetus having Monosomy or various forms of Trisomy. The common chromosomal disorders are :

Autosomal Disorders (Gain of entire chromosome)

- Down syndrome (Trisomy 21)
- Patau syndrome (Trisomy 13)
- Edward's syndrome (Trisomy 18)

Chromosomal Deletion Syndromes (Deletion of part of chromosome)

- Wolf Hirschhorn syndrome (Chromosome 4)
- Cri-du-chat syndrome (Chromosome 5)
- Retinoblastoma (Chromosome 13)
- Wilm's tumour (Chromosome 11)

Sex Chromosomal Disorders (Gain or loss of entire chromosome or part)

- Klinefelter's syndrome (47, XXY)
- Turner's syndrome (45, X)
- Super females (47, XXX)
- Super males (47, XYY)
- Fragile X Syndrome (46, XX*)

The chromosomal disorders are all potentially detectable by pre natal diagnosis. Since only those subgroups of women identified as being at higher risk (due to family history or age) are screened pre-natally, there is an opportunity to avoid only a proportion of these conditions at present.

Single Gene or Mendelian Disorders

Credit for the first recognition of a single gene trait is shared by William Bateson and Archibald Garrod who together proposed that alkaptonuria was a rare recessive disorder. Since then many more disorders have been identified - by 1966 almost 1500 single gene disorders or traits had been identified which follow the Mendelian rules of inheritance. An American physician, Victor McKusick published a catalogue of all known single gene disorders. An online version of McKusick's catalogue has been created which is known as "Online Mendelian Inheritance in Man" (OMIM) which can be accessed on the World Wide Web. As on 07 July 2008, there were 18,811 single gene traits or disorders which were included in this catalogue. There are mainly four categories into which single gene disorders are grouped, based on patterns of inheritance as indicated below :

Autosomal Dominant Disorders (AD)

An autosomal dominant trait is one which manifests in the heterozygous state i.e. in a person possessing both the abnormal or mutant allele and the normal allele. It is often possible to trace a dominantly inherited trait or disorder through many generations of a family. The disorder is transmitted to both sexes of the progeny. Any child born to a person affected with a dominant trait has a one in two (50%) chance of inheriting it and being similarly affected. Autosomal dominant traits can involve only one organ or part of the body e.g. Polydactyly. The clinical features can show striking variation from person to person and in some cases the findings can be undetected - "reduced penetrance" possibly due to the modifying influence of other genes. Examples of autosomal dominant traits or disorders are Huntington's chorea, Neurofibromatosis, Polyposis coli. There may be also some cases due to new mutations. In these cases it will not be possible to trace the trait in the family and hence pose problems in genetic counselling.

Autosomal Recessive Disorders (AR)

Most recessive disorders are individually rare, each with a birth prevalence of 1 in 15,000 to 1 in 1,00,000. However, since there are so many, they have a considerable impact with 1 in 500 live born individuals being identified as having one of these disorders before age 25 yrs. The recessive traits and disorders are only manifest when the mutant allele is present in a double dose i.e. homozygosity. Individuals who are heterozygous for a recessive mutant allele show no features of the disorders and are perfectly healthy i.e. they are carriers. It is usually not possible to trace an autosomal trait or disorder through the family tree. However, consanguinity can be detected in the ancestors. Generally speaking, the rarer a recessive trait or disorder, the greater the frequency of consanguinity among the parents of the affected persons. Autosomal recessive traits are transmitted both to sons and daughters equally and both are capable of transmitting it to their sons and daughters. The progeny may however, not manifest unless they are in homozygous state. The chance of having an affected child inheriting the recessive trait is 1 in 4. Common examples of autosomal recessive traits or disorders are : cystic fibrosis, albinism, alkaptonuria, and haemoglobinopathies.

Sex Linked Inheritance

It refers to the pattern of inheritance shown by genes which are located on either of the sex chromosomes. Genes carried on the X chromosome are referred to as X-linked, while genes carried on the Y chromosome are referred to as exhibiting Y-linked or "Holoandric inheritance".

X-linked Recessive disorders (XR) : An X linked recessive trait is one determined by a gene carried on the X chromosome and usually only manifests in males. These disorders are transmitted by healthy heterozygous female carriers to affected males, as well as by affected males to their obligate carrier daughters. The mode of inheritance whereby only males were affected by a disease which is transmitted by normal females was appreciated by the Jews nearly 2000 years ago. They were excused from circumcision, the son of all sisters of a mother who had sons with the "bleeding disease" i.e. Haemophilia. The sons of the father's sibs were not excused. A male transmits his X chromosome to each of his daughters and his Y chromosome to each of his sons. If a male affected with Haemophilia has children with a normal female, then all his daughters will be obligate "carriers", but none of his sons will be affected. A male can not transmit his X-linked disorder to his son except in very rare circumstances. For a carrier female having children with a normal male, each son has a 1 in 2 (50%) chance of being affected and each daughter has a 1 in 2 (50%) chance of being a carrier. Duchenne muscular dystrophy and Haemophilia are common examples of X-linked recessive disorders.

X-linked Dominant Disorders (XD) : There are few disorders in this category like familial Hypophosphataemia with rickets, Alport's syndrome etc. It superficially resembles autosomal dominant inheritance. Both sons and daughters of an affected female have a 1 in 2 (50%) chance of being affected. However, an affected male transmits only to his daughters and not to his sons. Affected females are more common than males but are less severely affected as compared to males.

Y-linked Inheritance : Y-linked or holandric inheritance implies that only males are affected. An affected male transmits Y-linked traits to all his sons but not his daughters. Hairy ears, H-Y histocompatibility antigens and genes involved in spermatogenesis are carried on Y chromosome and therefore transmitted accordingly.

Mitochondrial Genetic Disorders

Genes coding for proteins involved in oxidative phosphorylation are located in mitochondria in human cells. These are always inherited from the mother. Disorders involving these genes therefore do not behave like other Mendelian disorders. Some examples of mitochondrial genetic disorders are Leber's optic atrophy, infantile bilateral striatal neurosis and Kearns-Sayre syndrome.

Multifactorial Disorders

Many disorders demonstrate familial clustering which does not conform to any recognized pattern of Mendelian inheritance. Francis Galton, a cousin of Charles Darwin, had carried out research on human characteristics like stature, physique and intelligence based on studying identical twins. The differences among twins in these parameters could only be

due to environmental influences. He introduced to genetics the concept of “Regression co-efficient” as a means of estimating the degree of resemblance between various relatives. This model, polygenic inheritance, of quantitative inheritance in which many genes play a role in the phenotypic expression is now widely accepted to explain the pattern of inheritance of many relatively common conditions including cleft lip and palate, hypertension and diabetes mellitus. The underlying genetic mechanisms are however, still not well understood.

The liability / threshold model to explain multi-factorial inheritance of disorders proposes that a threshold exists above which the abnormal phenotype is expressed. This hypothesis (rather than proven fact) helps to explain the observed system of inheritance of certain multi-factorial diseases like cleft lip/palate, pyloric stenosis and spina bifida as follows :

- The incidence of the condition is greatest amongst relatives of the most severely affected patients.
- The risk is greatest amongst close relatives of the index case and decreases rapidly in more distant relatives.
- If there is more than one affected close relative then the risks for other relatives are increased.
- If the condition is more common in individuals of one particular sex, than relatives of an affected individual of the less frequently affected sex will be at higher risk than relatives of an affected individual of the more affected sex.
- The risk of recurrence for first degree relatives (siblings and offsprings) approximates to the square root of the general population incidence, for e.g. if the incidence in the general population of a disease is 1 : 1000, the risk for first degree relatives of an affected person will equal approximately 1 in 32 or 3%.

The inheritance patterns in insulin dependent diabetes mellitus or type - I diabetes mellitus lends a good example of the above elucidated multi-factorial inheritance. The concordance rate in monozygotic and dizygotic twins is 50% and 12% respectively. The sibling recurrence risk is 6%. These observations point to contributions both by environmental and genetic factors. Known environmental factors include diet, viral exposure in early childhood and certain drugs. The disease produces irreversible destruction of insulin producing beta cells in the pancreas by the body's own immune system probably as a result of an interaction between infection and an abnormal genetically programmed immune response. The polygenic susceptibility consists of one major locus (IDDM-1, which is in the HLA locus on chromosome 6p21), and up to 20 minor loci. The product of these gene loci are believed to interact in a complex and poorly understood manner to confer susceptibility to environmental triggers of auto immune pancreatic beta cell destruction.

Acquired Somatic Genetic Disease

Not all genetic errors are present from conception. During the billions of cell division (mitosis), which occur during the life time, the opportunity for occurrence of mutations due to DNA copy errors and numerical chromosomal errors exist. Accumulating somatic mutations and chromosomal abnormalities are now known to account for a large proportion

of malignancies and possibly explain the rising incidence with increasing age of many serious illnesses including the ageing process itself.

Public Health Issues in Genetic Diseases

Epidemiological studies have helped us understand how genetic diseases are distributed in a population. Genetic methods are increasingly allowing us to identify genetically susceptible individuals. New molecular genetic techniques now allow particular DNA sequences to be evaluated in patients and compare with control subjects and hold out the hope for future progress in early detection and even management (gene therapy). Various considerations in prevention of genetic diseases, thus needs detailed analysis.

Primary Prevention

Eugenics : It is science of improvement of genetic endowment through breeding. It has long attracted the attention of mankind. The term was first coined by Francis Galton. “Positive Eugenics” seeks to improve the genetic endowment in the population of “favourable traits” by encouraging persons with these traits to intermarry. However, as we now know, the inheritance of most of these traits like appearance, skin colour, height, intelligence etc. are inherited in a complicated manner and are difficult to control. “Negative Eugenics” in which people suffering from serious disorders which are genetic in origin are debarred from producing children is practiced in most communities. Many countries do not allow migration of people who are known to have serious genetic diseases. However, as new mutations continue to occur negative eugenics can not be an effective public health tool to reduce the burden of genetic diseases.

Genetic Counselling : More than 40 years ago genetic counselling services to cater for the needs of persons seeking information regarding genetic diseases were first introduced. Genetic counselling caters for the concerns of individuals / families who have a family history of serious diseases. Their concern may be whether they can develop the disease or whether they can transmit the disease.

Genetic counselling has been defined as a process of communication and education which addresses concerns relating to the development and / or transmission of a hereditary disorder. The person who seeks genetic counselling is known as “consultand”. During genetic counselling, the counsellor tries to provide the consultand with information which enables him/her to understand :

- The medical diagnosis and its implications in terms of prognosis and possible treatment
- Mode of inheritance of the disorder and the risk of developing and / or transmitting it
- Choices or options available for dealing with the risks

Genetic counselling is non directive, with no attempt to lead the consultand in any particular direction. The process presents medical scientific facts / risks so that the “consultand” can make their own decisions. Commonly, people seek counselling after the occurrence of a hereditary disorder in the family. Rarely, individuals / couples may seek pre-marital advice. Usually , for diseases like mental retardation, congenital abnormalities, etc., there is occasional seeking of such counselling which is thus

“retrospective” in nature. In certain occasions there may be an attempt to identify heterozygous individuals for a disease and explaining the risks of marrying another heterozygote for the same disease - “prospective” counselling. In both prospective as well as retrospective counselling, the outcomes sought would range from contraception, pregnancy termination or even adoption of a child.

Steps in Genetic Counselling

Establishment of diagnosis : It is the most crucial step in any genetic counselling. Misleading advice may be given based on incorrect diagnosis which may lead to tragic consequences. A correct clinical diagnosis will require proper history taking, detailed clinical examination and appropriate investigations. The family history may need to be obtained by a properly trained genetics nurse or counsellor. Chromosomal and molecular studies will also be needed to establish the inheritability and genetic basis of the disease. At times, for example in hearing loss, etiological heterogeneity may affect the ability to correctly calculate the “recurrence risk”. Other disorders like congenital cataract (AD, AR, XR), ichthyosis (AD, AR, XR), retinitis pigmentosa (AD, AR, XR) and polycystic kidney disease (AD, AR) can also show “genetic heterogeneity”.

Calculating and presenting the risk : This is the next step based on the genetic diagnosis and calculation of risk based on well established norms like use of Bayes Theorem or use of “empirical risks”. The recurrence risks need to be quantified, qualified and placed in context. A risk statement “1 in 4” can be misunderstood that once it has occurred it will recur only after 3 normal children. Inheritance does not have any “memory” and applies for each offspring. For a risk of recurrence of “1 in 25”, it must also be explained that “24 out of 25” chance is for a normal baby. The risk needs to be qualified by aspects like long term burden rather than its precise numerical value. For a trivial disorder like polydactyly even a risk of “1 in 2” may not deter having more children. Whether a disease can be successfully treated, associated with pain and suffering and whether pre-natal advice is available can be relevant to the decision making process. Placing the risk in context is equally important. For a disease with a population risk of 1 in 40, an additional risk of 1 in 50 may in fact be considered low. As an arbitrary guide, risk of 1 in 10 or greater can be regarded as high while 1 in 20 or less can be regarded as low.

Discussing the options : It is a natural follow up after making the diagnosis and presenting the “risks”. All the choices should be provided with no attempt made to guide the consultand to select one of them. The issues need to be broached with care and sensitivity as the realization of the disease, its risks and the likely outcomes may be cause of great emotional shock to the consultand.

Communication and support: It is provided by most genetic counselling clinics. The setting of the counselling must be agreeable, private and quiet with ample time for discussion and questions. As far as possible, technical terms must be avoided but no attempt must be made to hide facts and questions answered honestly and openly. It is necessary to reiterate the aspects covered specially the aspects of risk in written communication as all aspects may not have been clearly

understood by the Consultand during the limited duration of the counselling session. A letter summarizing the topics discussed is then sent to the Consultand. Informal contact through a network of genetic associates or nurse specialist are also an added features of genetic counselling clinics.

Other Health Promotional Measures : Problems of increased genetic diseases in late marriages and advancing age of mother are now common knowledge. Appropriate counselling is required to restrict pregnancies arising from late marriages or in women past 35 years.

Consanguineous marriages are another cause for concern. Community involvement will be needed to overcome this social occurrence. A consanguineous marriage is defined as one in between blood relatives with at least one common relative no more remote than great-great-grand parents. Hearing loss, mental retardation, alkaptonuria are common among offsprings of consanguineous marriages.

Specific Protection : Radiation, chemicals and drugs are known to produce mutations and teratogenic effect. Adequate protection is needed to be ensured for persons in the reproductive age group. X-Ray and other ionizing radiations produce mutations which are proportional to the dose of radiation. There is no threshold. Genetic effects are known to be cumulative and protection is routinely provided to all those who are likely to be occupationally exposed to radiation.

Chemicals like mustard gas, benzene, formaldehyde, caffeine, etc. are known mutagens in animals. Caution is therefore required to prevent exposure to these and basic dyes by human specially those in the reproductive age groups. A large number of drugs have been known to be teratogenic and need to be avoided in pregnancy.

Early Diagnosis : Increasing awareness of the role of genetics in the etiology of disease and its overall impact on the burden imposed on individuals, families and society has lead to introduction of several population genetic screening programs. The primary objective is to enable individuals to be better informed about genetic risks and reproductive options. A secondary objective is the prevention of morbidity due to genetic diseases and alleviation of the suffering. The scope of early diagnosis thus covers apparently healthy persons who may wish to be made aware of genetic disease in themselves or their offspring, diagnosis of the presence of genetic abnormalities in utero as well as the new born and for diagnosis of genetic disease or carrier state in the siblings of a person (adult or child) diagnosed with a genetic disease.

A number of tests of different types are available to detect carriers for Autosomal and X-linked recessive disorders and for pre-symptomatic diagnosis of heterozygotes for Autosomal dominant disorders. Biochemical or hematological techniques can be used to detect carriers of Autosomal recessive disorders like Tay-sachs disease (reduced hexosaminidase A levels in serum), sickle cell disease / trait (sickling of RBCs in deoxygenated condition), Duchenne muscular dystrophy (elevated serum creatinine kinase level) and G-6PD deficiency (reduced erythrocyte - G6PD activity). However these tests are reliable only in those cases where the gene involved is directly involved in the biochemical activity.

Table - 1 : Pre-natal diagnostic techniques			
Technique	Test & Result	Foetal age	Genetic conditions diagnosed
Chorionic villus sampling (2-3% risk of miscarriage)	Chromosome analysis	10-11 wks	Chromosomal abnormalities
	Biochemical assay		Metabolic disorders, Molecular defects
Amniocentesis (0.5-1% risk of miscarriage)	α -fetoprotein raised	16 wks	Neural tube defects
	Chromosome analysis		Chromosomal abnormalities
	Biochemical assay		Metabolic disorders, Molecular defects
Ultrasound (also indirect evidence of chromosomal disorders)		18 wks	Structural abnormalities (heart, kidney, limbs, CVS)
Fetoscopy (3-5% risk of miscarriage)		2nd trimester	Structural abnormalities & others
Radiography (now rarely used)		10 wks	Skeletal dysplasias
Maternal serum screening (usually standard screening for "at risk" mothers)	Fetoprotein raised	16 wks	Neural tube defects
	Quad test - α -fetoprotein reduced - Unconjugated oestriol reduced - HCG increased - Inhibin A increased		Down's syndrome

Table - 2 : Treatment modalities in genetic diseases	
Treatment	Disorder
<i>Enzyme induction by drugs</i> : Phenobarbitone	Congenital Non-haemolytic Jaundice
<i>Replacement of deficient enzyme / protein</i> : Blood transfusion a-glucosidase Factor VIII	SCID Gaucher's disease Haemophilia A
<i>Replacement of deficient vitamin / co-enzyme</i> : B ₆ D	Homocystinuria Vit D resistant rickets
<i>Substrate reduction in diet</i> : Phenylalanine Leucine/isoleucine/valine Galactose Cholesterol	Phenylketonuria Maple syrup disease Galactosaemia Fam. hypercholesterolaemia
<i>Drug therapy</i> : Pancreatic enzymes Penicillamine	Cystic fibrosis Wilson's disease
<i>Replacement of diseased tissue</i> : Kidney transplant BM transplant	Polycystic kidney disease X-linked SCID
<i>Removal of diseased tissue</i> : Colectomy Splenectomy	Polyposis coli Hereditary spherocytosis

Until the recent past, couples at high risk of having a child with a genetic disorder had to choose between taking the risk or considering other reproductive options. In the recent past reliable pre-natal diagnosis of abnormalities in an unborn child have been widely used to assist decision making by such couples. The ethical issues are however very complex. The techniques used are amniocentesis, chorionic villus sampling, ultrasonography, fetoscopy, foetal blood sampling, radiography and maternal serum screening. A summary of the techniques is indicated in Table - 1.

Treatment : A large number of genetic diseases are “treatable” and the disablement reduced provided the defect has been diagnosed in time. Some of these treatable conditions are enumerated in Table - 2. Although still in the realm of research, gene therapy to correct the genetic abnormality is a distinct possibility and needs serious consideration.

Strategy for public health action

The volume of new knowledge and technologies from genetic and genomic research is such that a concerted effort is needed to ensure the effective translation of these scientific advances into benefits for population health. International consensus has been achieved on a public health strategy for achieving this goal. This strategy recognizes the importance of knowledge integration. This integrated and interdisciplinary knowledge base is used for informing public policy, developing new health services (both preventive and clinical), communication and stakeholder engagement, and education and training of health professionals. A new initiative GRAPH *Int* (Genome-based Research And Population Health International) has been established to promote this strategy for public health action in the genomics era. It facilitates the responsible and effective integration of genome-based knowledge and technologies into public policies, programme and services for improving the health of populations. Practitioners of public health are expected to contribute to this endeavour by remaining aware of the growing importance of the understanding of genetic mechanisms in disease & of the potential to utilize the new genetic knowledge for the benefit of both individuals & society.

Summary

Our present understanding of human genetics owes much to the work of Sir Gregor Mendel in 1865 on breeding experiments on garden peas. In 1962, James Watson and Maurice Wilkins discovered the structure of DNA. The gigantic “Human Genome Project” started in 1991 by US Govt to map the complete human genome to tap its tremendous potential for diagnosis and management of human disease through ‘gene therapy’. Genetic disease may manifest at birth or later or may remain without manifesting. Broadly genetic diseases are classified as Chromosomal disorders - numerical chromosomal abnormalities arising due to non-disjunction during meiosis while structural chromosomal abnormalities results from chromosomal breakage syndrome; Single gene / Mendelian disorders-includes autosomal dominant, autosomal recessive & sex linked disorders; Mitochondrial disorders; Multifactorial disorders-viz spina bifida, diabetes mellitus, cleft lip & cleft palate etc; and Acquired somatic genetic disease-due to accumulation of somatic mutations & aging process itself.

Newer molecular genetic techniques allows to detect particular DNA sequence responsible for causation of disease and therefore escalating importance of prevention of genetic diseases by ethically utilizing preventive approaches viz Eugenics, Genetic counselling, avoidance of consanguineous & late marriages and avoiding exposure to radiation, mutagenic/ teratogenic chemicals and drugs. Besides, myriad of population genetic screening tests and prenatal diagnostic tests are also available for early detection and timely intervention. A new initiative GRAPH *Int* - Genome based research and population health international has been established to promote the strategy for public health action in this genomic era.

Study Exercises

- The Austrian monk who presented the results of his breeding experiments on garden peas in 1865 was (a) James Watson (b) Gregor Mendel (c) William Bateson (d) Johannsen
- The term ‘Gene’ was coined by (a) James Watson (b) Gregor Mendel (c) William Bateson (d) Johannsen
- The double helical structure of DNA was proposed by (a) Watson & Crick (b) Mendel & Wilkins (c) Bateson & Garrod (d) Johannsen & Maurice
- How many genes are estimated to be in the human genome (a) 50,000 (b) 1,00,000 (c) 1,50,000 (d) 2,00,000
- The process where genetic information is transmitted from DNA to RNA is called (a) Processing (b) Transcription (c) Translation (d) Sequencing
- The site for protein synthesis in the cell is the (a) Mitochondria (b) Nucleus (c) Cytoplasm (d) Ribosome
- How many amino acids are involved in formation of proteins (a) 10 (b) 15 (c) 20 (d) 25
- The triplet of nucleotide bases in mRNA which codes for a particular amino acid is called (a) Structural genes (b) Codon (c) Control genes (d) Genome
- The stability of DNA is based on (a) Coding (b) Non-coding (c) Mutation (d) DNA repair
- The process of cell division ensures that the human zygote which is a single cell at conception undergoes rapid division leading to cells in an adult (a) 10^4 (b) 10^{10} (c) 10^{14} (d) 10^{20}
- Edward’s syndrome is (a) Trisomy 21 (b) Trisomy 13 (c) Trisomy 18 (d) Trisomy 22
- Patau’s syndrome is (a) Trisomy 21 (b) Trisomy 13 (c) Trisomy 18 (d) Trisomy 22
- Concordance in monozygotic twins should be greatest when disease onset is early: True/False
- Multigenic diseases require a specific environment for their occurrence. True/False
- The burden of diseases of genetic etiology in a community is determined by all except (a) Gene pool (b) Breeding pattern (c) Migration (d) None
- Chromosomal deletion disorder associated with Chromosome 4 is called (a) Wolf Hirschhorn syndrome (b) Cri-du-chat syndrome (c) Retinoblastoma (d) Wilm’s tumour
- Chromosomal deletion disorder associated with Chromosome 13 is called (a) Wolf Hirschhorn syndrome (b) Cri-du-chat syndrome (c) Retinoblastoma (d) Wilm’s tumour

18. As on 07 July 2008, there were _____ single gene disorders included in Mckusick's catalogue (a) 16,811 (b) 17,811 (c) 18,811 (d) 19,811
19. The genes coding for proteins involved in oxidative phosphorylation are located in (a) Mitochondria (b) Nucleus (c) Cytoplasm (d) Ribosome
20. The concept of "regression coefficient" as a means of estimating the degree of resemblance between relatives was given by (a) James Watson (b) Gregor Mendel (c) William Bateson (d) Francis Galton
21. In multifactorial diseases, the incidence of a condition is greatest among relatives of the most severely affected patients : True/False
22. The science of improvement of genetic endowment through breeding is (a) Eugenics (b) Euthenics (c) Genetic counselling (d) None
23. The term 'Eugenics' was coined by (a) James Watson (b) Gregor Mendel (c) Francis Galton (d) Johannsen

24. The person who seeks Genetic counselling is called _____

25. GRAPH *Int* stands for _____

26. Chorionic Villous Sampling is ideally done at (a) 8 -10wks (b) 10 -12wks (c) 12 -14wks (d) 14 -16wks

Answers : (1) b; (2) d; (3) a; (4) b; (5) b; (6) d; (7) c; (8) b; (9) d; (10) c; (11) c; (12) b; (13) True; (14) False; (15) d; (16) a; (17) c; (18) c; (19) a; (20) d; (21) True; (22) a; (23) c; (24) Consultant; (25) Genome-based Research & Population Health International; (26) b.

Preventive Health Care of the Elderly

RajVir Bhalwar

In general, "elderly" age group is defined as persons aged 65 years and above. With improvements in health care, there have been resultant increases in life expectancy and increase in the percentage of "elderly population". For instance, the current estimates are that in our country the percentage of population who are aged 65 years and above, which was 3% a few decades back, is now 5% and is likely to increase to 10% by 2025 AD and 18% by 2050 AD. These demographic changes will require shifting our focus to cater to geriatrics. i.e. special preventive health care needs as well as medical care needs of the elderly population.

Peculiarities of elderly population in context of health needs

The peculiarities of health needs of elderly people are that their health problems cannot be seen in isolation. There is a wide gamut of social, psycho-emotional and physical correlates which determine the medical problems and this entire gamut of factors (and not simply the treatment of concerned condition) needs to be addressed. The important ones of these factors are as follows :

Social Aspects : As industrialization progresses, it will be difficult for the children to stay on with their parents and carry on with the conventional family occupations. As children move out and take up the vocation in other places, the problems

of isolation and lack of physical support of the old parents, left behind at ancestral places, will come up. Even day to day requirement of life like going out to pay the electricity / telephone bills, buying fresh fruits and vegetables and even cooking a proper nutritious meal would become difficult.

Psycho-Emotional Aspects : With loneliness at home, isolation will occur which would get aggravated if one of the spouses passes away. Friend circle will also get restricted because friends would also get old. The problem of isolation would get worse because of retirement when the old persons would find it difficult to keep them occupied. This complex interplay will not only increase the risk of mental stress and its consequences but also aggravate the impact of stress related diseases as IHD and hypertension.

Financial Issues : Unless backed up by adequate financial savings or pension plans, or else financially assisted by children, there will be definite reduction in income, to the extent that it may interfere with bare needs of life as adequate nutrition, clothing and shelter.

Issues Related to Health care System : At present we do not have a very effective health insurance system in our country, which coupled with the inadequacies of public / Govt. funded general health care system and inadequate training of medical, paramedical personnel in geriatric medicine would adversely affect the health care of the elderly.

Medical Problems of the Elderly

A description of medical problems of the elderly is given in this chapter. However, as said earlier, these problems should not be seen as isolated medical issues but should be viewed in the larger context of socio-economic-emotive determinants as

an overall health issue. For example, organizing an eye camp for the elderly would have little benefit if the transportation system, traffic control and street / domestic lighting is not improved.

Medical officers and public health programme managers should make special efforts to understand both the preventive as well as curative aspects of health care of the elderly since a significant proportion of our clientele would belong to this age group, and the proportion is likely to further increase, given the steady increases in life expectancy that are occurring in our population.

The health problems of elderly can be divided into 3 groups :

- (a) Problems which are important for both genders.
- (b) Problems which mainly concern the elderly males.
- (c) Problems which mainly concern the elderly females.

Problems which are Important for Both the Genders

Ocular Diseases : Age related diminution of vision and cataracts are major issues among elderly and significantly compromise the quality of life as well as Activities of Daily Living (ADL). Glaucoma also is an important cause of suffering among elderly.

Hearing Defects : Reduction in acuity of hearing not only compromises the quality of life but even drives an old person into emotional isolation because they find it difficult to communicate.

Reduced Muscular Strength and Coordination : Reduction in muscular strength due to reduction in lean mass coupled with reduced flexibility and neuromuscular coordination occurs with age and results in increased proneness to accidents and injuries.

Accidents and Injuries : There is marked increase in risk of accidents and injuries among the aged. The major physiopathological factors which contribute to such increased proneness are diminution of vision and hearing, reduced muscular strength and neuro-muscular coordination, and various environmental factors, notably wet, slippery floors and poor lighting. The commonest areas of accidents are the toilet (due to wet floor, and a large number of fixtures in a small space), kitchen (mainly due to open flames), staircases and roads.

Nutritional Deficiencies : Both macro and micronutrient deficiencies are common among elderly. They result due to interplay of four major reasons, viz., lack of financial resources to buy nutritious food items; reduced ability to go out to the market and buy nutritious raw items; reduced physical abilities with resultant reduced ability to cook nutritious meals; and physical ailments especially oro-dental problems causing difficulty in mastication and reduced sense of taste.

Dental Problems : Reduction in number of teeth / edentulousness interferes with mastication, digestive process and also with the desire to eat. Ill-fitting dentures further aggravate the problem.

Cardiovascular Diseases : The end result of atherosclerotic process becomes most evident in the elderly age group. The incidence (as well as mortality due to) of IHD, Stroke and Hypertension is significantly increased in this age group.

Increased Susceptibility to Adverse Effects of Physical Environment : People aged >65 years are more susceptible to adverse effects of heat (heat stroke and heat exhaustion) as well as environmental cold (generalized hypothermia and local adverse effects of cold).

Increased Susceptibility to Infections : Age >65 years increases the susceptibility to nearly all infections due to decline in immunologic defenses. More particularly, lower respiratory tract infections (pneumonia) and urinary tract infections are an important cause of morbidity and mortality among elderly.

Degenerative Neurological Diseases : Alzheimer's disease and Parkinsonism are almost exclusively encountered among elderly. Besides morbidity, these diseases substantially reduce the quality of life.

Complication of Diabetes : The micro vascular as well as macro vascular complications are more prominent during advanced age.

Cancers : Oral, gastric, lung and colorectal cancers are more common in elderly age group.

Problems which mainly affect the Elderly Male

Benign Prostatic Hypertrophy (BPH) : This is one of the commonest diseases affecting males >50 years, particularly >60 years age.

Prostatic Cancer : The incidence shows a steep climb after 50 years age. Yearly Digital Rectal Examination (DRE) is a good screening tool for both BPH and prostate cancer. In addition, Prostate Specific Antigen (PSA) could be useful screening test for prostate cancer after 50 years of age. Levels of < 4 ng/ml can be considered as normal, 4 to 10 ng/ml as suspicious and >10 ng/ml as strongly suspicious and need to be followed up with a biopsy.

Male Sexual Dysfunction : Male sexual dysfunction among elderly may manifest as either libido, erectile or ejaculation problems.

Problems which mainly concern with Elderly Females

Menopausal Problems : There are five areas which are predominantly affected by menopause - increased risk of cardiovascular diseases; genitourinary atrophy; skeletal bone loss; skin and hair changes; and neuroendocrine and vasomotor changes. Skin changes include loss of elasticity (apparent as lagging and wrinkled skin), dryness of mucosal surface, minor facial hirsutism and voice changes. Uro-genital changes include atrophic vaginitis, dyspareunia, pruritis vulvae and irritable bladder. Neuroendocrine changes include hot flushes (which may sometimes interfere with quality of life) and psychological/ mood problems.

Urinary Incontinence : The impact is considerable both from medical as well as psychological point of view.

Cancers and Other Disease of Female Genital Tract : The 3 major cancers of genital tract affecting the elderly women are uterine (endometrial), ovarian and cervical cancers. Prolapse of uterus is another debilitating problem among elderly females.

Osteoporosis : Osteoporosis occurs in both sexes (Type-II Osteoporosis) but the incidence as well as the impact is much higher among females especially after menopause (Type-I

osteoporosis). Osteoporosis represents only a small proportion of the problem, in any community, for every case of osteoporosis there would be additional 3-4 cases of osteopenia. Osteoporosis results in a large number of low-trauma fractures. The major fracture sites are hip, spine, wrist and pelvis. Risk factors for primary osteoporosis include low body weight, history of prior fracture, family history of maternal hip fracture, lack of dietary calcium and vitamin D, menopause, lack of weight bearing exercise, smoking and excessive alcohol use, tall and thin stature and white-race. Weight of <58 kg may indicate risk. In fact, a rough guide is to calculate an index as $\{0.2 \times (\text{Body weight in Kg} - \text{Age in years})\}$; if the result is less than 2, the same indicates increased risk.

Prevention & Control

Prevention and control of health problems of elderly would need multifaceted approach. A well coordinated approach from health, social welfare, rural / urban development and legal sectors is desirable.

Developing a Policy and Programme : A community based geriatric health care programme should start with development of a policy, which should be comprehensive so as to include not only medical aspects but the large gamut of social, economic and emotive aspects of geriatric problems as well. Strong political commitment and social action is imperative for the enunciation and implementation of such a policy. There is also a need to translate such policy into a comprehensive geriatric health care programme, to be delivered at the grass root level by the general health services, but coordinated at the district / state level by specialized personnel.

Social Measures : Developing social ethos wherein children voluntarily take the responsibility of looking after their aged parents is important. In fact, young people need to be educated and motivated to utilize the experience and support of their parents / grandparents in day to day household matters to facilitate passing on the cultural heritage to the children. There is also a need to develop regulatory mechanisms which make it obligatory for the members of society to look after their aged parents.

Developing a Health Insurance Scheme : A large majority of the elderly are those who are not covered by any formal public sector health care support, unlike retired govt. servants. The need is to develop an affordable health insurance scheme in which people contribute, along with the employer and the government, to cater to subsequent expenses on medical care during old age.

Pensionary Benefits : Similar to the health insurance schemes suggested above, there is need to develop pension schemes based on contribution from employee, employer and government, so that old people can feed for themselves during old age, even if not supported by their children.

Proper Construction of Roads, Walkways, Stair cases and Houses : Accidents and injuries are an important cause of morbidity and mortality among the elderly. Proper designing of roads / walkways, and stair cases, along with adequate enforcement of traffic rules is a clear need. In addition, construction of "elderly friendly houses", giving particular attention to construction of toilets, kitchens, bedrooms and

common galleries is important. In general, the principles of construction and maintenance are that the floor should not be slippery / wet; that the fixtures and furniture should be adequately separated giving enough space for movement; lighting should be adequate; staircases should have side-supports, made of non-slippery material and be well lighted; open flames should be restricted to the minimum and, preferably, enclosed.

Health Measures: These include the following :

Need to Initiate Primary Preventive Measures in Early Adulthood : While a number of diseases finally manifest in elderly age (as cardiovascular disease, osteoporosis, cancers), the basic pathologic processes start during early adulthood, even during adolescence. Therefore, it would be wise for children / young people to start prevention at young age itself through healthy lifestyle (adequate and regular physical exercise, healthy diet, avoidance of tobacco and alcohol use). The details are discussed in the section on healthy lifestyle.

Information, Education & Communication Strategies : Health education should focus towards three broad groups - firstly, the elderly persons, secondly, the middle aged who would move into elderly age group in near future and thirdly the younger people who are the potential care providers for their elderly parents / relatives. The major areas of education should address the issues of hygiene, nutrition, physical exercise, avoidance of tobacco and alcohol, accident prevention measures, awareness about recognition of early signs / symptoms of common geriatric problems and motivation to seek treatment, and education regarding periodic health check-up.

Training and Re-training of Medical and Paramedical Personnel : This should be undertaken regarding the special health needs of the elderly and updating their knowledge regarding prevention and treatment of common geriatric diseases.

Immunization : Vaccines which have a potential for use among elderly include those against streptococcal pneumonia, influenza and tetanus.

Periodic Health Assessment : Ideally, all people, males & females, should undergo a detailed health assessment once they are 45-50 years of age. Subsequently, a thorough health evaluation should be done once in every 5 years till 65 years age and thereafter every year or at least once in 2 years. Assessment should include general clinical examination, assessment of hearing & vision, assessment of Dental and oral health, nutritional status including obesity, cardiovascular status, musculoskeletal system including spine, per-rectal examination for males and gynecological and breast examination for females. Depending on availability, important investigation would include Hb%, GB, urine routine and microscopic, stool routine and microscopy and test for occult blood, blood sugar estimation, lipid profile, renal function parameters and an ECG if required. Depending on the requirement, bone densitometry, PSA, Colonoscopy, USG studies and histo-pathological studies may be undertaken as indicated.

Provision of Prostheses and Other Medical Aids : Elderly persons will often need devices as spectacles, hearing aids, walking aids, dentures, cervical collars, wheel chairs and

so on. The preventive health care for elderly should cater to provide these implements to all those who are in need, ensuring availability, accessibility and affordability.

Development of Gerontology Units : There is a felt need to develop specialized units which would take care of the special and wide health related needs of the elderly as well as train health care workers in these issues. It would be worthwhile if a coordinated approach between departments of community medicine, internal medicine, general surgery, gynaecology, orthopaedics, ENT and ophthalmology be developed to initiate such comprehensive care through gerontology units, for the population of three PHCs which is to be providing health care by various medical colleges. Subsequently, such units may be developed at the level of district hospitals.

Ensure Effective Communication : Elderly people need special efforts for communication. Hence, medical personnel dealing with elderly should very effectively communicate their findings and advise to this group and ensure a system of feedback to verify that their communication has been correctly understood by the elderly subjects.

Summary

Elderly age is defined as persons aged 65 years or more. In our country, proportion of elderly is consistently increasing and there is need to focus on their health needs. Health problems of elderly should not be seen as isolated medical issues but should be viewed in the larger context of socio-economic-emotive determinants as an overall health issue. Due to children moving out of home for employment, elderly face problems of isolation and lack of physical support. This isolation may be worsened by retirements or death of spouse, and predispose them to variety of lifestyle diseases. Financial crisis because of lack of income sources may compound the problem. Moreover the present health care system in our country is not very well geared up to cater to the health needs of elderly. The health problems of elderly can be divided into 3 groups, i.e. problems which are important for both genders, problems which mainly concern the elderly males and problems which mainly concern the elderly females.

Problems which are important for both the genders include-ocular diseases like age related diminution of vision, cataract and glaucoma; hearing defects; reduced muscular strength and coordination resulting in increased proneness to accidents and injuries; nutritional deficiencies; dental problems like reduction in number of teeth or edentulousness; cardiovascular diseases like IHD, stroke and hypertension; increased susceptibility to effects of heat and cold; increased susceptibility to infections, particularly lower respiratory tract infections (pneumonia) and urinary tract infections; degenerative neurological diseases like Alzheimer's disease and Parkinsonism; micro and macrovascular complications of diabetes and cancers like oral, gastric, lung, uterus, ovaries and colorectal cancers are more common in elderly age group. Problems which mainly affect the elderly males include benign prostatic hypertrophy (BPH); prostate cancer and male sexual dysfunction. Problems which mainly concern with elderly females include Menopausal Problems like increased risk of cardiovascular diseases, genitourinary atrophy; skeletal bone loss, skin and hair

changes, and neuroendocrine and vasomotor changes; Urinary incontinence; Osteoporosis; Cancers of female genital tract mainly uterine (endometrial), ovarian and cervical cancers.

Prevention and control of these problems need multifaceted approach. There is need to develop social ethos wherein children voluntarily take the responsibility of looking after their aged parents. The need is to develop an affordable health insurance scheme and pension schemes. There should be proper designing of roads / walkways, and stair cases, along with adequate enforcement of traffic rules. Houses should be constructed in such a manner that these are "elderly friendly houses". Primary preventive measures should start in early adulthood through life style modification. IEC about health problems of elderly should be targeted to elderly, adults who are likely to move in elderly group and also to younger people who are care provider to elderly. Training and retraining of health staff, so as to efficiently address health needs of elderly is required. Periodic health examination should be done at least every 5 years starting with age of 45 - 50 years till the age of 65, and thereafter it should be done at least once in every two years. All these measures should be communicated to elderly in an effective manner.

Study Exercises

Long Question : Describe your plan of providing comprehensive health care to the elderly persons in your district, in your capacity as the district health officer.

Short Notes : (1) Osteoporosis (2) Benign Prostatic Hypertrophy (3) Health problems of the elderly

MCQs

- 1) Elderly is defined as the person aged above: (a) 60 yrs (b) 65 yrs (c) 70 yrs (d) 75 yrs
- 2) The proportion of elderly in our country is: (a) 1% (b) 2% (c) 4% (d) 5%
- 3) Which of the following is not the primary disease of elderly age group: (a) Parkinsonism (b) Alzheimer's (c) Multiple sclerosis (d) Cerebrovascular disease
- 4) Which of the following malignancy is not commonly seen in elderly age group: (a) Stomach (b) Colorectal (c) Prostate (d) Testis
- 5) IEC strategies for prevention and control of health problems of elderly should be targeted to: (a) Elderly (b) People in late adulthood (c) Younger people (d) All of the above
- 6) Characteristics of "elderly friendly houses" does not include: (a) Furnitures should be adequately separated (b) Lighting should be adequate (c) Floor should not be slippery (d) Electrical appliances should not be used to avoid threat of electrocution
- 7) Periodic Health Assessment for elderly should ideally be done once in every: (a) 5 yrs (b) 4 yrs (c) 3 yrs (d) 1 yr
- 8) Routine Periodic Health Assessment for elderly should include all except: (a) Stool test for occult blood (b) blood sugar estimation (c) Renal function parameters (d) Pulmonary function tests
- 9) Risk factors for primary osteoporosis does not include: (a) High BMI (b) History of prior fracture (c) Family history of maternal hip fracture (d) Lack of weight bearing

- exercise.
- 10) Which of the following is not a postmenopausal problem:
 - (a) increased risk of cardiovascular diseases
 - (b) Genitourinary atrophy
 - (c) Skeletal bone loss
 - (d) Atrophy of ovary
 - 11) Major physio-pathological factors which contribute to increased proneness to accidents among elderly are all except:
 - (a) Reduced muscular strength
 - (b) Poor neuro-muscular coordination
 - (c) Restlessness
 - (d) Diminution of vision and hearing
 - 12) Elderly are at risk of nutritional deficiencies because of:
 - (a) Lack of financial resources to buy nutritious food items
 - (b) Reduced physical abilities with resultant reduced ability to cook nutritious meals
 - (c) Oro-dental problems
 - (d) All of the above
 - 13) Hot flushes occurring in postmenopausal women are mainly due to:
 - (a) Psychological response
 - (b) Neuroendocrine disturbance
 - (c) Macrovascular changes
 - (d) Microvascular changes
 - 14) A rough guide to calculate an index of risk of osteoporosis based on body weight is { $0.2 \times (\text{Body weight in Kg} - \text{Age in years})$ } the value of index which indicates increased risk if it is:
 - (a) >1
 - (b) <1
 - (c) >2
 - (d) <2

- 15) Normal level of PSA (Prostate specific antigen) is (in ng/dl) :
 - (a) <2
 - (b) <6
 - (c) <4
 - (d) <8
- 16) Presbyopia occurs in elderly because of:
 - (a) Cataract change in ocular lens
 - (b) Retinal degeneration
 - (c) Insufficiency of power of accommodation
 - (d) Corneal degeneration
- 17) Hearing loss among elderly is mainly because of:
 - (a) Sensorineural deafness
 - (b) Conductive deafness
 - (c) Degenerative changes in temporal cortex
 - (d) None of the above

Fill In the Blanks

1. The proportion of elderly in India is like to reach _____ by year 2050 AD.
2. Prostate Specific Antigen (PSA) of the level higher than _____ indicates strong suspicion of Ca prostate.
3. Females are at much higher risk of developing osteoporosis Type _____ especially after menopause.
4. Common fracture sites among elderly are _____
5. Hearing loss commonly occurring among elderly because of sensori-neural deafness is called as _____

Answers : MCQs : (1) b; (2) d; (3) c; (4) d; (5) d; (6) d; (7) d; (8) d; (9) a; (10) d; (11) c; (12) d; (13) b; (14) d; (15) c; (16) c; (17) a. **Fill In the Blanks :** (1) 18%; (2) 10 ng/ ml; (3) Type - I; (4) Hip, wrist, spine and pelvis; (5) Presbycusis

Dashrath R. Basannar

Demography is the scientific study of human populations. It is mainly concerned with

Size : It refers to the total number of persons in the given population.

Distribution : It refers to the arrangement of entire population with respect to the geographical areas at a given point of time.

Structure : It refers to the distribution of the given population with respect to age and sex.

Change : It refers to the increase or decrease in the size of the given population due to fertility, mortality and migration.

Development : It refers to the development of the given population with respect to socio economic aspects.

Other characteristic like genetic inheritance, intelligence and health.

Role of Demography in Public Health Administration : For effective planning, designing, evaluation and execution of health and health care needs for the entire population for the present as well as for the future, the knowledge about population with respect to its size, structure, change in its size

and their developments is essential. The following are number of the applications of demography in health related fields.

The knowledge in demography is helpful to public health administrators for various purposes :

- i) Mortality rates by age-sex and its geographical distribution with respect to various diseases are helpful in locating and identifying diseases of public health importance with respect to age-sex-location, for planning remedial measures to control these diseases, future planning for prevention of these diseases, for determining leading causes of mortality, for planning drugs/medicines/equipment/manpower/other medical facilities requirements etc.
- ii) Percentage distribution of population by age-sex-location are helpful in understanding health and health care needs of various age groups by sex by location, for planning, designing, evaluation and effective implementation of various public health programs. For example : Vaccination and immunization program for children under 5 years of age, Mother and Child Health program for mother and new born, Family planning program, old age program, nutritional program etc.
- iii) Determining the success or failure of health programs.
- iv) To describe the level of community health.
- v) To determine the leading causes of mortality and morbidity.
- vi) To determine the relative importance of different fatal

diseases with respective to age and sex.

vii) To discover solution to health problems and find clues for public health administration.

Sources of Demographic Data : The following are the sources of demographic data. The details of these sources have already been dealt with in detail in an exclusive chapter in the section on epidemiology :

1. Census
2. Vital Events Registers
3. Surveys
4. Sample Registration System

Measures of Population Projection : By "Population projections", we mean estimating and forecasting the population of a country or a region for a given time. There are mainly three types of population estimates namely inter-censal (during any two consecutive census period), post-censal (any period following latest census up to the present moment of time) and future (any period time after the present moment). Generally the data on population are available for census year only hence population estimates (inter-censal estimates) are required for calculating fertility rates, mortality rates etc. during the inter-censal period. Future population projections (future estimates) are very essential basically for understanding and planning future needs of the population for various purposes such as health, education, economic, social, employment, irrigation, food, housing, etc. The following measures of population estimates are commonly used.

i) Mathematical Methods : Some of the mathematical models which are commonly used for estimating inter-censal and post-censal population estimates are :

- Arithmetic Growth Method
- Geometric Growth Method
- Exponential Growth Method
- Component Projection Method

a) Arithmetic Growth Method : In this method it is assumed that there is an equal addition every year to the population during the inter censal period and this addition is taken to be average increase per year. Arithmetic Growth Method for estimating population is $P_t = a + t \times b$ where P_0 population at time t is, P_0 and P_1 are populations at two consecutive censuses. $a = P_0$ and $b = ((P_1 - P_0) \div 10)$ and inter census period = 10years. For example populations of a town A at censuses 1st Mar 1981 and 1st Mar 1991 were 50,000 and 90,000. Estimate population of the town on 1st Mar 1985. Here $a = 50,000$, inter-censal period = 10 years, $b = 4,000$ per year and $t = 4$, $P_4 = 50,000 + 4 \times 4,000 = 66,000$

b) Geometric Growth Method : This method assumes the population begets population at a constant rate of increase on the compound interest law. Geometric Growth Method for estimating population is $P_t = P_0 \times (1 + r)^t$ where r is growth rate

and $r = \left[\frac{P_1}{P_0} \right]^{1/10} - 1$. In the above example,

$$r = \left[\frac{90,000}{50,000} \right]^{1/10} - 1 = 0.0605.$$

$$P_4 = 50,000 \times (1 + 0.0605)^4 = 63,252.69$$

c) Exponential Growth Method : In this method it is assumed that there is an exponential growth. Exponential Growth Method for estimating population is $P_t = P_0 \times e^{rt}$

where r is exponential growth rate $r = \frac{1}{10} \times \log_e \left[\frac{P_1}{P_0} \right]$

In the above example $r = \frac{1}{10} \times \log_e \left[\frac{90,000}{50,000} \right] = 0.05878$ and

$$P_4 = 50,000 \times e^{0.05878 \times 4} = 63,252.69$$

d) Component Projection Method : This method is mainly used for future population projections (future estimates) using following model.

$$P_t = P_0 + B_{0-t} - D_{0-t} + I_{0-t} - E_{0-t}$$

Here 0 stands for base year from which population projected is made, t denotes the period of projection from the base year. $B_{0-t}, D_{0-t}, I_{0-t}, E_{0-t}$ represents number of births, number of deaths, number of immigration and number of emigration during the period 0-t respectively. P_0 Represents population at the base year 0.

This method makes assumptions about fertility, mortality and migration for the projection period based. This method requires information regarding age-sex distribution, age-sex specific mortality, fertility and migration distribution by age-sex for the base year 0 and estimates for the period t.

Demographic Transition : In 1929 the American demographer Warren Thompson, observed changes in birth and death rates in industrialized societies over the past two hundred years or so and then formulated a model called "Demographic Transition" that describes population change over time in fully developed country today, such as The United States or Canada, the countries of Europe, or similar societies elsewhere (e.g. Japan, Australia etc.). The model is a generalization that applies to these countries as a group and may not accurately describe to less developed societies. As shown in the Fig. - 1, Demographic Transition model recognises five demographic stages namely high stationary, early expanding, late expanding, low stationary and declining.

- **High stationary (first stage) :** The first stage is associated with pre Modern times, and is characterized by very high birth rates and very high death rate (30-50 per 1000) balance between them results in only very slow population growth that is referred to as the "High Stationary Stage" of population growth. This situation was true of all human populations up until the late 18th century.
- **Early expanding (second stage) :** The second stage is characterized by a rise in population caused by a decline in the death rate while the birth rate remains unchanged, or perhaps even rises slightly. The decline in the death rate in Europe began in the late 18th century.
- **Late expanding (third stage) :** The third stage is characterized by further decline in the death rate while birth rate tends to fall that results in increase in the population

growth. In general the decline in birth rates in developed countries began towards the end of the 19th century.

- *Low stationary (fourth stage)* : The fourth stage is characterized by a low birth rate and low death rate; the balance between them results in no population growth that is referred to as the “low Stationary Stage” of population growth.
- *Declining (fifth stage)* : The fifth stage is characterized by a birth rate lower than death rate the balance between them results in decline in population growth that is referred to as the “Declining Stage” of population growth.

Demographic transition in national Context : As shown in the Table - 1 and Fig. - 1 & Fig. - 2, India’s population growth during the twentieth century can be classified into four distinct phases as follows : 1901-1921, this period was characterised by a high birth rate and high death rate (46-49 per 1000) and growth rate was slow, close to zero and it was negative during 1911-21 and the year 1921 is called the year of great divide. There after growth rate steadily increased till 1991.

During 1921-1951, birth rate steadily declined from 48.1 in 1921 to 39.9 in 1951 and death rate also declined from 47.2 in 1921 to 39.9 in 1951 while growth rate steadily increased during this period which was more than 1 but less than 2. During this period India experienced rapid growth.

During 1951-1981, birth rate little further increased and then declined and death rate further declined and growth rate further increased and it crossed over 2 during this period. During this period India experienced explosive rapid growth.

During 1981-2001, birth rate further declined and came down to 26.1 and death rate further declined while growth rate started slowing down during this period. Growth rate during 1971 to 1991 was more than 2, first time after 40 years fall down below 2, still it characterises as very rapid growth.

From the Table - 1, it is evident that there is declining trend in CDR, it declined from 46.2 in 1911 to less than 10 i.e. 8.7 in 2001 and it was less than 7 in 2007 and it is close to some of

the developed countries like United States and Canada. During this period life expectancy at birth increased from 23.63 years for male and 23.96 years for female in 1901 to 62.30 years for male and 65.27 years for female in 2001. Similarly CBR declined from 49.2 in 1911 to almost half i.e. 26.1 in 2001.

India with 238.4 million population in 1901 almost doubled in 1961 in 60 years while it took just 30 years to double the population from 439.2 million in 1961 to 844.0 million in 1991. The population of India has increased nearly five times from 238 million to 1 billion during this century period.

In 2001 census India’s population was 1,028,737, i.e. about 16 percent of the world’s population on 2.4 percent of the globe’s land area. It is the second largest populous country in the world. If current trends of fertility and mortality continue, India may overtake China in 2045, to become the most populous country in the world. As per census 2001 report, state with highest population was Uttar Pradesh (166,197,921) and state with lowest population was Sikkim (540,851); union territories with highest population was Delhi (13,850,507) and union territories with lowest population was Lakshadweep (60,650) ; district with highest population was Medinipur (West Bengal) (9,610,788) and district with lowest population was Yanam (Pondicherry) (31,394).

National Policies to Control Population Growth : India was the first country in the world to launch a national family planning to control birth rates to stabilize the population in 1952. The role of family planning programme was mainly to deliver contraceptive methods and creating facilities for abortion. After 1952, sharp declines in death rates were observed, however, not accompanied by a similar drop in birth rates. The Government has passed Child Marriage Act in 1978 and this Act specified the minimum age at marriage for females and males to be 18 and 21 years respectively. The National Health Policy, 1983 stated that replacement levels of Total Fertility Rate (TFR) should be achieved by the year 2000. Half a century after formulating the national family welfare programme, reduced Crude Birth

Table - 1: Birth Rate, Death Rate and Growth Rate in India (1901-2001)

Census year	Total population (million)	Decadal Growth (%)	Average annual exponential growth rate (%)	Growth rate over 1901 (percent)	Birth Rate/1000 live births	Death Rate/1000 population
1901	238.4					
1911	252.1	5.75	0.56	5.75	49.2	46.2
1921	251.3	-0.31	-0.03	5.42	48.1	47.2
1931	279	11	1.04	17.02	46.4	36.3
1941	318.7	14.22	1.33	33.67	45.2	31.2
1951	361.1	13.31	1.25	51.47	39.9	27.4
1961	439.2	21.64	1.96	84.25	41.7	22.8
1971	548.2	24.8	2.2	129.94	41.2	19
1981	683.3	24.66	2.22	186.64	37.2	15
1991	844	23.86	2.14	255.03	29.5	9.8
2001	1027	21.34	1.93	330.8	26.1	8.7

Fig. - 2

Rate (CBR) from 40.8 (1951) to 26.4 (1998, SRS) ; the Infant Mortality Rate (IMR) from 146 per 1000 live births (1951) to 72 per 1000 live births (1998, SRS) ; Crude Death Rate (CDR) from 25 (1951) to 9.0 (1998) ; Total Fertility Rate from 6.0 (1951) to 3.3 (1997). The National Population Policy (NPP), 2000, recently adopted by the Government of India states that 'the long-term objective is to achieve a stable population by 2045, at a level consistent with the requirements of sustainable economic growth, social development, and environment protection'. It has been assumed in the policy document that the medium-term objective of bringing down the Total Fertility Rate (TFR) to replacement level of 2.1 by 2010 will be achieved. It is envisaged that if the NPP is fully implemented, the population of India should be 1013 million by 2002 and 1107 million by 2010.

Summary

Demography is the scientific study of human populations and it is mainly concerned with size, distribution, structure, change, development and other characteristics like genetic inheritance, intelligence and health. Demography plays an important role in public health administration for effective planning, designing, evaluation and execution of health and health care needs for the entire population for the present as well as for the future.

The important sources of demographic data are Census, Vital Events, Registers, Surveys, and Sample Registration System. There are mainly three types of population estimates namely inter-census (during any two consecutive census period), post census (any period following latest census up to the present moment of time) and future (any period time after the present moment). The measures of population estimates commonly used are Mathematical Methods - Arithmetic Growth Method, Geometric Growth Method, Exponential Growth Method, and Component Projection Method.

Demographic Transition model recognises five demographic stages namely high stationary, early expanding, late expanding, low stationary and declining. High stationary is characterized by very high birth rates and very high death rate. Early expanding is characterized by a rise in population caused by a decline in the death rate while the birth rate remains unchanged, or perhaps even rises slightly. Late expanding is characterized by further decline in the death rate while birth rate tends to fall that results in increase in the population growth. Low stationary is characterized by a low birth rate and low death rate the balance between them results in no population growth. Declining is characterized by a birth rate lower than death rate the balance between them results in decline in population growth.

In 2001 census India's population was 1,028,737, i.e. about 16 percent of the world's population on 2.4 percent of the globe's land area. It is the second largest populous country in the world. If current trends of fertility and mortality continue, India may overtake China in 2045, to become the most populous country in the world. As per census 2001 report, state with highest population was Uttar Pradesh (166,197,921) and state with lowest population was Sikkim (540,851).

National policies to control population growth : India was the first country in the world to launch a national family planning to control birth rates to stabilize the population in 1952. The Government has passed Child Marriage Act in 1978, the National Health Policy in 1983, and the National Population Policy (NPP) in 2000. It has been assumed in the policy document that the medium-term objective of bringing down the Total Fertility Rate (TFR) to replacement level of 2.1 by 2010 will be achieved. It is envisaged that if the NPP is fully implemented, the population of India should be 1013 million by 2002 and 1107 million by 2010.

Study Exercises

Short Notes : (1) Important sources of Demographic Data (2) Demographic Transition (3) Role of Demography in Public Health

MCQs

1. According to the demographic cycle, India is in the following phase (a) High Stationary (b) Early Expanding (c) Late Expanding (d) Low Stationary
2. According to Central Registration Act of 1969, birth is to be reported within : (a) 7 days (b) 14 days (c) 10 days (d) 21 days
3. Annual growth rate is between (a) Crude birth rate - Crude death rate (b) Crude birth rate - IMR (c) Total Fertility rate - Death rate (d) Crude birth rate - Total Fertility rate
4. Census in India is done every (a) 05years (b) 10years (c) 15 years (d) 20 years
5. The most cost effective family planning method is (a) Vasectomy (b) Barrier method (c) IUCD (d) Oral pills
6. The year of "Big Divide" is (a) 1900 (b) 1901 (c) 1920 (d) 1921
7. As per Census 2001 Average annual growth rate of India is (in %) (a) 2.01 (b) 1.93 (c) 1.80 (d) 1.86
8. As per Census 2001 Decadal growth rate of India is (in %) (a) 21.34 (b) 31.93 (c) 11.80 (d) 9.86
9. As per Census 2001, the % of world's population from India is (a) 26 (b) 16 (c) 10 (d) 06
10. As per Census 2001, lowest populated state of India is (a) Kerala (b) Sikkim (c) Goa (d) Nagaland
11. The annual growth rate of India presently characterized as (a) slow (b) rapid (c) very rapid (d) explosive

Answers : (1) c; (2) b; (3) a; (4) b; (5) a; (6) d; (7) b; (8) a; (9) b; (10) b; (11) c.

Contraceptive Technology

Rajvir Bhalwar

As per the National population policy - 2000 and the RCH program in our country, the couples should be given a choice out of various contraceptive methods. Promotion of contraception purely on a voluntary basis, without any coercion, and with provision of due information about the various contraceptive alternatives is the central ethos of our national family welfare programme. The strategies and operational details of the programme and the various contraception facilities being provided to the community are dealt with in the chapter on RCH program. The technical details of various methods of contraception are being dealt with in this chapter.

Broadly, methods of contraception would fall into two groups, viz. "Natural Methods" and "Artificial Methods". Artificial methods are further grouped into Temporary and Permanent methods.

Efficacy of Contraceptive Methods : Efficacy of a given contraceptive procedure is evaluated in terms of the "Pearl Index" which measures the number of failures (i.e. pregnancies occurring despite continuous usage of the particular method) per 100 woman years (HWY), or for every 1200 woman - months.

$$\text{Pearl Index (Failure rate per HWY)} = \frac{\text{Total failures (pregnancies despite use of the contraceptive)}}{\text{Total months of continuous use of the contraceptive}} \times 1200$$

The numerator (total failures) should include all pregnancies which occur during the period of observation, irrespective of their outcome (i.e. whether the pregnancy terminated in live birth, still birth or abortion etc.). The denominator is taken in months and hence the numerator is multiplied by 1200, to make it equal to 100 years. In the denominator, for every pregnancy which is continued till full term, 10 months are deducted, while for every pregnancy that terminates in abortion, 4 months are deducted, from the total period of follow up for each woman. When studying the effectiveness of contraceptives, it is recommended that at least 600 woman-months (50 woman-years), preferably more, of follow up should be done. A failure rate of 3.33 per HWY means that, given the fertile period of a woman is 30 years (usually 15 to 44 years age) and if a woman uses that contraceptive continuously for her entire fertile period, she is likely to have one pregnancy due to failure of the contraceptive. (Calculated as 3.33 failures in 100 years for 1 woman, hence $(30 \times 3.33) / 100 = 1$ failure in 30 years of usage. It also means that if 100 women use the contraceptive for 10 years continuously, thus giving 1000 woman years, then about 33 accidental pregnancies are likely to occur, in all, among these 100 women over the 10 years of use.

Natural Methods of Contraception

These methods utilize either total avoidance of sexual intercourse (Abstinence) or by discharging the semen outside female genitalia (Coitus interruptus or withdrawal method) or else by utilizing methods which observe the naturally occurring signs / symptoms of fertile versus non-fertile periods of the menstrual cycle and avoiding sexual intercourse during the fertile period. These methods, which are also sometimes referred as the "Standard Day Methods" (SDM) work on the principle that during one menstrual cycle, one ovum is

discharged; very rarely, a second ovum can be discharged after 24 hours. Secondly, after intercourse, sperms stay alive upto 5 days (rarely 7 days) but can actually fertilize the ovum for at most 4 days. With this background the most fertile period of women is from 10th day to the 18th day, provided the cycle is of 28 days. Natural methods are based on detecting the fertile period and avoiding intercourse during the period. These are :

(a) Rhythm Method : For women who have a regular 28 days cycle, the fertile period would be generally from day 7 to day 21 (the day of onset of menstrual bleeding is taken as the first day). Sexual intercourse is avoided during this period.

(b) Basal Body Temperature Method : The woman should record her oral temperature first thing on getting up in the morning, daily, and plot it on a graph paper with the days of menstrual cycle along horizontal axis and temperature along vertical axis. Immediately following ovulation there is increase in oral temperature by 0.5 to 0.8°F (0.2 to 0.4°C). Couples should avoid intercourse for 3 days, once the rise in temperature is noted.

(c) Cervical Mucous Method : The woman notices daily, the quality of vaginal mucus discharge, by putting a finger into the vagina. Following cessation of menstrual flow, no mucus is felt in the vagina for couple of days. These are called the “dry days”. Following the dry days, cloudy, white or cream coloured mucus of sticky consistency with little moisture appears. This indicates that ovulation is approaching. Thereafter, just before and at time of ovulation the mucus becomes copious, clear and slippery, resembling the white of an egg and can be stretched into a thread if the thumb and finger on which the mucus is stuck, are gently moved apart. This persists for 3 days and is called the “wet days”. Following this wet period, the mucus again becomes scanty, sticky and cloudy indicating the post ovulation phase, which persists till onset of next menstrual flow. The couple should abstain as soon as the first sign of mucus appears in the pre-ovulatory phase, during the wet days in ovulatory phase and for 3 days after the completion of wet period.

(d) Symptothermal Method : This is based on combined observation of changes in BBT, mucus changes and also by palpating the cervix with a finger high up in the vagina. The cervix becomes softer and cervical os becomes more open during the fertile period.

Natural methods are reasonable efficacious; however, the problem is mainly the difficulty in maintaining compliance. If consistently and properly used, the failure rates per 100 women per year (HWY) (indicating the number of women who will become pregnant during one year out of 100 women who are using these method are :

(i) Calendar Method - 9 / 100 HWY (9%)

(ii) BBT Method - 1 - 2 / 100 HWY (1-2%)

(iii) Cervical mucus Method - 3 / 100 HWY (3%)

(iv) Symptothermal Method - 2 / 100 HWY (2%)

(e) Lactational Amenorrhoea Method : Full or nearly full breast feeding means that at least 85% of the baby's food requirement is being provided by breast milk. For women who are fully breast feeding their infants, chances of pregnancy are very less for 6 months or when menstrual flow returns,

whichever is earlier. If used correctly and consistently, the failure rate is 1 to 1.5%. Chances of pregnancy are, however, more if the woman is not having full lactation or if not fully breast feeding the infant.

Artificial Methods

Artificial, Temporary Methods : The broad categories of contraceptives included in artificial (temporary) methods are Barrier methods, Spermicides, Intrauterine devices (IUDs), Oral contraceptives and Non-oral hormonal contraceptives.

Barrier Contraceptives

Condoms : Condoms are made of latex and are available as nonlubricated (Nirodh, Kohinoor), lubricated (Nirodh - Lubricated, Kamasutra, Kohinoor - Pink and Sawan) and more lately, coated with spermicidal jelly which is usually nonoxynol-9 (Share, Rakshak). The average shelf life is 5 years from date of manufacture and they should be stored in cool and dry place. If further lubrication is required then glycerin, K-Y jelly or a spermicidal jelly can be applied, but not Vaseline, oils or butter. Some couples may complain of initial reduction in pleasure due to slight decrease in sensations and interruption in sexual play (since the man has to put on the condom just before insertion). However, it should be explained to them that this is only a transient phenomena, and most couples will adapt well with passage of time. Besides contraceptive effect, condoms are also very effective in preventing transmission of HIV, STDs, HPV infection (and amniotic fluid infections while having sex during pregnancy).

The total “slippage” and “breakage” rate is 4% to 9%. The average failure rate is 12% to 14%, but if correctly used, it may be as low as 3%. Concurrent use of spermicidal jelly will further reduce the failure rate. Condoms are very good choice as temporary method, especially for couples in whom use of hormonal contraceptives and IUDs is not indicated among the female partner. The only contra-indication to condom use is allergy to latex rubber in which case condom made of polyurethane or silicon rubber may be used.

Diaphragm, Cervical Cap (Check Pessary), Vault Cap and Vimule : These are barrier methods to be used by the females but not much used now due to wide availability of other contraceptives.

Female Condoms : Available under trade name of “Femindon” and “Reality”. The device is inserted like a vaginal diaphragm. At present it is not much used as contraceptive but has potential in prevention of HIV transmission.

Spermicides : Most commonly used spermicide is nonoxynol-9. They are available as vaginal pessaries which are inserted high up in the vagina, 10 to 15mts before sex or as creams / jelly, as Delfen cream, Orthogynol jelly etc.

Foam Tablets : These are very commonly used. It is marketed in our country as “Today” as a vaginal foam suppository containing nonoxynol-9. The tablet is to be inserted high in the vagina (may be moistened slightly with water if vagina is dry), 10 minutes before sex act and the action lasts for 1 hour after sex. If properly used, failure rates are as low as only 0.5%.

Intra Uterine Devices (IUDs) : IUDs have been in use as contraceptives for many decades. However, their exact mode of

action is still not clear. In all probabilities, they act by inducing mild inflammatory changes and foreign body reaction in the endometrium, which combined with alterations in prostaglandin levels, incapacitate the sperms and ovum, prevent sperm from fertilizing the ovum, and even if fertilization occurs, makes the uterine environment inhospitable for the blastocyst to be implanted. The earliest IUDs, namely lippies loop, have now been almost phased out by copper-T and its subsequent variants. Copper - T 200 (Gynae-T) is made of propylene impregnated with BaSO₄ and carries 120mg of 0.25mm diameter copper wire wound around the vertical limb. The tail limb has a pair of threads (some variants have only one thread) which comes out of cervical os, into vaginal canal after the Copper-T has been inserted and can be felt with a finger to check that the Copper-T is in place. The copper has an exposed area of 200 sq. mm and hence the name Cu-T- 200. The US-FDA approved Cu-T-200 has an effective life of 4 years. Some additional variants available commercially in our country are Multiload ML Cu-T-250, ML Cu-T-375 and Nova Cu-T-200 (Nova T) which has a silver core added to the copper wire. The conventional Cu-T-200 has failure rate of 2%, while the newer variants have lower failure rate of 1-2%. In general Cu-T-200 is referred to a Group-I IUD; ML-250 and 375 as Group-II; while Nova-T and Cu-T-386A are referred to as Group-III IUDs. The advantages of IUDs is the ease of insertion (can be inserted at Sub centre level by paramedical workers), the semi-permanency (Cu-T-200 can be left in place and remains effective for 3 years) and the ease of removal. However, before advising IUD, proper history should be taken from the couple and correct advice given as per details given in succeeding paragraphs.

Conditions which are absolute contra - indications to IUD insertion / continuation

- (a) Pregnancy
- (b) Puerperal or Post abortal sepsis
- (c) Unexplained vaginal bleeding
- (d) Pelvic inflammatory disease within last 3 months
- (e) Known pelvic TB
- (f) STD during the past 3 months
- (g) Suspected neoplasia of genital tract
- (f) Uterine abnormalities

Conditions which increase the risk due to IUD, and alternative contraceptive may be considered, if possible

- (a) Post partum 48 hours to 4 weeks (more chances of perforation)
- (b) Women having increased chances of STD/ HIV transmission (prefer condom)
- (c) Age <20 years
- (d) Nulliparity
- (e) Endometriosis
- (e) Menstrual irregularities with increased bleeding or dysmenorrhoea

Women who are best suited for IUD include those aged >20 years, who have given birth to at least one child, have diseases or conditions like Obesity, Tobacco use, Headache, IHD, RHD, Diabetes, Thyroid disease, Benign breast disease and Irregular menstruation but without heavy bleeding and those who are breast feeding.

Timing of Insertion

- (a) The best time to insert is during or soon after menstrual periods, post partum within 48 hours of delivery and after abortion.
- (b) However, after delivery or abortion it is preferable to insert IUD 6 weeks after the delivery / abortion and the couple may be advised to use another method, as condom, for that period.
- (c) It may be noted that as far as possible insertion should not be delayed just because of timing. In fact, the best timing is the one which is most convenient to the potential user, if it can be reasonably ascertained that she is not pregnant.
- (d) It can also be inserted post coitus, even up to 5 days after coitus to prevent pregnancy

Instructions to be given to the lady, after insertion

- (a) For the next few periods (at least for next 3 periods) she should watch her pads for any expelled IUD and, after the periods, should feel for the threads (tails) coming out of the cervical os, to ensure that the device is in place. She should report if she cannot feel the threads or sees the device on her pads, or feels the device to be in the vagina
- (b) She should come for a routine health check up after the next menstrual period
- (c) She should report in case of persistent, irregular or heavy bleeding, severe pain in lower abdomen or abnormal vaginal discharge, or amenorrhoea (in which case pregnancy should be excluded)
- (d) She should also report if she feels that she has been exposed to STD or HIV

Indications for Removal

- (a) Abnormal or excessive bleeding
- (b) Persistent pelvic pain or cramping
- (c) Expiry of effective life span (3 to 4 years from date of manufacture, for Cu-T-200)
- (d) Pregnancy
- (e) Acute pelvic infection or neoplasm of genital tract
- (f) Displacement of IUD either inside the uterus or outside it
- (g) Personal reasons
- (h) After menopause (within one year)

Routine problems after insertion

The lady should be advised that she may face certain routine problems following insertion as follows, and she should not unduly worry about them :

- (a) Some cramping abdominal pain for a few days
- (b) Some vaginal discharge for a few weeks
- (c) Heavier menstrual bleeding and possibly inter-menstrual bleeding for a few weeks

Complications of IUD

- (a) Increased menstrual bleeding and sometimes inter-menstrual spotting
- (b) Cramping lower abdominal pain
- (c) Expulsion : The overall expulsion rate is 2 - 8% in first year. It is commonest in first 3 months, especially after the 1st period following insertion
- (d) Leucorrhoeic vaginal discharge
- (e) Perforation of uterus (occurs in approximately 1 per 1000 insertion)

- (f) Infection, especially during first month
- (g) Pregnancy, due to failure (1 to 2%)
- (h) Ectopic pregnancy (Rare, approximately 1 per 1000 women years. However, if pregnancy occurs with IUD in situ, then chances of its being ectopic are very high, almost 30%)

Oral Contraceptives

Hormonal Contraceptives have revolutionized the implementation of Planned Parenthood Programmes all over the world. Broadly, hormonal contraceptives could be either oral or parenterally administered. Oral contraceptives (OCs) can be further divided into two broad groups, viz. "Combined pills" (Containing both Estrogen & Progestogen) and "Progestogen only pills" (mini pills).

(a) Combined Pills : These can be of two types, viz. Monophasic pill in which every pill has same amount of Oestrogen as well as Progestogen, and the multiphasic pill in which, in a given pack for one menstrual cycle, the pills will have variable amount of Oestrogen & Progestogen. An example is "Triquila" available in our country. Monophasic pills can be, in turn, low dose pills which contain less than 0.05 mg of ethinyl estradiol (EE) in each pill along with progestogen. The other variety, i. e. high dose pills containing > 0.05mg EE per pill have been discontinued by now. Similarly, the earlier used sequential pills, which used only oestrogen in the tablets for first 14 days followed by combined Oestrogen & Progestogen for next 7 days have also been abandoned by now.

(b) Progestogen only (Mini pill) : These contain small amount of only a progestogen but no oestrogen. They are indicated for women >40 years age or who are lactating and have not completed 6 months from delivery. They are available under trade names of Microval or Femulen; they are generally not available in our country.

Choice of pill : Any of the low dose combined pill or else a triphasic pill (Triquilar) can be used. The choice will mainly depend on cost, since the triphasic pills are costly.

Commonly Available Pills : In our country, the following pills are commonly available :

Common low dose pills

- (a) Ovral-L or Mala-D - This contains L-norgesterol (LNGL) 0.15 mg and EE 0.03 mg per pill. Mala-D is available at subsidized rates in our country under the FW program.
- (b) Mala-N - This contains dl-NGL 0.30mg and EE 0.03mg per pill. This is available free of cost under the FW program in our country.

Triphasic pills : Triquilar contains L-NGL 0.05mg and EE 0.03mg for first 6 days, 0.75mg and 0.04 mg respectively for next 5 days and 0.125mg L-NGL with 0.03 mg EE for the next 10 days.

Mechanism of Action : Combined OCs produce contraceptive effect in different ways, viz. and inhibition of ovulation by bringing about changes in FSH & LH secretion, by altering the endometrium and by bringing about changes in cervical mucus.

Mode of Administration : The day on which menstrual flow starts is taken as day-1. The first pill is taken on Day-6, one pill every day for next 21 days. Thereafter the pill is stopped

and restarted after a gap of 7 days, irrespective of the onset or stoppage of menstruation during these pill free periods.

Very often the packet has 28 pills. In such cases, the last 7 tablets are actually iron tablets. In this scenario the next packet should be started on the very next day after the previous packet is finished, without any gap. Secondly, care should be taken to take the actual (hormonal) tablets on first 21 days and iron tablets on days 22 to 28.

Action to be taken when a Pill is Missed : If a pill is missed on a day, two pills should be taken on the next day, as soon as the woman remembers (preferably within 12 hours of last missed dose) and the other at bedtime; or else, if not remembered earlier, 2 tablets at bedtime on the next day. If 2 or 3 tablets are missed, the woman should take 2 tablets on each of the consecutive 2 or 3 nights and continue with rest of the packet as usual. In all such cases, when the pills have been missed the next packet should be started as usual after a gap of 7 days from the time last 21 days packet is finished. In such cases where this prompt initiation immediately after 7 days is delayed by 1 or 2 days, the women should use additional barrier method till the time of starting the next normal course of 1 pill a day (from the 7th or 8th day). These rules apply to all OC users, whether using combined or triphasic pills.

Effectiveness : Combined OC are very effective, with an overall failure rate of 0.1% (1 per 1000 women year). Failures are maximum during first year of use and are mainly due to missed pills, delay in starting the next course exactly after 7 days of finishing the last 21 days pack, and due to stopping the pill abruptly due to side effects without taking any other appropriate contraceptive measure.

Side Effects : These are of two categories, viz, minor side effects which are often temporary and the subject should therefore be properly counselled so that she does not unnecessarily discontinue the pills. The second category is the major side effects.

Minor Side Effects : These include nausea, vomiting and decrease in appetite for the initial 2 or 3 months; breakthrough bleeding usually during first few months; menorrhagia, irregular bleeding or oligomenorrhoea; breast heaviness and tenderness; headache; weight gain; acne and oily skin; and, rarely, depression and decline in libido.

Major Side Effects : These include increased risk of IHD, and stroke especially if the woman is also a smoker or hypertensive or diabetic or has history of venous thromboembolism. There is also risk of raised blood pressure especially if age is >35 years; slightly increased risk of breast cancer and possibly cervical cancer; interference with insulin action in diabetics; exacerbation of existing hepatic conditions and reduction in lactation.

Who Should Avoid OCs : The following women should avoid OCs and try to use some other contraceptive device :

- (a) Smokers, especially if age >35 years.
- (b) Women who are breast feeding their children, up to 6 months post partum.
- (c) Hypertensives.
- (d) Past H/o breast cancer.
- (e) Unexplained vaginal bleeding.

- (f) H/o stroke, thromboembolism or IHD
- (g) Cirrhosis of liver or active hepatitis or liver tumors
- (h) Using Rifampicin or anti-epileptics.
- (j) Undergoing major surgery or prolonged immobilization.
- (k) Diabetes with >20 years duration or with vascular complications.
- (l) Hyperlipidaemia.

Warning Features : Women should be educated to watch out for following features and seek medical attention should they occur :

- (a) Chest pain
- (b) Shortness of breath
- (c) Headaches which are severe or throbbing or occur on one side.
- (d) Blurred or diminished vision.
- (e) Swelling or severe pain in a leg
- (f) Missed periods, especially if 2 periods are missed.
- (g) Post coital or persistent irregular vaginal bleeding after 3 months of pill usage or excessive, white discharge especially if mixed with blood.
- (h) Yellowness of eyes or urine.

Advantages of OC use

- (a) Very effective, require minimal effort.
- (b) Return of fertility on stopping the pills is very prompt.
- (c) Can bring about relief in certain menstrual disorders as dysmenorrhoea.
- (d) May be protective against endometrial cancer and ovarian cancer.
- (e) May be protective against benign diseases of breast and ovaries.
- (f) Likely to be protective against ectopic pregnancy, PID, hirsutism, acne, osteoporosis and progression of rheumatoid arthritis.
- (g) At times, the increase in weight is quite welcome to women.

Non-Oral Hormonal Contraceptives

These are of 3 broad categories :

(a) Injectable : These include the progesterone only (Depot Medroxy Progesterone Acetate - DMPA and Norethesterone Enanthanate - NETEN) or the combined ones (DMPA 25mg Plus oestradiol 5mg or NETEN plus oestradiol 5mg)

(b) Contraceptive Implants : These include Norplant (6 capsules of levo-norgesterol) and Implanon (single rod of 3-keto desogesterol).

(c) Contraceptive Impregnated Devices : as progesterone releasing IUD (progestinsert, LNG-20, Levonova); or contraceptive vaginal rings.

Of the above, DMPA (Depot provera) and NET-EN are often used and available in India. DMPA is given 150mg i. m. inj and remains effective for 3 months; NETEN is given 200mg as an oil based i. m. inj and remains effective for 2 months. These are most effective when given within first 1-5 days of menstrual cycle. The failure rate is only 0.1 to 0.4%.

Absolute contra-indications for their use are pregnancy, unexplained vaginal bleeding and current breast cancer. Relative contraindications include less than 6 weeks postpartum among breast feeding women, history of breast cancer, jaundice,

cirrhosis, liver tumor, severe headache, undiagnosed breast disease, previous OC related liver diseases, and H/o IHD, hypertension or stroke. Fertility may take 6 to 12 months to return after discontinuation of this injection.

Emergency (post-coital; morning-after) contraception

Emergency contraception pills (ECPs) are a very good method of preventing pregnancy likely to occur due to unprotected sex or else due to suspected failure, as rupture of a condom. The following are the salient features of ECPs :

- (a) ECPs are hormonal oral contraceptives having the same hormones as used in OCs but in a higher concentration.
- (b) ECPs come in a pack of two pills. The first should be taken as soon as possible, but certainly within 72 hours of an unprotected sex. The second should be taken 12 hours after the first pill.
- (c) One ECP packet can protect only against one episode of unprotected sex.
- (d) ECPs are available free of cost at PHCs and with ANMs at subcentres, under the name of "E-Pill". They are also commercially available under brand names like Ecee-2, Norlevo, E-P-72 and Pill72.
- (e) ECPs are safe for all women including those who are breast feeding.
- (f) If the lady vomits within 1 hours of taking the pill, the dose should be repeated after taking an antiemetic as Meclizine HCL (Pregnidoxin)
- (g) Some women may have minor side effects as breast tenderness, headache, nausea, vomiting, spotting, fatigue, and dizziness which may last for maximum of 24 hours.
- (h) It should be clearly conveyed to the clientele that ECP is not an abortion pill since it cannot dislodge an implanted ovum.
- (j) ECP is quite effective in that they may prevent up to 75% pregnancy which would have otherwise occurred following unprotected sex.
- (k) After taking ECP, if onset of next menstrual cycle is delayed by more than 1 week of expected date, a pregnancy test should be done. She should also report if the period starts on time but the flow is scanty or is unusually foul smelling.
- (l) ECP should not be used as a regular contraceptive method.
- (m) In case E-pill or such ECP preparation is not available, the women can take 4 tabs of Mala-D at the earliest but within 72 hours of unprotected sex, followed by 4 Tablets of Mala-D after 12 hours of first dose.
- (n) Reassure the women that her next period will start on the expected date or sometime 2-3 days earlier or later than expected date.

Non-Hormonal Oral Contraceptives : Centchroman

This is a new form of oral contraceptive pill that does not contain any steroidal hormones, developed by the Central Drug Research Laboratory, Lucknow. It appears to be safe and economical and is sold under the brand names "Saheli" and "Centron". It is taken once a week and is very convenient. It is very effective and can increase client privacy. There are no known side effects, except that in about 8% of users there is a delay in menses.

Permanent Methods

Permanent methods include male sterilization (Vasectomy) and female sterilization (Tubectomy). Any couple who has at least one child and is voluntarily motivated can be offered sterilization procedure. Medical officers should emphasize on the clientele that these procedures are perfectly safe and do not carry adverse effects like decline in libido, low backache, obesity and so on, as are commonly thought of. In fact the sexual performance and pleasure may improve since the fear of unwanted pregnancy is removed.

Vasectomy : In the conventional procedure, an incision is given on the scrotal skin and a piece of vas deferens 1 to 1.5 cm long is removed. In the more recent technique of "No Scalpel Vasectomy" a puncture is made in scrotal skin using a reverse scissor and a hole of approx half a cm is created through which vas is ligated after removing a piece 1 cm long. The advantage of this method is that no stitches need to be given on the scrotal skin. It must be emphasized on the acceptor that it will take 3 months for him to become completely sterile. For this duration, he or his wife should use an alternative temporary method. After 3 months, seminal analysis should be done to confirm azoospermia. The following advice should be given for implementation during post operative period :

- He or his partner should use some other contraceptive procedure till such time the semen exam indicates definite azoospermia, which is generally after 3 months.
- To keep the local area clean and dry.
- To wear a T-bandage for 2 weeks
- To avoid cycling or lifting heavy weights for 2 weeks
- To get the stitches removed as advised by the surgeon.

There are very few complications of vasectomy and even these are minor. Some persons may get pain, local infection and haematoma which last for a few days and respond well to antibiotics and analgesics. Local granuloma formation may occur in a very few patients and subsides over time. The most important complications are, in fact, psychological, as feeling of low backache, development of abdominal obesity and reduced sexual drive. Subjects should be adequately educated and counselled about these psychological problems.

Overall failure rate of vasectomy is between 1 to 2 per 1000 person years (0.1 to 0.2 per 100 person years). The two important causes of its occurrence are firstly, mistakenly removing some other anatomical structure (as a local vein or spermatic chord) instead of vas. This problem is negligible in expert hands. The second reason is spontaneous recanalisation of the vas, the potential of which always exists to the tune of 0 to as high as 6%. Therefore, all persons undergoing vasectomy should be explained of this unforeseen complication and advised regular follow up for at least 3 years. In addition, another cause of pregnancy could be unprotected intercourse before complete azoospermia, which usually takes 3 months, but may be more in some subjects. It is therefore important to advise the subjects on these various aspects, since misconceptions and lack of knowledge may lead to serious domestic conflicts.

Tubectomy : In the conventional method (Pomeroy's method), a piece of the loop of Fallopian tubes about 1 cm long on both sides is removed. The same is done in minilaparotomy.

In Laparoscopic tubectomy the tubes are either blocked by electrocoagulation or sealed with a silastic band. The ideal time for tubectomy is soon after menstrual flow is over or in the post partum period. However, it can be done anytime in between the menstrual period but the woman should continue to use alternative contraceptive till her next menstrual flow.

Recanalisation : For couples who have undergone sterilization operation but now need children, recanalisation operations are available. The success of recanalisation depends on many factors, the most important being the fertility state of both the partners. In case of tubal recanalisation it also depends on the original method by which tubectomy was done - if the original method was spring loaded clip, the pregnancy rate following recanalisation may be as high as 88%, while for Pomeroy method it is about 60%. As regards recanalisation of vas, in expert hands, the patency rate may be as high as 80% but actual pregnancy rate may be lower due to various other factors as fertility status of the husband and wife.

Summary

As per present policy in the country, people are given choice to adopt contraceptive methods voluntarily out of various choices available. The various methods of contraception are divided broadly into artificial and natural methods. The natural methods include Rhythm method, Basal body temperature method, cervical mucous method, Symptothermal method and Lactational amenorrhoea method.

Artificial methods are further subdivided into temporary and permanent methods. Temporary methods include barrier contraceptives, spermicides, IUDs, oral & non-oral hormonal contraceptives. Most commonly used barrier contraceptive is condom which has the additional advantage of providing protection against STDs and HIV. It has average failure rate of 12-14 HWY, mainly because of incorrect technique of use.

IUDs act mainly by inducing inflammatory changes in endometrium, incapacitating the sperm & ovum and preventing implantation. IUDs are divided into Gp I, II & III. Before its insertion, various contraindications should be ruled out. It should be inserted soon after menstruation upto 10th day of cycle. It can also be inserted in immediate postpartum or ideally 6 weeks after delivery/abortion. It can be used as a postcoital contraceptive. After its insertion woman should be instructed regarding regular checking of IUD in place, and regular health checkups. Important complications include menorrhagia, dysmenorrhoea, expulsion, perforation, Infection & ectopic pregnancy. Average failure rate is 1-2 HWY.

OCPs are divided into combined pills and progesterone only pills. Progesterone only pills can be used in women >40 yrs. or lactating period upto 6 months of postpartum. Combined pills act by inhibiting ovulation, altering endothelium and changing cervical mucus. Combined pills can be monophasic or triphasic. Commonly used monophasic pills now come with low amount of estrogen i.e. < 0.05mg ethinyl estradiol. The first pill is taken on 6th day of period and is continued for 21 days, and after stopping for 7 days it is restarted. Failure rate is as low as 0.1 HWY. Major side effects are increased risk of IHD, CVA and venous thromboembolism.

Non-oral hormonal contraceptives include Injectable (DMPA, NETEN), Contraceptive Implants (Norplant, Implanon), Contraceptive Impregnated Devices (Progestininsert, LNG-20). Emergency contraception pills (ECPs) have the same hormones as combined pills but in higher dose, the 1st dose should be taken as soon as possible after unprotected sex (max 72 hr) and 2nd dose 12hr after the 1st dose.

Permanent methods include vasectomy and tubectomy. Vasectomy can be conventional or No scalpel vasectomy. An alternative temporary method should be used till azoospermia is achieved after vasectomy (usually 3 months). Tubectomy can be done by Pomeroy's method using conventional, laparoscopic or minilap procedure. In laparoscopic tubectomy, electrocoagulation or sialistic rings are used. Recanalisation after permanent methods is possible with varying degree of success results.

Study Exercises

Long Question : How will you educate a group of approximately 150 adult, married men and women aged 20 to 50 years, belonging to a rural background and most of them educated between 4th to 8th class, as regards the various available contraceptive procedures.

Short Notes : (1) Pearl Index (2) Compare and contrast OCs and IUDs (3) Emergency contraception.

MCQs & Exercises

- In Rhythm method for contraception, intercourse is avoided during : (a) 3-14 days (b) 5-25 days (c) 10-28 days (d) 7-21 days
- In Basal Body Temperature Method for contraception, increase in body temperature occurs : (a) Just before the ovulation (b) Ovulation period itself (c) Immediately after ovulation (d) Menstruation
- The failure rate of cervical mucus method if used correctly is : (a) 1 per HWY (b) 2 per HWY (c) 3 per HWY (d) 4 per HWY
- The failure rate of Condom is : (a) 12-14 HWY (b) 14-17 HWY (c) 17-20 HWY (d) 20-25 HWY
- The active agent in spermicidal jelly is : (a) 9-Xylenolol (b) 9- Xylene (c) 9- Nonoxynol (d) 9- Nonxyleneol
- In Cu T-200, 200 signifies : (a) Weight of Cu in mg (b) Surface area of Cu in sqmm (c) Length of Cu wire in mm (d) Diameter of Cu wire in μm
- The mechanism of action of IUD does not include (a) Inducing mild inflammatory changes and foreign body reaction in the endometrium (b) Incapacitate the sperms and ovum, prevent sperm from fertilizing the ovum (c) Makes the uterine environment inhospitable for the blastocyst to be implanted (d) Increases the reverse peristalsis of uterus
- Which of the following IUDs belong to Gp II IUDs : (a) Cu T- 200 (b) Lippe's loop (c) Cu T-380A (d) ML-250
- The presence of Cu-T in place is checked routinely by (a) Feeling the thread coming out of cervical os (b) Absence of menstruation (c) Feeling the metal tip in upper part of vagina (d) None of the above only X-ray can check it
- Which one is not an absolute contraindication for IUD insertion : (a) Pregnancy (b) Puerperal sepsis (c) Anaemia (d) Bleeding P/V of unknown etiology
- Which of the following is not the likely adverse effect of IUD : (a) Menorrhagia (b) Metrorrhagia (Intermenstrual bleeding) (c) Polymenorrhoea (d) Anaemia
- Single pill of MALA-D contains : (a) L-norgesterol (LNGL) 0.15mg and EE 0.03mg (b) L-norgesterol (LNGL) 0.03mg and EE 0.15mg (c) D-norgesterol (LNGL) 0.15mg and EE 0.03mg (d) D-norgesterol (LNGL) 0.03mg and EE 0.15 mg
- Which of the following is not the likely mechanism of action of OCPs : (a) Inhibition of ovulation by bringing about changes in FSH & LH secretion (b) By altering the endometrium (c) By bringing about changes in cervical mucus (d) Incapacitates sperm
- Which of the following is not the likely adverse effect of OCP : (a) Menorrhagia (b) Breast Heaviness (c) Oligomenorrhoea (d) Dysmenorrhoea
- The failure rate of OCP is : (a) 1 HWY (b) 2-3 HWY (c) 0.1 HWY (d) 10 HWY
- Which is not the contraindication for OCP use (a) Hyperlipidaemia (b) Cirrhosis of liver (c) Unexplained vaginal bleeding (d) Anaemia
- Which of the following is most cost effective method for permanent sterilization : (a) Vasectomy (b) Pomeroy's tubectomy (c) Laparoscopic tubectomy (d) No scalpel vasectomy
- After vasectomy/ no scalpel vasectomy, for at least how many months should the couple use alternative temporary method of contraception : (a) 3 weeks (b) 3 months (c) 2 weeks (d) 2 months
- Emergency contraceptive pill should be used within a max period of : (a) 24 hr (b) 48 hr (c) 72 hr (d) 96 hr
- What is a mini pill : (a) Pill containing lesser amount of estrogen and progesterone (b) Once a month pill (c) Progesterone only pill (d) Emergency pill

Match the Following :

1. Cervical mucus Method	a. 12 to 14 / HWY
2. Condoms	b. 3 / HWY
3. IUDs	c. 1 per 1000 women year
4. Combined OC	d. 1 to 2/ HWY

Fill in the Blanks

- Emergency Contraceptive Pills (Hormonal) come in a pack of ____ Pills, The first should be taken as soon as possible, but certainly within ____ hours of an unprotected sex. The second should be taken ____ hours after the first pill.
- The first pill is taken on Day _____, one pill every day for next ____ days. Thereafter the pill is stopped & restarted after a gap of ____ days, irrespective of the onset or stoppage of menstruation during these pill free periods.
- _____ Oral contraceptive pill is available free of cost under the FW program in our country. This contains _____ dl-NGL and _____ Ethinyl estradiol (EE) per pill.
- Oral Contraceptives produce contraceptive effect by _____ and _____ and _____
- The best time to insert Copper-T is _____

Answers : MCQs : (1) d; (2) c; (3) c; (4) a; (5) c; (6) b; (7) d; (8) d; (9) a; (10) c; (11) c; (12) a; (13) d; (14) d; (15) c; (16) d; (17) d; (18) b; (19) c; (20) c; **Match the Following :** (1) b; (2) a; (3) d; (4) c; **Fill in the Blanks :** (1) 2, 72, 12 (2) 1, 21, 7; (3) Mala-N, 0.30mg, 0.03mg (4) Inhibition of ovulation by bringing about changes in FSH & LH secretion, by altering the endometrium and by bringing about changes in cervical

mucus (5) During or soon after menstrual period.

Rina Tilak

The word 'Entomology' is derived from the Greek words 'ENTOMON' meaning an insect and 'LOGOS' meaning science, thus ideally making Entomology 'the branch of science which deals with the study of insects'; however, the scope of the subject has been broadened to include study of all Arthropods. Phylum Arthropoda constitutes all invertebrates with jointed appendages and presence of chitinous exoskeleton besides other features. The word Arthropoda is derived from two words 'ARTHRON' meaning jointed and 'PODA', which means legs or appendages. The Phylum has many important classes of which Class Insecta is the largest, constituting more than four million insect species. The other important classes are Arachnida, Crustacea and Myriapoda.

Vector borne diseases are one of the leading causes of morbidity and mortality the world over and pose a major public health challenge especially to the third world or developing countries. One of the important measures to combat these diseases is through control of vectors. To ensure effective vector control, the knowledge about their lifecycle, habits, habitat and diseases transmitted is essential. The chapters in this section will guide the reader on these aspects so that sound vector control strategies can be formulated, wherever and whenever, vector control is desired.

Classification of Arthropods

Diversity of structures amongst arthropods necessitates the sub-division of the phylum Arthropoda into a number of classes, orders, families, genera and species. The following classes include species of medical importance.

(a) Class Insecta : It comprises about 70% of all the known species in the animal kingdom. The insects are characterized by the presence of six legs, body divided into head, thorax and abdomen and presence of antennae besides other features. The head bears the mouthparts, eyes in the form of compound or simple eyes or at times may have no eyes and a pair of antennae. The thorax is subdivided into three segments with a pair of legs in each called the pro, meso and metathoracic legs. The class is further subdivided into 29 orders of which only 4 contain species of medical importance.

(i) Order Diptera : It possesses one pair of wings and a pair of 'halteres', which are vestigial wings. This is the largest order comprising about seventy thousand described species with world wide distribution. It contains such insects of medical importance as mosquitoes, sandflies, simulium flies and house-flies.

(ii) Order Anoplura : It comprises true or sucking lice, which are parasitic on mammals and the chewing lice, which infest birds as well as mammals. Lice of medical importance to man are human lice.

(iii) Order Siphonaptera : It contains many species of fleas including the rat flea, which is a vector of plague and endemic typhus.

(iv) Order Hemiptera : It contains the bedbugs and some other species like kissing or 'assassin' bugs, which act as vectors of 'Chagas' disease.

(b) Class Arachnida : It includes arthropods like ticks, mites, spiders and scorpions. The class is characterized by the presence of eight legs, body divided into two parts viz. cephalothorax (head and thorax are fused together) and abdomen and absence of antennae and wings. The cephalothorax bears six pairs of appendages, the first two pairs function as mouthparts (chelicerae and pedipalps) and last four pairs as walking legs.

(c) Class Crustacea : It includes lobsters, crabs, water fleas and cyclops; some species of these are intermediate hosts of certain human helminths, e.g. Cyclops as intermediate host of guinea worm infestation.

(d) Class Myriapoda : It includes centipedes and millipedes.

Modes of Disease Transmission

Arthropods transmit diseases to man through specialized modes of disease transmission. The modes of disease transmission by arthropods can be classified as under :

Direct Contact : When two hosts are in direct contact with other, the arthropod vector itself gets transferred from one host to the other, e.g. pediculosis and scabies.

Mechanical transmission : In this mode of transmission, the disease causing organism is transmitted on the outside or inside the bodies of arthropods without undergoing any development, propagation or any changes in the pathogenicity e.g. diseases transmitted by houseflies - diarrhoea, dysentery, cholera, hepatitis A & E etc.

Biological Transmission : The disease causing organism undergoes certain biological changes inside the body of the vector. Depending on the type of biological changes, biological transmission has been further classified as :

Cyclo-developmental : In this mode of transmission, the disease causing organism undergoes a part of its cycle in the vector and simply develops or grows inside the body of the vector, e.g. *Wuchereria bancrofti* (Filariasis) transmitted by *Culex* female.

Cyclo-developmental-propagative or Cyclo-propagative : In this mode of transmission, the disease causing organism undergoes a part of its life cycle in the vector and also grows/develops and multiplies inside the body of the vector. Example is *Plasmodium* sp (Malaria) transmitted by *Anopheles* female.

Propagative : In this transmission mode, the disease organism simply grows and multiplies in the body of the vector, e.g. *Yersinia pestis* (Plague) transmitted by rat flea and all bacterial, viral, spirochaetal or rickettsial diseases transmitted by arthropods.

Other Specialized Modes of Disease Transmission : These specialized modes of disease transmission are generally encountered in ticks and mites.

Trans-ovarian : The disease organism is transmitted to eggs through ovary of infected female, e.g. *Orientia tsutsugamushi*, the agent for Scrub typhus transmitted by trombiculid mite-*Leptotrombidium deliense*.

Table - 1 : Important arthropod borne diseases			
Disease	Vector	Causal organism	Reservoir
I Mosquito borne diseases			
Malaria	<i>Anopheles species</i>	<i>Plasmodium species</i>	Man
Filariasis	<i>Culex quinquefasciatus</i> <i>Aedes niveus group</i> <i>Mansonioides species</i>	<i>W bancrofti</i> (nocturnal, periodic) <i>W. bancrofti</i> (diurnal sub-periodic) <i>Brugia malayi</i>	Man Man Man, Primate
Chikungunya	<i>Aedes species</i>	Arbovirus group A	Man
Dengue fever & DHF	<i>Aedes species</i>	Arbovirus group B	Man
Yellow fever	<i>Aedes species</i>	Arbovirus group B	Man/ Monkeys
Japanese Encephalitis	<i>Culex vishnui group</i> (<i>C tritaeniorhynchus</i>)	Arbovirus group B	Mammals/ Birds
II Sandfly borne diseases			
Leishmaniasis			
Visceral (Kala azar)	<i>Phlebotomus argentipes</i>	<i>Leishmania donovani</i>	Man/Mammals
Cutaneous (Oriental sore)	<i>P. papatasi</i>	<i>L. tropica</i>	Man/Mammals
Espundia	<i>P. sergenti</i>	<i>L. braziliensis</i>	Man/Mammals
Sandfly fever	<i>P. sergenti, P. papatasi</i>	Virus	Man
III Fly borne diseases			
Bacillary dysentery	<i>M domestica</i>	<i>Shigella</i>	Man
Amoebic dysentery	<i>M domestica</i>	<i>E. histolytica</i>	Man
Gastroenteritis	<i>M domestica</i>	Specific/Non specific organisms	Man/animals
Typhoid	<i>M domestica</i>	<i>Salmonella typhi</i>	Man
Paratyphoid	<i>M domestica</i>	<i>Paratyphoid A&B</i>	Man
Cholera	<i>M domestica</i>	<i>Vibrio cholera</i>	Man
Poliomyelitis	<i>M domestica</i>	Virus	Man
Viral hepatitis (Type A)	<i>M domestica</i>	HAV	Man
Trachoma	<i>M domestica</i>	<i>C trachomatis</i>	Man
Yaws	<i>M domestica</i>	<i>T pertenue</i>	Man
IV Flea borne diseases			
Plague (Bubonic)	<i>Xenopsylla species</i>	<i>Yersinia pestis</i>	Rodents
Endemic/Murine Typhus	<i>Xenopsylla species</i>	<i>R. typhi</i>	Rodents/ Domestic animal
Chiggerosis (Jigger)	<i>Tunga penetrans (chigoe)</i>	-	-
<i>Dipylidium caninum</i>	<i>Ctenocephalides. felis/canis</i>	<i>Dipylidium caninum</i>	Dogs, cats, wild
<i>Hymenolepis diminuta</i>	<i>X cheopis / N.fasciatus</i>	<i>Hymenolepis diminuta</i>	Carnivores
<i>H nana</i>	<i>X cheopis / C canis/ Pulex irritans</i>	<i>H nana</i>	Rats, mice
V Louse borne diseases			
Epidemic typhus	<i>Pediculus humanus</i>	<i>R. prowazeki</i>	Man
Epidemic relapsing fever	<i>Pediculus humanus</i>	<i>Borrelia recurrentis</i>	Man
Trench fever	<i>Pediculus humanus</i>	<i>Bartonella quintana</i>	Man/animals
Dermatitis	<i>Pediculus humanus/ capitis</i>	Secondary organisms	Man
VI Tick borne diseases			
Kyasanur Forest Disease (KFD)	Hard ticks species	<i>Arbovirus group B</i>	Monkeys/Birds
Tick typhus	Hard ticks species	<i>R conorii</i>	Dogs
Tularaemia	Hard ticks species	<i>P tularensis</i>	Rabbits/ Rodents/ cattle
Relapsing fever	Soft Tick	<i>B duttoni</i>	Rats
VII Mite borne diseases			
Scrub typhus	<i>L. deliense</i>	<i>Orientia tsutsugamushi</i>	Rodents
Rickettsial pox	<i>Allodermanyssus sanguineus'</i>	<i>R akari</i>	Rodents
Scabies	<i>S scabei</i>	-	Man
VIII Cyclops transmitted diseases			
Dracontiasis	Cyclops species	<i>D medinensis</i>	Man
Fish tape worm	Cyclops species	<i>D. latum</i>	Fish
IX Reduviid bugs			
Chagas disease	Reduviid/Cone-nosed	<i>T cruzi</i>	Domestic animals/ man
X Tsetse flies			
Trypanosomiasis	<i>Glossina species</i>	<i>T gambiense and T rhodesiense</i>	Wild animals/ cattle/ man

Trans-stadial : The disease causing organism is transmitted from one stage to another e.g. Tick typhus organism - *Rickettsia conorii* transmitted from infected larva to nymph to adult.

Arthropod Borne Diseases

Arthropods are responsible for transmission of innumerable diseases. Some of the important arthropod borne diseases is listed in Table - 1 along with their vectors, causative organisms and reservoir hosts.

Summary

Entomology is the branch of science which deals with the study of insects, however, the scope of the subject has been broadened to include the study of all Arthropods. Amongst the many important classes of the phylum, Insecta is the largest constituting more than 4 million species. Vector borne diseases are one of the leading causes of morbidity & mortality especially in the developing countries. These diseases can be largely combated by effective vector control for which a sound knowledge of the bionomics of the vector is needed. The important classes of Phylum Arthropoda are Insecta, Arachnida, Crustacea, Myriapoda. The class Insecta is characterized by presence of six legs, body divided into head, thorax & abdomen. The class has 4 orders of medical importance, Diptera, Anoplura, Siphonaptera & Hemiptera. The order Diptera has 1 pair of wings and contains insects such as mosquitoes, sandflies, simulium flies and houseflies. The order Anoplura comprises true or sucking lice. Order siphonoptera includes the rat flea; the order hemiptera contains bed bugs. The class Arachnida includes ticks, mites, spiders and scorpions; body is divided into cephalothorax and abdomen and presence of eight legs. The class crustacea includes lobsters, crabs, water fleas and Cyclops. Myriapoda includes millipedes and centipedes.

Arthropods transmit diseases to man by different modes of transmission, mainly direct, mechanical & biological. In direct transmission, two hosts come in direct contact with each other e.g. pediculosis & scabies, mechanical transmission where disease causing organism is transmitted without undergoing any change in pathogenecity or development e.g. diseases transmitted by houseflies. Biological transmission is further divided into *cyclodevelopmental* - the disease causing organism undergoes part of its life cycle in the vector e.g. *Wuchereria bancrofti*; *cyclopropogative* - the disease causing agent undergoes part of the lifecycle in the vector & also multiplies inside the vector e.g. malaria transmitted by Anopheles female. The other mode is *propogative* where disease causing organism simply grows & multiplies in the body of vector e.g. *Yersinia pestis* (plague) transmitted by rat flea, other specialized modes are transstadial & transovarian.

Study Exercises

Short Notes : Modes of disease transmission.

MCQs & Exercises

- 1) Class Insecta is characterised by presence of how many legs? : (a) 4 (b) 5 (c) 6 (d) 8
- 2) Mosquito belongs to the order a) Diptera (b) Anoplura (c) Siphonoptera (d) Hemiptera.
- 3) Mode of transmission of malaria by Anopheles is : (a) Cyclo - developmental (b) Cyclo - propogative (c) Propagative (d) Cyclo - developmental propagative
- 4) *Orientia tsugtsugamushi* is the causal organism for the diseases (a) Scrub typhus (b) Epidemic typhus (c) Endemic typhus (d) Tick typhus.
- 5) Which of the following is not a mosquito borne disease : (a) Dengue (b) Filaria (c) Leishmaniasis (d) Yellow fever
- 6) Aedes species cannot transmit : (a) Chickungunya (b) Dengue haemorrhagic fever (c) Japanese Encephalitis (d) Yellow fever
- 7) Causal organism for bubonic plague : (a) *R typhi* (b) *Y pestis* (c) *H nana* (d) *H diminuta*
- 8) Murine Typhus is transmitted by : (a) Hard tick species (b) Soft tick species (c) Xenopsylla species (d) Trombiculid Mite species
- 9) Causal organism for epidemic Typhus : (a) *B quintana* (b) *R prowazeki* (c) *Borrelia recurrentis* (d) *R typhi*
- 10) KFD is transmitted by : (a) Soft Tick (b) Mite (c) Hard Tick (d) Lice
- 11) _____ is the largest class of Phylum Arthropoda constituting more than _____ insect species
- 12) Direct mode of transmission is seen in _____ & _____
- 13) Entomology is derived from the Greek word ENTOMON meaning _____ & LOGOS meaning _____
- 14) Arthropoda is derived from two words ARTHRON meaning _____ & PODA meaning _____
- 15) *Leptotrombidium deliense* is vector for _____

Answers : (1) c; (2) a; (3) b; (4) a; (5) c; (6) c; (7) b; (8) c; (9) b; (10) c; (11) Insecta ; 4 Million; (12) Pediculosis; Scabies; (13) Insect, Science; (14) Jointed, Appendages; (15) Scrub Typhus.

Rina Tilak

Control of arthropods is one of the key strategies in the management of vector borne diseases. A strategist should have sound knowledge of the bionomics, distribution, seasonal prevalence, vectorial capacity, insecticide susceptibility status and role of arthropods in diseases transmission coupled with the knowledge of identification features of the incriminated vectors for formulating effective control strategies. Once armed with this knowledge, the choice of effective vector management tools may be exercised; the range and sophistication of control methods is impressive. The various control options available are as follows :

- Environmental Control
- Chemical Control
- Biological Control
- Personal Protective measures
- Mechanical control
- Physical control
- Genetic control
- Legislative control

Environmental Control

The important environmental control measures which are increasingly being used are described below :

Environmental Management

This has been defined as “The planning, organization, carrying out and monitoring of activities for the modification and/or manipulation of environmental factors or their interaction with man with a view to prevent or minimize vector propagation and reducing man-vector-pathogen contact.” This is a naturalistic approach which attempts to extend and intensify natural factors which limit vector breeding, survival and contact with man.

(a) Environmental Modification : It is defined as “A form of environmental management consisting of any physical transformation that is permanent or long-lasting of land, water and vegetation aimed at preventing, eliminating or reducing the habitats of vectors without causing unduly adverse effects on the quality of the human environment”. Environmental modification includes drainage, filling, velocity alteration, land levelling and transformation of impoundment margins.

(b) Environmental Manipulation : It is defined as “A form of environmental management consisting of any planned recurrent activity aimed at producing temporary conditions unfavourable to the breeding of vectors in their habitats”. Examples of environmental manipulation activities are water salinity changes,

stream flushing and regulation of the water level in reservoirs, vegetation removal, shading and exposure to sunlight.

(c) Modification or Manipulation of Human Habitation or Behaviour : This means “A form of environmental management that reduces man-vector - pathogen contact”. Examples of this approach are siting of settlements away from vector sources, mosquito/rodent proofing, personal protection and hygienic measures against vectors and provision of mechanical barriers, providing facilities for water supply, disposal of waste water and excreta, laundry, bathing and recreation to prevent or discourage human contact with infested water.

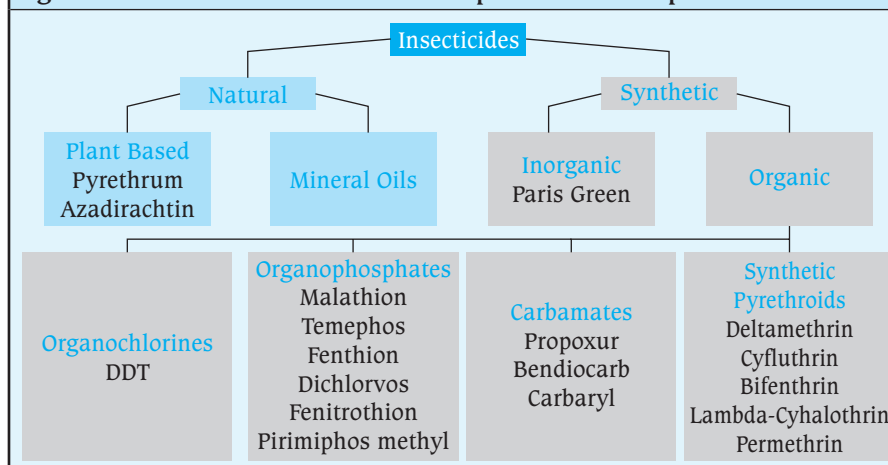

Chemical Control

The new era of control of vector borne disease began with the discovery of the insecticidal value of Dichloro Diphenyl Trichloro ethane (DDT). DDT was first synthesized by Othmar Zeidler in 1874 at Strasbourg, Germany. In 1939, Paul Muller of the Geigy Company in Basle, Switzerland, discovered its remarkably long residual insecticidal property, earning him the Nobel Prize in Medicine. The availability of several effective, safe and low cost pesticides, coupled with improvements in the techniques of their application, made it possible for many governments in the developed as well as developing countries to embark upon extensive countrywide programmes for the control or eradication of vector borne diseases. However, development of resistance amongst vectors to insecticides has necessitated reassessment of the place of pesticides in vector control programmes. Besides the technical and financial difficulties, there is a growing concern about the environmental contamination resulting from the persistent use of insecticides.

Classification of Insecticides

Pesticides may be classified in many ways based on mode of entry, target stage, chemical composition and mode of action. However, the most common classification used is based on chemical composition. According to this classification, the insecticides are classified in the following categories as presented in Fig. - 1.

Fig. - 1 : Classification of insecticides as per chemical composition

Natural Insecticides

Plant based

Pyrethrum : Pyrethrum extract is obtained from the dried heads of the flower *Chrysanthemum cinerariaefolium* and contains the active ingredients pyrethrins I and II, constituting 1 to 2% of the total weight of the raw pyrethrum. Pyrethrum is characterized by rapid knockdown action on arthropods even when used in very low dilution. It is very unstable in light and air and has practically no residual effect. This makes repeated applications necessary. Pyrethrum is available as 2% extract, which needs 20 times dilution to make it 0.1% solution, which is actually used for spraying. Using a 0.4 mm or lower calibre nozzle, 50 to 100 ml of pyrethrum solution in kerosene oil is sprayed per 100 m³ of space. Addition of an Organophosphorus insecticide to pyrethrum formulation is a common commercial practice for obtaining a better effect. It is one of the main insecticidal constituents in aerosol dispensers and also an insecticide of choice for ULV sprays. Pyrethrum is perhaps the most acceptable insecticide for use in cook houses, dining halls and other food preparation areas.

Azadirachtin : The active ingredient Azadirachtin is obtained from the seed kernels of neem plant *Azadirachta indica*. Azadirachtin has insecticidal, fungicidal, bactericidal, viricidal properties including insect growth regulating qualities besides deterrent, anti-ovipositional, anti-feedant, fecundity and fitness-reducing properties on insects. It has been variously formulated for mosquito larval and adult control in the form of liquid and cream formulations. Neem products contain up to 3% Azadirachtin.

Mineral Oils : Kerosene oil, diesel oil, petrol and crude engine oil have been successfully used as mosquito larvicides. The oil film cuts off the air supply, enters and blocks the trachea, may act as a stomach poison, and also lowers surface tension which prevents larvae from floating. Malariol is the best and easiest larvicidal oil to use for Anopheline and Culicine larvae. Malariol is used as it is @ 10 litres per 500 linear meters.

Synthetic Insecticides : These can be organic or inorganic. The only inorganic compound used in vector control (mosquito larvicide) was Paris green (Copper-aceto-arsenite). It acted as stomach poison when ingested by mosquito larvae. However, it is not used any more for mosquito control.

The Organic Insecticides fall into four major groups viz. Organochlorines, Organophosphates, Carbamates and Synthetic pyrethroids.

Organochlorine Compounds : These compounds are contact poisons and act on the nervous system. These or their degradation products are more or less stored in body fat and may be demonstrated in milk, urine or sweat. They all have variable residual action for variable periods and are toxic to man and animals. The most important and the only member of this group used in Public Health is DDT.

Dichloro-diphenyl-trichloroethane (DDT) : Currently DDT is being used for indoor residual spray in the North Eastern states of India. A deposit of 1 g of DDT/m² of surface area of walls and ceiling upto a height of 3.5 m in all dwellings applied at 8 weeks' interval, effectively controls majority of the mosquitoes and also other arthropods resting on the treated wall (Refer to

Chapter on Mosquitoes for further details on use). As per Govt. of India Gazette notification number S.O. 378(E) dt 26th May 1989, the use of DDT in Agriculture has been withdrawn and restricted to 10000 MT/ annum for Public Health programme except in case of North East as Insecticidal Residual Spray (IRS).

Organophosphorus Compounds : These insecticides are derivatives of phosphoric acid and act by inhibiting the activity of cholinesterase. Many of the insects, which have become resistant to Organochlorines are still susceptible to the members of this group. However, due to their extensive use in agricultural as well as public health field, more and more insects are developing resistance to Organophosphorus compounds. Some of the common compounds are Malathion, Temephos, Fenthion, Dichlorvos (DDVP) and Fenitrothion.

Malathion : It is one of the least toxic Organophosphorus compounds. Malathion is a broad spectrum insecticide, with efficacy against a large number of pests ranging from mosquitoes, houseflies, cockroaches, bedbugs, lice etc. It is available as Malathion Technical (95%) for use as space spray, 50% Water Dispersible Powder (WDP) and Emulsifiable Concentrate (EC) for residual control and 90% dust for use against fleas and lice. Malathion under the National Vector Borne Diseases Control Programme of India is being used as Indoor Residual Spray against mosquitoes in areas where the vectors have become resistant to DDT. The dosage of its application is 2 g/m² (Refer to Chapter on Mosquitoes for further details). As ULV spray it has been very widely used during outbreaks of Dengue and JE as an anti adult mosquito measure. However, development of resistance has been reported in a large number of vectors to Malathion.

Temephos : It is available as 50% EC. It is the only insecticide approved for use in potable water. Because of its low toxicity, it has been successfully used for the control of *Anopheles stephensi* breeding in wells and domestic containers at a dosage of 1ppm (Refer to Chapter on Mosquitoes for details). Sand impregnated with Temephos in 1% concentration has been used in some countries against *Aedes aegypti* which breeds in containers of clean and potable water. It has proved to be very successful in Guinea worm eradication programme in India.

Fenthion : It is formulated as 82.5% EC and as granules containing 2% toxicant. It is a good mosquito larvicide but can not be used in potable water bodies. It is highly effective as a larvicide against *Culex quinquefasciatus* or any other vector found breeding in non potable water bodies at a dosage of 1 ppm (Refer to Chapter on Mosquitoes for further details). It can also be used for housefly control as a larvicide (Refer to Chapter on Houseflies for details).

Pirimiphos methyl : This insecticide is being considered as an alternative insecticide for Indoor residual spray. It is available as 25% WP; 2 kg is mixed in 10 litres of water and sprayed @ 10 litres/ 250 sq m area to give a deposit of 2g/sqm. Three rounds of spray are recommended as is followed in case of Malathion.

Dichloro-dimethyl-dichlorvinyl-phosphate (DDVP or Dichlorvos) : It differs from other organophosphorus compounds in that it possesses a much greater vapour pressure at ordinary temperature which produces fatal insecticidal

vapour. It is available as 72.6% EC. It can be combined with solid substances like wax and used as tablets or bricks thus allowing it to evaporate slowly. It is one of the common insecticides used for disinsecting aircraft. It is an effective housefly larvicide.

Fenitrothion : It is available as Fenitrothion 40% water dispersible powder (WDP). The insecticide has shown promise as an effective insecticide for control of bedbugs; however toxicity constraints have limited its widespread use.

Carbamates : These compounds are derivatives of carbamic acid and resemble Organophosphorus compounds in their mode of action. Some of the preparations produce a rapid knockdown effect like that of pyrethrum. The inhibition of Acetylcholine esterase is reversible with Carbamates and hence these compounds are less toxic. Some of the compounds in common use are Propoxur, Carbaryl and Bendiocarb.

Propoxur : It is formulated as WDP as well as EC. It is considered as the least toxic Carbamate compound for man and domestic animals. It has a flushing out effect and therefore is commonly used for cockroach and bedbug control. It is also used in bait formulations against houseflies and cockroaches.

Bendiocarb : Bendiocarb is an alternative insecticide for Indoor residual Spraying. It is available as 80% WP. For indoor residual spraying, it is recommended @ 200 mg/sqm. Two rounds of spray are recommended for effective control against malaria.

Synthetic Pyrethroids : These are synthetic derivatives or analogues of natural Pyrethrum. These are broad spectrum, highly potent with quick knock down action and long residual life. Synthetic pyrethroids are many times more effective than the previously available insecticides. Their relative safety to man and higher animals, their efficient biodegradability together with their higher target specific toxicity makes them very attractive materials for integrated vector control. The commonly available products are Permethrin, Allethrin, Phenothrin, Cypermethrin, Cyfluthrin, Deltamethrin and Bifenthrin. The Synthetic pyrethroids are formulated as WDP, EC, SC, Flow, EW and ULV formulations. Being broad spectrum, these insecticides are being used for vector control as residual spray, space spray and topical application as well as for treatment of clothing.

Deltamethrin : It is one of the most widely used Synthetic pyrethroid molecule in the field of vector control. It is available in many formulations for various vector control strategies viz. SC 2.5% (Flow) formulation for treatment of bednet and routine household pest control activity; 2.5% WP formulation for Indoor Residual spray in Malathion resistant areas and 1.25 ULV for space spraying. The target dose (for Indoor Residual Spray) is generally 20 mg of a.i. (active ingredient) per sq m of surface area.

Cyfluthrin : Besides Deltamethrin, this is the next most widely used molecule. It is available as 0.5% EW formulation for treatment of bednets; 5% EC for household use and 10% WP for use as indoor residual spray in Malathion resistant areas.

Permethrin : Widely used for control of lice, scabies and for treatment of clothing and bednets. The product is formulated in varying concentration as Shampoo formulation for use as anti-lice treatment and 5% cream for use in scabies treatment. Bed nets treated with Permethrin at the manufacturing stage itself

are available as Pretreated or Long Lasting Nets (LLNs).

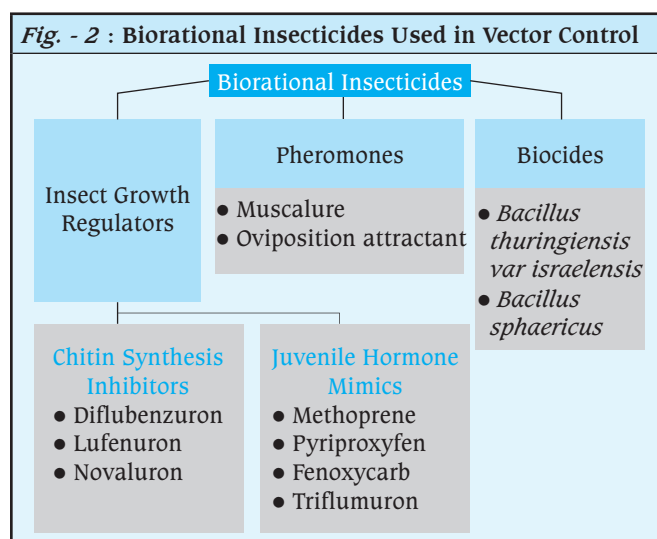

Other Synthetic pyrethroids used in Public health : There is a large range of molecules used in the field of Public health besides the ones listed above. These molecules are Allethrin, Resmethrin, Phenothrin, Cypermethrin, Imiprothrin, Bifenthrin, Cyhalothrin, Cyphenothrin etc. These are all available as WP, EC or Aerosol formulations for use against pests like cockroaches, houseflies and mosquitoes.

Newer Group of Insecticides

Phenyl pyrazoles : Fipronil is the only member of this class of insecticide. Fipronil acts by antagonizing the effect of GABA. It is available as 0.3% Gel for use against cockroach as a crack and crevice treatment. It is a systemic material with contact and stomach activity. It has a unique action called 'cascade effect' which is evident due to necrophagy seen in cockroaches. When cockroaches consume the insecticide bait, they are killed; these dead cockroaches when consumed by other cockroaches bring about the death of these cockroaches and this goes on for about two months or so, thus obviating the need to retreat the area at lesser intervals.

Neo Nicotinoids : Imidacloprid is the sole member from this class. It acts by causing irreversible blockage of postsynaptic acetylcholine receptors. Imidacloprid is a systemic insecticide, having notable contact and stomach action. Imidacloprid is available as 2.15% Gel for use against cockroaches and as Bait for use against houseflies, where it is formulated with housefly pheromone - Muscalure.

Biorational Insecticides : 'Biorational' means any substance of natural origin that has a detrimental or lethal effect on specific target pest, e.g. insects. These insecticides are non-toxic to man, plants and animals and have little or no adverse effects on the environment. An overview of the biorational insecticides is presented in Fig. - 2.

Insect Growth Regulators : A new approach to vector control is the use of substances that adversely affect insect growth and development. The enzymes and hormones that regulate developmental processes within an insect's body can sometimes be exploited as chemical control weapons. These compounds,

often known as Insect Growth Regulators (IGRs) can be used to stimulate development at inappropriate times or inhibit it at other times. They are quite selective in their mode of action and potentially act only on target species. Most of the IGRs that have shown effectiveness against insect pests, cause the rapid death of the insect through failure of a key regulatory process to operate or function. IGRs generally control insects either through inhibition of chitin synthesis or interference with metamorphosis by mimicking the action of juvenile hormone. The major groups of IGR compounds include :

Chitin Synthesis Inhibitors : These chemicals inhibit the moulting process by blocking the activity of chitin synthetase, an enzyme needed by epidermal cells when constructing a new exoskeleton. Because of this mode of action, Chitin Synthesis Inhibitors (CSIs) are highly specific to arthropods. They act rather slowly (2-5 days), but eventually disrupt any process that involves construction of new cuticle (e.g., molting, hatching, pupation). They are most effective when used against the immature stages of a vector. Diflubenzuron, is used for controlling mosquitoes, houseflies etc. It is available as 25% EC, WP & 0.5% Granules and is used @ 1.0 g/ acre of surface water as mosquito larvicide. Lufenuron, is a systemic CSI and is especially effective for flea and tick infestation control on animals. Novaluron is a recent addition to the list, which has been found effective against the mosquitoes. It is a contact larvicide and is available as 10% EC. It is used @ 20 µg a.i./ l and the efficacy lasts up to 3 months.

Juvenile Hormone Analogues or Mimics : Juvenile hormone analogues or Juvenile Hormone Mimics (JHM's) act by inhibiting the developmental changes associated with embryogenesis, morphogenesis, and reproduction. During normal development, JH levels are elevated in larvae (or nymphs) and decrease prior to pupation (or adult eclosion). Contact exposure to JH analogues during the egg stage or after the last larval molt can inhibit development, delay maturation, and eventually result in death. Since the onset of mortality is usually quite slow (days to weeks), these chemicals are not used during epidemics; however, these chemicals are much in demand for routine vector control due to their specificity and safety to non-target organisms. Several compounds (e.g., Methoprene, Pyriproxyfen, Fenoxycarb, Triflumuron) have been successfully incorporated into vector management programmes especially Dengue and Malaria and in products used for controlling ants, fleas, and other household pests. Pyriproxyfen can cause sterilization and inhibition of growth of adult insects; it has a residual effect up to 3 to 6 month indoors and 30 days outdoors. It is widely used against mosquitoes @ 2gm a.i./ sq m.

Pheromones : Pheromones are semiochemicals (chemicals which mediate interactions between organisms) secreted by an organism which provokes specific reaction in receiving organisms of the same species. These chemicals may further be classified based on the type of interaction mediated e.g. sex pheromone (muscalure secreted by houseflies), oviposition attractant (mosquito larvae), aggregation pheromone (cockroach, bedbugs), alarm pheromones, trail pheromones etc. The scope of pheromones in vector control is promising, however so far only two pheromones viz. Muscalure (in combination with Imidacloprid insecticide as baits against

houseflies) and oviposition attractant (*Aedes* control) have been exploited in the field of vector management.

Biocides : The development of insecticide resistance amongst the major pests and vectors coupled with the non target toxicity, necessitated development of safer alternatives to insecticides. This led to the screening, promotion and use of a large number of biorational products of which biocides are one of the most important control options. The two biocides used in the field of vector control are *Bacillus thuringiensis var israelensis* and *Bacillus sphaericus*. Both these products are widely used as larvicides in Mosquito control programmes and act as stomach poison.

Bacillus thuringiensis var israelensis (Bti) : It was discovered in 1976 and has been found to be effective as mosquito larvicide. It is a gram positive spore forming bacteria. Bti produces toxins which are present in parasporal body called the 'protein crystal'. It primarily kills by the action of delta-endotoxin. When the mosquito larva ingests the protein crystal (inactive protoxin), it is activated inside its midgut by the action of proteases into active protoxin; these bind to the cell receptors present on midgut epithelium and cause disturbance in osmoregulatory mechanism which leads to swelling and eventual bursting of the epithelium and finally death of the larvae. The product is available as WP, Granules, AS & Briquette. Bti 12 AS is used @ 20ml/m² and has been found to be effective up to 15 days (for details refer chapter on mosquito). Bti however, suffers from the disadvantage that it can not be used in polluted waters or where particulate matter is more; it also cannot recycle in nature. It is used in non potable water bodies.

Bacillus sphaericus : A naturally occurring bacterium used against mosquito larvae. It is more effective in polluted water and can recycle and persist in nature. It is available in various formulations like Bti viz. pellets, briquettes, granules & WP. It is used @ 20ml/m² and has been found to be effective up to three weeks.

Fumigants : Some of the fumigants used as pesticides are carbon tetrachloride, methyl bromide, ethylene dibromide, chloropicrin, carbon disulphide and dichlorvos (DDVP).

Application Techniques

Control of arthropods in different habitats necessitates the use of different types of spraying equipment as well as a variety of formulations such as liquids, granules and dusts. For example control may involve treatment of small domestic or peridomestic water collections which are ideal breeding places for *Aedes* mosquitoes; applications to stagnant waters in cesspools, ditches and drains where *Culex* mosquitoes breed, large bodies of standing water where certain *Anopheles* mosquito species may be breeding; or aerosol spraying of extensive areas to halt epidemics. To meet with diverse situations, significant progress has been made in improving the spraying equipment. The Ultra Low Volume (ULV) equipment for ground and aerial spray to control mosquitoes and other haematophagous arthropods has resulted in not only the elimination of several impediments like frequent mixing and reloading but helped in increasing the speed of application and reducing the dosages and costs. It is specially recommended for control of an outbreak of vector borne disease.

Formulations

Manufacturers combine pesticides with other materials to make usable concentrations called formulations. These formulations are designed to kill insects readily without causing undue hazards to non-target organisms when diluted and applied correctly. Factors influencing application and efficacy of an insecticide are its toxicity, size and shape of its particles, concentration in formulation; type of solvent used, type of surface to be sprayed, atmospheric temperature and humidity, type of sprayer and its nozzle, training of the spraying personnel, the bionomics, morphology and physiology of the particular arthropod. No single preparation can meet the requirement of vector control in all spheres of human ecology. Solutions, emulsions, suspensions, water dispersible powders, dusts and granules to suit different conditions and problems are therefore, prepared and used.

Technical Grade Pesticide

This is the basic toxic agent in its purest commercial form. Some technical grade pesticides are liquids; others occur in solid form. Technical grade Malathion is used in ultra low volume space applications.

Types of Formulations

Formulations essentially are of three types : Solid or dry, liquid and gaseous formulations.

Solid or Dry formulations

Dusts : Dusts are normally ready-to-use formulations with a low percentage of active ingredient (usually 1 - 10%) plus a very fine inert carrier such as talc, chalk, diatomaceous earth, clay or volcanic ash. These materials are usually low in cost, easy to apply, non-staining and non-toxic to vegetation. Dusts are always used dry and can easily drift into non-target areas if they are not applied carefully. For this reason, outdoor applications should be made only when the wind is calm. A common use for dusts is in crack and crevice or spot treatments indoors in out-of-sight areas (behind equipment, in wall voids and so on) which remain dry. The residual pesticidal activity of dust is normally fairly long, provided the dust stays dry, but quickly loses its toxicity in the presence of moisture. They don't adhere well to vertical surfaces.

Dusts are used on people during mass delousing operations to control outbreaks of lice borne diseases. Dusts are also used for flea control during plague outbreak. Dusts aren't generally absorbed through the skin, but may be dangerous if inhaled into the respiratory tract.

Granules : These are basically the same as dust formulation, except the carrier particles are larger and thus don't stick to leaves allowing penetration in dense foliage. This is a real advantage when the pesticide must reach the water surface for mosquito control in vegetated swamps, or if it must get to the ground surface through trees and shrubs for chigger control. Granules are also available in timed-release formulations that release a dosage of the pesticide over an extended period of time. Other advantages of using granules are that they provide longer lasting effects and their use results in less drift than generally occurs with liquids or dusts.

The percentage of insecticide in granules and pellets varies

from 1 to 5%. These can be used in irrigation channels, irrigated or flooded lands, paddy fields and particularly where there is vegetation on the water surface. After sinking, these formulations disintegrate slowly releasing small particles of insecticides. These can be effectively used also in small water collections such as ornamental tanks and earthen pots, tree holes and other domestic or peridomestic breeding places of *Aedes* mosquitoes.

Wettable Powder : This formulation consists of the technical grade pesticide, an inert carrier and a wetting agent (usually a synthetic detergent) that helps it mix with water. These usually contain 50 to 75% of the toxicant. Most of these can be put directly into water and require only slight agitation to make suspension; others may require mixing with a small amount of water to form a paste or slurry. The required volume of water is then added to paste or slurry followed by thorough agitation of the mixture.

When water is added to a wettable powder it makes a suspension; this enables the pesticide to stay on porous surfaces like concrete, plaster or unpainted wood. Water penetrates these surfaces, leaving the carrier and the maximum amount of the pesticide on the surface available to kill pests. Suspensions have other advantages, too. They have no solvent odour, and they don't tend to irritate or penetrate skin. However, they generally need agitation to keep pesticidal particles from settling out. Also, they tend to clog sprayer nozzles and strainers, especially when the wettable powder is stored for long periods in humid areas or when a high concentration is used.

Liquid formulations

Emulsifiable Concentrates : Emulsifiable concentrates consist of the technical grade pesticide (typically 45% to 75%), a solvent, and an emulsifying agent, usually a synthetic detergent. This agent is used to allow the concentrate to be diluted in water, resulting in an emulsion.

Emulsifiable concentrates are usually clear but emulsions look similar to milk. Finished sprays are emulsions or solutions diluted to field strength. Unlike solutions, most emulsions need a little periodic agitation to keep the concentrate from separating out of the water. Emulsions are used for residual treatments. Pests that contact these surfaces are killed by the pesticidal residue. Emulsions may damage aluminium, varnish, and painted surfaces due to the action of solvents such as Xylene. Emulsions may also be corrosive to metal sprayers and their fittings and hence sprayers made of stainless steel, aluminium or other non-corrosive materials should be used.

Oil Solutions : These formulations consist of a technical grade pesticide dissolved in a solvent such as kerosene or diesel oil. Solutions are available as ready-to-use formulations (for example ordinary household fly and mosquito sprays with a low percentage of pesticide) and as solution concentrates. These concentrates contain a high percentage of insecticide and must ordinarily be diluted in oil or another suitable solvent. Some concentrates are used without dilution in Ultra Low Volume (ULV) applications. Oil solutions applied as finished sprays often kill insects on contact, since the oil helps the pesticide penetrate the insect's waxy body wall.

Ultra-Low Volume (ULV) : While most items of ULV pesticide

dispersal equipment use the readily available solutions or technical grade formulations, there are special ULV formulations available for e.g. Deltamethrin 1.25 ULV etc.

Gaseous formulations : Gases are primarily used in fumigation operations. They may be prepared as liquefied gases and packaged in pressure containers or in a material form that reacts with the moisture in the air to form a gas. The gas molecules can penetrate cracks, crevices and tightly packed material. Gases are the most dangerous pesticides used and hence special safety equipment and training are necessary when using gases and must never be attempted except by trained pest management personnel operating in pairs. One of the common gaseous formulations viz. Calcium cyanide (powder) and Aluminium phosphide (tablet) are used for rodent control.

Special formulations

Resin Strips : Pesticide-impregnated resin strips release vapours as they are heated or exposed to normal room temperatures. The use of resin strips in rooms occupied by the young, the elderly or in food preparation and food serving areas is strictly prohibited.

Baits : Baits are commonly used to manage scavenging pests such as rodents, ants, flies, and cockroaches, which are particularly difficult to manage with standard techniques. Baits consist of the toxicant mixed with a food attractive to the target pest or with water. For this reason, baits made with local foods are normally more effective than premixed formulations. Recent development is the use of pheromone Muscalure with Imidacloprid as bait for houseflies.

Gel : One of the special formulations developed for use against cockroaches is Gel formulation. Gels comprise some food attractant mixed with the toxicant and some stabilizing agents. Examples are Fipronil and Imidacloprid Gels marketed against cockroaches.

Shampoo : This formulation has been specially developed for use against head lice infestation. Permethrin is the most common ingredient of the commercially available anti-lice Shampoo formulations worldwide.

Beads / Pellets / Briquettes : Small floating beads, pellets or briquettes incorporating biocides - *Bti* and *B sphaericus* have been developed against Anopheline larvae. These formulations can be made as controlled release formulations as well.

Paints and Lacquers : These can be used for incorporation of insecticides especially for control of pests on ships. These preparations remain effective for long periods. The new insecticide, Imidacloprid is also available as a paint formulation against houseflies.

Mats / Coils : These are special formulations which have been developed as controlled release formulation for indoor use against mosquitoes. These have synthetic pyrethroids such as Allethrin, which acts as toxicant to knock down the mosquitoes when used indoors.

Aerosols : Aerosols are pressurized cans containing a small amount of pesticide driven through a small nozzle. They're commonly used as space sprays for flying insects viz. mosquitoes and houseflies and as residual sprays for Mites/

Ticks depending on the formulation. Care should be taken while handling aerosol cans since they can explode if punctured or overheated, even after the pesticide has been dispensed. Common insecticides used as aerosols are Pyrethroids, Malathion, DDVP and repellents like DEET and DEPA. These are used for disinfecting aircrafts, tents, rooms, other small enclosures, uniforms and for topical application. An emission of nearly 15 seconds is enough for a 100 m³ space.

Equipment

Equipment used for vector control can be broadly classified as ground equipment and equipment used for aerial applications.

(a) Ground Equipment

- (i) Sprays for production of fine or coarse spray which may be either manually operated or power operated.
- (ii) Sprayers for the production of mist which may be either with gaseous energy nozzles (manual operated or power operated) or with centrifugal nozzles.
- (iii) Devices for the production of aerosols which may be mechanical, thermal or gaseous energy aerosol generators.
- (iv) Dusting equipment which may be manually operated or power operated.
- (v) Applicators for granules and pellets, manually or power operated.

(b) Aerial Equipment

Equipment for aerial sprays is essentially the same but with certain modifications. The equipment in common use is the boom and nozzle system.

Sprayers

The equipment commonly used for spraying various insecticidal formulations are the hand operated sprayers, power operated sprayers, aerosol dispensers, fog generators and dusters.

(a) Hand Operated

These are hand sprayers, knapsack sprayer and compression sprayer.

(i) Hand Sprayer : The hand sprayer is used for space spraying of small apartments. It is provided with a small can for holding ½ to 1½ litres of spray fluid and a cylindrical plunger type air pump. The nozzle size is less than 0.4 mm in order to produce a fine spray. The simplest form is the familiar 'flit gun' producing intermittent spray. A number of other light hand sprayers have been designed, which can be pressurized in the manner of compression sprayers and are used to produce a mist or fine droplet spray.

(ii) Knapsack Sprayer : This is designed to fit on to the back of the operator and usually has a capacity of 15 to 20 litres. It incorporates a light but powerful diaphragm pump actuated by a lever carried forward to the operator's hand where it is worked by an up-and-down movement. These sprayers are used both for larviciding and residual spraying. The nozzle size used for residual spraying varies between 0.78 to 1.0 mm so as to produce a coarse spray.

(iii) Compression Pneumatic Sprayer : This is the commonest type of equipment used in National Vector Borne Diseases Control Programme for the application of insecticides. It has

a hand operated pump incorporated to build up adequate pressure. When the pressure is released by a trigger on the lance, the liquid is forced out from the tank to the nozzle by the compressed air and a continuous spray of the insecticide formulation is produced. It is slung over the shoulder with one strap or may be carried on the back with two straps. It is operated by one person.

(b) Power Operated Sprayers

These are useful for application of insecticides over large areas. These are hydraulic sprayers in which the spray liquid is expelled to the nozzle by positive displacement by the plunger pump. Insecticide tanks built into a truck or mounted over a hand trolley are connected directly to a power operated compressor. By means of a long hose the spraying fluid is conveyed under pressure through the lance to the nozzle.

(c) Insecticidal Fog Generators

Several types of fog generators are now available for the production of insecticidal fogs in the open on a large scale. In these fogging machines the oily solution of the insecticide is finely atomized by the powerful blast of hot exhaust gases from a petrol engine.

(d) Aerosol Dispensers

These are used for disinfestations of aircrafts, tents, rooms and similar small enclosures. It contains insecticide and a propellant. Common aerosols contain Synthetic pyrethroids or their combination, which are routinely used for mosquito, cockroaches and fly control.

(e) Dust Gun

Insecticidal dusts are applied against lice and fleas in rat burrows or on water surfaces as dry powders diluted with inert dusts. Small light weight guns are used for mass delousing of infested people.

Residual Spraying

This is the application of insecticides to surfaces so that the insecticide particles remain on the surface in the form, size and quantity suitable for insects to pick up on contact and sufficient to exert a lethal effect over a long period. Organochlorine, Organophosphorus, Synthetic pyrethroids and Carbamate compounds can thus be applied on the inside walls of houses and also on thick bushes in forests. The type of surface to which an insecticide is applied influences its toxicity against insects and its persistence. Solutions and emulsions quickly get soaked in the absorbent surfaces of soft bricks and mud walls which take in a large portion of insecticidal material deposited on them; but when suspended in water it remains over the surface after the water evaporates or gets absorbed. The nozzles of sprayers used for residual spraying must conform to the need of having a droplet size which is neither too large nor too small. Similarly, safety precautions should be observed, as follows, while spraying as per standard WHO guidelines :

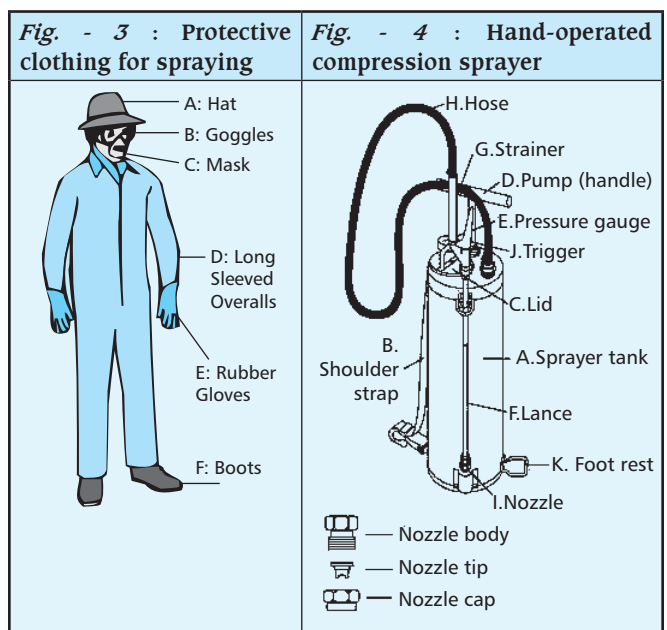

- Do not eat, drink or smoke while working.
- Wash your hands and face with soap and water after spraying and before eating, smoking or drinking.
- Shower or bathe at the end of every day's work and change into clean clothes.

- Wash your overalls and other protective clothing at the end of each working day in soap and water and keep them separate from the rest of the family's clothes.
- If the insecticide gets on your skin, wash off immediately with soap and water.
- Change your clothes immediately if they become contaminated with insecticides.
- Inform your supervisor immediately, if you do not feel well.
- Wear protective clothing (Fig. - 3) :
 - Broad rim hat (protects head, face and neck from spray droplets).
 - Goggles or face shield (protects face and eyes against spray fall-out).
 - Face mask (protects nose and mouth from airborne particles of the spray fall-out).
 - Long sleeved overalls (Keep overalls outside of boots).
 - Rubber gloves.
 - Boots.

Preparations

The Household : Inform the householder of the spraying schedule and the purpose of spraying, giving them time to prepare and vacate the house. Occupants MUST leave houses before spraying. Rooms occupied by sick people who cannot be moved must NOT be sprayed. Remove all household items, including water, food, cooking utensils and toys from the house. Move and cover, or take out the furniture to allow easy access for spraying walls. Items that can not be removed should be well covered.

Equipment : Indoor residual spraying of insecticides is normally done using hand-operated compression sprayers. Before starting a spray operation, the equipment must be checked. Faulty sprayers may result in poor control or over-treatment. Examine the sprayer visually to ensure that all parts are present, assembled correctly and are in good condition (Fig. - 4).

- A. Sprayer tank
- B. Shoulder strap
- C. Lid
- D. Pump (handle)
- E. Pressure gauge
- F. Lance
- G. Strainer
- H. Hose
- I. Nozzle - check correct type of nozzle is fitted and is not damaged or worn (flat fan nozzle with 55° to 60° swath and 0.75 l/min flow rate at 700 g/ sq cm).
- J. Trigger on/off valve. Is the strainer inside valve handle clean?
- K. Footrest

Before using an insecticide, use clean water to ensure that the equipment operates properly and does not leak. Wear protective clothing. To check, follow the steps below :

- (a) Pour clean water into the tank (never fill tank more than 3/4 full) (Fig. - 5).

Fig. - 5

- (b) Fit the lid. Turn the handle to lock the lid in position (Fig. - 6).

Fig. - 6

- (c) Operate the pump using both hands and with foot on the footrest. Pump to the working pressure of 55 psi (Fig. - 7).

Fig. - 7

- (d) Check tank is holding pressure. Listen for hissing sound of escaping air (Fig. - 8).

Fig. - 8

- (e) Check to make sure there are no leaks along lance and hose, especially where hose joins tank and trigger on/off valve (Fig. - 9).

Fig. - 9

- (f) Operate trigger on/off valve to make sure that spray is emitted from the nozzle (Fig. - 10).

- (g) Check the spray pattern from the nozzle by spraying a dry wall surface. Look to see that the pattern is even and without streaks. Ensure nozzle does not drip when trigger on-off valve is released (Fig. - 11).

- (h) Calibrate the nozzle with water in the tank. Pump to 55 psi (700 g/ sq cm). Open the trigger on-off valve for one minute, collect the discharge and measure the amount in a measuring jug. Empty the jug. Discharge for a further one minute and measure the amount. Repeat again and calculate the average of the three, one-minute measurements.

With the above procedure, the average discharge of an 8002 nozzle is about 750 ml per minute. If the discharge is incorrect, check the nozzle and the screen filters to ensure they are not clogged. If necessary replace nozzle. Repeat the calibration.

If the nozzle is clogged : The opening in a nozzle is very small and must not be damaged. Clogged nozzles should be put in a

container with water for several hours before the blockage is removed by a very soft toothbrush. NEVER clean nozzle with a hard pin or piece of wire and NEVER put a nozzle to your mouth to blow through it.

Mixing, Handling and Spray Techniques

Prepare the insecticide spray according to the manufacturer's instructions. The insecticide may be mixed separately in a bucket and poured into the sprayer. Water soluble sachets, tablets and insecticides granules are added directly to the water filled tank. These formulations mix readily with water and reduce the hazards associated with handling and mixing in a separate container. When the sprayer has been filled with water to the maximum level indicated on the tank, the lid of the tank is fitted and the sprayer pumped to a pressure of 55 psi by pumping 55 times (700 g/sq cm). The contents of the tank should be thoroughly mixed by shaking the tank before starting to spray (Fig. - 12).

Spraying in a room should commence from the backside of a door clockwise completing the plain surfaces of walls. Then the crevices on the walls and inside portion of windows etc. should be sprayed. Thereafter the pillars, under surfaces of furniture and lastly the ceilings should be taken for spray.

Spray is done from roof to floor, using downward motion, to complete one swath; then stepping sideways and spraying upwards from floor to roof. Spray is applied in vertical swaths 52-56 cm wide. Swaths should overlap by 5 cm and spraying should be undertaken as shown in Fig. - 13. Normal swath coverage will take 2.7 sec if height of wall is assumed to be 3 meters and hence in one minute 22-23 swaths will cover a wall of 10-11 metres length and 3 metres height i.e. 30 - 33 sq m. It takes about 5 minutes to spray a house with an average surface area of 150 sq m.

Fig. - 13

To ensure the correct swath width, keep the spray tip about 45 cm from the wall. Lean forwards as you spray from top of the wall and move back as you bring the nozzle downwards (Fig. - 14).

Fig. - 14

The flow of liquid from the nozzle tip at 700 g/sq cm pressure is 750 ml/minute. Hence 30 sq m surface will be covered with 750 ml of the insecticide solution.

Time your spray speed to cover one meter every 2.2 seconds, i.e. 4.5 seconds for a 2 m high wall. Timing may be aided by mentally counting “one thousand and one - one thousand and two - one thousand and three -...”. Adjust the mental counting procedure according to the local language (Fig. - 15). If spray stops due to a blockage in nozzle, unscrew the nozzle cap, remove blocked nozzle and replace with a new one. The blocked nozzle should be cleaned as explained above. Do not let spray drip on the floor. Re-pressurize the tank when the pressure falls.

Fig. - 15

Procedures after Spraying

- Advise the occupants to stay outside until the spray is dry.
- Instruct the householder to sweep or mop the floor before children or pets are allowed to re-enter.
- Instruct the householder not to clean the sprayed surfaces.

Disposal of Remains of Insecticides and Empty Packaging:

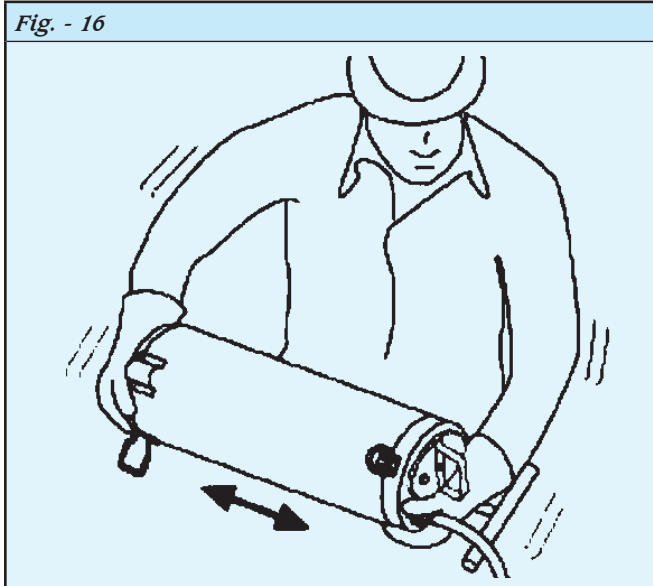

At the end of the day's work, put the washings from the sprayer into pit latrines, if available, or into pits dug especially for this purpose and away from sources of drinking water. Dilute any insecticide with more water before putting into pits. It is advisable to prepare only sufficient insecticidal solution to avoid disposal of remaining insecticidal solution. Never pour the remaining insecticide into rivers, pools or drinking water sources. All empty packaging should be returned to the supervisor for SAFE disposal. Never re-use empty insecticide containers. Empty insecticide containers should NOT be burned or buried.

Maintenance of Equipment : After completing the day's work, de-pressurize the tank and empty any remaining insecticide, following the instructions given in the previous section. Clean the tank as explained below :

- De-pressurize the tank.
- Fill the tank half-full with clean water.
- Replace the lid.

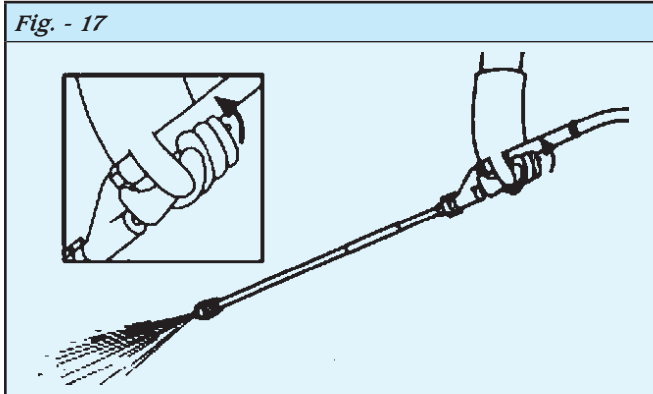

- Shake the tank so all inside surfaces are washed (Fig. - 16).

Fig. - 16

- Pump up to 700 g/ sq cm pressure. Spray water through nozzle (Fig. - 17).

Fig. - 17

- De-pressurize the tank and pour out any remaining water into pit latrines or into a pit away from sources of water.
- Unscrew trigger on/off valve handle and check and clean the strainer.
- Reassemble the trigger on/off valve (Fig. - 18).

Fig. - 18

- Remove the nozzle tip and wash
- Refit the nozzle
- Clean the outside of tank.

Fig. - 19

- With lid open, turn tank upside down, open the on/off valve and let all the water drain out of the hose and lance.
- Ensure the lance is parked to protect nozzle when not in use.
- When storing the sprayer for a long period, hang it upside down with lid open to allow air circulation. Allow lance to hang from D-ring on the tank with the trigger valve kept open (Fig. - 20).

Fig. - 20

Space Spraying

It is an ideal method for bringing about rapid control of vectors in emergency or epidemic situations and may also be used for seasonal control of flying insect pests or vectors. An additional objective may be to reduce or interrupt the transmission cycle of insect-borne diseases. However, it may not be ideal for all vectors or situations and as such may not be an economical method of control. Among the disease vectors affecting public health, the most important and widespread are mosquitoes, houseflies, sandflies and other biting flies; some of these may be targeted for space treatment.

Immediate killing of actively flying insects requires a cloud of insecticide droplets that they will encounter in flight. To

be cost-effective and obtain good biological efficacy, space spraying requires :

- (a) Knowledge of the behaviour and biology of the target species - to understand where and when space treatments will be effective;
- (b) Knowledge of insecticides and formulations most suitable for space spraying;
- (c) Knowledge of pesticide application technology - to know which equipment is needed and how to use it; and
- (d) Monitoring and surveillance of the target species and vector-borne disease problem to evaluate the efficacy of the programme.

A space spray - technically a fog (sometimes referred to as an aerosol) is a liquid insecticide dispersed into the air in the form of hundreds of millions of tiny droplets less than 50 μm in diameter with a view to cause by contact, immediate knock down of the flying or resting insects in confined spaces. Space sprays, even when they settle on surfaces do not have much residual action. It is only effective while the droplets remain airborne. Therefore, they have to be repeated at frequent intervals. Space sprays are applied mainly as thermal fogs or cold fogs.

Thermal Fog

Thermal fog is produced by special devices known as thermal foggers that use heat to break up the chemical into very small droplets (usually in 5-30 μm diameter range) which then disperse in the air. When the chemical (usually diluted with oil-based carrier) is heated, it is vaporized in a combustion chamber and then expelled via an outlet tube to form a dense fog cloud when it condenses on contact with cool ambient air.

The insecticide used in thermal fogs is diluted in a carrier liquid, which is usually oil-based. Hot gas is used to heat the pesticide spray, decreasing the viscosity of the oil carrier and vaporizing it. When it leaves the nozzle, the vapour hits colder air and condenses to form a dense white cloud of fog. Most of the droplets are smaller than 20 μm . The droplet size is affected by the interaction between the formulation, the flow rate and the temperature at the nozzle (usually > 500°C). The volume of spray mixture applied in vector control is usually 5-10 litres per hectare, with an absolute maximum of 50 litres per hectare. The hot emission gas is obtained from engine exhaust, friction plate/engine exhaust or from a pulse jet engine.

Advantages

- Easily visible fog, so dispersal and penetration can be readily observed and monitored;
- Good public relations in some circumstances as people can see something being done about the problem; and
- Low concentration of active ingredient in the spray mixture and reduced operator exposure.

Disadvantages

- Large volumes of organic solvents are used as diluents, which may have bad odour and result in staining;
- High cost of diluents and spray application;
- Householders may object and obstruct penetration of fog into houses by closing windows and doors;
- Fire risk from machinery operating at very high temperatures with flammable solvents; and
- Can cause traffic hazards in urban areas.

Cold Fog

The cold fog is produced by a special device (cold fogger) that breaks up the chemical into microscopic droplets by mechanical means, basically with a high-pressure pump and an extremely fine nozzle. The spray droplets are generated without any external heat. With cold fogs, the volume of spray is kept to a minimum. Ultra-low-volume insecticide formulations are commonly used for such applications. The cold fogger may dispense formulations in a very concentrated form and generate the droplets (usually in the 5-30 micron diameter range) in a precise manner. However, its ability to penetrate dense foliage or obstacles is not as good as that of the thermal fogging. Cold fogging is sometimes called Ultra Low Volume (ULV) treatment as it allows the utilization of only a very small amount of chemical for coverage of a large area.

Like thermal fogging, cold fogging also does not have lasting residual effects. It is, therefore, essential to carry out fogging at the time when the vectors are most active to hit them directly.

Advantages

- The amount of diluents is kept to a minimum, resulting in lower application cost and increased acceptability. Some formulations are ready to use, thereby reducing operator exposure
- Mostly water-based and water-diluted formulations are used which pose a low fire hazard and are more environmental friendly
- Application is more efficient because a lower volume of liquid is applied
- No traffic hazard as the spray cloud is nearly invisible

Disadvantages

- Dispersal of the spray cloud is difficult to observe
- Higher technical skills and regular calibration are required for efficient operation of equipment.

Space Spray Equipment

Selection of appropriate equipment for space spraying depends on the size and accessibility of the target area as well as the human resources and operational capacity of the programme. Sometimes smaller machines may be needed in conjunction with vehicle-mounted equipment to treat narrow pathways and other areas inaccessible to vehicles or sheltered from prevailing air movements. Cold fog equipment is recommended where thermal fogs may cause a traffic hazard. Aerial application of space sprays may be justified where access with ground equipment is difficult and/or extensive areas need to be treated very quickly.

Equipment for Thermal Fogging

Hand-carried Thermal Foggers : These are used for treating houses and certain outdoor areas of limited size or accessibility, e.g. markets, hotel grounds and parks. There are two types of hand-carried thermal foggers; pulse jet and friction plate.

Vehicle-mounted Thermal Foggers : Large thermal fog generators use an air-cooled motor to run an air blower, fuel pump and insecticide pump. Air from the "roots type air blower" is delivered into the combustion chamber. There it is mixed with gasoline vapour and ignited so that temperatures reach 426-648°C. The diluted insecticide liquid is pumped via a simple flow delivery valve and injected into a cup in the fog head or directly

into the nozzle. The insecticide liquid is vaporized by the blast of hot gases. Despite this high temperature, insecticides show very little degradation of active ingredient. This is because the time spent at that temperature is only a fraction of a second, which is not long enough to cause serious degradation. The hot gases then pass out of the machine. As the hot oil vapour is discharged through a relatively large nozzle into the cooler outside air, it condenses to form very small droplets of thick white fog. Delivery rates of up to 10 litres per minute can be achieved with larger machines.

Aircraft Application of Thermal Fogs : For aircraft application of thermal fogs, the diluted insecticide formulation is fed into the aircraft exhaust. The exhaust is adapted with vanes to swirl the fog droplets as they are formed. The application of thermal fogs by aircraft is very limited.

Equipment for Cold Fog Application

Hand-carried Cold Foggers : Most of these machines have gasoline engine or electric operated which drives a blower unit to discharge air through the nozzle. Air may also slightly pressurize the insecticide formulation tank so that the liquid is fed via a restrictor to the nozzle. However, negative pressure generated by the air flow passing through the nozzle allows liquid to flow from the tank. In addition to hand-carried units, knapsack cold fogging units are also available as are several electrically driven models.

Vehicle-mounted Cold Foggers : A high volume air blower forces air at a rate of approximately 6 m³ per minute at low pressure to nozzle. The pesticide container may be pressurized to force the formulation to the nozzle, or positive-displacement pumps may be used.

Alternatively a high-pressure, low-volume air source is used with an air compressor, rather than a blower. On these machines, nozzles ranging from the standard industry "paint gun nozzle" to proprietary nozzles that atomize well up to a flow rate of 0.5 litres per minute are available. Another design uses a rotary nozzle coupled with an electric motor which operates at a very high speed.

Aircraft Application of Cold Fogs : Both fixed-wing aircraft and helicopters have been used to apply cold fogs. Conventional low-volume nozzles (e.g. flat fan) have been used on fixed wing aircraft to create fine sprays, using moderate or high pressures. However, the droplet spectrum is generally poor so preference is given to the use of rotary atomizers or very-high-pressure

systems.

Insecticide Products for Space Spraying

Space-spraying formulations are generally oil-based. The oil carrier inhibits evaporation of small fog droplets. Only insecticide products with high flash points are used for thermal fogging. Diesel is used as a carrier for thermal fogging, but creates a thick smoke and oily deposits, which may lead to public rejection. For environmental reasons, water-based formulations have been made available in recent years. These formulations may also contain substances that prevent rapid evaporation. Table - 3 lists selected insecticides suitable for space spraying against mosquitoes. These insecticides may also be used against other insect pests and vectors, but different dosages may be required.

Space Spray Treatments - General Considerations

Optimum Droplet Size : Space treatments are only effective while the droplets remain airborne. Droplets fall by gravity and some are deposited on horizontal surfaces while the majority is lost to the atmosphere especially in outdoor spraying. Droplets bigger than 30 μm in diameter are less effective as they do not remain airborne for sufficient time. Droplets smaller than 5 μm in diameter do not readily come in contact with flying insects, as the movement of the smallest droplets is affected by the air turbulence created by the insect's flight. It is generally accepted that droplets should be generated in the range of 10-30 μm so that even with some evaporation and after some time, they remain in the correct range for optimal airborne suspension and insect impact. The optimum droplet size for space spraying against mosquitoes is 10-20 μm .

Spray Concentration : For a flying insect to be killed, it must acquire a lethal dose of insecticide in the droplets that impact on it. The lower the concentration of active ingredient, the larger the number of droplets of a given size required to achieve a lethal dose. Ultra-low-volume spraying aims, largely for operational reasons, to minimize the total volume of diluted insecticide applied (usually < 2 litres per hectare).

Wind Speed : Wind speed has a profound effect on droplet distribution and impingement on insects. Spraying should not take place when wind speed exceeds 15 km/hour. The type of terrain and vegetation affects air movement and hence the distribution of the droplets. In open terrain with relatively sparse vegetation, wider effective swaths can be obtained than in urban areas where the obstruction of buildings alters the

Table - 3 : Insecticides Used for Space Spraying

S No.	Insecticide	Dilution	Equipment required	Remarks
1	Pyrethrum 2% Extract	1 litre in 19 litre Diesel (0.1%)	Flit gun/ Thermal Fogging machine	For space spray indoors (Keep rooms closed for 30 min) or outdoors
2	Pyrethrum 2% EC	1 litre in 19 litre Water	ULV Fogging machine	For space spray indoors
3	Malathion Tech	5 litres in 95 litre Diesel (5%)	Thermal Fogging machine	For space spray outdoors
4	Deltamethrin 1.25 ULV	1 litre in 199 litre Diesel	Thermal Fogging machine	For space spray outdoors
5	Deltamethrin 1.25 ULV	1 litre in 19 litre Diesel	ULV Fogging machine	For space spray outdoors
6	Deltamethrin 1.25 ULV	1 litre in 19 litre Water	ULV Fogging machine	For space spray indoors

flow of air.

Wind direction : With vehicle-mounted and aerial spraying the spray route must take account of the wind direction to maximize the distribution of the spray throughout the target area. Fig. - 21 illustrates the spray application route relative to wind direction.

Temperature Effects : In direct sunlight the ground is heated. This causes air to rise. In the middle of the day, outdoor space spraying will largely be wasted as the spray droplets will tend to rise upwards rather than drift horizontally. Ideally an inversion is needed, i.e. colder air closer to the ground. This generally occurs early in the morning after the ground temperature has fallen during the night, but can also occur in the evening when the sun has set and ground temperatures begin to fall.

Time of Treatment : Knowledge of the time of peak flight activity of the target species is crucial to ensure that space treatments are planned to coincide, as far as possible, with these times. Fortunately, peak flight activity of many vectors is around dusk and/or dawn, when weather conditions are often favourable for space treatment. *Aedes aegypti* and *Aedes albopictus*, mosquito vectors of Dengue fever and Chikungunya are active during daytime with peak flight activity in the morning and afternoon. With these species, a compromise is usually made outdoors by spraying in the early morning or late afternoon. The timing is less important if indoor spraying is conducted.

Indoor Fogging

Personnel conducting this work require training on the safety measures to be followed. Several rules apply :

- Protect all water containers and foodstuffs.
- Remove fish or cover fish tanks.
- Ensure all occupants and animals remain outside the house during spraying and stay outside for 30 minutes after spraying. Ensure that the building is ventilated before

reoccupation.

- Close all doors and windows before spraying and keep them closed for 30 minutes after spraying to ensure maximum efficacy.
- Spray operators should work backwards and away from the fog to minimize exposure.
- For small single-storey houses, the spray can be delivered from the front door or through an open window without having to enter every room of the house, provided that adequate dispersal of the insecticide droplets can be achieved.
- For large single-storey buildings, it may be necessary to apply the spray room by room, beginning at the back of the building and working towards the front.
- For multi-storey buildings, spraying is carried out from top floor to the ground floor and from the back of the building to the front. This ensures that the operator has good visibility at all times.

Outdoor Ground Fogging

Advanced route planning should precede outdoor ground fogging operations and may require a combination of vehicle-mounted and hand carried or knapsack equipment in areas with difficult or limited vehicle access. Consideration must also be given to the following :

- Spraying should not be undertaken when it is raining, when winds exceed 15 km/hour, or in the heat of the day.
- Doors and windows of houses and other buildings should be open to allow penetration of the spray cloud for improved efficacy.
- For vehicle-mounted equipment, in areas where the roads are narrow and the houses are close to the roadside, the spray should be directed backwards from the vehicle. In areas where the roads are wide, with buildings far from the roadside, the vehicle should be driven close to the roadside and the spray should be directed at an angle (downwind) to the road rather than directly behind the vehicle.
- The nozzle of vehicle-mounted cold fog machines may be directed upwards at an angle when there are barriers that impede airflow, e.g. boundary walls and fences; for vehicle-mounted thermal foggers, the nozzle should be directed horizontally.
- A track spacing of 50 metres is generally recommended, with the vehicle moving upwind so that the fog drifts downwind away from it and the operators.

Aerial Application of Fogs : Suppression of vector populations over large areas can be carried out using space sprays released from aircraft, especially over areas where access with ground equipment is difficult and extensive areas need to be treated very rapidly.

Evaluation

Evaluation of the efficacy of spray operations is carried out using techniques that are largely specific to the target insect. Space sprays are transient and only insects flying at the time of the application are affected.

Area Spraying

This is carried out for treatment of land against mites and ticks and also as an anti-larval measure over vast water surfaces.

Against mites and ticks, suspensions are used on land and vegetation; WDP is used for anti-larval treatment of lakes and swamps. Aerial spraying is resorted to for agricultural purposes and sometimes for veterinary and rarely medical purposes. Dusts are applied to manure yards and dry refuse yards to control flies and other pests. For all such uses, power driven sprayers and dust guns are used. The larvicidal oils are applied by spraying it on the surface of water by means of a knap-sack sprayer or hand pumps or by a mop stick.

Resistance of Vectors to Insecticides

History : Ever since the introduction of the potent synthetic insecticides into public health programmes at the close of the Second World War, the main problem has been the development of resistance to them by the arthropods they formerly controlled. In 1947, DDT resistance was discovered in the housefly and *Culex molestus* in Italy. In 1951, DDT resistance was noticed in body louse in Korea and in *Anopheles sacharovi* in Greece. In 1955, Dieldrin resistance was discovered in *Anopheles gambiae* in Northern Nigeria. In 1959, in Western India the oriental rat flea was found to have developed resistance to DDT. The number of arthropods showing resistance is on the increase.

Definition : Resistance is defined as “the development of an ability in a strain of insects to tolerate doses of toxicants which would prove lethal to the majority of individuals in a normal population of the same species”. A more pertinent definition of resistance promoted by the Insecticide Resistance Action Committee (IRAC) is “the selection of a heritable characteristic in an insect population that results in the repeated failure of an insecticide product to provide the intended level of control when used as recommended”. It is important to remember that resistance does not mean that it is impossible to control the population.

The word *tolerance* is normally used when the increase in LC₅₀ is less than the indicated minimum for the tests, but is nevertheless statistically significant. It is generally due to sub-lethal exposure to insecticide and is not passed on to offspring. *Vigour tolerance* is a term, which has been applied to enhanced insecticidal tolerance resulting from extra vigour of the strain rather than from any specific defence mechanism.

Types : Resistance is of two types i.e. physiological and behavioural. Physiological resistance is the one described above. Behavioural resistance means the development of ability to avoid a lethal dose. This term is applied most often to mosquitoes in relation to DDT.

Resistance Mechanisms

Metabolic Resistance : This is the most common resistance mechanism encountered amongst insects, based on detoxification enzymes. In resistant strains, these enzymes are generally more enhanced thus enabling the insects to metabolize or degrade the insecticide before their lethal effect is exerted. The enzyme systems involved in these processes are Esterases, Monooxygenases and Glutathione-S-transferases (Table - 4).

- (i) Esterases - Dominant mechanism of resistance conferring resistance to OP compounds. It also affects Pyrethroids and Carbamates.
- (ii) Monooxygenases are importantly involved in the resistance mechanism in insects to Pyrethroid class of insecticides. It also affects DDT and OPs.
- (iii) Glutathione S transferase - It has been implicated in DDT resistance.

Target - Site Resistance : This is the second most common resistance mechanism encountered in insects. The site of action of the insecticide is modified so that the insecticide no longer binds effectively at that site. Resistance to DDT and pyrethroids is due to the modified gene *Kdr*, which leads to reduction in the sensitivity of the site to the binding of DDT and Pyrethroids. On the other hand, an altered site of action as a cause of resistance to Organophosphates (OPs) and Carbamates has been definitely established with cholinesterase inhibitors. In these cases, mutated forms of AChE (MACE - modified acetylcholinesterase) are produced that is inhibited more slowly than the normal enzyme in susceptible strains. This produces resistance against a large number of compounds of the OPs and Carbamates and the resultant extensive cross-resistance which makes it a serious type of resistance.

Reduced Penetration : Not a major resistance mechanism, may contribute to the overall development of resistance to an insecticide. Modification in cuticle (applicable for contact poison) or digestive tract linings (in case of stomach poisons)

Table - 4 : Biochemical resistance mechanisms conferring resistance to important classes of insecticides in mosquitoes (dot size gives the relative impact of the mechanism on resistance)

Biochemical Mechanism of Resistance					
	Metabolic			Target-site	
	Esterases	Monooxygenases	GSH-S transferases	<i>kdr</i>	MACE
Pyrethroids	•	●		•	
DDT		•	●	•	
Carbamates	•				●
Organo-phosphates	●	•			●

Source : Prevention & management of insecticide resistance in vectors and pests of public health importance. Manual by Insecticide Resistance Action Committee (IRAC).

leads to prevention or reduced penetration of insecticides in the body of the insects has been reported in a number of resistant insects e.g. houseflies.

Behavioural Resistance : It is a modification in the behaviour of insects to avoid toxic doses of the insecticide. It is also a contributory factor in development of resistance and not an important resistance mechanism. It may be stimulus dependent (when insects avoid insecticide treated surface) or independent (selective and sustained occupation of an untreated area).

Cross Resistance : Cross resistance occurs when a resistance mechanism that allows insects to resist one insecticide also confers resistance to insecticides of the same chemical class or different chemical class which act on the same target site in the insect. e.g. kdr resistance to DDT and to Pyrethroids, OPs and Carbamates due to altered AChE.

Multiple Resistance : It is a common type of resistance when different resistance mechanisms are present simultaneously in resistant insects. It may combine to produce resistance to multiple classes of insecticides.

Genetic Basis of Resistance : Resistance develops in arthropods after a long period of insecticidal pressure. It is brought about by the accumulation of the contributing genes through successive selection with a number of insecticides, each of which confers some cross-resistance. This is called polygenic or multiplicate resistance. In contrast, the resistance may be due to a single gene and bear no similarity to the complexities involved in the multiplicate resistance. Monogenic resistant strains are more vulnerable to counter measures such as addition of synergists; hence the importance of distinction between the two types.

Resistance genes may be dominant, semi-dominant or recessive; most of the resistance reported so far are either semi-dominant or recessive and therefore may be managed effectively as compared to situations when resistance is genetically dominant.

Resistance Management : The factors that favour development of resistance are frequency of application, dosage and persistence of insecticide, rate of reproduction (short lifecycle and high rate of reproduction) and population isolation.

Resistance management can be attained by rotation of insecticides, using mixture of insecticides at their optimum dosage (efficacy & persistence of the two insecticides being mixed should be broadly similar) and fine scale mosaic (using two insecticides in different houses in the same village).

Biological Control

Intentional manipulation of populations of living beneficial organisms, called natural enemies, in order to reduce the numbers of pests or amount of damage is called Biological Control.

Natural control strategies that employ biological agents for pest suppression are classified as biological control tactics. In conventional usage, this term usually refers to the practice of rearing and releasing natural enemies like parasites, predators, or pathogens. Biological control is a particularly appealing pest control alternative because, unlike most other tactics, it does not always have to be reapplied each time a pest outbreak occurs. However, Biological control is not a “quick fix” for

most pest problems. Natural enemies usually take longer to suppress a pest population than other forms of pest control and therefore often regarded as a disadvantage or limitation of biological control. It also may be difficult to “integrate” natural enemies when pesticides are still in use. Beneficial insects are often highly sensitive to pesticides and their resurgence (recovery to pre-spray densities) is usually much slower than that of pest populations. Rapid pest resurgence often leads to a vicious cycle of continued chemical usage that prevents natural enemies from ever becoming re-established.

The biological agents are broadly classified as Predators, Parasites and Pathogens.

Predators

Predators are insects or other insectivorous animals, each of which consumes much insect prey during its lifetime. Predators are often large, active, and/or conspicuous in their behaviour, and are therefore more readily recognized than are parasites and pathogens. Most commonly used predators are the larvivorous fishes for the control of mosquitoes.

Larvivorous Fish : There are areas and habitats where larvivorous fish, such as *Gambusia affinis* (Fig. - 22) and *Poecilia reticulata* (Fig. - 23), can make considerable contribution to vector control. The larvivorous efficiency of *Gambusia* is due to the fact that a single full grown fish eats about 100 to 300 mosquito larvae per day, is a surface feeder, hence it is suitable for feeding on both Anophelines and Culicines, is small and inedible and can tolerate salinity. *Poecilia*'s larvivorous efficiency is due to its capability to negotiate margins of ponds more easily, tolerate handling and transportation very well, survives and reproduces when introduced into new water bodies, survives in new places (water bodies) and multiplies easily and can survive in good numbers for years and does not require constant care.

Fig. - 22 : *Gambusia affinis*

Fig. - 23 : *Poecilia reticulata*

Release of fishes is done at the rate of 5-10 fish per linear meter. If the larval density is high up to 20 fishes can be released. Fishes should be released in the morning hours or in the evening.

Criteria for selecting a water body for a fish hatchery are :

- It should be a permanent water body.
- Depth of water should be at least 1.5 metre or more.
- Water should be confined and without big natural outlet.
- The minimum size of water body should be at least 5m X 4m. The water body of 10 m X 5 m can support 50,000 fish.
- It should be free from other carnivorous fish.
- Water should not be contaminated by chemical or other harmful substances.
- Easily accessible for daily or periodic inspection and for collection of fish.
- De-weeding in ponds and shallow water bodies and cleaning of margins should be carried out periodically.

Parasites

Parasites are those organisms which depend on their host for shelter or food. Many parasites are very specific to the type of host insect they can attack, and they are not harmful to humans. Although insect parasites are very common, they are not well known because of their small size. Some of the categories of Parasites are as follows :

Nematodes : Nematode *Romanormis culicivorax* and *R iyengari* have been evaluated and have been found to give variable control of mosquitoes. The mode of action of the nematodes is presented in Fig. - 24.

Fungi : Fungal agents *Lagenidium* and *Culicinomyces* have shown immense potential as mosquito larval control agents and can be exploited for use against mosquitoes.

Pathogens

The pathogens which have been found promising are the Bacterial agents' *Bacillus thuringiensis var israelensis* and *Bacillus sphaericus* in mosquito larval control. However, these have been classified as Biocides or Microbial insecticides (discussed earlier). Viruses like Nuclear Polyhedrosis virus and Irido virus have also shown promise against mosquito larvae.

Genetic Control

This is defined as "the use of any condition or treatment that can reduce the reproductive potential of noxious forms by altering or replacing the hereditary material". The various methods of genetic control fall into two general groups : those

leading to population control, reduction or elimination through the release of partially or completely sterile insects in sufficient numbers to overcome the reproductive capability of the natural population; and those leading to population control or population replacement through the release of partially sterile or fully fertile genetically altered insects.

New genetic control methods, such as those involving sex distortion mechanisms or the selection and release of strains refractory to pathogens, sensitive to selected ecological factors, or susceptible to insecticides, are being tested under field conditions. However, unless some new and revolutionary ideas emerge, the genetic control measures so far known are capable of achieving only "management" or "manipulation" of insect population rather than complete suppression or reduction in densities.

Personal Protective Measures

The role of personal protective measures in arthropod-borne disease control is to prevent the arthropod vector from biting and feeding on its host, whether susceptible or already infected, thereby blocking the chain of transmission of disease from one host to another. Biting can be prevented either by protective clothing or chemically by using appropriate repellents.

Protective Clothing

Individual personal protection against bites of arthropods can be achieved by wearing long trousers, rolled down sleeves of shirts, socks, shoes and anklets, particularly when going out on patrols and exercises in areas heavily infested with arthropods. These measures will vary according to the nature of problem faced in a particular locality. Personal protective measures have already been described as part of control measures against different arthropods elsewhere in this chapter.

Repellents

Insect repellents are chemicals which repel insects when applied to body surfaces or clothing. The suitability of substances for use as repellents is dependent primarily on their inherent repellency and duration of effectiveness. The important factors are the ease of application on the skin; odour, appearance or feel on the skin e.g. oily or greasy; the likelihood of being rubbed off, or absorbed by the skin; irritant effect or toxicity if absorbed; and its stability under high humidity, high temperature, rain and perspiration. The efficacy may also be influenced by the amount of sweating, rubbing and the avidity of the insect itself. Moreover as is the case with insecticides, repellents exhibit specificity of action so that some species of insects are more sensitive to one and some to other repellents.

Common Repellents : The following compounds are among the most effective when used alone as repellents against one or more groups of arthropods : benzyl benzoate, DEET (N, N-diethyl-m-tolamide), dibutyl phthalate, DEPA (di ethyl phenyl acetamide), and Neem oil. Repellents are formulated as liquids, gels, creams and in pressurized containers. Some of the common compounds are discussed below :

(a) N, N-diethyl m-toluamide (DEET) : DEET has been reported to be an outstanding all-purpose repellent. It provides 6-8 h of protection against mosquitoes, 2-3 hour against Chrysops, 9 hour against Culicoids. It feels less oily on the skin than the

other repellents. DEET can also be used very effectively for impregnation of clothing. In experiments conducted at AFMC it has been shown to provide repellence up to two launderings of the clothing. As a skin application DEET may be used for protection against mosquitoes, sand flies, fleas and other biting Diptera. It is a good repellent against all haematophagous arthropods and also against leeches.

(b) Dibutyl Phthalate (DBP) : It is more persistent but somewhat less rapid repellent. When smeared on clothing, its effect lasts up to 2-4 washes, ironing destroys it. It is specifically useful against ticks and mites as it is an acaricidal, as well as a repellent. DBP is a good repellent against leeches and Dimdam flies.

(c) Benzyl Benzoate : The oily liquid has a faintly pleasant aromatic odour and sharp bitter taste. It has been applied in 5% emulsion to skin as repellent for many arthropods. Clothing impregnated with benzyl benzoate show repellence to fleas, chiggers and other arthropods. A mixture of equal parts of diethyltoluamide and benzyl benzoate with the addition of an emulsifier acts as a good impregnant for clothing against trombiculid mites.

(d) Diethyl phenyl acetamide (DEPA) : It is available as cream and sprays. It is a broad spectrum repellent and can be used for topical application against mosquitoes, ticks & mites or any other haematophagous arthropod and leeches. It can also be applied on clothing/uniform as repellent. It can withstand 2-3 launderings and ironing. It matches DEET in its spectrum and efficacy.

Application Procedures

Skin Application : Repellents like DEET and DEPA are applied to the skin as cream formulation. These are generally effective against such pests as midges, mosquitoes, sandflies and so on. A good repellent applied in this way gives protection from insect bites for about five to seven hours.

Impregnation of Clothing : Application to clothing is carried out when longer protection against insects is required. Application of DBP, DEET or DEPA to clothing to protect one self from mites and ticks is much more persistent than skin treatment and remains effective for a period up to a month.

(i) Hand Application (Repellent Drill) : Hand Application of repellent is the simplest way to treat the clothing. The fingers of one hand are dipped into the chemical in an open container or a few drops of the chemical are poured into one hand, both the hands are rubbed together and then they are wiped lightly on the inside and also on the outside of all the openings of all garments to produce a thin layer of the chemical on them. The chemical should be applied more particularly to the opening such as inside the neckband of shirts, turn ups of trousers and tops of socks turned inside out. 60 ml per man per fortnight of DBP is enough to impregnate two shirts, two pairs of trousers, 2 pairs of socks, anklets and two sets of underclothing. The application should be started a fortnight before the mite borne disease (like scrub typhus) season in any area begins, and repeated every fortnight thereafter until the season lasts. This should be done on a parade as a drill supervised by a person who has had training and experience of the procedure. The repellents DEET, DEPA require lesser quantities for impregnation.

(ii) Spraying / Impregnation : The chemical can be applied to the entire clothing by spraying or the clothing can be impregnated with a solution or emulsion of the repellent when large quantities of clothing are required to be treated. Clothing should be soaked in the solution, then wrung out lightly and dried. DEPA is available as spray formulation for treatment of clothing.

Barrier Application : Considerable protection may also be obtained by treating only the openings of the clothes inside the neckband and cuffs of shirts, inside the waistband, fly and turn ups of trousers and on the socks above and inside the shoes and below its tongue. These methods, called the barrier application, are particularly useful when people go for amateur camping or trekking or when sufficient supplies of repellents are not available.

Household Products

Use of mosquito coils, vapourising mats, liquid vapourisers consisting of pyrethroids is an important measure in reducing man-vector contact. These products basically aim at deterring the insects from entering the rooms and with continued contact bring about death of the exposed insects. The allergic risks which these products pose on continued exposure especially to children necessitates adoption of safer preventive measures for personal protection.

Mosquito Nets

Mosquito nets are very effective means of protection against the bites of haematophagous arthropods. Untreated or insecticide treated nets may be used as per the availability. The bednets may be treated manually or may be purchased as pre-treated nets.

Manually Treated Bednets : Insecticide treated bednets may be manually treated with Synthetic pyrethroids like Deltamethrin 2.5% SC or Cyfluthrin 05 EW. These nets have to be treated every six months as per the procedure described in Box - 1.

Long Lasting Insecticide Nets (LLINs) : The advancement in the insecticide treated net technology has seen the development of pretreated or Long Lasting Insecticide Nets (LLIN's). These nets may also be treated manually or may be pretreated with insecticide Permethrin or Deltamethrin (Box 2). The shelf life of these nets is 5 years.

Mechanical Control & Physical Control

Use of flyswatters, fly traps for housefly control, use of lice combs, glue traps for various pests like cockroaches and rodents, other mechanical trapping devices used for other vectors are few examples of the use of this control option in vector control.

Physical control measures exploit devices which aim to control vectors by affecting them physically or their environment. Sometimes they may be indistinguishable from environmental or cultural methods. Fly electrocutors and use of temperature extremes (hot water for bedbug control, sun exposure and boiling in hot water of infested material for lice control) are some physical control measures used in public health for vector/ pest control.

Box - 1 : Steps for treatment of bednets
(a) <i>Measure the total area of the net in m² .</i> (2 x length x height + 2 breadth x height + length x breadth) in metres. Average area of a single net is 10 sq m.
(b) <i>Measure the absorption capacity</i> <ul style="list-style-type: none"> • Measure 1 litre of water and take it in a tub. • Immerse the dry net, when completely wet, take it out by gently wringing the net to prevent dripping of water. • Measure the remaining water in the tub. 1 litre - the remaining water gives us the absorption capacity of the net.
(c) <i>Wash the net to be treated and dry it.</i>
(d) <i>Calculate the dosage of the insecticide required</i> <ul style="list-style-type: none"> • Deltamethrin 2.5% SC- dosage required 25 mg a.i. per m². 1 ml of the 2.5% insecticide contains 25 mg; therefore the dosage will be 1ml per m² to give the dosage of 25 mg a.i./m². So if the net is of 10 m² and the absorption capacity is say 500 ml then we need to add 10 ml of insecticide in 500 ml of water to give the reqd. dosage. • Cyfluthrin 05% EW- dosages required 50 mg a.i. / m². 1 ml of the 05% insecticide contains 50 mg; therefore the dosage will be 1ml per m² to give the dosage of 50 mg a.i. /m². So if the net is of 10 m² and the absorption capacity is say 500 ml then we need to add 10 ml of insecticide in 500 ml of water to give the reqd. dosage.
(e) <i>Put the net in the insecticide solution prepared as per the procedure given above and knead it well to ensure the net is completely soaked in soln.</i>
(f) <i>Take out the net and spread it in shade, once semi dry it can be hung for drying.</i>

Box - 2 : Long Lasting Insecticide Nets (LLIN's)
A Long lasting insecticide net is a treated net which can withstand insecticidal efficacy up to at least 20 washes with more than 80% mortality after 24 hrs (95% Knockdown after 60 min).
The treatment is done by either incorporating Insecticide <ul style="list-style-type: none"> • In the yarn itself which is made into textile and then used for making nets e.g. Olyset Net. <ul style="list-style-type: none"> - It is Permethrin impregnated (500 mg a.i./m² net) Polyethylene net. - Washing cleans the surface and hence it is recommended to be heated up (i.e. sun dried) after washing for the active ingredient to "migrate " to the surface. <p style="text-align: center;">OR</p> <ul style="list-style-type: none"> • By coating around fibres, e.g. Perma Net. <ul style="list-style-type: none"> - It is a regular polyester net treated with 55 mg a.i./ m² Deltamethrin. - Resists multiple washes. - Biological activity lasts as long as the net itself (3 to 4 years for polyester nets, 4 to 5 years for polyethylene ones).
Manually treated LLIN <ul style="list-style-type: none"> • Any untreated net can be treated with long lasting formulation of Deltamethrin using K-O Tab. • Low cost as compared to pretreated nets.

Legislative Control

Use of laws and bye-laws to prevent / reduce propagation and spread of vectors is an effective means of vector management, although stringent in approach.

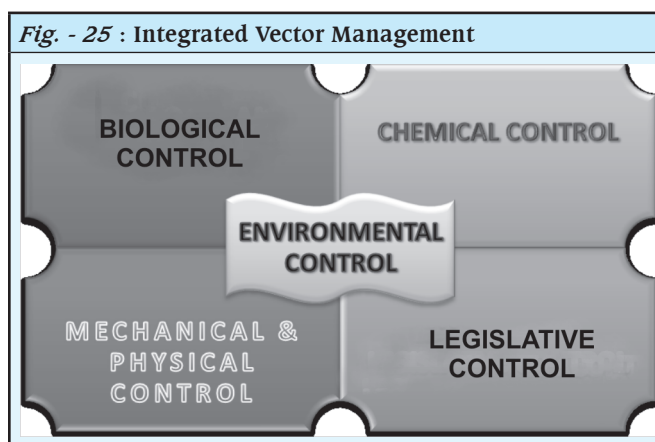

Integrated Vector Management

Development of resistance, effects on non-target organisms and damage to the environment can all be minimized with selective and judicious use of multi-faceted control tactics (Fig. - 25). This approach, commonly known as integrated control, requires an understanding of ecological principles as well as a thorough knowledge of the pest's life history and population dynamics. Today, integrated pest control forms the foundation of Integrated Vector Management programs (IVM) that take a comprehensive and multi-disciplinary approach to

solving pest problems. These programs emphasize management rather than eradication. They take a broad ecological approach to pest problems, focusing on all members of a pest complex in an effort to identify the optimum combination of control tactics that will reduce vector populations below economic thresholds and maintain these levels with the least possible impact on the rest of the environment.

IVM is a dynamic approach which requires a broad knowledge of vector biology, ecology and behaviour on the one hand and that of system analysis approach on the other so that a variety of control measures, such as environmental, chemical, biological, genetic and personal protective measures, can be integrated with a view to achieve the ultimate aim of combating human disease. Chemical and biological methods may provide temporary control of vectors but implementation

of environmental control measures leads to permanent control. In this approach, initial costs may be high and programmes may require years for implementation, but authorities at all levels should be advised to include environmental changes and improvements relating to vector control in all long term planning. However, these methods require elaborate organization, longer time and liberal finances. Species control and vector control are the two modifications circumscribing the wider concept of vector control.

Future Policy

The aim of future vector control by use of insecticides should be to reduce the intensity of chemical selection by reducing the frequency and coverage of insecticide sprays in public health programmes, minimizing the agricultural use of persistent chemicals as far as possible and by supplementing the chemical control methods by other methods whenever feasible. There is a need to strengthen existing surveillance methods and incorporating the benefits of the newer methods like Remote sensing, Geographical Information System, Global Positioning System etc. whenever and wherever, feasible. There is a continued effort to evolve safer alternatives for vector control coupled with intensive research using molecular biology tools for production of Genetically Modified Vectors (GMV) to address the problems of vector control.

Summary

Arthropod control is one of the key strategies in the management of vector borne diseases. This requires a sound knowledge of bionomics, insecticide susceptibility & role in arthropod borne disease transmission. The various control options available are environmental, biological, chemical, personal protective measures, mechanical, physical, genetic & legislative control. Environmental control consists of a naturalistic approach with the aim of minimizing vector propagation & reducing man-vector-pathogen contact. Environmental modification consists of transformation that is permanent like drainage, filling and velocity alteration. Environmental manipulation aims at producing temporary conditions unfavourable to the breeding of vectors in their habitats like water salinity changes, stream flushing etc.

Chemical control began with the discovery of the insecticidal value of Dichloro Diphenyl Trichloro ethane (DDT). Insecticides

form a part of extensive countrywide programmes for control & eradication of diseases and are broadly divided into natural & synthetic. Natural insecticides can be plant & mineral based whereas Synthetic insecticides can be organic or inorganic. The organic Insecticides fall into four major groups viz. Organochlorines, Organophosphates, Carbamates and Synthetic pyrethroids. Organochlorine Compounds are contact poisons and act on the nervous system, the only member of this group used in Public Health is DDT.

Currently DDT is being used only in North Eastern states of India for Indoor Residual Spray. A deposit of 1 g a.i of DDT/m² of surface area of walls and ceilings up to a height of 3.5 m in all dwellings applied at 8 weeks' interval effectively controls majority of the mosquitoes and also other arthropods resting on the treated wall. Organophosphorus Compounds - insects which have become resistant to Organochlorines are still susceptible to the members of this group. Some of the common compounds are Malathion, Temephos, Fenthion, Dichlorovos (DDVP) and Fenitrothion. Malathion is one of the least toxic Organophosphorus compounds. Malathion is a broad spectrum insecticide with efficacy against a large number of pests ranging from mosquitoes, houseflies, cockroaches, bedbugs, lice etc. Malathion (25% WP), under the National Vector Borne Diseases Control Programme is being used as Indoor Residual Spray against mosquitoes in areas where the vectors have become resistant to DDT. As ULV spray, Malathion has been very widely used during outbreaks of Dengue and JE as an anti adult mosquito measure. Temephos (Abate) is the only insecticide approved for use in potable water (20ml a.i/sqm). Fenthion (Baytex) 82.5% EC is a good mosquito larvicide but cannot be used in potable water bodies. It is highly effective as a larvicide against *Culex quinquefasciatus*. Dichloro-dimethyl-dichlorovinyl-phosphate (DDVP or Dichlorvos) produces fatal insecticidal vapour and can be combined with solid substances like wax and used as tablets or bricks. It is one of the common insecticides used for disinfecting aircraft and is also an effective housefly larvicide. Carbamates are derivatives of carbamic acid; some of the compounds in common use are Propoxur, Carbaryl and Bendiocarb. Synthetic Pyrethroids are broad spectrum, highly potent, have quick knock down action and long residual life. Synthetic pyrethroids are many times more effective & safer than the previously available insecticides and include insecticides like Permethrin, Allethrin, Phenothrin, Cypermethrin, Cyfluthrin, Deltamethrin, Bifenthrin etc. Deltamethrin, Cyfluthrin are used for bednet treatment & routine household pest control activity.

Equipment for vector control can be broadly classified as ground equipment and equipment used for aerial applications. Commonly used for spraying various insecticidal formulations are the hand operated sprayers, power operated sprayers, aerosol dispensers, fog generators and dusters. Residual Spraying is the application of insecticides to surfaces so that the insecticide particles remain on the surface in the form, size and quantity suitable for insects to pick up on contact and sufficient to exert a lethal effect over a long period. Organochlorine, Organophosphorus, Synthetic pyrethroids and Carbamate compounds can thus be applied on the inside walls of houses and also on thick bushes. Before starting a spray operation, the

equipment must be checked; the average discharge of an 8002 nozzle is about 750 ml per minute. Spraying in a room should commence from the backside of a door clockwise completing the plain surfaces of walls to the crevices on the walls and inside portion of windows etc. The pillars, under surfaces of furniture and lastly the ceilings should be taken for spray. Spray is done from roof to floor, using downward motion, to complete one swath; then stepping sideways and spraying upwards from floor to roof. Spray is applied in vertical swaths 52-56 cm wide. Swaths should overlap by 5 cm.

Space Spraying is an ideal method for bringing about rapid control of vectors in emergency or epidemic situations and may also be used for seasonal control of flying insects, pests or vectors. Space sprays are applied mainly as thermal fogs or cold fogs. Thermal fog is produced by special devices known as thermal foggers that use heat to break up the chemical into very small droplets (usually in 5-30 micron diameter range) which then disperse in the air. The insecticide used in thermal fogs is diluted in a carrier liquid, which is usually oil-based. Cold fog is produced by a special device which breaks up the chemical into microscopic droplets by mechanical means basically with a high-pressure pump and an extremely fine nozzle. The spray droplets are generated without any external heat. With cold fogs, the volume of spray is kept to a minimum. Ultra-low-volume insecticide formulations are commonly used for such applications. The cold fogger may dispense formulations in a very concentrated form and generate the droplets (usually in the 5-30 micron diameter range) in a precise manner. However, its ability to penetrate dense foliage or obstacles is not as good as that of thermal fogging. Cold fogging is sometimes called Ultra Low Volume (ULV) treatment as it allows the utilization of only a very small amount of chemical for coverage of a large area. Space-spraying formulations are generally oil-based. Diesel is used as a carrier for thermal fogging, but creates a thick smoke and oily deposits, which may lead to public rejection. Insecticides used for fogging are Pyrethrum 2% Extract, EC, Malathion Tech, Deltamethrin 1.25 ULV. The lower the concentration of active ingredient, the larger the number of droplets of a given size required to achieve a lethal dose. Suppression of vector populations over large areas can be carried out using space sprays released from aircraft, especially over areas where access with ground equipment is difficult and extensive areas need to be treated very rapidly. Area Spraying is carried out for treatment of land against mites and ticks and also as an anti-larval measure over vast water surfaces.

Biological Control is the manipulation of populations of living beneficial organisms in order to reduce the numbers of pests or amount of damage. The biological agents are broadly classified as Predators, Parasites and Pathogens. Predators are often large, active, and/or conspicuous in their behaviour e.g. larvivorous fishes for the control of mosquitoes like *Gambusia affinis*. Parasites like Nematodes - *Romanomermis culicivorax* and *R iyengari* have been evaluated and have been found to give variable control of mosquitoes. Fungi *Lagenidium* and *Culicinomyces* have shown immense potential as mosquito larval control agents and can be exploited for use against mosquitoes. Pathogens - *Bacillus sphaericus* and *Bacillus thuringiensis var israelensis* which acts via delta endotoxin are

promising control options. Bti 12 AS is used @ 20ml/m².

Genetic Control is the "use of any condition or treatment that can reduce the reproductive potential of noxious forms by altering or replacing the hereditary material".

Personal protective measures to prevent the arthropod vectors from biting and feeding on their host can be achieved by use of mosquito nets, wearing of long trousers, rolled down sleeves of shirts, socks, shoes and anklets (particularly when going out and in areas heavily infested with arthropods) and use of repellents by application on body surfaces or clothing (are effective in reducing man-vector contact). The commonly used repellents are benzyl benzoate, N, N-diethyl-m-toluidide (DEET), Dibutyl phthalate (DBP), Diethyl phenyl acetamide (DEPA) and Neem oil.

The development of resistance, effects on non-target organisms and damage to the environment can all be minimized with selective and judicious use of multi-faceted control tactics. Integrated Vector Management is a dynamic approach which requires a broad knowledge of vector biology, ecology and behaviour on one hand and that of system analysis approach on the other so that a variety of control measures such as environmental, chemical, biological, genetic and personal protective measures can be integrated with a view to achieve the ultimate aim of combating human disease.

Study Exercises

Short Notes : (1) Environmental Management (2) Biological control (3) Biorational insecticides (4) IRS

MCQs & Exercises

- Organophosphorus insecticides include all except (a) Temephos (b) Malathion (c) Propoxur (d) Dichlorvos
- Deltamethrin belongs to which group of insecticides (a) Carbamates (b) Synthetic Pyrethroids (c) Organophosphates (d) Organochlorides.
- Which of the following is a chitin synthesis inhibitor : (a) Imidacloprid (b) Novaluron (c) Fenoxycarb (d) Cyfluthrin.
- Maximum amount of pesticide on surface is available for killing pests in this formulation (a) Dusts (b) Granules (c) Wettable powder (d) Liquid formulation.
- Hand operated equipment for vector control does not include : (a) ULV fogging machine (b) Hand sprayer (c) Knapsack sprayer (d) Compression pneumatic sprayer
- Commonest type of equipment used in National Vector Borne Disease Control Programme (a) Power operated sprayer (b) Hand sprayer (c) Knapsack sprayer (d) Compression pneumatic sprayer
- Insecticide not used for bed net treatment : (a) Deltamethrin (b) Permethrin (c) Cyfluthrin (d) Allethrin
- Space spraying is used as method of bringing down rapid control of vector in (a) Emergency (b) Epidemic (c) Seasonal control of flying insects (d) All.
- Which of these is not true for thermal fogging (a) easily visible fog (b) Low conc. of active ingredient (c) Pyrethrum 2% & Malathion tech used (d) Mostly water diluted formulations used.

10. Predators used in biological control are all except
(a) *Poecelia reticulata* (b) *Gambusia affinis* (c) *Bacillus sphaericus* (d) *Gaurami*

11. Match the Following :

1. Pyrethrum	(a) Malathion
2. DDT	(b) Temephos
3. Broad spectrum insecticide used in IRS where resistance to DDT has occurred	(c) Available as 2% Extract. Require 20 times dilution to get 0.1% solution. Has rapid knockdown action.
4. Available as 50% EC. Used in potable water	(d) Used as IRS in the dose of 1g/m ² of surface area of walls & ceilings up to a height of 3.5m.
5. Mosquito larvicide, cannot be used in potable water bodies, highly effective against <i>Culex quinquefasciatus</i>	(e) Fenthion
6. Effective housefly larvicide, available as 76% EC & in aerosol formulations.	(f) Propoxur
7. Flushing out effect makes it useful for cockroach & bed bug control	(g) Available as 2.5% SC, 2.5% WP & 1.25 ULV in space sprays
8. Deltamethrin	(h) DDVP
9. Cannot be used in potable water, available as 12AS	(i) Available as 2.15% gel for use against cockroaches & bait against houseflies
10. Imidacloprid	(j) Bti

Fill in the Blanks :

- 12) Residual insecticidal property of DDT was discovered by _____
13) Mechanism of action of Pyrethrum _____

- 14) _____ effect is unique action of Fipronil.
15) _____ powder & _____ tablet is used for rodent control.
16) Average discharge of an 8002 nozzle is _____
17) Mechanism of action of Bti is by the action of _____

Answers : (1) c; (2) b; (3) b; (4) c; (5) a; (6) d; (7) d; (8) d; (9) d; (10) c; (11) 1-c; 2-d; 3-a; 4-b; 5-e; 6-h; 7-f; 8-g; 9-j; 10-i; (12) Paul Muller; (13) Rapid knockdown; (14) Cascade (15) Calcium cyanide & Aluminium phosphide (16) 750ml/min (17) Delta-endotoxin

156 Housefly

Rina Tilak

Houseflies live in close association with man. Despite the best and most extensive efforts taken to control it, housefly control has remained a challenge. The important genera include *Musca*, *Fannia* and the biting flies, *Stomoxys*, *Sarcophaga* and the various blowflies viz. *Chrysomya*, *Calliphora* and *Lucilia*.

However, the most abundant and widely distributed is the Housefly.

Classification and Distribution

The houseflies have a world wide distribution with about 1700 genera under family Muscidae, order Diptera to which the medically important flies - houseflies and stable flies belong. There are 70 species of flies in genus *Musca*, of which *Musca domestica* (common housefly) and *Musca sorbens* (bazaar fly) are abundantly encountered in tropical and subtropical countries.

Morphology

Adult houseflies are 6-9 mm in length, greyish in colour with 4 distinct longitudinal black stripes on the thorax. The head bears a pair of compound eyes which are close together in males but are widely separated in females. The mouth parts, collectively known as the proboscis are capable of considerable extension and retraction and are adapted for lapping-sponging. The antennae generally remain hidden in the antennal groove on the head. The thorax bears four narrow black stripes, a pair of clear transparent wings and a pair of halteres (knob like structure behind the wing), three pairs of legs - each terminating in five segments of tarsus; the last segment bears a pair of claws and pair of pad-like 'pulvilli' provided with a large number of glandular hairs. These glandular hairs secrete a substance which keeps the pads wet and sticky and enables the flies to cling to vertical and smooth surfaces. The abdomen is short, broadly oval with five visible segments (Fig. - 1).

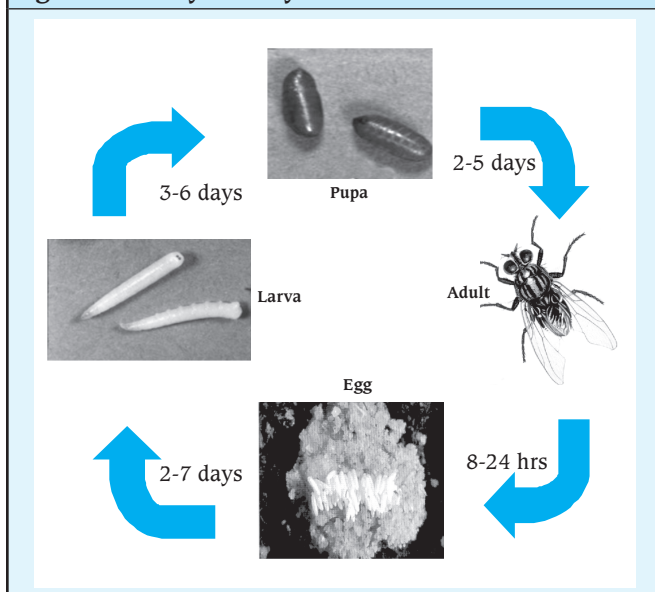

Fig. - 1 : *Musca domestica*

Life History

The life cycle of housefly undergoes complete metamorphosis with egg, larva (maggot), pupa and adult stages (Fig 2).

Fig 2 : House fly - Life cycle

Houseflies breed in decaying organic matter of animal or plant origin. The eggs are pearly white, oval in shape and measure about 1 mm in length. They are laid in cracks & crevices in moist manure heaps or any decaying animal or vegetable matter. A female fly may lay 300 to 900 or more eggs in 5 to 6 batches during her lifetime. In summer, the eggs hatch after 8-12 h, whereas in winter it may take 2 to 3 days. There are three larval stages or instars in the life of a fly. The larvae are photophobic and thus are found in the deeper layers of the manure. After 3-5 days, the third stage larva moves from deep moist burrows to the neighbouring dry soil and contracts to form a dark brown barrel shaped pupa about 6 mm in length. The pupa neither feeds nor grows. Within 2-5 days, the adult fly emerges out of the pupal case. Under favourable conditions of temperature and food supply, the whole life cycle from egg to adult may be completed in about less than a week's time. During winter it may take as many as 20 to 22 days. The length of life is usually 2-3 weeks but in cooler conditions it may be as long as three months.

Bionomics

The housefly has a remarkable capacity to reproduce. It is estimated that at an average of 7 day's developmental cycle for each generation, one female housefly, laying about 120 eggs, could produce a progeny of 5,598,72000,000 adult flies by the end of 5 months in summer. However, nature does not allow this as a large number of eggs, larvae and pupae are lost due to desiccation, starvation, predators and adverse climatic conditions. A high percentage of flies remain near the breeding places. Depending on the prevailing wind and availability of food, some of them may migrate up to 20 km from breeding places (however most stay within 1-2 km of the larval habitat if sufficient food is available). High temperature is lethal to larvae and so the heat generated in tightly packed manure heap quickly kills them. The adult houseflies are attracted to light. The housefly is omnivorous and a voracious feeder; it is particularly partial to faecal matter, sputum, discharges from wounds and open sores. It is also easily attracted to sugars, milk and other articles of food meant for human consumption. The solid or semi-solid foods are softened by extrusion of a vomit drop and then sucked up. Well fed fly defecates every 5 min, particularly while feeding, and vomits every 2-3 minutes. Water is an essential part of a fly's diet and flies do not ordinarily live more than 48 hours without access to it.

Ecology of Adult Flies

An understanding of the ecology of flies is essential for effective management of houseflies. Flies are mainly active during daytime when they feed and mate. They are generally found resting indoors on floors, on the ground and walls at less than 5 feet from the ground; whereas outdoors they rest on fences, walls, steps, pit latrines, clothes lines, grasses, weeds and garbage cans. At night, flies rest above 5 feet height on walls, on hanging wires and vertically suspended articles and ceilings, usually close to their daytime food sources.

Vector Potential

Immediately after visiting a dirty place, the fly may rest on any foodstuff or drink meant for human consumption or an exposed part of body e.g. mouth, eyes or a wound, and deposit the

disease producing organisms. The housefly is thus a mechanical carrier of the causative organisms of diarrhoeas, dysenteries, gastroenteritis, cholera, enteric group of fevers, intestinal worms, poliomyelitis, viral hepatitis A, other enteroviruses, trachoma, conjunctivitis, anthrax, yaws and tuberculosis. At times, the housefly may cause conditions known as internal and external myiasis, in which the flies breed in sloughing wound, intestinal contents and suppurating cavities.

Fly Control

(a) Environmental Control : The best method of control of houseflies is to eliminate their breeding places and to maintain a high standard of environmental sanitation, especially by proper disposal of human and animal excreta, swill, garbage and all other decaying organic rubbish, offal and carcasses. Access of flies to faeces should be prevented by fly proofing the latrines and latrine pans and prompt removal of faeces. Their access to food is prevented by fly-proofing cook houses and messing blocks and by use of fly-proof cupboards and containers. The doors of all entrances and windows should open outwards and preferably should have vacuum levers especially in cookhouses. Constant vigilance is necessary to destroy all flies that gain entrance, otherwise the fly-proofed rooms become large fly-traps. In pantries and mess rooms, fly-proof cupboards for food storage and wire gauze, weighted with beads afford protection to food in jugs or bowls but their repair and cleanliness requires constant supervision. When the table is being laid, cups should be inverted in saucers and bowls should be kept either upside down or under cover when not in use.

(b) Insecticidal Control (Box - 1)

(i) Space Spray : For immediate destruction of flies and especially for prevention of fly borne diseases, pyrethrum (0.1%) spray is useful, mainly in cook houses and dining rooms before meal times and in canteens. Certain combinations of space sprays containing Pyrethrum or Synthetic pyrethroids and/or Organophosphorus/Carbamate compounds are available commercially. ULV spray in large areas may also prove effective in controlling houseflies.

(ii) Baits : Propoxur baits have been in use since long for fly control. Recent introduction in this concept is Imidacloprid baits containing Imidacloprid as the toxicant with Pheromone - Muscalure, which helps in attracting the flies to the bait. This bait has been found to be effective for use in areas with low to moderate fly infestation. However, while using these baits in cookhouses/ dining areas, care should be taken that they are not placed close to cooking or serving place.

(iii) Cord and Ribbons : During the night, houseflies prefer to rest on strings and hanging wires or any object; this fact is utilized for killing them by use of insecticide treated cords and strips which are hung from ceilings in kitchens, dining halls, store rooms, dairy farms and poultry houses to provide effective control during the fly season. Dark coloured material is preferred for treatment @ 1m cord or strip for each square metre of floor space. The period of effectiveness ranges from 1 to 6 months. For this any insecticide with high vapour pressure and quick knock down effect should be used. These treated materials should not be hung over food containers,

water containers/ troughs or within reach of animals or pets. Curtains treated with Synthetic pyrethroids will be of additional benefit.

(iv) Larvicides : Insecticides such as DDVP (2%), Fenthion (4%) have been used as larvicides to control fly breeding but the use of larvicides may favour the development of resistance, the choice should therefore be made carefully. Insecticides like Dimilin (IGR) may be used to retard development of resistance. Larvicides should be applied at a rate sufficient to wet the upper 10-15 cm of the breeding medium thoroughly i.e. 0.5 - 5 l/m².

Box - 1 : Newer Insecticides Against Houseflies			
Insecticide	Formulation	Dilution	Area to be sprayed
Cyphenothrin	5%EC	10 ml + 990 ml of water	500 ml/sq m
Diflubenzuron	2.5% WP	8 g in 1 litre water	500 ml/sq m
Diflubenzuron	5% G	As it is	50 g/sq m
Imidacloprid bait	0.5%	As it is	5 g / bait station
Propoxur bait	2%	As it is	Moisten and keep in bait stations

(v) Paints : The concept of using insecticidal paint for housefly is catching up. Imidacloprid baits wetted with water may be used as paint on housefly resting places.

(vi) Residual Spray : The housefly has developed resistance to most of the Organochlorine as well as Organophosphorus and Carbamate group of insecticides routinely used in public health. Residual sprays are ideally not recommended for fly control.

(c) Mechanical Control

(i) Fly Traps : Various types of fly traps such as the cage trap and the kerosene tin trap were used in the past with fairly good results. These are no longer in use because of the availability of more potent and convenient methods. Newer mechanical fly catching devices have been developed which have bags with attractants inside, which attract the houseflies and on entry inside the bag, they get trapped and eventually are killed.

(ii) Swatting : It is used in situations where infestation is so low that routine fly control measures are either not indicated or feasible. However, it is important to remember that fly population of a cook house or dining room cannot be greatly reduced by persistent swatting. A good swat is the one, which is resistant enough to affect a rapid hit. The flaps should be perforated and washable.

(iii) Fly Paper : Commercially available fly papers may be used or alternately sticky fly papers (Fig. - 3) can be prepared by mixing 8 parts of powdered resin and 5 parts by weight of crude castor oil and heating the same in a water bath while stirring constantly. The paste mixture is spread on glazed paper. The latter can be prepared by coating an ordinary paper with a hot

solution of 1 g of glue in 3ml of water and allowing it to dry. The fly papers do not give lasting results and hence are not much in use for control purpose. They are however considered an effective method for monitoring fly density.

Fig. - 3 : Fly paper

(d) Physical Control : Use of light traps (electrocutors) is very useful in the dining areas & other public eating places. The light traps should be placed away from dining tables & food.

Summary

Houseflies live in close association with man. The most abundant and widely distributed is the Housefly - *Musca domestica*. Adult houseflies are 6-9 mm in length, greyish in colour with 4 distinct longitudinal black stripes on the thorax. The head bears a pair of compound eyes. The thorax bears a pair of clear transparent wings, three pairs of legs - the last segment of the tarsus bears a pair of claws and a pair of pad-like 'pulvilli' provided with a large number of glandular hairs. These secrete a substance which keeps the pads wet and sticky for clinging to vertical and smooth surfaces. The life cycle of housefly undergoes complete metamorphosis with egg, larva, pupa and adult stages. Houseflies breed in decaying organic matter of animal or plant origin, eggs are laid in cracks & crevices in moist manure heaps or any decaying animal or vegetable matter. The larvae are photophobic and thus, are found in the deeper layers of the manure. After 3-5 days, the third stage larva moves from deep moist burrows to the neighbouring dry soil and contracts to form a dark brown barrel shaped pupa. Within 2-5 days, the adult fly emerges out of the pupal case. Under favourable conditions of temperature and food supply, the whole life cycle from egg to adult may be completed in about less than a week's time. During winter it may take as many as 20 to 22 days.

The housefly has a remarkable capacity to reproduce. High temperature is lethal to larvae and so the heat generated in tightly packed manure heap quickly kills them. The adult houseflies are attracted to light. The housefly is omnivorous and a voracious feeder. It is particularly partial to faecal matter, sputum, discharges from wounds and open sores. The housefly is a mechanical carrier of the causative organisms of diarrhoeas, dysenteries, gastroenteritis, cholera, enteric group

of fevers, intestinal worms, poliomyelitis, viral hepatitis A, other entero- viruses, trachoma, conjunctivitis, anthrax, yaws and tuberculosis.

The best control of houseflies is to eliminate their breeding places and to maintain a high standard of environmental sanitation, especially by proper disposal of human and animal excreta. Access of flies to faeces should be prevented by fly proofing the latrines and latrine pans and prompt removal of faeces. Their access to food is prevented by fly-proofing cook houses and messing blocks and by use of fly-proof cupboards and containers. The doors of all entrances and windows should open outwards and preferably should have vacuum levers. Insecticidal Control : Space Spray of pyrethrum (0.1%) useful for immediate destruction of flies & for prevention of fly borne diseases. Propoxur baits have been in use since long for fly control. Recent introduction is Imidacloprid baits. Use of insecticide treated cords and strips provide effective control during the fly season. Other useful insecticides are DDVP (2%), Fenthion (4%), Dimilin etc. Mechanical fly catching devices have been developed which have bags with attractants inside, which attract the houseflies and on entry inside the bag, they get trapped and eventually are killed. Swatting is used in situations where infestation is so low that routine fly control measures are either not indicated or feasible. Commercially available fly papers may be used or alternately sticky fly papers can be prepared. Use of light traps (electrocutors) is very useful in the dining areas & other public eating places, however, they should be placed away from dining tables & food.

Study Exercises

MCQs

- Housefly transmits all except (a) Poliomyelitis (b) Hepatitis B (c) Tuberculosis (d) Intestinal worms.
- Environmental control measures for housefly control do not include (a) Fly proofing (b) Pyrethrum spray (c) Proper garbage disposal (d) Vacuum levers in doors.
- Anti adult control measure is (a) Fenthion (b) DDVP (c) Dimilin (d) Imidacloprid bait.

Fill in the Blanks

- Size of a housefly is _____
- _____ secrete a substance which keeps pads wet & sticky for clinging to vertical & smooth surfaces.
- Larvae of housefly are _____

Answers : (1) b; (2) b; (3) d; (4) 6-9mm; (5) Pulvilli; (6) Photophobic.

Mosquitoes qualify to be rated as one of the most important vectors, the world over, from amongst the numerous species of blood sucking arthropods, due to the sheer magnitude of morbidity and mortality caused by them. The mosquitoes belong to phylum Arthropoda, class Insecta, order Diptera and family Culicidae. The family Culicidae is divided into sub-families Culicinae, the Chaoborinae and the Dixinae. Of these, only the sub-family Culicinae, which comprises all the true mosquitoes, is of medical importance. Amongst the mosquito genera, only *Anopheles*, *Culex*, *Aedes* and *Mansonia* are of importance in India. The mosquitoes are further classified as 'Anophelines', which comprises only one important genera - *Anopheles* and 'Culicines' comprising three important genera viz. *Culex*, *Aedes* and *Mansonia*.

Distribution

Mosquitoes have a worldwide distribution, being found in the tropics, temperate zones and also in the arctic circles. They have even been found breeding in underground tunnels, deep mines and at altitudes as high as 4000 m above sea level.

Morphology

Mosquitoes are about a centimetre long and greyish black in colour. The division of the body into the head, thorax and abdomen is sharply defined. The head bears two large compound eyes, a pair of antennae and the mouthparts which are collectively called 'proboscis'. The mandibles and maxillae of only the female are developed for cutting the human skin and therefore only the female mosquitoes can suck blood and transmit diseases.

Sexual dimorphism is clearly seen in mosquitoes; males can be identified by their antennae, which are densely haired and look like moustache, whereas, in females the antennae is sparsely haired.

The palps are also helpful in identification of males and females of Anophelines and Culicines; In *Anopheles* male, the palpi are long and club shaped at the termination; in the females, they are as long as proboscis and are straight. In Culicines, the male palpi are long and tapering and deflected out, whereas in females, the palpi are much shorter than proboscis and budlike.

The thorax bears a pair of wings and three pairs of legs. The thorax of Culicines is humped in all the three genera, giving them a hunchback appearance while resting; whereas, Anophelines rest with their head, thorax and abdomen in the same line and forming an angle of 45° with the surface, with the exception of *Anopheles culicifacies* which rests like the Culicines i.e. with the body parallel to the surface. The abdomen of mosquitoes consists of 10 segments of which 7 or 8 are clearly marked out and the terminal ones form the male and female external genitalia.

Life History

Mosquitoes undergo complete metamorphosis through the

stages of egg, larva, pupa and adult. Water is required for egg laying with variations existing among genera and species for the type of water desired by them. The number of eggs laid at each oviposition varies between 50 and 150. Anophelines prefer to lay their eggs singly in clean water collections and have lateral floats; *Culex* sp prefers dirty/ polluted water and the eggs are deposited as raft; *Aedes* sp prefers to lay eggs singly on some substratum/ debris in containers (natural or artificial), whereas *Mansonia* sp breeds in water bodies with aquatic vegetation namely *Pistia* and lay their eggs on the under surface of the leaves in star shaped clusters. The eggs hatch into larvae in one to two days, but in cold weather, the hatching may be delayed. Mosquito larvae feed voraciously on micro-organisms, water algae or other organic matter and breathe through spiracles. Larvae pass through four stages or 'instars' in five days depending on the species, the temperature of the water and availability of food supply. In Anophelines, the larvae rests parallel to the surface and have palmate hair on the dorsal surface of the abdomen and do not possess siphon tube, whereas in case of Culicines, the larvae rest at an angle with the head downwards and possess a single siphon tube. At the end of the fourth instar, the fully grown larva casts its skin and becomes a comma shaped 'pupa', which is a motile but non-feeding stage and has two respiratory trumpets originating from the cephalothoracic area. During this stage, it undergoes transformation to the adult usually within 1-2 days. The adult mosquito wriggles out of the pupal skin through a 'T' shaped slit and balances itself on the water surface or some near by floating object until its wings are dry and then flies off. The total duration of the life cycle varies between seven days to one month. The life span of adult mosquitoes is up to a maximum of 6 months in the temperate zones, but in the tropics they seldom survive for more than a month.

Bionomics

The females of all the medically important mosquitoes are normally bloodsuckers, as they require a blood meal for maturation of eggs. Females are fertilized during swarming (nuptial dance) at dusk. The source of the blood meal varies with the species. Those feeding on human blood are called anthropophilic and those feeding on animals are called zoophilic. They are attracted by the body odours, carbon dioxide and heat emitted from animals or humans. Majority of species are nocturnal in their feeding habits, while others feed indiscriminately by day or night. Some are outdoor biters (exophagous) and some are indoor biters (endophagous). After blood meal, female goes in search of a quiet place indoors (endophilic) or outdoors (exophilic) to rest for a variable period, usually 2 days and matures her eggs. When the eggs are fully matured, she goes in search of water collection for oviposition (act of laying eggs). Male mosquitoes feed on flower-nectar and plant-juices and do not survive long after fertilizing the female mosquito.

Genus Anopheles

Members of this genus have 58 species in India. Females of only 9 species of Anopheline mosquitoes are the vectors of human Plasmodia in India (Fig. - 1). In certain parts of the world, some species of Anopheline mosquitoes transmit *Wuchereria bancrofti* and *Brugia malayi* infections as well.

All important vector species are preferentially anthropophilic. The time of feeding is also variable; some species prefer dusk for their blood meals, others late night while still others select early morning. Knowledge of the habits is useful in designing control measures. *An identification key for common Anophelines of India is presented at the end of the section.* Detailed entomological techniques are given in the WHO manual and a pictorial identification key has also been published by Das et al.

Genus Culex

Members of this genus are found in temperate and tropical zones throughout the world. There are 240 Indian species in this Genus. Adult mosquitoes of this genus are generally dull in colour and inconspicuous due to unspotted wings (Fig. - 2). Their breeding sites vary from clear water, such as wells and springs, to collections of muddy, brackish or polluted water; but unlike Anopheline mosquitoes, these mosquitoes generally prefer stagnant and muddy pools. *C quinquefasciatus* is the common house mosquito and is prevalent universally; it bites at night and is the most important vector of Filariasis caused by *Wuchereria bancrofti*.

Genus Aedes

Some members of the genus *Aedes* have almost worldwide distribution while others have restricted habitats. The chief species in India are *Aedes aegypti*, *Ae albopictus* and *Ae vittatus*. They are black or dense brown and medium sized mosquitoes with silvery white scales forming patterns on the thorax, bands on the legs and rings around each abdominal segment.

These mosquitoes are mostly anthropophilic and are adapted to domestic or semi-domestic environments. These are container breeders. The cigar shaped eggs are laid singly on

damp surfaces on stagnant water. During the pre-monsoon period, the breeding is restricted to water collections meant for domestic use. Communities or sections of the cities with water scarcity, which leads to water storage practices, are mostly harassed by *Ae aegypti*. In the shore areas, barges and country crafts provide ample place for *Aedes* breeding and constitute a permanent source of *Aedes* infiltration in the shore establishments and cities. They are well adapted for breeding in small collections of water in a wide variety of natural and artificial containers such as masonry tanks, earthenware pots, small and large tins, barrel drums, coconut shells, stored or discarded motor car tyres, junk and hardware, flower pots, fire buckets, depressions in tree trunks, leaf axils etc. They may breed in tree holes if these are situated within about 20 metres of human habitat.

The eggs after maturing may remain viable for considerable periods even after drying-up of the breeding sites, and hatch out during rains. Such surviving eggs rapidly build up the adult mosquito population, once it starts raining. Their capacity to complete life cycle indoors enables them to breed in urban areas throughout the year, irrespective of the prevailing external climate.

Aedes mosquitoes are day biters with dawn and dusk as peak biting time. They may feed indoors or outdoors and rest near the breeding places in dark, shady corners outdoors, whereas indoors they rest behind cupboards, hanging clothes, inside shoes, umbrellas, below the furniture and in containers providing breeding sites. *Aedes aegypti* prefers to breed in artificial containers, whereas *Aedes albopictus* prefers natural containers.

Aedes mosquitoes are the vectors of urban and rural yellow fever (not in India), dengue, dengue haemorrhagic fever

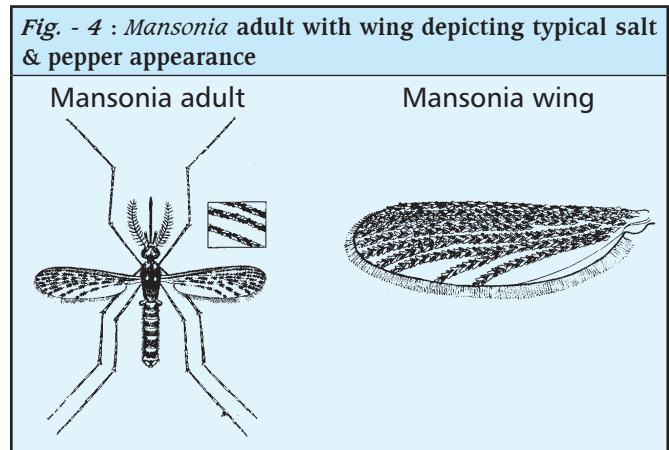

and chikungunya. *Ae niveus* has been reported as vector of *W bancrofti* (diurnally sub periodic) infection in Nicobar Islands. *Ae aegypti* and *Ae albopictus*, the two important vector species can be easily distinguished by their thoracic pattern. *Ae aegypti* has sickle or lyre shaped pattern on the thorax, whereas *Ae albopictus* has a single central mark present on the thorax (Fig 3).

Genus *Mansonia* (Fig 4)

This has wide distribution in tropical countries. In India, *Mansonia annulifera*, *M uniformis* and *M indiana* are the prevalent species in Kerala. The adult mosquitoes are robust and yellowish brown. The wings are covered with flat, broad scales, which give the wings a speckled appearance as if sprinkled with mixed salt and pepper. The female lays eggs in cluster

anchored to the under surface of the leaves of aquatic plants such as *Pistia*, *Lemna*, *Eichhornia* and *Salvinia*. On hatching out, the larvae obtain oxygen from the plant cells through their modified siphon tubes by attaching themselves to the rootlets of these plants. The pupae are similarly attached to the plant stems by the modified breathing trumpets. When matured they detach themselves and come to the water surface. They are persistent biters, particularly during darkness. *Mansonia* mosquitoes are the vectors of *B malayi* infection of filariasis in several pockets in rural areas of Kerala, Tamil Nadu, Andhra Pradesh, Madhya Pradesh, Assam and West Bengal.

Some of the important differences between Anopheline and Culicine mosquitoes are shown in Table - 1.

Table - 1 : Important differences in Anopheline and Culicine mosquitoes		
Stage	Anopheline	Culicine
Egg	<ul style="list-style-type: none"> Boat shaped Laid singly Possess lateral floats 	<ul style="list-style-type: none"> Elongated Aggregation occurs into rafts of hundreds of eggs in <i>Culex</i> <i>Aedes</i> eggs are laid singly <i>Mansonia</i> eggs are laid on under surface of leaves of aquatic plants in star shaped clusters
Larva	<ul style="list-style-type: none"> No siphon tube but only apertures on 8th abdominal segment Larvae rest parallel to the surface of water Swim with swift wriggling movements Palmate hairs for floatation arranged in pairs on all abdominal segments 	<ul style="list-style-type: none"> Single siphon tube on 8th abdominal segment <ul style="list-style-type: none"> In <i>Culex</i>, siphon tube is long and narrow In <i>Aedes</i>, it is short and broad In <i>Mansonia</i>, larvae are attached through siphon tube to roots of aquatic plants Larvae rest at an angle to surface Swim with slow snail or worm like movements No palmate hairs for floatation
Pupa	<ul style="list-style-type: none"> Pupa is comma shaped In Anophelines, respiratory trumpets are short stumpy and funnel shaped 	<ul style="list-style-type: none"> Pupa is comma shaped In Culicines, respiratory trumpets are longer, slender and trumpet shaped
Adult	<ul style="list-style-type: none"> Wings usually spotted Rests at an angle to surface, with the exception of <i>A culicifacies</i> In the males, palpi are long and club shaped at the termination; in females, they are as long as proboscis and are straight 	<ul style="list-style-type: none"> Wings usually not spotted Rests parallel to the surface Thorax is humped In the males, palpi long and tapering and deflected out; in females, palpi are much shorter than proboscis and budlike

Vectors of Malaria

There are 58 species of Anopheline mosquitoes in India but only 9 are incriminated as vectors and another 5 species have been found to be of local importance in transmission of malaria. In Northern and Peninsular India, the main vectors are *A culicifacies*, *A stephensi* and *A fluviatilis*, while the local vectors are *A sondaicus*, *A annularis* and *A varuna*. In Eastern India, the main vectors are *A dirus*, *A sondaicus*, *A philippinensis*, *A minimus*, and *A maculatus*. In Andaman and Nicobar Islands, the main vector is *A sondaicus* while the new vectors are *A dirus*, *A maculatus* and *A tessellatus*. A detailed list of these vectors is presented in Table - 2.

The following characteristics of vector mosquitoes play an important role in the epidemiology of malaria.

(a) Breeding Habits : The breeding habits of mosquitoes show a lot of variation and hence vector mosquitoes tend to be confined to certain geographical areas only. A few examples are as shown in Box - 1.

Box - 1 : Breeding Habits of Vectors	
Slow moving water, seepages, terraced rice fields	<i>A fluviatilis</i>
Brackish waters	<i>A sondaicus</i>
Wells, cisterns and over head tanks	<i>A stephensi</i>
Tanks, pools, burrow pits and ditches	<i>A philippinensis</i> , <i>A annularis</i>
Forest pools, streams and slit trenches	<i>A dirus</i>

(b) Vectorial Capacity : Only certain species act as vectors; moreover, within the known vector species, some are more efficient while some are less. The exact reasons for this are

not known. Certain new species are emerging as secondary vectors in different parts of the country. The Vectorial capacity (C) can be expressed as a mathematical expression to measure vector efficiency and assess risk and impact of interventions as follows :

$$C = \frac{ma^2p^n}{(-\log_e p)}$$

where :

m = density of vectors in relation to man

a = number of blood meals taken on man per vector per day

p = proportion of vectors surviving per day

n = incubation period in the vector (days) - 8 days when they survive $(1/(-\log_e p))$ days.

Theoretically, incidence of infection rises when $C > 1$, incidence falls when $C < 1$.

(c) Density : For effective transmission of malaria in a locality, the mosquito vector must attain and maintain a certain density. This is called *critical density* and it varies from one mosquito to another and also under different environmental conditions. *A culicifacies* needs a very high density for transmission of malaria, while *philippinensis*, *dirus* and *fluviatilis* need much lower critical density.

(d) Longevity : A mosquito, after an infective blood meal, must live for at least 10 days to complete the development of malaria parasites. Therefore aim in malaria control programme is to reduce the life span of mosquitoes to less than 10 days.

(e) Tropism : Some mosquitoes like *A fluviatilis* prefer human blood and are called anthropophilic. Others like *A culicifacies* preferably feed on animal blood and are called zoophilic. This preferential feeding habit is called tropism.

Table - 2 : Malaria Vectors of India and Vectors of local importance

S No.	Name of Species	Role in transmission
1	<i>A stephensi</i>	Primary urban vector in most of India except North-East and Rajasthan
2	<i>A culicifacies</i>	Primary rural vector all over India except North-East
3	<i>A fluviatilis</i>	Primary rural vector in foothill areas of the country
4	<i>A minimus</i>	Primary vector in North Eastern regions, West Bengal
5	<i>A philippinensis</i>	Primary vector in rice field ecosystem of North Eastern regions
6	<i>A dirus</i>	Primary vector in regions of evergreen forests in the North East
7	<i>A sondaicus</i>	Primary vector in Andaman & Nicobar Islands
8	<i>A varuna</i>	Eastern ghats (Andhra Pradesh), Singbhum hills (Bihar) & Kerala
9	<i>A annularis</i>	Secondary vector in rice field ecosystem in Uttar Pradesh and coastal areas of Orissa
<i>Vectors of local importance</i>		
1	<i>A aconitus</i>	Orissa, Assam
2	<i>A jeyporiensis</i> (var <i>candidiensis</i>)	In certain localities in Kerala, Karnataka and Assam
3	<i>A maculatus</i>	In certain localities in Assam & Meghalaya
4	<i>A tessellatus</i>	Lakshadweep Islands (on epidemiological grounds)
5	<i>A subpictus</i>	In Madhya Pradesh

(f) **Biting Behaviour** : Some vector mosquitoes bite at or soon after dusk, others either during late night or early hours of the morning. However, some species may be active at two different periods during the same night.

(g) **Resting Habits** : A female mosquito after a blood meal rests either indoors (endophilic) or outdoors (exophilic) for maturation of its eggs. The common resting places are either human dwellings, cattle sheds or mixed dwellings.

(h) **Flight Range** : The range of flight and dispersion varies from one vector to another. Some have a short flight range e.g. flight range for *A. dirus*, *A. annularis* and *A. fluviatilis* is upto 1 km distance; whereas *A. culicifacies* and *A. stephensi* fly up to 2 km and *A. sudaicus* may fly even up to 8 or 10 km.

(j) **Resistance to Insecticides** : When a vector mosquito in a locality becomes resistant to a particular insecticide, use of an alternative insecticide is recommended.

Vectors of Filariasis

(a) **Culex quinquefasciatus** : This species is the main vector of bancroftian filariasis in India. It preferentially breeds in dirty water collections such as in drains, cesspools, soakwells and septic tanks. When denied such opportunities, it can also breed in clean water.

(b) **Mansonioides** : *Mansonioides* species are the vectors of *B. malayi* infection in India. In Kerala, *M. annulifera* and *M. uniformis* are the major vector species. These mosquitoes are associated with aquatic plants like *Pistia stratiotes*, *Eichhornia speciosa* and *Salvinia auriculata*.

(c) **Aedes niveus** : This species has been incriminated as a vector of diurnally subperiodic form of Bancroftian filariasis in Nicobar group of islands.

(d) **Other Species** : In India, Anopheline mosquitoes have not been found to play any significant role in the transmission of any type of filarial infection unlike in some other parts of the world.

Mosquito Surveillance

In places which are endemic for mosquito borne diseases or outbreak prone, it is deemed mandatory that mosquito surveillance system be established. The aim of the surveillance should be to inform about changes in density and major characteristics of vectors, to forecast an impending outbreak and to recommend appropriate strategies for mosquito control which would prevent outbreak.

Steps for Establishing Mosquito Surveillance System

Step 1 : Acquaint yourself with basics of mosquito identification both larval and adult mosquitoes up to genera level (*Culex*, *Anopheles* and *Aedes*) and mosquito bionomics.

Adult

Identification of mosquito : Mosquitoes are identified from other such flies by the presence of forward projecting mouthparts or proboscis, wing veins (veins 2, 4 and 5 are branched) and a fringe of scales along the posterior margin of wings (Fig. - 5).

Fig. - 5 : Identification of mosquito

Identification of Male & Female Mosquito : The mosquito sexes can be identified by their antennae. It's bushy in males and not so bushy in females (Fig. - 6).

Fig. - 6 : Identification of Male & Female Mosquito

Identification of Anopheles, Culex and Aedes : If the wings are spotted, it is anopheline vector species; whereas, if the legs are having silvery stripes against dark black legs it is *Aedes* and if there are no spots on the wings or stripes or legs, it is *Culex* adult. The length and shape of terminal area of palpi can also be used for discriminating, as explained in Table - 1 earlier.

Larvae : If the larvae have siphon tube at its tail end, it belongs to Culicine group and could be *Culex* or *Aedes*. For this reason, the larvae of Culicines are suspended upwards down, at an angle with the water surface. If the siphon tube is long and narrow, it is *Culex* species, whereas short and broad siphon tube indicates it is *Aedes*. It is also important to remember that *Aedes* is essentially a container breeder and will be found only in artificial or natural containers. The Culicine larvae float at an angle to the water surface as shown in Fig. - 7.

Fig. - 7 : Culicine Larva

Anopheles in contrast does not have siphon tube and floats parallel to the water surface of water as shown in Fig. - 8.

Fig. - 8 : Anopheline Larva

Step 2 - Sector Allocation and Mapping : Once armed with the basic information, start by dividing the entire area of your responsibility into four or five sectors and make a map of the sector. Each sector should be covered every fortnight or at least once a month for surveillance.

Step 3 - Conduct a Preliminary Survey : First a baseline survey (larval and adult) is conducted to determine the prevalence, abundance and distribution of the vector species.

Step 4 - Data Compilation and Preparation of Spot Map : The data collected in preliminary survey is compiled and analyzed to determine the above mentioned variables and a spot map is prepared with clearly marked out areas where density is high, medium or low or where potential of breeding exists.

Step 5 - Establish Monitoring / Catching Stations : In each of the four or five sectors, establish four fixed stations (minimum two if manpower is less), with preferably two from the high density and two from the medium density spots and an equal number of random stations (2 each from the high density and the medium density areas). Poor or worst ventilated houses

located close to the breeding places, discarded bathrooms, abandoned buildings are considered ideal; for room selection, the room which has fewer openings is selected.

Step 6 - Conduct Fortnightly Surveys : Conduct surveys in the fixed and random stations and record your data in the format given in Appendix 'A' and 'B' at the end of this chapter.

Larval Sampling Procedure : The mosquito larval sampling should be done by standard larval ladles. The method is as follows :

Dip the ladle sideways : A minimum of five dips may be taken for calculation of larval density (Fig. - 9).

Fig. - 9 : Larval Sampling

Transfer the larvae in enamel bowl : count the total number of larvae in the bowl after five dips.

Calculate larval density : For example :

- Total no. of dips taken-5
- Total number of larvae counted -50
- Larval density (Total no. of larvae/ no. of dips)-50/5 = 10

Other larval sampling procedures like larval nets (when the water body has vegetation) or well nets (when mosquito breeding is noticed in wells) may be used in specific situations. The density is calculated in the same way and given as larvae/ larval net or well net.

Adult Sampling Procedure

Aspirators / Suction tube : This is the most common method of sampling adult mosquitoes (Fig. - 10). It is normally undertaken in the mornings. Before using suction tube ensure that muslin cloth or gauge piece is placed between the glass tube and the rubber tubing to prevent mosquitoes being sucked inside your mouth.

Fig. - 10 : Aspirator / Suction Tube

- With the aid of a torch look for resting mosquitoes on the walls, ceilings (when it's low), behind and under furniture/ wall hangings etc.

- For practical purposes, while undertaking mosquito surveillance, one insect collector should spend at least 15 minutes in each of the 4 fixed and each of the 4 random stations. Thus, 2 insect catchers should be deputed; one for the 4 random stations and one for the fixed stations (15 minutes at each station) on the day surveillance is being conducted in that sector.
- While using suction tube, keep the end of rubber tubing in your mouth and place the opening of the glass tube 1-2 cm from the resting mosquito. Move the end closer to the mosquito by applying gentle suction to draw the mosquito inside the tube, now place your finger over the tube to keep the mosquito from flying away.
- Do not collect more than five mosquitoes in one tube. After collection, transfer the mosquitoes in transport cages by gentle blowing.
- Density of mosquitoes is calculated by the following formula :

$$\text{Density (Per Man Hour)} = \frac{\text{Total No. of mosquitoes collected}}{\text{Man Hour spent in collection}}$$

If 2 persons have collected 18 mosquitoes and each man has spent 1 hr each (15 minutes per station), the density is calculated by the following method :

2 Persons X 1 hr = 2 Man Hour

Total mosquitoes collected in 2 Man Hour - 18

∴ Mosquitoes collected Per Man Hour (PMH) - 18/2 = 9

Density = 9 PMH

Total Catch or spray sheet collection : Involves the use of Pyrethrum for collection of mosquitoes resting indoors (Box - 2). This is a more efficient method of sampling as it can also collect those mosquitoes which are hiding under furniture or resting on high ceilings or where the density of mosquitoes resting is low.

Other types of mosquito sampling devices : The other sampling tools are the window traps, magoon traps, direct bait collection and light traps.

Surveillance of *Aedes* mosquitoes

(i) Larval survey : Three indices are commonly used to record *Ae aegypti* and *Ae albopictus* density levels :

House Index (HI) : Percentage of houses or premises positive for *Aedes* larvae.

$$HI = \frac{\text{No. of houses positive for Aedes larvae}}{\text{No. of houses inspected}} \times 100$$

Container Index (CI) : Percentage of water-holding containers positive for *Aedes* larvae.

$$CI = \frac{\text{No. of positive containers}}{\text{No. of containers inspected}} \times 100$$

Breteau Index (BI) : Number of positive containers per 100 houses in a specific location.

$$BI = \frac{\text{No. of positive containers}}{\text{No. of houses inspected}} \times 100$$

(An HI >5% &/or a BI >20 for any locality is an indication that the locality is dengue sensitive and therefore adequate preventive measures should be taken).

(ii) Oviposition Traps : "Ovitrap" provide a sensitive and economical method for detecting the presence of *Ae aegypti* and *Ae albopictus* in situations where *Aedes* density is low and general larval surveys produce unsatisfactory results (e.g. when the Breteau Index is < 5). The standard ovitrap is a wide-mouthed glass jar of approximately 250 ml which is painted black on the outside to attract the *Aedes* females to oviposit. A piece of hardboard/ wooden paddle or filter paper is placed diagonally inside the glass as an oviposition substrate. In addition, the jar is partially filled with clean water and placed in a shaded and protected place (rain, people/ animal) for oviposition.

(iii) Adult Survey : Human bare-leg catches (landing / biting catches) of *Aedes* adults (both male & female) or indoor resting collections of adults are normally used to assess adult *Aedes* populations. The data collected are calculated to reflect the number of female *Aedes* mosquitoes landing/biting on single human bait per hour (e.g. number per man hour). The collectors should move from house to house and not collect in one place for more than 15 or 20 minutes. In a similar manner, indoor resting collections can be made and the data expressed as numbers collected per man-hour or per house. Adult indices can also be elicited just like the larval indices i.e. 'Adult House Index', 'Adult Room Index' and 'Adult Breteau Index'.

Box - 2 : Total Catch or Spray sheet collection

- Remove all animals, small items of furniture, food items. Close all windows and doors and close / cover all openings with cloth.
- Spread white cotton bed sheets to cover the entire surface area (no. of sheets will depend on the size of the room). Ensure that sheets have been placed under furniture also. Sheets placed on furniture should not touch the floor as it will prevent the insecticide from reaching underneath.
- Prepare the Pyrethrum solution from 2% Pyrethrum extract available to a workable strength of 0.2% by mixing 100 ml of Pyrethrum with 900 ml of Kerosene to make a total volume of 1 litre of prepared soln. of 0.2%.
- Use a hand sprayer (Flit gun) for spraying. After entering the room first close the door of the room and then start spraying in open spaces and holes in the wall and thereafter proceed to apply spray towards the ceiling until the room is filled with fine mist; always taking care to move in a clockwise direction. After spraying, close the door and keep the room closed for at least 10 min.
- After 10 min, open the door, move gradually from the doorway picking up the mosquitoes by forceps in a container. A torch may be needed for collection of mosquitoes in rooms.

Mosquito Control

Anti-adult measures and anti-larval measures are the two most important mosquito control measures. Personal protection against their bites aids these measures in control of disease. Methods related to environmental management by way of minor manipulations or major engineering steps should always be an important consideration in overall anti-malaria plan. The details of these various mosquito control methods have already been presented in detail in an earlier chapter on principles of vector control and the readers are suggested to go through the details.

Anti-adult Measures

(a) Residual Insecticides : Indoor residual spray is considered to be the most important tool for controlling mosquito borne diseases. This is a more practicable and simpler method of interruption of transmission of disease. However, there are certain conditions under which the absolute efficacy of this procedure may be doubted, for instance, where vector is exophilic though biting indoors or where the surfaces sprayed are subject to frequent mud plastering or white washing. Even when local conditions do not appear to be absolutely favourable, the application of residual insecticide gives relative success in disease control. DDT, Malathion and the members of synthetic pyrethroids like Cyfluthrin, Deltamethrin etc. are the residual insecticides of choice depending upon the susceptibility of the vectors. The dosages and formulations of common adulticides used in mosquito control are given in Appendix 'C'.

(b) Space Sprays : Space treatments are usually designed to provide rapid knock-down and mortality with little or no residual effect. Such treatments must be considered in conjunction with other control methods as part of an integrated vector management programme. The details of space spraying and other adult measures are given in the Chapter on "Principles of Vector Control".

Anti-larval Measures

Larval control is the only effective method of radical mosquito control. In urban areas, this method complements the adult mosquito control. Anti-larval work is carried out by preventing breeding and destruction of larvae and pupae. For long term and permanent mosquito control, greater emphasis should be placed on the prevention of breeding during non-transmission season than on larvicidal measures during breeding season.

(a) Vector Engineering : Avoidance of man-made mosquitogenic conditions is of primary importance. The details are presented in the Chapter on "Principles of Vector Control".

(b) Dry Day : Intermittent drying once a week is an effective method of prevention of breeding especially for container breeders like *Aedes* by observance of a weekly 'dry day'. All fire fighting tanks, ornamental ponds or water storage tanks, fire buckets, and all domestic water containers should be emptied, scrubbed and allowed to remain dry for a few hours on the weekly 'dry day'.

(c) Larvicidal Measures : Destruction of larvae is achieved by application of larvicidal oils, Organophosphorus insecticides, use of IGR's, biocides and use of larvivorous fish. The details are presented in the Chapter on "Principles of Vector Control".

The list of anti-larval chemicals along with their dosages is presented in Appendix 'D'.

Personal Protection

Individual personal protection against mosquito bites is achieved by use of mosquito nets, repellents and protective clothing. The details are presented in the Chapter on "Principles of Vector Control".

Summary

The mosquitoes are rated as the most important vectors amongst the blood sucking arthropods. They belong to phylum Arthropoda, class Insecta, order Diptera & family Culicidae. Amongst the mosquito genera, only *Anopheles*, *Culex*, *Aedes* and *Mansonia* are of importance in India. The mosquitoes are further classified as Anophelines which comprises only genus *Anopheles* & Culicine comprising three important genera viz. *Culex*, *Aedes* & *Mansonia*.

The length of the mosquito is about 1 cm and the body is divided into head, thorax & abdomen. Head has two compound eyes, antennae & mouth parts collectively called proboscis. Males can be identified by their densely haired antennae which look like moustache. Thorax in all the three genera of Culicines is humped. Mosquito undergoes complete metamorphosis through stages of egg larva, pupa & adult. Numbers of eggs laid vary between 50 & 150. Larvae pass through 4 instars in 5 days and become a pupa. Duration of lifecycle varies between 7 days to 1 month. Female mosquitoes are blood suckers (anthropophilic - prefer to feed on humans & zoophilic- prefer to feed on animals). Mosquitoes as per their biting habits may either be exophagus or endophagus and depending on their resting preference may be endophilic or exophilic. Males feed on plant juices & flower nectar.

The genus *Anopheles* comprises 58 species in India, of which 9 are vector species with most of them being anthropophilic. *Culex* adults are dull in colour & have unspotted wings and prefer stagnant water. *Culex quinquefasciatus* is the main vector of bancroftian filariasis in India. Chief species of *Aedes* in India are *aegypti*, *albopictus* & *vittatus*. They are well adapted for breeding in small containers of water such as masonry tanks, earthenware pots, small and large tins, barrel drums, coconut shells, stored or discarded motor car tyres, junk and hardware, flower pots, fire buckets, depressions in tree trunks, axils of leaves & tree holes. *Aedes* mosquitoes are the vectors of urban and rural yellow fever (not found in India), dengue, dengue haemorrhagic fever and chikungunya. *Mansonia* species lay eggs in cluster anchored to the under surface of the leaves of aquatic plants.

Mosquito surveillance is done to elicit information on vector density and major characteristics of vectors, to forecast an impending outbreak and to recommend appropriate strategies for mosquito control which would prevent outbreak. It is thus important to identify mosquitoes from other such flies; they are identified by the presence of forward projecting mouthparts or proboscis and wing venation (veins 2, 4 and 5 are branched) besides other characteristics. If the wings are spotted, it is generally anopheline mosquitoes; whereas, if the legs are having silvery stripes against dark black legs, it is *Aedes*

and if there are no spots on the wings or stripes on legs, it is *Culex* adult. If larvae have siphon tube at its abdominal end, it belongs to Culicine group. Larvae are sampled using standard larval ladders & larval density is calculated by dividing the total no. of larvae by the no. of dips. Adult sampling is generally done using aspirators & suction tube. The mosquito density is calculated by Total no. of mosquitoes collected divided by the man hours spent in collection. Other methods are spray sheet collection & use of window trap, magoon trap or direct bait collection. *Aedes* larval surveys include computing indices viz. Container, House & Breteau index. The adult sampling procedures are the landing catch and resting catch, whereas breeding can be detected by oviposition traps.

Study Exercises

MCQs & Exercises

- Wings in mosquito are attached to (a) Thorax (b) Abdomen (c) Both (d) None
- Branched veins in a mosquito wing are (a) 1,3,6 (b) 2,4,5 (c) 2,4 (d) 1,6.
- Eggs are laid in rafts in (a) *Aedes* (b) *Culex* (c) *Anopheles* (d) *Mansonia*.
- Boat shaped eggs with lateral floats and larva without siphon tubes are features of (a) *Anopheles* (b) *Aedes* (c) *Culex* (d) *Mansonia*.

Fill in the Blanks :

- _____ is the main rural vector of Malaria.
- Respiratory apparatus in larvae of Culicine is _____

- Most important vector of *Wuchereria bancrofti* is _____
- Vector species can be distinguished by their thoracic pattern in _____

True or false

- Mosquitoes can be found in altitudes as high as 4000mts.
- The palpi & proboscis in *Culex* female are equal.

Answers : (1) a; (2) b; (3) b; (4) a; (5) *Anopheles culicifacies*; (6) Siphon tube; (7) *Culex quinquefasciatus*; (8) *Aedes*; (9) True; (10) False.

Appendix 'D' : Insecticides Used for Mosquito Larval Control					
Insecticide	Dilution rate	Dosage /sq m	Area in linear metre to be sprayed by 10 lit of solution/ suspension	Frequency of application	Remarks
MLO	As it is	20 ml	500	Weekly	Applied along shore of water body
Temephos 50% EC	2.5 ml in 10 lit for water depth up to 50 cm. 5 ml in 10 lit for >50 cm depth	20 ml	500	Weekly	Applied in all water bodies
Fenthion 82.5% EC	5 ml in 10 lit for water depth up to 50 cm. 25 ml in 10 lit for >50 cm depth	20 ml	500	Weekly	Not used in potable water
Fenthion 2G	-				Not used in potable water
<i>Bacillus thuringiensis</i> H -14 (12 AS)	250 g in 10 lit	20 ml	500	Fortnightly	Not used in potable water
<i>Bacillus sphaericus</i>	500 g in 10 lit	20 ml	500	Once in three weeks	Not used in potable water

158 Fleas

Rina Tilak

Fleas are one of the few important vectors which have been historically linked with mankind the world over, since time immemorial. Plague, transmitted by rat flea, was one of the vector borne diseases which played an important role in redefining geographical boundaries for many centuries.

Distribution

Fleas are distributed all over the world and belong to the order Siphonaptera comprising about twenty five hundred species

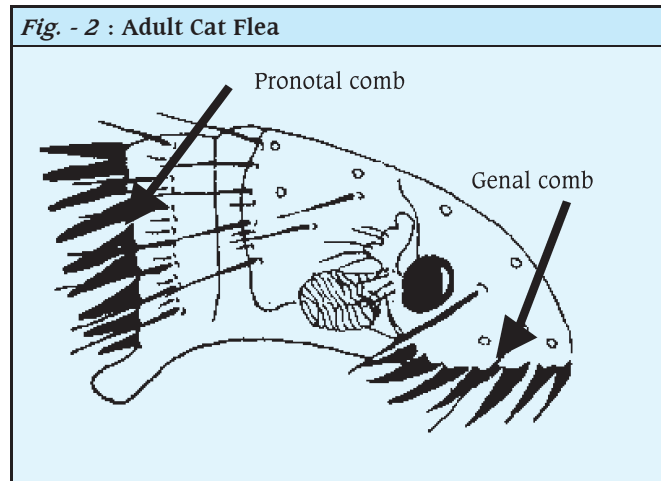

and sub-species. Fleas can be classified into two main groups viz. the 'comblless' fleas and the 'combed' fleas, depending on whether they have chitinsed teeth like structure called 'genal comb' around the mouth, or not.

The Comblless fleas contain the important genus *Xenopsylla* which has about sixty species and sub-species including the well known vectors of plague viz, *X cheopis*, *X astia* and *X braziliensis*. The oriental rat flea (Fig. - 1), *X cheopis*, is widely distributed in the tropics and is the principal vector of plague in India. *X astia* is also found in India, Burma, Sri Lanka, Hongkong and Iran. *X braziliensis* is found in Africa, especially in Nigeria, Congo, Kenya and in South America but in India its distribution is very restricted. The other important comblless flea is *Pulex irritans* (Human flea), which occurs only in the

hills of the tropical countries of the Eastern Hemisphere. It breeds in and around dwellings and principally attacks man besides animals and rats.

The Combed fleas are the cat fleas - *Ctenocephalides felis* (Fig. - 2), the dog flea - *C. canis* and the rat fleas of temperate zones, *Nosopsyllus fasciatus*. In addition to the genal comb, they also possess 'pronotal comb' on the thorax (Fig. - 2). These fleas serve as intermediate host of certain veterinary cestodes (dog-tapeworm) but are more of a biting nuisance to man. *Tunga penetrans*, a sandflea is found in tropical and sub-tropical regions of North and South Americas, Africa and occasionally in Western India.

Morphology

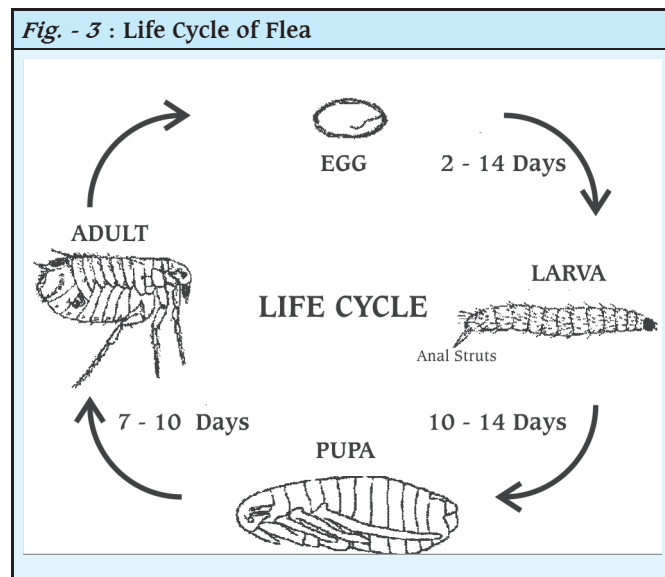

Adult fleas are small, bilaterally compressed, highly chitinised, wingless, 6 legged, blood sucking ectoparasites of many warm blooded vertebrates. The size varies from 1.5 to 6 mm in length and the colour from light amber to dark brown.

They have a compact appearance without a sharp division between the head, thorax and abdomen. The head is roughly triangular and bears a pair of three segmented antennae, the mouth parts and in certain flea species, a row of powerful teeth like spines collectively known as the 'genal comb', arranged on the lower border of the head, and a set of 'pronotal combs' on the thorax. However, the rat fleas are devoid of both these combs. The mouth parts are adapted for biting, piercing and

sucking blood, which forms the only food for both sexes. The thorax of the flea is compact without any wings. The legs are long and powerful and are adapted for the purpose of hopping and jumping. The abdomen consists of 10 segments, the 9th and 10th being modified for sexual functions. In the female, the abdomen has a rounded terminal outline whereas in the male it has a rather cocked up appearance. The body and the legs are provided with stiff setae, which give the insect a bristly appearance. The tapering pharynx continues into the oesophagus leading into the conical proventriculus. This is an important structure involved in the transmission of bubonic plague.

Life History

The flea undergoes a complete metamorphosis through the successive stages of egg, larva, pupa and adult (Fig. - 3). When the female is ready to lay eggs, it leaves the body of the vertebrate host and lays eggs in dark place in the host's nest, debris, accumulation of dust, in cracks or crevices in the floor of granaries etc. or under carpets in houses. During her lifetime of 6 months or a year, the female lays 300 to 500 eggs in small batches of about a dozen at a time. A temperature between 18°C and 27°C and humidity about 70% favour egg laying. However, most fleas complete their life cycle in one to two months. The eggs are just visible to the naked eye and hatch in 2-10 days depending on temperature and humidity. The larvae are very active, slender, 13 segmented and yellowish white with a number of bristles. They feed on the excreta of rodents and on partially digested blood discharged from the faeces of adult fleas. Larvae complete their development in a week or two and enter quiescent stage, spin cocoons which are whitish, translucent and so loosely spun that the pupae can be seen within them. Hence the pupa closely resembles the adult which usually emerges within a week. It is important to note that presence of ground vibration (caused by movement of hosts i.e. rodents, animals, humans or earthquakes) is essential for the emergence of adult from the pupa. The whole metamorphosis takes two to four weeks, but may need several months under less favourable conditions.

Bionomics

The adult fleas are temporarily parasitic on their host while their immature forms are free living. Both, males and females are haematophagous and frequently leave the host between blood feeds. After the death of the host, its body becomes cold and the flea seeks a new host. Fleas feed frequently and much more than their actual requirements, and as a result much of the ingested blood is passed out in a semi-digested state. Fleas are not strictly host specific and may attack unusual hosts when hungry or with rise of ambient temperature, when they feed more frequently. They are very sensitive to light and air currents. They always hide under dark objects and when blown up, they at once get agitated. Adult fleas can survive several months without food. They are able to jump up to 16 cm and hop 30 cm.

Vector Potential

Flea transmits mainly the zoonoses to man, chiefly from rodents and also from dogs and cat. The most important microorganism that is conveyed to man from rat is *Yersinia pestis* causing bubonic plague. The most important vector species is *X cheopis*, however, *X astia* and *X braziliensis* are also effective vectors. *Rickettsia typhi*, causative organism of endemic (murine) typhus, is also transmitted from its rodent reservoir to man by the same rat fleas. Cat and dog tapeworms use fleas as their intermediate hosts for the development of cysticercoid stages. Cats and dogs become infested by the ingestion of infested fleas. Children also get infected similarly due to accidental ingestion of the infested fleas. The South American and African flea *Tunga penetrans* burrows under the soft skin in between toes and under the nail bed and causes a disease called 'chigger', 'jigger' or 'chigoe' in endemic areas.

Modes of Transmission of Diseases

Bubonic plague is transmitted by infected fleas called 'Blocked flea'. When a flea (*Xenopsylla* species) feeds on a host suffering from plague, it ingests plague bacilli (*Y pestis*) along with the blood meal. The blood is digested in the stomach, however, the bacilli rapidly multiply and block the proventriculus thereby rendering the proventriculus partially blocked and incapable of preventing regurgitation of stomach contents (the normal role or functioning of the proventriculus) while feeding. Since the stomach is filled with plague bacilli, the amount of blood digested is minimal and hence this flea feels hungrier and bites repeatedly and in the process, regurgitates plague bacilli in the wound thus causing plague in the host. After a few days, the multiplying plague bacilli completely block the proventriculus thus rendering it totally ineffective in preventing regurgitation. Since no amount of blood gets digested, this flea though bites repeatedly and inoculates the bite wound with bacilli, lives

for a very short duration. A partially blocked flea is thus more efficient in transmitting plague as compared to a completely blocked flea.

Endemic typhus is transmitted through the faeces of the rat flea which contains the semi digested blood along with the causative organism *R typhi*. The flea has a habit of defaecating while feeding and hence while scratching the bitten area; the organism finds its way in to the host's body. The organism can also find an entry into the body through conjunctiva, inhalation and skin abrasions and also by accidental ingestion of infected flea.

Flea Control

Chemical control of fleas is one of the best methods of flea control. These are effective against both adult as well as larval fleas. The areas or places generally frequented by fleas like rodent burrows and rat runs are treated. The insecticidal treatment is either done in the form of residual sprays, dusting or treatment of rodent burrows. Dusting is done by applying a patch of insecticide dust of about 20-25cm wide and 0.5cm thick in all infested areas. For rodent burrows, 30 g of insecticidal dust is used.

In plague susceptible areas, treatment is undertaken when flea index i.e. *X cheopis* index exceeds 1 (the other flea indices are presented in Box - 1). However, during an outbreak, no rodent control activity is undertaken. In the event of a plague case occurring, immediate treatment of the patients dwelling and of other dwellings within 200 m is undertaken.

(a) Vector Control : DDT has become non-effective against fleas in many parts of the world. Malathion resistance has also appeared in certain parts of India. Prior susceptibility tests should be carried out to find out the most effective insecticide. Indoor residual spraying at the lower one metre of the wall surface and adjacent floor area is effective. Patch dusting also brings about marked reduction in flea density. For this, dusts of Propoxur (1%), Malathion (5%) or Carbaryl (5%) may be applied at a dosage of 2 to 3 g per m² of surface area under grain bins, on rat runs, furniture, upholstery, rugs and bedding. The dust of Deltamethrin (0.05%) may also be used for dusting in rodent infested area.

(b) Disinfestation : Disinfestations of pet animals like dogs and cats along with good environmental sanitation of the household and public places (by keeping houses well swept and floors washed) help in flea control. Pet animals may be treated with dusts, sprays or dips of Malathion, Propoxur, Permethrin or Pyriproxyfen. Animal premises may be sprayed with insecticides (Malathion, Deltamethrin, Pyrethrum etc.) @ 4 - 8 l/100 m². Insecticidal treatment of animals and their premises should be carried out simultaneously. Lufenuron

Box - 1 : Flea Indices

- **General flea index** - Average number of fleas (all species included) per rodent. e.g. if, in all, 20 fleas were recovered from a total of 4 rodents examined, the index would be $20/4 = 5$.
- **Specific flea index** - (important is *X cheopis* index). This is same as general flea index but calculated exclusively for *X cheopis*. e.g. in above example, if a total of 2 of the 20 fleas were *X cheopis*, this index would be $2 / 4 = 0.5$
- **Percentage incidence of flea species** - This is the percentage of each species of fleas, out of the total fleas sampled per rodent.
- **Rodent infestation rate** - If 10 rodents were caught and 6 were infested with fleas, this index would be $6/10=60\%$

tablets are recent introduction in the armoury of flea control measures against cats and dogs; it is taken up by the female flea during feeding and acts by inhibiting egg development. A dose of 30 mg Lufenuron per Kg of body weight for cats & 10 mg/Kg of body weight for dogs is ideal for flea control. Details of insecticides used in flea control are shown in Table - 1.

Table - 1 : Flea control measures		
Insecticide	Concentration	Dilution
a) For Fleas :		
Propoxur 20%	1%	Mix 50 ml + 950 ml water
Malathion 50%	5%	Mix 100 ml + 900 ml water
Deltamethrin 2.5%	0.05%	Mix 20 ml + 980 ml water
b) For Animal treatment:		
Propoxur 1%	1% spray/dust	As it is
Malathion 50%	0.25% Dip	Mix 5ml in 1 l of water
Deltamethrin 0.0025%	0.0025% shampoo	As it is
Permethrin 1%	1% shampoo	As it is
c) For Premises :		
Pyrethrum 2% Extract	0.2%	Mix 100 ml + 900 ml water
Malathion 50%	2%	Mix 40 ml + 960 ml water
Chlorpyrifos 20%	0.5%	Mix 25 ml + 975 ml water

(c) Rodent Control : It is an indirect method of flea control. Though a radically effective method during non-epidemic period, it is dangerous during epidemics, because the fleas leave dead rats quickly and starts attacking human beings. However, a constantly sustained campaign keeps the rodent population down and aids significantly in keeping the flea index constantly low. In general, during control of urban plague, insecticides to kill rat fleas should be applied a few days earlier or at least at same time (and not after) when rat poison baits are being applied. The detail on rat poisons is presented in the chapter on rodents.

(d) Personal Protection : This is achieved by the use of protective clothing such as wearing long trousers, socks and shoes. Use of a high charpoy with the net, and application of repellents viz. DEET are necessary precautions while in endemic or epidemic areas of flea borne disease. Using flea collars for pets are effective means of keeping them free from infestation (for 3-4 months).

Summary

Fleas are important vectors, linked with mankind since long. Fleas can be classified into two main groups, 'combless' fleas and the 'combed' fleas. The combs can be genal comb arranged on the lower border of the head or pronotal combs on the thoax. *Xenopsylla* species are combless fleas and include the well

known vectors of plague viz, *X cheopis* (Rat flea), *X astia* and *X braziliensis*. The combed fleas are the cat fleas - *Ctenocephalides felis*, the dog flea, *C canis* and the rat fleas of temperate zones, *Nosopsyllus fasciatus*. Adult fleas are small, bilaterally compressed, highly chitinised, wingless, 6 legged, blood sucking ectoparasites of many warm blooded vertebrates. The mouth parts are adapted for biting, piercing and sucking blood, which forms the only food for both sexes. The flea undergoes a complete metamorphosis through the successive stages of egg, larva, pupa and adult. Eggs are laid in dark place in the host's nest, debris, accumulation of dust, in cracks or crevices in the floor of granaries etc. or under carpets in dwelling houses. A temperature of 18° and 27°C and humidity about 70% favour egg laying. The adult fleas are temporarily parasitic on their host while their immature forms are free living. Both males and females are haematophagous.

Flea transmits mainly the zoonoses to man, chiefly from rodents and also from dogs and cat. The most important microorganism that is conveyed to man from rat is *Yersinia pestis* causing bubonic plague. *Rickettsia typhi*, causative organism of endemic typhus, is also transmitted from its rodent reservoir to man by the same rat fleas. Bubonic plague is transmitted by infected fleas called 'Blocked flea'; Endemic typhus is transmitted through the faeces of the rat flea.

Chemical control of fleas is one of the best methods of flea control effective against both adults & larvae. The insecticidal treatment is either done in the form of residual sprays, dusting or treatment of rodent burrows. In Plague susceptible areas, control is undertaken when flea index i.e. *X cheopis* index (the average number of fleas per rodent) exceeds 1. However, during an outbreak, no rodent control activity is undertaken. Flea control can be achieved by Indoor Residual Spraying using Propoxur (1%), Malathion (5%) or Carbaryl (5%). Disinfestation of pet animals like dogs and cats and use of flea collar, along with good environmental sanitation of the household and public places helps in flea control. Use of a high charpoy, insecticide treated nets and application of repellents viz. DEET are necessary precautions while in endemic or epidemic areas of flea borne disease.

Study Exercises

Short Notes : (1) Blocked Flea (2) Flea Index.

MCQs

- Combed flea is (a) *Xenopsylla cheopis* (b) *Xenopsylla astia* (c) *Pulex irritans* (d) *Ctenocephalides felis*.
- Flea transmits all except (a) Bubonic Plague (b) Endemic typhus (c) Epidemic typhus (d) Chiggerosis.
- The insecticides that can be used for flea control are (a) Propoxur (b) Malathion (c) Deltamethrin (d) All.

Fill in the Blanks

- The Rat flea lives for a duration of _____
- Average no. of fleas per rodent gives the _____

True or false

- Presence of ground vibration (caused by movement of hosts i.e. rodents, animals, humans or earthquakes) is essential for the emergence of adult from the pupa.
- A partially blocked flea is more efficient in transmitting plague as compared to a completely blocked flea.

Answers : (1) d; (2) c; (3) d (4) 06 months to 01 year; (5) Flea Index; (6) True; (7) True.

Human Lice

Rina Tilak

Human lice are true ecto-parasites of man. There are three species of human lice viz. *Pediculus capitis* (head louse), *Pediculus humanus* (body louse) and *Phthirus pubis* (crab or pubic louse). Adults (both female & male) as well as nymphs are haematophagous, however, only body louse has been incriminated as vector.

The head louse infests the hair on the head and may be found in the neck region and behind the ears. The body louse infests the hairs of chest and axilla, seams of clothing in contact with the body and sometimes linen. The crab louse infests the hair of the pubic region and occasionally invades eyelashes and eyebrows.

Morphology

Lice are small (4.5mm), dorso-ventrally flattened, wingless insects with simple metamorphosis. They are permanent obligatory ecto-parasites living entirely on mammals. The mouthparts are of a sucking and piercing type. They have no eyes. The legs are short, stout, and thick with claws for grasping hairs and fibres. The abdomen is oval or somewhat circular in shape. In the females, the last abdominal segment

is bilobed while in the male, it is pointed from which the aedeagus (penis) projects. *Phthirus* resembles *Pediculus* in its general morphology, but its body is almost circular, all the three pairs of legs of *Pediculus* are equal whereas in *Phthirus*, the first pair is less developed. *P capitis* has a smaller and deeply pigmented body, while that of *P humanus* is larger and non-pigmented. Abdominal segments of *P humanus* are rounded with shallower inter segmental indentations while those of *P capitis* are clearly marked and deeper. Antennae and legs of *P humanus* are longer and thinner than those of *P capitis* (Fig. - 1 & 2).

Life History

The life histories of all the three varieties are similar (Fig. - 3). After fertilization, the female lays eggs either on the hairs or under clothing chiefly along the seams of the vests, pants and shirts etc. Freshly laid eggs are white and proportionally large for the size of the insect. They are firmly cemented to the hair or seams of the clothing, singly or in groups. As the embryos develop they become yellowish. The number of eggs laid depends upon the food supply and the temperature. Under optimum favourable conditions, the louse lays 4 to 9 eggs in each batch. Total number of eggs laid during the life span of 4 to 5 weeks may be 300 in a body louse, 150 in a head louse and 50 in a crab louse. Within a weeks time, the immature stages called nymph emerge and begin sucking blood at once and throughout their development feed frequently during the

Fig. - 1 : Head Louse

Fig. - 2 : Body Louse

day and night, mostly when the host is quiet. There are three nymphal stages and the young ones resemble the adults except in size. It takes about 21 days between hatching of the eggs and appearance of the adults.

Bionomics

Lice prefer warm and moist environments; 38°C is the optimum temperature. Higher temperature and death of the host are detrimental and make lice leave the body of the host. The average life of a louse is 30 to 50 days. Females live longer than the males.

Once lice are acquired by a human host, their multiplication depends on the neglect of personal hygiene. Following factors are responsible for the dissemination of lice.

- Close contact with lousy persons; sharing the same bed and clothing etc. In fact any prolonged crowding of human beings in unsanitary surroundings will spread lousiness. Hence lice and louse borne diseases are closely associated with wars and disasters among prisoners and refugees.
- Indirect contact - for example exchange of beddings, clothing, blankets, towels, hats, combs and brushes.
- Hair bearing eggs from lousy persons scattered in public conveyance are picked up from the seats and cushions of railway carriages and buses etc.
- Head lice easily pass from one child to another in school by close contact while playing and also by sharing of combs.
- The pubic or crab lice spread through sexual contact and sometimes from toilet seats, beds and by close personal contact. Small children may become infested with crab lice on their eyebrows and eyelashes from their mothers or other close contact.

Vector Potential

Body lice are responsible for the transmission of *Rickettsia prowazeki*, causing Epidemic typhus, *Bartonella quintana* causing Trench fever, and *Borrelia recurrentis* causing Relapsing fever. The presence of lice on any part of the body is termed '*pediculosis*' which causes irritation with loss of sleep and scratching which may lead to secondary infections. Toxic reactions to the saliva injected into the skin may lead to weariness and a general feeling of illness. The skin of a heavily louse infested person becomes hardened and deeply pigmented and results in a condition known as '*Vagabonds*' disease or melanoderma.

Prevention and Control

Regular washing of hair with soap and warm water and combing with lice comb may prevent/reduce head lice infestation. Similarly, regular washing of clothes with hot water (more than 60°C) and ironing and changing of clothes prevents body louse infestations.

In the past, use of anti louse powder (10% DDT) was used for reduction of infestation in a controlled community by dusting the lousy individuals and garments. Currently, the insecticides of choice are Permethrin dust (0.5%), Propoxur dust (1.0%); for mass treatments against body louse, dusts should be applied through neck openings, up sleeves and from all sides of the loosened waist of trousers. Socks, head coverings, the inner surfaces of extra garments and bedding should also be treated. Treatment of clothing with synthetic pyrethroid or use of pretreated uniforms may prove an effective means of prevention of body lice infestation amongst Armed Forces personnel during war.

Shampoo formulations like Phenothrin (0.2-0.4%), Permethrin (1%) and Malathion (5%) lotion are ideally used for head lice infestation. For application on hair, the hair of the infested persons should be wetted thoroughly before application. The insecticidal shampoo is thoroughly massaged on the head and left for minimum 10 min. Thereafter, the shampoo is rinsed off from the hair, hair is towel dried and combed with lice comb to remove dead/ stunned lice.

Summary

Human lice are true ecto-parasites of man. There are three species of human lice viz. *Pediculus capitis* (head lice), *Pediculus humanus* (body louse) and *Phthirus pubis* (crab or pubic). They are obligatory ecto-parasites living entirely on mammals. After fertilization, the female lays eggs either on the hairs or under clothing chiefly along the seams of the vests, pants and shirts etc. The number of eggs laid depends upon the food supply and the temperature (38°C). It takes about 18 days between hatching of the eggs and appearance of the adults. Dissemination of lice occurs with close contact, in unsanitary surroundings, exchange of beddings, hats, comb & brushes. Transmission occurs through public conveyance, in school & through sexual contact.

Body lice are responsible for the transmission of *Rickettsia prowazeki*, causing Epidemic typhus, *Bartonella quintana* causing Trench fever, and *Borrelia recurrentis* causing Relapsing fever. Insecticides of choice are Permethrin dust (0.5%), Propoxur

dust (1.0%) and insecticide treated uniforms for body louse and shampoo formulations like Phenothrin (0.2-0.4%), Permethrin (1%) and Malathion (5%) for head lice infestation.

Study Exercises

MCQs & Exercises

- 1) Lice cause all of the following except (a) Epidemic Typhus (b) Trench fever (c) Relapsing fever (d) Endemic Typhus
- 2) Body louse infests (a) Hair on chest & axilla (b) Seams of clothing (c) Linen (d) All

Fill in the Blanks :

- 3) Presence of lice on any part of the body is called as _____
- 4) Dust application through neck openings, up sleeves & trousers is used for _____ against _____ louse.

Answers : (1) d; (2) d; (3) Pediculosis; (4) Mass treatment, body.

Sand Flies

Rina Tilak

Sand-flies bite humans and transmit diseases to them. There are about 700 species of sand-flies of which only 70 species have been incriminated as vectors so far. The sand-flies belong to the subfamily Phlebotominae of the family Psychodidae. The haematophagous species belong to the three genera of *Phlebotomus*, *Lutzomyia* and *Sergentomyia*, the former two being more important as vectors of diseases. The medically important *Phlebotomus* vector species in India include *P argentipes*, *P papatasi*, *P sergenti* and *P braziliensis*.

Morphology

The adult sand-fly is a small, greyish yellow to brown insect and about 1.5 to 4.0 mm in size. The insect is typically characterized by large conspicuous eyes and stilt like legs. The entire body is densely covered with hair. The antennae are long filamentous and give a beaded appearance. The mouth parts are very short and are adapted for biting and piercing in the females. The thorax is markedly humped and bears a pair of lanceolate wings which are held erect over the body when the fly is at rest. The wings are densely hairy and the second vein branches twice, the first branching in the centre of the wing and second at the margin. Legs are long, slender and used for hopping as sand-flies are poor fliers. The abdomen consists of 10 segments; the last two are modified for sexual functions. The abdomen of a female is rounded posteriorly; in the males, it is modified and bears claspers (Fig. - 1).

Life History

The sand-flies prefer to breed in dark places rich in organic matter and moisture. Sand-flies lay torpedo shaped eggs in small batches which hatch out in one or two weeks under optimum

favourable conditions. The larvae are legless and whitish with a dark head capsule and pass through four instars. The larvae feed on organic excrement of lizards and mammals and other decaying material. Its life span is from 2 to 6 weeks, depending on the temperature and humidity. The larva bears two anal spines. The pupa is golden brown in colour and naked and requires about 10 days for development after which the adult emerges. Male sand flies emerge about 24 h before females, for their external genitalia to rotate 180° for achieving the correct position for mating before the females have emerged. The total period required from egg to the adult stage is about 4 weeks under favourable conditions. In the tropics, the breeding goes on throughout the year. In north India, they appear about the middle of March and persist until November, with their maximum density in March and April.

Bionomics

The sandflies live entirely on plant juices or similar fluids from other available sources but the females need a blood meal in order to develop eggs. Phlebotomines are crepuscular or nocturnal biters and most of the biting occurs outdoors with only a few species feeding indoors. The adults are weak fliers and generally confine themselves up to 50 yd from their breeding place and are not found resting beyond 3 ft on the wall. After fertilization and a blood meal, the female lays eggs in shady, damp and warm places with sufficient supply of organic matter such as insect remnants and faeces and excrements of tiny animals which form the future larval food. Such conditions are found under stones, in stables and poultry houses, around soakage pits, grease traps and water sinks, in hollowed trees and rodent burrows, bases of walls and embankments. Large population of sandflies can build up in dwellings where cattle are kept at night; the cattle provide an abundant source of blood, while the stables and houses provide suitable resting place.

Vector Potential

Sand-flies are responsible for the transmission of various species of *Leishmania* causing Kala-azar or Visceral leishmaniasis, Oriental sore or Cutaneous leishmaniasis, and Espundia or Mucocutaneous leishmaniasis (naso-oral). Sand-flies also transmit the virus of sand-fly fever, also known as papatasi or Phlebotomus fever or 3 day fever and the re-emerging viral disease - Chandipura disease. It also transmits *Bartonella bacilliformis* or Oraya fever also known as Bartonellosis or Carrion's disease. In addition, the sand-flies have biting nuisance causing skin reactions (Herara) in sensitized persons.

Phlebotomus Control

(a) Prevention of Breeding : This is primarily achieved by good environmental tidiness. Places providing humidity, darkness and organic matter should be dealt with by removing all collections of rubble and heaps of rubbish; obliterating all cracks and fissures in the floors of the buildings and indoor constructions, sides of culverts, gutters, *nullahs*, cattle sheds and poultry houses which are common breeding places for sand-flies. Cracks and holes in the walls up to a metre from the ground should be sealed by plastering and the earthen floor of cattle sheds should be rammed down and made hard to make

it difficult for the larvae to burrow. Empty buildings should be kept in good repairs; soak pits and grease traps should be well maintained.

(b) Anti-larval Measures : Anti larval measures are generally difficult to undertake as identification of larval breeding sites is difficult. Even if insecticidal control is planned, it has been found to be of little importance in the control of sand-flies.

(c) Anti-adult Measures : Anti adult measures are based on the principle that sand-flies make short flights with relatively long pauses on entering or leaving any place or shelter. Therefore, any surface treated with residual insecticide on which the flies rest will have a lethal impact. The anti adult measures are the same as followed under the National Programme for Indoor residual spraying against mosquitoes; this strategy has proved to have a dramatic impact on the density of sand-flies in the area. If outdoor resting sites have been identified, they can also be sprayed with residual insecticides. Outdoor fogging may provide additional benefit in reduction of Sand-fly density.

(d) Personal Protection : Use of repellents viz. DEET is one of the most efficient methods of preventing bites from sand-flies; the repellents may be applied topically or sprayed on clothes. A sand-fly net is useful, but it reduces air movements and causes great discomfort. Use of insecticide treated mosquito nets has been found very effective in protecting against bites of sand-flies. Personal protection may also be achieved by barrier clothing.

(e) Other Measures: These include encouragement of gardening (cultivation of ground) and planning of embankments with native aromatic plants. Free cross ventilation and ingress of sunlight keeps the sand-fly out of habitations or animal sheds. Electric fans are useful as the air current drives them away. Electric light shades smeared with Vaseline, traps a large number of sand-flies. Siting of human habitation beyond 50 yards of the breeding place is an effective method of preventing transmission of sand-fly borne diseases as also sleeping on cots.

(f) Treatment of Animals: Earlier practice of culling of dogs or killing of rodents is no more undertaken. Dogs are treated by dipping in insecticide solution (Deltamethrin 50 ppm) or applying insecticide solution (1-2 ml of 65% Permethrin or Imidacloprid 10%). Even insecticide treated dog collars and treatment of non-reservoir animals reduces transmission of Leishmaniasis.

Summary

Sand-flies belong to the subfamily Phlebotominae, bite humans and transmit diseases to them. The medically important vector species in India include *P argentipes*, *P papatasi*, *P sergenti* and *P braziliensis*. The adult sand-fly is a small, greyish yellow to brown insect about 1.5 to 4.0 mm in size; body is densely covered with hair. Sandflies possess a pair of lanceolate wings. The wings are densely hairy and the second vein branches twice. Sand-flies prefer to breed in dark places rich in organic matter and moisture. Females have piercing mouth parts and are blood suckers. The males live entirely on plant juices or similar fluids from other available sources. After fertilization

and a blood meal, the female lays eggs in shady, damp and warm places with sufficient supply of organic matter such as insect remnants and faeces.

Prevention of breeding is achieved by good environmental tidiness. All collections of rubbish should be removed from places providing humidity, darkness and organic matter. Cracks and holes should be sealed. Earthen floor of cattle sheds should be rammed down and made hard to make it difficult for the larvae to burrow. The anti adult measures are the same as followed under the National Programme for Indoor residual spraying against mosquitoes. Use of repellents like DEET is one of the most efficient methods of preventing bites from sandflies. Other methods like treated nets or barrier clothing may be used. Free cross ventilation and ingress of sunlight keeps the sandflies out of habitations or animal sheds.

Some Annoying Pests

Rina Tilak

Simulium Flies

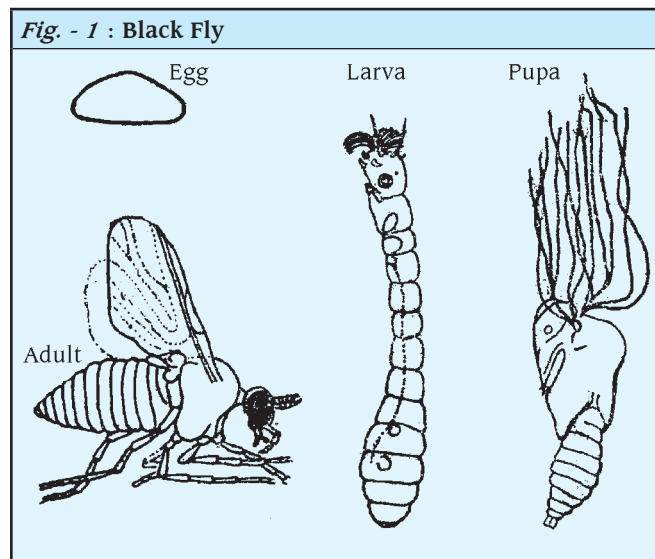

Simulium flies are commonly known as Black flies. They have a world wide distribution. They belong to the family Simuliidae, which contains over 1800 species; however, the important genera are only four which bite humans and out of these four genera, Simulium is the most important. The members of this family are found from sea level to a height of 2000 m. In India, these have been reported from Kumaon Hills, Himachal Pradesh, Kashmir, Assam, Arunachal Pradesh, Manipur, Nagaland, Bengal, Bihar, Maharashtra, Tamil Nadu and Nilgiri Hills. In Arunachal Pradesh, they are known as Dimdam flies.

Life History

The adults are small; stout bodied with a humped thorax and blood sucking flies varying in length from 1 to 5 mm. The colour varies from dark amber to bright yellow to orange. The name "black fly" is therefore, a misnomer.

Simulium flies breed in fast flowing turbulent mountain streams and torrents because they require well aerated water. A female lives for 2 to 3 months and lays several batches of eggs under the rocks, stones, vegetation or debris submerged just below the water surface (Fig. - 1). Eggs hatch in one to two days; in temperate zones the hatching period may be one week. The larvae are attached to submerged objects with their heads downstream. They feed on microscopic animals and plants and do not swim. The larva undergoes six moults in about 10 to 14 days in the tropics and 3 to 4 weeks in temperate regions.

The silken pupa is also firmly anchored to the substratum. The pupal stage may extend from 4 to 5 days to 2 to 3 weeks. The imago emerges from the submerged pupal case and comes on to the water surface where it rests for a while and after sometime starts flying. In the tropics and subtropics breeding is continuous throughout the year. The life span of the adult is about three months.

Bionomics

Simulids are strong fliers. Their normal flight range is about 4 to 5 km. Flights up to 20 to 40 km with favourable wind are not unusual. Both male and female Simulids feed on plant juices, nectar and pollens of flowers; the females however,

require blood meal for development of eggs and are voracious and persistent biters. They may enter through any opening in the clothing such as sleeves or through the lower opening of trousers for biting. They bite only by day in the open and are especially active on bright sunny days and retire at night to the neighbouring vegetation where the females mature their eggs.

Vector Potential

Several species of simuliids are known vectors of Onchocerciasis, a filarial disease due to *Onchocerca volvulus* occurring in tropical Africa, Central America and Venezuela, where *S damnosum*, *S metallicum* and *S neavei* are the vectors. In India, Simuliids however, are not vectors of any known human disease. But the very annoying and persistent attacks in large numbers make working in the open virtually impossible. The immediate trauma caused by its bite produces a red haemorrhagic spot leading to papule formation. In certain cases, it may lead to secondary infections and ulcers like 'ulcus tropicum.' In sensitized persons, allergic reactions like lymphangitis, lymphadenitis, rhinitis and fever may occur. Their bites are responsible for loss of livestock.

Control Measures

Control of the biting flies has been achieved by use of larvicides and aerosol treatment. In the Onchocerciasis control programme in Africa, Temephos 200 g/l emulsion has been used as a larvicide with good results. BTI has also been used @ 0.54 - 0.72 l/m² with great success. Aerosols and fogs produced by fogging machines are useful in killing adult flies. Clearing of vegetation around the perimeter also reduces Dimdam fly nuisance. Other compounds like Permethrin and Etofenprox have also been evaluated and found effective. Use of protective clothing will prevent the flies from ascending up the sleeves and trousers or entering into the shirt front. Socks should be pulled over the bottom of trousers. Additional protection may be obtained by treating the clothing and the exposed parts of the body with any of the repellents such as Dibutyl phthalate (DBP), Diethyl toluamide (DEET) or Diethyl phenyl acetamide (DEPA).

Bugs

Bugs (Order Hemiptera) have been associated with man since antiquity. They have a world wide distribution and consist of two important families viz. Cimicidae and Reduviidae. Family Cimicidae includes the 'bed bugs', *Cimex lectularius* of temperate regions and *C rotundatus* or *C hemipterus* of the tropics. Family Reduviidae includes the cone nose *Triatomine* bugs, also known as 'kissing' or Assassin bugs. In India, bedbugs have a great nuisance value.

Morphology

Bed bugs are small, 5 to 6 mm long, dorso-ventrally flattened, wingless, dark brown insects with a mahogany tint (Fig. - 2). They have a very short and broad head attached to the thorax. The head bears antennae and a pair of well developed eyes. On either side of the thorax, the stink-glands are situated which give off the nasty, pungent or offensive odour associated with this group.

Fig. - 2 : Bed Bug - Adult

Life History

A bed bug passes through egg stage and 4 nymphal stages. The fertilized females lay flask shaped, operculated eggs singly in hidden sites, such as cracks and crevices in the walls and floorings, spaces in the wood work of furniture, behind pictures, mattresses, pillows etc. A female lays 2 to 10 eggs a day with a total up to 200 to 300 in her life time of 6 to 8 months. The eggs usually take 5 to 10 days to hatch. The nymph starts feeding within an hour or two after emergence and continues to feed intermittently in all the further stages of development. There are four nymphal stages, each lasting 6 to 7 days; at the end of each, a skin is cast off. It takes 4 to 6 weeks for the development from egg stage to adult.

Bionomics

Adults can subsist without food for months under favourable conditions. Bugs are disseminated through travelling bags, laundry, furniture, bedding, old charpoys, soiled clothing, infested household goods, public conveyance and public places. Bed bugs like lice have been companions of man for centuries. Hiding in cracks and crevices during the day, they become active during the night and come out of their hiding places to feed on hosts and engorge completely in 3-6 min. They may travel long distances for sucking blood. They are gregarious, occurring in great assemblages. All stages are parasitic and thrive on human blood.

Medical Importance

Bedbugs have all along been suspected for the transmission of various diseases but so far have not been incriminated for any human disease. They are of public health importance primarily for their biting nuisance and demoralizing effect as their infestation may cause insomnia and pruritis / dermatitis.

Prevention and Control

The first and foremost principle for the prevention of bedbug infestation is to maintain a very high standard of hygiene. All furnitures and belongings of new occupants should be thoroughly checked for the presence of bed bugs and immediate measures taken to prevent their multiplication by one of the appropriate insecticides. Residual insecticides applied directly into the hiding places control the bedbugs. Solution of Malathion @2% or Chlorpyrifos @0.5% may be used. Disinfestations of blankets, beddings, mattresses and mosquito nets may be carried out by subjecting them to heat at or above 70°C. Synthetic pyrethroids like Bifenthrin (0.096%), Permethrin (0.125%), Cyfluthrin (0.04%) and Deltamethrin (0.03%) can also be used to achieve optimum results. Residual insecticidal spraying for malaria control undertaken systematically and methodically will also help in reducing the density of bed bugs as a collateral benefit. Insecticide treated bed-nets will also help in reducing the menace of bed bugs.

Debugging : The bed (Bed stand) need not be inclined against the wall nor the coir netting loosened. The cots should be thoroughly treated on all sides with insecticidal spray. All cracks and crevices should be fully flooded. The chairs, tables and other items of furniture may be similarly treated. The insecticide formulation may also be directly applied to the hiding places such as joints, cracks and crevices in the cots/chairs/tables and folds or creases in the mattresses and other items of beddings.

Slow drip technique involving the use of the common two inches thick paint brush for treatment of the infested cots and other items of furniture is reportedly superior as compared to the routine method of spraying with compression sprayer. In this technique, the ready to use solution of insecticide in water is taken in a plastic mug of one litre capacity, a paint brush is dipped in the solution, and the solution so lifted is slowly drained into the cracks and crevices as well as the joint spaces from different directions. The process is repeated by turning the cot upside down so that all such hiding places are thoroughly flooded with insecticide.

Cockroaches

One of the most annoying pests encountered in an urban area are the Cockroaches. The common domestic species which infest buildings are *Blatella germanica*, the German roach; *Periplaneta americana*, the American roach and *Blatta orientalis*, the Oriental roach (Fig. - 3). The German cockroach, although a native of Europe, is the most widely distributed species.

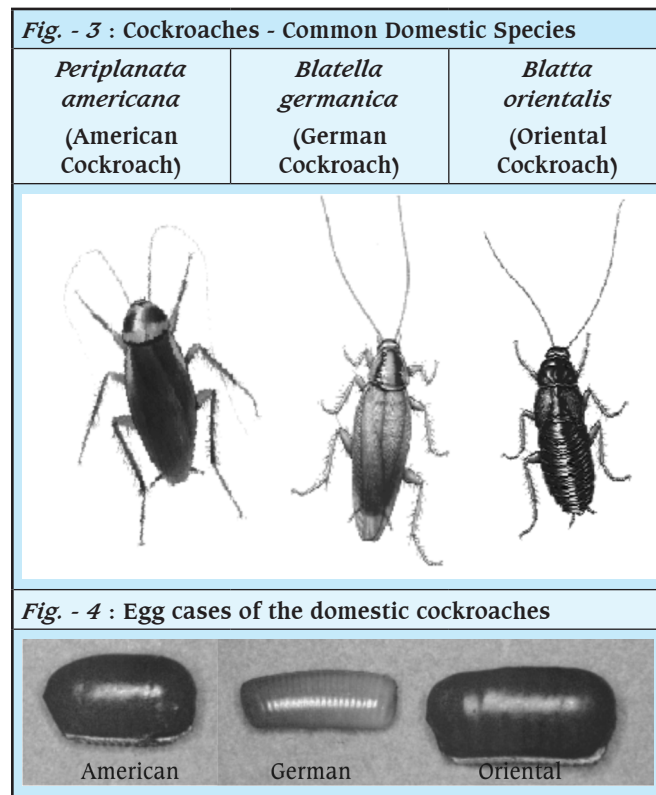

Morphology

Cockroaches are dorso-ventrally flattened creatures with colour varying from dark brown to black. The head is flexed backward and the antennae are filiform. Most of the species have two pairs of wings. In some of them the wings are vestigial. In the oriental cockroach, the wings are short in the females but much developed in the males which possess the power of flight.

Life History

They have simple metamorphosis and lay 16 to 48 capsulated eggs depending on the cockroach species (Fig. - 4). The eggs

hatch out in 2-6 months in most of the species, depending on temperature and humidity. The young ones are almost white and wingless. They moult a number of times and the total developmental period may be 6 months to 1 year. They may produce three generations in a year and usually have a long life span.

Bionomics

They breed in warm moist places in the humid microclimate of the kitchen and pantry, laying eggs in cracks, crevices and sinks. They can run swiftly by means of long well developed legs. They are highly gregarious and primarily nocturnal in habit, but may be seen during the day as well. The mouth parts are adapted for biting and chewing and they are omnivorous, feeding on any material meant for human consumption like meat, milk, grains and sugar.

Disease Potential

They are filthy, annoying pests imparting a nauseating 'cockroach' odour to the food articles and utensils they come in contact with and the places they infest. They destroy food, damage fabrics, books and other household articles. They may enter houses and other buildings from outdoors through infested containers or from adjoining rooms and apartments or through drains. On account of their indiscriminate roaming and feeding habits, they mechanically spread diseases like cholera, typhoid, dysentery, protozoal cysts, intestinal worms etc. by polluting food with infective material carried on their legs and bodies.

Control Measures

(a) **Prevention** : This includes :

- (i) Good house-keeping is the key to cockroach control, whether in the home, restaurant, hotel or grocery stores.
- (ii) All cracks and crevices should be properly filled up.
- (iii) All areas should be kept thoroughly clean so that no food particles, debris, dust and rubbish remain to support and nourish cockroaches.
- (iv) Keeping surveillance on the occurrence or increase in the density of cockroaches in a house by use of sticky traps or else by use of visual assessment method, whereby light is switched on late in night and the cockroaches counted for a stipulated time period, say five minutes. This method also indicates the hiding places in a room of the cockroaches besides indicating the level of infestation.

(b) **Control** : Cockroach infestation can be controlled with insecticidal sprays, dusts or baits. The insecticide should be applied thoroughly to runways, cracks, crevices, undersides of tables and even under the table spreads, rear of sinks, meat safes and other harbourage areas. Use of 2-5% dust or 1-3% solution or emulsion of Organophosphorous compounds like Malathion or Carbamate insecticide such as Propoxur gives excellent results. To obtain a quick effect in heavy infestations or to drive them out from the hiding places, a direct spray containing 0.3% Pyrethrum or 0.5 to 1.0% DDVP or Fenitrothion may be used. Small pills of flour containing boric powder left on dining table, food safes and pantry boards or under table cloth also kill cockroaches. Abemectin and Synthetic pyrethroids (Table - 1) are currently being used for control. Newer insecticides, Fipronil and Imidacloprid Gel have been found to be very effective in controlling cockroaches. Fipronil has been demonstrated to have "cascade effect" (secondary killing of cockroaches due to necrophagy amongst them, whereby they consume Fipronil killed cockroaches and get killed in turn). It is important to remember that chemical control gives only temporary results and maximum efforts should be made to improve the environmental sanitation and housing conditions. Moreover, there are reports that the German cockroach has become resistant to several Organo-chlorine, Organo-phosphate, Carbamate & Pyrethroid insecticides. The insecticides used for cockroach control are summarised in Table -1.

Insecticide	Concentration	Use
Boric acid	100%	Baits/ sprinkle along corners
Imidacloprid Gel	1.85 - 2.15%	Cracks and crevices
Fipronil Gel	0.01 - 0.03%	Cracks and crevices Has a cascade effect
Fenitrothion	1 - 2%	Spray
Malathion	3%	Spray
Cyphenothrin	0.5%	Spray
Deltamethrin	0.03%	Spray

Summary

Simulium flies have worldwide distribution & are commonly known as Blackflies; in Arunachal Pradesh, they are known as Dimdam flies. As they require well aerated water, they breed in fast flowing turbulent mountain streams. The life span of the adult is about three months. The colour varies from dark amber to bright yellow to orange. Male and female Simulids feed on plant juices; the females require blood meal for development of eggs. They can enter through any opening in the clothing and bite during the day. Simulids are vectors for Onchocerciasis in some parts of the world; however, they do not cause any disease in India. Control can be achieved by the use of larvicides like temephos & BTI. Use of aerosols & fog with clearing of vegetation is other means of achieving control, besides protective clothing & use of repellants.

Bugs have a world wide distribution and consist of two important families' viz. Cimicidae (bed bugs) and Reduviidae (kissing bugs). Bed bugs are small, 5-6 mm long, dorso-ventrally flattened, wingless, dark brown insects. The nasty pungent odour which this group emanates is because of the presence of stink glands. Metamorphosis is incomplete with presence of egg stage & 4 nymphal stages. Females lay flask shaped, operculated eggs singly in hidden sites. It takes 4 to 6 weeks for the development from egg stage to adult. Bugs can stay without food for months & can travel long distances through traveling bags, laundry, furniture, bedding, old charpoys, soiled clothing etc. Bugs so far have not been incriminated for any human disease; though have been suspected for transmitting diseases. Infestation though can cause insomnia, pruritis, dermatitis etc. Prevention includes maintenance of hygiene, thorough check of furniture & belongings. Insecticides viz. Malathion @2% or Chlorpyrifos @0.5% etc. may be used. Disinfestations of blankets, beddings, mattresses and mosquito nets may be carried out. Debugging can be used for treatment of the cots (charpoy).

Cockroaches are one of the most annoying pests encountered in an urban area. The common domestic species are *Blattella germanica* (infest buildings), *Periplaneta americana* & *Blatta orientalis*. Cockroaches are dorso-ventrally flattened with colour varying from dark brown to black. They breed in warm moist places (humid microclimate of the kitchen), laying eggs in cracks, crevices and sinks. Feed on any material meant for human consumption, their mouth parts are adapted for biting & chewing. They destroy food, damage fabrics, books and other household articles. Cockroaches spread diseases like cholera, typhoid, dysentery, protozoal cysts, intestinal worms etc. by polluting food with infective material carried on their legs and bodies. Prevention comprises of good housekeeping, filling up of all cracks & crevices. Infestation can be controlled with insecticidal sprays (Malathion or Propoxur), dusts or baits. Spray containing 0.3% Pyrethrum or 0.5 to 1.0% DDVP brings about quick effect. Newer insecticides, Fipronil and Imidacloprid have been found to be very effective in controlling cockroaches.

Study Exercises

MCQs & Exercises

- 1) *Cimex lectularius* & *C rotundatus* consist of two important families of (a) Simulium flies (b) Bugs (c) Cockroaches (d) None.
- 2) Which of the following in relation to bugs is not correct (a) Head bears antennae (b) Pair of well developed eyes (c) 5 nymphal stages (d) Flask shaped operculated eggs.
- 3) Prevention & control of bed bugs can be achieved by all except (a) Malathion @2% (b) Chlorpyrifos @ 0.5% (c) Debugging of bed stands (d) Fipronil Gel.
- 4) Sticky traps and Visual assessment method are used for surveillance of (a) Bed bugs (b) Cockroaches (c) Simulium (d) All of these.

Fill in the Blanks

- 5) Simulium flies are known vectors of _____
- 6) Nasty, pungent or offensive odour associated with bugs due to the presence of _____
- 7) _____ gel is an effective insecticide against cockroaches and has a cascade effect.

True or False

- 8) Black flies are black in colour.
- 9) A female bed bug lays 2 to 10 eggs a day with a total up to 200 to 300 in her life time of 6 to 8 months.
- 10) The mouth parts in cockroaches are adapted for biting and chewing.

Envenomizing Pests

Rina Tilak

Scorpions

Scorpions are one of the commonly encountered venomous arthropods of the class Arachnida (Fig. - 1). At least 1000 species of scorpions have been described, but only 20 species are of medical importance. The last segment of their bodies is modified to form a flexible tail, with a vesicle holding poison gland and a sharp spine. They vary in size from about 2 to 20 cm and are cryptozoic and nocturnal, spending the day concealed under stones or fallen tree branches or in burrows and venturing out after sunset in search of food. The common Indian species belongs to the genera *Buthus* (*Mesobuthus*) and *Palamnoeus*; the former are more poisonous.

Fig. - 1 : Scorpion

Scorpion sting as a rule is not more dangerous than bee or wasp sting as the chemical nature of the poison is similar to

formic acid. It is, however, much more painful, and if sufficient poison has been injected, may cause distressing symptoms which may take twenty four hours to pass off. Stings of red scorpion (*Mesobuthus tamulus*) can be serious with massive release of catecholamines, producing raised BP, arrhythmias, cardiac failure and pulmonary oedema. Profuse sweating, dilated pupils and priapism can occur.

Box - 1 : Prevention of Scorpion Sting

Do not encroach their hiding places especially if ill equipped (i.e. barefoot or wearing loose / open sandals in areas with loose stones, fallen debris etc.)

Scorpions are active at nights. Always carry a torch while moving in infested areas at night.

Erect barrier up to 20 cm by means of tiles at the base of walls and steps to prevent scorpion encroachment.

Fill cracks and crevices to deny hiding places.

In infested areas, people should sleep with mosquito nets properly tucked. It is advisable to use treated bed nets.

Clear all junk and rubbish from around the house.

Shake the shoes / clothes well before putting them on.

Lastly use chemicals if problem still remains unresolved.

A Scorpion sting case needs immediate medical attention. A local anaesthetic (1% Lignocaine) at the site of sting or a strong oral pain killer is advised. For stings with less pain, ice therapy works well.

There is no commercially available antivenin for treatment of *Mesobuthus tamulus* stings in India. The effects are more marked in children, it is, however, very rare that a fatal dose of the venom is injected. If the sting is on the extremities, an immediate ligature may be helpful. Application of a strong

solution of ammonia relieves pain in a majority of cases; a series of injections of 1% Novocaine or Lignocaine and Adrenaline at the spot and along the nerve may be necessary in others. Barbiturates in large doses are useful in reducing restlessness. Patients developing priapism, dilated pupils, sweating and bradycardia may require early energetic treatment with vasodilators. Preventive measures include alertness in avoiding contact with scorpions in infested areas, putting on clothes and shoes after shaking them well and proper housekeeping. Propoxur 2% or Chlorpyrifos @ 0.2-0.5% may be used. Synthetic pyrethroids are generally not used as they irritate the scorpions and risk is increased further.

Ants

Ants are common annoying insects. They have also been experimentally incriminated in the mechanical transmission of excremental infections. They should therefore be kept away from foodstuffs by placing the legs of food safes, tables etc. in anti-formicas viz. bowls or tins containing water or waste crude oil. Insecticidal sprays like Pyrethrum or Malathion are effective. Ordinarily, the ant-bite causes only a sharp stinging; the bites of some of the larger ants may be very painful involving faintness and shivering. Dilute ammonia or any other alkaline solution applied relieves the pain.

Bees, Wasps and Hornets

In bees and wasps, venom is produced in glands at the posterior end of the abdomen and is expelled by contraction of muscles of the venom sac, which has a capacity of up to 0.1 ml. Uncomplicated stings cause immediate pain, a wheal-and-flare reaction and local edema and swelling that subside in a few hours. In sensitized individuals there may be alarming symptoms.

Honeybees often lose their stinging apparatus and the attached venom sac in the act of stinging and subsequently die, it should be removed gently by pulling it out, care being taken not to squeeze the venom in the wound. The site should be cleansed and disinfected and ice packs applied to slow the spread of venom. Elevation of the affected site and administration of analgesics, oral antihistamines and topical calamine lotion relieve symptoms. Local application of an alkaline solution of sodium bicarbonate or ammonia or soap and applying pressure with a moistened piece of lint are useful in relieving pain. Papain diluted roughly 1:5 with tap water is said to produce immediate relief of pain. Disturbing the honey-comb may bring the whole swarm on the person responsible or any one who happens to be in the vicinity. Their stings may cause serious allergic symptoms requiring adrenaline and/or morphine administration. Wasp's nests should not be destroyed in the daytime; they are generally destroyed at night when all wasps are inside. Insecticidal treatment includes use of 1% Dichlorvos, 0.015% Deltamethrin or 0.5% Chlorpyrifos.

Centipedes

Centipedes (Myriapoda) possess a pair of legs to each apparent segment of the body; the first pair is modified to form poison claws. The bites of small centipedes' gives rise to mild local inflammation but the larger centipede *Scolopendra gigantea* may cause a severe painful bite with marked local and general

reaction (usually swelling, erythema and lymphangitis; dizziness, nausea and anxiety are occasionally described and rhabdomyolysis and renal failure have also been reported).

Solution of ammonia is useful for local application and in bites of the larger centipedes morphia may be necessary to allay the pain. 2-4% Malathion as spot application is very useful.

Leeches

Leeches (Hirudinea) are a class of annelid worms that attach to their hosts with chitinous cutting jaws and draw blood through muscular suckers. They are particularly troublesome near streams and rivers, in leafy forests and marshy jungles.

The two important species are:

- *Haemadipsa zeylanica*, which is a small land leech, about 2.5 cm long with great power of penetration into the interstices of clothing, putties or laced boots. They often drop from tree leaves onto man or animals passing by and suck blood.
- The other variety is *Limnatis nilotica* - the large aquatic leech which on being ingested, fastens itself to the mucus lining of the mouth, pharynx, larynx or nasal cavities of man or animal producing prolonged bleeding unless removed. Leech bites are painless but the bleeding may be prolonged (after the leech has detached) due to a powerful anti-coagulant, hirudin, present in its saliva.

Gum boots or jungle boots are very effective in protecting from leech bite. A frequent search of the body for the presence of leeches should be made. The leech should not be dragged or pulled off the skin because of the risk of breaking and leaving behind its suction apparatus which is liable to cause inflammation and suppuration. Salt, vinegar or a tobacco infusion application or a touch of the lighted end of a cigarette induces the leech to relinquish its hold; tincture of iodine should be applied to the bitten spot and a piece of adhesive plaster may be applied on it. Internally attached leeches may detach on exposure to gargled saline or may be removed by forceps. Repellents DEET & DEPA can be used to provide protection. The repellents can be applied on to the clothing as well as topically over the skin. At night a properly adjusted mosquito net, preferably insecticide treated bed net provides good protection. Aquatic leeches can be removed from drinking water by filtering through a sieve or a piece of muslin.

Spiders

There are more than 30,000 recognized species of spiders, however, only about 100 can defend themselves aggressively and have fangs sufficiently long to penetrate human skin. The true spiders (Arachnida) have poison glands and inject venom into their prey. The common species of spiders as a rule do not bite man. If by chance it happens to bite, the bite amounts to no more than a pin prick. Envenomations of the brown or fiddle spiders (*Loxosceles* species) and widow spiders (*Latrodectus* species) may be life-threatening. Some spiders, especially those belonging to the genus *Latrodectus* produce severe effects in man. Important species are *L hasselti*, the 'red-backed' spider and *L mactans* the black widow and the allied species. The acute symptoms generally subside after a few days, but pain may persist for some time. In *Latrodectus* bites, the death rate

may amount to 6% or higher.

Identification of the offending spider should be attempted, both because specific treatments exist for bites of spiders. Initial management includes local cleansing, application of sterile dressings and cold compresses, and elevation and loose immobilization of the affected limb. Analgesics, antihistamines, antibiotics, and tetanus prophylaxis should be administered if indicated. Use of sedative is contraindicated. Intra venous administration of widely available equine antivenom rapidly relieves pain and can be life-saving. Because of the risk of anaphylaxis and serum sickness, antivenom should be reserved for severe cases involving respiratory arrest, uncontrollable hypertension, seizures, or pregnancy. Intravenous Calcium gluconate or Magnesium sulphate also gives dramatic relief to cramps. Spot (Infested area) treatment with 3% Malathion, 0.03% Deltamethrin, Chlorpyrifos @ 0.2-0.5% has been found to be effective against spiders.

Summary

Scorpions are one of the commonly encountered venomous arthropods of the class Arachnida. The common Indian species belongs to the genera *Buthus* (*Mesobuthus*) and *Palamnoeus*. Scorpion sting (chemically similar to formic acid) is much more painful than bee or wasp sting, though not more dangerous. Hypertension, arrhythmia, cardiac failure and pulmonary oedema may be encountered following stings of *Mesobuthus tumulus* (Red scorpion). Prevention includes avoiding hiding place of scorpions especially when ill equipped, erecting barriers & filling up of cracks & crevices. There is no commercially available antivenin for treatment of *Mesobuthus tumulus*. Application of a strong solution of ammonia relieves pain in a majority of cases; in others, injections of 1% Novocaine or Lignocaine and Adrenaline bring relief. Preventive measures include alertness in avoiding contact. Propoxur 2% or Chlorpyrifos @ 0.2-0.5% may be used.

Ants are common annoying insects; need to be kept away from food stuffs. Ants have been involved in mechanical transmission of diseases & their bites may sometimes also be very painful. Dilute ammonia relieves pain. Other means of prevention are use of anti-formicas & Pyrethrum or Malathion spray.

Bee, Wasps & Hornet stings are often painful, the honey bee often leaves sting along with poison gland in the puncture, this should be promptly removed and pain relief may be obtained by applying alkaline solution of sodium bicarbonate or ammonia. Insecticides which can be used are Dichlorvos & Deltamethrin.

Centipedes possess a pair of legs on each segment of the body. Bites can cause mild reaction to severe pain. Ammonia and Morphine is used for treatment.

Leeches are a class of Annelid worms; the two important species are the land leech & the aquatic leech. Leech bites are painless but bleeding may be prolonged due to presence of anti-coagulant. Ideally, leech should not be dragged or pulled off the skin. Prevention is by wearing gum boots and searching the body for leeches. DEET & DEPA can be used to provide protection.

The true spiders (Arachnida) have poison glands. Important species are the red backed spider & black widow spider. Treatment of a bite is immediate washing and ligation. Aspirin or morphine is used for pain relief. Intravenous Calcium gluconate or Magnesium sulphate gives relief from cramps.

Study Exercises

MCQs & Exercises

- 1) *Buthus* (*Mesobuthus*) and *Palamnoeus* are common Indian species of (a) spiders (b) scorpions (c) bugs (d) flies
- 2) Hypertension, arrhythmia, cardiac failure and pulmonary oedema may be encountered following stings of (a) Scorpion (b) Spider (c) Wasps (d) All of these
- 3) Scorpion sting can be treated by (a) Ammonia (b) Lignocaine (c) Barbiturates (d) All
- 4) This should not be used to treat stings of bees, wasps & hornets (a) Magnesium sulphate (b) Adrenaline (c) Morphine (d) Papain
- 5) *Scolopendra gigantia* is a species of (a) Spider (b) Scorpion (c) Centipede (d) None

Fill in the Blanks

- 6) Stings of red scorpion can be serious due to release of _____
- 7) Class of annelid worms which suck blood, cause painful bites _____

True or False

- 8) Erecting a barrier up to 20 cm by means of tiles at the base of walls to prevent scorpion encroachment.
- 9) Stings of Bees, Wasps & Hornets should not be removed.

Answers : (1) b; (2) a; (3) d; (4) a; (5) c; (6) Catecholamines; (7) Leeches; (8) True; (9) False.

Rina Tilak

Ticks and mites belong to class Arachnida, which are characterized by the presence of two distinct body parts - cephalothorax and abdomen and four pairs of legs. Antennae are absent and eyes may or may not be present. Metamorphosis is incomplete and the adults resemble the nymphs except for the fact that nymphs lack genital aperture while in the adult the sexes are distinct. The larvae are morphologically distinct with three pairs of legs.

Ticks

Taxonomy & Morphology

Ticks belong to the super-family Ixodoidea. They are distinguished from other acarines by their relatively large size and absence of prominent hairs on the body. They are oval in shape and of varying colours and dorsoventrally compressed. Females are larger than males and are capable of great distention. Both sexes as well as the other stages i.e. nymphs and larvae thrive on blood alone and lead an intermittent parasitic life during a major part of their life cycle. They are free living on the ground in between various moults during development. There are two families, Family Ixodidae which is the hard tick and Family Argasidae which is the soft tick. The hard tick is more a jungle tick while the soft tick is a domestic or household tick like a bedbug.

Ixodidae or Hard Ticks

The dorsum of the adult male is covered by a dark shield, like that of the tortoise, called the scutum. This may be ornate with grey or white 'patterns'. In females and immature males, it covers only the anterior part behind 'the capitulum' which is the false head, actually formed by the mouthparts anteriorly and therefore visible from above (Fig. - 1).

Fig. - 1 : Hard Tick - Dorsal and Ventral Aspect

Argasidae or Soft Ticks

These are oval with leathery cuticle and devoid of scutum. Their mouth parts are placed ventrally and hence not visible from above and they possess no festoons (Fig. - 2).

Life History

All species of ticks pass through four stages during their development viz. egg, larva, nymph and adult. The total period

required for full development of a tick is from six weeks to 2 years. Fully engorged fertilized female drops off to the ground and lays eggs in cracks and crevices in the soil under stones or among roots of shrubs and grass and such other sheltered spots. Hard ticks deposit all their eggs in a single act of oviposition after which they die. Eggs take a few weeks to several months to hatch. Larvae are six legged and do not feed for about a week after emergence. Thereafter, they become hungry and active and climb on vegetation for attachment to passing hosts (this is called questing). They feed for about three days and drop off when engorged and remain quiescent for digestion of blood. After the first moulting, the nymphs emerge with their fourth pair of legs and seek a new host in the same manner as the larvae, feed and again drop off. They again moult and become sexually mature. The adults are also parasitic and exhibit questing. Copulation takes place after the last moult and the male dies after fertilizing the female. The female engorges and then deposits eggs.

Fig. - 2 : Soft Tick Dorsal and Ventral Aspect

Bionomics

Hard ticks are open jungle dwellers and thrive on animal hosts; hence they do not attach themselves to human beings voluntarily, except when a person comes across them accidentally. Argasidae (soft ticks), on the other hand, although preferentially parasitic on animals and birds attack man voluntarily. These are found in human dwellings and cattle sheds and attack man and animals during their sleep. They however, live away from their hosts, like bedbugs, in cracks and crevices and only emerge at night to feed on the host. Ticks can survive starvation for a long time.

Vector Potential

Ticks produce diseases in man by transmitting the viruses, rickettsiae, spirochaetes and bacilli of infectious diseases and through toxin present in their saliva. Some of the factors which account for high vector potential are that all the stages are essentially haematophagous and are persistent blood suckers and while feeding they attach firmly and cannot be easily removed. They are resistant to varying environmental conditions and relatively protected from natural enemies. The trans-stadial and transovarian transmission of infection helps in maintaining infection for several years. Ticks have the power to regenerate lost parts such as amputated legs and also the ability to repair mutilated mouth parts, which conserves them for long.

Soft Ticks

Soft ticks of the genus *Ornithodoros* transmit various types of spirochaetae causing relapsing fevers in certain parts of the world. *O. moubata* is the vector of *Borrelia duttoni* in Africa; *O. lahorensis* has a very wide distribution in Central Asia and North West India. In India, they are found in Kashmir and are known as *O. crossi*.

Hard Ticks

These are much more ubiquitous and produce larger varieties of human diseases. The most important of all are the various rickettsial infections transmitted by the hard ticks of the genera *Ixodes*, *Dermacentor*, *Amblyomma*, *Haemaphysalis*, *Rhipicephalus*, *Hylomma* and *Boophilus*. Viruses causing Kyasanur Forest Disease, Colorado tick fever and other Haemorrhagic fevers and Encephalitides are transmitted. These also transmit *P. tularensis*, the causative organism of Tularaemia. Tick paralysis is an acute ascending flaccid paralysis due to an unknown toxin the tick's saliva introduces through the bite of certain species of ticks of the genera *Dermacentor*, *Ixodes* and *Amblyomma*. It affects mostly children and young domestic animals in Australia, South Africa, North America, Southern U.S.A. and N.W. Pacific. Even a single tick bite may cause fatal paralysis. In certain cases, reaction from improper or partial removal of ticks or due to the bite itself may cause itching, swelling and ulceration at the site of the bite. Otoparasitism is an invasion of the auditory canal by ticks.

Mites

The vector mites belong to the order Acarina and family Trombiculidae which comprises many hundreds of species of world wide distribution. They are found in great abundance in areas with hot, humid climate, thick vegetation and presence of small vertebrates like rodents. The foothills in subtropical and temperate regions offer them ideal conditions. In the tropics, they are found even at heights in mountain valleys. These have also been found in the Alpine-subarctic terrain in the Himalayas as well as at the level of coniferous forest-glacial valleys in Pakistan. They are known by various names such as chiggers, harvest mites, kedany or scrub mite. Important species of the genus *Leptotrombidium* are *akamushi* which is distributed widely in Japan, South East China, Korea, Malaysia and Philippines and *L. deliense* which is vastly distributed in the tropical regions of South East Asia, Indian sub-continent, Sri Lanka and Maldive Islands. In India, it is present in the whole of the Shivalik range from Kashmir to Assam, the Eastern half of the plains adjoining the foothill ranges, the Eastern and Western ghats and the Vindhya range in Central India.

Morphology

The adult is about 3-4mm in size, is densely covered with hair and has a figure of eight (Fig. - 3). The mouth parts consist of a pair of chelicerae and a pair of palps, together giving the mite an appearance of having a false head. The adult resembles the nymph except that it is larger and more densely covered with hairs; 'Kedany' meaning hair in Japanese language. The larva is pale yellow to orange-red in colour with a circular body bearing three pairs of legs and branched hairs on the body and on the legs. They are found in nature in the interior of ear

cusps or on rumps of rats, mice, shrews, bandicoots and other small mammals, reptiles and birds in orange coloured clusters of as many as 50 to 200 larvae. A cluster of 5 to 6 larvae is as big as a pin-head. When the cluster detaches, a scab is formed showing an evidence of recent infestation.

Fig. - 3 : Trombiculid Mite (Adult)

Life History

The stages in the life history of a mite are egg, larva, nymph and adult. The eggs are laid singly on the surface of the soil. The larva leaves the egg-shell and becomes very active. Moving quickly over the surface of the soil and low lying vegetation, it seeks a suitable host such as rat, mouse, bandicoot and shrew and so on. While feeding, it buries the whole length of its chelicerae in the host's skin and injects an irritant secretion which causes tissue lysis. The larva feeds on the lymph and the tissue fluid but not on blood of the host. The orange red colour of the larva is therefore not due to ingested blood. The larvae feed for 2 to 3 days and then drop off to the ground concealing themselves in loose soil, and here they develop into nymphs and finally into adults. Generally, it takes 6 to 12 weeks for its development from egg to adult stage. Only the larval stages are parasitic; the nymphs and adults are never parasitic and feed on small insects in the soil or their eggs.

Bionomics

The mites are distributed in areas ideal for their survival called as "Mite Islands". Mite Islands are patches of ground characterized by thick vegetation cover, mainly the scrub jungles or other tall grasses offering protection from direct sunrays and desiccation, nearly 100% relative humidity at ground level and ideal ambient temperature of $27 \pm 5^\circ\text{C}$. Such conditions also provide sanctuaries for small vertebrate life such as rats, mice, bandicoots, and shrews which are hosts for larval mites (shrews are considered as the index animal for scrub typhus). These animals are also the reservoirs of rickettsiae for which the trombiculid mites are vectors. Hence, these mite islands may also become typhus endemic foci. Mites are most active during the whole rainy season and their prevalence in such mite islands is related to the intensity and length of the monsoons. In dry season, the adults migrate deeper into the soil, the egg laying ceases and the mite islands shrink; during monsoon,

there is prolific activity and the mite islands expand. Patchy distribution of mite islands and their selective choice of locality explain the patchy nature of typhus endemic foci. The typical terrains favourable for the mites to thrive and propagate are as under :

- Man-made rural and urban wastelands like overgrown clearings produced by shifting cultivations.
- Domestic sub-urban waste lands produced around neglected patches in and around villages and even big towns, such as neglected gardens and plantations or overgrown clearings therein; deserted villages are heavily infested.
- Around the edges of moist depressions, water meadows, grassy but not swampy river banks and moist sites such as seepages along over ground canal areas.
- The hedgerow types of features ranging from a simple bushy hedgerow to belts of forests following water courses and ravines which are commonly left in deforested areas in and below the foothills.
- The scrub at the outskirts of the forests and low lying patches overgrown with elephant grass in sunny clearings inside thick forests.

Vector Potential

Larval mites belonging to several genera attack man but only the Genus *Leptotrombidium* contains species of medical importance. In India, *Leptotrombidium deliense* is the vector of *Orientia tsutsugamushi* causing Scrub typhus; in Japan, the closely related variety *L. akamushi* (kedani mite) transmits Scrub typhus. Rickettsiae taken up by larvae while feeding on rodents are carried through its nymph, adult stages and then its eggs (trans-stadial transmission). The larvae hatching out of these infected eggs are capable of transmitting the rickettsiae to the next host. The infection is thus trans-ovarially transmitted for some generations and hence the mite also acts as a reservoir of infection. Larvae feed only once during their life time. Therefore, transmission of infection occurs in second or subsequent generations. When a larva lying on the ground comes in contact with a human being (instead of a rodent as would happen in the normal course), it attaches on to him and feeds on his lymph; in the process, the rickettsiae contained in the mouth parts are injected into the lymph of the human being thereby causing scrub typhus.

Control of Ticks and Mites

A. Insecticidal Control

a. Area Treatment : This is the only reliable Acarine control method in camp sited areas or areas amenable for such treatments. Before the application of an insecticide to the areas infested with hard ticks and mites, clearing of bushes by cutting them is advantageous. If possible a bulldozer should be employed. When the top soil is bare and dry, an area becomes considerably safe and more suitable for insecticidal action. Initial coverage of the area should be thorough. It may require repetition after 8 weeks and occasionally a third time during the hot-humid season. If people have to go to some nearby stream for bathing or washing their clothes, the selected area should be similarly treated as the stream edges covered with vegetation are favourite sites for acarines. "Malathion 50% EC" (as 5% solution) should be sprayed in a dosage of 4 kilograms

of active ingredient (a.i.) per hectare of ground surface area, or else "Cyfluthrin EC" applied in dosage of 0.1 Kg (100 grams) of active ingredient per hectare. Malathion 5% may also be used (4 Kg of active ingredient of malathion will be present in 8 litres of 50% EC commercial supply; this 8 litres will be mixed with 72 litres of water to get 80 litres of 5% solution which should then be sprayed over one hectare of ground surface area).

b. On Vegetation : In areas where vegetation cannot be removed for various reasons, control of ticks on vegetation can be achieved by insecticide dusting or spraying from the ground or air at the dosage varying from 0.5 to 2 Kg/hectare. In woody and bushy areas, the dosage is increased proportionately. Malathion, Fenthion, Propoxur and Permethrin are suitable.

c. Premises : Against soft ticks, application of insecticide to floors and walls of infested premises on alternate days after initial scraping and scorching are necessary. Treatment for 2 weeks before occupation gives good control. During this period sweeping of floors should be discontinued. Such a series of applications repeated 6 weeks afterwards gives adequate protection to people staying in such habitations as camps during disasters or migratory labour camps, etc. The insecticides should also be applied to beds, mattresses, rugs and furniture. In known tick infested areas, particularly where there is a history of relapsing fever, infested houses/ areas should be avoided as far as possible. Organophosphorus compounds like Malathion and Fenitrothion or Carbamate compounds like Propoxur can be used either as 0.5 to 1.0% spray or as 5 to 10% dust.

d. Domestic Animals : Dogs and other domestic animals can be freed of ticks by a wash or spray containing 2% Malathion, 1% Propoxur, Deltamethrin (0.025%) etc. Only half these concentrations should be used if the animal is to be dipped and the entire animal should be immersed except the head. Dusts containing 5% Malathion, Propoxur (1%), Cyfluthrin (0.1%), Deltamethrin (0.05%), Temephos (2%), Fenthion (2%) etc. may also be used. The premises which animals visit or is tied in, should also be treated.

B. Personal Protection

- a. The repellent materials used for personal protection against ticks and mites are Dibutyl-phthalate (DBP), Diethyl phenyl acetamide (DEPA) and Diethyltoluamide (DEET). These are more effective when applied to the clothing than to the skin. The effect may last for nearly six washings or weeks which ever is earlier. However, if it is ironed, the concentration falls below effective limits. DEET/ DEPA may be used for application on the exposed parts of the body to reinforce the use of protective clothing treated with DEET/ DBP/DEPA when working in an uncontrolled area or under acute emergency when application of repellent on the clothing prior to entry in an unknown or uncontrolled area is absolutely impossible. The persistence of DEPA on clothes post ironing is superior to that of DEET, whereas both are equally effective when applied topically. Permethrin may also be used for treatment of clothing.
- b. Wearing shirts with rolled down sleeves tightly buttoned at the cuffs, the lower ends of trousers tucked in socks and wearing of proper boots considerably reduces the risk against ticks and mites.

- c. Clothes for drying should be hung on ropes especially fixed for the purpose and not on the vegetation. Bush and grass on the periphery of a camp becomes infested by larval mites and ticks brought in by the rats migrating into the camp. Therefore, purposeless wandering in such areas should be discouraged.
- d. More mites and ticks are picked up by standing or sitting than by walking over the infested ground. Therefore, while in such areas it is unsafe to lie down on a grassy ground. The immediate vicinity of a tree base should be avoided for resting, so also the green edges of a stream or an irrigation channel. Open grassy grounds should be avoided in tick infested areas.
- e. Before retiring at night or after leaving a tick infested area one should take a bath and carefully search one's body and clothing for presence of ticks. If a tick is found attached to the body it should be removed immediately, because every added moment of its attachment increases the danger of transmission of infection. Pulling of a tick has the danger of breaking off its parts, therefore, it should be removed by making the surrounding skin taut, slipping the point of a flat needle or a scalpel under the mouth parts and then removing the mouth parts by raising the point of the needle with a minimum of tissue damage. Iodine or any other antiseptic should then be applied to the site.
- f. Use of Insecticide treated mosquito net gives some protection against soft ticks.

C. Habitat Management : Vegetation management is another control option for ticks. Removal of shrubs, trees, or tall grass can be useful in recreational areas. Wherever this is not possible, area treatment with insecticide may be the only viable option.

Anti-Rodent Measures

Persistent anti-rat hygiene is of great value in reducing the risk of diseases conveyed to man through ticks and mites. The main objective should be to reduce ingress of rodents by proper disposal of camp and kitchen refuse and removal of overgrown vegetation and rubble which afford them shelter. Rat destruction requires forethought; because if the feeding of larval ticks and mites is interrupted by the death of rodent hosts, a number of released acarines may reattach themselves to another host, which may be man. Active rat destruction may be adopted when the first infestation is at its peak i.e. a month or so after the rain starts. It is better to trap and then destroy them so that their parasites do not escape. When dead rats are collected from any endemic foci, the soil under and immediately around them should be treated with insecticide. Soft tick control is further achieved by rat-and-tick-proofing of dwellings. All cracks and crevices, fissures and other points of ingress should be closed and all doors should be made tight fitting to keep away rodents.

Camp Siting

In civil life, camps may need to be sited for temporary settlements of labour population when large industrial / urbanization projects are being launched in possibly infested areas or during disaster like situations. Before any area in the known endemic tract is selected for camping or before the

insecticide treatment is undertaken, the degree of risk should be assessed by determining the prevalence of adult and larval Acari.

(a) Mite Survey : Superficial layers of earth are scraped from moist areas around the roots of scrub and mixed with water in a bowl. Adult mites resembling a figure of 8 float in a few minutes. For non parasitic larvae, pieces of dark cardboard are placed edge wise forming tent fashion structures on the ground at intervals, larvae crawl up the cardboard and congregate at its top edge within a few minutes. Rats caught from the area should be examined for the clusters of larvae or scabs in ear-cusps and shrews for clusters on their rumps. If the ears or rump is infested, they should be carefully cut with fine scissors and placed in 70% alcohol vials. Rodent trapping is done in field (Camps, fringe areas) by specialized traps called Sherman traps, whereas in peri-domestic areas, Wonder traps may also be used. The trapping procedure is described in a subsequent chapter on rodents. Once the traps are brought to the laboratory, the rats are transferred in to large polythene bags, anaesthetized and thereafter ectoparasite screening is undertaken. While carrying out the survey, one must protect oneself adequately with protective clothing and repellents.

As a rough guide, it can be said that the Scrub typhus risk in any area during the monsoon is considered low if only up to 10% of the rats have been found infested on consecutive two surveys unless cases have occurred already; if 20-40% of rats have been found infested the contraction of infection is very probable; and if 50% or more rats have been found infested the risk is high and the site should be considered as dangerous. Similarly, even if a single rat is found infested with more than 100 larval mites, the area should be avoided, being a very high risk area.

(b) Tick-Survey : Ticks are collected by sweeping flags made of white flannel across the vegetation (Flagging/dragging method). The larvae, nymphs and adults get attached to them and are easily detected against the white background of the flag. They should be picked up by forceps and placed in 70% alcohol vials. Parasitic stages of ticks on various animals can be collected by catching rodents, shrews and other animals. Physical examination of a volunteer for ticks attached on his body after he has travelled for a stipulated / fixed period of time in an area delineated for survey also provides information on tick presence/ abundance. Dry ice traps are one of the most effective means of sampling ticks.

Summary

Ticks and mites belong to class Arachnida; body is divided into cephalothorax & abdomen with 4 pairs of legs. Ticks belong to two families : Ixodoidea (hard tick) and Argasidae (soft tick). All stages thrive on blood & lead an intermittent parasitic life. Dorsum of hard tick is covered by scutum which is replaced by the leathery cuticle in soft ticks. All species of ticks pass through 4 stages - egg, larva, nymph & adult. Eggs are laid in cracks & crevices. Hard ticks deposit all their eggs in a single act of oviposition, after which they die. Larvae are six legged and do not feed for about a week, thereafter they attach to passing hosts. They feed on blood & drop off. The nymphs and adults (both sexes) are parasitic and exhibit questing. Male dies after

fertilizing the female. Hard ticks thrive on animal hosts & soft ticks attack man voluntarily. Ticks produce diseases in man by transmitting viruses, rickettsiae, spirochaetes and bacilli of infectious diseases. Rickettsial infections are transmitted by the hard ticks of the genera *Ixodes*, *Dermacentor*, *Amblyomma*, *Haemaphysalis*, *Rhipicephalus*, *Hylomma* and *Boophilus*. Hard ticks also transmit virus causing KFD and *P. tularensis*, the causative organism of Tularaemia. Soft ticks transmit various types of spirochaetes causing relapsing fever.

The vector mites belong to the order Acarina, family Trombiculidae. Found in great abundance in areas with hot, humid climate, thick vegetation and presence of small vertebrates like rodents (*Mite Island*). They are known by various names such as chiggers, harvest mites, Kedany or scrub mite. Important species of the genus *Leptotrombidium* are *akamushi* and *deliense*. They possess a figure of eight shaped body with eight legs. They are found in nature in the interior of ear cusps or on rumps of rats, mice, shrews, bandicoots and other small mammals. The stages in the life history of a mite are egg, larva, nymph and adult. The eggs are laid singly. The larva seeks a suitable host such as rat, mouse, bandicoot or shrew and feeds on the lymph and tissue fluid. Mites are vectors for various rickettsial diseases. *Leptotrombidium deliense* transmits *Orientia tsutsugamushi* causing Scrub typhus.

Control of ticks & mites can be achieved by clearing of bushes in areas infested by ticks & mites followed by application of insecticides. Malathion 50% EC (@ 5% solution) should be sprayed in a dosage of 4 kg of active ingredient (a.i.) per hectare. In areas where vegetation cannot be removed, dusting can be done by Malathion or Fenthion. Insecticides should also be applied to beds, mattresses, rugs and furniture. Dogs and other domestic animals can be freed of ticks by a wash or spray containing 2% Malathion or 1% Propoxur. The repellants used for personal protection against ticks and mites are Dibutyl-phthlate (DBP), Diethyl phenyl acetamide (DEPA) and Diethyltoluamide (DEET). Clothes for drying should be hung on ropes. Before retiring at night or after leaving a tick infested area, one should take a bath and carefully search one's body and clothing for presence of ticks. Anti rodent measures like proper disposal of refuse & removal of overgrown vegetation helps in reducing the risk of diseases conveyed to man through ticks and mites. It is better to trap and then destroy rats so that their parasites do not escape.

Mite survey for nymphs and adults is done by soil sampling method, whereas larvae are sampled by rodent trapping. Ticks are surveyed by flagging/ dragging method as well as by direct host collection method through rodent trapping or by screening the host body for attached tick stages. Scrub typhus risk is considered low if only up to 10% of the rats have been found infested on consecutive two surveys unless cases have occurred already.

Study Exercises

MCQs & Exercises

- Which of these regarding ticks is not true (a) Females are larger than males (b) Both sexes thrive on blood alone (c) They are free living on the ground in between various moults (d) All are true.
- Soft ticks are involved in transmission of which of these (a) Relapsing fever (b) Kyasanur forest disease (c) Tick paralysis (d) Tularaemia.
- Mite island is an area having (a) 100% relative humidity (b) Temperature of $27 \pm 5^\circ\text{C}$ (c) Scrub jungles or other tall grasses (d) Rats, mice, bandicoots, and shrews (e) All of these
- Which is the parasitic stage in mites (a) Egg (b) Larva (c) Nymph (d) Adults

Fill in the Blanks

- Ticks & mites belong to the class _____.
- Hard ticks deposit all their eggs in a single act of _____ after which they die.
- The most important vector species of trombiculid mite transmitting scrub typhus is _____.
- The most effective means of sampling ticks is _____.

True or false

- Hard ticks belong to Family Ixodidae and soft tick to Family Argasidae.
- The total period required for full development of a tick is from six weeks to 2 years.
- Copulation in case of ticks takes place after the last moult & the male dies after fertilizing the female.
- The mite larva feeds on lymph and the tissue fluid but not on blood.
- Only the adult stages of ticks are parasitic, whereas the larvae and nymph feed on plant juice.

Answers : (1) d; (2) a; (3) e; (4) b; (5) Arachnida; (6) Oviposition; (7) *Leptotrombidium deliense*; (8) Dry ice collection; (9) True; (10) True; (11) True; (12) True; (13) False.

Rina Tilak

Rodents are the largest order of mammals with over 2000 living species placed in about 30 families. The word 'Rodent' has been derived from "rodere", which means to gnaw; the incisors of the rodents keep growing and to keep them in check, the rodents gnaw continuously. Rodents range in size from 5 gm (pygmy mice) to over 70 kg (capibaras). They have a world wide distribution with the exception of Antarctica. The habitat of the rodents is equally diverse with some preferring terrestrial life, while some live underground, others are adapted to desert life while some have inhabited the aquatic environment.

Public Health Importance

Rodents are capable of transmitting a large number of diseases to man through transfer of ectoparasites, which are vectors of diseases like murine typhus, plague, scrub typhus etc. (Table - 1 & 2) besides consuming and contaminating stored food with their urine and droppings, destruction to immovable property, gnawing on wiring and electrical insulations etc., which at times may lead to fire hazard.

Bionomics

Rodents use their sense of vision, hearing, touch, smell and taste for exploring new areas or food with certain senses more developed amongst rodents based on their needs for e.g. diurnal rodents have better vision as compared to their counterparts who are active at night. The rodents also possess the ability to perceive ultrasounds and use chemical, tactile, visual, auditory cues and intraspecific chemicals viz. pheromones for communication. Rats tend to be cautious and mice are more curious. Most rodents are omnivorous with few exceptions. They reproduce rapidly and exhibit crepuscular to nocturnal habit.

Types of Rodents

Rodents may be classified broadly into two types : viz. commensal (domestic rodents) and sylvatic or wild rodents.

Three species of urban rodents, *Mus musculus* (house mouse), *Rattus norvegicus* (Norway or brown rat) and *Rattus rattus* (roof or black rat) are the principal rodents encountered in peridomestic and domestic environments.

Table - 2 : Diseases transmitted through ectoparasites being harboured by the rodents.

Disease	Agent	Vector
Murine typhus	Rickettsia	Flea
Plague	Bacteria	Flea
Scrub typhus	Rickettsia	Trombiculid mite
Indian tick typhus	Rickettsia	Hard Tick
Rickettsial Pox	Rickettsia	Mouse mite
Kyasanur Forest Disease	Virus	Hard Tick
Rocky Mountain Spotted Fever	Rickettsia	Hard Tick
Colorado tick fever	Virus	Hard Tick
Lyme disease	Spirochaete	Hard Tick
Human Granulocytic Anaplasmosis	Bacteria	Hard Tick
Babesiosis	Parasite	Hard Tick
Relapsing fever	Bacteria	Soft Tick
Western Equine Encephalitis	Virus	Mosquito
Cutaneous Leishmaniasis	Parasite	Sandfly

Rattus norvegicus - (*Sewer rat*) : It generally frequents the sewers. It is a burrowing rat and is easily identified by its heavy body, coarse brownish to reddish grey fur with greyish belly. It is a good climber, nocturnal in habit and eats anything which is edible. It has poor vision but keen senses of smell, touch, taste and hearing and usually lives within 150 feet of food and water source. It feeds on familiar food, preferring meats and grains and has been found to be cautious of new items or food.

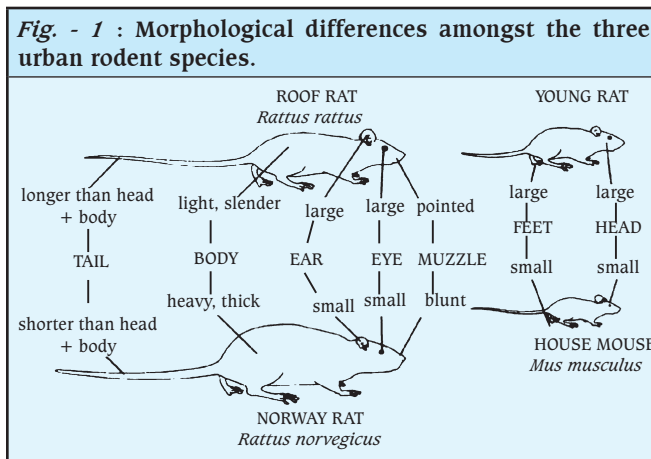

Table - 1 : Diseases transmitted directly by rodents or through contaminated water, food or animal.

Disease	Agent	Mode of spread
Rat bite fever	Bacteria (<i>Spirillum minus</i>)	Bite or scratch from an infected rodent or contact with a dead rodent, eating or drinking food or water that is contaminated by rat faeces
Leptospirosis	Spirochaete (<i>Leptospira icterohaemorrhagica</i>)	Water & food contaminated with urine from infected animals
Salmonellosis	Bacteria (<i>Salmonella spp</i>)	Water & food contaminated with faeces from infected animals
Tularaemia	Bacteria (<i>Francisella tularensis</i>)	Handling infected animal carcasses, eating or drinking contaminated food or water, breathing in the bacteria
Haemorrhagic fever with renal syndrome	Virus	Breathing in dust that is contaminated with rodent urine or droppings, direct contact with rodents or their urine and droppings
Lymphocytic Chorio Meningitis (LCM)	Virus	Breathing in dust that is contaminated with rodent urine or droppings, direct contact with rodents or their urine and droppings
Plague	Bacteria (<i>Yersinia pestis</i>)	Direct contact with infected animal

Rattus rattus : It is a slender rat and is a very agile climber thus earning its common name - the roof rat. It usually nests indoors in roof and wall cavities. It exhibits a strong fear of new things (neophobic). It is nocturnal and an omnivorous feeder with preference for fruits and propensity to hoard food.

Mus musculus : It resembles the roof rat, though smaller in size. It can be distinguished by its dusky grey fur and smaller feet. It commonly inhabits man made structures and therefore called house mouse. It has poor vision and is colour-blind, but has a well developed sense of smell which is used to locate food items and recognize other mice and an acute sense of hearing to respond to unusual noises as a means of detecting and escaping danger. Mice are omnivorous and known nibblers, eating small amounts of food at a time with preference for cereals or foods rich in fat and protein. They are poor swimmers and their normal activity range is usually within 10-30 feet from nest. Mice are habitual gnawers, curious and avid collectors of nesting materials; a habit which can be exploited while trapping them by attaching nesting material to traps.

The morphological differences amongst the three commensal or urban rodents are depicted in Fig. - 1.

Detection of Rodent Infestation

It is important to ascertain presence and level of rodent infestation prior to undertaking control measures. Following methods of detection may be employed for assessment :

Rub marks : During movement of rodents along rat runs, the oil and dust from the body of the rodents leaves rub marks especially in case of roof rats.

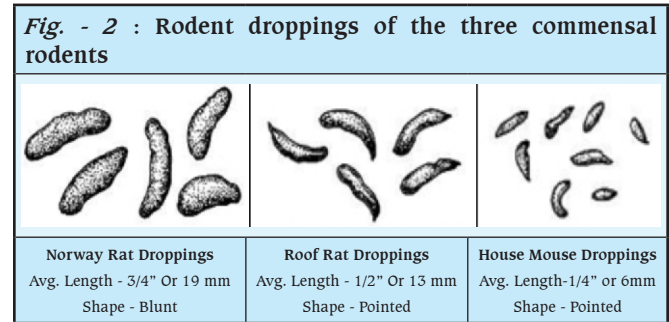

Gnawing marks : Due to the continuous gnawing habit of rodents, wood scrapings around doors, windows and frames may be the obvious visible signs of rodent activity.

Droppings : By seeing the droppings, it is possible to identify the type of rodent infesting a given structure. The same has been presented in Fig. - 2. Droppings are ideally visible along rat runs, near rodent burrows and at the feeding sites.

Run Ways : Rodents generally use the same path for travelling; the common runways or rat runs are seen along walls, behind stored objects and similar places.

On inspection, when no signs are visible, it is presumed that

there is no rodent infestation. In low to medium infested areas, no daytime rodent sightings or activity is noticed however, their presence is detected by the above mentioned methods of detection. The high-density infestation levels are detected by daytime sightings, active gnawing, droppings and heightened night time sightings.

Prevention and Control

The best method of prevention is to deny rodents a place to live / nest and food to eat. This is achieved by the following methods :

Eliminating the Hiding and Nesting Sites : The rodents prefer to breed in dark and undisturbed areas, which are available in plenty by the debris / garbage/ clutter present in the houses/ surroundings. The following measures will ensure denial of breeding / hiding place for the rodents.

- Keep surroundings clean and free from debris to prevent rodents entry and breeding in the premises.
- Good housekeeping will deny hiding and nesting places to rodents.
- Deny dark, sheltered and undisturbed places in the house by routinely displacing furniture.
- Make all openings to constructions rodent proof through engineering methods. The following measures can be adopted by individuals to make their houses rodent proof:
 - Install doors to fit tightly.
 - Rodent proof a door by placing sheet metal channel at bottom and cuffs at sides, over channel.
 - Reinforce doors with thick aluminium sheets of 22 gauge or thicker.
 - Steel wool and copper mesh can be packed tightly into holes to close openings or protect other areas from gnawing.
 - Make the drainage points rodent proof by using sieves secured with cement.
 - Use materials such as mortar for sealing holes in concrete buildings.
 - Fill all gaps in basements/ building or holes in walls with cement or steel wool.
 - Rodent proof utility wires to limit access to buildings using rolling plastic tubes made from rectangular sheets of plastic. The tube rolls when the rodent tries to walk over it.
 - Rodent proof air vents and chimneys using 1/4" hardware cloth.

Eliminating Food Sources

- Spillage should be cleaned daily.
- Garbage should not be stored outside in plastic bags as plastic garbage bags are not rodent-proof, instead metal bins or heavy duty plastic bins with tight-fitting lids should be used.
- Fallen fruits and nuts from the ground should be promptly disposed of.
- Pet food dishes and leftovers should also be promptly removed after feeding.
- Animal waste should be cleaned frequently.
- Food scraps should not be placed in compost piles.
- Food grains or other food materials should be stored in rodent proof containers and wherever feasible be placed in cupboards.

In situations where preventive measures have failed to address the problem of rodent nuisance effectively, control of rodent infestation is achieved through the following three methods :

- Trapping
- Baiting
- Fumigation

Trapping : Trapping can be an effective method of controlling rodents, but it requires more skill and labor than most other methods. Trapping is recommended where poisons seem inadvisable and is the preferred method to try first in homes, garages and other small structures, where only a few rodents

may be present. Traps should be laid out at or before dusk along rat runs, near their feeding areas, areas of high activity or potential entry points. Traps should be placed at 3-10 ft apart for mice and about 20 ft for rats. It is also pertinent to use the correct trap for the rodents; larger rodents may require larger traps as compared to traps used for mice. For successful trapping, it is advisable that baited traps should be placed.

Types of Traps : There are various types of traps available in the market for use. The traps either trap live rats or kill the rats. Commonly available traps are :

Cage Traps (Fig. - 3)

- Used for capturing rodents live.
- These traps are designed to catch and hold one or more animals by means of a falling or sliding door, triggered when the rodent enters or nibbles at a bait.

Sherman Traps (Fig. - 4)

- Are foldable box traps made of Aluminium.
- Used for trapping rodents for research purposes or during epidemic investigation (Procedure of trapping is presented in Box - 1).
- Traps live rodents.
- Have an added advantage of ensuring that ectoparasites are not lost, even if the trapped rodent dies.
- Generally baited with freshly made baits rich in fat e.g. *pakor*as (fried snack of onion mixed with gram flour) or fried fish, chicken etc.

Box - 1 : Trapping Procedure for Rodents using Sherman Traps
Number the Sherman traps with marking pens starting from 1-40.
Prepare flags bearing the same numbers i.e. 1-40 with cardboard pieces.
Carry freshly prepared <i>pakor</i> as for the traps.
The laying of traps should be carried out in the late afternoons and should be completed before dusk.
Personnel involved in laying/ collecting of rodent traps should wear trousers tucked in boots/anklets and full sleeved shirt. Wear heavy duty gloves while laying/ collecting traps and use repellents on exposed skin.
Identify suspected mite islands (a patch of ground with vegetation, temp in the range of $27 \pm 5^{\circ}\text{C}$, Relative Humidity in the range of 80-100% and which provides an ideal place for rodents to hide).
Check the working condition of Sherman trap before placement.
Place <i>pakor</i> a in traps; ensure it is placed at the closed end of the trap.
Place the trap in the bushes or where rodent is likely to frequent. Place the trap with its opening facing the likely direction of rodent entry. Ensure that the trap opening is not obstructed. The trap should be placed on flat ground so that it does not tumble if approached by rodent or any other movement in the area.
Place flag bearing the same number as the trap, close to the trap so that it is visible from a distance.
Tie a bandage to the nearby bush to indicate the site of trap placement to enable retrieval in the poor light conditions of dawn - the time for trap collection.
Make a spot map of trapping area with the trap numbers indicated on the map.
Collect the trap before dawn next day.
Use heavy duty gloves and a torch for collection of traps at dawn. (All protective measures as followed earlier should be ensured). If a trap is closed, do not try to open the trap, put the trap in a cardboard carton for transportation to the lab.
If a trap is open, fold it and place in carton/ plastic bags.
Once the traps are brought to the laboratory, the rats are transferred in to large polythene bags, anaesthetized, blood collected for testing for presence of rodent borne diseases by conventional serology/ PCR, rodent identified and thereafter subjected to ectoparasite screening.

Fig. - 3 : Cage Trap

Fig. - 4 : Sherman Trap

Trigger or Snap Traps

- These traps are generally more effective than cage traps.
- Simple, inexpensive, wood-based snap traps are readily available.
- For rats, bait the traps with fried food items like chicken, pakoras etc. tied securely to the trigger.

Break Back Traps

- These traps are similar to snap traps but have a quicker killing action and hence there are no misses.
- These traps are considered more humane as the rats die instantaneously.
- They are generally used in fields by farmers.
- Not preferred indoors.
- Traps need to be baited with food similar to that used for other traps.

Advantages : Trapping is an effective rodent control option when permanent rodent control measures are not in place or inappropriately implemented. It is one of the most preferred and safer rodent control options in domestic and peri-domestic environments. It has an advantage that it allows user satisfaction in terms of success of the trapping procedure being obvious. Trapping as a rodent control option also ensures proper disposal of carcasses or live trapped rodents thereby preventing odour nuisance from the dead rodents. Traps are especially effective indoors where use of rodenticides may pose threat to the non target organisms viz. people or pets and in kitchens, pantries or food serving areas due to possibility of contamination of food.

Limitations : This is a temporary control option as after initial success, the rodents become 'trap wise' (a phenomenon wherein rodents avoid traps as they are able to associate traps and their getting trapped in them) and the efficacy of the trapping process is then compromised. The trapping process should be stopped when rodents are sighted but are not being trapped.

Glue Boards : Glue boards are an alternative to rodent traps and may control rodents in low infestation areas. They are effective options for rodent control in areas where food is commercially prepared, where the use of rodenticides is unsafe and for monitoring rodent population. A combination of traps and glue boards may prove more advantageous than a single method. The mode of action of rat glue boards is the same as

that of fly papers. It entangles mice and rats in much the same manner as flypaper catches houseflies. Like traps, glue boards need to be placed along walls where mice and rats travel. It is however important to place the glue boards in dust free areas and away from direct sunlight or extremes of temperature so that the tackiness of the glue is maintained.

Baiting : In the event of emergency rodent control or at times when there is a failure to achieve effective rodent control through non chemical strategies mentioned in the preceding paragraphs, baiting emerges as an attractive alternative to address the problem. The process of baiting utilises special chemicals called rodenticides for killing the rodents. The use of rodenticides or the process of baiting should be undertaken by trained individuals and requires utmost care as they pose threat to non target organisms, as well as hazards of accidental/deliberate poisoning.

Factors Influencing Baiting : The adaptive behavioural responses of rodents for selecting palatable and nutritious food, while rejecting palatable though harmful food poses one of the biggest challenges in making the rodents consume the toxic baits. This is further challenged by the phenomenon of 'neophobia' exhibited by rats and their learned food aversions. It is thus essential to undertake 'prebaiting' (the food material without the bait is placed for 3-5 days to remove fear of new food amongst the rodents) prior to actual baiting. It is further important that the rodenticide should preferably be tasteless and odourless in lethal concentrations and have a delayed effect.

Time & Place of Baiting : Baiting should be done in the evenings along rat runs, feeding and activity areas etc which are generally frequented by the rodents as evidenced by the signs of infestation elicited through the procedure given earlier.

Types of Rodenticides : Rodenticides are classified as acute rodenticides and anticoagulants. They are used mostly mixed with food or as contact poisons in the form of dusts (tracking powder).

Acute Rodenticides : These kill the rodents on ingestion of a single dose of the toxic bait. There are a large number of acute rodenticides, however, not all are considered ideal for use in domestic environments due to safety concerns. The acute rodenticides are Red squill, Norbromide, Sodium fluoroacetate,

Strychnine, ANTU etc. Some commonly available acute rodenticides are Zinc phosphide and Barium carbonate.

Zinc Phosphide : It is a black powder with a garlic odour. The garlic odor attracts rodents but has a repulsive effect on other mammals, though, birds cannot perceive the smell and unintentionally feed on them leading to unwarranted death. It is mixed in the proportion of 1 : 8 or 1 : 10 with wheat flour and made into pellets with a little edible oil. Upon ingestion, Zinc phosphide reacts with dilute acids in the gastrointestinal tract and produces phosphine which enters the blood stream and causes death within four hours of consumption of a single dose of the bait.

Barium Carbonate : It is a white powder mixed in the proportion of 1 : 4 with wheat flour. A single dose consumption of the product causes kill within eight to twenty four hours.

Advantages : Being highly toxic, these rodenticides bring about a rapid kill with a single dose consumption of the bait, which is one of the greatest advantages especially when the rodent populations are very high.

Limitations : These rodenticides need to be used with care as they may cause toxicity to non target organisms. The consumption of a single dose of the bait leads to very painful death of the rodent, which when sighted by the other rodents is quickly registered as an association of the new bait with these deaths, thus leading to avoidance of the bait - i.e. development of the phenomenon termed as "bait shyness". Once this develops, baiting with acute rodenticides is rendered ineffective and needs to be discontinued.

Anticoagulants : These substances kill by preventing normal blood clotting and causing internal haemorrhage through effective blocking of vitamin K cycle, which results in inability to produce essential blood-clotting factors (mainly coagulation factors II (prothrombin), VII (proconvertin), IX (Christmas factor) and X (Stuart factor)). The antidote to anticoagulant poisoning is therefore Vitamin K itself. Anticoagulants are of two types, multiple dose and single dose anticoagulants.

(a) Multiple Dose Anticoagulants : These are the earliest known anticoagulants also called the *first generation anticoagulants*. Multiple dose consumption of the product kills the rodents, which generally takes about 1-2 weeks post ingestion of lethal dose. The common examples in this category are :

- **Warfarin** : It is the earliest product used for rodent control from this category. The product is not a very popular product now for rodent control as it has a delayed action. This product requires a higher concentration of the toxicant (usually between 0.005 and 0.1%) and consecutive intake over days in order to accumulate the lethal dose. The product is mixed in the proportion of 1 : 19 with wheat flour and made into baits.
- **Coumatetralyl** : Is an anticoagulant of the Warfarin type. The toxicity of the product is known to increase with continued ingestion or exposure to the bait. For the product to be toxic, it should constantly remain present in the blood for more than 1 to 2 days. A single exposure, even though relatively large, may not produce toxic symptoms as the compound is quite rapidly metabolized. It is marketed in India as tracking powder (0.0375%) which

can be mixed with wheat flour and made into baits as in case of Warfarin.

Advantages : The greatest advantage of these products are that they cause apparently painless deaths and hence do not result in the development of 'bait shyness' and therefore can be used wherever continuous rodenticiding is required e.g. granaries, ships etc.

Limitations of Multiple Dose Rodenticides : As multiple dose consumption of the bait is required for the desired kill; single dose consumption of the bait will lead to sublethal dosing thereby giving rise to development of resistance.

(b) Single Dose Anticoagulants : Are derivatives of 4-hydroxycoumarin and are referred to as *second generation anticoagulants* or as "*superwarfarins*". These are far more toxic and lethal than their first generation counterparts and are applied in lower concentrations in baits (0.001 - 0.005%). The rodents die after ingestion of a single dose of the bait as in case of the acute rodenticides, however, the cause remains haemorrhage. Single dose anticoagulants commonly used are Bromadiolone, Difethialone, Brodifacoum etc. *Bromadiolone* is used in the form of ready-to-use baits of low concentration containing 0.005% bromadiolone. Single dose consumption of the bait kills the rodents. Bromadiolone kills all the commensal rodents viz. sewer rats, roof rats, house mice and is also effective against Warfarin resistant sewer rats.

Advantages : These single dose anticoagulants are effective against strains of rodents that have developed resistance to first generation anticoagulants. A single dose is lethal to cause kill and hence development of resistance also may not take place readily.

Limitation : As a single dose of these rodenticides is lethal to rodents; the use of this class of products may pose threat to non target organisms and hence needs to be used with care and under supervision.

Fumigation : Fumigation is the choice method for killing rodents in burrows, enclosed structures / places. It is however, carried out by trained professionals due to the risk posed by the noxious gases released during the process. The fumigants commonly used are Aluminium phosphide and Calcium cyanide. Sulphur dioxide, Carbon disulphide, Carbon monoxide and Methyl bromide are also used especially in godowns, granaries and aircrafts.

Fumigation with Aluminium phosphide and Calcium cyanide involves identification of burrows, locating the exit and entry points and then sealing one of the ends. The fumigants in the form of tablet (Aluminium phosphide) or in the form of powder (Calcium cyanide - 30 g /rodent burrow) are introduced in the burrows and the burrow closed with wet soil to release the gas - (Phosphine in case of Aluminium phosphide and Cyano gas in case of Calcium cyanide). Fumigation with Cyano gas has been extensively used in India for fumigating rat burrows in fields during Plague outbreaks, whereas Aluminium phosphide tablets are generally preferred for use in peri-domestic areas and agricultural fields.

Ultrasonic Repellent Device : The ability of rats to perceive ultrasonic sound has been exploited by using devices generating ultrasonic sounds. These are electrical devices and are popular

gadgets claiming efficacy in repelling rodents from infested rooms. Ultrasonic sounds, however, have very limited use in rodent control as they are directional, don't penetrate behind objects and lose their intensity with distance. They can be used in small rooms in a limited area.

Summary

Rodents are the largest order of mammals with over 2000 living species. 'Rodent' has been derived from "rodere", which means to gnaw. Rodents range in size from 5 gm to over 70 kg. Rodents are capable of transmitting a large number of diseases to man through transfer of ectoparasites, which are vectors of diseases like murine typhus, plague, scrub typhus. Rodents use their sense of vision, hearing, touch, smell and taste for exploring new areas or food. The rodents also possess the ability to perceive ultrasounds and use chemical, tactile, visual, auditory cues and intraspecific chemicals like pheromones for communication.

Rodents are broadly classified into domestic & wild rodents; principal rodents encountered in peridomestic and domestic environments are *Mus musculus* (house mouse), *Rattus norvegicus* (Norway or brown rat) and *Rattus rattus* (roof or black rat). *Rattus norvegicus* or the sewer rat generally frequents the sewers. It is a burrowing rat and is easily identified by its heavy body. *Rattus rattus* is a slender rat & is a very agile climber. *Mus musculus* has dusky grey fur and smaller feet. Detection of rodent infestation can be done by rub marks, gnawing marks, droppings & runways. Rodents are mostly omnivorous with preference for cereals or foods rich in fat and protein.

Prevention is achieved by denying rodents a place to live/ nest and food to eat, keeping surroundings clean and making all openings to constructions rodent proof etc. Food source need to be eliminated and garbage should not be stored outside, animal waste should be cleaned and food grains / other food materials should be stored in rodent proof containers.

Control of rodent infestation is achieved through trapping; The traps used are Cage traps, Sherman traps, Snap traps & Break back traps. Traps should be laid out at or before dusk along rat runs, near their feeding areas, areas of high activity or potential entry points. Traps are the most preferred and safe rodent control options in domestic and peri-domestic environments as success of the trapping procedure being obvious, they however have the limitation of being temporary control options as the rats become trap wise.

Other alternative are use of glue boards, baiting & use of rodenticides. The acute rodenticides are Red squill, ANTU, Zinc phosphide & Barium carbonate (advantage of rapid kill but can lead to development of bait shyness.), the other rodenticides are the anticoagulants. Multiple dose anticoagulants are Warfarin & Coumatetralyl; They have the advantage of causing painless deaths but multiple dose consumption is required for the desired effect. Single dose anticoagulants (bromadiolone) have the advantage of killing the rodents by consumption of a single dose with the added advantage of anticoagulants i.e. no development of bait shyness takes place, thus making them ideal for continuous use. Fumigation can be done using Aluminium phosphide and Calcium cyanide.

Study Exercises

MCQs & Exercises

- 1) Which of these is known as roof rat (a) *Mus musculus* (b) *Rattus norvegicus* (c) *Rattus rattus* (d) All of these.
- 2) Rodents are capable of transmitting which of these diseases to man through vectors (a) Murine typhus (b) Leptospirosis (c) Rat bite fever (d) All of these.
- 3) Detection of rodent infestation prior to deciding control measures can be done by (a) Rub marks (b) Gnawing marks (c) Droppings (d) All of these.
- 4) This trap is generally used for trapping rodents for research purposes / outbreak investigation (a) Cage traps (b) Sherman traps (c) Trigger trap (d) Break back traps.
- 5) Acute rodenticides are all except (a) Red squill (b) ANTU (c) Zinc phosphide (d) Warfarin.

Fill in the Blanks

- 6) Burrowing rat which is easily identified by its heavy body, coarse brownish to reddish grey fur with greyish belly & frequents sewers is _____
- 7) These traps have a quick killing action & are generally used in fields _____

True or False

- 8) Rodents range in size from 5 gm (pygmy mice) to over 70 Kg.
- 9) Mice are omnivorous and known nibblers, eating small amounts of food at a time with preference for cereals or foods rich in fat and protein.
- 10) Traps should be placed at 3-10 ft apart for mice and about 20 ft for rats.

Answers : (1) c; (2) a; (3) d; (4) b; (5) d; (6) *Rattus norvegicus*; (7) Break back traps; (8) True; (9) True; (10) True.

Rina Tilak

Snakes are one of the most widely distributed animals spanning across continents (with the exception of Antarctica), inhabiting the sea and present as high as 16,000 feet (4900m) in the Himalayan Mountains, though conspicuous by their absence from Ireland and Iceland (1). There are over 3000 species of snakes distributed world wide and about 275 species are found in the Indian sub-continent (2).

Morphology & Biology

Snakes, which belong to the class Reptilia, are limbless reptiles characterized by elongated body which is divided into head, body and tail. The whole body of the snake is covered with scales which are an important tool for their identification. A thin skin, in turn covers the scales which is periodically shed or cast off during the process of moulting; during this period the snake is blind (as the skin covers the eyes as well) and lethargic.

Snakes locate their prey by their senses of vision, smell or thermo-sensitivity. The remarkable vision of some snakes enables them to detect movement; snakes smell by using their forked tongue which collects airborne particles and then passes them to the Jacobson's organ or the vomeronasal organ in the mouth for examination. The body of the snakes which is in direct contact with the ground is also very sensitive to vibration, thus enabling snakes to sense other approaching animals by detecting vibrations on the ground. Some snakes like pit vipers and pythons have infrared-sensitive receptors present between the nostril and eye or have labial pits on their upper lip just below the nostrils (common in pythons) which allow them to "see" the radiated heat and thus locate prey especially warm-blooded mammals.

Of the roughly 725 species of venomous snakes worldwide, only 250 are able to kill a human with one bite. The official records state about 2, 50,000 snake bite cases occur in India every year, of which, over 50,000 die due to inadequate first aid or unscientific treatment methods (3). The Indian snake bite statistics are alarming as the figures are highest in the world, though India does not host the largest number of snakes in the world.

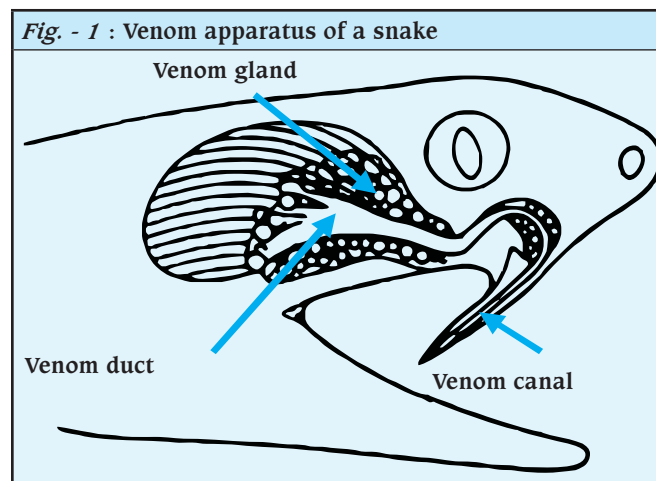

Venom Apparatus

The Venom apparatus of a snake (Fig. - 1) comprises a venom gland which opens through the venom duct into fangs located in front of the upper jaw which have a venom canal along which venom is introduced while biting into the tissues of the prey. If a human is bitten, venom is injected either subcutaneously or intramuscularly.

Classification of snakes

The venomous snakes of the Indian continent may be broadly classified into two important families i.e. Elapidae and Viperidae. Snakes belonging to family Elapidae are the Cobras, Kraits and Coral snakes. This group is characterized by the presence of short permanently erect fangs. Sea snakes belong

to family Hydrophilidae. The members of family Viperidae are divided into two subgroups viz. the pit vipers and the typical vipers; they possess long fangs which are normally folded up against the upper jaw and are erected while striking.

Venomous Indian Snakes : The important venomous snakes in India are Cobra (*Naja naja*), Common Krait (*Bungarus caeruleus*) and three types of vipers i.e. Russell's (*Daboia russelii*), Saw scaled (*Echis carinatus*) and the Hump nosed viper (*Hypnale hypnale*). The polyvalent antivenom available as of now in India, however, has the antivenom targeted against poisoning by only the first four types of snakes. The identification of snakes is a very specialized task and is best left to the herpetologists, however, certain common identification marks and distribution of the venomous snakes of India is presented below:

- a) **Cobra**: Found all over India, are active during day and night. Raises a hood which may have no mark e.g. king cobra (*Ophiophagus hannah*), or hood may be spectacled or bicellate (*Naja naja*) or monocled (monocellate i.e. single circular mark) - *Naja kaouthia* (Fig. - 2).
- b) **Krait**: Found all over India, are generally encountered at night. It is the most venomous of all land snakes. The common krait or *Bungarus caeruleus* is identified by paired white lines on the body, whereas the other variety is the banded krait *Bungarus fasciatus* (Fig. - 3).
- c) **Saw Scaled Viper**: Found all over India and prefers dry scrub or desert. *Echis carinatus* is identified by the White loop marks along body and arrow or birds foot mark on head (Fig. - 4)
- d) **Russell's Viper**: Found throughout India up to 3000 m altitude. *Daboia russeli* is identified by the black edged chain like marks and white V on head (Fig. - 5)
- e) **Hump Nosed Viper**: *Hypnale hypnale*, the hump nosed viper is found in the Western ghats. It is identified by its characteristic hump nose, whereas the other features resemble *Echis carinatus* (Fig. - 6).

Snake Venom

Snake venom contains more than 20 different constituents which evoke varied responses in the body. These constituents are: procoagulant enzymes, haemorrhagins, cytolytic or

necrotic toxins, haemolytic and myolytic phospholipases A2, pre-synaptic neurotoxins and post-synaptic neurotoxins. It is important to note that not all venomous snake bites lead to clinical effects as most of the time insufficient or no venom enters the wound.

Envenomation Symptoms : The local symptoms and signs of snake bite are fang marks, local pain and bleeding, bruising, lymphangitis, lymph node enlargement, inflammation (swelling, redness and heat), blistering, local infection, abscess formation and necrosis. The systemic action of snake venom is either on the nervous system (Neurotoxic) or on the haematological system (anti-haemostatic). It may also cause local damage or reaction as a result of the constituents of venom which primarily function to spread the venom throughout the body. Symptoms seen in neurotoxic type (due to elapid bites) are drooping eyelids, vision disturbances, difficulty in breathing,

difficulty in speaking, opening of mouth or protruding the tongue, difficulty supporting the neck and head and difficulty in swallowing. The presentation in haematotoxic type (due to vipers) is continuous bleeding from bite site, bleeding from gums or nose, appearance of bruises and dark urine.

Syndromic Approach as Guidelines

A “syndromic approach” as laid down by WHO may be useful in prompt and effective management of snake bite especially when the snake has not been identified; the envenomation symptoms provide the relevant guidelines as presented in Table - 1.

Table - 1 : Snake identification based on Envenomation Syndrome	
Envenomation Syndrome	Snake species
<p><i>Local swelling with bleeding/ clotting disturbance</i></p> <ul style="list-style-type: none"> • Above + Shock or renal failure • Ptosis, external ophthalmoplegia, facial paralysis and dark brown urine • Paralysis with dark brown urine and renal failure along with bleeding/clotting disturbance 	<p><i>All Viper species</i></p> <ul style="list-style-type: none"> • Russell's & Saw scaled viper • Russell's viper - reported from South India • Russell's viper - reported from South India
<p><i>Paralysis with minimal or no local envenoming</i></p>	<p><i>Krait</i></p>
<p><i>Local envenoming (swelling etc) with paralysis</i></p>	<p><i>Cobra or King cobra</i></p>

Prevention of Snake Bites

Snake bites can be effectively prevented by following certain simple preventive measures; the following do's and don'ts should be followed to prevent snake bites:

- Do not try to kill a snake. Many people are bitten because they try to kill a snake or get too close to it- leave snakes alone.
- While trekking/ hiking, stay out of tall grass unless you are wearing thick leather boots and remain on hiking paths as much as possible.
- Keep hands and feet out of areas you cannot see. Do not pick up rocks or firewood unless you are out of a snake's striking distance.
- Be cautious and alert when climbing rocks.
- Wear boots and avoid moving barefoot in snake infested areas.
- Always carry a torch while moving in darkness.
- Remove garbage or any other junk material lying in and around the house - keep surroundings rubble free.
- In snake infested areas, shake shoes well before wearing.
- Dust bedding before sleeping, use mosquito nets while sleeping in camp sited areas and preferably avoid sleeping on ground.

First Aid

Whenever dealing with a snake bite case, it is pertinent to remember that a substantial proportion of all snake bites are actually due to non-poisonous snakes; secondly, almost 50% of bites by venomous snakes do not inject enough poison and hence it is important to reassure the person. The following measures (Do's & Don'ts) can save lives even in case of venomous snake bites, if timely action is taken (See Box - 1).

Box - 1 : Snake Bites - Do's and Don'ts
Do's
Calm the patient down to slow down blood circulation and retard the spread of venom.
Have the victim lie down with the affected limb lower than the heart.
Immobilize the bitten limb, using a splint if possible and position it below the level of the heart.
Get the victims to hospital urgently, lying flat, if possible - do not wait for the symptoms to develop.
<i>Start Artificial Respiration</i> , this can be life saving in Cobra and Krait bites as the victim may stop breathing, however they are not dead.
Remove any rings, bracelets, boots, or other restricting items from the bitten extremity as it may swell.
Start antivenin in hospital after assessment of envenomation symptoms by a qualified medical person.
Don'ts
Do not apply any tourniquet or compression bandage (4).
Do not give incision or attempt to suck out venom as it is ineffective at removing venom; and in Viper bites will cause serious bleeding.
Do not give the victim alcoholic drinks or Aspirin.
Do not wash the bitten area as it may increase the venom flow.
Do not cool the area of the bite.
Do not try to catch the snake; we do not need another victim. If the snake has been killed, take it to the hospital.
Do not give antivenin in any other place other than in a hospital.

Summary

Snakes are one of the most widely distributed animals. There are over 3000 species of snakes distributed worldwide and about 275 species are found in the Indian sub-continent. Snakes belong to the class Reptilia, are limbless and characterized by elongated body which is divided into head, body and tail. The whole body is covered with scales, which are covered by skin. The skin is shed or cast off during the process of moulting. Snakes locate their prey by their senses of vision, smell or thermo-sensitivity, body is also very sensitive to vibration. Of the roughly 725 species of venomous snakes worldwide, only 250 are able to kill a human with one bite.

The snakes are classified into families: Elapidae and Viperidae. Elapids are the Cobras, Kraits and Coral snakes. Viperidae are further divided into two subgroups- the pit vipers and the typical vipers. The important venomous snakes in India are Cobra, Common Krait and the three types of vipers i.e. Russell's, Saw scaled and the Hump nosed viper.

Not all venomous snake bites lead to clinical effects as most of the time insufficient or no venom enters the wound. The local symptoms and signs of snake bite are fang marks, local pain and bleeding, bruising, lymphangitis, lymph node enlargement, blistering, local infection, abscess formation and necrosis. The systemic action of snake venom is either on the nervous system or on the haematological system. Neurotoxic symptoms due to elapid bites are drooping eyelids, vision disturbances, difficulty in breathing, difficulty in speaking and opening the mouth. Haematotoxic symptoms (due to vipers) are continuous bleeding from bite site, bleeding from gums or nose, appearance of bruises and dark urine.

Prevention of snake bite is by avoiding snake infested areas, staying out of tall grass, while hiking-keeping hands and feet out of areas one cannot see, wearing boots, keeping surroundings rubble free & dusting the beds before sleeping.

First aid involves reassurance, making the victim lie down with the affected limb lower than the heart. It is important to start artificial respiration and remove any rings, bracelets, boots etc.

Antivenom should only be given in a hospital after assessment of envenomation. It is not advisable to apply any tourniquet or compression bandage or give incision. The victim should not be given any alcoholic drinks or Aspirin nor should the bitten area be washed.

Study Exercises

MCQs & Exercises

- 1) The common poisonous snakes of India are (a) Cobra (b) Common Krait (c) Russell's vipers (d) All of these.
- 2) Which of these should not be done in case of snake bite (a) Victim should be made to lie down with affected limb lower than the heart. (b) Give incision (c) Start artificial respiration (d) Start antivenom

Fill in the Blanks:

- 3) Snakes belong to the class _____
- 4) The most venomous of all land snakes, identified by paired white lines on the body is _____
- 5) The skin which covers the scales of snakes is periodically shed of & the process is called as _____

True or false:

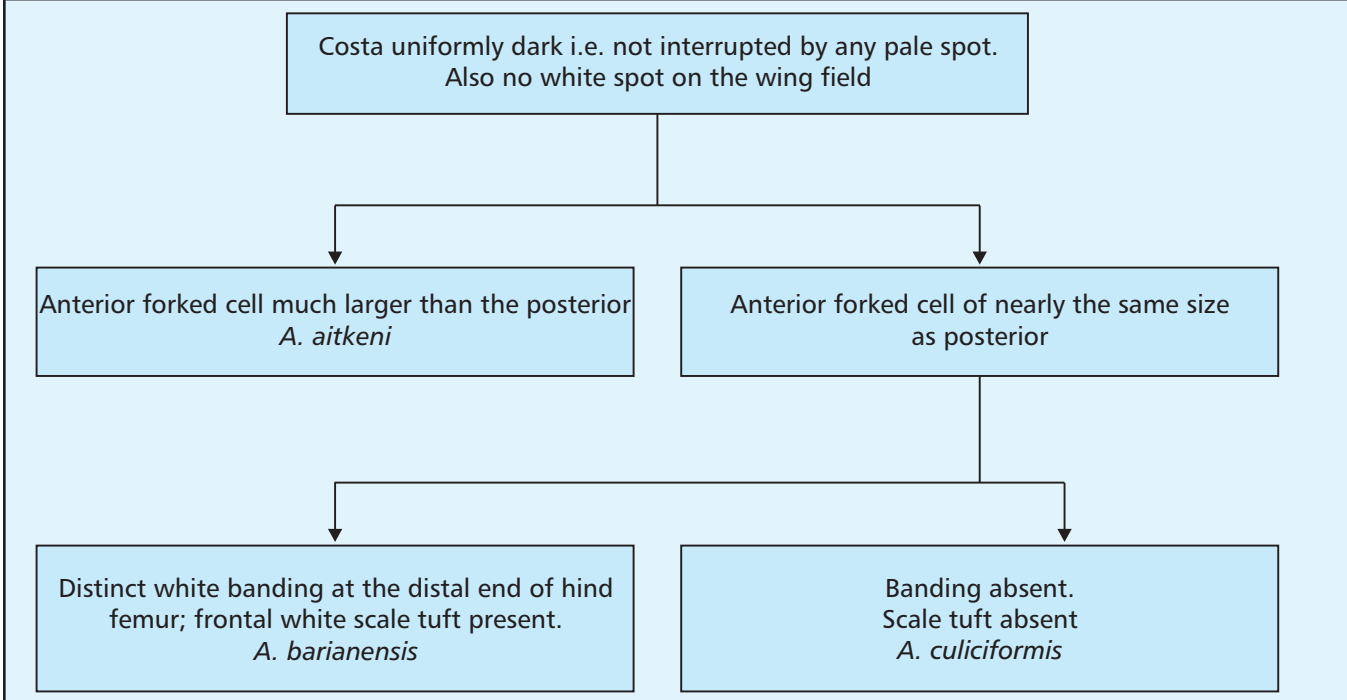

- 6) The body of the snakes which is in direct contact with the ground is not very sensitive to vibration.
- 7) Drooping eyelids, vision disturbances, difficulty in breathing, difficulty in speaking are symptoms seen in bite due to elapids.

Answers: (1) d; (2) b; (3) Reptilia; (4) Krait; (5) Moulting; (6) False; (7) True.

RajVir Bhalwar

One way of broadly classifying human diseases is according to whether they are “infectious (communicable)” or else, “non - communicable”. Out of these two, infectious diseases account for lion's share of death, ill - health and suffering in the developing countries. For this reason an epidemiologist must have a sound understanding of the epidemiologic principles concerning infectious disease practice.

General Terms and Definitions

Infection & Infectious Disease : This refers to the entry and development or multiplication of an infectious agent in the human (or, animal) body, with an implied response (e.g. immunological response) on the part of the human or animal. It must be remembered that “infection” by itself does not mean “infectious disease”. An infectious disease is that part of the spectrum of “infection” which is clinically apparent. In fact, this is the basic difference between epidemiologic practice and clinical practice as regards infectious disease - the clinician is mainly interested in “infectious disease” while the epidemiologist is interested in “infection” and its dynamics - including the subclinical cases, the carriers, the reservoirs or the infectious agent and its modes of transmission.

Colonisation : Colonisation indicates presence of infectious agent in the human body but without any evidence of specific host immune responses to the agent. In short, colonization means “infection less specific immune response”.

Endogenous Infection : Infection due to a colonizing agent; e.g. *E Coli* normally colonises the human GIT; however, under certain circumstances, it may enter the blood stream and cause endogenous infection.

Contamination : Refers to an infectious agent being present in inanimate articles like food, water, linen, patient care items or routine usage items like cutlery, toys etc. often, the term is also used to denote presence of infectious agent on skin surface, particularly on hands.

Pollution : Refers to presence of either infectious agent or such other disease causing noxious agents (as industrial effluents) or mechanical agents (as sound), usually in the general environment, air or water (e.g. sound pollution, water pollution, air pollution).

Infestation : Infestation may refer to human beings, animals or personal usage items, wherein it implies either the presence and development of insect vectors on the body or linen (e.g. louse infestation) or else on the mucus membranes (e.g. roundworm infestation). Infestation is also sometimes used for describing a state wherein an accommodation or such articles as containers have the presence of arthropods or vectors (e.g. cockroach or rat infestation in the houses).

Communicable Disease : A communicable disease is one that is caused by an infectious agent (or its toxic products, e.g. preformed toxins of *B cereus* or *C botulinum*) which can

be transmitted to a human being either directly, or indirectly (through food, water, insect vectors, soil), or else a disease which can be transmitted between humans and animals. All infectious diseases are not necessarily communicable; e.g. osteomyelitis or brain abscess are infectious diseases but not communicable. Similarly, an infectious disease may be communicable in one form (e.g. pneumonic plague) but not in the other form (e.g. bubonic plague).

Dead-End Infection : A state when an infectious disease, which is usually “communicable”, cannot be transmitted any further between human beings or from humans to animals or vice versa, for various agent, host and environmental reasons. Examples are Japanese Encephalitis, Rabies, Tetanus, Bubonic plague, Scrub typhus in humans.

Subclinical Infection (Inapparent infection) : It is a state when there is a host immune response following entry of the infectious agent; the agent may also multiply in the host body, but there are no clinical manifestations of the disease. Thus, the presence of infection cannot be recognized clinically though the infectious agent is constantly passed out of the human body and hence a person with subclinical infection is a greater health hazard for community than those having apparent disease (since the latter can be identified, treated and isolated if required). Diseases like Viral hepatitis A, have large number of subclinical infections; on the other hand, diseases like measles hardly have any subclinical infections. Thus, infections which have a large proportion of subclinical infections in their spectrum are less amenable to prevention; on the other hand, diseases which have very few or no subclinical infections are more amenable to prevention by surveillance methods.

Latent Infection : This refers to a state when the infectious agent lies “dormant” within the host body, without any clinical manifestations but does not come out of the human body (thus it is different from subclinical infection). After a period of time, under certain circumstances, the agent which had been lying dormant, reactivates and produces a different type of disease (e.g. Herpes Zoster; Brill - Zinsser disease) or else the same type of disease (e.g. reactivation Tuberculosis).

Zoonoses : Zoonoses are infections which are normally transmitted between vertebrate animals, either directly, or indirectly through a vehicle or insect vector. Those which are of health importance are the ones that are transmitted to man from vertebrate animals, either directly, or indirectly through vehicle or vectors. These are called “anthropozoonoses” and include a long list of infections like Rabies, Plague, Bovine TB, Salmonellosis, Japanese Encephalitis, Scrub and Murine typhus, Echinococcosis, Anthrax, Brucellosis and so on. The second group are infections which primarily infect man but can be transmitted to animals; these are called as zoonanthroposes. The third group is amphixenosis which includes infections that may be transmitted from man to animals and vice versa.

Opportunistic Infections : The term refers to disease, caused by infectious agents, which are normally not pathogenic, due to a decline in the general or specific immune status of the host. The term has assumed greater importance following identification of HIV infection whose clinical manifestations comprise of a wide variety of such opportunistic infections like *P carini*, *T gondi*, CMV etc.

Nosocomial Infection : This is an infection contracted while in hospital, as a result of health care or related procedure. Such infections would include those whose clinical presentation may start after discharge from the hospital but NOT those which were “incubating” in the patient’s body at the time of admission. The field of “Nosocomial Epidemiology” is fast becoming a specialized one. Hospital epidemiologists should ensure prevention and control of such hospital infections.

Eradication : The term refers to a complete cessation of transmission of the infectious agent. Usually this would imply that the infectious agent as well as the disease has also been completely reduced to zero. Small pox is the only example wherein eradication has been achieved.

Control : This refers to reducing the transmission of a disease to a level when it no longer remains a “public health problem”. Control is more pragmatic than eradication but needs ongoing preventive measures, and consequently continuing expenditure, alongwith an efficient surveillance system to give an early warning of increase in the level of transmission.

Elimination : Elimination implies either a ‘regional eradication’ (say from a country or continent), or else reduction of disease to zero without total removal of infectious agent.

Epidemiologic “Chain” of Infection

There are 4 inter - related factors, which together are referred to as the “epidemiologic chain of infection” :

- (a) The infectious agent and its characteristics.
- (b) The human host who is susceptible to the infectious agent, and various factors which determine such susceptibility.
- (c) Characteristics of the infectious process which are determined by the interactions between agent and the host.
- (d) Inter - connecting the agent and host are the “channels (or modes) of transmission of the agent to the host. Let us discuss the details of each of these components of the chain of infection.

Agent

There are three broad groups of characteristics that are important in respect of infectious disease agent viz. the reservoir and immediate sources of the agent; the characteristics of an agent that are connected with its survival in environment; and the characteristics of agent which determine the production of infection and consequent to infection, the production of disease.

Reservoir and Immediate Source of Agent : Any infectious agent has a primary habitat, called the “reservoir of infectious agent” which can be defined as “a person, animal, or inanimate environment (like soil), where an infectious agent lives, depending primarily for its survival, and where it propagates itself so that it can be transmitted to a human host”. On the other hand, a source of infection is the person, animal, or their excretions or inanimate environment from where the infective form of the agent is immediately available to the susceptible human host. Let us take the example of hookworm. The adult forms live in human gut, depending primarily on the human being for their survival; they multiply there and propagate themselves, the eggs being passed out for further transmission

to another human so as to further propagate the species. The worms do not depend primarily for survival and multiplication on any other animal, soil, plants, etc. Thus, the “reservoir of infection” is “human being, infected with Hookworm”, (human reservoir). On the other hand, infection of another human being occurs due to skin contact with soil contaminated with infective stage larvae. Thus, the “source” is “soil contaminated with infective stage larvae”.

Types of “Reservoir of Infection” : The most important “reservoir” for large majority of human infectious agents is the human being himself. The “human reservoir” of infectious agents can occur in two forms, viz. Cases and Carriers :

a) Cases : Those who have clinically apparent disease.

b) Carriers : A carrier is a human being who harbours an infectious agent and sheds it, thus becoming a potential source of infection for other human beings, but does not exhibit any manifestation of the disease. The fact that they cannot be detected despite being a potential source of infection for other makes carriers extremely important from epidemiological point of view. Depending on the stage of disease in its natural progression, a person may be a carrier either during the incubation period (incubatory carriers) as occurs in measles, mumps, Hepatitis A, etc. The importance of the incubatory carrier state lies in the fact that after the incubation period is over and the disease manifestations come up, we may isolate and treat the person, but the damage has already been done by him, by transmitting the infection during incubation period. Secondly, he may be having subclinical or clinically inapparent disease (contact or healthy carrier) e.g. Hepatitis A, Cholera, Poliomyelitis, Diphtheria etc. A subclinical carrier should be differentiated from a subclinical case, which refers to a person who has the infection beyond the incubation period but do not show clinical manifestations and *do not shed the organisms* so that the infection cannot be transmitted to other human hosts; e.g. subclinical case of Japanese Encephalitis in which the infectious agent is present in the body, but the low titer viraemia is inadequate to infect the mosquito vector. Thirdly, the person may continue to shed the infectious agent even after apparent recovery, during the convalescent stage, and hence known as convalescent carrier as occurs in cholera, typhoid and bacillary dysentery. Such “convalescent carriers” may be short term or temporary carriers (lasting upto 4 weeks or so) or chronic carriers (lasting beyond 4 weeks; may be upto years as in chronic typhoid infection of gall bladder) (103).

Animals and Other Forms of Reservoir : Besides human beings, animals form another reservoir wherein the infectious agent lives primarily, thrives, multiplies and is available for being transmitted to the human host. Such diseases fit in the scope of “zoonoses” as has been already described. Finally some infectious agents like fungi may primarily thrive and multiply in the contaminated soil.

Characteristics of Agent Concerned with Survival in Nature: The capability of an agent to thrive outside the reservoir and withstand adverse environmental effects like drying, heat, acidity, etc is known as “survival capacity in nature”. Some agents can hardly survive outside the human body (e.g. measles, chicken pox). Others may survive for limited time

provided conditions are favourable (e.g. cholera vibrio, polio virus, Hepatitis A, etc. can survive in water, ice, sewage, milk, etc; HIV can survive in blood and blood products; however all of them are quite vulnerable to drying, heat and disinfectants). Finally some organisms or their intermediate forms are quite sturdy and can withstand adverse environment very well (e.g. clostridial spores, cysts of intestinal protozoans, ova of helminthes etc). Usually, agents which have very poor survival in nature tend to adopt the direct modes of transmission like droplet infection or direct mucous contact. Survival in nature becomes all the more crucial for the agent, if human being is the only reservoir.

Characteristics of Agent Involved in Production of Infection and Disease : The various characteristics of an infectious agent which determine the production of infection, as well as the causation of disease are (104) :

Infectiousness : this is the relative ease with which the agent is transmitted to the host. Infectiousness is more of function of environmental factors; e.g. infectiousness of measles would be higher in overcrowded conditions but lesser in affluent communities.

Infectivity : This is the ability of the agent to cause infection, i.e. to enter, survive and multiply in the host. A useful epidemiologic measure of infectivity is *Secondary Attack Rate (SAR)*. It is defined as the number of susceptible persons who, within the duration of one incubation period, following exposure, develop the disease out of the total susceptibles who were exposed. SAR is usually measured by conducting studies in closed communities or families wherein the first case which brings in the infection is called the index case.

Thus,

$$\text{SAR} = \frac{\text{No. of susceptible exposed to index Case, who develop the disease, within the duration of maximum incubation period of the disease}}{\text{Total number of susceptibles exposed to the Index case}} \times 100$$

Pathogenicity : It is the ability of the agent to produce manifest disease out of those who have been infected. Generally, agents which have high pathogenicity have features which protect them from non - specific host defenses, and elaborate toxins or similar products (e.g. Diphtheria, Tetanus) or else, may cause such host immune response that leads to disease (e.g. Rheumatic fever, Glomerulonephritis).

Virulence : Higher in order, from infectivity and pathogenicity, is virulence. It is the ability of the agent to produce severe disease. If "serious" infection is being measured in terms of death, then Case Fatality Ratio (CFR) becomes a reasonably good measure of virulence.

Infective Dose : Infective dose is important for certain infectious disease agents like *V cholera* and *S typhi* in which, if the inoculum is not adequate, then infection may not settle, or at least, manifest disease may not occur. On the other hand, in infections like plague, even a very small dose may be enough to cause infection.

Host Factors

Like the agent is on one end of the epidemiological chain of infection, the "HOST" is at the other end of the chain. The host factors which determine the dynamics of infection fall into two broad categories :

(a) Host Attributes which Affect the Probability of Being Exposed to the Infectious Agent : These include *age* (e.g. young children, because of hygienic innocence and habit of "orally exploring" the items, are more susceptible to exposure to soil transmitted helminthic infections); *Sex* (e.g. females, by virtue of leading a mainly indoor life may be less exposed to sylvatic zoonoses like Kyasanur Forest Disease), *Economic status* (poverty, squalor and infection form an almost invincible trinity and this needs no further highlighting), *Occupation* (e.g. agricultural workers and veterinarians are much more likely to be exposed to certain zoonoses), *Education* (by way of improving the knowledge regarding causation and prevention of infection, may help in reducing the chances of exposure), *Living conditions* (Poor housing, overcrowding, lack of sanitary eating and drinking facilities will all increase the chances of exposure), *Life style and behavioural factors* (e.g. permissive attitude toward sex will increase the probability of exposure to reservoir of STDs), and *use of Personal protective measures* (e.g. use of mosquito nets and repellents decrease the chances of exposure to mosquito borne diseases).

(b) Host Factors that Influence Occurrence of Infection and Disease : Once the host has been "exposed" to the infectious agent, certain factors will determine whether disease will actually occur and the severity of the same. These include "*status of host immunity*", whether actively or passively (or naturally or artificially) acquired; *Age* (In general, extremes of age viz. the very young, i.e. < 2 years and the old, > 65 years are more susceptible); *Genetic make up* (known to occur in respect of diseases like tuberculosis and malaria); and *Availability & utilization of health services* (by providing chemoprophylaxis, immunization and health education at the primary preventive level and early diagnosis and prompt treatment)

Herd Immunity : Herd immunity refers to the level of immunity that is present in a population against an infectious agent. It is, thus, concerned with the protection of a "population" from infection, the protection being brought about by the presence of immune individuals. It may be defined as "the resistance of a group to attack by a disease to which a large proportion of the members are immune, thus decreasing the probability that a person having the infectious agent will transmit it to another susceptible person in the same population". In general, while dealing with childhood infectious diseases amenable to prevention by immunization, vaccination coverage of about 85% is likely to provide adequate herd immunity, which will effectively block the disease transmission, even if remaining 15% children are not immunized (though there may be many exceptions to this generally held belief).

Factors Affecting the Process of Infection as a Result of Interaction Between Agent and Host

There are certain features which are peculiar to each infectious disease as follows :

Incubation Period : Incubation period is the time period between the entry of infectious agent (or its toxin) into the human body to the point when the earliest clinical manifestations of the disease are apparent. During this period, the host does not exhibit any outwardly clinical manifestations, though immunological and histopathological changes within the body would definitely occur. If, during this period, the organism is also shed from the body of the host, the host qualifies to be an “incubatory carrier”. Incubation period is usually measured in terms of “median incubation period”, i.e. the time in which half of the infected subjects will develop clinical manifestations, following entry of the organism into the body. Along with the median incubation period, a “range” is also given which indicates the minimum and maximum incubation periods. Incubation period of a disease is found out by studying the time taken for onset of secondary cases following exposure to the index case, in family groups or in closed communities, or else during investigation of “common - vehicle, point source epidemics”. Different diseases have different values of median incubation period and range, and a specialist in Public health should remember them well.

Latent Period : In infectious disease epidemiology, latent period refers to the time that elapses between the entry of the agent in the human body to the point when the shedding of organism starts.

Period of Communicability (Infectious Period) : This is the duration for which the host sheds the agent, i.e. remains infectious. This may be very long in case of diseases like leprosy and HIV infection.

Generation Time : The generation time is the duration between the entry of infectious agent into the body to the peak infectivity of the host. As a crude calculation, generation time (G) is equal to (latent period + period of maximum communicability). The relationship between the various landmarks of a typical infectious disease is depicted as follows :

Landmarks : A = Entry of agent into host; B = Shedding of agent starts; C = Clinical manifestations start; D = Maximum infectivity of host; E = Clinical disease ends; F = Shedding of agent ends; G = Convalescence ends; A to B = Latent period; A to C = Incubation period; A to D = Generation time; C to E = Clinical phase; E to G = Convalescence phase; B to F = Period of communicability; B to C = Incubatory carrier phase; E to F = Convalescent carrier; E to G = convalescent phase; C to F = Subclinical (healthy) carrier phase (if clinical disease did not occur).

Biological Gradient (Gradient of Infection) : Biological gradient of a disease refers to the range of manifestations that may occur in the host as a result of infection. Thus, it is like a “spectrum”, ranging from inapparent infection at one end, and passing through mild illness, clinical disease, serious forms of disease, to death at the other extreme of the spectrum. Diseases like viral Hepatitis - A, poliomyelitis and cholera have a classically wide biological gradient with all varieties of severity as outlined above being present. On the other hand, measles and chicken pox tend to have only the middle part of the spectrum with either subclinical cases or deaths being uncommon. Diseases like rabies occupy only the other extreme of the spectrum, having a very serious biological gradient, with certain death being the only outcome.

Frequency of Disease : As has been repeatedly stressed in this chapter, the epidemiologist should not go simply by observed number of cases of a disease but convert it into some form of frequency measure (like incidence or prevalence) by relating the number of cases to a denominator (the population at risk). Depending on the “frequency” of the disease, the occurrence may be

- **“Epidemic”** : This is the occurrence of disease frequency, in a defined population or area, which is clearly in excess of the normal expectation.
- **“Endemic”** frequency refers to continued transmission of a disease, in a defined population or area, at a relatively low level (without any importation from an outside area or population). It would also be appreciated that the difference between an epidemic and an endemic situation is dependent on two factors - firstly, the high frequency and the “abrupt increase” which occurs in epidemic situation, compared to “continued transmission” in endemic settings. Depending on the “frequency” with which this continued transmission is going on in an endemic scenario, the endemicity could be described as “hypoendemic” or “low endemic”, (incidence being low), mesoendemic, hyperendemic, and holoendemic. In both hyperendemic as well as holoendemic situations, the transmission continues at a very high frequency; however in the latter situation, exposure to infection generally occurs during early childhood so that by the time adulthood is achieved, the population becomes immune and a high level of herd immunity occurs. For this reason, epidemic outbreaks of the disease are not likely in holoendemic situations (the classical example being “stable malaria” situations). The epidemiologist should note that half - hearted or unscientific measures (e.g. sudden introduction of insecticidal spray programs without full coverage and without concurrent coverage with surveillance for prompt diagnosis and treatment for a disease like Malaria) would tend to convert a “stable”, holoendemic situation into an “unstable” meso - endemic one, thus increasing the propensity to epidemic outbreaks.
- **“Sporadic”** frequency which refers to few, scattered cases of infection, which do not have any relation to each other temporally or spatially (i.e. according to place or time). The difference between a “low endemic” disease and sporadic disease is based on this fine dividing line - that in a low endemic disease, the frequency of disease is low but the cases would show a reasonable relation to each other according to place or time which will not be the case in sporadic situations.

Channels of Transmission

The two end points in the epidemiological chain of infection are the infectious agent and the (susceptible) host. Now, to complete this link, the infectious agent must be transmitted to the susceptible host. Such establishment of the link between agent and host is of two types, viz “direct” and “indirect” modes of transmission.

(a) Direct Modes of Transmission : A direct mode of transmission is one in which the infectious agent has to be in a state of actual physical or physiological proximity with the susceptible host, or even if not in such proximity, should be

within a very close distance so as to be able to directly come in contact with the host. There are five methods of such direct transmission

- Contact of host skin or mucous membranes with the infectious agent contained in a living tissue; e.g. sexually transmitted diseases.
- Contact of skin or mucous membranes with the infectious form of the agent contained in inanimate environment. The examples include transmission of hookworm (infective form in soil) and leptospirosis (infective form in water or soil contaminated with urine).
- Inoculation of the agent, directly from the *reservoir* into the skin or mucous as in Rabies.
- “Vertical transmission” from mother to child, through the placenta, e.g. HIV, syphilis, “TORCH” agents etc.
- Direct transmission due to the agent being within a reasonably close distance of the host, as occurs in “*droplet infection*”. Droplets are actually very finely dispersed aerosol containing the infectious agent, which are formed when a person harbouring the agent in his respiratory tract undertakes such activities like coughing, sneezing, talking etc. if another susceptible host is within a ‘reasonably close’ distance (usually taken to be 1 meter at the most), such infective droplets can be directly deposited on to the mucous membrane of oral cavity or respiratory passage (i.e. the relevant portal of the respiratory tract infections). TB, common cold, influenza, measles, mumps, pertussis, diphtheria, meningococcal infection, leprosy etc. are transmitted by such mode.

(b) Indirect Modes of Transmission : An indirect mode of transmission can be defined as one in which its infectious agent requires an “intermediary agency” to convey it from the source of infection to the susceptible host. Like for direct modes, there can be five types of indirect modes of transmission :

Vehicle Borne : The various types of “vehicles” which can convey the infectious agent, from the source of infection to the susceptible host include anything which is eaten (e.g. food, sweets, milk products, confectioneries and so on, or anything which is drunk (e.g. milk, ice, water, beverages etc). Infections of the gastrointestinal tract are classically transmitted by this mode and include such common examples as cholera, typhoid, hepatitis - A, ascariasis, amoebiasis and so on. A vehicle also would include anything which can be “injected” (e.g. blood and blood products, drugs, vaccines, diluents; examples are HIV, Hepatitis B, Malaria etc).

“Fomites” : These are defined as inanimate objects of general use by the infected person (e.g. utensils, linen, fountain pens, tooth brushes etc.) The infectious agent may remain on the surface of such fomites and may be transmitted to the susceptible host usually when such objects are put into the mouth or come in contact with conjunctiva.

Fingers : Fingers form a very important mode of indirect transmission. If Contaminated, they can transport a number of gastrointestinal infection (especially, shigella, *Salmonella typhi*, vibrio and Entamoeba).

Air : Often droplets containing the infectious agent may dry up, or may settle down on the dust. Now, if the agent can

survive environmental adversaries like drying or heat, it can be carried for long distances by air currents, alongwith the dust or droplet nuclei; and if deposited on the portal of entry of a susceptible host, can initiate infection. Important examples are legionnaires disease, ‘Q’ fever, tuberculosis, nosocomial infections. Air borne infected nuclei and dust should be differentiated from “droplet infection”. As explained, the latter is a ‘direct’ method of transmission in which the agent is directly deposited from the immediate source of infection onto the portal of entry of a susceptible host, the intervening distance being very short (maximum 1 meter). On the other hand, in an air borne transmission the agent is not directly deposited from the source of infection on to the portal of entry of susceptible host but transported indirectly by air over long distances.

Vector Borne Indirect Transmission : A vector is a living invertebrate which transfers the infectious agent from the source of infection to another susceptible host. Usually the term encompasses arthropods, and to a smaller extent, molluscs like snails. Such transmission by a vector could be either “mechanical”, in which the vector simply acts as a “fomite”, transferring the infectious agent from the host on to another vehicle like food, by carrying the agent on its body surface or in the gut (finally excreting them in the faeces). The common example is of the housefly, which mechanically transmits a number of oro - faecal disease agents from the faeces to the food. Secondly, it could be a “biological” transmission, wherein the infectious agent is transmitted, not simply in a mechanical form, but undergoes, within the body of the vector, one or more of the biological changes pertaining to the stages in its life cycle. Such biological changes may occur in one of the following three ways :

- Take the example of plague bacillus. After being taken up by the rat flea following a blood meal on the rodent, the bacilli so taken up with the blood, multiply enormously, increasing in number, in the mouth parts of the rat flea. However, there is no developmental change as regards stages of life cycle of the bacillus. Such a method of biological transmission in which the agent “multiplies” but does not “develop” in the body of the vector before being finally transmitted to the susceptible host, is known as “*propagative*” mode.
- As another example, once a female culex mosquito takes in a microfilaria along with the blood meal, the microfilaria so taken up will undergo developmental changes of life cycle in the body of the mosquito (the three larval stages, finally becoming the infective stage larva). However, there is no multiplication and for each one microfilaria taken up with blood meal, there will be, finally, only one infective form larva. Thus, if the agent undergoes developmental changes in the body of the vector but no multiplication, the same is known as “developmental” or “*cyclo developmental*” method.
- Finally, let us consider the sequence of events that occur following ingestion of malarial male and female gametocytes along with blood meal by a mosquito. The gametocytes transform into gametes, form a zygote, followed by oocyst and sporozoites. Thus, there are developmental changes

pertaining to the life cycle of the agent. In addition, for one each of male and female gametocyte taken in by the mosquito, there will be formed, not one but thousands of sporozoites; thus, if in addition to developmental changes, there is multiplication, it is known as “*cyclo - propogative*”.

Summary

Infection/ Infectious disease refers to the entry and development or multiplication of an infectious agent in the human (or animal) body, with an implied response (e.g. immunological response) on the part of the human or animal. An infectious disease is that part of the spectrum of “infection” which is clinically apparent. Colonization indicates presence of infectious agent in the human body but without any evidence of specific host immune responses to the agent. Infection due to a colonizing agent is called endogenous infection. Contamination refers to an infectious agent being present on inanimate articles.

Pollution refers to presence of either infectious agent or such other disease causing noxious or mechanical agents, usually in the general environment, air or water. Infestation may refer to human beings, animals or personal usage items, wherein it implies either the presence and development of insect vectors on the body or linen or on the mucous membranes.

A communicable disease is one that is caused by an infectious agent or its toxic products which can be transmitted to a human being either directly, or indirectly. Dead - end infection is a state when an infectious disease, which is usually “communicable”, cannot be transmitted any further between human beings or from humans to animals or vice versa, for various agent, host and environmental reasons. Subclinical infection is a state when the agent may also multiply in the host body, but there are no clinical manifestations of the disease; whereas Latent infection refers to a state when the infectious agent lies “dormant” within the host body, without any clinical manifestations but does not come out of the human body. Zoonoses are infections which are normally transmitted between vertebrate animals, either directly, or indirectly through a vehicle or insect vector. Opportunistic infection refers to disease, caused by infectious agents, which are normally not pathogenic, due to a decline in the general or specific immune status of the host.

Nosocomial infections are those contracted while in hospital, as a result of health care or related procedure. The term Eradication refers to a complete cessation of transmission of the infectious agent. Control refers to reducing the transmission of a disease to a level when it no longer remains a “public health problem”. Elimination implies either a ‘regional eradication’ or else reduction of disease to zero without total removal of infectious agent.

Four inter-related factors are together referred to as the “epidemiologic chain of infection” - these are : agent, host, interaction between agent and host; and modes of transmission. There are three broad groups of characteristics that are important in respect of infectious disease agent, viz. the reservoir and immediate sources of the agent; the characteristics of an agent that are connected with its survival in environment; and, the characteristics of agent which determine the production of infection and, consequent to infection, the production of disease.

The “human reservoir” of infectious agents can occur in two forms, viz. Cases and Carriers. Those who have clinically apparent disease are cases, whereas a carrier is a human being who harbours an infectious agent and sheds it, thus becoming a potential source of infection for other human beings, but does not exhibit any manifestation of the disease. Carriers are of various types - subclinical, incubatory and so on. Infectiousness is the relative ease with which the agent is transmitted to the host ; whereas Infectivity is the ability of the agent to cause infection, a useful measure being Secondary Attack Rate (SAR). Pathogenicity is the ability of the agent to produce manifest disease out of those who have been infected. Virulence is the ability of the agent to produce severe disease.

The host factors which determine the dynamics of infection fall into two broad categories - Host attributes which affect the probability of being exposed to the infectious agent (like age, sex, SES etc.) and host factors that influence occurrence of infection and disease (like status of host immunity, genetic make - up etc.). Herd immunity refers to the level of immunity that is present in a population against an infectious agent.

Certain features which are peculiar to each infectious disease are as follows : *Incubation period* is the time period between the entry of infectious agent (or its toxin) into the human body to the point when the earliest clinical manifestations of the disease are apparent; whereas, *Latent period* refers to the time that elapses between the entry of the agent in the human body to the point when the shedding of organism starts.

Infectious period is the duration for which the host sheds the agent. *Generation time* is the duration between the entry of infectious agent into the body to the peak infectivity of the host. Depending on the “frequency” of the disease, the occurrence may be either *Epidemic*, which is the occurrence of disease frequency, in a defined population or area, which is clearly in excess of the normal expectation; or *Endemic* frequency refers to continued transmission of a disease, in a defined population or area, at a relatively low level (without any importation from an outside area or population). Depending on the “frequency” with which this continued transmission is going on, the endemicity could be described as *hypoendemic*, *mesoendemic*, *hyperendemic* and *holoendemic*. Sporadic frequency refers to few, scattered cases of infection, which do not have any relation to each other temporally or spatially.

There are two broad modes of disease transmission - direct and indirect; A direct mode of transmission is one in which the infectious agent has to be in a state of actual physical or physiological proximity with the susceptible host (for example, inoculation or vertical transmission), whereas an indirect mode of transmission can be defined as one in which its infectious agent requires an “intermediary agency” to convey it from the source of infection to the susceptible host (for example, vehicle or vector - borne). Vector - borne transmission may be of many types - cyclo - developmental, propogative or cyclo - propogative, depending on whether only development or multiplication or both (of the causative organism) occurs in the vector.

Study Exercises

Long Question : Discuss, with suitable examples, the various modes of transmission of infectious diseases.

Short Notes : (1) Herd Immunity (2) Survival of infectious agent in nature (3) Nosocomial infections (4) Incubation period (5) Carriers.

MCQs & Exercises

1. Presence of an infectious agent in an inanimate article or on skin surface, particularly hands, is called (a) pollution (b) contamination (c) infection (d) infestation
2. Which mode of transmission is followed in transmission of microfilaria through female culex mosquito (a) cyclo - propagative (b) propagative (c) cyclo - developmental (d) vehicle - borne
3. Malaria and Filariasis are mainly transmitted through vehicle - borne mode of transmission . Yes/ No
4. All of the following are examples of direct modes of transmission except (a) Fomites (b) inoculation into skin or mucus membranes (c) droplet infection (d) vertical transmission
5. Latent period + period of maximum communicability will give a crude estimate of the (a) lead time (b) lag time (c) generation time (d) incubation period
6. The level of immunity that is present in a population against an infectious agent is known as (a) innate immunity (b) acquired immunity (c) selective immunity (d) herd immunity
7. In calculation of secondary attack rate, exposure to which case is being taken into account (a) primary case (b) index case (c) secondary case (d) subclinical case
8. Case Fatality Ratio (CFR) is a reasonably good measure of (a) Pathogenicity (b) Infectivity (c) Virulence (d) Infectiousness
9. Epidemiologic chain of infection usually involves all of the following factors except (a) Disinfectants (b) Infectious agent (c) Human host (d) Modes of transmission
10. The presence and development of insect vectors on the body or linen e.g. louse is known as (a) Infection (b) Infestation (c) Infectiousness (d) Infectivity
11. A significantly large amount of subclinical infection occurs in all of the following diseases except (a) Hepatitis A (b) Hepatitis B (c) Rubella (d) Measles
12. All of the following diseases are examples of Anthroponoses except (a) *Trypanosoma cruzi* (b) Hydatid disease (c) Trichinosis (d) Plague.
13. All of the following organisms are quite sturdy and can withstand adverse environment very well, except (a) Clostridal spores (b) Cysts of intestinal protozoans (c) Ova of helminths (d) Hepatitis A virus
14. The time in which half of the infected subjects will develop clinical manifestations, following entry of the organism into the body, is known as (a) Lead time (b) Median Latent period (c) Median Incubation Period (d) Generation time
15. That subset of Endemic frequency, wherein exposure to infection generally occurs during early childhood so that by the time adulthood is achieved, the population becomes immune and a high level of herd immunity occurs, is known as (a) Hyper - endemic (b) Holo - endemic (c) Meso - endemic (d) Hypo - endemic

Answers : (1) b; (2) c; (3) No; (4) a; (5) c; (6) d; (7) b; (8) c; (9) a; (10) b; (11) d; (12) a; (13) d; (14) c; (15) b.

History

The concept of immunity has intrigued mankind for thousands of years. According to the prehistoric views, disease was caused by supernatural forces and illness was a form of punishment for “bad deeds” or “evil thoughts” visited upon the soul by the Gods or by one’s enemies (1). The first written descriptions of the concept of immunity may have been made by the Athenian Thucydides who, in 430 BC, described that when the plague hit Athens “*the sick and the dying were tended by the pitying care of those who had recovered, because they knew the course of the disease and were themselves free from apprehensions. For no one was ever attacked a second time, or not with a*

fatal result” (3). The term “*immunes*”, is also found in the epic poem “Pharsalia” written around 60 B.C. by the poet Marcus Annaeus Lucanus to describe a North African tribe’s resistance to snake venom (2). The first clinical description of immunity which arose from a specific disease causing organism is probably *Kitab fi al-jadari wa-al-hasbah* (4) written by the Islamic physician Al-Razi in the 9th century. However, it was with Louis Pasteur’s Germ theory of disease that the fledgling science of immunology began to explain how bacteria caused disease, and how, following infection, the human body gained the ability to resist further insults (3).

Burnet and Medawar, Nobel Prize winners in 1960 put forth the concept that man had learnt to tolerate his own tissues (self) and was intolerant to foreign tissues (i.e. not self). The concept of ‘self’ and ‘not self’, therefore, means that under normal conditions the body tolerates its own tissues (immunological tolerance), and recognizes and destroys foreign tissues. In the

modern sense, therefore, immunity has been defined as the ability of the body to recognize, destroy and eliminate antigenic material foreign to its own (5, 6).

The Immune System

The *immune system* is a collection of mechanisms within an organism that protects against infection by identifying and killing pathogens and tumour cells.

Structure and Function of Immune System

Tissues and organs important for the immune function include:

- Cells derived from stem cells : liver, bone marrow
- Cells that are stored, multiply, interact and mature in : thymus, spleen, lymph nodes, blood
- Transport : lymphatic vessels
- Accessory organs
- Appendix, tonsils, intestines

The immune system protects organisms from infection with layered defenses of increasing specificity. Most simply, physical barriers prevent pathogens such as bacteria and viruses from entering the body. If a pathogen breaches these barriers, the innate immune system provides an immediate, but non-specific response. Innate immune systems are found in all plants and animals. However, if pathogens successfully evade the innate response, vertebrates possess a third layer of protection, the adaptive immune system. Here, the immune system adapts its response during an infection to improve its recognition of the pathogen. This improved response is then retained after the pathogen has been eliminated, in the form of an immunological memory, and allows the adaptive immune system to mount faster and stronger attacks each time this pathogen is encountered (7,8).

Antigen

Antigen is defined as a substance which when introduced into the tissues stimulates the production of specific antibodies and combines specifically with the antibody so produced (3). By far the best antigens are proteins (e.g. diphtheria toxin, tetanus toxin); others are polysaccharides (e.g. blood group antigens), lipids and nucleic acids. There are also incomplete antigens called 'haptens' which by themselves are not antigenic but can provoke an immune response by combining with one of the body's proteins in such a way that the protein becomes 'foreign' to the body. Penicillin is an example of 'hapten'. On contact with an antigen the host can respond in three different ways :

- (a) Circulating antibody is formed.
- (b) A delayed-type cell mediated hypersensitivity reaction may result on second contact with the antigen.
- (c) Tolerance, which means that on second contact with the same antigen no response will be provoked.

The type of response in a particular case will depend largely on the antigen itself, the dosage, and the route of application and possibly on other lesser-known factors (9).

Antibody

Antibody is a protein substance that appears in the body as a result of invasion of antigen. It is capable of reacting specifically

with the same antigen, which provokes its production. The sites of maximum antibody formation are the lymph nodes and spleen. Smaller collections of antibody producing cells are widely scattered in various tissues throughout the body. Plasma cells also produce antibodies. Antibodies may be antitoxic such as diphtheria and tetanus, antibacterial like typhoid or antiviral such as polio.

Immunoglobulins

These comprise of families of closely related globulin molecules, which are synthesized by cells of reticulo-endothelial system (RES). The human immunoglobulin system is divided into five major classes IgG, IgA, IgM, IgD and IgE. The molecule of each immunoglobulin is understood to consist of K (Kappa) and L (Lamda) polypeptide chain (10).

(a) IgG : Repeated exposure to antigen leads to its accumulation in serum. It comprises about 80 per cent of serum antibodies in an adult. Antibodies to gram positive pyogenic bacteria, antiviral and antitoxic antibodies are found exclusively among IgG globulins. This is the immunoglobulin, which is transported across the placenta. Maternally derived IgG is slowly replaced by actively synthesized IgG which appears at 1-3 months of age and then rapidly rises and adult level is reached by the age of one or two years. Normal adult serum level of IgG is 600-1800 mg/100 ml.

(b) IgA : This fraction has been found to contain isohaemagglutinins, anti-brucella, anti-diphtheria antibodies and comprises about 10 per cent of the serum antibodies. Saliva, colostrum and tears are relatively rich in this fraction. Nasal and bronchial secretions, bile, intestinal juices and prostatic fluid also contain IgA. It seems to play a decisive role in local immunity. IgA synthesis begins two weeks after birth. Normal adult serum level is 70-380 mg/100 ml.

(c) IgM : This fraction is found to have high agglutinating and complement fixation ability. Wasserman antibodies and bactericidal antibodies against Gram negative organisms (endotoxins) are almost exclusively found in IgM. It accounts for 5 to 10 per cent of serum antibodies. It cannot pass through placenta. Normal adult serum level is 20-130 mg/100 ml.

(d) IgD : Not much is known about it. Normal adult serum level is 4-40 mg/100 ml.

(e) IgE : The antibodies in this fraction have the ability to fix themselves firmly to tissues and remain so. They are likely to play an important role in allergic reactions.

Immunity

The word "immunity" derives from the latin *immunis*, meaning exemption from military service, tax payments or other public services and is defined as "Ability of an organism to recognize and defend itself against specific pathogens or antigens (11) (Box - 1).

Types of Immunity

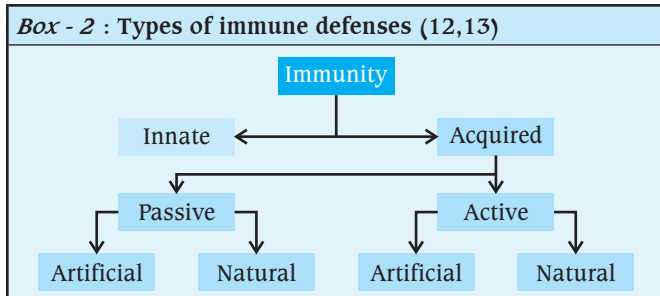

The normal individual has two levels of defence against foreign agents. *Natural or innate immunity*, - which is present in neonatal animals and in invertebrates. Adaptive or acquired immunity - that is confined to vertebrates (Box - 2).

Nonspecific Defense Mechanisms		Specific Defense Mechanisms (Immune System)
First line of defense	Second line of defense	Third line of defense
<ul style="list-style-type: none"> • Skin • Mucous membranes • Secretions of skin and mucous membranes 	<ul style="list-style-type: none"> • Phagocytic White blood cells • Antimicrobial proteins • The inflammatory response 	<ul style="list-style-type: none"> • Lymphocytes • Antibodies

Acquired (Adaptive) immunity : This develops only after exposure to inducing agents such as microbes, toxins, or other foreign substances.

Active Immunity

Naturally acquired active immunity : It occurs when a person is exposed to a live pathogen, and develops a primary immune response, which leads to immunological memory. This type of immunity is "natural" because it is not induced by man.

Innate (natural) Immunity : This is made up of several components.

- *Physical barriers* are the first line of defense against infection. The skin and mucous membranes provide a continuous surface which must be breached and back this up with mechanical protection through cilia and mucous.
- *Physiological factors* such as pH, temperature and oxygen tension limit microbial growth. The acid environment of the stomach combined with microbial competition from the commensal flora inhibits gut infection.
- *Protein secretions* into external body fluids such as lysozyme also help resist invasion. Soluble factors within the body such as complement, interferons and other molecules such as C-reactive protein are of considerable importance in protection against infection.
- *Phagocytic cells* are critical in the defense against bacterial and simple eukaryotic pathogens. Macrophages and Polymorphonuclear leucocytes (PMN) can recognise bacterial and yeast cell walls through broadly specific receptors (usually for carbohydrate structures) and this recognition is greatly enhanced by activated complement (opsonin) (7).

Artificially acquired active immunity : It can be induced by a vaccine, a substance that contains antigen. A vaccine stimulates a primary response against the antigen without causing symptoms of the disease.

Passive Immunity : Passive immunity is the transfer of active immunity, in the form of readymade antibodies, from one individual to another.

Naturally acquired passive immunity : Passive immunity can occur naturally, when maternal antibodies are transferred to the fetus through the placenta or through breast milk (14,15).

Artificially acquired passive immunity : This is a short-term immunization induced by the transfer of antibodies, which can be administered in several forms; as human or animal plasma or serum, as pooled human immunoglobulin (16).

Active versus Passive Immunity : Some differentiating points between active and passive immunity are given in Table - 1.

Host Defenses

There are two different types of host defenses that the body exhibits as a result of exposure to an antigen. These are :

- The humoral immune response involves the activation and clonal selection of B cells, resulting in the production of antibodies.
- The cell-mediated immune response involves the activation and clonal selection of cytotoxic T cells (17).

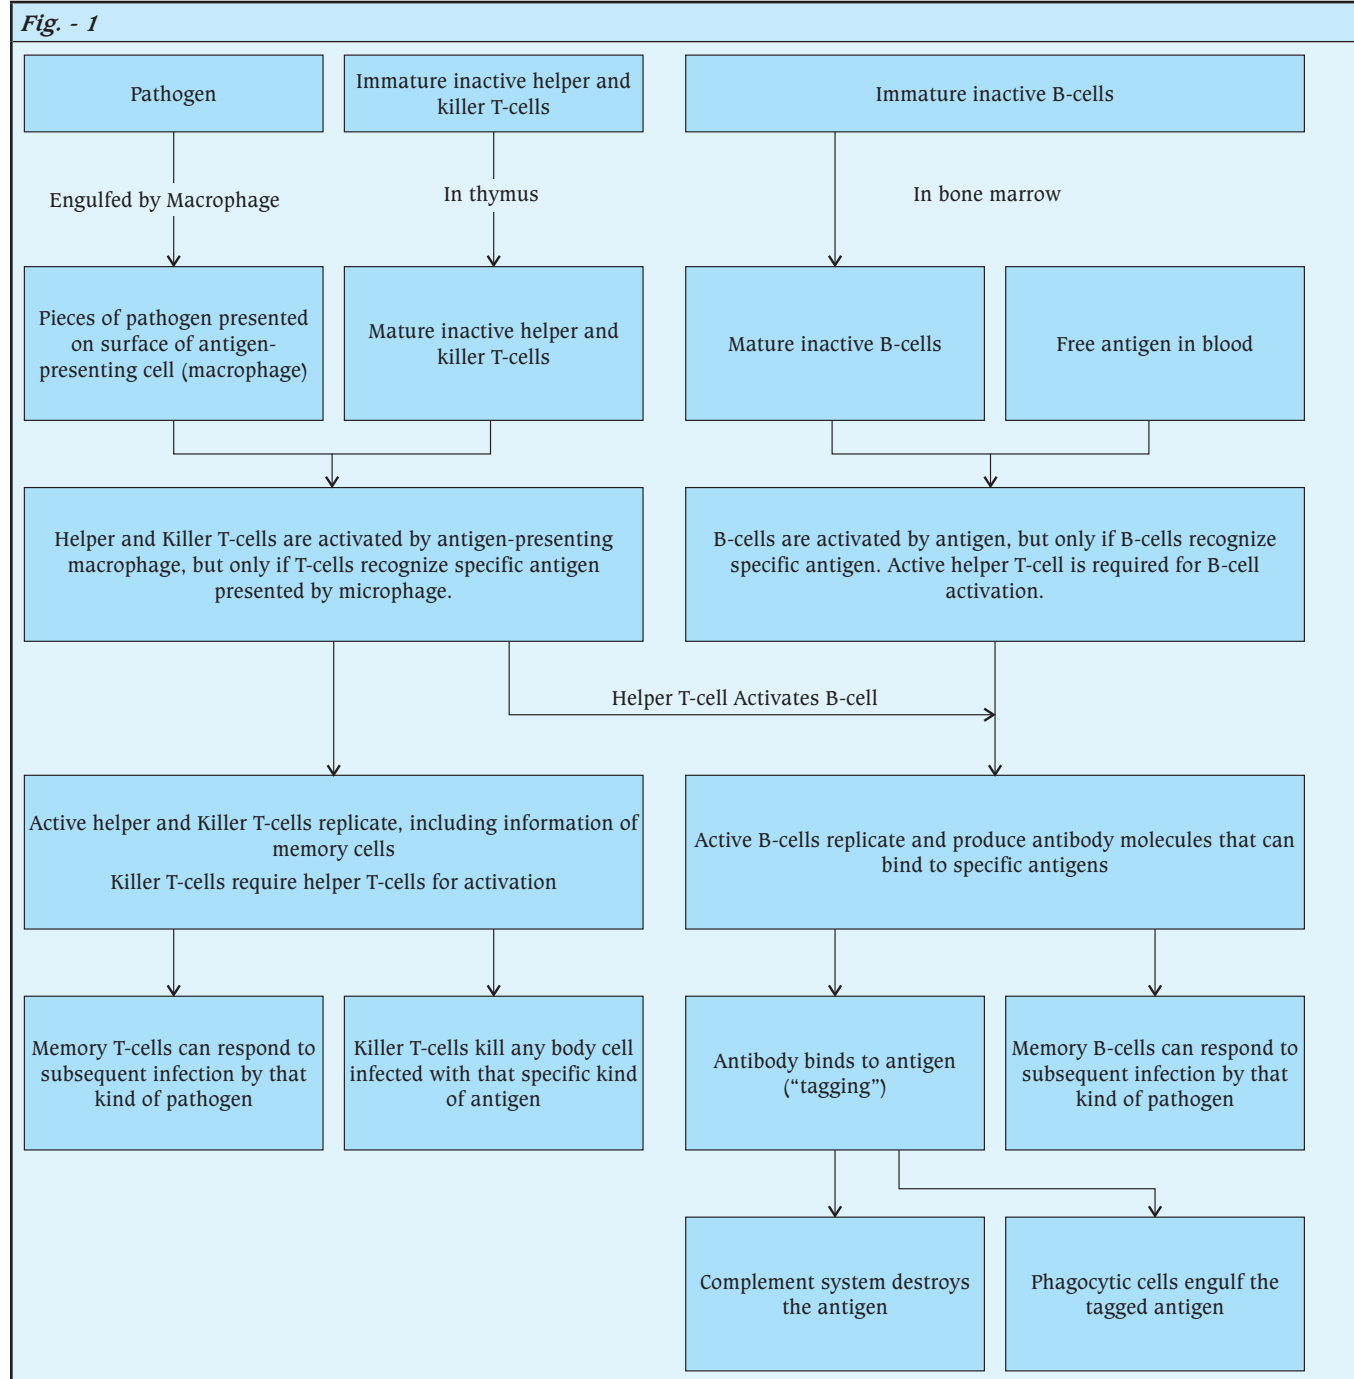

Humoral Immunity : An immunocompetent but as yet immature B-lymphocyte is stimulated to maturity when an antigen binds to its surface receptors and there is a T helper cell nearby (to release a cytokine). This sensitizes or primes the B cell and it undergoes clonal selection. Most of the family of clones becomes plasma cells. These cells, after an initial lag, produce highly specific antibodies at a rate of as many as 2000

Active Immunity	Passive Immunity
Usually produced in response to bacteria, viruses, toxins or toxoids.	Produced by serum containing already prepared antibodies
Body cells take an active part in the production of immunity.	Cells of body do not take part in the production of antibodies.
It takes sometime to develop the antibody in the system.	No time is lapsed to get the antibodies circulating in the system.
Immunity lasts long	Immunity lasts for a short period, usually 10-14 days.
Used for pre-pathogenic prophylaxis and treatment of sub-acute or chronic infections in order to increase	Used for treatment of acute infection and for tiding over the crisis or incubation period.

molecules per second for four to five days. The other B cells become long-lived memory. Humoral immunity is active when the organism generates its own antibodies and passive when antibodies are transferred between individuals. Similarly, cell mediated immunity is active when the organisms' own T-cells are stimulated and passive when T cells come from another organism (17, 18).

Cell-mediated Immunity : Macrophages engulf antigens and process them internally. This sensitizes the T cells to recognize these antigens. T cells are primed in the thymus, where they undergo two selection processes. The first positive selection

process weeds out only those T cells with the correct set of receptors that can recognize the MHC molecules responsible for self-recognition. Then a negative selection process begins whereby T cells that can recognize MHC molecules complexed with foreign peptides are allowed to pass out of the thymus. Cytotoxic or killer T cells (CD8+) do their work by releasing lymphotoxins, which cause cell lysis. Helper T cells (CD4+) serve as managers, directing the immune response. The process by which T cells and B cells interact with antigens is summarized in Fig. - 1.

Local Immunity : Local immunity is believed to be produced by fixation of various specific humoral antibodies in tissues, cells; or it may be nonspecific response of local tissues, induced by a local application of antigen, against a subsequent infection threatening systemic disease e.g. oral poliomyelitis vaccine (OPV) used for producing immunity against poliomyelitis.

Herd Immunity : Herd Immunity is the immunity of a group of people or a community taken as a whole. In the epidemiology of infectious diseases, consideration of herd immunity is of greater importance than that of individual immunity. Epidemics disappear from a community long before 100 per cent of its members become immune, either naturally or artificially through mass immunization. Epidemiological immunity is usually established even when, say only 80 to 85 % people in the community become immune. The other 20 % people enjoy freedom from infection by virtue of their belonging to the 'herd'. Herd immunity can also develop through the process of natural selection by weeding out of the susceptible successive generations due to death from disease. The level of herd immunity at a given time depends on the herd structure which is constantly changing. (19).

Types of Immune Response

The first encounter with an antigen is known as the *primary response*. Re-encounter with the same antigen causes a *secondary response* that is more rapid and powerful (20) (Fig. - 2). Immune response depends on

- Nature and dose of antigen
- Route of administration
- Type of adjuvants used
- Nutritional status of the recipient

Immunisation

Immunisation is the process by which an individual is exposed to an agent that is designed to fortify his or her immune system against that agent. The material is known as an *immunogen*. Immunization is the same as inoculation and vaccination in that inoculation and vaccination use a viable infecting agent like immunization does.

History of Immunization : While Dr. Edward Jenner (1749-1823) has been recognized as the first doctor to give sophisticated

immunization, it was British dairy farmer Benjamin Jesty who noticed that "milkmaids" did not become infected with smallpox, or displayed a milder form. Jesty took the pus from an infected cow's udder and inoculated his wife and children with cowpox, thereby making them immune to smallpox. By injecting a human with the cowpox virus (which was harmless to humans), Jenner swiftly found that the immunized human was then also immune to smallpox.

Vaccines : These are immunobiological substances designed to produce specific protection against diseases by stimulating production of protective antibody or other immune mechanisms. A number of agents can be used to provide protection against diseases. This protection can be active where antibodies are produced by our own body in response to vaccines or passive where antibodies are received in ready made form of immunoglobulins or non-human antisera (See Box - 3).

Box - 3 : Milestones in vaccination	
1798	Smallpox
1885	Rabies
1897	Plague
1923	Diphtheria
1926	Pertussis
1927	Tuberculosis (BCG)
1927	Tetanus
1935	Yellow Fever
After World War II	
1955	Injectable Polio Vaccine (IPV)
1962	Oral Polio Vaccine (OPV)
1964	Measles
1967	Mumps
1970	Rubella
1981	Hepatitis B

Immune Response to Vaccination : The vaccine mimics infection with the respective pathogen, but without risk of the disease. The consequent immune response may be manifested through antibody (humoral immunity) or cell mediated immunity (CMI), or both. Maternal CMI is not transferred to the foetus. Therefore BCG can be given at birth, OPV is given by mouth; it establishes local infection in a proportion of children. Maternal antibody in the infant's circulation is a very weak inhibitory factor; hence OPV also can be given at birth. Hepatitis B surface antigen is an excellent immunogen, overcoming, to a large extent, the inhibiting effect of maternal antibody; hence that too can be given at birth. On the other hand, live measles vaccine may be completely inhibited in the presence of detectable maternal antibody in the infant's circulation. Therefore measles vaccine is given after a delay of 9 months from birth and MMR only after 12 months (8).

The goal of all vaccines is to promote a primary immune reaction so that when the organism is again exposed to the antigen, a much stronger secondary immune response will

be elicited. Any subsequent immune response to an antigen is called a secondary response and it exhibits the following features :

- A shorter lag time
- More rapid buildup
- A higher overall level of response
- A more specific or better "fit" to the invading antigen
- Utilizes IgG instead of the large multipurpose antibody IgM

Types of vaccines : Traditionally, there are four types of vaccines (Table - 2).

- Live (attenuated)
- Inactivated (killed)
- Toxoids
- Subunit and recombinant

Live Vaccines : These are prepared from live attenuated organisms. They are very potent immunizing agents because :

- Live organisms multiply in the host
- All major and minor antigenic components are present
- Target organs may be colonized
- May replace wild strains in the community

Drawbacks : Safety is an issue because mutation may take place resulting in disease. Live vaccines can not be used for immuno-deficient patients as well as during pregnancy.

Precautions : Two live vaccines are usually not used together. They are to be given at different sites or three weeks apart. Besides, live vaccines have exacting storage requirements.

Example :

- Bacterial
 - BCG
 - Typhoid oral
- Viral
 - Measles, Mumps, Rubella
 - Oral Polio
 - Yellow fever, Influenza
- Rickettsial
 - Epidemic typhus

Inactivated (Killed) Vaccines : These are prepared from organisms killed by heat or chemicals. Killed vaccines are very safe but less efficacious than live vaccines. They require multiple doses which may be administered as a series of primary doses followed by regular booster doses. The only absolute contraindication is hypersensitivity.

Example :

- Bacterial
 - Typhoid, Pertussis, Cholera
- Viral
 - Rabies, Hepatitis B, Japanese encephalitis

Toxoids : These are produced from detoxicated toxins. The body produces antibodies against the toxin in response to toxoids. They offer no protection against infection. Toxoids are very safe and highly effective.

Example : Diphtheria, Tetanus

Table - 2 : Immunizing Agents	
Live attenuated Vaccines

Non Human (Antisera)	
Diphtheria	Bacterial
Tetanus	
Gas gangrene	
Botulism	
Rabies	Viral

Passive Immunisation : Passive immunization may be administered using human or animal products. Conventionally human products are called *immunoglobulins* and animal products are called *anti-sera*. Animal products are cheaper but suffer from the disadvantage of greater chances of immediate or delayed hypersensitivity.

Human Immunoglobulins : Non-specific or generalized protection is offered by normal immunoglobulins while protection against specific diseases is given by using hyper-immune immunoglobulins.

Normal Immunoglobulins : These provide non specific immediate ready made protection for upto three weeks. No live vaccine should be given for 12 weeks following administration of immunoglobulins. They should be administered at least two weeks after a live vaccine

Example : Measles, Hepatitis A

Specific Hyperimmune Immunoglobulins : These are made from plasma of recently recovered patients. They are to be given immediately after exposure. Peak blood levels are usually achieved in two days. They have a half life three to five weeks

Example : HBIG, VZIG, Rabies, Tetanus

Animal anti-sera or anti-toxin : Animal anti-sera are generally equine in origin. Their biggest draw back is that they may cause anaphylactic reactions or serum sickness.

Examples : Diphtheria, Tetanus, Rabies, Botulism, Gas gangrene, Snake Bite.

National Immunization Schedule

Any immunization schedule is drawn up keeping two important factors in mind. Firstly the vaccines need to be administered in doses and schedules which produce an adequate immunological response in the recipient. Secondly the schedule should be administratively convenient and one which is likely to be most acceptable to the target population. The National Immunization Schedule drawn up for India factors in both these aspects (21) (Table - 3).

Table - 3 : Schedule		
Infants	At Birth	BCG, OPV - 0 (Institutional delivery)
	6 weeks	BCG (If not given at birth) DPT - 1, OPV - 1
	10 Weeks	DPT - 2, OPV - 2
	14 Weeks	DPT - 3, OPV - 3
	09 months	Measles
Children	16 - 24 mths	DPT and OPV
	5 - 6 yrs	DT*
	10 yrs	TT*
	16 yrs	TT *
(If there is no clear evidence of previous immunization two doses one month apart to be given)		
Pregnant Women	Early pregnancy	TT - 1
	One month later	TT - 2
(In case of clear evidence of primary immunization or two doses during previous pregnancy, only single dose to be given)		

Storage of Vaccines

Sensitivity to heat : All vaccines are sensitive to heat to some extent, but some are more sensitive than others. The commonly used EPI vaccines may be ranked according to their sensitivity to heat as given in Box - 4.

Box - 4 : Sensitivity to Heat	
Most Sensitive	
	OPV
	Measles
	DPT, Yellow Fever
	BCG
	Hib, DT
	Td, TT, Hepatitis B
(Note : However, that all freeze-dried vaccines become much more heat-sensitive after they have been reconstituted, and it is then even more important that they are not exposed to heat.)	

Sensitivity to Cold : Some vaccines are also sensitive to being too cold. For these vaccines, freezing or exposure to temperatures < 0°C can also cause loss of potency, and again, the vaccine will become useless. For these vaccines, it is therefore essential to protect them not only from heat, but also from freezing. The vaccines sensitive to freezing (as well as to heat) are as given in Box - 5.

Box - 5 : Sensitivity to Cold	
Most Sensitive	
	Hep B
	Hib (Liquid)
	DTP
	DT
	Td
	TT
Least Sensitive	

Sensitivity to Light : Some vaccines are also very sensitive to strong light, so they must always be protected against sunlight or fluorescent (neon) light. BCG, measles, MR, MMR and rubella vaccines are sensitive to light (as well as to heat). Normally, these vaccines are supplied in vials made from dark brown glass, which gives them some protection against light damage, but care must still be taken to keep them covered and protected from strong light at all times (22,23).

Recommended Storage Temperatures

The recommended conditions for storing vaccines are shown in Table - 4. This table indicates the maximum times and temperatures in each case (24).

Each time some damage due to heat occurs, the loss of potency accumulates, and eventually, if the cold chain is not correctly

Table - 4 : WHO recommended vaccine storage conditions					
	Primary	Intermediate		Health Centre	Health Post
		Region	District		
	6 months ^a	3 months	1 month	1 month	Daily use
OPV	-15°C to -25°C		+2°C to +8°C		
BCG	WHO no longer recommends that freeze-dried vaccines be stored at -20°C. Storing them at -20°C is not harmful but it is unnecessary. Instead, these vaccines should be kept in refrigeration and transported at +2°C to +8°C.				
Measles					
MMR					
MR					
Yellow Fever					
Hib freeze-dried					
HepB					
DTP-HepB					
Hib liquid					
DTP					
DT					
TT					
Td					

Diluent vials must NEVER be frozen. When the manufacturer supplies a freeze-dried vaccine packed together with its diluent, ALWAYS store the product at between +2°C and +8°C. Where space permits, diluents supplied separately from the vaccine may safely be stored in the cold chain at between +2°C to +8°C
Note a : 6 months is the maximum recommended storage time at primary level. This includes the period required to obtain clearance from the National Regulatory Authority.

maintained, all potency will be lost, and the vaccine becomes useless.

Expiry Date : Even when stored at the correct temperature, vaccines do not retain their potency forever, and therefore all vaccines have an expiry date (24).

Diluents for Vaccines : Diluents for vaccines are less sensitive to storage temperatures than the vaccines with which they are used, but may be kept in the cold chain between +2°C to +8°C if space permits. When vaccines are reconstituted, the diluent should be at same temperature as the vaccine, so sufficient diluent for daily needs should be kept in the cold chain at the point of vaccine use. However, diluent vials must never be frozen. This will risk cracking the glass and allowing contamination of the contents, so diluent vials must never be kept in a freezer, or allowed to be in contact with any frozen surface (25). Each vaccine requires a specific diluent and therefore, diluents are not interchangeable. Likewise, diluent made by one manufacturer for use with a certain vaccine cannot be used for reconstituting the same type of vaccine produced by another manufacturer.

Cold Chain

Cold chain is a system of transporting and storing vaccines at recommended temperature from manufacturer to the point of use. All the vaccines can be stored at temperatures between +2°C to 8°C. However for long term storage, OPV and measles can be stored at sub zero temperatures in deep freezers. DPT, DT and TT should never be frozen. BCG and diluent ampoules should not be frozen. Diluents required for measles and BCG should be stored at +2°C to +8°C in the refrigerator.

Cold chain includes :

- Walk in cold rooms (WICs)
- Deep freezers
- Ice - lined refrigerators (ILRs)
- Refrigerators
- Cold box
- Vaccine carrier
- Day carrier
- Ice packs

Walk In Cold Rooms : These are used for the storage of large quantities of vaccines. They require constant electric supply. Vaccines can be stored up to 3 months. They serve a region of 4-5 districts.

Deep Freezers and ILRs : These are provided at the district and CHC level and can store up to 1 month supply of vaccines. Capacity is 300/240 L. They can be used for storing OPV and measles. Ice packs are also prepared.

Small Deep Freezers and ILRs : These are provided at the PHC and can store up to 1 month supply of vaccines. Capacity is 140L. They do not have a freezer compartment.

Refrigerators : While using a refrigerator for the purpose of keeping vaccines, certain Do's and Don'ts have to be followed as shown in the box.

Vaccine Carriers : Used for transporting small quantity of vaccines to sub center. These are made of insulating material. Each carries four ice packs. The vaccines should be used on the same day. They should be kept away from direct sunlight.

Day Carriers : These are made of insulating material and carry two ice packs. They can keep few vials for 6-8 hrs at a time.

Using refrigerator to keep vaccines - Do's and Don'ts

Do's

- Keep in cool room away from sunlight
- At least 10 cm away from the wall
- Keep ice pack in freezer
- Defrost periodically
- Check temp. and maintain record

Don'ts

- Open unless necessary
- Keep vaccine in the door
- Keep food inside
- Keep more than one month's requirement
- Keep expired vaccines

Ice Packs : These are flat plastic water bottles filled with water. They are available in three capacities : 400ml, 500ml and 600ml. They are prepared by keeping in freezer.

Quality of Cold Chain : The quality of the cold chain is monitored by the National Quality Control Lab located at Kasauli. The quality check is done before release of the vaccines. Reverse Cold Chain is also maintained to check vaccines for their potency.

Vaccine stock management : Vaccine stock management is done at three points :

- When vaccine consignments arrive at the storage point
- While vaccines and diluents remain in storage
- When vaccine & diluent stocks leave a storage point (26).

UIP Vaccines

BCG Vaccine

The BCG vaccine was first used to immunize humans in 1921. Following its introduction into the WHO Expanded Programme on Immunization in 1974, the vaccine soon reached global coverage rates exceeding 80% in countries endemic for TB. At present, about 100 million children receive BCG vaccine each year. Although the oldest of currently used vaccines, BCG is still controversial in that there are conflicting data on its protective efficacy. (27). A number of BCG vaccine strains are available, although the French Pasteur strain 1173 P2, the Danish strain 1331, the Glaxo strain 1077 and the Tokyo strain 172 account for about 90% of BCG vaccinations worldwide.

Administration of the Vaccine : WHO recommends intra-dermal application of the vaccine, preferably on the deltoid region of the arm using special syringe as early as possible after birth. Newborn vaccinees should receive half the dose given to older children. Within a few months of vaccination, the local reaction is replaced by a small scar. Presence of a typical scar is used as a marker of previous BCG vaccination but is not a marker of protection against TB.

Vaccine Efficacy : Vaccine efficacy ranges from 0 to 80 percent.

Duration of Protection : The duration of protection after neonatal BCG vaccination is not well known but commonly believed to decline gradually to non-significant levels after 10-20 years.

Adverse Events : Complications following BCG vaccination are rare : Significant local reactions, such as extensive local ulceration and regional lymphadenitis occur in <1 : 1000 persons (31).

Indications and Contraindications as recommended by WHO

- For all infants living in areas where TB is highly endemic
- For infants and children at particular risk of TB exposure in otherwise low-endemic areas
- For persons exposed to multi-drug-resistant Mtb BCG vaccination is contraindicated
- For persons with impaired immunity (symptomatic HIV infection, known or suspected congenital immunodeficiency, leukaemia, lymphoma or generalized malignant disease);
- For patients under immunosuppressive treatment (corticosteroids, alkylating agents, anti-metabolites, radiation);
- In pregnancy.

New vaccines against TB : In recent years, there has been a dramatic increase in the number of candidate TB vaccines evaluated in research laboratories. Currently, the most favoured research strategies include recombinant modified BCG vaccines, attenuated strains of MTB, subunit vaccines and DNA vaccines.

BCG Vaccine (Summary)

- Attenuated *M. tuberculosis var bovis* developed in 1921.
- Protects against TB Meningitis, Miliary TB especially in Children
- Maternal antibodies do not interfere with BCG vaccine as CMI is not transferred trans-placentally, hence should be given as early as possible after birth
- Vaccine efficacy ranges from 0 to 80 percent. Neonatal immunization induces long term protection
- Supplied freeze dried, store frozen or refrigerated
- Use reconstituted BCG within 4-6 hours
- Inject intra-dermally over left shoulder at the insertion of deltoid.
- Local lesion due to bacterial multiplication; Heals leaving scars; If no scar, repeat BCG

Polio Vaccine

An effective IPV (Salk vaccine), comprising all three serotypes, was licensed after large-scale field trials in 1955. Starting in 1963, trivalent OPV (Sabin vaccine) replaced IPV as the primary means of prevention of poliomyelitis in most countries, because of the ease of administration, enhanced mucosal immunity providing a more effective barrier to transmission and community wide circulation of wild poliovirus, secondary spread of Sabin-derived vaccine virus from vaccinees to close contacts thus immunizing some unvaccinated contacts and lower cost (32).

Oral Polio Vaccine : The oral polio vaccine is a suspension of over 1 million particles of polioviruses type 1, 2 and 3 together. It is supplied with a stabilizing agent - magnesium chloride. The virus survives the acidity of the stomach and confers local immunity. However, for reasons not clearly understood,

the 'take' rate is relatively low in our children. For the above reason, multiple doses of OPV are necessary before 90 - 95% of children develop immune responses to all 3 poliovirus types. In addition to the "Routine OPV doses", "Pulse OPV doses every year on National Immunization days (NID's) till the age of 5 years are also mandatory. The risks due to OPV comprise cases of Vaccine-Associated Paralytic Poliomyelitis (VAPP), outbreaks of circulating vaccine-derived polioviruses (cVDPVs) and long-term carriers of VDPVs identified among immunodeficient persons (iVDPVs) (33).

Eradication is defined as no case of paralytic poliomyelitis by wild polio virus in last 3 calendar years along with absence of wild polio virus in the community, where excellent clinical and virological surveillance exists and the coverage of routine OPV is more than 80%.

Polio elimination is defined as zero case of paralytic poliomyelitis by the wild polio virus in one calendar year with other criteria same as in eradication.

Pulse Polio Immunization : On National Immunization Days (NIDs), pulse doses of oral polio vaccine has to be administered, simultaneously to all susceptible infants and children which would produce immunity to all.

Injectable Killed Polio Vaccine (IPV) : IPV is formaldehyde killed poliovirus grown in monkey kidney cell/human diploid cells containing 20, 8 & 32 D antigen against type 1, 2 and 3 poliovirus, respectively. It is highly immunogenic. Seroconversion is 90-95%, after 2 doses and 99% after 3 doses. It produces excellent humoral immunity as well as local pharyngeal and possible intestinal immunity. The vaccine is very safe. However, it is not available at present in the Indian market for routine use and is licensed only for use in immunocompromised children.

Oral Polio Vaccine (Summary)

- Live attenuated Poliovirus types 1, 2 and 3 developed by Sabin, 1961
- Temperature sensitive, store frozen or refrigerated
- Can be given simultaneously with any other vaccine
- Multiple doses necessary to ensure vaccine virus take and antibody response to all 3 types of polioviruses
- First dose is recommended in the newborn period or as early as possible
- IAP recommends additional doses of OPV as a part of Pulse Polio programme every year till the age of 5 yrs.

Injectable (Killed) Oral Polio Vaccine (Summary)

- Formaldehyde Killed Polio Virus grown in monkey kidney or human diploid cell
- Contains 20, 8 and 32 D antigen units against type 1, 2 and 3 Polio Viruses respectively
- Seroconversion 90-95% after 2 doses and 99% after 3 doses
- Thermostable and is indicated in immunocompromised individuals, HIV infection and disease.

DPT Vaccine

Diphtheria is a potentially acute disease caused by exotoxin producing *Corynebacterium diphtheriae*. The combination

of diphtheria toxoid, whole cell killed pertussis vaccine and tetanus toxoid is popularly known as the triple antigen. While the two toxoids are highly immunogenic and antibodies to them are almost completely protective, the pertussis vaccine, given in 3 doses, has a protective efficacy of about 70-80% only.

Administration of the vaccine : DPT must be injected IM. The preferred site is the antero-lateral aspect of the thigh. Immunization should begin by six weeks of life and completed before the ninth month at the latest, although it can be given at any period before 5 years of age. Initially three doses at monthly intervals are injected intramuscularly. Booster doses are given during the second year and just before the child starts going to school (34).

Adverse events and Contraindications : Local pain, redness and fever after DPT are almost entirely due to the pertussis component. Convulsions following DPT vaccine are rare, and when occur they may be the earliest signs of some incipient neurological disease in the infant. For these reasons, progressive neurological diseases are the only contraindication to first dose of DPT immunization (35-39).

DPT Vaccine (Summary)

- Diphtheria toxoid (Ramon & Glenny, 1923)
- Killed *Bordetella pertussis* (Madsen, 1923)
- Tetanus toxoid (Ramon & Zoeller, 1927)
- Toxoids adjuvanted (Aluminium hydroxide/phosphate)
- DPT vaccine supplied as liquid, store refrigerated
- Aluminium adjuvanted vaccines should not be frozen
- Inject intramuscularly, antero-lateral thigh
- Alert parents about local reaction and fever; Paracetamol to be given to reduce pain/fever
- Progressive neurological disease or serious adverse reaction to earlier dose are contraindications for DPT; replace with DT Vaccine

Tetanus Toxoid

Indian Academy of Paediatrics recommends TT at 10 and 16 years. After completing the full course of 7 doses, there is no need for additional doses during pregnancy, at least for the next 10 years. Thereafter a single booster would be sufficient to extend immunity for another 10 years. For pregnant women who have not had previous immunization, at least 2 doses should be given during pregnancy so that protective antibody would be transferred to the infant in order to prevent neonatal tetanus. Td is the preferred preparation for active tetanus immunization in wound management of patients greater than or equal to 7 years of age.

Tetanus Immunoglobulin (TIG)

It is a liquid or freeze-dried preparation containing immunoglobulins, mainly IgG obtained from plasma or serum containing specific antibodies against the toxin of *Clostridium tetani*.

Adverse Effects : Local pain, fever, flushing, headache and chills may occur.

Indications : Subjects already sensitized with serums of animal origin, existence of prior or present allergic manifestations

(asthma, eczema etc.), burns, injuries, open and compound fractures, unimmunised or inadequately immunised mothers.

Dosage : Prophylaxis 250 - 500 I.U. IM. Therapeutic : Tetanus neonatorum 500 - 1000 I.U. intramuscular or 250 I.U. intrathecal. In adults and children : 500 - 1000 I.U. IM and / or 250 - 500 I.U. intrathecally.

Measles Vaccine

Measles vaccine consists of live attenuated Measles virus, developed by Enders, in 1960. The original virus strain was isolated from a child by the name Edmonston; therefore the virus strain was also named Edmonston. In liquid suspension the vaccine virus is very heat-labile; in the freeze-dried state the shelf life of the vaccine is one to two years. The vaccine may be stored frozen or refrigerated. But, after reconstitution, the vaccine should be injected within 4-6 hours. During such interval the liquid vaccine should be kept cold, either in the refrigerator or vaccine carrier.

Administration of the vaccine : The vaccine should be injected subcutaneously. The preferred site is right upper arm. It can also be injected over the antero-lateral thigh, but SC. The vaccine induces both humoral and cellular immune responses comparable to those following natural infection.

Vaccination schedule and vaccine efficacy : The optimum age for measles vaccination depends on the local epidemiological situation and on programmatic considerations. Given the immaturity of the immune system as well as the presence of neutralizing maternal antibodies, vaccination of infants before or at 6 months of age may often fail to induce immunity. In most developing countries, children are vaccinated against measles at 9 months of age, when seroconversion rates of 80-85% may be expected. A single dose of live, attenuated measles vaccine is generally felt to provide lifelong protection (40,41).

Adverse Reactions : Adverse reactions following measles vaccination, alone or in fixed combinations, are generally mild and transient. Slight pain and tenderness at the site of injection may occur within 24 hours, sometimes followed by mild fever and local lymphadenopathy. Thrombocytopenia purpura occurs in approximately 1 in 30,000 vaccinated individuals.

Measles Vaccine (Summary)

- Live attenuated Measles virus vaccine developed by Enders, 1960
- Vaccine further attenuated (e.g. Schwarz, Edmonston-Zagreb)
- MV supplied freeze dried, Store frozen or refrigerated
- Use reconstituted vaccine within 4-6 hours (Refrigerate, do not freeze)
- Inject SC, preferably right upper arm
- Recommended age 9 months (270 days) plus
- During Measles outbreak, may be given at 6 months Plus
- If given at < 9 months, repeat dose after interval of at least 3 months
- Alert parents of fever 5-10 days later; Paracetamol may be given

Non UIP Vaccines

Mumps Vaccine

Mumps can be prevented by vaccination given either as a monovalent vaccine or as part of MMR vaccine. A live attenuated monovalent mumps vaccine was first developed by Hilleman in 1966. The mumps component in MMR vaccine contains live attenuated mumps virus. Mumps vaccines are recommended for use in a 1-dose schedule, given at age 12-18 months (42)

Adverse Reactions : In general, adverse reactions to mumps vaccination are rare and mild. The most common adverse reactions following mumps vaccination are parotitis and low-grade fever.

Rubella Vaccine

A live attenuated Rubella vaccine was developed by Waller in 1962. The current rubella vaccine available commercially is derived from RA 27/3 vaccine strain grown in human diploid cell cultures. It is available either as a monovalent vaccine or as a part of combination vaccine - MMR. It contains live attenuated virus not less than 1000 TCID₅₀. It is a highly immunogenic vaccine with positive antibody response in 95% of susceptible vaccinees. It provides long term and probably life long protection (43, 44, 45,46).

The primary purpose of rubella vaccination is to prevent the occurrence of congenital rubella infection including CRS. Two approaches are recommended by WHO :

- (a) Prevention of CRS only, through immunization of adolescent girls and/or women of childbearing age
- (b) Elimination of rubella as well as CRS through universal vaccination of infants and young children (with/ without mass campaigns), surveillance, and assuring immunity in women of childbearing age.

MMR Vaccine

MMR Vaccine is available as single as well as multidose (5 dose) vial. The diluent for injection is available separately. The dose of the reconstituted vaccine is 0.5 ml per dose, to be administered subcutaneously in the upper arm. The vaccine should be stored between +2 to +8°C in the ordinary compartment of the fridge. Reconstituted vaccine should be used within 6 hours.

IAP recommends a dose of MMR vaccine to all children. For infants given measles vaccine at 9 months, MMR vaccine may be given between 12-15 months of age. If measles vaccine is given later, a 3 months gap is advisable. If measles vaccine was missed altogether, one MMR dose should be given at or after 12 months. The vaccine can be given along with any other vaccine like DPT, OPV but at different sites using different syringes and needles (47).

Hepatitis B Vaccine

The main objective of hepatitis B immunization strategies is to prevent chronic hepatitis B virus (HBV) infection and its serious consequences, including liver cirrhosis and hepatocellular cancer (HCC) (49). Younger the age at infection, higher the chance of becoming chronically infected as carrier. The World Health Organization recommends universal Hepatitis B vaccination.

Administration of the Vaccine

Two types of hepatitis B vaccines are available - plasma derived vaccines and recombinant vaccines. The two vaccines show no differences in terms of reactogenicity, efficacy or duration of protection. The complete vaccine series induces protective antibody levels in >95% of infants, children and young adults. Hepatitis B vaccine should be given IM at antero-lateral thigh in infants. In older children/adults it should be administered at deltoid region. The minimum recommended interval between the doses is four weeks. Longer dose intervals may increase the final anti-HBs titres but not the seroconversion rates (49). As an adjuvanted vaccine, it should not be frozen. If frozen accidentally, the vaccine should be discarded.

Using the principles described, the IAP recommends the commencement of HB immunization at birth. Two alternate schedules are available :

a) Infants

1. Birth, 6 and 14 weeks
2. 6, 10 and 14 weeks. (Combined DTPw/Hepatitis B vaccine can be preferred)

b) *For older children, adolescents and adults* : The recommended schedule is elected date, 1 month and 6 months. Booster dose is not recommended as of date.

Adverse Events : In placebo-controlled studies, with the exception of local pain, reported events such as myalgia and transient fever have not been more frequent than in the placebo group. Reports of severe anaphylactic reactions are also very rare.

Contraindications and Precautions : Hepatitis B vaccination is contraindicated for persons with a history of hypersensitivity to yeast or to any vaccine component. Pregnancy is not a contraindication to vaccination. Limited data indicate no apparent risk for adverse events to developing foetuses when hepatitis B vaccine is administered to pregnant women (50).

Passive immunization against hepatitis B : Temporary immunity may be obtained using hepatitis B immune globulin (HBIG) for post-exposure prophylaxis. HBIG prophylaxis may be indicated :

- (i) For newborn infants whose mothers are HBsAg-positive.
- (ii) Following percutaneous or mucous membrane exposure to HBsAg-positive blood or body fluids.
- (iii) Following sexual exposure to an HBsAg-positive person.
- (iv) To protect patients from recurrent HBV infection following liver transplantation.

HBIG does not interfere with generation of antibody response to hepatitis B vaccine. As a rule, HBIG should be used as an adjunct to hepatitis B vaccine. However, in full-term newborns, the protection against perinatally acquired infection achieved by immediate (<24 hours) hepatitis B vaccination is not significantly improved by the addition of HBIG.

Dosage : Following exposure to HBsAg.

Adults : 1000 - 2000 I.U., IM.

Children : 32-48 I.U./kg body wt. This should be administered within 7 days (preferably within 48 hrs) after exposure to HBsAg.

Neonates : Initial dose is 100 - 200 I.U. The first dose should be administered within 5 days after birth. The booster dose should be 32 - 48 I.U./kg of body wt., between 2 & 3 months after initial dose.

Hepatitis B Vaccine (Summary)

- Safe, immunogenic, effective HB vaccine available since 1982
- Highly purified preparation of HBsAg
- HBsAg is a glycoprotein that makes up outer envelope of HBV
- Two types of vaccine : Plasma derived and Recombinant DNA
- To be shipped and stored at 2° C - 8° C
- IM Injection at deltoid in adults, adolescents and children and antero-lateral thigh in neonates and infants upto 2 years
- Immunogenicity is > 95% in a variety of vaccination schedules
- No booster dose recommended

Typhoid Vaccine

The choice of vaccine depends upon the age of commencement of the vaccine and the availability.

1. The Whole Cell Typhoid Vaccine : The heat-killed phenol-preserved and the acetone killed lyophilized whole cell *Salmonella typhi* vaccine was developed one century ago. This typhoid vaccine is extremely safe from serious reactions and is reasonably effective.

Primary course include 2 doses, 4 or more weeks apart and a single booster dose is recommended every 3 years. In field trials the vaccine has been associated with fever and systemic reactions in 9%-34% of the recipients, and with short absences from work or school in 2%-17% of cases. This vaccine is extremely cheap and well suited for giving to children of families who cannot afford more expensive vaccines (51).

2. The Vi Polysaccharide Vaccine : The Vi polysaccharide, purified and adjuvanted is another satisfactory typhoid vaccine with reasonable efficacy & low reactogenicity. As polysaccharide antigens are T cell independent, this vaccine is non-immunogenic below 2 years of age, induces IgM response without IgG response, not able to induce immunological memory; hence not able to induce booster effect. When a dose is repeated 3-5 years later, it induces response similar to the first dose. Adverse reactions seem limited to fever (0%-1%), headache (1.5%-3%) and erythema or induration >1 cm at the site of injection (7%) (52).

3. Oral Ty21a Vaccine : This is a live attenuated strain of *S. typhi* Ty21a that was developed in the early 1970s by chemical mutagenesis. It is genetically stable, and does not revert to virulence. Indeed it does not induce a true "infection" as only very limited multiplication occurs in the gastrointestinal tract after oral feeding. It is not excreted in large numbers and is non-transmissible under natural conditions. Very large number of bacteria are necessary as oral doses in order to achieve sufficient degree of local immunity, which is the main basis of protection afforded by this vaccine. The bacteria are acid-

labile. Hence the stomach acidity has to be either neutralised or bypassed when Ty21a is fed orally. The vaccine is administered orally as enteric coated capsules and is registered for use from 6 years of age. The vaccine is to be given in three sittings, on alternate days. The protective efficacy is as good as other available typhoid vaccines. Immunization needs to be repeated every 3-5 years (53,54).

Typhoid Vaccines (Summary)

Whole Cell

- Killed *S. typhi*, often with *S. paratyphi* A (TA)
- Developed by Wright, 1896
- Liquid, store refrigerated, inject subcutaneously
- Primary course : 2 doses 4 weeks
- Boosters : Once in 3-5 years
- Dose : 0.5 ml SC

Vi polysaccharide

- Vi polysaccharide, developed by Robbins, 1984
- Liquid, adjuvanted, store refrigerated
- Inject IM; give at or after 2 years of age
- Dose 0.5 ml
- To be repeated 3 years later

Oral

- Live attenuated *S. typhi*, developed by Germanier, 1975
- Strain name : Ty 21 a
- Enteric coated capsules : store refrigerated, administered orally on alternate days, 3 doses
- To be repeated 3-5 years later
- Recommended age : 6 years and above

Hib Conjugate Vaccine

Haemophilus influenzae type b vaccine is a very effective and safe vaccine. Both PRP-T and PRP - CRM 197 conjugate Hib vaccine are now available in India. All Hib-containing vaccines should be stored at between +2°C and +8°C. Liquid Hib vaccine should never be frozen (55).

Vaccine Administration : As Hib disease is age dependant and Hib immunization involves boosting of natural immunity, 3 doses when initiated below 6 months, 2 doses between 6 to 12 months and 1 dose between 12 to 15 months should be given. A booster is recommended at 15 to 18 months. Beyond 18 months, a single dose is recommended up to 5 years of age and above 5 years Hib vaccination is not recommended (56,57).

Hib vaccine has not been associated with any serious adverse effects. However, redness, swelling and pain at the site of injection may occur in as many as 25% of those who have been vaccinated (58).

Hib Vaccine (Summary)

- *H. influenzae* b capsular polysaccharide
- Conjugated to protein antigens to improve immunogenicity
- Monovalent or DPT / Hib conjugate
- 3 doses 1-2 months apart
- Booster at 15-18 months
- Beyond 18 month a single dose up to 5 years

Japanese B Encephalitis Vaccine

Currently, the three types of JE vaccines in large scale use are (59) :

- The mouse brain-derived, purified and inactivated vaccine, which is based on either the Nakayama or Beijing strains of the JE virus and produced in several Asian countries
- The cell culture-derived, inactivated JE vaccine based on the Beijing P-3 strain
- The cell culture-derived, live attenuated vaccine based on the SA 14-14-2 strain of the JE virus.

Both the mouse-brain derived and the cell culture-based vaccines are considered efficacious and to have an acceptable safety profile for use in children. However, with the mouse-brain derived vaccine, rare cases of potentially fatal acute disseminated encephalomyelitis and hypersensitivity reactions have been reported among vaccinated children in endemic regions and in travellers from non endemic locations (60-62).

Many Asian countries have adopted a schedule of 2 primary doses preferably 4 weeks apart, followed by a booster after 1 year. In some countries, subsequent boosters are recommended, usually at about 3-year intervals up to the age of 10-15 years (59).

This vaccine is based on the genetically stable, neuro attenuated SA 14-14-2 strain of the JE virus, which elicits broad immunity against heterologous JE viruses. Case control studies and numerous large-scale field trials in China have consistently shown an efficacy of at least 95% following 2 doses administered at an interval of 1 year (63).

The Indian strain of the Japanese B Encephalitis vaccine produced by Central Research Institute, Kasauli, is available through central and state health authorities for use in endemic areas during epidemic situation in the specific regions of the country where the infection is prevalent.

Meningococcal Vaccine

Meningococcal meningitis and septicaemia are caused by various sero groups of *Neisseria meningitidis*. Endemic disease occurs worldwide and is mostly caused by meningococci of serogroups A, B or C. The group A meningococcus is the predominant cause of large epidemics. Vaccines are available against four serogroups of meningococci A, C, W-135 and Y. No effective serogroup B vaccine is presently available. The vaccines are either monovalent i.e. A, C, etc. or polyvalent i.e. A-C, A-C-Y, A-C-Y-W135 etc. The efficacy rate of a single dose of serogroup A or serogroup C vaccine is 90% in adults and children over 2 years of age. The four polysaccharide antigens (A, C, Y and W135) have been combined into a tetravalent vaccine. It is available in single-dose and multi-dose vials distributed as lyophilized powder that contains 50 micrograms of each component per dose. The vaccine should be stored at -20°C (64, 65).

Dosage and Route of Administration : For both adults and children, vaccine is administered s.c. as a 0.5 ml dose. Protective levels of antibody can be expected after 7-10 days.

Indications

- Routine immunisation of recruits may be considered (66).
- In household contacts, as an adjunct to chemoprophylaxis.

- (iii) Routine immunization for asplenic people and those with previously described immunodeficiencies.
- (iv) Vaccination is recommended for outbreak control for disease caused by any of the serotypes carried by the vaccine.
- (v) Travellers to hyperendemic or endemic areas.

Precautions and Contra-indications : Adverse reactions are mild and consist of pain and tenderness at the site of injection for 1-2 days (67,68). No adverse effects have been documented among women vaccinated during pregnancy or their newborns. There are no known contraindications. The vaccine is not recommended for use in children under 2 years of age (69,70).

Revaccination : The need for revaccination of older children and adults has not been determined, antibody levels decline rapidly over 2 to 3 years and if indications still exist for immunisation, revaccination may be considered within 3 to 5 years (71).

Varicella Vaccine

Takahashi et al developed a live attenuated vaccine for varicella from Oka strain in Japan. The recommended dose is 0.5 ml which provides at least 1350 plaque forming units of the virus. The vaccine is administered SC in the upper arm/thigh region. It is recommended after the age of 1 year. Up to the age of 12 years, one dose is required and if given after 12 years, 2 doses are needed at an interval of 1 month. Both humoral and cell mediated immunity develops in more than 95% cases after a single dose between 1-12 years and 99% after 2 doses in children 13 years and above (72-74).

Varicella Vaccine (Summary)

- Developed by Takahashi in 1971 in Japan
- Live attenuated Oka Strain
- Vaccine available as lyophilized powder
- Dissolve in 0.5 ml diluent
- SC Injection
- Single dose 12 months - 12 years
- Two doses beyond 13 years; 1 month apart
- Efficacy 95- 99%
- No booster dose recommended

Hepatitis A Vaccine

Several inactivated or live attenuated vaccines against hepatitis A have been developed, but only 4 inactivated hepatitis A vaccines are currently available internationally. All 4 vaccines are similar in terms of efficacy and side-effect profile. The vaccines are given parenterally, as a 2-dose series, 6-18 months apart. The dose of vaccine, vaccination schedule, ages for which the vaccine is licensed, and whether there is a paediatric and adult formulation varies from manufacturer to manufacturer. No vaccine is licensed for children aged < 1 year (75, 76). Vaccine efficacy is 94-100% and the duration of protection is long lasting, hence no booster dose is recommended at present. The current vaccines are well tolerated and no serious adverse events have been statistically linked to their use. Contraindications to hepatitis A vaccination include a known allergy to any of the vaccine components (77).

Hepatitis A Vaccine (Summary)

- Inactivated vaccine containing HM 175 strain grown in MRC5 cell line
- 2-dose series, 6-18 months apart.
- Efficacy - 94-100%
- No booster dose

Pneumococcal Vaccine

Two types of vaccine are currently available - a 23 valent polysaccharide vaccine (available in India) and a 7 valent conjugate polysaccharide vaccine in some countries of the world (78). 23-valent polysaccharide vaccine is capable of prevention of 85% of meningitis and bacteremia caused by pneumococcus. Each dose is 0.5 ml containing 25 µg of individual serotype polysaccharide. A single IM injection is recommended after the age of 2 years with booster every 3-5 years till the age of 10 years (79, 80). The 7 valent conjugate polysaccharide vaccine manufacturer recommends three IM injections in infants aged under 6 months, the first dose usually given at 2 months of age, with an interval of at least 1 month between doses.

Influenza Vaccine

Both inactivated and live, attenuated influenza vaccines are available. There are 3 types of inactivated influenza vaccine, namely whole virus vaccines, split virus vaccines and subunit vaccines. In most countries, whole virus vaccines have been replaced by less reactogenic split virus and subunit vaccines. The multivalent vaccine usually contains 3 virus strains (usually 2 type A and 1 type B) with composition changed periodically in anticipation of the prevalent influenza strains expected to circulate in the country (81, 82). The vaccine is given in 2 doses in children 6 months to 9 years of age and one dose above 9 years of age. The dose is 0.25 ml between 6 months to 3 years IM and 0.5 ml after the age of 3 years (83).

Live, Attenuated Influenza Vaccines : For several years, live, attenuated influenza vaccines for nasal application have been used successfully in the Russian Federation. The temperature-sensitive vaccine virus will replicate well in the relatively cool environment of the nasopharynx, but poorly in the lower respiratory tract. This vaccine is reported to be safe and highly efficacious following 1 single dose in adults and children >3 years of age (84-86). Based on data from industrialized countries, and listed in order of priority, the following groups of individuals may be targeted for vaccination in order to reduce the incidence of severe illness and premature death.

1. Residents of institutions for elderly people and the disabled.
2. Elderly, non-institutionalized individuals with chronic heart or lung diseases, metabolic or renal disease, or immunodeficiencies.
3. All individuals >6 months of age with any of the conditions listed above.
4. Elderly individuals above a nationally defined age limit, irrespective of other risk factors.

Rabies Vaccine

There are 2 types of rabies vaccines available in India :

1. Nerve tissue vaccine

2. Tissue culture vaccines
 - Human diploid cell vaccine
 - Purified chick embryo cell vaccine
 - Vero cell vaccine

Nerve tissue vaccine is no longer recommended because of its poor efficacy and life threatening adverse reactions in the form of neuroparalytic conditions of 1 : 2000 to 1 : 8000 doses (87,88).

Tissue Culture Vaccines

All tissue culture vaccines are having almost equal efficacy and any one of them can be used.

Post exposure prophylaxis : After thoroughly cleaning the wound with soap and water and appropriate tetanus prophylaxis, rabies immunoglobulin either human or equine in the dose of 20 IU and 40 IU/kg body weight respectively is infiltrated around the wound in case of severe bite or bites in the upper extremities, trunk, head and face. Currently IM injection of RIG is not recommended (89,90).

Pre-exposure prophylaxis : 1 ml of any of the tissue culture vaccine is given IM over the deltoid region on day 0, 7 and 28 for the high risk group.

In order to reduce the cost of post-exposure treatment, intradermal multisite regimens using a fraction of the intramuscular volume per intradermal inoculation site have been developed (91).

Rabies Vaccine - Tissue Culture Vaccine (Summary)

Post exposure Prophylaxis

- 1 ml per dose irrespective of age in deltoid region in infants >2 years; and in anterolateral aspect of thigh in infants < 2 years.
- Schedule Day 0, 3, 7, 14 and 28
- Re-exposure within 5 years - 2 doses - day 0 and 7; after 5 years full course. Earlier if anti rabies antibody titer falls below 0.5 IU / ml

Pre exposure Prophylaxis

- 1 ml per dose, any Tissue Culture Vaccine, IM
- Schedule Day 0, 7 and 28
- Indicated for High Risk Group
 - Laboratory staff working with Rabies Virus
 - Veterinarians
 - Wild life staff

Rabies Immunoglobulin : It is a liquid or freeze dried preparation containing immunoglobulins mainly IgG obtained from plasma or serum of donors immunised against rabies and contains specific antibodies that neutralise the rabies virus. It provides passive protection when given immediately to individuals exposed to rabies virus with minimum interference of active immunization with human diploid - cell vaccine (92).

Adverse Effects : Local tenderness, muscle soreness or stiffness at the injection site, low grade fever, sensitization to repeated injections of human globulin in immunoglobulin deficient patients.

Indications : All injuries, even licks, on mucous membranes by wild animals (or even pet animals) suspected to be suffering from rabies.

Immunization against Cholera

Until recently, the only available cholera vaccines was phenol-killed whole cell killed vaccine, administered in 2 doses, 2 weeks apart. Unfortunately, the protective efficacy of vaccine is only about 50%; duration of protection hardly exceeds 6 months.

Live, Attenuated CVD 103-HgR vaccine : A live, attenuated oral cholera vaccine containing the genetically manipulated Classical *V. cholerae* strain CVD 103-HgR has been available since 1994 which confers a high level of protection (> 90%) against moderate and severe cholera. Both the whole cell killed and the CVD 103-HgR vaccines may be recommended for travellers to high-risk regions (93).

Development of New Vaccines : Current Situation

Rotavirus Vaccine

Acute diarrhoea is responsible for nearly 1.9 million deaths per year in children under age five. Rotavirus is responsible for as much as one fourth of these casualties, almost all of which occur in developing countries.

Status of vaccine development : RotaRix, a vaccine developed by GlaxoSmithKline (GSK), and RotaTeq vaccine developed by Merck against rotavirus diarrhoea are now licensed in many countries. In addition to being available in the private market, it has now been introduced in the public sector immunization programmes of many countries (94).

Recommendations : Routine immunization of all infants without contraindications. It is provided as a single 2ml oral dose in a buffered stabilizer solution. It is stored at 36-46°F (2-8°C), and administered at 2, 4, and 6 months of age. Minimum age of first doses is 6 weeks. First dose should be administered between 6 and 12 weeks of age (until age 13 weeks). Minimum interval between doses is 4 weeks. Maximum age for any dose is 32 weeks (95).

Challenges : A vaccine must be effective against numerous rotavirus strains (serotypes), including those prominent in developing countries. These vaccines, since they are live, oral ones, must be shown not to interfere with oral polio vaccine & must be efficacious. Even more importantly, they must be shown to be safe in general, and in HIV-infected children in particular. Price will also be an issue for large-scale introduction (94).

Human Papillomavirus (HPV) Vaccine

Sexually transmitted HPV is the major cause of cervical cancer, the most common cause of cancer deaths among women in developing countries. About 500,000 cases occur each year, 80% of them in developing countries. Cervical cancer kills some 240,000 women annually.

Status of vaccine development : Gardasil, an HPV vaccine recently licensed by Merck, covers four types of HPV, including the cancer-causing types 16 and 18 and types 6 and 11 for non-cancerous genital warts. A second vaccine, developed by GSK, covers HPV types 16 and 18 alone and is expected to be licensed in 2007.

Challenges : HPV types 16 and 18 cause around 70% of HPV cervical cancers globally, but the vaccines in development will

not cover the 30% of cancers attributed to other HPV types. Because these other types are numerous and individually only contribute a small percentage, significantly expanding vaccine coverage against them may present technical challenges for manufacturers. The duration of the immunity conferred by the vaccines is not yet known, and only time and follow up studies will provide this critical information. Access to the vaccines is likely to be an issue in developing countries due to limited resources for the implementation of vaccination programmes (94).

International Vaccination Requirement

Immunization Against Yellow Fever

Yellow fever (YF) is endemic in tropical regions of Africa and South America. Vaccination is the most effective method for the prevention of spread of the disease by international travel (96). Two types of vaccines are available (97).

(i) 17 D Vaccine : This is the approved vaccine for international travel. It is a live, attenuated chick embryo grown 17D-strain freeze-dried vaccine. For storage at WHO approved centers, the vaccine can be kept for 3 months at +4°C. If the storage is for a longer duration, a temperature of -25°C is to be maintained. After reconstitution, it should be used within half an hour.

(ii) Dakar Vaccine : It is also called French Neurotropic Vaccine developed at the Pasteur Institute Dakar. It is thermostable and can be easily transported. However, it has produced post-vaccinal encephalitis in children. WHO has not approved use of this vaccine for international travel.

Administration of vaccine : 17-D vaccine is given SC at the insertion of deltoid in a single dose of 0.5 ml. Immunity begins within 10-12 days and lasts for at least 10 years however the persistence of neutralizing antibody 30-35 years after immunization with 17D yellow fever vaccine has been observed (98). Yellow fever vaccination is available at designated centers certified by the Government of India. Armed Forces Clinic, New Delhi is one of such centers.

International certificate of vaccination is required only for one disease i.e. yellow fever. The period of validity of the certificate is shown in Table - 5.

Protection is recommended against certain other diseases for international travellers although the international certificate is not required. These diseases are as under :

(a) Cholera : Cholera vaccine may be taken by all travellers proceeding to endemic areas. It offers partial protection against the disease.

(b) Enteric Infections : Vaccination and revaccination against typhoid is strongly advised for all travellers proceeding to endemic areas.

(c) Hepatitis A : A single IM injection of human normal immunoglobulin 500 mg or 1.2 mg/kg body weight is effective

almost immediately and its efficacy lasts for six months. Active immunisation with HAVRIX is available in our country.

Type of vaccination	Certificate	
	Valid for	Valid from
Yellow fever-primary vaccination	10 years	10 days after vaccination
Yellow fever-re-vaccination	10 years	at once after revaccination

(d) Tetanus : A booster dose of Tetanus toxoid should be taken if 5 years or more have elapsed since the last injection of a complete course or booster.

Immunization in Special Circumstances (99)

1. Immunization in preterm infants : All vaccines should be administered as per schedule irrespective of birth weight or period of gestation except Hepatitis B. If the weight of the baby is less than 2 kg and mother is HBsAg negative, then Hepatitis B vaccine is postponed till the baby attains a weight of 2 kg or 2 months of age. However, if the mother is HBsAg positive, then both Hepatitis B vaccine and Hepatitis B immunoglobulin is administered within 12 hours of birth followed by 3 more doses at 1, 2 and 6-12 months.

2. Children receiving corticosteroids : Children receiving corticosteroids at the dose of 2 mg/kg/day for more than 14 days should not receive live virus vaccines until steroid has been discontinued for at least 1 month.

3. Vaccination in HIV/AIDS : Following table summarizes the recommendation of WHO and Advisory Committee on Immunization Practices and American Academy of Paediatrics. Vaccination recommendations in HIV infected symptomatic and asymptomatic Children (Table - 6).

Vaccine	Known Asymptomatic		Known Symptomatic	
	WHO	ACIP / AAP	WHO	ACIP / AAP
BCG	Yes*	No	No	No
DPT/DtaP	Yes	Yes	Yes	Yes
OPV	Yes	No	No	No
Measles / MMR	Yes	Yes	Yes	Yes
IPV	-	Yes	-	Yes
Hepatitis B	Yes	Yes	Yes	Yes
Hib	-	Yes	-	Yes
Pneumococcal	-	Yes	-	Yes
Influenza	-	Yes	-	Yes
Varicella	-	Consider	-	Consider
Hepatitis A	-	Yes	-	Yes

* For regions where risk of TB is high

4. Vaccination schedule for children not immunized in time : Table - 7 depicts the schedule which should be followed in case of unimmunized child.

Age	Less than 5 years	More than 5 years
First Visit	BCG, OPV, DPT, HB	TT/ Td, HB
2nd visit (1 month later)	OPV, DPT, HB	TT/ Td, HB
3rd visit (1 month later)	OPV, DPT, MMR, Typhoid	MMR, Typhoid
1 Year later	OPV, DPT, HB	HB
Every 3 years	Typhoid booster	Typhoid booster

5. Lapsed Immunization : A lapse in the immunization schedule does not require reinstatement of the entire series. Immunizations should be given at the next visit as if the usual interval had elapsed and the immunization schedule should be completed at the next available opportunity. In case of an uncertain immunization status, it is appropriate to start the schedule of unimmunized child.

6. Immunization of Adolescents : Reasons for adolescent immunization fall into the following broad categories :

- To boost the waning immunity by giving booster doses.
- To counter a specific risk e.g. due to travel, life style etc.

Vaccine	Age
Tetanus Toxoid	Booster at 10 and 16 years
Rubella vaccine	As part of MMR vaccine or (Monovalent) 1 dose to girls at 12-13 years of age, if not given earlier
MMR Vaccine	1 dose at 12-13 years of age. (if not given earlier)
Hepatitis B. Vaccine	3 Doses (0, 1 and 6 m) if not given earlier
Typhoid Vaccine	TA, Vi or Oral typhoid vaccine every 3 years
Varicella Vaccine*	1 dose upto 12-13 years, and 2 doses after 13 years of age. (if not given earlier)
Hepatitis A Vaccine*	2 doses (0 and 6 months) if not given earlier

Varicella* and Hepatitis A* vaccine are additional vaccines. These vaccines are recommended depending upon the epidemiology of these diseases especially in the adolescent age group where fatal complications are likely to occur.

International Certificate of Vaccination : These are individual certificates and should not be used collectively. Certificates are printed in English and French; an additional language may be used. The dates should be recorded in the following sequence; Day, Month, Year, the month to be written in letters e.g. 20 March 1999. A certificate issued to a child who is unable to write should be signed by the parent or guardian. The signature of

an illiterate person should be indicated by his left thumb mark certified by another person. The certificates requires signature of medical practitioner; his official stamp is not accepted as a substitute nor is the signature of the clinical nurse. The correct procedure for the doctor is to do the vaccination himself and sign the certificate as the vaccinator. On all international vaccination certificates, name of manufacturer of vaccine as well as the batch number must be given. Medical officers are also advised to refer to standard WHO publication on requirements for international travellers (100).

Summary

The modern word “immunity” derives from the latin *immunis*, meaning exemption from military service, tax payments or other public services and is defined as “Ability of an organism to recognize and defend itself against specific pathogens or antigens”. The immune system is a collection of mechanisms within an organism that protects against infection by identifying and killing pathogens and tumour cells. The physical barriers prevent pathogens entering the body. If a pathogen breaches these barriers, the innate immune system provides an immediate, but non-specific response. However, if pathogens successfully evade the innate response, vertebrates possess a third layer of protection, the adaptive immune system.

An antigen is defined as a substance which when introduced into the tissues stimulates the production of specific antibodies and combines specifically with the antibody so produced. By far the best antigens are proteins; others are poly-saccharides, lipids and nucleic acids. There are also incomplete antigens called ‘haptens’ which by themselves are not antigenic but can provoke an immune response.

An antibody is a protein substance that appears in the body as a result of invasion by an antigen. It is capable of reacting specifically with the same antigen, which provokes its production. The sites of maximum antibody formation are the lymph nodes and spleen. Immunoglobulins comprise of families of closely related globulin molecules, which are synthesized by cells of reticuloendothelial system. The human immunoglobulin system is divided into five major classes IgG, IgA, IgM, IgD and IgE.

Types of immune defenses can broadly be divided into Innate and Acquired Immunity. Acquired Immunity can further be divided into Active and Passive immunity with Artificial and Natural types in each. Active immunity : (a) Naturally acquired active immunity occurs when a person is exposed to a live pathogen, and develops a primary immune response, which leads to immunological memory. (b) Artificially acquired active immunity can be induced by a vaccine, a substance that contains antigen. Passive immunity is the transfer of active immunity, in the form of readymade antibodies, from one individual to another.

Two different types of Host defenses that the body exhibits as a result of exposure to antigen : (a) The humoral immune response (b) The cell-mediated immune response. The cells of the tissue attacked are as much concerned in offering resistance to the infecting agent as the antibodies or phagocytes; this is the local immunity. Herd Immunity is the immunity of a group of people or a community taken as a whole. The first encounter with an

antigen is known as the primary response. Re-encounter with the same antigen causes a secondary response that is more rapid and powerful.

Immunisation is the process by which an individual is exposed to an agent that is designed to fortify his or her immune system against that agent. The material is known as an immunogen. Immunization is the same as inoculation and vaccination. Vaccines are immunobiological substances designed to produce specific protection against diseases by stimulating production of protective antibody or other immune mechanisms. The Vaccine mimics the infection with the respective pathogen, but without risk of the disease. The goal of all vaccines is to promote a primary immune reaction so that when the organism is again exposed to the antigen, a much stronger secondary immune response will be elicited.

There are four types of traditional vaccines : Live (attenuated), Inactivated (killed), Toxoids, Subunit and recombinant. Live Vaccines are prepared from live attenuated organisms and are very potent immunizing agents. Safety is an issue and they cannot be used for immunodeficient patients and during pregnancy. Examples include BCG, Typhoid oral, Measles, Mumps, Rubella and Oral Polio. Inactivated (Killed) Vaccines are prepared from organisms killed by heat or chemicals, are very safe but less efficacious than live vaccines. They require multiple doses. The only absolute contraindication is hypersensitivity, e.g. Typhoid, Rabies, Hepatitis B. Toxoids are produced from detoxicated toxins. The body produces antibodies against the toxin in response to toxoids. They offer no protection against infection, are very safe and highly effective, e.g. Diphtheria, Tetanus.

Passive immunization may be administered using human or animal products. Conventionally human products are called immunoglobulins and animal products are called anti sera. Non specific or generalized protection is offered by normal immunoglobulins while protection against specific diseases is given by using hyperimmune immunoglobulins.

Immunization schedule drawn up keeping two important factors in mind - the vaccines need to be administered in doses and schedules which produce an adequate immunological response in the recipient; and secondly the schedule should be administratively the most convenient and one which is likely to be most acceptable to the target population. The National Immunization schedule drawn up for India factors in both these aspects.

Cold chain is a system of transporting and storing vaccines at recommended temperature from manufacturer to the point of use. All the vaccines can be stored at temperatures between +2 to +8°C. However, long term storage of OPV and Measles requires them to be stored at sub zero temperatures in deep freezers. DPT, DT and TT

should never be frozen. BCG and diluent ampoules should not be frozen, as ampoules are likely to crack. Diluents required for measles and BCG should be stored at +2 to +8°C in the refrigerator. Cold Chain includes Walk in cold rooms (WICs), Deep freezers, Ice - lined refrigerators (ILRs), Refrigerators, Cold box, Vaccine carrier, Day carrier and Ice packs. The quality

of the cold chain is monitored by the National Quality Control Lab at Kasauli. The quality check is done before release of the vaccines. Reverse Cold Chain is also maintained to check vaccines for their potency.

UIP VACCINES includes BCG Vaccine, Oral PolioVaccine, DPT Vaccine and Measles Vaccine. NON UIP VACCINES includes Mumps Vaccine, Rubella, MMR, Hepatitis B Vaccine, Typhoid Vaccine, Japanese B Encephalitis, Meningococcal Vaccine, Hepatitis A, Varicella, Pneumococcal, Rabies and Influenza Vaccine. International Vaccination Requirement is for Yellow fever (YF) which is a mosquito-borne, viral haemorrhagic fever that is endemic in tropical regions of Africa and South America.

Study Exercises

MCQs & Exercises

1. Wasserman antibodies and bactericidal antibodies against Gram negative organisms (endotoxins) are almost exclusively found in (a) IgG (b) IgM (c) IgA (d) IgE
2. Cytotoxic or killer T cells (CD8+) do their work by releasing _____, which cause cell lysis.
3. Antibody binds to antigen & this is called _____.
4. Influx of susceptible people and occurrence of new births increase the herd immunity. True/ False
5. Tuberculosis (BCG) was discovered in (a) 1923 (b) 1927 (c) 1935 (d) 1943
6. Hepatitis B (a) 1963 (b) 1971 (c) 1981 (d) 1993
7. World Health Organization (WHO) certified the eradication of smallpox in (a) 1975 (b) 1977 (c) 1979 (d) 1981
8. The immunization against quarantinable disease under the International Health Regulations, is carried out for which disease? (a) Polio (b) Yellow fever (c) Plague (d) Malaria
9. When vaccines are reconstituted, the diluent should be at same temperature as the vaccine. True/ False
10. The vaccines must be kept in the cold chain between _____ at all times, or optionally, at -15 to -25°C if cold chain space permits. (a) 0 and +4°C (b) +2 and +6°C (c) +2 and +8°C (d) +6 and +10°C
11. While vaccines and diluents remain in storage it is necessary to follow the principle of "EEFO" which stand for _____.
12. The BCG vaccine was first used to immunize humans in (a) 1971 (b) 1941 (c) 1931 (d) 1921
13. Eradication is defined as no case of paralytic poliomyelitis by wild polio virus in last _____ years along with absence of wild polio virus in the community, where excellent clinical and virological surveillance exists and the coverage of routine OPV is more than 80%.
14. Polio elimination is defined as _____ cases of paralytic poliomyelitis by the wild polio virus in one calendar year with other criteria same as in eradication.
15. Indian Academy of Paediatrics recommend _____ at 10 and 16 years

Answers : (1) b; (2) lymphotoxins; (3) Tagging; (4) False; (5) b; (6) c; (7) c; (8) b; (9) True; (10) c; (11) "earliest expiry first out"; (12) d; (13) 3 calendar; (14) Zero; (15) TT.

Rajesh Vaidya and VK Bhatti

The fields of preventive medicine and public health share the goals of promoting general health, preventing specific diseases, and applying the concepts and techniques of epidemiology to attain these goals. Preventive medicine seeks to enhance the lives of individuals by helping them improve their own health, whereas public health attempts to promote health in populations through the application of organized community efforts.

Classification of Diseases

Diseases can broadly be classified as communicable and non - communicable. Communicable Diseases are illnesses caused due to invasion by specific microorganisms or their toxic products. The transmission of the agent or its products

occurs from a source reservoir by direct or indirect means. Non - communicable Diseases are diseases, which are not caused by specific microorganisms and are not spread from one person to the other. These diseases may be metabolic, degenerative, neoplastic, mental, allergic, constitutional or accidental.

Principles of Prevention and Control

The practical application and aim of epidemiological investigation and intelligence are to prevent and control the entry and spread of diseases in communities. The amenability of a disease to prevention and control depends upon the knowledge of its aetiology, epidemiology, mode of contraction, route and mode of transmission of the aetiological agent, the natural history or course of the disease and the incubation period. The better the knowledge of these factors, the greater is the amenability of the disease to prevention and control. The principles of prevention and control are applicable to non - communicable diseases as well as communicable diseases. However, a better knowledge of the specific aetiological agent and epidemiology makes it easier to apply the principles of

prevention and control to most communicable diseases. The ever increasing knowledge of the aetiological and epidemiological factors involved in the causation of non communicable diseases has now made the control and prevention of many non communicable diseases possible as well.

Natural History of Disease

The disease process is a dynamic one and is initiated by a disturbance of the balance between man and environment. The term 'natural history of disease' is applied to its course in man. Disease as seen in the hospital is but an episode in the natural history. The natural history of disease can be seen as having three stages : The pre disease stage, the latent (asymptomatic) disease stage, and the symptomatic disease stage. Another classification of the natural history is the pre pathogenesis phase (pre disease phase), the pathogenesis phase (the latent and symptomatic disease stage) and the post pathogenesis phase. In the pre disease stage the individual possesses various factors that promote or resist disease, these include genetic make up, demographic characteristics (especially age), environmental exposures, nutritional history, social environment, immunologic capability and behavioural patterns. Over time, these and other factors may cause a disease process to begin. Thus potentially man is always in the midst of disease but only when the agent, host and environmental factors, the three components of the epidemiological triad, interact that the disease process is initiated. The pathogenic period begins with the entry of disease agent in the human host as a result of the disease provoking stimuli. If the disease producing process is underway but no symptoms of disease are apparent, the disease is said to be in the latent stage. This stage represents a window of opportunity during which detection followed by treatment provides a better chance of cure or at least of effective treatment. Once the agent becomes established and multiplies, there are tissues or physiologic changes in the host and the disease process is advanced enough to produce clinical manifestations, it is said to be in the symptomatic stage. The end result of the disease process may be complete recovery, chronicity, disability or death. (1 - 3).

Levels of Prevention and Control

The modern concept of health as 'the state of complete physical, mental and social well being and not merely the absence of disease or infirmity' warrants the application of preventive and control measures in the three phases in the natural history of disease discussed above. Prevention of disease means barring or preventing its initial entry into man or a community while 'control' means arresting the further progress and propagation after its entry in an individual host or a community at large. Prevention entails anticipatory action to remove the possibility that a disease will ever occur. Control entails action to prevent invasion of the non - affected but exposed individuals in the affected community. As far as the non - communicable diseases are concerned, some are amenable to simple means of protection e.g. ill effects of cold and heat, while others require more intricate and elaborate preventive and control measures. The natural history and epidemiology of the non - communicable diseases such as cancer, cardiovascular diseases, accidental injuries and occupational diseases, have to be studied in detail to detect vulnerable points or links where preventive or control

measures can be applied (1 - 3).

The objective in the pre - pathogenic phase is to achieve primary prevention, firstly through health promotion by socio - economic improvement and providing healthful housing, adequate nutrition, clothing, healthy living & working environments, and secondly by giving specific protection through immunization, environmental sanitation, use of specific nutrients, protection against occupational hazards, accidents, protection from carcinogens or allergens and so on. In the pathogenic phase, secondary prevention aims at early case detection & treatment as well as uncovering the vulnerable community in the submerged part of the iceberg. It limits dissemination of infection and prevents occurrence of secondary cases in the community by reducing the infectious pool. The methods employed in early case detection are :

- (a) Case finding measures - individual or mass or by contact tracing.
- (b) Screening surveys.
- (c) Surveillance techniques and
- (d) Selective examination of high risk groups.

In the post - pathogenic phase, disability limitation helps early rehabilitation of the patients. The objective is to halt the further progress of the disease process by instituting adequate therapy to limit the disability, prevent further complications through physiotherapy and other techniques of physical medicine. A rapid rehabilitation prevents the recovered individual from lapsing back into ill health, both physical and mental and protects the community from social disruption and diseases. Rehabilitation aims not only at restoring and retraining a patient to live and work within the limits of his disability but to the maximum of his residual capacity. This is termed as the tertiary prevention. The various levels and stages of prevention in relation to the periods in the natural history of disease are shown in Table - 1.

<i>Table 1 : Levels of Prevention</i>		
Levels of prevention	Appropriate response	Period in the natural history where applied
Primary prevention	Health promotion (e.g. encourage healthy lifestyle changes, balanced nutrition and clean environment) Specific Protection (e.g. immunization, Occupational and automobile safety measures)	Pre - pathogenesis
Secondary prevention	Early Diagnosis & treatment	Pathogenesis
Tertiary prevention	Disability limitation (i.e. institute medical or surgical treatment to limit damage from the disease) Rehabilitation (i.e. identify and teach Methods to reduce physical and social disability)	Pathogenesis and Post - pathogenesis

Communicable diseases can be classified according to the aetiological agent or as per the route and mode of transmission. Usually both methods are employed. However, as they have a definite chain of transmission from the reservoir or source through a route upto the susceptible host or recipient, it is more convenient from the point of view of prevention and control, to classify them according to their mode of transmission.

The later, which also indicates the portal of entry & venue of exit of the infecting organism is as follows :

- (a) Contact transmission - direct and indirect.
- (b) Vehicle transmission - water, food, milk etc.
- (c) Vector transmission - by arthropods.
- (d) Air-borne transmission - droplet, droplet nuclei and infected dust.
- (e) Animal-borne transmission - zoonoses
- (f) Trans placental transmission

Control Measures

These aim at exterminating the causative agent in its reservoir at the source of its production, its destruction soon after exit and before it starts its spread by interrupting its path of transmission. Action at these levels requires knowledge of the multifarious factors concerned with the inanimate or animate reservoir or source, various links in the chain of transmission and different approaches to the recipient susceptible host. The practical measure of control broadly fall under three main heads. One or all of these measures may be applied according to the circumstances of the case (1, 4 - 6).

Control of Reservoir and Source of Infection : The first link in the chain of causation is the existence of infected persons, cases (clinical or subclinical) or carriers, who constitute the primary source of infection. The general measures of control of the reservoir of infection are :

- (a) Early detection of cases.
- (b) Notification
- (c) Isolation
- (d) Treatment.
- (e) Quarantine.
- (f) Surveillance.
- (g) Disinfection.

Block the channels of Transmission : This may be achieved by general environmental control, specific control measures such as safe water supply, sanitary disposal of sewage & other waste products, high standard of food hygiene, vector control, personal hygiene, proper ventilation, prevention of overcrowding and dust control.

Protection of Susceptible Population : This is carried out by immunization, chemoprophylaxis, good nutrition, health education and personal protection.

Control Measures on the Occurrence of an Infectious Disease

In public health practice, the action to control the communicable diseases has to be crystallized into the form of a 'drill' which should involve no elaborate thought or preparation because the etiological agents travel fast and gain momentum and invasive force as they proceed from person to person. The usual sequence of action to control the spread of an infectious disease is as follows :

- (a) Early detection of case.
- (b) Isolation of the case for the entire period of infectivity.
- (c) Prompt and effective treatment of case.
- (d) Disinfection of discharges and fomites.
- (e) Notification.
- (f) Surveillance of contacts.
- (g) Mass immunization of the vulnerable community.
- (h) Investigation of the current outbreak.
- (j) Survey to assess endemicity.

Immunization : One of the most satisfactory control measures is that it renders the host immune from infectious disease by an infectious agent. Active immunization is a cornerstone of public health measures for the control of many infectious diseases and is considered one of the most cost - effective methods of individual, institutional, and community protection from many infectious diseases. Immunization is dealt with in detail in other sections of this book.

Chemoprophylaxis : Chemoprophylaxis is the prevention of infection or its progression to clinically manifest disease through the administration of chemical substances, including antibiotics. Chemoprophylaxis may be specifically directed against a particular infectious agent or it may be non - specifically directed against many infectious agents. The use of antibiotics before surgical procedures is an example of non - specific Chemoprophylaxis to prevent wound infections in the postoperative period. Examples of specific Chemoprophylaxis are as follows (9) :

Use of Chemoprophylaxis to prevent development of infection

- Using chloroquine to prevent malarial parasitaemia.
- The use of silver nitrate, erythromycin or tetracycline instilled into the eyes of a newborn to prevent gonococcal ophthalmia by transmission of *Nisseria gonorrhoeae* from an infected mother during birth.
- To use of tetracycline, sulfonamides or streptomycin in close contacts of confirmed or suspected cases of plague pneumonia to prevent plague.
- Use of Rifampicin in close contacts of meningococcal meningitis patients.

Chemoprophylaxis to prevent the progression of an infection to active manifest disease

- Use of co - trimoxazole or pentamidine to prevent subclinical latent infection with *Pneumocystis carinii* from progression to clinically manifest pneumocystis pneumonia in immunosuppressed persons such as HIV - infected individuals.
- Use of pyrimethamine - sulfadiazine - folic acid to prevent asymptomatic infants congenitally infected with *Toxoplasma gondii* from clinically manifest chorioretinitis and other sequelae of congenital toxoplasmosis.

Chemoprophylaxis to treat an infectious disease to prevent complications of the disease

- Penicillin to treat streptococcal sore throats caused by *Streptococcus pyogenes* group A to prevent acute rheumatic fever.
- Benzathine penicillin for treatment of syphilis in its primary, secondary, or early latency period to prevent

late manifestations of the disease such as cardiovascular syphilis.

Disinfection

Definitions (4)

(a) **Disinfection** : This means destruction outside the body, of specific microorganisms, which cause communicable diseases.

(b) **Disinfectants** : These are the agents used for disinfection.

(c) **Antiseptics** : These are the chemical agents, which inhibit the growth and multiplication of microorganisms, but are not strong enough to destroy them completely. A sufficiently diluted or weakened disinfectant becomes an antiseptic.

(d) **Disinfestations** : This means destruction of undesirable animal forms, especially arthropod ectoparasites present upon the persons or on domestic animals. The term also includes destruction or avoidance of endoparasites like helminthes, and rodent destruction. However, in practice this term mainly refers to the destruction of ectoparasites like lice, sarcoptes, bugs and fleas and their ova and eggs.

(e) **Disinfestants** : These are the agents used for disinfestation. Disinfestants which are specially used against arthropods are called 'insecticides' and 'acaricides' depending on their special values in practice. A number of disinfectants are disinfestants if used in adequate strength, but all disinfestants or insecticides are not disinfectants.

(f) **Detergents** : These are surface cleansers and degreasers. They dissolve grease and oily matter and thereby help removal of dirt etc., from any material when rinsed or washed with water consequently removing the micro - organisms sheltered by grease and dirt.

(g) **Deodorants** : These are substances, which mask the unpleasant odours without having disinfecting or antiseptic powers. Many disinfectants and antiseptics mask putrefactive odours also.

Objective

The object of these processes is to cut the links in the chain of the spread of communicable diseases and reduce nuisance. They can, therefore, be considered as supplementary to environmental sanitation. The main objective can be achieved with minimum effort and maximum success if the aetiology and mode of transmission of each disease is clearly understood, ecology and bionomics of their agents are known, procedures are rational and specifically directed against the paths of its spread and not employed merely as placebos to appease the ignorant mind. Much time, energy and money are wasted on disinfection of places which only require ventilation and cleansing. Some situations may need only the disinfection and other may need only disinfestation while a few may need both. Agents and procedures adopted will, therefore, depend upon the situation as well as nature of the problem. Disinfection is discussed hereunder.

Disinfection Procedures

Concurrent Disinfection : It means the disinfection of the patient himself, of his excreta & discharges & of all articles used by him or likely to have been contaminated during the course of his illness, including hands and clothing of attendants.

Terminal Disinfection : It means the disinfection of the room or premises and their contents after the patient has recovered, died or has been removed elsewhere. This includes the vehicle or ambulance, the wheel chairs and stretcher used by the patient. This is either 'local' or 'complete'.

(i) **Local** : It is the disinfection of the bedding and the bedsheet occupied by the patient, the walls, floor, furniture including the kit box, shelf, lockers and their contents and all other surfaces or articles within 2 meters all round the bed.

(ii) **Complete** : It is the disinfection of the whole room and all its contents.

Prophylactic Disinfection : It means chemical treatment or boiling of water, pasteurization of milk, washing of hands and so on.

Classification of Disinfecting Agents : Disinfecting agents can be classified as follows :

(a) Natural Agents

- Fresh air
- Sunlight

(b) Physical Agents

- Dry Heat : Burning; Hot dry air; Contact heat - ironing
- Moist Heat : Boiling (with or without chemical agent); Steaming - current steam and steam under Pressure.
- Radiation : Ionizing radiation; Ultraviolet rays.

(c) Chemical Agents

- Solids
- Liquids
- Gases
- Aerosols

It will not, however, be correct to suppose that the action of any agent is circumscribed in or confined to its particular group only. Many disinfectants act both by physical action and chemical action e.g. soap acts by physically removing the grease and dirt which shelter the organisms as well as by its chemical action. Often, in practice, disinfection by chemical agents can be complemented or supplemented by physical agents. Thus clothing can first be soaked in a chemical agent, then steamed and finally washed, dried in the sun and ironed. Similarly disinfection by boiling can be accelerated or aided by the addition of a chemical or soap.

Natural Agents

Fresh air dilutes the bacterial content in enclosed places and desiccates micro - organisms by dehumidification. Sunlight disinfects due to the desiccating effect of its heat rays and the action of its ultraviolet rays. Indeed, this disinfecting power of the sun has made life possible in the unsanitary tropical and subtropical environments. Although these agents are slow in action and frequently unreliable owing to the resistance of certain organisms, they are valuable adjuncts to artificial methods. In their absence the saprophytic life of all germs is prolonged. Thus, during epidemics, cinema theatres act as foci for the dissemination of infection since they usually admit no direct sunlight and little fresh air, whilst respiratory moisture delays desiccation.

Physical Agents

Heat kills ectoparasites and micro - organisms by coagulating

their protoplasm. It may be employed in a dry or moist form. To ensure perfect sterility, the former demands a higher temperature and / or longer exposure than the latter. Heat, especially in the moist form, is the only physical agent that is reliably used for artificial disinfection and disinfection in preventive medical practice.

Dry Heat : Burning is a certain and rapid method of disinfecting and disinfection but has only a limited scope. It may, however, be the only available method on active service. For example, clothing contaminated by excreta of cholera patients may be burnt, or the ground which has been contaminated by an anthrax carcass may be disinfected by burning straw or oil on the top of it. Contact heat applied by pressing irons over clothing may be used to disinfest louse and mites. Hot air ovens are used to disinfect glass ware such as petridishes, sharp instruments, swabs, dressing, chalk, Vaseline etc. The temperature of the air in the oven should be maintained at 160°C for at least one hour.

Moist Heat : Boiling is quite effective in killing all non-sporing organisms, spores being very resistant require boiling for an hour and a half. Boiling is largely used for sterilizing instruments and is useful for disinfecting bed clothing, underwear and similar articles. Blood stains become fixed by boiling owing to the coagulation of protein; these should, therefore, be first removed by soaking in cold soapy water. Another disadvantage of boiling is that it is unsuitable for thick bedding of woollens. The effect of boiling can be enhanced by adding soap or washing soda to water. Steaming is the most efficient procedure of disinfection and disinfection. The usual method is to expose the infected articles to 'saturated steam' in 'current steam' or 'under pressure'.

Radiation

Ionizing Radiation : Gamma radiation or electron beams have the advantage of combining great penetrative power with little or no effect on the object to be sterilized. Bandages, catgut, dressing and surgical instruments may be sterilized by ionizing radiation. These methods are used commercially. The isotope used is Cobalt 60.

Ultraviolet Rays : Ultraviolet rays delivered from an apparatus hung in the ceiling at the entrance of special purpose rooms like the one in which premature infants are kept or in operation theatres, temporarily disinfect the objects and air entering inside.

Steam Disinfection : Steam in contact with boiling water from which it is generated has the temperature of 100°C and is called as 'saturated steam'. When it comes in contact with colder objects it immediately condenses and every gram of it transfers a latent heat of 537 calories to that object and it contracts to about 0.0015th of its volume and creates a partial vacuum. To fill the empty space more steam immediately rushes, condenses, releases the latent heat and again creates a partial vacuum. Continued repetition of this process achieves penetration of steam throughout the mass of the fabric. Heat is thus transferred to the exposed articles until its temperature is raised to 100°C. Intimate contact with saturated steam is instantly fatal to all non - sporing organisms.

Steam introduced at atmospheric pressure is known as 'current'

or 'unconfined' steam; and at pressure in excess of that is called 'pressure' or 'confined steam'. The penetration of the pressure steam is no better than the current steam unless the chamber is vacuumised. By increasing pressure after creating vacuum much higher temperatures can be attained than the 100°C obtained with current steam. This renders 'pressure steam' disinfection more effective. This temperature of steam with a 0.33 kg per square cm rise of pressure above the atmosphere is 109°C, at 0.66 kg it is 115°C, at 1 kg 121°C, at 1.33 kg 126°C, and at 2.66 kg per square cm it goes upto 141°C and so on.

Chemical Agents

Chemical disinfectants may be solid, liquids, gases or aerosols. Solids act as disinfectants only in solution. A few disinfectants as powders, act better when dissolved. Gases like sulphur dioxide and formaldehyde also act as better disinfectants in the presence of adequate moisture. The disinfecting power of a chemical depends upon its basic toxicity, concentration, penetrating power, the medium in which it is to act, the resistance of organism required to be killed, the extent to which the organism is protected by organic matter like pus or faeces, and the period of contact allowed. The ideal chemical disinfectant should be capable of destroying all micro - organisms in all probable media within half an hour; it should be harmless to man and higher animals; it should not spoil metals, clothing and other household goods in the concentration usually employed; for convenience of transportation. It should be obtainable in a highly concentrated form; it should be capable of forming a solution or stable emulsion in water (even in hard water); and finally it should be cheap. The main problem with any disinfectant, however, is the ability of its particles to gain contact with bacteria. Capsulated organisms resist penetration to a marked degree; the organisms locked up even in microscopic masses of pus, mucus, faeces etc. are protected against most disinfectants unless the time of contact is long and the concentration high. Disinfection by chemicals is thus a complex process and the estimation of the true disinfecting power of any chemical agent is difficult (7, 8).

Estimation of Germicidal Power : The best known test for assessing germicidal power is the 'Rideal - Walker phenol coefficient test' (RW). In this test the bactericidal power of any chemical is compared with that of phenol under identical conditions. This is done by observing the comparative sterilizing effects of a series of dilutions of the particular chemical and those of phenol against a standard dose of a standard culture of the Lister strain of *B. typhosum*, in a standard time, at a standard temperature. The RW coefficient is obtained by dividing the highest sterilizing dilution of the agent under test by the highest dilution of phenol sterilizing in the same time. For example, if cresol diluted 1 : 1200 and phenol diluted 1 : 100 both produce sterility, say, in 15 min, the RW coefficient of cresol would be 12 i.e. cresol has 12 times the disinfecting power of phenol. The test, however, does not indicate the disinfecting powers of disinfectants under natural conditions. For example, the mercurial salts show a high RW coefficient but their disinfecting action is arrested by albuminous materials. Chlorine and potassium permanganate lose a great deal of potency in the presence of organic matter, while others like cresol are only slightly handicapped. Various

modified tests, like Chick - Martin's test, take into account the effects of extraneous material. However, the unmodified Rideal - Walker test is useful for comparing the germicidal power of different batches of the same disinfectant.

Solids

Quicklime : It is used in the burial of animals dead of anthrax; for disinfecting byres and stables after the occurrence of a case of anthrax; and as 25 per cent lime wash for walls, ceiling and floors of barns, sheds, stables, kitchen, stores and so on. Slaked lime is used as a deodorant in and around urinals, soakage pits, grease traps; to promote bacterial growth by retarding acidity in deep trench latrines; and as a final spread over shallow trenches.

Chlorine Compounds : Bleaching powder, water sterilizing powder, sodium hypochlorite and many other kindred substances containing chlorine are used to sterilize water and vegetables. Bleaching powder in combination with boric acid has been used as eusol in surgery. The practice of sprinkling bleaching powder in drains, gutters, latrine pails etc. is wasteful and useless.

Liquids

Coal Tar Derivatives : These are obtained by its fractional distillation and are most widely used of all the liquid disinfectants. This group includes the aniline dyes, the phenols and the cresols.

Cresol : It is a dark brown, oily, readily emulsifiable liquid. Liquor cresoli fortis, known in the Armed Forces as 'disinfecting fluid black' or simply as cresol, is the most convenient and the most useful general disinfectant. It turns white on dilution with water and is extremely stable. Liquor cresoli fortis has a RW coefficient of 12, but cresol commercially supplied may have a 10 RW. All containers are marked with the RW of the contained cresol so that, by increasing or decreasing the amount of dilution with water a final disinfectant liquid of known strength can be made. For general use, like scrubbing bedsteads the dilution of 1 per cent of RW 10 cresol is enough. In this dilution it is not dangerously toxic if swallowed, is only mildly irritating to the skin, and possesses high germicidal power. For disinfecting bedpans, sputum or excreta a dilution of 2.5% of RW 10 cresol is needed. Even in this dilution cresol does not destroy fabrics. Although it is rapidly fatal to micro-organisms when it comes in contact with them, its penetration into a mass of sputum or faeces is not good. Therefore, as a measure of greater safety, a 5 per cent emulsion is used for disinfecting sputum of tuberculosis cases and faeces of some excremental disease cases. Cresol is of great value in the disinfection of the receptacle after the contained infective material has been disposed of.

Izal : This is saponified cresol, officially known as 'disinfecting fluid white (Izal)'. This correct nomenclature should always be used. It is used in 3 per cent strength for disinfecting mouthpieces of telephones and microphones, of RT sets and PA sets and the face pieces of respirators. It should not be used for any other purpose.

Dettol : This is chloroxylenol. It is non - irritating but inactivated by organic matter. It is active against streptococci but has no effect on some gram - negative bacteria.

Commercial Formalin : This is a 40 percent aqueous solution of formaldehyde. It is a powerful disinfectant, but since it is very irritating to the hands, eyes and respiratory passages, it is not used as a general disinfectant. It can be used in a 5 per cent dilution for disinfecting rooms, tents, huts, or vehicles and for spraying fur - coats, leather, rubber, metal and similar articles which are destroyed by steam. It is used for disinfecting valuables like jewellery, gold and ornaments and watches. It is used for preserving tissues required to be sent to the laboratory for examination.

Gases

Sulphur Dioxide : This gas has been used for fumigation against rats in ships and warehouses by the Clayton apparatus in which a forced draft from a blower ensures complete combustion of sulphur. By means of pipes led from the generator, a concentration of 15 per cent sulphur dioxide is attained in the air in enclosed places. Sulphur dioxide is not dangerous to human life, but tarnishes metals, discolours paints, destroys pictures, spoils grain and entails a risk of fire.

Formaldehyde

The gas is generated popularly by pouring liquid formalin over crystals of potassium permanganate placed in a deep pan. About 300 ml of formalin and 150 gm of potassium permanganate are required for 1000 cft of space. The room is to be kept closed for 6 to 12 hours to allow disinfection.

Aerosols

Aerosols are mists released into the air by a special atomizer to disinfect the air in enclosed places. Their action is believed to be either due to collision with and absorption by organisms or condensation of vapour on bacteria - carrying particles, quickly destroying their bacterial content. The ideal aerosol should be non - irritating to the mucosa, non - toxic even after prolonged exposure, invisible, inodorous, non - corrosive, non - inflammable, highly bactericidal in low concentrations, and capable of penetrating organisms in dried secretions such as saliva. The most effective and irritating particles have a diameter of less than 1 micron and act at dilution ranging 1 in 100 million to 500 million volume of air. Aerosol has an advantage over ultra violet rays in the disinfection of air in enclosed places due to their penetration to the remote corners of rooms. Aerosols so far tried for killing bacteria suspended in the air, fall into three groups viz. hypochlorites, resorcinols and glycols. Insecticide aerosols are effective against insects only. They contain Freon gas, Pyrethrum and DDT in solutions.

General Recommendations

To summarize, disinfection of the following must always be considered in all cases of infectious illness :

- (a) The patient's excreta and discharges, linen, utensils and other articles used by the patient.
- (b) The quarters occupied by the patient before removal to hospital and their contents.
- (c) The vehicle in which the patient is conveyed to hospital.
- (d) On recovery of the patient, the ward/ room in which the patient was treated and its contents.
- (e) In the case of carriers or contacts disinfection should be carried out at the discretion of the officer in medical charge.

Details of Procedures to be followed

(a) **Concurrent Disinfection** : It should always be considered as extremely important. Concurrent disinfection of various infective materials in appropriate cases should be carried out as follows :

- (i) Sputum should be received directly into sputum cups containing 2.5 per cent cresol and afterwards burnt.
- (ii) Nasal, aural and eye discharges should be received directly into small pieces of linen, cotton or cotton wool, and immediately burnt. Vaginal or urethral discharges and those from open sores should also be similarly received on pads left in situ under dressings and burnt after removal at frequent intervals. Handkerchiefs should be soaked in 2.5 percent cresol solution before washing with soap and ironing.
- (iii) Contents of bed pans and urine bottles used by patients suffering from gastro - intestinal diseases as well as their vomits should be thoroughly mixed with an equal quantity of 2.5 per cent cresol and allowed to stand for 2 hours before throwing down the sluice or water closet or incinerated. Bed pans and bottles should subsequently be steeped in 2.5 per cent cresol for 15 min to half an hour and then washed.
- (iv) Bed linen, blankets etc. which have been soiled with infectious discharges, exudates or excreta should be steeped in 2.5 percent cresol for half an hour before removal from the ward. Special bedding and clothing marked with 'I' are reserved for use of patients suffering from infectious diseases.

(b) **Terminal Disinfection** : It is complementary to the concurrent disinfection. All clothing, mattresses, bedding, linen, personal wear and similar articles within the specified areas for local or complete disinfection as indicated are packed in sacks, or sheets soaked in 2.5 per cent cresol and removed to the disinfection center for steam disinfection. After disinfecting, the articles of clothing and linen are washed with soap, dried in the sun and ironed. The floor, the walls and wall - skirting, bedsteads, shelves and any other metal or wooden article, other than those which are removed for steam disinfection, are disinfected in situ by scrubbing or spraying with 2.5 per cent cresol. After a suitable period of contact with the disinfectant, these may be washed.

(c) Some Special Disinfections

(i) **Vehicle or Aircraft** : Spray or swab with 5 per cent formalin or 2.5 per cent cresol followed by washing in hot water with soda.

(ii) **Crockery and Cutlery** : Steep for half an hour in 2.5 per cent cresol followed by washing in hot water with soda.

(iii) **Toys, Book and Papers** : If of small value, they may be burnt. If valuable, spray or swab with 5 per cent formalin followed by exposure to the air for two to three days.

(iv) **Shaving Brushes** : Thoroughly wash in 5 per cent soap solution containing one per cent soda ash at 50°C. Allow to stand in one per cent soda ash at 50°C for half an hour. Soak for half an hour in 10 percent formalin solution at 50°C. Allow to dry in the shade, bristles downwards.

(v) **Latrine Seats** : Scrub with 2.5 per cent cresol, which should then be allowed to dry on the seat.

Summary

The fields of preventive medicine and public health share the goals of promoting general health, preventing specific diseases. The amenability of a disease to prevention and control depends upon the knowledge of aetiological agent, the natural history or course of the disease and the incubation period. The disease process is a dynamic one and is initiated by a disturbance of the balance between man and environment. The natural history of disease can be seen as having three stages: the pre-pathogenesis phase (pre-disease phase), the pathogenesis phase (the latent and symptomatic disease stage) and the post-pathogenesis phase. The objective in the pre-pathogenic phase is to achieve primary prevention. In the pathogenic phase, secondary prevention aims at early case detection & treatment. In the post-pathogenic phase, disability limitation helps early rehabilitation of the patients. Control Measures aim at exterminating the causative agent in its reservoir at the source of its production, its destruction soon after exit and before it starts its spread by interrupting its path of transmission. The practical measures of control broadly fall under three main heads; these are: Control of Reservoir and Source of Infection comprising of Quarantine, Surveillance, Disinfection etc.; Blocking the channels of Transmission, which may be achieved by general environmental control, specific control measures such as safe water supply, sanitary disposal of sewage etc., Disinfection means destruction outside the body, of specific microorganisms, which cause communicable diseases. It must always be considered in all cases of infectious illness. Disinfection Procedures involve Concurrent Disinfection, Terminal Disinfection and Prophylactic Disinfection. The various Disinfecting agents can be classified as Natural Agents, Physical Agents and Chemical Agents.

Study Exercises

Long Question : (1) Discuss Natural History of Disease and Levels of Prevention and Control of diseases. (2) Classify and discuss various disinfecting agents

Short Notes : (1) Control Measures used in infectious diseases (2) Chemoprophylaxis (3) Terminal Disinfection (4) Physical Agents of Disinfection (5) Rideal - Walker phenol coefficient test

MCQs

1. The objective of Prevention and Control measures in the pre-pathogenic phase is to achieve (a) Primary prevention (b) Secondary prevention (c) Tertiary prevention (d) None of the above
2. Broad categories of Disinfecting Agents are all except (a) Natural Agents (b) Physical Agents (c) Chemical Agents (d) Gaseous Agents
3. The temperature of the air in the oven should be maintained at (a) 160°C for at least one hour (b) 170°C for at least one hour (c) 180°C for at least one hour (d) 190°C for at least one hour

4. Steam introduced at pressure in excess of atmospheric pressure is known as (a) Current Steam (b) Unconfined Steam (c) Saturated steam (d) Confined steam
5. Contents of bed pans used by patients suffering from gastro-intestinal diseases should be thoroughly mixed with an equal quantity of ____ per cent cresol and allowed to stand for ____ hours before throwing (a) 0.5% for 1hr (b) 0.5%, 2hr (c) 2.5%, 1hr (d) 2.5%, 2hr

Answers : (1) a; (2) d; (3) a; (4) d; (5) c.

Public Health Laboratory : Microbiological Procedures

Aniruddha Hazra, LS Vaz & Nandita Hazra

Outbreaks of communicable diseases are public health emergencies which result in increased morbidity and mortality and place acute demands on the health system. A surveillance network, including available laboratory support and aimed at a simplified syndromic surveillance of priority communicable disease syndromes is important for early detection, control and prevention of outbreaks. Laboratory support is an integral component of any disease surveillance system as well as outbreak investigation system (1, 2).

Syndromic Approach to Investigation of Outbreaks

The underlying principle of the “*Syndromic Approach*” to communicable disease surveillance and field investigation of an outbreak is that the case definition is based on a syndrome and not on a specific disease e.g. acute diarrhoeal syndrome. Syndromic surveillance may be the ideal type of public health surveillance to detect outbreaks whether they are intentional or naturally occurring events. These systems monitor for disease by tracking symptom complexes that are representative of most diseases. The system looks for significant increases in the frequency of a given syndrome against a baseline and provides timely notification of any increase (3). Syndromic surveillance is already being practiced in India e.g. Acute Flaccid Paralysis Surveillance.

Disease Syndromes according to Clinical Criteria

For the purposes of routine disease surveillance as well as field investigation of priority communicable diseases, the syndromes based on clinical criteria are as given below (2) :

- Acute Diarrhoeal Syndrome
- Acute Haemorrhagic Fever Syndrome
- Acute Jaundice Syndrome
- Acute Neurological Syndrome
- Acute Respiratory Syndrome
- Acute Dermatological Syndrome
- Acute Ophthalmological Syndrome
- Acute “Systemic” Syndrome

Some of the diseases or pathogens which cause outbreaks are enumerated in Table - 1. The list is not exhaustive as many illnesses are restricted geographically or may present with unexpected clinical features.

Planning for Clinical Specimen Collection

Proper collection of an appropriate clinical specimen is the first step in obtaining an accurate laboratory diagnosis of an infectious disease. The important considerations for specimen collection and handling are :

- Based on the preliminary information on the syndrome responsible for the outbreak, decide on the possible differential diagnosis for further investigations.
- The quantity and nature of the supplies required in the field such as containers, reagents, rapid kits, transport media etc. and the level of expertise of the personnel required in the field must be considered before setting out to investigate the outbreak.
- Keep *outbreak investigation kit* always ready with the team (see Table - 2).
- Specimens obtained in the acute phase of the disease, preferably prior to administration of antimicrobial drugs, are more likely to yield the infective pathogen.
- Once in the field, ensure proper collection, storage and transport of the specimen in leak - proof containers labeled properly and accompanied by complete patient information in standard formats.
- Universal safety precautions require that workers should

Table - 1 : Diseases and pathogens encountered in outbreak investigations	
Syndrome	Diseases / Pathogens
Acute Diarrhoeal Syndrome	Possible Diseases/ Pathogens : (a) <i>Watery Diarrhoea</i> : Cholera, Viral gastroenteritis (Norwalk - like and Rotavirus), Enterotoxigenic <i>E.coli</i> , Giardiasis, Cryptosporidium (b) <i>Dysentery</i> : Shigellosis, Salmonellosis, Enterohaemorrhagic <i>E. coli</i> , Amoebic dysentery, Campylobacteriosis, <i>Clostridium difficile</i>
	Other Causes : Ebola and other haemorrhagic fevers*
Acute Haemorrhagic Fever Syndrome	Possible Diseases / Pathogens : Dengue haemorrhagic fever and shock syndrome, Malaria, Relapsing fever
	Other Causes : Yellow fever, other arboviral haemorrhagic fevers
Acute Jaundice Syndrome	Possible Diseases / Pathogens : Hepatitis A to E, Leptospirosis
	Other Causes : Yellow fever
Acute Neurological Syndrome	Possible Diseases/ Pathogens : Poliomyelitis or Guillain Barré syndrome, Japanese encephalitis, Meningococcal meningitis, Leptospirosis, Malaria
	Other Causes : Rabies and other lyssaviruses, Tick - borne encephalitis viruses, Trypanosomiasis
Acute Respiratory Syndrome	Possible Diseases / Pathogens : Influenza, Diphtheria, Streptococcal pharyngitis, Bacterial pneumonias including : Pneumococcal pneumonia, <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , Mycoplasma, Respiratory anthrax, Pertussis, Pneumonic plague, Legionellosis
	Other Causes : Hantavirus pulmonary syndrome, Respiratory Syncytial Virus (RSV), Q fever, SARS
Acute Dermatological Syndrome	Possible Diseases / Pathogens : Chickenpox, Measles, Rubella, Typhus, Cutaneous anthrax
	Other Causes : Monkeypox, Parvovirus B19
Acute Ophthalmological Syndrome	Possible Diseases / Pathogens : Epidemic adenoviral keratoconjunctivitis, Haemorrhagic conjunctivitis (adeno - or enteroviral), Trachoma (<i>Chlamydia trachomatis</i>)
Acute "Systemic" Syndrome	Possible Diseases / Pathogens : Dengue fever and other Arboviral fevers, Viral Hepatitis, Typhoid fever, Malaria, Leptospirosis, Brucellosis, Anthrax, Bubonic Plague, Typhus
	Other Causes : Hantaviral disease, Lassa fever, Lyme disease, , Relapsing fever, Rift Valley fever, Yellow fever, Borreliosis
* NOTE : Ebola and other haemorrhagic fevers may initially present as bloody diarrhoea. If such aetiology is suspected, refer to "Acute Haemorrhagic Fever Syndrome" for appropriate specimen collection guidelines. Source : Adapted from (2)	

handle all clinical specimens as if they were infectious.

- Ensure that appropriate bio - safety and waste management measures are followed.
- Inform the receiving laboratory about the tentative date and time of arrival of the specimen.
- The aim should be to reduce the time to confirmation so that timely public health actions can be taken. Only, a few initial cases need confirmation. Rest with similar clinical manifestations should be treated as confirmed.

Collection & Transportation of Clinical Specimens

The appropriate clinical specimens that should be collected in various disease syndromes for the laboratory confirmation of the pathogen responsible for the outbreak are summarized in Table - 3.

The general guidelines for collection and transportation of clinical specimens are given in the successive paragraphs.

Blood Specimen Collection : Blood and separated serum are the most common specimens taken to investigate outbreaks

of communicable disease. Venous blood is to be collected for identification of the pathogen in culture and serum for PCR, specific antibodies, antigens, or toxins and viral pathogens. For specific antibodies, paired sera are required to be collected. Finger prick method is to be used for slides for microscopy or for absorption onto special filter paper discs for analysis. Whenever possible, blood specimens for culture should be taken before antibiotics are administered to the patient.

Handling and transport

- Blood culture bottles and blood sample tubes should be transported upright and secured in a screw cap container or in a rack in a transport box. Cushion or suspend bottles during transport over rough terrain to prevent lysis of red cells. They should have enough absorbent paper around them to soak up all the liquid in case of a spill. If the specimen will reach the laboratory within 24 hours, most bacterial pathogens can be recovered from blood cultures transported at ambient temperature.

Table - 2 : Proposed Components of the Outbreak Investigation Kit	
Generic Outbreak Investigation Kit	
Disposable storage vials (5ml & 10 ml)	Rubber bands
Disposable sample collection vials	Ziploc plastic bags
Vacuutainer (plain and EDTA)	Absorbent material (tissue paper, cotton wool, newspaper)
Cryovials	Filter paper
Syringes and needles disposable (5ml & 10 ml)	Vaccine carrier with ice - packs
Tuberculin syringes and needles	Dry ice packs
Lancets	Glass marking pen
Slides, cover slips and slide holding box	Specimen labels
Tourniquet	Adhesive tape
Gloves	Scissors
Masks (triple layer surgical mask)	Scalpel/ blade
Disposable caps	Spatula
Goggles	Forceps
Disposable gowns	Loop holder
Swabs & gauze pads	Parafilm (small rolls)
Povidone iodine 10%	Leak proof screw capped containers
Isopropyl alcohol 70%	Pasteur pipettes/ pipettes and pipette aids (rubber teats)
Band - aid	Sodium hypochlorite concentrate (4%)
Spirit lamp/ gas lighter	Hand disinfectant
Match - box	Stationary (writing pads, pens, pencils, erasers, sharpeners etc.)
Test tube rack	Calculator
Centrifuge tubes	Torch with spare batteries/ rechargeable batteries
Puncture proof discarding bags (disposable)	OT test kit
Thermometers	Water sampling kits
Tongue depressors (disposable)	Distilled water (100ml)
CSF collection kit	Normal saline in dropper bottle
Stool culture bottle	Magnifying glass
Throat swabs	Patient register book
Blood culture bottles	Laboratory request forms
Viral transport medium (VTM)	Epidemiological survey formats
Cary Blair medium/ Stuart's transport medium	Epidemiological reporting formats
Rapid diagnostic kits (e.g. H2S method kit for water testing, latex agglutination for meningitis, card test for dengue etc.) wherever possible	Outbreak investigation guide/ module
Sharps disposal boxes	Laptop Computer with case
Selected Entomological & Vector Dissection Equipment	
Aspirator and flashlight for indoor/ outdoor mosquito collection	WHO susceptibility kit for adult & larvae with reagents
Kit for outdoor mosquito collection	Bioassay kit
Ladle bottles for keeping larvae, strainer, dropper, trays and funnel net for wells	Charts/ synoptic keys for identification of vectors
White bed sheet to spread on floor	Pyrethrum spray with flit gun
Dissecting microscope	Staining equipment & material
Dissection needle	Filter paper
Petridishes	Mosquito net
Slides, coverslips	Physiological saline
Note : Any other item, as per the requirements of the outbreak. Source : Adapted from (1, 2, 4, 5)	

Table - 3 : Clinical Specimens needed and Laboratory Tests to be Performed in Various Disease Syndromes			
Syndrome	Specimens Required	Laboratory Tests To Be Done	
		Field / Peripheral Lab	Zonal/ Referral Lab
Acute Diarrhoeal Syndrome* *(including suspected food-borne outbreaks)	<ul style="list-style-type: none"> Freshly passed stool Rectal swab Faecal swab Environmental sampling especially water for available chlorine and bacteriological examination <p><i>If food-borne outbreak is suspected:</i> Refrigerate all remaining food items for further testing if necessary.</p>	<ul style="list-style-type: none"> Hanging drop / Iodine & wet mount of stool specimen Parasite : Macro- and microscopic examination OT test for available chlorine in water Rapid H₂S test for bacteriological examination of water 	Earlier tests, plus <ul style="list-style-type: none"> Faecal leukocytes Toxin detection test for cholera toxin (if kit available) MPN test for bacteriological examination of water Stool culture for enteropathogens; sensitivity testing, if available Serotyping Referral of samples for further characterization and testing, if required
Acute Haemorrhagic Fever Syndrome	<ul style="list-style-type: none"> Blood Blood smear Serum Post - mortem tissue specimens (e.g. skin biopsy and/ or liver biopsy) 	<ul style="list-style-type: none"> Peripheral smear for malarial parasite Total leukocyte count Differential leukocyte count Platelet count Rapid diagnostic tests for diagnosis of dengue fever 	Earlier tests, plus <ul style="list-style-type: none"> <i>Viral</i> : Culture; Antigen detection; Antibody levels (IgM/ IgG) <i>Parasitic</i> : Demonstration of pathogen <i>Yellow fever</i> : post-mortem liver biopsy Referral of samples for further characterization and testing, if required
Acute Jaundice Syndrome	<ul style="list-style-type: none"> Blood Serum Urine Environmental sampling especially water for available chlorine and bacteriological examination 	<ul style="list-style-type: none"> OT test for available chlorine in water Rapid H₂S test for bacteriological examination of water Dark ground microscopy of peripheral blood for leptospirosis Rapid test kit for diagnosis of viral hepatitis (HbsAg antigen detection and anti-HCV) 	Earlier tests, plus <ul style="list-style-type: none"> MPN test for bacteriological examination of water Urine microscopy Rapid tests for detection of antibodies to <i>Leptospira</i> Blood for <i>Leptospira</i> : Culture; Serotyping <i>Yellow fever</i> : post-mortem liver biopsy <i>Viral</i> : Culture; Antigen detection; Antibody levels (IgM/ IgG) Referral of samples for further characterization and testing, if required
Acute Dermatological Syndrome	<ul style="list-style-type: none"> Vesicular fluid Crust Serum Lesion swab (vesicular exudate) Tzanck smears (vesicle floor scrapings) 	<ul style="list-style-type: none"> Giemsa stain for Tzanck smears (scrapings of floor of vesicles) 	Earlier tests, plus <ul style="list-style-type: none"> Electron microscopy of vesicle fluid <i>Bacterial</i> or <i>Viral</i> : Culture; Antibody levels (IgM/ IgG); Immunofluorescence
Acute Ophthalmological Syndrome	<ul style="list-style-type: none"> Conjunctival swab and smear Throat swab Serum 	<ul style="list-style-type: none"> Giemsa stain for HP bodies (<i>C.trachomatis</i>) 	Earlier tests, plus <ul style="list-style-type: none"> Chlamydial : Microscopic examination, Culture, Antigen detection <i>Viral</i> : Antigen detection Antibody levels (IgM/ IgG)

Table - 3 (Contd..)

Syndrome	Specimens Required	Laboratory Tests To Be Done	
		Field / Peripheral Lab	Zonal/ Referral Lab
Acute Neurological Syndrome	<ul style="list-style-type: none"> CSF Blood Serum Stool Urine Throat swab Post - mortem tissue in suspected rabies (e.g. corneal impressions, brain tissue, skin biopsy from neck) Environmental sampling especially water for available chlorine and bacteriological examination 	<ul style="list-style-type: none"> Gram stain of CSF & CSF cytology India ink mount of CSF Dark ground microscopy of peripheral blood for leptospira OT test for available chlorine in water Rapid H₂S test for bacteriological examination of water 	<p>Earlier tests, plus</p> <ul style="list-style-type: none"> MPN test for bacteriological examination of water Latex agglutination tests for detection of capsular antigen in CSF (if kit available) Rapid tests for detection of antibodies to Leptospira CSF for bacterial culture (if facilities available) Blood for bacterial culture ELISA for JE virus <i>Poliomyelitis</i> : Stool culture, Antigen detection, Intratypic differentiation <i>Rabies</i>: Demonstration of <i>Negri</i> bodies by Seller's stain in post-mortem tissue, virus isolation, fluorescent antibody test Referral of samples for further characterization and testing, if required
Acute Respiratory Syndrome	<ul style="list-style-type: none"> Throat swab Per-nasal swab / nasopharyngeal swab (for suspected pertussis) Sputum Bronchoalveolar lavage/ tracheal aspirate Blood for culture Serum Urine (for Legionella) 	<ul style="list-style-type: none"> Gram stain of throat swab and sputum* Albert's stain of throat swab* Inoculation of blood culture bottles and swabs in appropriate transport media <p><i>* For diphtheria & other organisms</i></p>	<p>Earlier tests, plus</p> <ul style="list-style-type: none"> Bacterial culture (and antimicrobial susceptibility, wherever applicable) from throat swab, sputum, blood Toxin detection tests for bacteria <i>Viral</i> : Culture; Antigen detection; Antibody levels (IgM/ IgG) Serotyping Referral of samples for further characterization and testing, if required
Acute "Systemic" Syndrome	<ul style="list-style-type: none"> Blood smears (thick and thin) Blood Serum Bubo aspirate Post-mortem tissue specimens (e.g. liver biopsy) CSF (if meningeal signs present) Urine Stool Clotted blood (5 or 10 ml) Tracheal or lung aspirate 	<ul style="list-style-type: none"> Peripheral smear for malarial parasite Rapid diagnostic tests for diagnosis of malaria, dengue fever and typhoid (Typhidot test) Platelet count Total leukocyte count Differential leukocyte count Gram stain (bacteria) Bubo aspirate: stab deeply into Cary Blair transport medium OT test for available chlorine in water Rapid H₂S test for bacteriological examination of water 	<p>Earlier tests, plus</p> <ul style="list-style-type: none"> Widal test Weil-Felix reaction Stool culture for enteropathogens Blood culture and sensitivity <i>Viral</i> : Culture; Antigen detection; Antibody levels (IgM/ IgG) Serotyping Yellow fever: post-mortem liver biopsy MPN test for bacteriological examination of water Referral of samples for further characterization and testing, if required

- If serum will be required for testing, separation from blood should take place as soon as possible, preferably within 24 hours at ambient temperature and ideally as soon as clot formation occurs. If the specimen will not reach a laboratory for processing within 24 hours, serum should be separated from blood prior to transportation. Sera may be stored at 4 - 8°C for up to 10 days. If testing is delayed for a long period, serum samples may be frozen.
- If separation on site is not possible, or is inadvisable for safety reasons, the blood sample should be stored at 4 - 8°C and protected from excessive vibration while transporting. Unseparated blood samples should not be frozen.

Method of Preparation of Blood Films : Blood films should be made by trained personnel. If this is not possible, they can be spread from heparinized or EDTA blood specimens sent to the laboratory.

Steps for making thick films for microscopy

- Label the slide with patient identification number and name.
- Disinfect and prick site with a lancet.
- Touch one or more large drops of blood onto the centre of the slide making sure that the slide does not touch the skin.
- Spread the blood in a circle about 1 cm in diameter using the corner of another glass slide or with a needle. Thickness of the film should be such that it is possible to read newsprint through it.
- Air dry the film in a horizontal position. Do not dry the film by heating over a flame or other heat source.

Steps for making thin films for microscopy

- Label the slide with patient identification number and name.
- Touch another drop of blood to the glass slide about 2 cm from one end making sure that the slide does not touch the skin.
- Place the slide horizontally on a flat surface.
- Hold the side of a second clean glass slide (the spreader) on to the center of the specimen slide and move it back until it touches the drop and the blood spreads along its base.
- At an angle of about 45°, move the spreader firmly and steadily across the specimen slide and air dry the film quickly. Do not dry over a flame or other heat source.
- Fix the dried film by dipping the glass slide in methanol or other fixative for a few seconds and air dry.

Handling and Transport : Air dried and/ or fixed films are transported at ambient temperature, preferably within 24 hours of specimen collection. They must not be refrigerated. Thick and thin films are usually kept in separate slide boxes.

Cerebrospinal Fluid (CSF) Specimen Collection : The specimen must be taken by a physician or a person experienced in the procedure. Standard lumbar puncture tray is needed. CSF is used in the diagnosis of viral, bacterial, parasitic, and fungal meningitis.

Handling and transport

- CSF specimens for bacteriology are transported at ambient temperature, generally without transport media. They must

never be refrigerated as many of the relevant pathogens do not survive at low temperatures.

- CSF specimens for virology do not need transport medium. They may be transported at 4 - 8°C for up to 48 hours or at - 70°C for longer periods.

Eye Specimen Collection : Conjunctival and corneal swabs and smears are the usual specimens collected. Strict aseptic technique is essential when collecting and processing these specimens.

Method of collection of conjunctival swabs : Clean the skin around the eye with a mild antiseptic. Moisten a swab in sterile saline and roll over the conjunctiva in a circular manner. Insert the swab into a sterile screw - cap tube containing the appropriate transport media for bacteria e.g. Stuart's transport media.

Handling and transport

- Specimens for detection of bacterial pathogens are transported at ambient temperature in appropriate bacterial transport medium.
- Specimens for viral detection are transported at 4 - 8°C in virus transport medium.
- Microscopic slides are air dried and transported at ambient temperature in a slide box.

Faecal Specimen Collection : Stool specimens are most useful for microbiological diagnosis if collected soon after onset of diarrhoea (for viruses < 48 hours and for bacteria < 4 days), and preferably before the initiation of antibiotic therapy. If required, two or three specimens may be collected on separate days. Stool is the preferred specimen for culture of bacterial, viral, and parasitic diarrhoeal pathogens. Rectal swabs showing faeces may also be used from infants. In general, rectal swabs are not recommended for the diagnosis of viruses.

Method for collecting a stool specimen

- Collect freshly passed stool, 5ml liquid or 5g solid (pea - size), in a container
- Label the container.

Method of collecting a rectal swab from an infant

- Moisten a swab in sterile saline
- Insert that swab tip just past the anal sphincter and rotate gently
- Withdraw the swab and examine to ensure that the cotton top is stained with faeces
- Place the swab in sterile tube/ container containing the appropriate bacterial or viral transport medium
- Break off the top part of the stick without touching the tube and tighten the screw cap firmly
- Label the vial with patient's name type of specimen and date of collection.

Handling and transport

- Stool specimens should be transported at 4 - 8°C. Bacterial yields may fall significantly if specimens are not processed within 1 - 2 days of collection. Shigella are particularly sensitive to elevated temperatures. If the laboratory is at a distance, samples should be transported in Cary Blair medium in cases of diarrhoea. In cases of suspected cholera samples should be transported in Alkaline peptone water or Thiosulphate Citrate Bile salt Sucrose Agar. (TCBSA).

- Specimens to be examined for parasites should be mixed with 10% formalin or Polyvinyl Alcohol; three parts stool to one part preservative. Transport at ambient temperature in containers sealed in plastic bags.

Bedside Microscopy : In cases of suspected cholera “darting motility” can be demonstrated if a slide and microscope are available. A hanging drop preparation of the sample is ideal for making this diagnosis.

Method of preparation of Hanging Drop

- Take a clean glass slide & make a thin ring of plasticine (good quality) and apply it over the slide.
- Thickness of the ring should not be more than 1mm, so that there is no difficulty in focusing the slide with 40X high power objective.
- Take a clean coverslip & put on small drop of liquid culture over the coverslip with the help of a small sized inoculating loop (about 1mm diameter).
- Put the slide containing plasticine ring over the coverslip containing the drop of liquid culture without touching the drop and then invert the slide so that the drop hangs.
- Put the condenser low and focus the slide in low power (10X objective) and try to focus the edge of the drop.
- Examine next in high power i.e. 40X objective for checking the motility against the stationary background.

Respiratory Tract Specimen Collection : Preferably, specimens should be taken within the first 3 days after onset of symptoms for most respiratory infections. Specimens are collected from the upper or lower respiratory tract, depending on the site of infection. Upper respiratory tract pathogens (viral and bacterial) are found in throat or nasopharyngeal specimens. Lower respiratory tract pathogens are found in sputum specimens.

Method of collecting a throat swab : Hold the tongue down with the depressor. Use a strong light source to locate areas of inflammation and exudate in the posterior pharynx and the tonsillar region of the throat behind the uvula. Rub the area back and forth with a Dacron or calcium alginate swab. Withdraw the swab without touching cheeks, teeth or gums and insert into a screw - cap tube containing transport medium.

Method of collecting per - nasal and post - nasal swabs (for suspected pertussis)

- Seat the patient comfortably, tilt the head back and insert the nasal speculum.
- Insert a flexible calcium alginate/ Dacron swab through the speculum parallel to the floor of nose without pointing upwards. Alternately, bend the wire and insert it into the throat and move the swab upwards into the nasopharyngeal space.
- Rotate the swab on the nasopharyngeal membrane a few times, remove it carefully and insert it into a screw - cap tube containing transport medium.

Method of collecting sputum : Instruct patient to take a deep breath and cough up sputum directly into a wide - mouth sterile container. Avoid saliva or postnasal discharge. Minimum volume should be about 1 ml.

Handling and transport : All respiratory specimens except sputum are transported in appropriate bacterial/ viral media. Transport as quickly as possible to the laboratory to reduce

overgrowth by commensal oral flora. For transit periods up to 24 hours, transport bacterial specimens at ambient temperature and viruses at 4 - 8°C, in appropriate media.

Collecting Specimens of Skin Lesions : For most dermatological conditions, diagnosis may be established on the basis of physical examination and clinical history without the collection of diagnostic specimens.

Method of collection

1. Vesicular or vesiculo - pustular rash (for diagnosis of viral infections)

- Pierce roof of fluid - containing vesicle with sterile lancet.
- Swab fluid with two sterile swabs. Try to get a good amount of fluid onto the swab.
- Take a clean labeled microscope slide and make a smear with one swab in the central area of the slide. Make two slides if possible. The slides should be left to dry in air.
- Place the second swab directly into virus transport medium.

2. Crusting stage

- Gently ease off crust with a lancet or scalpel and a pair of disposable forceps.
- Take 5 - 10 crusts; place them in a plastic screw - cap vial. Make sure the lid is tightly closed.
- If cutaneous anthrax is suspected, the vesicular fluid under the eschar is a better diagnostic specimen than a piece of the eschar.

3. Aspiration of abscesses

- Aspiration of abscesses should only be performed by experienced personnel
- Disinfect the skin overlying the abscess/bubo with 70% isopropyl alcohol
- Aspirate the fluid from the abscess with a sterile needle and syringe. Only enough fluid to perform the diagnostic tests is required to be sent even though all may be aspirated.
- Transfer the aspirate aseptically into a sterile tube with transport medium.

Handling and transport : Specimens for bacteriological analysis should be transported in Stuart's or Amies transport medium. Swabs for suspected viral pathogens should be transported in virus transport medium. If processing takes longer than 2 hours, bacteriology specimens can be maintained at ambient temperature for 24 hours. Specimens for virus isolation may be refrigerated at 4 - 8°C, and transported to the laboratory as rapidly as possible.

Urine Specimen Collection : Give the patient clear instructions to pass urine for a few seconds, and then to hold the cup in the urine stream for a few seconds to catch a *midstream clean catch* urine sample. This should decrease the risk of contamination from organisms living in the urethra.

Handling and transport : Transport to the laboratory within 2 to 3 hours of collection. If this is not possible, do not freeze, but keep the specimen refrigerated at 4 to 8°C. Keeping the specimen refrigerated will decrease the risk of overgrowth of contaminating organisms.

Post - mortem Specimen Collection : Strict precautions, including respiratory protection from aerosolized particles, must be taken when carrying out post - mortem specimen

collection in communicable disease outbreaks. Collect the specimens as soon as possible, since viral titres decline while bacteria multiply rapidly after death. Thorough post - mortem examinations may only be accomplished by experienced medical personnel. Prior experience and training is also advised even for the minimal collection of specimens from cadavers.

Handling and transport

- Fixed specimens can be stored and transported at ambient temperature.
- Tissue specimens for isolation of bacterial pathogens can be transported at ambient temperature in transport media for up to 24 hours.
- Transport tissue specimens for isolation of viral pathogens in viral transport medium or sterile saline at 4 - 8°C for 24 - 48 hours. For longer periods, freeze and store at - 70°C.
- If rabies is suspected and brain samples are collected, freeze unfixed specimens immediately after collection. Formalin - fixed samples are also useful and may be transported at ambient temperature.

Labeling and Identification of Specimens

Adequate labeling ensures that the laboratory results can be linked to the correct patient. Each patient should be assigned a unique identification number. This unique identification number and the patient name should be present on specimens, epidemiological data forms, and the laboratory transmittal forms. Glass slides for microscopy must be labeled individually, using glass - marking pencil. This should not interfere with the staining process.

Label on specimen : The label may be a piece of paper attached to the specimen container. Alternatively, the information may be written directly on the specimen container with the following essential details :

Patient Name _____	Identification No. _____
Specimen Type _____	Date & Time of Collection _____

Note : Do not attach the label to the top of the specimen container.

Laboratory Investigation Form

A laboratory request form must be completed for each specimen and contain information to interpret the necessary tests. This may include :

- *Patient information* : Age (or date of birth), sex, complete address
- *Clinical information* : Date of onset of symptoms, clinical and immunization history, risk factors or contact history where relevant, antimicrobial drugs taken prior to specimen collection etc.
- *Laboratory information* : Acute or convalescent specimen, other specimens from the same patient.

For a large number of patients, it may be practical to submit the

requests to each relevant laboratory as a 'line listing'.

Transport of Clinical Specimens Using the Triple Packaging System

The specimen should be transported in a basic triple packaging system (see Fig.1) to ensure biosafety, transient temperature and quality of the specimen (2, 8). EPI vaccine carriers or other commercially made containers may be used as a tertiary container to transport specimens. *Vaccine Carriers that have been used for specimen transport must never be reused for carrying vaccines.* Gloves should be worn at all times when handling the specimen.

Triple Packaging System for Transport of Clinical Specimens

See Fig. - 1, legend for the figure as follows :

- a Primary container
- b Secondary container (sealed plastic bag holding primary container)
- c Sealed plastic bag holding case investigation form
- d Absorbent material such as cotton wool
- e Four ice packs. Place ice packs at the bottom of the box and along the sides. Then place an ice pack on top of the specimen. If the specimen should remain cold, but not frozen, wrap the specimen in paper or cardboard to prevent direct contact with ice packs.

Points to Remember During Transport of Clinical Specimens

- Avoid repeated thawing and freezing of specimens.
- Freeze the specimen only if transport is assured at -20°C.
- Store and transport all specimens at 2 - 8°C, except CSF obtained from suspected cases of pyogenic meningitis.

- f Insulating material
- g Tertiary container (outer carton of double - ply corrugated cardboard or plastic)
- h Address labels on tertiary container
- i Diagnostic specimen label on tertiary container

Common Staining Techniques Used in Field Investigations of Disease Outbreaks

Gram Staining : This is the most extensively used differential stain that divides bacteria into two major groups. Those which retain crystal violet dye after treatment with iodine and alcohol appear purple or bluish purple and are designated as Gram positive. Those bacteria which lose the crystal violet show the colour of the counter stain employed. The commonly - used counter stain is safranin which gives a pink/ red colour to bacteria and these organisms are labeled as Gram negative. Smear prepared from throat swab, nasal swab, ear discharge, pleural fluid, CSF, urethral discharge, sputum, centrifuged deposit of urine, bacterial culture, vaginal discharge etc. can be stained by this method.

Reagents

- Crystal violet (*primary stain*)
- Gram's iodine (*mordant*)
- Acetone Iodine/ Acetone alcohol (*decolouriser*)
- Safranin solution (*counterstain*)

Staining procedure

- Make a thin smear on a clean glass slide, dry it in air and fix by passing through flame of a burner.
- Cover the smear with crystal violet, keep for one minute.
- Wash the slide with water, then cover with Gram iodine and let it stand for one minute.
- Wash the slide with water.
- Decolour with acetone / alcohol, rocking the slide gently for 10 - 15 seconds till the violet colour comes off the slide.
- Wash with water immediately.
- Counterstain with safranin. Let the counterstain stand for 30 seconds.
- Wash with water, blot dry and examine under the oil immersion lens of a microscope.

Albert's Staining : Albert's staining is most common staining technique used for examining the specimens, suspected to have *Corynebacterium diphtheriae*; which are gram positive rods of varying length and often containing volutin (polyphosphate) granules which appears purple black against the light green cytoplasm of the bacillus. The appropriate specimens are throat swab/ nasal swab smear or bacterial culture from suspected cases of diphtheria. *C. diphtheriae* appear as bacilli with dark green protoplasm and purple black granules, other bacteria will stain light green.

Procedure for staining

- Make a smear, dry in air, and fix by heat.
- Cover slide with Albert's stain-I & leave for 4 - 6 minutes.
- Wash in water and blot dry.
- Cover the slide with Albert's stain-II and allow to act for 1-2 minutes.
- Wash, blot dry and examine under oil immersion lens of microscope.

Staining For Malarial Parasite

- Prepare thick and thin smear from malaria case on a glass slide.
- Dehaemoglobinize the thick smear by placing the film in a vertical position in a glass jar containing distilled water for 5 minutes. When film becomes white, take it out and dry in upright position.
- Fix the thin smear in methanol for 15 minutes.
- Dilute the Geimsa's stain solution, one part with 9 parts of boric buffer pH 7.2.
- Immerse the smears in this stain for 1 hour.
- Wash the smear in buffer solution.
- Blot dry.
- Examine the slide under oil immersion of microscope.

Observation : Examine thin film first. If no parasite is found then only examine thick film. If parasite are seen in the thick film but the identity is not clear, thin film should be re - examined more thoroughly so as to determine the nature of infection.

Thin film examination

- Area of the film examined should be along the upper and lower margins of tail end film as parasites are concentrated over there.
- A minimum of 100 fields should be examined in about 8 - 10 minutes.

The following stages of the parasite can be observed in a peripheral blood thin smear :

- Ring, trophozoite, schizont and the gametocytes in case of *Plasmodium vivax*.
- The infected erythrocytes are usually enlarged in *P. vivax*.
- However, in case of *P. falciparum* infection, it is mainly the ring stages which are seen and occasionally schizonts and trophozoites. During the late stages of the disease even crescent shaped gametocytes can be seen in the peripheral blood.

Observations on thick smear

- Only elements seen are leucocytes and malarial parasites.
- Morphology of malarial parasites is distorted.
- Species of parasites cannot be identified.

Appearance in thick film

- Trophozoites appear as streaks of blue cytoplasm with detached nuclear dots. The ring forms are rarely seen.
- Schizonts and gametocytes, however, retain their normal appearance and are seen if present in the smear (the pigments are seen more clearly).

Negative (India Ink) Staining : Negative staining is sometimes a very useful technique for demonstrating the capsulated organisms like Meningococcus/ Pneumococcus/ Cryptococcus, the causative agents of meningitis. After the staining procedure the background will appear dark. The bacterial cells will be stained purple. The capsule (if present) will appear clear against the dark background.

Procedure

- Using a Pasteur pipette, put a drop of CSF sediment (obtained after centrifuging the CSF at 2000 - 3000 rpm for 10 - 15 min) or any other appropriate specimen on a clean glass slide.

Table 4 : Priority communicable diseases and their laboratory diagnosis				
Disease	Sample	Laboratory Test	Result	
Chickenpox	Vesicle scrapings	Tzanck smear of scrapings from base of vesicles	Multinucleated giant cells & intranuclear inclusion bodies.	
		Electron microscopy (EM)	Herpes virus particles in fluid.	
		Antigen or nucleic acid detection	Varicella-zoster virus detected.	
	Blood /Nasal / throat swabs	Culture	Human fibroblasts cell line used. Confirmed by Immunofluorescence using Monoclonal Ab on cell line (<i>time consuming</i>).	
		Immunofluorescence (IF)	Viral antigens detected. <i>More labour intensive but more sensitive than EM.</i>	
		Virus isolation	Culture by inoculating into human amnion, fibroblast, HeLa cells, Vero cells.	
Measles	Serum	Immunofluorescence and capture RIA or EIA	Detection of Varicella Zoster Virus (VZV)-specific IgM.	
		ELISA & PCR	Detection of Varicella Zoster Virus antigen/ nucleic acid.	
	Throat gargle fluid	Throat and Nasopharyngeal (NP) secretions	Giemsa-stained smears	Multinucleated giant cells.
		Viral isolation	Measles virus is present in acute stage in throat and nasopharyngeal secretions. It is also excreted in urine intermittently for at least 7 days after rash onset. At least one specimen for virus isolation, along with blood for serology is required.	
	Serum	Immunofluorescence	Viral antigens detected (<i>more labour intensive</i>).	
		Serological tests (ELISA)	Capture ELISA for measles IgM (reference gold standard test). Measles specific IgM antibodies detected using IgM capture ELISA. A single blood specimen collected 3 to 28 days after rash onset is usually satisfactory for IgM serology. Indirect ELISA for measles IgM. For IgG serology, the first (acute) sample is obtained as soon as possible after appearance of rash and no later than 7 days afterwards. The second (convalescent) sample is collected 10 to 20 days after the first sample. Both paired sera tested simultaneously.	

Disease	Sample	Laboratory Test	Result
Rubella	Blood (within 2-3 days of onset of symptoms); Nasopharyngeal washings / throat garglings	Virus isolation	<i>Viral culture is labour intensive.</i>
	Serum	Serological tests (ELISA)	IgM & IgG antibodies (IgM alone indicates current acute infection & IgG indicates past infection or vaccination). Rubella-specific antibodies are detectable in the IgM fraction within two days after onset of the rash, or even earlier. The titre of rubella specific IgM antibodies remains higher than those in the IgG fraction for about five days after the appearance of the rash.
Influenza	Nasopharyngeal aspirate/ washings using saline; lower nasal swab/ nasopharyngeal swab/ throat swab; bronchoalveolar lavage	Immunofluorescence for Rubella specific IgM antibodies	The test is useful from about one to two days before the rash, prior to the appearance of a detectable level of HI antibody, to about four weeks afterwards.
		Immunofluorescence (Direct Fluorescent Antibody Staining)	Demonstration of viral antigen.
	Serum (Acute phase serum and convalescent phase serum)	Reverse transcriptase PCR	Detection of nucleic-acid sequences.
	Nasopharyngeal aspirate, washings using saline, lower nasal swab/ nasopharyngeal swab/ throat swab; sputum; bronchoalveolar lavage	Haemagglutination inhibition	Rise in antibody titres in paired (acute and convalescent) serum samples.
Diphtheria	Throat swabs	Viral culture	Virus identification by immunofluorescence of cell cultures or Haemagglutination-Inhibition (HI) assay of cell culture medium (supernatant).
		Albert's stain	<i>Corynebacterium diphtheriae</i> appears as green rods containing green-black volutin granules. The rods may be arranged in rows or in V-formation or joined at angles, giving the appearance of Chinese characters.
Meningococcal disease	CSF	Culture of throat swab/ swab from membrane at any other site (inoculated on Loeffler's serum slope)	Bacilli showing cuneiform (Chinese letter) arrangement on Gram stain with metachromatic granules (seen in smears stained with methylene blue or Albert's stain).
		Gram stain	Meningococci appear as gram-negative intracellular diplococci (inside polymorphs).
	Blood	Ag detection by Latex Agglutination/ <i>Immunofluorescence</i>	Demonstration of meningococcal antigen.
Molecular Diagnosis by PCR		Detection of meningococcal DNA sequences.	
		Culture	Isolation of meningococci.

Disease	Sample	Laboratory Test	Result
Avian Influenza	Nasopharyngeal aspirate; Nasopharyngeal swabs; Nasal washings; Throat swab	Immunofluorescence; Enzyme immunoassay (for influenza A nucleoprotein)	Rapid antigen detection.
	Serum (Acute phase serum and convalescent phase serum)	Serology	IgM & IgG antibodies (IgM alone indicates current acute infection & IgG indicates past infection or vaccination).
		Virus culture	Virus identification by immunofluorescence of cell cultures or Haemagglutination-Inhibition (HI) assay of cell culture medium (supernatant). Detection of nucleic-acid sequences.
SARS (new strain of corona virus)	Throat and nasal swabs; rectal swab; nasopharyngeal aspirate; throat washings and urine	Polymerase chain reaction and Real-time PCR assays. Reverse transcription PCR for viral RNA	Detection of nucleic-acid sequences.
	Serum (paired samples)	ELISA; Immunofluorescence	Demonstrates rising antibody titres.
		Viral isolation	Vero E6 cell monolayers examined daily for diffuse, refractile, rounding cytopathic effects characteristic of SARS-CoV confirmed on staining by the indirect immunofluorescence technique and RT-PCR.
Hepatitis A	Serum	Antibody detection: ELISA	Anti HAV IgM & IgG antibodies (IgM alone for current/acute infection & IgG for past infection).
Hepatitis B	Serum (Acute & Chronic phase sera)	Serological demonstration of viral markers	HBSAg in blood; anti-HBc IgM indicates recent infection; anti HBc IgG indicates remote infection; HBeAg denotes high infectivity.
	Blood in sterile container (serum)	Viral loads by Real time PCR & HBV DNA by PCR	Molecular analyses to detect HBV DNA are rarely required and should be performed only in a well-defined clinical context.
Hepatitis C	Serum	ELISA	Antibody detection.
	Serum	Viral loads by Real time PCR & HCV RNA by PCR	HCV RNA in blood detected. Molecular analyses to detect HCV RNA are rarely required and should be performed only in a well-defined clinical context.
Hepatitis E	Serum	ELISA	Anti HEV IgG & IGM antibodies (<i>IgM in the bile & faeces during incubation period</i>).
	Whole blood in EDTA/ Serum	HEV RNA by PCR	Molecular analyses to detect HEV RNA are rarely required and should be performed only in a well-defined clinical context.

Disease	Sample	Laboratory Test	Result
Leptospirosis	Serum	Detection of group specific anti Leptospiral IgG & IGM antibody by latex agglutination test and a sensitive test such as ELISA	Specific IgM antibody detection confirms recent infection.
		Detection of species specific anti Leptospiral IgG & IGM antibody using Microscopic Agglutination Test (MAT) is the Gold Standard	Live Leptospira strains seen to be immobilized and agglutinated by patient's serum.
Cholera	CSF/ Urine/ Body fluid (freshly passed urine sample alkalinized to pH 9 with Sodium bicarbonate)	Dark ground illumination	Motile leptospira.
	Blood in EDTA; Urine (alkalinized)	Culture in EMJH medium. Isolation facility available at Leptospira Surveillance Centres	Motile leptospira seen in dark ground illumination.
	Faeces (rice water) OR Rectal swab moistened with transport medium OR Lubricated catheter to pass sample directly into screw capped container OR Strips of blotting paper soaked in stool and sent in plastic envelopes OR Bedside inoculation onto media	Hanging Drop preparation -darting motility	Demonstration of <i>Vibrio cholerae</i> .
		Dark ground illumination or phase contrast	Demonstration of immobilization by antiserum (may be observed under a simple microscope too using a hanging drop preparation)
		Isolation of cholera vibrios (in a stool specimen or sample by rectal swab) after enrichment for 6 hours. Venkatramanliquidmedium(<i>Holding medium</i>) or Cary - Blair medium (<i>Transport medium</i>); Alkaline peptone water or Monsur's media (<i>Enrichment media</i>)	Non lactose fermenting colonies; catalase and oxidase positive with a positive cholera red reaction. Serogrouping into O1 and non O1, biotyping into Classical and El Tor strains and serotyping into Ogawa, Inaba and Hikojima can be done at centres where facility exists. Strains may be dispatched to a higher centre for confirmation.

Disease	Sample	Laboratory Test	Result
Typhoid	Blood for culture	Blood culture (highest positivity if sent in first week of fever)	Pale non-lactose fermenting colonies of Salmonella. Organisms are motile, indole & urease negative, ferment glucose and mannitol but not lactose. Strains may be biochemically differentiated on the basis of H ₂ S and acid with/without gas production.
	Serum (<i>in first week</i>)	Widal Test	Baseline titres.
	Serum (<i>in second week and thereafter</i>)	Widal Test	Demonstration of O & H agglutinins in a paired sera Significant one time titres: - O agglutinins > 100 H agglutinins > 200 OR Four fold rise in titres in paired sera
	Faeces	Stool enrichment with Selenite F or Tetrathionate broth followed by faeces culture on a selective medium like Wilson Blair media or DCA.	Black colonies with metallic sheen on Wilson Blair media.
	Urine	Urine culture (2nd & 3rd week)	Salmonella shed intermittently so requires repeated sampling.
FOOD POISONING			
Salmonella	Faeces & food specimens	Gram staining	Salmonella are gram-negative organisms.
		Culture	Isolation of salmonella from food macerated in sterile saline.
Botulism	Faeces & food specimens	Gram staining of food samples	Gram positive sporing bacilli.
		Isolation from faeces & food specimens	Food is macerated in sterile saline and filtrate is inoculated into mice/ guinea pigs intraperitoneally after protection with polyvalent antitoxin.
<i>Cl. perfringens</i>	Serum, autopsied liver tissue	Toxin detection	Retrospective diagnosis by demonstration in patient's serum.
<i>B.cereus</i>	Faeces & food specimens	Isolation on selective media	Heat resistant <i>Cl. perfringens</i> Type A isolated.
	Faeces & food specimens	Isolation on selective media (MYPA - Mannitol egg Yolk Phenol red Polymyxin Agar media)	Isolation of <i>B.cereus</i> which produces lecithinase & ferments glucose but not mannitol.
<i>Enteropathogenic E coli</i> (EPEC)	Faeces	Plated on Blood agar & MacConkey media	Tested for agglutination by polyvalent & monovalent EPEC O antisera
<i>Enterotoxigenic E coli</i> (ETEC)	Faeces	In Vivo test (ligated rabbit ileal loop) In Vitro test (Tissue culture test, Serological test) Genetic test (DNA Probe)	Demonstration of enterotoxins.

Disease	Sample	Laboratory Test	Result
MALARIA			
<i>P. falciparum</i> <i>P. vivax</i> <i>P. malariae</i> <i>P. ovale</i>	Blood Smear (Thick smear and thin smear) Blood in double oxalate, EDTA vacutainer; finger prick blood directly collected in the QBC capillary tube Whole blood in EDTA; blood from finger prick Serum Whole blood	Blood Smear for Malaria parasite Quantitative buffy coat Rapid diagnostic tests(RDT) or Immunochromatographic tests Serology for antibody detection by ELISA Polymerase Chain Reaction for detection of gene or Multiplex PCR for all four species Virus Culture	Detection of malaria parasite & characteristic morphological changes in the RBCs to detect the plasmodium species. <i>The thick smear after dehaemoglobinisation is used for screening for malaria parasite and thin smear for speciation.</i> Detection of malaria parasite, both ring form (trophozoite) and gametocytes using the fluorescent microscope. PfHRP2 or pLDH detection using monoclonal antibody against one of these antigens. PfHRP2 persists to be positive even after therapy unlike pLDH. Both these tests should be supplemented with microscopy. This does not necessarily detect current infection. Detection of relevant gene sequence.
Dengue (4 serotypes DEN 1,2,3,4)	Acute phase serum; plasma; Buffy coat (leucocytes) washed to remove antibodies; CSF; autopsy tissue from fatal cases especially liver, spleen, lymph node. Serum (<i>three serial serum samples during acute, convalescent phase & late convalescent phase, respectively</i>) Autopsy tissue or serum Whole blood	Dengue IgM Dengue IgM & IgG ELISA Dengue IgM & IgG Rapid strip Test (ICT) Viral antigen detection Platelet count Haematocrit	Isolation of dengue virus. Early dengue-IgM in 3-5 days of onset of infection, later a rise in IgG is seen. Test should be repeated at least once after 2-3 days if negative at first. Demonstration of dengue virus antigen in autopsy tissue or serum samples by Direct fluorescence or viral nucleic acid detection using Immunohistochemistry (IHC). Thrombocytopenia (platelets less than or equal to 100,000/mm ³). Evidence of plasma leakage documented >20% increase of PCV for age and sex.

Disease	Sample	Laboratory Test	Result
Japanese Encephalitis Group B Arbovirus (flavivirus)	CSF, autopsied brain in saline, whole blood (collected in initial 2-3 days)	Virus isolation can be performed using Vero, LLCMK2 and PS cells	Viral culture.
	Autopsy tissue in saline or serum samples Serum	Viral antigen detection PCR-based tests Serological testing using IgM-capture ELISA or using Haemagglutination Inhibition Tests (performed at specialized centres)	Demonstration of JE virus antigen in autopsied brain tissue by fluorescence antibody test. Nucleic acid detection. Detects specific IgM.
Trachoma <i>C. trachomatis</i>	Conjunctival scrapings	Giemsa-stained Culture : Clinical specimens are inoculated onto McCoy cells, HeLa cell lines (Tissue culture)	<i>C. trachomatis</i> inclusion bodies or Halberstaedter Prowazek (HP) bodies seen. Confirmed by demonstration of cytopathic effects in cell lines.
	Stool or nasopharyngeal washings Serum Cerebrospinal fluid (CSF)	Viral isolation in cell lines Serology Cell count in cytology and biochemistry	Demonstration of cytopathic effects in cell line. Neutralizing antibodies. Increased number of white blood cells (10 to 200 cells/mm ³ , primarily lymphocytes) and a mildly elevated protein from 40 to 50 mg/100 ml.
Plague	Whole blood; sputum; aspirates from buboes, body fluids or tissues Serum (Acute phase serum and convalescent phase serum)	Confirmed by Gram stain/ culture Passive haemagglutination testing of paired serum samples	Gram stain shows bipolar staining Gram negative bacilli. Culture of <i>Y. pestis</i> confirmed by specific phage lysis of lawn cultures. Four-fold change in antibody titre to the F1 antigen in paired serum specimens, confirmed by F1 antigen haemagglutination inhibition test.
	<p>Note :</p> <p>Blood should be collected in a sterile container for serology. If serum needs to be transported across a long distance, it should be centrifuged and separated into a sterile container and sent on ice (4°C), preferably with a human courier.</p> <p>Any material for culture should be sent in saline and not in formalin.</p> <p>24-hour samples are not acceptable for culture.</p> <p>Tissue sent for culture or antigen detection tests should not be allowed to dry and may be placed into a sterile container with some saline in it.</p> <p>A second sample for serology (paired sera) is a must for evidence of rising titres.</p>		

- Add another smaller drop of Indian Ink (about 1/3rd the size of CSF drop) on the slide. Mix the two drops thoroughly using a match stick.
- Put a coverslip on the resultant mixture.
- Examine the preparation under the microscope first using 40x objective and then 100x objective to look for the characteristic encapsulated cells.

Interpretation of Laboratory Tests

The interpretation of laboratory tests for some priority communicable diseases are listed in Table - 4.

Summary

Outbreaks of communicable diseases are public health emergencies which result in increased morbidity and mortality. A surveillance network, including available laboratory support aimed at a simplified syndromic surveillance of priority communicable disease syndromes is important for early detection, control and prevention of outbreaks. The underlying principle of the “Syndromic Approach” to communicable disease surveillance and field investigation of an outbreak is that the case definition is based on a syndrome and not on a specific disease. When investigating outbreaks, it is important to keep an open mind about possible causes, and ensure that adequate clinical samples are taken to eliminate any uncertainty. Proper collection of an appropriate clinical specimen is the first step in obtaining an accurate laboratory diagnosis of an infectious disease. The specimen should be transported in a basic triple packaging system to ensure biosafety, transient temperature and quality of the specimen.

The effective control of a communicable disease outbreak depends upon early detection and reporting of suspect cases, adequate knowledge regarding collection of appropriate clinical specimens, their transportation under optimum conditions and specific diagnostic tests to facilitate rapid confirmation of the causative agent responsible for the disease outbreak.

Study Exercises

Short Notes : (1) Syndromic surveillance (2) Laboratory diagnosis of Acute Jaundice Syndrome (3) Preparation of peripheral blood smear for diagnosis of malaria (4) Hanging drop preparation (5) Triple packaging system for transport of clinical specimens

MCQs

1. The underlying principle of “Syndromic Approach” to communicable disease surveillance is that the case definition is based on (a) a specific disease (b) a group of diseases (c) a syndrome (d) None of the above
2. The possible pathogens in Acute Diarrhoeal Syndrome are all except (a) *Vibrio cholerae* (b) Rotavirus (c) *Leptospira* (d) *Cryptosporidium*
3. Albert’s staining is used for the demonstration of metachromatic granules in (a) *Plasmodium falciparum* (b) *Corynebacterium diphtheriae* (c) *Chlamydia trachomatis* (d) *Clostridium difficile*
4. Serum should be separated from blood prior to transportation if the time taken to reach the laboratory is (a) > 6hours (b) > 12 hours (c) > 18 hours (d) > 24 hours

Answers : 1(c); 2 (c); 3 (b); 4 (d).

Rajesh Vaidya

Malaria is the most important parasitic disease of man. It is defined as an acute and chronic disease caused by obligate intracellular protozoa of the genus *Plasmodium*. Four species of *Plasmodium* are capable of infecting humans : *Plasmodium malariae* (Laveran, 1881), *Plasmodium vivax* (Grassi and Feletti, 1890), *Plasmodium falciparum* (Welch, 1897) and *Plasmodium ovale* (Stephens, 1922). The parasites are transmitted to humans by female Anopheles mosquitoes. The illness that ensues is highly variable but is generally characterized by paroxysms of fever and chills, anaemia and splenomegaly (1). Approximately 5% of the world population is infected by malarial parasites and the disease is responsible for nearly one million deaths annually world wide. Although drugs against malaria have been available for many years, widespread drug resistant strains of parasite and insecticide resistant strains of mosquito vectors have made its treatment and control difficult.

History

Few diseases have had a greater impact on human social and economic development than malaria. Fossil mosquitoes have been found in geologic strata 30 million years old. Malaria was linked with poisonous vapours of swamps or stagnant water on the ground since time immemorial. The disease was finally named by the Italians in the 18th century malaria (from the Italian *mala* "bad" and *aria* "air"). The first references to periodic fevers can be found in early Hindu and Chinese writings. In the fifth century B.C., the Greek physician Hippocrates described the clinical manifestations and some of the complications of malaria.

The first major breakthrough in understanding the etiology of the disease was in 1880, when Laveran, a French army surgeon in Algeria, described exflagellated gametocytes of *Plasmodium falciparum* in a fresh blood film from a patient with malaria. Even after that, transmission remained a mystery until the 1880s. It was only in 1897, that Ronald Ross, a British army surgeon in India, conclusively established the major features of the life cycle of plasmodia by a careful series of experiments in naturally infected sparrows. During the 20th century, progress was made in vector control technology and in the development of potent synthetic antimalarial compounds. One of the major landmarks was in 1955 when, encouraged by the high potency, low toxicity, ease of administration and low cost of DDT and other residual insecticides, the World Health Organization (WHO) launched a worldwide program of malaria eradication. This program was hindered by the development of DDT resistance in the mosquito populations and by the development of chloroquine resistance in some strains of *Plasmodium falciparum*. Soon it was realized by the world that "Malaria" was here to stay and subsequently in 1978, the World Health Assembly changed its focus from eradication to malaria control based on the assessment of localized control potential. This ranged from reducing morbidity and mortality with chemotherapy to comprehensive campaigns stressing

personal protection and vector control to community - based bioenvironmental interventions (1, 2).

Epidemiology

Global : Malaria is endemic in over 105 countries and is responsible for over 300 - 500 million clinical cases and over a million deaths annually. Out of around 3000 deaths a day, over 90% are in Sub Saharan Africa. Out of the 11 countries of the South East Asian Region (SEAR) of WHO, 10 are malaria endemic. Maldives has no endogenous transmission since 1984. SEAR accounts for 30% of global morbidity and 8% of global mortality due to malaria. An estimated 82.8% of the total population here is at risk of malaria. Out of the total population, 41.5% are at moderate to high risk, 41.7% are at low risk while the remaining 16.8% are considered free from the risk of malaria.

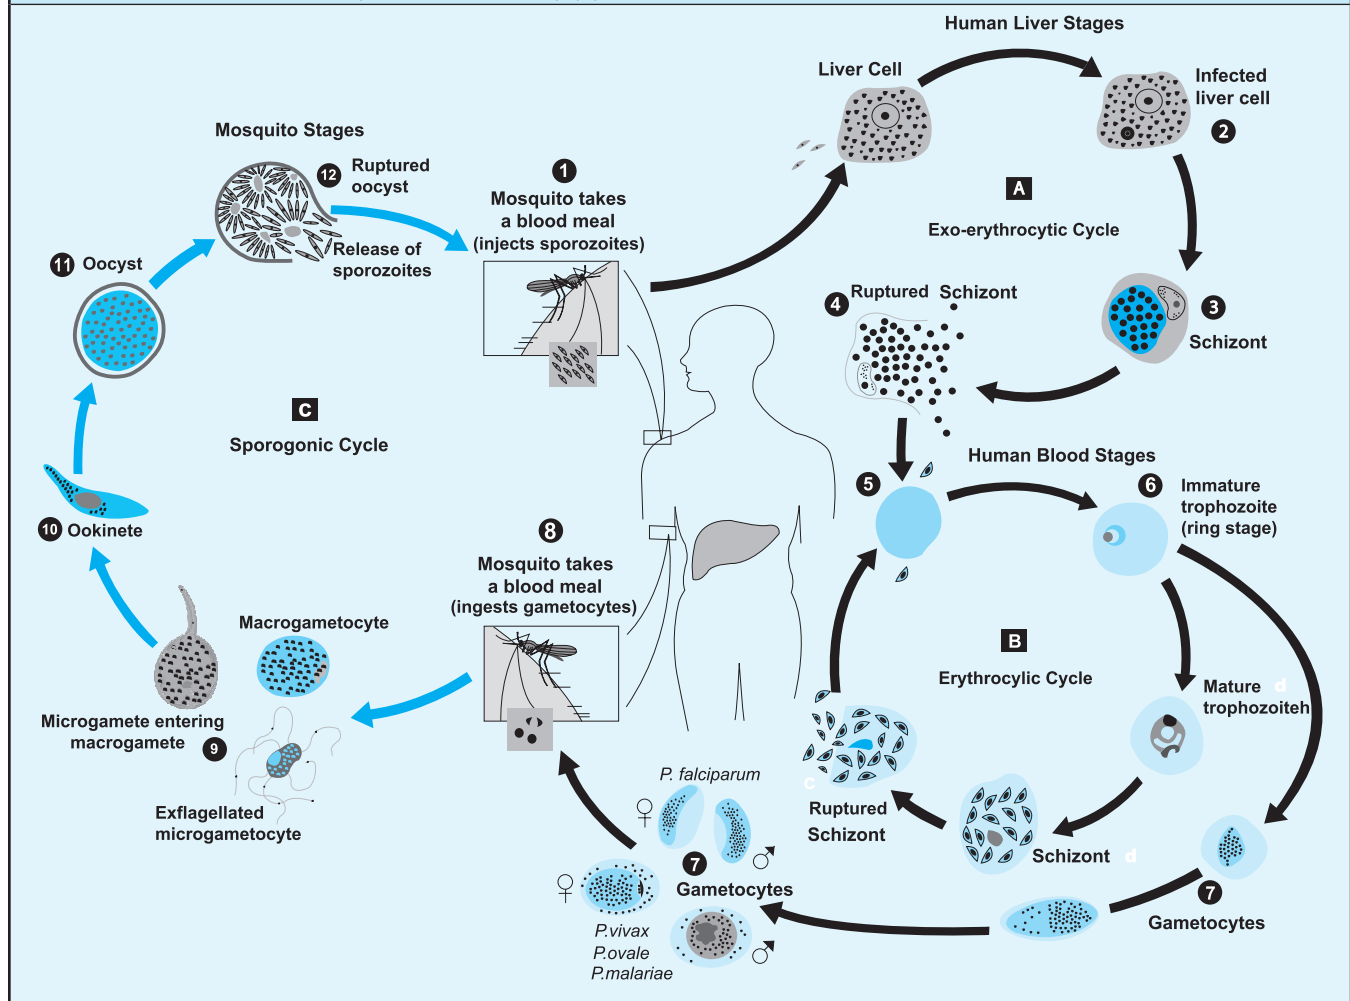

India : Malaria transmission occurs in almost all areas of India except areas above 1800 meters, above mean sea level. 95% of the Indian population lives in malaria risk prone areas. Malaria in India is unevenly distributed. In most parts of India about 90% malaria is unstable with relatively low incidence but with a risk of increase in cases in epidemic form every 7 to 10 yrs. This depends on the immune status of the population and the breeding potential of the mosquitoes, rainfall being the leading cause of malaria epidemic as it increases vector density. In North - East India, efficient malaria transmission is maintained during most months of the year. Intermediate level of stability is maintained in the plains of India in the forests and forest fringes, predominantly tribal settlements in eight states (Andhra Pradesh, Gujarat, Jharkhand, MP, Chattisgarh, Maharashtra, Orissa and Rajasthan). The reported incidence is between 2 and 2.5 million cases annually with some fluctuations every year for last over two decades. 44.3% of these are due to *Plasmodium falciparum*.

Agent : The causative organisms of the disease malaria are protozoa of the genus *Plasmodium*, family *Plasmodiidae*, suborder *Haemosporidiidae*, order *Coccidia*. There are 120 or so species of *Plasmodium* which are recognized taxonomically by the presence of two types of asexual division : schizogony, in the vertebrate host; and sporogony, in the insect vector. Within the vertebrate host, schizogony is found both within erythrocytes (erythrocytic schizogony) and in other tissues (exo - erythrocytic schizogony). However diseases in humans is caused by four parasites which have, in the recent past, been described as follows (3) :

- *Plasmodium vivax* : Benign Tertian, Simple Tertian, Tertian
- *Plasmodium malariae* : Quartan
- *Plasmodium falciparum* : Malignant Tertian (MT), Subtertian, Aestivo - Autumnal, Tropical, Pernicious
- *Plasmodium ovale* : Ovale Tertian.

The cyclopropagative life cycle of the *Plasmodium* occurs in two stages (Fig - 1). The sexual stage starts with the 'gametogony' in the human host and progresses through 'sporogony' in the mosquito. The asexual stage starts with injection of sporozoites by the infective mosquito into the human host and progresses through three phases of 'schizogony'. The broad outline of events occurring during the two stages is as follows (4).

Fig. - 1 : Life Cycle of malaria (*Plasmodium vivax*) (5)

Sexual Cycle in Mosquito (Sporogony)

The vector female anopheline mosquito ingests male and female gametocytes from a malarial subject. In the mosquito's stomach the male gametocyte becomes rounded, its chromatin splits into 5 to 8 particles, which get arranged along its edge. Cytoplasm around each chromatin particle elongates into a 'flagellum' and together with chromatin separates from the main mass as a 'microgamete'. Female gametocyte extrudes polar bodies and becomes a 'macrogamete' ready to be fertilized. Syngamy of microgamete and macrogamete forms 'zygote'. This becomes an elongated, motile 'ookinete'. Penetrating the stomach wall, this comes to lie under its external basement membrane, becomes rounded & develops into 'oocyst'. As the oocyst matures, it increases in diameter and rapidly undergoes division and subdivision to form a large number of haploid sporozoites (varying from new hundreds to thousands). Finally, the oocysts rupture, releasing the elongated sporozoites into the body cavity, majority of which find their way into the salivary glands. Sporozoites injected in human host through the mosquito bite start schizogony.

Asexual Cycle in man (Schizogony)

Pre - erythrocytic Phase : Sporozoites injected by infective mosquito into human body circulate for approximately 30 minutes and thereafter leave the peripheral blood. Fully matured, pigmentless schizonts, containing cryptozoites are seen in the parenchymal liver cells. The cycle lasts approximately 8 days in *Plasmodium vivax*, 6 days in *Plasmodium falciparum* and 9 days in *Plasmodium ovale*. On full maturity of the pre - erythrocytic schizonts, the liver cells rupture and cryptozoites enter the erythrocytes.

Erythrocytic Phase : The earliest intracorporeal form of parasite is the 'trophozoite' which has a fine ring of cytoplasm with a small chromatin dot. It grows in the parasitised RBC that becomes pale and, in some species, enlarged or distorted. The haemoglobin changes into haemozoin pigment and is seen in the cytoplasm of the parasite as black or brown granules. Fully developed trophozoite fills the RBC and undergoes segmentation. The chromatin divides into a number of particles which migrate towards the periphery. The cytoplasm around each particle separates off forming merozoites; the pigment concentrates in the centre of the RBC. This is called 'rosette' or 'schizont'. The parasitised RBC eventually ruptures releasing

merozoites which enter other RBCs repeating the asexual cycle. Each asexual cycle is completed in 48 hours in *Plasmodium falciparum*, *Plasmodium vivax* and *Plasmodium ovale* and in 72 hours in *Plasmodium malariae*.

Gametogony : After a few cycles of erythrocytic schizogony, male and female gametocytes appear in the blood. The female macrogametocyte has a dense and deeply staining cytoplasm and a small compact nucleus, while the male microgametocyte has a less dense and faintly staining cytoplasm and a relatively large and diffuse nucleus. The gametocyte of *Plasmodium vivax* is large and round filling the enlarged RBC, the gametocyte of *Plasmodium falciparum* is sausage or crescent shaped. Gametocytes remain within the corpuscles until taken up by the mosquito or their final disintegration.

Persistent Tissue Phase (Exoerythrocytic phase) : After the establishment of blood infection the initial tissue phase (pre - erythrocytic phase) disappears completely in *Plasmodium falciparum*, whereas in *Plasmodium vivax*, *Plasmodium ovale* and *Plasmodium malariae* it continues in the form of a persistent tissue phase in the liver. These exoerythrocytic forms never arise from the merozoites of erythrocytic schizogamy and are now considered responsible for relapses of vivax, ovale and quartan malaria.

Most of the severe morbidity and mortality in malaria is caused by *Plasmodium falciparum*. When compared with the three other species infecting humans, the incubation period is shortest, the exoerythrocytic schizonts release 2.5 to 20 times as many merozoites, and the duration of untreated infections is the least. By contrast, *Plasmodium malariae* has the longest duration of untreated infection and sometimes is almost a commensal infection in adults. Certain characteristics of the four species are given in Table - 1 (6).

Reservoir and Source : For human plasmodia the only reservoir is a malaria case. In some parts of Africa, Chimpanzees may act as reservoir of *Plasmodium malariae*. The source of infection is a malaria case with adequate number of mature viable gametocytes circulating in the blood. It has been estimated that

in order to infect a mosquito, the blood of a human carrier must contain at least 12 gametocytes per mm³ and the number of female gametocytes must be more than the male gametocytes.

Period of Communicability : The human case of malaria becomes infective to mosquito when mature, viable gametocytes develop in the blood of the patient in sufficient density.

Host : All ages are equally affected. Children are usually effective carriers of gametocytes. Gender does not affect the incidence or severity of malaria infection and disease per se, but because they are often related to frequency of exposure (via occupation, social behaviour, and migration). Racial immunity against one or more species of malaria parasite has been observed in certain parts of the world. Negroes with sickle cell trait have been found to be relatively immune to *Plasmodium falciparum* infection. Individuals lacking the Duffy a and b blood group determinants (Duffy - negative blood type) are resistant to infection with *Plasmodium vivax*. Economic Status is inversely related to incidence of malaria mainly because of poor housing. Ill ventilated and poorly lighted houses provide ideal resting places for mosquitoes.

Acquired Immunity : In general, populations in endemic areas continuously exposed to infected mosquitoes develop immunity to malaria illness and, to a lesser degree, to malaria infection. Clinical manifestations, asexual parasitemia, and the production of gametocytes are all reduced by acquired immunity. In areas with high falciparum transmission, newborns will be protected during the first few months of life presumably by maternal antibodies transferred to them through the placenta. As these antibodies decrease with time, these young children become vulnerable to disease and death by malaria. If they survive to an older age (2 to 5 years) they will have reached a protective semi - immune status.

Environment : Optimal conditions for malaria transmission occur when the temperature is between 20°C and 30°C and the mean relative humidity is at least 60%. Sporogony does not occur at temperatures below 16°C or at temperatures higher than 33°C. Water temperatures regulate the duration of the

Table 1 : Selected characteristics of four species of Human Malaria

	<i>P. falciparum</i>	<i>P. vivax</i>	<i>P. ovale</i>	<i>P. malariae</i>
Exocrythrocytic cycle (days)	5 - 7	6 - 8	9	12 - 16
Erythrocytic cycle (hr)	48	42 - 48	49 - 50	72
Usual incubation period in days (range)	12 (9 - 14)	13 (12 - 17) or longer	17 (16 - 18) or longer	28 (18 - 40) or longer
Earliest appearance of gametocytes (days)	10	3	7	?
Secondary exoerythrocytic cycle	none	present	present	none
Average merozoites per tissue schizont	40,000	10,000	15,000	2000
Size of tissue schizont	60 μm	45 μm	70 μm	45 μm
Duration of untreated infection (yr)	1 - 2	1 - 4	1 - 4	3 - 50
Average parasitemia (per mm)	20,000 or greater	10,000	9000	6000
Minimum duration (and range) of sporogony cycle in mosquito in days	9 (9 - 22)	8 (8 - 16)	12 (12 - 14)	16 (16 - 35)
Usual periodicity of febrile attacks (hr)	none	48	48	72

aquatic breeding cycle of the mosquito vector. A high relative humidity increases mosquito longevity and therefore increases the probability that an infected mosquito will survive long enough to become infective. Malaria infections and malaria illness are often more common during rainy seasons because the number of breeding sites is increased and because female anophelines survive longer when the humidity is high. However, too much rainfall can be deleterious to vector larvae and pupae by washing them away, thus decreasing transmission; and prolonged droughts may be associated with increased transmission if they reduce the size and flow rates of large rivers sufficiently to produce suitable breeding sites.

The proximity of human habitation to breeding sites directly influences vector - human contact and, therefore, transmission. The stability of breeding sites is influenced by water supply, soil, vegetation, etc. Irrigation schemes, dams, and other man-made changes can alter the pattern of malaria transmission (6).

Vectors : There are 56 species of anopheline mosquitoes in India but only six are regarded as primary vectors and another three or four as secondary or local vectors. As per the global classification, India is covered by 3 out of the 12 epidemiological zones. The present distribution of malaria vectors in these zones is given below (7) :

Northern and Peninsular India

(a) **Main Vectors** : *Anopheles culicifacies*, *Anopheles stephensi*, *Anopheles fluviatilis*.

(b) **Local Vectors** : *Anopheles sundaicus*, *Anopheles annularis* and *Anopheles varuna*.

Eastern India

Main Vectors : *Anopheles dirus*, *Anopheles sundaicus*, *Anopheles philippinensis*, *Anopheles minimus*, *Anopheles maculatus*.

Andaman and Nicobar Islands

(a) **Main Vectors** : *Anopheles sundaicus*

(b) **New Vectors** : *Anopheles dirus*, *Anopheles maculatus* and *Anopheles tessellatus*.

A number of characteristics of vector mosquitoes play an important role in the epidemiology of malaria (8, 9). These include breeding habits, vectorial capacity, density, longevity, tropism, biting behaviour, and flight range.

Breeding Habits : The breeding habits of mosquitoes show a lot of variation. Hence, vector mosquitoes tend to be confined to certain geographical areas only. *Anopheles fluviatilis* breeds in slow moving water, seepages and terraced rice fields. *Anopheles sundaicus* prefers to breed in brackish waters. The main urban vector *Anopheles stephensi* commonly breeds in wells, cisterns and over head tanks. Tanks, pools, burrow pits and ditches are the preferred breeding spots for *Anopheles annularis* and *Anopheles philippinensis* while *Anopheles dirus* is usually found breeding in forest pools, streams and slit trenches.

Vectorial Capacity : Why only certain species and not others act as vectors is not exactly known. A complexity of factors determines the vectorial status of a mosquito. Certain new species are emerging as secondary vectors in different parts of

the country.

Density : For effective transmission of malaria in a locality, the mosquito vector must attain and maintain a certain density. This is called *critical density* and it varies from one mosquito to another and also under different environmental conditions. *Anopheles culicifacies* needs a very high density for transmission of malaria.

Longevity : A mosquito must live for at least 10 days after an infective blood meal, to complete the development of malaria parasites.

Tropism : Some mosquitoes like *Anopheles fluviatilis* prefer human blood and are called anthropophilic. Others like *Anopheles culicifacies* preferably feed on animal blood and are called zoophilic. This preferential feeding habit is called tropism. It has obvious bearing on the transmission of malaria.

Biting Behaviour : Some vector mosquitoes bite at or soon after dusk, others either during late night or early hours of the morning. However, some species may be active at two different periods during the same night.

Resting Habits : A female mosquito rests either indoors (endophilic) or outdoors (exophilic) after a blood meal for maturation of its eggs. Knowledge of these habits is necessary for organizing antiadult measures. The common resting places are either human dwellings, cattle sheds or mixed dwellings.

Flight Range : The range of flight and dispersion varies from one vector to another. Knowledge of this is important for planning control measures. Some have a short flight range e.g. *Anopheles dirus*, *Anopheles annularis* and *Anopheles fluviatilis*. The species with flight range upto Two km distance are *Anopheles culicifacies* and *Anopheles stephensi*. *Anopheles sundaicus* may fly upto 8 or 10 km.

Mode of Transmission : The most prevalent mode of transmission of malaria is through the bite of the infected female anopheles mosquito. The mosquito is infective only if the sporozoites are present in its salivary glands. However, Malaria can also be transmitted by intravenous or intramuscular injection of infected blood or plasma in an otherwise healthy person. The parasite can stay alive for nearly two weeks at -4°C in bottled blood. Rarely transmission can also occur from infected mother to the newborn.

Epidemiologic Terminology (10)

A number of descriptive terms are used to describe the malaria situation in a given area. Stable endemic Malaria is said to be present when natural transmission occurs over many years and there is a predictable incidence of illness and prevalence of infection. Transmission is generally high and epidemics are unlikely. Unstable malaria describes the situation where malaria occurs in settings where transmission rates vary from year to year and collective immunity is low. Epidemics are more likely in this setting. Autochthonous (indigenous) malaria is malaria contracted locally. Secondary cases are those derived from imported cases and are referred to as introduced malaria. The term induced malaria is used for malaria infections acquired by blood transfusion, shared needles, intentional inoculation, or laboratory accidents.

A number of parameters are commonly used to classify

malaria in an area. Malaria incidence is the number of new infections or cases detected per time unit (e.g. annually) per unit of population (e.g. per 1000). Malaria prevalence is the total number of cases or infections at one point in time, per unit of population. When the measure used is microscopically proven parasitemia, malaria prevalence and parasite rate are synonymous.

Annual Parasite Incidence : Number of new parasitologically confirmed cases per 1000 population per year. This tool of evaluation has been introduced under the National Programme, which measures not prevalence but the incidence of malaria and based on this, areas are divided into high & low risk zones.

Infant Conversion Rate : Fraction of parasitologically negative infants becoming positive per time unit.

Spleen Rate : Proportion of individuals in a stated age range with enlarged spleens. The degree of endemic malaria is determined by examination of a statistically significant sample of a population and is assessed and classified as follows :

Hypoendemic : Spleen rate or parasite rate of 0 to 10% in children between the ages of 2 and 9.

Mesoendemic : Spleen rate or parasite rate of 11 to 50% in children between the ages of 2 and 9.

Hyperendemic : Spleen rate or parasite rate consistently over 50% in children between the ages of 2 and 9. Adult spleen rate is also high.

Holoendemic : Spleen rate or parasite rate consistently over 75% in children between the ages of 2 and 9. Adult spleen rate is low and the transmission index is high.

Pathophysiology

A detailed description of pathophysiology is beyond the scope of this chapter. However in short, the pathophysiology of malaria results from destruction of erythrocytes, the liberation of parasite and erythrocyte (Cytokines, Nitric Oxide etc) material into the circulation, and the host reaction to these events. *P. falciparum* malaria differs from the other three human species of malaria parasite because infected erythrocytes also sequester in the microcirculation of vital organs, interfering with micro circulatory flow and host tissue metabolism, which results in severe organ damage.

Clinical Features

Uncomplicated Malaria : The classical (but rarely observed) malaria attack lasts 6 - 10 hours. It consists of three typical stages. In the *Cold Stage*, there is a general sensation of cold followed by rigors. The temperature rises to 40°C and stays for nearly one hour. At this time parasites are demonstrable in the blood. This stage is followed by the *Hot Stage* which is characterized by fever, headaches and vomiting. The skin feels hot and dry. This lasts from 2 to 6 hours. The last stage is the *Sweating Stage*. The patient sweats profusely and temperature returns to normal. This stage lasts from 2 - 4 hours.

Classically, the attacks occur every second day with the "tertian" parasites (*Plasmodium falciparum*, *Plasmodium vivax*, and *Plasmodium ovale*) and every third day with the "quartan" parasite (*Plasmodium malariae*). More commonly, the patient presents with a combination of symptoms of fever, chills,

sweats, headaches, nausea, vomiting, body aches and general malaise. Physical findings may include elevated temperature, perspiration, weakness, enlarged spleen etc. In *Plasmodium falciparum* malaria, additional findings may include mild jaundice, enlargement of the liver and increased respiratory rate.

Severe Malaria : Severe malaria occurs when *Plasmodium falciparum* infections are complicated by serious organ failures or abnormalities in the patient's blood or metabolism. The manifestations of severe malaria include cerebral malaria, with abnormal behaviour, impairment of consciousness, seizures, coma, or other neurologic abnormalities, severe anaemia due to hemolysis, hemoglobinuria, pulmonary edema or Acute Respiratory Distress Syndrome (ARDS), which may occur even after the parasite counts have decreased in response to treatment, abnormalities in blood coagulation and thrombocytopenia, cardiovascular collapse and shock.

Relapse : In cases of *Plasmodium vivax* and *Plasmodium ovale* infections, recurrent attacks could be due to re - activation of hypnozoites in the liver. This can occur any time after 30 to 180 days of the primary attack. The relapses have the characteristic symptoms of malaria. Splenomegaly may be a prominent feature in these patients. Such long - term relapses commonly occur in patients who have either not taken primaquine or taken incomplete treatment.

Recrudescence : In *Plasmodium falciparum* and *Plasmodium malariae* infections, the parasites can remain in the blood for months or even years and cause recurrent symptoms from time to time. In falciparum malaria, such recrudescence can occur within 28 days of the primary attack and may indicate partial resistance to chloroquine. However, treating every case of recurrent *Plasmodium falciparum* as resistant malaria is unjustified. One should consider the possibility of re - infection in most of these cases.

Diagnosis

Peripheral smear examination for malarial parasite is the gold - standard in confirming the diagnosis of malaria. Thick and thin smears prepared from the peripheral blood are used for the purpose. The thick smear of correct thickness is the one through which newsprint is barely visible. Thick smears are used to detect infection and to estimate parasite concentration. Thin film examination is the gold standard in diagnosis of malarial infection.

The QBC Test, developed by Becton and Dickenson Inc., is a new method for identifying the malarial parasite in the peripheral blood. It involves staining of the centrifuged and compressed red cell layer with acridine orange and its examination under UV light source. It is faster and easier.

The other tests include Para Sight F test, OptiMal Assay, the Immuno Chromatographic Test (ICT Malaria Pf. test), Polymerase Chain Reaction, detection of antibodies by Radio Immuno Assay, Immunofluorescence or Enzyme Immuno Assay (11, 12).

Rapid Diagnosis of Malaria (Dipstick Test) : The immunochromatographic tests for the detection of malaria antigens, developed in the past decade, have opened a new and

exciting avenue in malaria diagnosis. However, their role in the management and control of malaria appears to be limited at present. Immunochromatographic tests are based on the capture of the parasite antigens from the peripheral blood using either monoclonal or polyclonal antibodies against the parasite antigen targets. Currently, immunochromatographic tests can target the Histidine - Rich Protein 2 of *Plasmodium falciparum*, a pan - malarial Plasmodium aldolase, and the parasite specific lactate dehydrogenase. Pf LDH is cleared rapidly from blood, the test becomes negative within days of treatment, but P/HRP2 is cleared very slowly from the blood, and may remain positive for up to one month after the acute infection, particularly if the parasitaemia was high. This is a disadvantage in areas where transmission is high, and infections frequent. These RDTs are kit based, much faster, need only little training and diagnostic sensitivity similar to trained microscopists (13, 14).

Treatment

WHO recommends that all malaria endemic countries should have their own national anti - malaria drug policy and defines it as 'An antimalarial treatment policy is a set of recommendations and regulations concerning the availability and rational use of antimalarial drugs in a country. It should be the part of the national essential drug policy and the national malaria control policy and in line with the overall national health policy'.

India's first national anti - malaria drug policy was drafted in 1982. Thereafter the policy has been reviewed periodically based on sensitivity studies and current National Drug Policy on Malaria has been revised in 2007. The main purpose of the national anti - malaria drug policy is to provide a framework for the safe and effective treatment of uncomplicated and severe malaria as well as prevention of malaria in travellers and vulnerable groups, such as pregnant women and young children. Detailed discussion of treatment of malaria is beyond the scope of this chapter. The main treatment guidelines based on national anti - malaria drug policy are as follows (15) :

Microscopically positive *Plasmodium falciparum*/ *Plasmodium vivax* cases :

- *Plasmodium falciparum* cases should be treated with chloroquine in therapeutic dose of 25 mg/kg body weight over three days and single dose of Primaquine 0.75 mg/kg bw on the first day only.
- *Plasmodium vivax* cases should be treated with chloroquine in full therapeutic dose of 25 mg/kg body weight over three days. Primaquine can be given in dose of 0.25mg/kg bw daily for 14 days.

When diagnosis by microscopy or Rapid Diagnostic Kits (RDK) is not possible, cases showing signs and symptoms of malaria without any other obvious causes should be considered as "clinical malaria" and treated with chloroquine in full therapeutic dose of 25 mg/kg body weight over three days in low risk area while in high risk area single dose of Primaquine 0.75 mg/kg bw should also be given on the first day.

Plasmodium falciparum in chloroquine resistant areas is treated with 4mg/kg body weight of artesunate daily for 3 days along with 25mg/ kg body weight of sulphadoxine/sulphalene + 1.25 mg per kg bw of pyrimethamine on the first day.

In severe and complicated malaria of *Plasmodium falciparum*

(clinically/microscopically confirmed), parenteral artemisinin or quinine is the drug of choice, irrespective of chloroquine resistance status of the area.

- Quinine salt : 10mg /kg body weight 8 hourly in 5% dextrose saline is preferred. Patients should be switched over to oral quinine as early as possible and oral dose is 10 mg/kg body weight eight hourly not exceeding 2gm in a day in any case. Minimum total duration for quinine therapy should be for 7 days including both parental and oral doses.
- Injectable form of artemisinin derivatives may be used for the management of severe and complicated malaria (For adults and non - pregnant only). Artesunate : 2.4 mg/kg bw IM/IV followed by 1.2 mg/kg body weight after 12 hours then 1.2 mg/kg body weight once daily for total duration of 5 days.

Prevention and Control Measures

The malaria prevention and control measures aimed at breaking the 'man - mosquito - man' cycle of transmission include a number of methods which are complementary to each other. None of the measures will be successful if applied alone in any given environment. At the same time use of all of them together may not be feasible for technical or administrative reasons. Local environmental conditions, resources and feasibility will have to be studied before optimum measures may be implemented (16, 17). The various measures are described in greater detail in section of Entomology.

Personal Protective Measures : Individual personal protection against mosquito bites is achieved by use of mosquito nets, repellents and protective clothing. The feeding and resting habits of the vectors and the cultural practices and sleeping habits of people are important determinants of the efficacy of personal protective measures.

The use of mosquito net is the most effective personal protective measure. Net should be put up before dusk and tucked all round under the bedding. For making the mosquito nets more effective, the nets are now being treated/medicated with synthetic pyrethroids like deltamethrin, cyfluthrin etc. These nets can be used by pregnant women & small children. These nets are also effective against sand flies.

Commercially available repellants such as Odomos, Mosfree have been found to be very effective when applied on clothing or on exposed parts of the body. The wearing of long trousers and shirts with rolled down sleeves after dusk should be encouraged in all epidemic areas. Screening of houses and barracks as a measure is effective only when all doors, windows and ventilators in the building are screened by wire mesh of proper gauge and size (1.2 to 1.5mm).

Anti - larval Measures : Larval control is the only effective method of radical mosquito control. In urban areas, this method complements the adult mosquito control. Anti - larval work is carried out by preventing breeding and destruction of larvae and pupae. For long term and permanent mosquito control, greater emphasis should be placed on the prevention of breeding during non - transmission season than on larvicidal (chemical & biological) measures during breeding season.

Anti - Adult Measures : The principle of malaria control by intercepting its transmission, by shortening the life span of the

vector species to a period shorter than the extrinsic incubation period of the parasite, has come to be established. This principle has been successfully employed by the application of residual insecticides to the resting places of mosquitoes, viz. the inside of all the walls of habitations, this is known as Indoor residual spraying. Other methods of adult mosquitoes control include Space Sprays, Genetic Control etc.

Vector Engineering : Avoidance of man - made mosquitogenic conditions is of primary importance. A positive aspect of mosquito breeding prevention should be kept in view and deliberately incorporated in the planning and execution of all engineering constructions and town planning schemes. Drainage in water supply projects may lead to mosquitogenic conditions. Besides these, indiscriminate digging, disposal of discarded tins, containers and water collections, overhead storage tanks and septic tanks without covers are potential mosquito breeding places in urban areas. Clean edging and water dewatering, channelling, filling or draining, exposing to sunlight, shading or covering are the usual methods adopted. Underground drainage constitutes the best method of bio - engineering method for control of mosquito breeding (17).

Environmental Management : Environmental management approaches to vector control aim at modifying the environment to deprive the target vector population of its requirements for breeding, resting and feeding purposes. This reduces human - vector contact and renders conditions less conducive for disease transmission. These include periodic flushing in streams by means of small dams with siphons and sluice gates and changing the salinity of breeding habitats (17).

Chemoprophylaxis : Chemoprophylaxis is a valuable supplementary measure under high risk situations, but not a substitute for other control measures. Early colonists devised many indigenous methods of taking quinine regularly (including 'Indian tonic water'), which were generally neither pleasant nor fully effective. Quinine (a poor prophylactic) was relied upon by armies and colonists until after the Great War. But it was only after the introduction of chloroquine, the antimalarial biguanides and subsequently pyrimethamine that finally brought safe and effective antimalarial prophylaxis into existence. In the current age of increasing drug resistance, many prophylactic drugs can no longer be relied upon, particularly in areas of multiple drug resistance such as South - East Asia and South America. Therefore recommendations for each region vary depending upon the drug sensitivity studies. In India the current recommendations on Chemoprophylaxis as per National Drug Policy on Malaria (2007) is as follows (15) :

- In chloroquine sensitive areas - chloroquine 10 mg/kg body weight and followed by a weekly dose of 5 mg/kg body weight . This is to continue till 1 month after delivery in case of pregnancy and in travellers till one month after return from endemic area. The terminating dose should be radical treatment for *P. vivax* i.e. 25 mg/kg body weight over 3 days along with 0.25 mg/kg body weight of primaquine for 14 days.
- In chloroquine resistant areas - chloroquine 5 mg/kg body weight weekly supplemented with proguanil 200mg daily.
- Chemoprophylaxis with chloroquine is not recommended beyond 3 years because of its cumulative toxicity.

Malaria Vaccine : Despite considerable effort and expense, a generally available and highly effective malaria vaccine has till date not been developed. An ideal malaria vaccine is one that would prevent the infection at the first instance and if this is not possible, should decrease the intensity of infection and should be successful in preventing malaria transmission. The path of vaccine development has proved long and strewn with pitfalls, but there has been progress. Research is now concentrated on all stages of the parasite life cycle : the sporozoite, the liver stage, the asexual blood stage, and the gametocyte.

Summary

Malaria is the most important parasitic disease of man. It is defined as an acute and chronic disease caused by obligate intracellular protozoa of the genus *Plasmodium*. Approximately 5% of the world population is infected by malarial parasites and the disease is responsible for nearly one million deaths annually world wide. The causative organisms of the disease malaria are protozoa of the genus *Plasmodium*, family *Plasmodiidae*, suborder *Haemosporididae*, order *Coccidia*. However diseases in humans is caused by four parasites namely *Plasmodium vivax*, *Plasmodium malariae*, *Plasmodium falciparum* and *Plasmodium ovale*. Most of the severe morbidity and mortality in malaria is caused by *Plasmodium falciparum*. The cyclopropagative life cycle of the *Plasmodium* occurs in two stages the sexual stage and the asexual stage. For human plasmodia, the only reservoir is a malaria case. All ages are equally affected. Optimal conditions for malaria transmission occur when the temperature is between 20°C and 30°C and the mean relative humidity is at least 60%. There are 56 species of anopheline mosquitoes in India but only six are regarded as primary vectors. The most prevalent mode of transmission of malaria is through the bite of the infected female anopheles mosquito. Clinical Features can be divided into Uncomplicated Malaria and Severe Malaria. Severe malaria occurs when *Plasmodium falciparum* infections are complicated by serious organ failures or abnormalities in the patient's blood or metabolism. Peripheral smear examination for malarial parasite is the gold - standard in confirming the diagnosis of malaria. However immunochromatographic tests for the detection of malaria antigens, have been developed in the past decade for Rapid Diagnosis of Malaria. Treatment is based on National Drug Policy on Malaria 2007. The malaria prevention and control measures aimed at breaking the 'man - mosquito - man' cycle of transmission include a number of methods which are complementary to each other; these are Personal Protective Measures, Anti - larval Measures, Anti - adult Measures, Environmental Management, Chemoprophylaxis and Malaria Vaccine.

Study Exercises

Long Questions : (1) Discuss the epidemiology, diagnosis and treatment of Malaria (2) Discuss in detail Prevention and control measures against malaria.

Short Notes : (1) Spleen rate (2) Characteristics of vector mosquitoes in transmission of malaria (3) Life cycle of the *Plasmodium* (4) Rapid Diagnosis of Malaria (5) Chemoprophylaxis of malaria.

MCQs

1. Malignant tertian malaria is caused by (a) *Plasmodium vivax* (b) *Plasmodium malariae* (c) *Plasmodium falciparum* (d) *Plasmodium ovale*
2. The cyclopropagative life cycle of the *Plasmodium* occurs in _____ stages (a) Two stages (b) Three stages (c) Four stages (d) Five stages
3. Most of the severe morbidity and mortality in malaria is caused by (a) *Plasmodium vivax* (b) *Plasmodium malariae* (c) *Plasmodium falciparum* (d) *Plasmodium ovale*
4. In order to infect a mosquito, the blood of a human carrier must contain at least _____ no. of gametocytes per mm^3 (a) 10 (b) 12 (c) 14 (d) 16
5. Main Vector of malaria in Andaman and Nicobar Islands is (a) *Anopheles dirus* (b) *Anopheles sundaicus* (c) *Anopheles maculatus* (d) *Anopheles stephensi*
6. A Hyperendemic area is defined as one in which (a) Spleen rate or parasite rate consistently over 10% in children between the ages of 2 and 9 years (b) Spleen rate or parasite rate consistently over 30% in children between the ages of 2 and 9 years (c) Spleen rate or parasite rate consistently over 50% in children between the ages of 2 and 9 years (d) Spleen rate or parasite rate consistently over 75% in children between the ages of 2 and 9 years
7. Rapid Diagnostic test of Malaria based on detection of antibodies against Histidine - Rich protein 2 is used for diagnosis of (a) *Plasmodium falciparum* (b) *Plasmodium vivax* (c) *Plasmodium ovale* (d) All of the above
8. Gold - standard in confirming the diagnosis of malaria is (a) Peripheral smear examination (b) Immuno chromatographic test (c) Polymerase Chain Reaction (d) Radio immuno assay
9. Drug of choice in severe and complicated malaria of *Plasmodium falciparum* (a) Artesunate (b) Quinine (c) Chloroquine (d) None of the above
10. In severe and complicated malaria recommended dose of Quinine is (a) 2.5mg /kg body weight 8 hourly (b) 5mg /kg body weight 8 hourly (c) 10mg /kg body weight 8 hourly (d) 15mg /kg body weight 8 hourly

Answers : (1) c; (2)a; (3) c; (4) b; (5) b;(6) c; (7) a; (8) a; (9) b; (10) c.

Lymphatic Filariasis is widely known as Elephantiasis. More than a billion people in more than 80 countries are at risk of suffering from the disease. India accounts for one - third of the people infected with the disease (1). Filariasis is caused by three species of nematode worms belonging to the super family Filarioidea and family Onchocercidae which are transmitted

to man by the bite of infective mosquitoes. The three species are *Wuchereria bancrofti*, *Brugia malayi* and *Brugia timori*. *Wuchereria bancrofti* is the most widespread among these three species (2). Several mosquito species are known to transmit the infection. However, *Culex quinquefasciatus* and *Mansonia annulifera* are the two most important vectors in India. In tropical and subtropical areas the prevalence of infection is continuing to increase. The major reason for this increase is the rapid and unplanned growth of cities which greatly enhances breeding of the mosquitoes that transmit the disease. This painful and profoundly disfiguring disease is usually acquired

in childhood, but manifests its most disfiguring forms in adults (3, 4). The disease due to lymphatic filariasis is characterized by disfigurement of the limbs (elephantiasis) and genitalia (hydrocele and other anatomical changes in the male genitalia). Consequently, it often has adverse economic and psychosexual effects as well as medical consequences (5). Lymphatic filariasis is one of the six infectious diseases considered eradicable by WHO with the available tools (6).

In 1863, Demarquay first described the microfilariae that are the larvae which live in the blood stream. Microfilariae were found in urine by Wucherer in 1868. Patrick Manson was the first to speculate in 1878 that filariasis may be transmitted by mosquitoes (2). The disease has been known in India since ancient times. It finds mention in “*Susruta Samhita*” which dates back to the 6th century B.C. Madhavakara described the signs and symptoms of the disease in his treatise ‘*Madhava Nidhana*’ in 7th century A. D. In 1709, Clarke called elephantoid legs in Cochin as ‘Malabar legs’ (7).

Epidemiology

Global : According to the World Health Organization, about 1.25 billion people are at risk of suffering from lymphatic filariasis. As on 31 Dec 2006, 83 countries are considered endemic for filaria. The highest proportion of cases is in the WHO South - East Asia Region with 64% followed by the WHO African Region with 32%. The WHO European Region remains free of lymphatic filariasis transmission (8). Approximately one third of those at risk live in India, another one third in Africa and the remainder in other parts of Asia, the Pacific and the Americas. The most highly - endemic countries are Bangladesh, Democratic Republic of Congo, India, Indonesia, Madagascar, Nigeria and the Philippines (9). The total number of persons infected worldwide is estimated to be 120 million, one third of whom have serious disfigurement and incapacitation (1). Almost 25 million men suffer from genital disease, most commonly hydrocele, while an estimated 15 million people, mostly women suffer from lymphoedema of the leg (elephantiasis). Among the three parasitic worms responsible for the disease, *Wuchereria bancrofti* is the most prevalent particularly in hot and humid climates of Asia, Africa, the Americas and the Pacific. *Brugia malayi* is found in Southern India, South East Asia and South and Central China. *Brugia timori* has only been found in parts of Indonesia (2). More than half of all cases of Lymphatic filariasis live in South East Asia. Of the estimated 700 million people living in endemic areas in the region, about 60 million are estimated to be infected or suffering from the disease (10).

India : One - third of the people infected with the disease live in India (1). The disease has been described as being second only to malaria as a major public health problem. The disease is endemic to most parts of the country. Indigenous cases have been reported from about 250 districts in 20 states / union territories. Local transmission is known to occur in Andhra Pradesh, Assam, Bihar, Chhattisgarh, Goa, Jharkhand, Karnataka, Gujarat, Kerala, Madhya Pradesh, Maharashtra, Orissa, Tamil Nadu, Uttar Pradesh, West Bengal, Pondicherry, Andaman & Nicobar Islands, Daman & Diu, Dadra & Nagar Haveli and Lakshadweep. The North Western and North Eastern parts of India appear to be free from indigenously acquired

filarial infection. These include the states of Jammu & Kashmir, Himachal Pradesh, Punjab, Haryana, Chandigarh, Rajasthan, Delhi, Uttaranchal Sikkim, Arunachal Pradesh, Nagaland, Meghalaya, Mizoram, Manipur and Tripura (7). Almost all the cases in India are caused by *Wuchereria bancrofti* (94%) while the remaining 6% are attributed to *Brugia malayi* (7).

Over 400 million people live in filariasis endemic areas in India. Three fourths of those at risk live in rural areas. An estimated 49 million individuals in India are infected. Of these, over twenty million people suffer from chronic forms of filariasis while another 28 million are thought to be microfilaria carriers (11 - 13).

Agent : The three species of nematodes causing lymphatic filariasis, *Wuchereria bancrofti*, *Brugia malayi* and *Brugia timori* are threadlike in appearance. They have five stages in their life cycle. Unlike other vector borne diseases, the infective stage of the parasite is not injected into the human body by the mosquito vector. The infective third - stage larvae are deposited on skin by the vector and penetrate on their own or through the opening created by mosquito bites within minutes to reach the lymphatic system. They then proceed to shed their cuticle and develop a new surface as they moult into the fourth stage larvae (10). These fourth - stage larvae migrate to central lymphatic vessels and develop into sexually mature adult male or female worms over a period of approximately 9 months. The adult worms are significantly larger than larval stages, with male worms being 20 - 40 mm in length and female worms 40 to 100 mm in length. The adults reside mostly in the afferent lymphatics. The preferred sites for the adult worms seem to be the lymphatics of the lower extremities, upper extremities and the genitalia.

The mean reproductive life span of adult worms is approximately 5 years. Following copulation female worms discharge large numbers (10,000 per day) of microfilariae measuring $150 \times 7 \mu\text{m}$ into the blood stream via the lymphatics. The number of microfilariae in the peripheral blood is variable. There is usually a surge in their numbers during the night. These microfilariae are ingested by the mosquito vectors during feeding. The microfilariae exsheath in the mosquito stomach to become first stage larvae. They penetrate the stomach wall and move to the thoracic muscles of the mosquito where they moult twice to develop into the infective third stage larvae. The infective forms then move to the mouth parts of the mosquito and the cycle repeats. The extrinsic incubation period is usually two weeks (2, 3, 13).

Vector : A wide range of mosquitoes can transmit the parasite, depending on the geographic area. The primary vectors for Filaria are the night biting *Culex* and Anopheles mosquitoes. *Culex quinquefasciatus* is the principal vector in urban areas in South East Asia. In rural areas of both Asia and Africa, Anopheles species are the important vectors particularly *Anopheles gambiae* and *Anopheles funestes* (2). *Aedes* and *Mansonia* are also responsible for transmitting the infection in the parts of Asia and the Pacific region (3).

In India, the most important vector for lymphatic filariasis is *Culex quinquefasciatus*. It is the vector for *Wuchereria bancrofti*. It is a ubiquitous mosquito and is present all over the country.

Culex breeds in polluted water. Important breeding sites are wet pit latrines, septic tanks, drains, disused wells and paddy fields. *Mansonia annulifera* and *Mansonia uniformis* are the vectors for *Brugia malayi* in India. *Mansonia* lay eggs on the under surface of the leaves of plants (7).

Filarial nematodes are poorly transmitted by the vectors. A very small proportion; usually less than 1% of mosquitoes are infective even in endemic areas (14). Repeated mosquito bites over several months result in lymphatic filariasis. People exposed to intense transmission for a long period are at the greatest risk for infection. Visitors to endemic areas from non endemic areas for short periods rarely develop disease (2, 15).

Host Factors : Varied patterns of infection and disease are seen in different endemic areas. Infection is usually acquired in childhood (16). The prevalence of infection rises with age from 5 years to 30 years beyond which it stabilizes. Prevalence may decline somewhat among the elderly. Signs of disease start becoming apparent during late adolescence and rise steadily with age (2). Both sexes are equally susceptible. Minor differences, however, are shown by various groups. It has been postulated that females in the reproductive age group may be more resistant to infection than males because of hormonal factors (17).

Lymphatic filariasis is primarily a disease of the poor as it occurs mostly in rural areas or urban slums. The increase in lymphatic filariasis over the past few years has been attributed to the expansion of slum areas and poverty, particularly in India and Africa. As many filariasis patients are physically incapacitated, it has a significant economic impact. Lymphatic filariasis also exerts a heavy social burden. Among men, genital damage may be a severe handicap leading to physical limitations and social stigmatization. Enlargement of a leg or arm, the genitals, vulva and breasts may result in severe stigmatization of women (1).

Environment : Environmental conditions that enhance vector breeding and survival increase infection rates. The optimum conditions for the breeding of the vectors and the development of parasites in them are temperature between 15°C and 35°C and relative humidity above 60%. The density of *C quinquefasciatus* is at its minimum during the monsoon, but due to favourable atmospheric conditions, somehow the maximum infectivity rate in the mosquitoes occurs during this period. India presents areas of widely variable endemicity because of its large size and variable climates from region to region (18).

Clinical Features

The incubation period is very variable stretching from 8 to 16 months or even longer. The adult worms induce an immunological reaction. A wide variety of clinical manifestations can be seen in lymphatic filariasis. A large proportion of infected persons remain asymptomatic despite the presence of microfilariae. The manifestations result from either acute inflammation or chronic lymphatic obstruction. Clinical manifestations range from those without apparent clinical disease to those with lymphedema and severe disfigurement of the limbs and genitalia. Fever may or may not be present in both the acute and chronic forms. The various presentations can include lymphangitis and adenitis, funiculitis and hydrocoele, abscess formation, lymphoedema and elephantiasis, chyluria and monoarticular

arthritis. Occult filariasis in which the classical features of the disease are absent and microfilaria can not be demonstrated in blood, can present as tropical pulmonary eosinophilia. About 40% of patients have renal involvement with proteinuria and haematuria (2, 4, 5, 14).

Diagnosis

Diagnosis in symptomatic patients living in endemic areas is based on appropriate history and typical clinical findings. In patients above 15 years of age the appearance of lymphedema of the extremities or disease of the male genitalia is most likely due to filarial infection.

A definitive diagnosis can be made only by detection of the parasites. The standard method for diagnosing active infection is the identification of microfilariae in a blood smear by microscopic examination. The microfilariae exhibit nocturnal periodicity with surges of circulating microfilariae at night. Blood collection should be done at night to coincide with the appearance of the microfilariae. A small dose of Diethylcarbamazine (DEC) can increase microfilaraemia during the day as it causes the microfilariae to be expelled from the pulmonary vascular bed. A thick smear should be made and stained with Giemsa or Haematoxylin and Eosin. Microfilariae are sometimes detected in chylous urine, hydrocoele fluid and ascites fluid (19). An alternative to microscopic detection of microfilariae is provided by serologic techniques for the diagnosis of lymphatic filariasis. Patients with active filarial infection are found to have elevated levels of antifilarial IgG4 in the blood and these can be detected using routine assays (19).

The difficulty in detection of microfilariae led to the development of simple immunochromatographic tests. These are very sensitive, very specific and simple "card tests" to detect circulating parasite antigens without the need for laboratory facilities. They use only finger - prick blood droplets taken anytime of the day (1, 20). Adult worms are difficult to detect. Sonographic examination of the scrotum or breast using high frequency ultrasound may result in the identification of adult worms within dilated lymphatics (2, 5).

Treatment

Diethylcarbamazine (DEC) is the drug used most widely for treatment of lymphatic filariasis. It exerts no direct lethal action on the adult worms but changes them in a manner which makes their removal by the host's immune system possible (2). It is considered safe and effective against all filarial infections. The dose is 9 - 12 mg / kg orally in three divided doses for 14 or 21 days. The full dose must be reached slowly, starting with 50 mg daily to avoid side effects. For treatment of tropical eosinophilia, a 21 day treatment regimen must be followed. This course may be repeated twice at intervals of 4 - 6 weeks. Ivermectin has also been found effective in a single oral dose of 200 - 400 µg / kg body weight. Two drug regimens have also been found effective. The combination that may be used include 400 mg albendazole with 6mg / kg DEC or 400 mg albendazole with 150 µg / kg ivermectin once a year. Symptomatic treatment such as analgesics, antipyretics and antihistaminics may be required. Surgical procedures to correct elephantiasis must be preceded by drug therapy.

In filariasis endemic areas, the primary goal of community treatment is to eliminate microfilariae from the blood of infected individuals so that transmission of the infection by the mosquito can be interrupted. Recent studies have shown that single doses of Diethylcarbamazine (DEC) have the same long - term effect in decreasing microfilaraemia as the 12 day regimens of DEC. The use of single doses of two drugs administered together (Albendazole with DEC or Ivermectin) is 99% effective in removing microfilariae from the blood (1).

Prevention and Control

Active disease surveillance, vector control, personal protection and mass treatment of communities in endemic areas are the corner stone of lymphatic filariasis control. The success of control measures depends on the level of co - operation by the public. The importance of health education cannot be overemphasized. Vector control and personal protective measure are dealt with in detail in the chapter on Entomology.

The WHO strategy of the Global Programme to Eliminate Lymphatic Filariasis aims to stop the spread of infection and morbidity control. To interrupt transmission, districts in which lymphatic filariasis is endemic must be identified and then mass treatment programmes implemented to treat the entire at - risk population.

Mass Treatment involves once - yearly administration of single doses of two drugs given together, albendazole plus either diethylcarbamazine (DEC) or ivermectin. An alternative community - wide regimen with equal effectiveness is the use of common table / cooking salt fortified with DEC in the endemic region for a period of one year (1). This programme is in operation on a national level in India (7, 22 24).

Summary

Lymphatic Filariasis is widely known as Elephantiasis. According to the World Health Organization as on 31 Dec 2006, 83 countries are considered endemic for filaria. The most highly - endemic countries are Bangladesh, Democratic Republic of Congo, India, Indonesia, Madagascar, Nigeria and the Philippines. One - third of the people infected with the disease live in India. Almost all the cases in India are caused by *Wuchereria bancrofti* (99.4%) while the remaining 6% are attributed to *Brugia malayi*. The three species of nematodes causing lymphatic filariasis : *Wuchereria bancrofti*, *Brugia malayi* and *Brugia timori* are threadlike in appearance. In India, the most important vector for lymphatic filariasis is *Culex quinquefasciatus*. It is the vector for *Wuchereria bancrofti*. *Mansonia annulifera* and *Mansonia uniformis* are the vectors for *Brugia malayi* in India. The prevalence of infection rises with age from 5 years to 30 years beyond which it stabilizes. Lymphatic filariasis is primarily a disease of the poor as it occurs mostly in rural areas or urban slums. The incubation period is very variable stretching from 8 to 16 months or even longer. Clinical manifestations range from those without apparent clinical disease to those with lymphedema and severe disfigurement of the limbs and genitalia. A definitive diagnosis can be made only by detection of the parasites. The standard method for diagnosing active infection is the identification of microfilariae in a blood smear by microscopic examination. Immunochromatographic tests are very sensitive, very specific

and simple “card tests” to detect circulating parasite antigens without the need for laboratory facilities. Diethylcarbamazine (DEC) is the drug used most widely for treatment of lymphatic filariasis. Other drugs used are Albendazole and Ivermectin. The use of single doses of two drugs administered together (albendazole with DEC or ivermectin) is 99% effective in removing microfilariae from the blood. Control of the disease can be achieved by active disease surveillance, vector control, personal protection and mass treatment of communities in endemic areas are the corner stone of lymphatic filariasis control. The WHO strategy of the Global Programme to Eliminate Lymphatic Filariasis aims to stop the spread of infection and morbidity control. To interrupt transmission, districts in which lymphatic filariasis is endemic must be identified and then mass treatment programmes implemented to treat the entire at - risk population.

Study Exercises

Long question : Discuss the epidemiology, prevention and control of Lymphatic Filariasis.

Short Notes : (1) Clinical Spectrum of Filariasis (2) Treatment of Lymphatic Filariasis and mass treatment regimen.

MCQ

1. Most prevalent parasitic worm in India (a) *Wuchereria bancrofti* (b) *Brugia malayi* (c) *Brugia timori* (d) None of the above
2. *Brugia timori* has only been found in parts of (a) South India (b) Indonesia (c) China (d) Bangladesh
3. The most important vector for lymphatic filariasis in India (a) *Culex quinquefasciatus* (b) *Culex tritaeniorhynchus* (c) *Mansonia annulifera* (d) *Mansonia uniformis*
4. Drug most widely used for treatment of lymphatic filariasis (a) Diethylcarbamazine (DEC) (b) Ivermectin (c) Albendazole (d) None of the above
5. Dose of Diethylcarbamazine (DEC) (a) 1 - 3mg / kg orally in three divided doses (b) 3 - 6 mg / kg orally in three divided doses (c) 6 - 9 mg / kg orally in three divided doses (d) 9 - 12 mg / kg orally in three divided doses

Answers : (1) a; (2) b; (3) a; (4) a; (5) d.

173 Leishmaniasis

Rajesh Vaidya

Leishmaniasis encompasses a varied collection of diseases ranging in severity from a spontaneously healing skin ulcer to overwhelming visceral disease (1). The disease is named after Leishman, who first identified the organisms in smears taken from a man who had died of "Dum Dum" fever in 1901 (2). An estimated two million cases of all forms of Leishmaniasis taken together occur worldwide every year (3, 4). The disease is caused by 21 species of the genus *Leishmania* which are pathogenic to humans and transmitted by the bite of 30 species of the phlebotomine sandfly (3, 4). There are four main types of the disease : Cutaneous, Diffuse cutaneous, Mucocutaneous and Visceral Leishmaniasis which is commonly called Kala Azar (3). *Leishmania* species are members of the family Trypanosomatidae, order Kinetoplastida. They reside as intracellular amastigotes within macrophages in mammals and as extracellular promastigotes in the gut of their insect vectors, phlebotomine sand flies (5). Leishmaniasis has also emerged as an AIDS - associated opportunistic infection (6).

Epidemiology

Global : Leishmaniasis is endemic in 88 countries on five continents. More than 90% of Cutaneous Leishmaniasis cases occur in Iran, Afghanistan, Syria, Saudi Arabia, Brazil and Peru. More than 90% of Visceral Leishmaniasis cases occur in Bangladesh, Brazil, India and Sudan. The World Health Organization estimates that 350 million people are at risk of

Leishmaniasis world wide. The true incidence and prevalence are uncertain because of the large number of undiagnosed cases, the lack of screening, and underreporting (7 - 9). Every year, an estimated one and a half to two million children and adults develop symptomatic disease and the incidence of infection is substantial when sub - clinical infections are included. The number of new cases of Cutaneous Leishmaniasis each year in the world is estimated to be about 1.5 million while the number of new cases of Visceral Leishmaniasis is estimated to be about 5,00,000. An estimated 12 million people are presently infected worldwide. Leishmaniasis is associated with about 2.4 million disability - adjusted life years and around 7,00,000 deaths per year (7 - 9). Since 1993, the geographical distribution of Leishmaniasis has expanded significantly.

The disease is endemic in three countries of the WHO South East Asia Region, Bangladesh, India and Nepal. Approximately 200 million people in the Region are "at risk" from the disease. The disease is reported in 45 districts in Bangladesh, 52 in India and 12 in Nepal. Of the estimated 5,00,000 people in the world infected each year, nearly 1,00,000 are estimated to occur in the Region (10).

India : India is one of the world's largest foci of Visceral Leishmaniasis, accounting for 50% of the total burden of this disease. Leishmaniasis is endemic in eastern States of India. A total of 52 districts in the country are considered endemic for the disease. An estimated 165.4 million population is at risk of Kala Azar in four states. In India, about 1,00,000 cases of Visceral Leishmaniasis are estimated to occur annually. Of these, the State of Bihar accounts for more than 90 per cent of the cases. Cutaneous Leishmaniasis usually occurs in the dry, north eastern states of India, bordering Pakistan extending from

Amritsar to Kutch and Gujrat plains. Cases of Anthroponotic Cutaneous Leishmaniasis has been reported from Bikaner city (10, 11).

Agent : The disease is caused by 21 protozoan species of the genus *Leishmania* (order Kinetoplastida). The amastigote forms are obligate intracellular parasites while the promastigotes are extracellular in the arthropod vectors.

These human pathogens include the *Leishmania donovani* complex with three species (*Leishmania donovani*, *Leishmania infantum* and *Leishmania chagasi*). The *Leishmania mexicana* complex has three main species which are *Leishmania mexicana*, *Leishmania amazonensis* and *Leishmania venezuelensis*. The other major pathogenic species are *Leishmania tropica*, *Leishmania major* and *Leishmania aethiopica*. The different species are morphologically indistinguishable, but they can be differentiated by isoenzyme analysis, molecular methods, or monoclonal antibodies. In India, *Leishmania donovani* is the only parasite causing this disease.

The life cycle is relatively simple. Amastigotes are oval or round in shape and approximately 2 to 3 μm in diameter. They have a large, eccentrically located nucleus, a specialized mitochondrial structure, the kinetoplast, which contains a substantial amount of extranuclear DNA and a flagellar pocket and flagellum, which lie within the confines of the cell. They multiply by simple binary division. In the gut of the sand fly, leishmania live and multiply as extracellular, flagellated promastigotes that vary morphologically from short, stumpy forms to elongated ones ranging from 10 to 15 μm in length and 2 to 3 μm in diameter. A single flagellum extends from the anterior pole. After development in the sand fly gut, which takes approximately 1 or 2 weeks depending on the *Leishmania* species, infectious metacyclic promastigotes migrate to the proboscis (5, 12, 13).

Vector : *Leishmania* species are transmitted by female sand flies of the genus *Lutzomyia* in the Americas and *Phlebotomus* in other parts of the world. Depending on the species, sand flies live in forested areas, rodent burrows, or debris in peri-domestic habitats. Sandflies breed in cracks and crevices in the soil and buildings, tree holes, caves. They are weak fliers, but they can be carried considerable distances by the wind. Sand flies probe with their proboscis to form a venous pool, from which they obtain blood by capillary action (5, 14, 15). A total of about 30 species in *Phlebotomus* genus (old world) and *Lutzomyia* genus (new world) have been identified as vectors. Sandflies are active in the evening and night-time hours. In India, *Phlebotomus argentipes* is a proven vector of Kala Azar. Cutaneous Leishmaniasis is transmitted by *Phlebotomus papatasi* and *Phlebotomus sergenti*.

Host : Most leishmaniasis are zoonotic and humans become infected only when accidentally exposed to the natural transmission cycle. The animal host may be wild animals, such as rodents, and domestic animals, such as dogs. However, in the anthroponotic forms humans are the sole reservoir host. Indian Kala - Azar is anthroponotic with humans being the only known reservoir of infection.

Infection can occur in all age groups and both genders. In India peak age of infection is 5 to 9 years. Males are affected

more often than females probably due to greater exposure. Population movement is important in spreading infection between endemic and non endemic regions. The disease usually strikes the poorest of the poor (10, 16, 17). It is common in various farming practices, forestry, mining and fishing who have greater risk of being bitten by sand - flies. Recovery from Kala - Azar gives a lasting immunity.

Environment : The disease is mostly confined to the plains. It does not occur in altitudes over 2000 feet. Prevalence usually shows a rise during and after rains. The diseases are largely confined to rural areas and those urban areas where opportunities for breeding of sand flies exist. Overcrowding, poor ventilation and accumulation of organic matter in the environment facilitates transmission. Developmental projects like forest cleaning, and cultivation projects, large water resources schemes, and colonization and resettlement programmes are bringing human beings into areas of high vector and reservoir concentration (5, 18).

Transmission : The disease is transmitted by the bite of infected female sandflies. Rarely other modes of transmission might result in infection. Visceral Leishmaniasis can be directly initiated by amastigotes via blood (shared needles, transfusion, transplacental spread) or organ transplantation. Cutaneous infection can develop after inadvertent needlestick injury if the needle or syringe contains infected material (6, 12 14).

Clinical Features : The outcome of leishmanial infection is dependent on a series of complex and only partially understood interactions between *Leishmania* species - specific virulence factors and the genetically determined cell - mediated immune responses of their mammalian hosts. The incubation in man is extremely variable. It usually ranges from 3 to 8 months but can be as short as 10 days to as long as two years.

Leishmaniasis has several diverse clinical manifestations : ulcerative skin lesions, destructive mucosal inflammation, and disseminated visceral infection (Kala Azar). Epidemiology, immunopathology, and outcome are similarly diverse, since infection occurs in multiple endemic regions, in both children and adults, and is caused by nearly two - dozen distinct *Leishmania* species. Nevertheless, all forms of this protozoal infection share three pathogenetic features : resident tissue macrophages are targeted and support intracellular parasite replication; the host immunoinflammatory response regulates expression and outcome of disease; and persistent tissue infection is characteristic (6, 12, 13). Each of the three major clinical syndromes can present with a wide spectrum of findings. Each of these syndromes is associated with more than one *Leishmania* species, and any given species is capable of producing more than one syndrome. Variations are common, particularly among people who are concurrently infected with HIV or other immunosuppressive illness (5, 12, 13).

Cutaneous Leishmaniasis : The typical lesion of Cutaneous Leishmaniasis (5, 12) develops at the site where promastigotes are injected by the vector. Promastigotes are taken up by mononuclear phagocytes. They transform to amastigotes and multiply within the macrophages. A papule is formed at the site of inoculation. The papule enlarges and then ulcerates. Multiple lesions may be present in the same patient. Depending

on the location, Old World Cutaneous Leishmaniasis is known locally as Oriental sore, Bouton d'Orient, Bouton de Crete, Bouton d'Alep, Bouton de Briska, Aleppo evil, Baghdad boil, and Delhi boil.

There can be marked variation in the appearance of the lesions. The classic wet lesion of *Leishmania major* and *Leishmania braziliensis* is "pizza - like" with a raised outer border, granulating base, and overlying white, purulent exudate. Infection by *Leishmania tropica* produces dry lesions in the Middle East and India. The ulcer tends to be smaller and covered with a crust. Contiguous mucosal involvement may be seen in some patients. Some leishmanial lesions are papular or nodular, without ulceration. Cutaneous lesions persist for months, and in some cases years, before they heal, leaving flat, atrophic scars as evidence of disease. Once a lesion has resolved, the person is usually left with immunity against the infecting *Leishmania* species. Cutaneous Leishmaniasis should be considered in the differential diagnosis of subacute or chronic skin lesions in people who have lived, worked, or traveled in endemic areas.

Mucosal Leishmaniasis (Espundia) : A small proportion of people infected with *Leishmania braziliensis* develop mucosal lesions in the nose, mouth, pharynx, or larynx months to years after resolution of the primary skin lesion. The condition is known as Espundia in Latin America. Mucosal Leishmaniasis often begins with nasal stuffiness and inflammation. Ulceration of the nasal mucosa and septum follows. The lips, cheeks, soft palate, pharynx and larynx may eventually be involved, resulting in substantial disfigurement. Mucosal involvement is also observed with other *Leishmania* species, although the pathophysiology may be somewhat different. Destructive involvement of the nose and mouth has been reported with *Leishmania tropica* in Saudi Arabia. Mucosal involvement has been reported rarely in immunocompetent people and more frequently in those who are immunosuppressed with neoplasms or AIDS. (5, 12).

Visceral Leishmaniasis : The majority of infections of Visceral Leishmaniasis are sub clinical. Only a minority of those infected develop full - blown Visceral Leishmaniasis, or Kala - Azar. The disease is characterized by fever, weight loss, and hepatosplenomegaly.

Malnutrition is known to suppress cell - mediated immune responses and may contribute to progression to symptomatic Visceral Leishmaniasis. The incubation period is typically weeks to several months, but it may be as short as 10 days or as long as several years. The onset of Visceral Leishmaniasis is usually insidious, but it can be abrupt, with high fever. Full - blown, progressive Visceral Leishmaniasis, or Kala - Azar, is associated with fever, abdominal enlargement, weakness, loss of appetite, and weight loss. The clinical findings are similar with disease due to *Leishmania donovani* and *Leishmania infantum / chagasi*. Symptoms may be present for weeks to months before patients come to medical attention in rural, endemic areas. The fever pattern may be intermittent, remittent or rarely continuous. The spleen is firm, non - tender, and over time becomes massively enlarged. There is hepatomegaly with the enlarged liver having a sharp edge and smooth consistency. Some patients in India develop hyperpigmentation leading to

the name Kala - Azar, which means "black fever" in Sanskrit. The late stages of disease are characterized by malnutrition, severe wasting, and progressive debilitation. Stunting may be seen in children. Death often occurs due to a secondary bacterial infection, such as pneumonia, septicemia, dysentery, or tuberculosis, or with measles or other viral infection.

Laboratory findings include anaemia, neutropenia, thrombocytopenia and pronounced hypergammaglobulinemia. The anaemia is usually normocytic, normochromic, unless there is concomitant iron deficiency. Leukopenia can be profound with white blood cell counts below 1000/mL. The globulin level can reach 9 or 10 g/dl.

Post - Kala - Azar Dermal Leishmaniasis : Some patients of Visceral Leishmaniasis in India and Africa develop skin lesions following treatment, ranging from hyperpigmented macules to frank nodules. Skin lesions typically appear in India 1 or 2 years after treatment and may persist for as long as 20 years. Persistence of lesions beyond one year is associated with high anti - leishmanial antibody titers and negative leishmanial skin test responses. Anti - leishmanial treatment is indicated in Indian post - Kala Azar dermal Leishmaniasis. In a few instances in India, Visceral Leishmaniasis has recurred in patients with post - Kala - Azar dermal Leishmaniasis. The differential diagnosis includes leprosy (5, 12, 13).

HIV - Visceral Leishmaniasis Co - infection : *Leishmania* with HIV co - infection is has emerged as a serious new disease and is increasingly frequently being reported. Immunocompromised individuals progress to full blown Visceral Leishmaniasis far more often than immunocompetent people who get infected. AIDS and Visceral Leishmaniasis are mutually reinforcing. Visceral Leishmaniasis quickly accelerates the onset of AIDS and shortens the life expectancy of HIV - infected people. Similarly AIDS increases the risk of Visceral Leishmaniasis by 100 - 1000 times in endemic areas. This combination of HIV and Leishmaniasis produces cumulative deficiency of the immune response since *Leishmania* parasites and HIV destroy the same cells, exponentially increasing disease severity and consequences. Visceral Leishmaniasis is considered a major contributor to a fatal outcome HIV in co - infected patients. Another implication of this combination is that Leishmaniasis can be transmitted directly person to person through the sharing of needles, as is often the case among intravenous drug users (13, 19).

Diagnosis

Cases of Leishmaniasis should be confirmed by demonstration of the parasite, which is straightforward if parasites are plentiful as in Visceral Leishmaniasis but can be difficult otherwise.

Parasite Identification : The diagnosis of Leishmaniasis is most often confirmed by identifying leishmania amastigotes in Wright - Giemsa - stained touch preparations or tissue sections or by isolating the parasite in culture. Amastigotes are seen in macrophages in tissue sections, but they may appear to be extracellular in touch preparations. *Leishmania* can be grown as promastigotes in NNN medium, Schneider's insect medium, and other tissue culture media. The cultures are incubated at

24 to 26°C to approximate sand fly temperatures.

Serology : Antileishmanial antibody titers are typically present in high titer in people with Visceral Leishmaniasis and at low titer or undetectable in those with Cutaneous Leishmaniasis. They can be measured by a number of assays. Enzyme - Linked Immunosorbent Assay (ELISA), indirect immunofluorescent tests, and agglutination assays have all been used (20).

Skin Test : The intradermal leishmanin (Montenegro) skin test is positive in the majority of people who have asymptomatic, self resolving *Leishmania donovani* and *Leishmania infantum/chagasi* infections and in people with Cutaneous or Mucosal Leishmaniasis. The skin test is negative in people with progressive Visceral Leishmaniasis or Diffuse Cutaneous Leishmaniasis, but it becomes positive in the majority of people who are successfully treated for Visceral Leishmaniasis.

Treatment

The drug of choice for the treatment of Visceral Leishmaniasis is Sodium stibogluconate, a pentavalent antimonial compound except in regions that are considered Sodium stibogluconate unresponsive. The dose is 20 mg Sb/kg/day IV or IM daily for 20 - 30 days. However, resistance is on the rise and resistance levels as high as 43% have been reported from Bihar where Visceral Leishmaniasis is endemic. Patients resistant to stibogluconate should be treated with alternative agents, such as liposomal amphotericin (0.5 - 3 mg/kg) on alternate days or pentamidine (2 - 4 mg/kg) on alternate days for 15 doses. Amphotericin B deoxycholate is the drug of choice in India, whereas the lipid formulation liposomal amphotericin is used in Europe (2). The dose of Amphotericin B used in India is 1mg/kg IV infusion daily or alternate day for 15 - 20 infusions. The dose can be increased in patients with incomplete response with 30 injections. Miltefosine, the first effective oral treatment for Visceral Leishmaniasis, including for antimony - resistant infection has been approved for self - administered outpatient therapy (13, 21, 22). The drug is to be used in a dose of 100 mg daily for four weeks. Supportive treatment includes rest, high - calorie diet, blood transfusions, and treatment of secondary infections.

Prevention and Control

Leishmaniasis can be prevented by interrupting sand fly transmission or by removing or treating reservoirs of infection. (18, 23). The short - term visitor to an endemic area should use personal protective measures to avoid sand fly bites. Sand flies tend to bite from dusk to dawn. The application of DEET (diethyltoluamide) - containing insect repellents to exposed skin and under pant and shirt cuffs, the use of fine - mesh screens or insect nets, and the application of insecticide (usually permethrin or other pyrethroids) to clothing and bed nets - decrease the risk of transmission of Leishmaniasis. Further details on vector control are given in the chapter on Entomology.

Vaccine

There is experimental evidence to indicate that Leishmaniasis should be vaccine preventable. However, there is currently no vaccine against any form of Leishmaniasis for general human use. One major factor may be the lack of a conceived

market for human Leishmaniasis vaccines. Leishmaniasis is a considered a local/regional problem and not a global one (24). A number of candidate vaccines are undergoing clinical trials. Killed parasites as vaccines produced encouraging results in Brazil in the 1970s. Trials have tested autoclaved *Leishmania major* plus BCG versus adjuvant (BCG) alone. In Ecuador, two doses of a killed multi - leishmania species cocktail plus BCG reduced Cutaneous Leishmaniasis incidence by 73% the first year (13,25).

Summary

Leishmaniasis encompasses a varied collection of diseases ranging in severity from a spontaneously healing skin ulcer to overwhelming visceral disease. Leishmaniasis is endemic in 88 countries on five continents. The World Health Organization estimates that 350 million people are at risk of Leishmaniasis world wide. Leishmaniasis each year in the world is estimated to be about 1.5 million while the number of new cases of Visceral Leishmaniasis is estimated to be about 5,00,000. India is one of the world's largest foci of Visceral Leishmaniasis, accounting for 50% of the total burden of this disease. The disease is caused by 21 protozoan species of the genus *Leishmania* (order Kinetoplastida). The amastigote forms are obligate intracellular parasites while the promastigotes are extracellular in the arthropod vectors. *Leishmania* species are transmitted by female sand flies of the genus *Lutzomyia* in the Americas and *Phlebotomus* in other parts of the world. In India, *Phlebotomus argentipes* is a proven vector of Kala - Azar. The disease is transmitted by the bite of infected female sandflies. The incubation in man is extremely variable. It usually ranges from 3 to 8 months but can be as short as 10 days to as long as two years. There are three main types of the disease : Cutaneous, Diffuse Mucocutaneous and Visceral Leishmaniasis which is commonly called Kala Azar. Immunocompromised individuals progress to full blown Visceral Leishmania with HIV co - infection is has emerged as a serious new disease and is increasingly frequently being reported. AIDS and Visceral Leishmaniasis are mutually reinforcing. Cases of Leishmaniasis should be confirmed by demonstration of the parasite by identifying leishmania amastigotes in Wright - Giemsa - stained touch preparations or tissue sections or by isolating the parasite in culture. The drug of choice for the treatment of Visceral Leishmaniasis is Sodium stibogluconate. However, resistance is on the rise and these patients should be treated with alternative agents, such as liposomal amphotericin (0.5 - 3 mg/kg) on alternate days or pentamidine (2 - 4 mg/kg) on alternate days for 15 doses.

Study Exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of Kala - Azar

Short Notes : (1) Life cycle of *Leishmania* parasite (2) Visceral Leishmaniasis (3) HIV - Visceral Leishmaniasis Co - infection (4) Treatment of Visceral Leishmaniasis

MCQs

1. The disease is endemic in following three countries of the WHO South East Asia Region except (a) Bangladesh (b) India (c) Nepal (d) Sri lanka

2. The disease is reported in _____ no of districts in India (a) 51(b) 52(c) 53(d) 54
3. State which accounts for more than 90 per cent of the cases in India (a) Uttar Pradesh (b) Bihar (c) Assam (d) Madhya Pradesh
4. Leishmania donovani complex comprises of all except (a) Leishmania infantum (b) Leishmania chagasi (c) Leishmania venezuelensis (d) Leishmania donovani
5. Cutaneous Leishmaniasis is also known as all the following except (a) Oriental sore (b) Aleppo evil (c) Delhi boil (d) Espundia

Answers : (1) d; (2) b; (3) b; (4) c; (5) d.

Dengue & Dengue Haemorrhagic Fever

Rajesh Vaidya

Dengue is a vector borne viral disease which occurs in tropical and sub - tropical regions around the world, predominantly in urban and semi - urban areas. Dengue fever (DF) is the most rapidly spreading vector borne viral disease and is a major international public health concern (1, 2). The disease is caused by the four serotypes of the Dengue virus which are arboviruses of the genus *flaviviruses*. The principal vector for the disease is the mosquito *Aedes aegypti*. The disease can present in several forms, from asymptomatic illness to life threatening diseases like Dengue Haemorrhagic Fever (DHF) and Dengue Shock Syndrome (DSS).

The virus is widely distributed in the tropical and subtropical

regions of the world. The global prevalence of Dengue has grown dramatically in recent decades. The World Health Organization reports that the disease is now endemic in more than 100 countries in Africa, the Americas, the Eastern Mediterranean, South - East Asia and the Western Pacific. South - East Asia and the Western Pacific are most seriously affected. WHO currently estimates there may be 50 million cases of Dengue infection worldwide every year. 2.5 billion people live in Dengue endemic countries and are at risk of acquiring the infection (4, 5).

Epidemiology

Global Situation : The geographical extent of the disease has risen significantly in the recent past. It has spread to new areas and reemerged in areas where it appeared to have been controlled. Tropical areas in South - East Asia, Africa, Western Pacific and the Mediterranean are most seriously affected. Prior to 1970 only nine countries had experienced DHF epidemic, a number that had increased by more than four times by 1995. During 1998 over 1.2 million cases with 3, 442 deaths were

reported to WHO which is the largest for any single year. WHO currently estimates there may be 50 million cases of Dengue infection worldwide every year with around 24,000 deaths (5). The rapid rise in the geographical extent of the disease has been attributed to the enhanced geographic distribution of the four Dengue viruses and of their mosquito vectors, particularly the predominantly urban *Aedes aegypti*. A rapid rise in urban population particularly urban slums has contributed to the rise in the number of cases (3, 5). The WHO expects the spread of the disease to continue because of increasing urbanisation, increasing population movement, and proliferation of man-made larval habitats of the mosquito vector.

1.3 billion people living in South - East Asia are at risk of Dengue fever. In 2003 only eight countries in South - East Asia Region reported Dengue cases. By 2006, ten out of the 11 countries which form part of the WHO South - East Asia region were reporting the disease. Bhutan reported the first Dengue outbreak in 2004. An outbreak, with a high case fatality rate (3.55%) was first reported in Timor - Leste in 2005. Nepal reported Dengue cases for the first time in Nov 2006 (6 - 8).

Indian Situation : Large parts of India are endemic for Dengue Fever. The disease is reported from most parts of the country except those at high altitudes. The first major outbreak in India was reported during 1963 in Kolkata. The next major outbreak of Dengue / Dengue Haemorrhagic Fever was reported in Delhi and neighboring states in 1996. Following this outbreak, the reporting of Dengue fever was made mandatory to ensure early preventive measures in case of outbreak. Out of 18 endemic states, the most affected states are Delhi, West Bengal, Kerala, Tamil Nadu, Karnataka, Maharashtra, Rajasthan, Gujarat and Haryana (9). Data for the last 10 years reveals that the largest number of cases and deaths due to Dengue/DHF were reported in 1996 while the next increase was in 2003. 12, 317 cases with 184 deaths were reported to the National Vector Borne Diseases Control Programme in India in 2006 (9). Delhi recorded several outbreaks of Dengue fever between 1967 and 2006. The outbreak in 2006 was estimated to have resulted in 10, 344 cases and 162 deaths (10, 11).

Agent Factors : DF / DHF is caused by Dengue virus which belongs to genus *Flavivirus* family *Flaviviridae* and includes serotypes 1, 2, 3 and 4 (Den - 1, Den - 2, Den - 3 and Den - 4). The Dengue virus is composed of single - stranded RNA. Each serotype provides specific lifetime immunity and short - term cross - immunity. All serotypes can cause severe and fatal disease. There are genetic variations within the serotypes. Some genetic variants within each serotype appear to be more virulent or have greater epidemic potential. When a person has had classic Dengue, a second infection later by another serotype increases the likelihood of suffering from DHF as explained by the immune enhancement mechanism (1, 2, 4). Infection with one serotype provides life - long homologous immunity but does not provide protection against other serotypes, and instead may exacerbate subsequent infection (4, 6, 7).

Vector : *Aedes aegypti* is the main vector of Dengue transmission in India. Another important vector is the *Aedes albopictus*. The mosquito is a peri - domestic and domestic breeder. Mosquito breeding can occur in any water - storage containers, such as desert coolers, flower vases, coconut shells, construction sites,

overhead uncovered or partially covered water tanks, discarded buckets, tyres, utensils and large containers used for collecting rain water which are not emptied and cleaned periodically. The mosquitoes rest indoors on various objects, in closets and other dark places. Outside, they rest where it is cool and shady. *Aedes* mosquito can fly upto a limited distance of 400 meters but can spread over vast distances mechanically in various types of vehicles used by man. *Aedes aegypti* is primarily a day time biter (4, 6, 12, 13).

Environmental Factors : The outbreaks of DF/DHF are most likely to occur in post - monsoon period when the breeding of the mosquitoes is highest. High temperature and high humidity during these seasons prolongs the life span of the vector. The spread of Dengue has resulted from several factors including human behaviour, climate and movement of humans. Usually urban areas, having high population density, poor sanitation and large number of desert coolers, flower vases, construction sites, overhead tanks etc which promote mosquito breeding, are at high risk. Dengue fever/DHF can also occur in rural areas where the environment is friendly for mosquito breeding like storage water for cattle feeding and drinking, cement cisterns and underground cemented water sumps (4, 6, 8).

Transmission : The infection is transmitted by the bite of an infected female mosquito *Aedes aegypti*. Mosquitoes acquire the virus while feeding on the blood of an infected person. After an extrinsic incubation period of 8 to 10 days, an infected mosquito can transmit the virus for the rest of its life. Trans - ovarian transmission of the Dengue virus in mosquitoes maintains the virus in nature. Humans are the main host of the virus, although studies have shown that in some parts of the world monkeys may become infected. The virus circulates in the blood of infected humans for two to seven days (4, 6, 12, 13).

Clinical Presentation

The incubation period of Dengue fever is usually 5 - 6 days, but may vary from 3 to 10 days. Infection with Dengue virus can result in four different clinical syndromes. They are undifferentiated fever, the Classic Dengue fever, Dengue Haemorrhagic fever (DHF) and Dengue Shock syndrome (DSS) (14 - 16).

Undifferentiated Fever : This is the most common manifestation of Dengue infection. Almost 90% of those infected remain either asymptomatic or only mildly symptomatic. The patient has fever, headache, body ache and may develop a mild rash.

Classic Dengue Fever : This is characterized by abrupt onset of high fever, severe headache, severe muscle and joint pain (Break Bone Fever), rash and other haemorrhagic manifestations.

Dengue Haemorrhagic Fever : DHF is a potentially deadly complication that is characterized by high fever, accompanied by headache, anorexia, vomiting and abdominal pain. Petechiae on the extremities, face, and trunk are the manifestations of haemorrhage. Bleeding from nose, gums and gastrointestinal tract may be found. In moderate cases, spontaneous mucocutaneous bleeding, nasal bleeding and GI bleeding usually occur. In severe cases, the patient's condition may suddenly deteriorate after a few days of fever. Any case with fever, or recent history of acute fever, haemorrhagic manifestations, low

platelet count (100,000/mm or less), and objective evidence of “leaky capillaries” in the form of elevated haematocrit (20% or more over baseline), low albumin, or pleural or other effusions meets the case definition for DHF.

Dengue Shock Syndrome : Patients may rapidly develop varying degree of circulatory disturbances and go into a critical state of shock. Patients with DHF who develop evidence of circulatory failure manifested indirectly by rapid and weak pulse, narrow pulse pressure (< 20 mm Hg) or hypotension for age, cold, clammy skin and altered mental status meet the criteria for DSS. Frank shock is direct evidence of circulatory failure. Prolonged shock is often complicated by metabolic acidosis and severe bleeding. Case fatality rates can exceed 20% in such patients. A major cause of deaths due to DHF is leakage of plasma in the pleural and abdominal cavities leading to hypovolaemic shock. Encephalitic signs associated with intracranial haemorrhage, metabolic and electrolyte disturbances, and hepatic failure may occur.

Differential Diagnosis

Differential diagnosis must include all other arboviral fevers, measles, rubella and other systemic febrile illnesses, especially those accompanied by rash (6). The presence of marked thrombocytopenia with concurrent haemoconcentration differentiates DHF / DSS from other syndromes such as endotoxic shock from bacterial or meningococcaemia.

Alarming Signs

- (a) Minute spots on the skin suggesting bleeding within the skin.
- (b) Nose bleeds and gum bleeds, haemetemesis.
- (c) Abdominal pain and/or passage of black tarry stool.
- (d) Refusal to food or drink.
- (e) Abnormal behaviour or drowsiness.
- (f) Difficulty in breathing or cold hands and feet, reduced amount of urine being passed.

Diagnosis

Patients suspected to be suffering from Dengue fever must undergo repeated clinical laboratory tests : Complete Blood Counts including WBC, platelets, haematocrit, Liver function tests, and urine analysis for microscopic haematuria. These blood tests may indicate a diagnosis of Dengue fever and DHF / DSS. Thrombocytopenia (100,000 cells or less per mm) and haemoconcentration as evidenced by a greater than 20% rise in average haematocrit for age and sex are the haemotological criteria for diagnosis.

Laboratory tests essential for confirmatory diagnosis of Dengue infection include isolation of the virus, demonstration of a rising titre of specific serum Dengue antibodies, and demonstration of a specific viral antigen or RNA in the tissue or serum. Virus isolation can be done by inoculation of clinical material in tissue culture, mosquitoes or suckling mice and further detection is performed using fluorescent antibody test or haemagglutination inhibition test. Viral antigen can be demonstrated by doing direct fluorescent antibody test using specific monoclonal antibodies for Dengue virus. Viral RNA or genomic sequence can also be detected in autopsy specimen, serum, CSF or culture supernatant by doing Polymerase Chain Reaction (PCR) and gene sequencing.

Serological diagnosis is based on detection of IgM antibodies. IgM antibodies against Dengue virus appear around 5 days after onset of symptoms and are detectable for one to three months after the illness. The tests employed are IgM capture ELISA test and Rapid IgM strip test. IgM capture ELISA test kit is available from NIV Pune and commercial sources and Rapid IgM Strip Test kit is available commercially.

Treatment

The basics of management of cases of Dengue fever are fluids, rest, antipyretics (avoid aspirin and non - steroidal anti-inflammatory drugs) and close monitoring of blood pressure, haematocrit, platelet count and level of consciousness. Liberal fluids intake including home available fluids like rice water, kanji, fruit juices, plain water or ORS solution are recommended for patient with excessive sweating, nausea, vomiting or diarrhoea to prevent dehydration (1, 3). Monitoring must be continued after defervescence. If the level of hydration falls intravenous fluids, guided by serial haemotocrits, blood pressure, and urine output must be given. The volume of fluid needed is similar to the treatment of diarrhoea with mild to moderate isotonic dehydration.

Management of DHF : Patients of DHF need regular assessment by serial haematocrit levels. Urine output should be monitored closely in areas where serial haematocrit estimation is not possible. A rise in haematocrit of 20% or more or single haematocrit value of more than 40%, platelets count of 50,000/cmm or less and spontaneous haemorrhage are all danger signs.

Management of DSS : DSS patients present with shock. Volume replacement is the most important treatment measure and immediate administration of intravenous fluids to expand plasma volume is essential. Close observation with good nursing care is imperative. Blood transfusion should be given in case with significant haemorrhage. Fresh frozen plasma or concentrated platelet transfusion may be given when disseminated intravascular coagulation causes massive bleeding. Readers may refer to standard texts for details on management of patients (3, 4, 14 - 17)

Prevention and Control

Vector Control : Vector control and personal protective measures are the mainstay of prevention of Dengue infections. Both aspects are dealt with in detail in the chapter on Entomology.

Surveillance : Epidemiological surveillance of the disease as well as the vector form an important part of control measures. The disease surveillance should include fever surveillance, diagnosis based on standard case definitions, and reporting of DF/DHF cases to state health authorities. Vector surveillance includes both larval and adult vector surveillance (18). A number of indices have been described and are currently used to monitor the vector population :

House index : Percentage of houses positive for larvae of *Aedes aegypti*. House index of more than 10% indicates high risk of transmission

Breteau index : Number of positive containers for *Aedes aegypti* per 100 houses. An index of more than 50 indicates high risk of transmission while index below five indicates low risk of transmission.

Notification : Dengue is a cross border disease. With massive air travel, outbreaks can rapidly cross international borders. Outbreaks must, therefore, be notified at the earliest to both the national as well as international health authorities.

Vaccine : No effective vaccine is available for Dengue. Research into Dengue vaccines has focused on the use of live attenuated or inactivated vaccines, infectious clone derived vaccines, and nucleic acid vaccine (19).

Summary

Dengue is a vector borne viral disease which occurs in tropical and sub - tropical regions around the world. Dengue fever is the most rapidly spreading vector borne viral disease and is a major international public health concern. WHO currently estimates there may be 50 million cases of Dengue infection worldwide every year. 2.5 billion people live in Dengue endemic countries and are at risk of acquiring the infection. Large parts of India are endemic for Dengue Fever. The first major outbreak in India was reported during 1963 in Kolkata. Indian data for the last 10 years reveals that the largest number of cases and deaths due to Dengue/DHF were reported in 1996 while the next increase was in 2003. DF / DHF is caused by Dengue virus which belongs to genus *Flavivirus* family *Flaviviridae* and includes serotypes 1, 2, 3 and 4. All serotypes can cause severe and fatal disease. *Aedes aegypti* is the main vector of Dengue transmission in India. Another important vector is the *Aedes albopictus*. The infection is transmitted by the bite of an infected female mosquito *Aedes aegypti*. The incubation period of Dengue fever is usually 5 - 6 days, but may vary from 3 to 10 days. Clinical Presentation comprises of Undifferentiated Fever, Classic Dengue Fever, Dengue Haemorrhagic Fever and Dengue Shock Syndrome. Complete Blood Counts, Liver function tests, and urine analysis for microscopic haematuria indicate a diagnosis of Dengue fever and DHF / DSS. Confirmatory diagnosis of Dengue is done by isolation of the virus, demonstration of a rising titre of specific serum Dengue antibodies, and demonstration of a specific viral antigen or RNA in the tissue or serum. The basics of management of cases of Dengue fever are fluids, rest, antipyretics. In DSS volume replacement is the most important treatment measure and immediate administration of intravenous fluids to expand plasma volume is essential. Prevention and Control comprise of Vector Control, epidemiological surveillance of the disease as well as the vector and notification at the earliest to both the national as well as international health authorities.

Study exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of Dengue.

Short Notes : (1) Spectrum of clinical presentation of Dengue (2) Enlist Alarming sign's in Dengue Fever (3) Indices of vector population

MCQs

1. Prior to 1970 only _____ countries had experienced DHF epidemic (a) 3 (b) 5 (c) 7 (d) 9
2. In which city was the first major outbreak in India during 1963 reported ? (a) Mumbai (b) Kolkata (c) Delhi (d) Chennai

3. Dengue virus has how many serotypes (a) 2 (b) 4 (c) 6 (d) 8.
4. IgM antibodies against Dengue virus appear around _____ days after onset of symptoms (a) 3 (b) 5 (c) 7 (d) 9
5. House index of more than ____ % &/or Breteau index of more than ___ indicates high risk of transmission (a) 5 & / or 40 respectively b)10 &/ or 50 respectively (c) 15 &/ or 60 respectively (d)20 &/ or 70 respectively

Answer : (1) d; (2) b; (3) b; (4) b; (5) b.

Rajesh Vaidya

Chikungunya fever is an arboviral illness characterized by severe, persistent joint pains, fever and rash. The disease resembles dengue fever and is spread by the bite of infected mosquitoes. It is rarely life - threatening. However, widespread occurrence of the disease causes substantial morbidity and economic loss. Chikungunya virus disease has occurred sporadically in India and Southeast Asia for at least 200 years. Epidemics with symptoms resembling Chikungunya fever have been recorded as early as 1824 in India (1). Over the last 40 years, several widespread epidemics have occurred in many cities of India and Southeast Asia affecting thousands of people (2, 3). Occasionally, epidemics of Dengue and Chikungunya have occurred simultaneously in the same community, making clinical differentiation of the two diseases difficult. Unlike Dengue which has become endemic in many parts of Asia, Chikungunya virus disappears and reappears at irregular intervals. The name Chikungunya originates from Swahili, and means "that which bends up," which refers to the characteristic posture assumed by patients suffering severe joint pains. Chikungunya virus was first isolated during a 1952 epidemic in Tanzania (2, 3).

Epidemiology

Global : The Chikungunya virus is probably maintained in nature by transmission between jungle primates (4). The disease displays a striking epidemiological profile with major epidemics appearing and disappearing cyclically, usually with an inter - epidemic period of 7 - 8 years and sometimes as long as 20 years (1). Currently, Chikungunya is a major arboviral disease in urban parts of Africa and Asia. The known geographic distribution of the virus includes large parts of Sub - Saharan Africa, Southeast Asia including Indonesia, Philippines, and India, as well as islands in the South - West Indian Ocean (2, 3). Other affected regions include Mauritius and Seychelles in the Indian Ocean. Imported cases have been reported by European countries like France, Germany, Italy, Norway and Switzerland (5 - 7).

India : The virus was first isolated in India from Kolkata in 1963 (8). In the mid sixties outbreaks resembling Chikungunya were reported from various parts of India including Vellore, Kolkata and parts of Maharashtra (1). The last outbreak of Chikungunya virus infection was reported in 1971. There has been no active or passive surveillance of Chikungunya and therefore, it appeared that the virus had disappeared from the country (9). Since 2005, however, there have been several reports of outbreaks from widespread parts of the country and the re - emergence of the virus has been confirmed (10 - 12). In the present outbreak, 151 districts of eight states of India have reported Chikungunya fever as of Oct 2006. The affected states are Andhra Pradesh, Andaman & Nicobar Islands, Tamil Nadu, Karnataka, Maharashtra, Gujarat, Madhya Pradesh, Kerala and Delhi. More than 1.25 million cases have been reported from the country with 7, 52, 245 cases from Karnataka and

2, 58, 998 from Maharashtra. In some areas attack rates have reached up to 45% (1).

Agent : The Chikungunya virus is an arbovirus belonging to the group *alphaviruses* of the family *Togaviridae*. It is believed that there are two distinct lineages of the Chikungunya virus, one containing Western African and the second comprising all Southern and East African strains. The virus originated in Africa and was subsequently introduced into Asia (12).

Vector : Chikungunya is transmitted by mosquitoes, including many *Aedes species* which bite during daylight hours. In some parts of the world *Culex species* are important vectors. In India, the two important vectors are *Aedes aegypti* and *Aedes albopictus*, both of which also transmit dengue virus (13).

Transmission : There appear to be two distinct transmission cycles for Chikungunya virus. A sylvatic cycle between wild primates and arboreal *Aedes* mosquitoes, similar to that of sylvatic Yellow fever virus in the same region has been seen in Africa. Urban Chikungunya outbreaks are associated with *Aedes aegypti* transmission in a human - mosquito - human cycle. Urban outbreaks are sporadic in occurrence but explosive in nature. Till recently it was believed that there is no direct person - to - person transmission. However, vertical maternal foetal transmission of the virus has been documented in an outbreak at La Reunion Island (14). The virus has been isolated from monkeys in Africa (15). There is a risk for travellers in areas where Chikungunya is endemic and in areas affected by epidemics (16, 17).

Clinical Features

The Incubation period is usually 2 - 3 days with a range of 1 - 12 days (3). The onset is with fever, chills, headache, photophobia, backache, nausea, vomiting, arthralgia, and rash. The acute illness usually lasts about 3 to 5 days but can be very severe. Most patients recover completely within 5 to 7 days. More than three fourths of the patients complain of severe arthralgia. One or more joints may be involved, with swelling and redness. Another characteristic feature is the rash which is maculopapular and mainly involves the trunk. In some cases the joint pains may persist for weeks, months or even longer. Chikungunya may also be asymptomatic (2, 5, 18 - 21). Children may suffer from febrile convulsions. Infrequently, haemorrhagic manifestations (petechiae, purpura, epistaxis) also have been reported.

Diagnosis

Any illness with the classical triad of fever, rash, and joint pains in endemic areas must give rise to suspicion of Chikungunya. The definitive diagnosis can only be reached by serology or isolation of the virus. Alphaviruses can usually be recovered from blood taken during the first few days of illness. Seroconversion can be shown in acute and convalescent serum samples drawn two weeks apart. Virus - specific IgM antibodies can be detected by capture ELISA in patients recovering from Chikungunya infection and they decline within 3 - 6 months. Haemagglutination inhibition antibodies appear as the viraemia declines. Patients usually become positive by the 5th to 7th day of illness. RT - PCR can be used for molecular diagnosis at specialized centre (12, 20).

Differential Diagnosis

Chikungunya infection is often mistaken for dengue, which has a similar distribution in Asia and Africa. It may also be confused with West Nile virus infection.

Treatment

Treatment is symptomatic and includes antipyretic and anti-inflammatory drugs. Aspirin should be avoided because of reports of mild haemorrhagic manifestations. Movement and mild exercise tend to improve stiffness and morning arthralgia, but heavy exercise should be avoided as it may exacerbate rheumatic symptoms. Although the joint symptoms may persist for months, Chikungunya is generally an acute, self-limited infection with no deaths reported. Patients should be nursed under mosquito nets during the viraemic stage to avoid transmission of the disease (2, 5, 21).

Prevention and Control

There is no vaccine against this arboviral disease. No specific treatment is available. Prevention is entirely dependent upon taking steps to avoid mosquito bites and elimination of mosquito breeding sites. Control measures consist of vector control activities as outlined for dengue earlier. Details about vector control and personal protective measures are given in the Chapter on Entomology.

Summary

Chikungunya fever is an arboviral illness characterized by severe, persistent joint pains, fever and rash. The name Chikungunya originates from Swahili, and means "that which bends up," which refers to the characteristic posture assumed by patients suffering severe joint pains. The disease appears and disappears cyclically, usually with an inter-epidemic period of 7-8 years. The known geographic distribution of the virus includes large parts of Sub-Saharan Africa, Southeast Asia including India. Chikungunya is transmitted by mosquitoes, including many *Aedes species*. In India, the two important vectors are *Aedes aegypti* and *Aedes albopictus*. Urban Chikungunya outbreaks are associated with *Aedes aegypti* transmission in a human-mosquito-human cycle. The incubation period is usually 2-3 days with a range of 1-12 days (3). The onset is with fever, chills, headache, photophobia, backache, nausea, vomiting, arthralgia, and rash. Most patients recover completely within 5 to 7 days. More than three fourths of the patients complain of severe arthralgia. Any illness with the classical triad of fever, rash, and joint pains in endemic areas must give rise to suspicion of Chikungunya. The definitive diagnosis can only be reached by serology or isolation of the virus. Treatment is symptomatic and includes antipyretic and anti-inflammatory drugs. There is no vaccine against this arboviral disease. No specific treatment is available. Prevention is entirely dependent upon taking steps to avoid mosquito bites and elimination of mosquito breeding sites.

Study Exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of Chikungunya.

Short Note : Control measures for Chikungunya.

Rajesh Vaidya

Japanese Encephalitis (JE) is an arboviral disease spread by Culicine mosquitoes. The disease presents periodically in epidemic form in areas such as northern India, parts of central and southern India. An overwhelming majority of the infections are asymptomatic. However, among symptomatic individuals case fatality rates may be higher than 20%. The public health importance of this vaccine preventable disease lies in the fact that most infections occur among children and that a sizeable proportion of the survivors are left with permanent neurological and/or psychiatric sequelae (1). The incidence of Japanese encephalitis has shown an increasing trend in recent times and the disease is fast becoming a major public health problem in India (2).

Epidemiology

Global : Japanese encephalitis infections occur throughout the temperate and tropical zones of Asia. The annual incidence of Japanese encephalitis disease varies considerably from one country to the other as well as within affected countries, ranging from less than 10 to more than 100 per 100,000 population. Nearly 3 billion people or close to half the global population live in Japanese encephalitis endemic regions. Over 50,000 cases are reported worldwide every year with 10,000 deaths (3). The disease periodically becomes hyperendemic in areas such as northern India, parts of central and southern India, southern Nepal, and northern Vietnam (3). Other countries reporting large number of cases of Japanese encephalitis include Philippines, Thailand, Cambodia, Myanmar, and Sri Lanka. Though named Japanese encephalitis, the disease is now rare in Japan, due to extensive vaccination and adequate vector control.

India : In India Japanese encephalitis was first reported in 1955 from Vellore in Tamil Nadu (4). Currently this disease is reported from 26 states in India. Of these, only 15 states are reporting JE regularly. The total population at risk is estimated to be 160 million (5). A disturbing feature of Japanese encephalitis reporting in India has been the occurrence of several large outbreaks from different parts of the country. The first major outbreak of JE was reported from West Bengal in 1973 in two districts followed by another outbreak in 1976. Subsequently outbreaks have been reported from the states of Bihar, Uttar Pradesh, Assam, Manipur, Andhra Pradesh, Karnataka, Madhya Pradesh, Maharashtra, Tamil Nadu, Haryana, Kerala, West Bengal, Orissa and union territories of Goa and Pondicherry (2). In the recent past the reported annual incidence in India has ranged between 1,765 and 3,428 and deaths between 466 and 707 (6).

Agent : Japanese encephalitis virus belongs to the family Flaviviridae, which are single - stranded RNA viruses. Like other flaviviruses, the Japanese encephalitis virus is an enveloped, plus sense virus. It is antigenically related to several other flaviviruses including dengue virus, St. Louis encephalitis virus, Murray Valley virus and West Nile virus (2). The envelope glycoprotein of the JE virus contains specific as well as cross

- reactive, neutralizing epitopes. The virus contains several structural and non - structural polypeptides, which are encoded by a single long open reading frame (7). The virus has two sub types, *Nakayam* and *Jagar* - 01 (2). The major genotypes of this virus have different geographical distribution, but all belong to the same serotype and are similar in terms of virulence and host preference (3).

Vector : Anthropophilic culicine mosquitoes transfer the virus to humans from animal amplifying hosts, principally domestic pigs and wading birds. The virus is transmitted chiefly by the bites of mosquitoes of the *Culex vishnui* complex; with individual vector species differing in specific geographic areas. In India and many endemic areas in Asia, *Culex tritaeniorhyncus* is the principal vector. This species feeds outdoors beginning at dusk and during evening hours until dawn. It breeds in water pools, marshes, flooded rice fields, and small stable collections of water around cultivated fields. This vector has a wide host range, including domestic animals, birds, and humans. In temperate zones, the vectors are present in greatest numbers from June through September and are inactive during winter months (8).

Host Factors : Pigs and aquatic birds (mainly herons and egrets of the *Ardeidae* family) are the natural hosts for the virus. Pigs are considered amplifying hosts since they allow manifold virus multiplication without suffering from disease and maintain prolonged viraemia (6). Viraemic adult pigs remain asymptomatic, but pregnant sows may abort or deliver still births. Humans are dead end accidental hosts.

Among humans, the virus has no specific age or sex predilection. In areas where the virus has been recently introduced, all age groups are affected equally. In endemic areas, however, most people are infected below the age of 15 years. In hyper - endemic areas, half of all Japanese encephalitis cases occur before the age of four years, and almost all before 10 years of age. Only one out of 250 to 500 JE viral infections lead to symptomatic disease. Those endemic regions where childhood JE vaccination has been widely implemented have experienced a shift in the age distribution of cases towards older children and adults (3). In India, Japanese encephalitis is considered to be largely a paediatric problem. Young children below 10 years of age are more likely to die, and if they survive, are more likely to have residual neurological sequelae (2).

Environmental Factors : Environmental factors related to transmission of JE are related principally to temperature and humidity conditions conducive to breeding and survival of the vector. In tropical and subtropical areas, transmission intensifies in the rainy season. In temperate locations, transmission usually starts in April and may last until October. In irrigated areas, transmission may occur even in the dry season (3). Habitats supporting the transmission cycle of JE virus are principally in rural, agricultural locations. In many areas of Asia, appropriate ecologic conditions for virus transmission occur near and even within urban centres (8). In many Asian countries, major outbreaks of JE occur at intervals of 2 - 15 years (3).

Clinical Features

The incubation period of Japanese encephalitis ranges from

4 to 14 days (3). The virus initially multiplies at the site of the bite and in the draining lymph nodes. Subsequently, viremia develops, leading to inflammatory changes in the heart, lungs, liver, and reticuloendothelial system. Most infections are cleared before the virus can invade the central nervous system (CNS). However, neurologic invasion can develop leading to involvement of large areas of the brain, including the thalamus, basal ganglia, brain stem, cerebellum, hippocampus, and cerebral cortex (9). Most infected persons develop mild symptoms or no symptoms at all. Symptoms soon after exposure appear 6 - 8 days after the bite of an infected mosquito. The disease is characterized by sudden onset of fever, chills, body ache and mental confusion. Severe cases may progress to coma. In children, gastrointestinal pain and vomiting may be the dominant initial symptoms. Irritability, vomiting and diarrhoea or an acute convulsion may be the earliest objective signs of illness in an infant or child. JE may present as a mild disease, leading to an uneventful recovery, or may rapidly progress to severe encephalitis with mental disturbances, general or focal neurological abnormalities and coma.

Out of the approximately 50,000 cases of JE that are estimated to occur each year, about 10,000 end fatally, and about 15,000 of the survivors are left with neurological and/or psychiatric sequelae, requiring rehabilitation and continued care (2, 3). Approximately 33 - 50% of patients who survive have major neurologic sequelae at one year, including seizure disorders; motor or cranial nerve paresis, or movement disorders. Nearly 75% of symptomatic patients with JE who are evaluated five years after the disease score lower than uninfected subjects on standardized tests (9).

Diagnosis

JE is clinically indistinguishable from other forms of viral encephalitis. History of exposure to mosquitoes in an endemic area or during an epidemic may be elicited. A CBC count often shows nonspecific modest leukocytosis in the first week of illness. A mild anaemia also may be present. Some studies have reported thrombocytopenia in children with Japanese encephalitis (9). Neutrophils predominate in early CSF samples but a lymphocytic pleocytosis is typical. CSF protein is moderately elevated in about 50% of cases (2).

Confirmation of a suspected case of Japanese encephalitis is mainly based on serology using IgM - capture ELISA which detects specific IgM in the cerebrospinal fluid or in the blood of almost all patients within 7 days of onset of disease. Other methods include conventional antibody assays on paired sera for the demonstration of a significant rise in total JE - specific antibody, as well as a dot - blot IgM assay, suitable for use in the field (3).

Case Definitions for JE Diagnosis and Reporting (6)

Clinical Suspect : Febrile illness of variable severity associated with neurological symptoms ranging from headache to meningitis or encephalitis. Symptoms can include headache, fever, meningeal signs, stupor, disorientation, coma, tremors, paralysis (generalized), hypertonia, loss of coordination (Patient with fever, altered sensorium lasting more than 6 hours, no skin rash & other known causes of encephalitis excluded).

Probable : A suspected case with presumptive laboratory results: Detection of an acute phase anti - viral antibody response through IgM in serum/ elevated and stable JE antibody titres in serum through ELISA/ HI/ Neutralizing assay.

Confirmed : A suspect case with confirmed laboratory result: JE IgM in CSF or 4 fold or greater rise in paired sera (acute and convalescent) through IgM/IgG ELISA, HI, Neutralization test or detection of virus, antigen or genome in tissue, blood or other body fluid by immuno - chemistry, immunofluorescence or PCR.

Treatment

There is no specific anti - viral medicine available against JE virus. The cases are managed symptomatically. Clinical management of JE is supportive and in the acute phase is directed at maintaining fluid and electrolyte balance and control of convulsions, if present. However, treating raised intracranial pressure and convulsions have been reported to decrease the mortality and morbidity significantly (10).

Prevention and Control

Vector control and vaccination are the two primary strategies for control of Japanese Encephalitis. In countries such as Japan and Korea the incidence of JE has decreased over several decades, primarily as a result of extensive use of JE vaccines. Improved socioeconomic conditions, changed life styles and control measures such as centralized pig production and the use of insecticides may also have contributed to this development (3). Details on vector control are available in the chapter on Entomology.

Vaccines : Three types of vaccines are currently in use against Japanese encephalitis. The mouse brain - derived, purified and inactivated vaccine, which is based on either the *Nakayama* or *Beijing* strains of the JE virus and is produced in several Asian countries including India. Another inactivated vaccine is the cell culture - derived, vaccine based on the viral *Beijing P - 3* strain. A live attenuated vaccine widely used in China is the cell culture - derived vaccine based on the *SA 14 - 14 - 2* strain of the JE virus (3).

The mouse brain - derived JE vaccine is used in India. It is produced by the Central Research Institute, Kasauli. Three doses are required to produce primary immunization. Two doses of 1 ml (0.5 ml for children below three years) are administered sub - cutaneously within a gap of 7 - 14 days followed by third dose any time after one month and before one year of the second dose. A booster is required after 3 years (6). Several other Asian countries have adopted a similar schedule of two primary doses four weeks apart, followed by a booster after one year. In some countries, subsequent boosters are recommended, usually at about 3 - year intervals up to the age of 10 to 15 years (3). For travellers aged more than one year visiting rural areas of endemic countries, the established practice is to administer 3 primary doses at days 0, 7 and 28 or two primary doses preferably four weeks apart.

The mouse brain - derived JE vaccine is been considered safe. Local reactions such as tenderness and swelling occur in about 20% of vaccinees. Mild systemic symptoms, including headache, myalgia, gastrointestinal symptoms and fever may

also occur. Being a killed vaccine, only contraindication to the use of this vaccine is a history of hypersensitivity reactions to a previous dose. Pregnant women should be vaccinated only when at high risk of exposure to the infection. The vaccine can be given to HIV infected individuals (3). The biggest limitation of the mouse derived killed vaccine is that rapid large scale production of the vaccine is not feasible.

The live attenuated vaccine was licensed in China in 1989. Extensive use of this and other vaccines has significantly contributed to reducing the burden of JE in China. The vaccine has recently been licensed for use in India. It is administered in two doses at an interval of one year.

WHO Position on JE Vaccines : The World Health Organization recommends that JE immunization should be integrated into the EPI programmes in all areas where JE constitutes a public health problem. The most effective immunization strategy in JE - endemic settings is one time catch - up campaigns including child health weeks or multi - antigen campaigns in the locally - defined primary target population, followed by incorporation of the JE vaccine into the routine immunization programme (3).

Summary

Japanese encephalitis is an arboviral disease spread by culicine mosquitoes. The public health importance of this vaccine preventable disease lies in the fact that most infections occur among children and that a sizeable proportion of the survivors are left with permanent neurological and/or psychiatric sequelae. Nearly 3 billion people or close to half the global population live in Japanese encephalitis endemic regions. Over 50,000 cases are reported worldwide every year with 10000 deaths. In India Japanese encephalitis was first reported in 1955 from Vellore in Tamil Nadu. Currently this disease is reported from 26 states in India. Japanese encephalitis virus belongs to the family Flaviviridae, which are single - stranded RNA viruses. Anthropophilic culicine mosquitoes transfer the virus to humans from animal amplifying hosts, principally domestic pigs and wading birds. The virus is transmitted chiefly by the bites of mosquitoes of the *Culex vishnui* complex. In India and many endemic areas in Asia, *Culex tritaeniorhyncus* is the principal vector. Pigs and aquatic birds are the natural hosts for the virus. Humans are dead end accidental hosts. In hyper - endemic areas, half of all Japanese encephalitis cases occur before the age of four years, and almost all before 10 years of age. Only 1 in 250 to 500 JE viral infections result in symptomatic disease. The incubation period of Japanese encephalitis ranges from 4 - 14 days. The disease is characterized by sudden onset of fever, chills, body ache and mental confusion. Severe cases may progress to coma. JE is clinically indistinguishable from other forms of viral encephalitis. Confirmation of a suspected case of Japanese encephalitis is mainly based on serology using IgM. There is no specific anti - viral medicine available against JE virus. The cases are managed symptomatically. Vector control and vaccination are the two primary strategies for control of

Japanese Encephalitis. Three types of vaccines are currently in use against Japanese encephalitis. The mouse brain - derived, purified and inactivated vaccine, which is based on either the *Nakayama* or *Beijing* strains of the JE virus. A live attenuated vaccine widely used in China is the cell culture - derived vaccine based on the *SA 14 - 14 - 2* strain of the JE virus. The World Health Organization recommends that JE immunization should be integrated into the EPI programmes in all areas where JE constitutes a public health problem.

Study Exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of Japanese encephalitis.

Short Notes : (1) Case definitions for JE, Diagnosis and Reporting (2) Vaccines for Japanese Encephalitis

MCQs :

1. Currently this disease is reported from ____ no. of states in India (a) 23 (b) 24 (c) 25 (d) 26
2. Japanese encephalitis virus is (a) Single - stranded RNA Virus (b) Double - stranded RNA Virus (c) Single - stranded DNA Virus (d) Double - stranded DNA Virus
3. In India principal vector for JE is (a) *Culex quinquefasciatus* (b) *Culex tritaeniorhyncus* (c) *Aedes vittatus* (d) *Aedes niveus*
4. Natural host for the virus are (a) Humans (b) Cattle (c) Pigs (d) Monkeys
5. Cell culture - derived vaccine is based on the _____ strain of the JE virus (a) *SA 14 - 14 - 1* (b) *SA 15 - 15 - 1* (c) *SA 14 - 14 - 2* (d) *SA 15 - 15 - 2*

Answers : (1) d; (2) a; (3) b; (4) c; (5) c.

Rickettsial diseases occur in all parts of the world and are a significant cause of morbidity and mortality (1). The occurrence of rickettsial diseases often goes unrecognized because of difficulties in arriving at a definitive diagnosis. Lately, however, Rickettsiae are being recognized as emerging or re-emerging pathogens in many places of the world making them the cause of some of the oldest and most recently recognized infectious diseases (2, 3). New genetic tools have led to the discovery of many new rickettsial diseases over the past 20 years (4). Of the 14 currently recognized rickettsioses, six have been described within the last 12 years (5). Although rickettsiae require living cells for growth, they are true bacteria as they have metabolic enzymes and cell walls, and are susceptible to antibiotics. Most rickettsial infections result in zoonotic diseases which are maintained in nature through a complex interaction between mammalian reservoirs and invertebrate factors (ticks, mites, fleas, and lice). An important feature of rickettsial infections is that some invertebrate vectors can also serve as reservoirs. Humans are usually accidental hosts and play little role in natural disease transmission.

Different authors have grouped Rickettsial diseases in several ways. Rickettsial diseases are usually divided into four groups:

Spotted fever group; Typhus group; Scrub typhus (or *Orientia* group); and others (1, 6).

Epidemiology

Global : The geographic as well as temporal distribution of rickettsial diseases is largely determined by their vectors. Louse borne rickettsial diseases are reported from across the world. Common flea species like the dog, cat, and rat flea are also global in distribution. As a consequence, rickettsial diseases transmitted by them are also reported from all parts of the world. Ticks are more restricted in their distribution. Tick borne diseases are, therefore, more localized in their distribution. The geographic distribution of rickettsial agents is described in Table - 1.

India : Rickettsioses are reported from many parts of India. A large number of studies have documented outbreaks of rickettsial diseases, particularly Scrub typhus among Indian Armed Forces personnel from different parts of the country (7 - 13). Occurrence of Rickettsioses, including scrub typhus as well as spotted fevers have been reported from Himachal Pradesh, Maharashtra, Assam, West Bengal, Kerala and Tamil Nadu (2, 14 - 19).

Agent : Rickettsiae are a diverse collection of organisms with several differences. The common threads that hold the rickettsiae into a group are their epidemiology and their obligate intracellular lifestyle. The classification of rickettsia has seen a significant reorganization in the recent past particularly

Table - 1 : Epidemiologic Features of Rickettsial Diseases (20)

Disease Group	Disease	Agent	Vector	Animal Reservoir	Geographical Distribution
Typhus Group	Epidemic typhus	<i>Rickettsia prowazekii</i>	Human body louse (<i>Pediculus humanus corporis</i>),	Humans	Mountainous regions of Africa, Asia, and Central and South America. <i>India</i> - J&K, Himachal, Uttarakhand, W Bengal, Arunachal Pradesh.
	Murine typhus	<i>Rickettsia typhi</i>	Rat flea (<i>Xenopsylla cheopis</i>)	Rats, mice	Worldwide
	Indian Tick Typhus	<i>Rickettsia conorii</i>	Tick (<i>Ixodes sp</i> <i>Boophilus sp</i> <i>Haemophysalis sp</i>)	Dogs, rodents	Africa, India, Europe, East, Mediterranean, <i>India</i> - Uttaranchal
Spotted Fever Group	Rickettsial pox	<i>Rickettsia akari</i>	Mite	House mice	Russia, South Africa, Korea, Turkey, Balkan countries
	Rocky Mountain spotted fever	<i>Rickettsia rickettsii</i>	Tick	Rodents	Mexico, Central and South America
Orientia	Scrub typhus	<i>Orientia tsutsugamushi</i>	Mite (<i>L deliense</i>)	Rodents	Asia and Australia <i>India</i> - J&K, Himachal, Uttarakhand, W Bengal, Arunachal Pradesh
Others	Q fever	<i>Coxiella burnetii</i>	Inhalation of infectious aerosols; tick	Goats, sheep, cattle, cats	Worldwide

due to technological advances in molecular genetics. The order *Rickettsiales* has two families *Rickettsiaceae* and *Anaplasmataceae*. The family *Rickettsiaceae* has two genera : *Rickettsia* and *Orientia*. The family *Anaplasmataceae* has five genera. At least 26 agents from the order *Rickettsiales* have been recognized as human pathogens (1). *Rickettsia* are small (0.3 X 2 μm) aerobic, obligate intracellular parasites. They are Pleomorphic, usually coccobacillary. They appear blue with Giemsa's stain and their growth is enhanced in the presence of sulphonamides.

Host : Groups at risk for exposure to agents of rickettsial diseases are travellers, wood cutters, farmers and armed forces personnel as their occupational or recreational activities bring them in contact with habitats that support the vectors or animal reservoir species associated with these pathogens (21).

Transmission : Rickettsiae are transmitted to humans by the bite of infected ticks and mites and by the contamination of the bite or other skin wounds with the faeces of infected lice and fleas. The rickettsiae present in the dried excreta of insects may also enter through the conjunctivae or even through inhalation. In ticks and mites transovarial and trans -stadial transmission of rickettsia frequently occurs. After entering the body rickettsia spread through the bloodstream to infect vascular endothelium in the skin, brain, lungs, heart, kidneys, liver, gastrointestinal tract and other organs.

Clinical Features

Most rickettsial diseases are characterized by the classical triad of fever, headache, and rash. Hepatosplenomegaly and myalgia are often accompanying features. Rash is absent in Q fever and in several of the newly recognized rickettsial infections. About half the patients infected by a tick or mite bite develop a typical eschar at the bite site.

Diagnosis

Confirmation of diagnosis is done most often by serology. Titres of specific antibodies rise to diagnostic levels usually by the second week of illness (1). Indirect Fluorescent Antibody (IFA) and ELISA tests are available for serology. The Weil - Felix test, which uses the OX and K strains of *Proteus mirabilis*, is still the most widely used diagnostic test in India. However, the test is not very sensitive. PCR is also being increasingly used to confirm the diagnosis (4).

Treatment

Tetracyclines are the antibiotic of choice against rickettsial infections. Doxycycline is the most commonly prescribed drug. Chloramphenicol should be used for infections in pregnant women but caution should be exercised in the third trimester because of the risk of "gray baby syndrome". Chloramphenicol is not considered effective against Ehrlichioses. The clinical features, diagnosis and treatment of common rickettsial diseases is given in Table - 2.

Prevention and Control

The essential method of prevention is avoidance of potentially vector infected areas and the use of personal protective measures. The use of insect repellents such as DEET and DEPA in combination with appropriate clothing such as long sleeves and anklets may be useful in avoiding contact with vectors.

Scrub Typhus

Scrub typhus is caused by *Orientia tsutsugamushi* and transmitted by the bite of infected larvae of the mite *Leptotrombidium deliense*. It is a zoonoses with humans being accidental, dead end hosts. Scrub typhus was first described by Hashimoto from Japan (22). It is reported most often from Southeast Asia and Japan and is the most commonly reported

Table 2 : Clinical Features and Treatment of Rickettsial Diseases

Disease	Incubation period	Clinical Features	Weil Felix Reaction	Treatment
Epidemic typhus	6 - 15 days	Headache, chills, fever, prostration, confusion, photophobia, vomiting, rash (generally starting on trunk)	OX - 19	Doxycycline 100mg BD for 7 - 10 days or till person is afebrile. Chloramphenicol 60 - 75mg/kg/day in 4 divided doses for pregnant women
Murine typhus	8 - 16 days	As above, generally less severe	OX - 19	Same as above
Indian Tick Typhus	5 - 10 days	Fever, eschar, regional adenopathy, maculopapular rash on extremities	OX - 19 or OX - 2	Same as above Alternative - Ciprofloxacin
Rocky Mountain spotted fever	2 - 14 - days	Headache, fever, abdominal pain, macular rash progressing into opular or petechial (starting on extremities)	OX - 19 or OX - 2	Same as above
Scrub typhus	6 - 21 days	Fever, headache, sweating, conjunctival injection, adenopathy, eschar, rash, respiratory distress	OX - K	Doxycycline 100mg BD. Rifampicin 600 - 900mg/day, Azithromycin and Ciprofloxacin are other alternatives
Q fever	3 - 30 days	Fever, headache, chills, sweating, pneumonia, hepatitis, endocarditis	None	Doxycycline. Rifampicin, Ciprofloxacin are other alternatives

rickettsial infection in India. Globally over one billion people are at risk for scrub typhus and an estimated one million cases occur annually (22).

Epidemiology

The disease is largely limited to Southeastern and Eastern Asia, Northern Australia, India, Pakistan, Ceylon and other islands in the region. In India, it is present in whole of the Shivalak ranges from Kashmir to Assam, Eastern and Western Ghats and the Vindhya and Satpura ranges in the central part of India. The distribution of the disease corresponds with the distribution of *Leptotrombidium deliense* and *Leptotrombidium akamushi*. The vector mite is now known to be present in diverse ecological niches such as equatorial rain forests, semi-deserts and Alpine subarctic terrains in the Himalayan regions. Endemic foci are usually associated with specific habitats such as abandoned plantations, gardens or rice fields, overgrown forest clearings, shrubby fringes of fields and forests, river banks and grassy fields. These ecological patches which attract the natural host of mite vectors are called "mite islands". Within the mite islands there may be a limited area of intensive transmission of rickettsiae called "Typhus Island". Outbreaks of scrub typhus have been repeatedly reported in India both among civilians and personnel of the Armed Forces (8 - 13, 16, 17, 19).

Agent : *Orientia tsutsugamushi* is the agent of scrub typhus in India. It differs from other rickettsiae in its antigenic structure. At least eight serotypes are recognized. Infection with one strain does not produce immunity against infection by others.

Vector : The infection is transmitted through the larval mites or "chiggers" belonging to the family *Trombiculidae*, genus and subgenus *Leptotrombidium*. More than 150 species have been described but only a few are known to be of importance to man. About 204 trombiculid mite species have been described from India so far. The important mite species are *Leptotrombidium deliense*, *Leptotrombidium akamushi*, *Leptotrombidium scutellare* and *Leptotrombidium pallidum*. Transovarian transmission of rickettsiae occurs in mites for several generations. Only the larval stage takes a blood meal.

Host : A number of small rodents particularly wild rats of subgenus *Rattus* are the natural hosts for scrub typhus (22) The rodents and acarine hosts do not succumb to the disease. Thus the field rodents and the vector mites act as a reservoir and between the two the infection perpetuates in nature. The migration of infested or infected rodents leads to establishment of new foci of disease.

Transmission : The infection is transmitted to man through the bite of infective mite larvae, which feeds on lymph and tissue fluid rather than blood. Rather than biting or piercing the skin, mite larvae prefer to insert their mouthparts down hair follicles or pores. A large numbers of the *Orientia tsutsugamushi* are present in the salivary glands of the larvae and these are injected into its host when it feeds (23). Human infection takes place when man accidentally picks up an infective larval mite while walking, sitting, or lying on the infested ground.

Clinical Features

Scrub typhus has a broad clinical spectrum varying from mild or inapparent infection to organ failure and death. After an

incubation period ranging from 6 to 21 days (usually 10 - 12 days), patients usually present with fever and headache. Other symptoms and signs include myalgia, chills, cough, adenopathy, and diarrhoea. The patient is often labeled as "fever of unknown origin" because of the non specific symptoms. In about half the patients, a skin ulcer may develop after the onset of fever at the site of the mite bite. The ulcer is approximately 1 cm in diameter and fills with fluid, eventually rupturing and forming a black eschar. A macular rash may appear on the body on 5th to 7th day and last for a few hours to a few days. Complications such as pneumonitis, myocarditis, encephalitis and peripheral circulatory failure may occur. Deaths usually occur as a result of late presentation or a delayed diagnosis (22).

Diagnosis

A high index of suspicion in occupational settings like the armed forces can aid timely clinical diagnosis. The diagnosis can be confirmed by Weil - Felix (WF), Fluorescent Antibody (FA), Complement Fixation (CF) or Microscopic Agglutination (MA) test. Initial laboratory diagnosis may be difficult since antibody levels may be low during early infection. Most serological tests become positive only in the second week of illness. PCR has now become one of the important diagnostic techniques for scrub typhus. A nested PCR on the eschar provides a rapid diagnostic test for scrub typhus in the early, acute stage (24). Ready to use ELISA kits are also available commercially.

Most of these tests may not be available in remote areas where most cases occur. The Weil - Felix test (WF) using *Proteus OXK* strain is still the most commonly used test, though it lacks sensitivity. Only half the patients will have positive Weil - Felix test during second week of illness. A four fold rise in titre or a single reading of at least 1:80 are considered significant (22).

Treatment

Tetracyclines are the antibiotic of choice. The dosage is Tetracycline, 500 mg four times a days or doxycycline 200 mg once (or 100 mg BD) a day for 7 to 14 days. Alternatives include Chloramphenicol 500 mg four times a day or Rifampicin, 900 mg per day for seven days. Early treatment results in better outcomes and faster resolution (22, 23).

Prevention and Control

Avoidance of exposure to the vector and personal protective measures are the mainstay of prevention of scrub typhus. Outdoor camp sites should be selected carefully to avoid mites. Camp sites should be cleared of vegetation and treated with insecticide (Malathion / Fenthion) before occupation. Anti rodent measures like denying shelter and food to rodents by proper storage of food, hygienic disposal of refuse and keeping the area cleared of all junk, and rubble must be followed. Application of repellants to all clothing is the most important single preventive measure (25, 26).

Epidemic Typhus

Epidemic typhus is the classical form of rickettsial disease. About 30 million cases including three million deaths occurred in the Soviet Union & Eastern Europe during 1918 - 1922. During World War II, typhus struck heavily in concentration

camps in Eastern Europe and North America.

The disease is caused by *Rickettsia prowazekii* and transmitted by the human louse *Pediculus humanus corporis*. The infection is transmitted by the entry of the infectious faeces, the gut contents, or the body fluid of the louse through abrasion on the skin which may result from simultaneous scratching. The rickettsiae present in the dried excreta of insects may also enter through the conjunctivae or even through inhalation. Once infected, the lice remain infective throughout their remaining life.

Epidemic typhus is characterized by sub - acute onset, with fever interposed by rigors, accompanied by headache, nausea, giddiness, vomiting and flushed dry skin. On the third day, the temperature rapidly rises up to 40° C, face and eyes become suffused, headache and bodyache become severe, and the peculiar stuporose, drunken, confused and delirious state, similar to that found in enteric fever is seen. The patient has a foul smell and heavily coated tongue. The spleen is enlarged and haematuria and albuminuria occur. Blood pressure falls. Temperature remains high for 12 - 14 days. Rash occurs on 5th or 6th day. The case fatality varies widely and is influenced by the nutritional state and age of patient. In healthy, well fed young adults the case fatality is less than 5 percent. Diagnosis is confirmed by Microscopic Agglutination (MA), Complement Fixation (CF) and Fluorescent Antibody (FA) tests.

Man has no natural immunity; one clinical attack confers high immunity but not life long and a second attack may occur. All ages and sexes are susceptible. The immunity is type specific; therefore, an attack does not confer immunity against other rickettsial diseases. Cases are infectious to the louse during the last two or three days of the incubation period, and throughout the febrile period, for a total of about 12 to 13 days. Doxycycline or chloramphenicol (for pregnant women) are the drug of choice for treatment.

A high standard of personal hygiene to prevent louse infestation, avoidance of contact with those likely to be infected with the disease and infested with louse and preventive immunization are the important preventive measures. Treatment of louse infested individuals can be carried out by application of dust of 10% DDT, 1% malathion or 1% indane powder to the person as well as his clothing. Treatment can also be done with phenothrin dust 0.3 - 0.4%. Other lotions or shampoo formulations can also be applied for better results like permethrin lotion (1.0%) or deltamethrin lotion (0.03%).

A formalin inactivated epidemic typhus vaccine prepared from rickettsia grown in embryonated eggs was used to protect troops during World War II. It is given in 2 subcutaneous injections of 1 ml each at an interval of 10 to 14 days. Booster doses are recommended every 6 months. A recent advancement is the development of a vaccine consisting of live attenuated strain 'E' rickettsial organisms. It has been tried extensively and appears to be effective when tested under field conditions. It is not yet available for general use.

Brill - Zinsser Disease

It is a recrudescence episode of epidemic typhus which occurs years after the initial attack, in persons who have recovered from the epidemic disease acquired while residing in the

endemic country (27, 28). The recurrence is presumed to be precipitated by stress or a waning immune system. The illness is similar to louse borne typhus but is usually milder. Weil - Felix reaction may be negative in very low titre.

Endemic (Murine) Typhus

It is an acute febrile illness caused by *Rickettsia typhi* and transmitted to humans by the rat flea *Xenopsylla cheopis*. The mode of transmission is by contamination of the broken skin by rickettsia - laden faeces, and dried flea faeces gaining entry through conjunctivae or the upper respiratory tract by aerosol. Complement fixing antibodies against murine typhus have recently been detected in paired sera from local cases of fever of unknown origin by workers of NIV, Pune. Similar studies elsewhere indicate that murine typhus is endemic in practically every town of India especially where rats abound. Control measures should be directed against rodents and rat fleas. There is no specific vaccine. Epidemic typhus vaccine does not protect against murine typhus. However following attack by one disease, there is some cross - protection against the other disease.

Q Fever

It is an acute infectious disease caused by *Coxiella burnetii*. The disease has world - wide distribution. During World War II it was a cause of major epidemics in Europe (Balkan grippe). Apart from two case reports, studies on human Q fever in India have been mainly limited to sero epidemiological surveys in several parts of the country. Isolation of and demonstration of its antibodies from human milk have also been reported.

Small mammals and possibly some birds are the permanent reservoirs of infection with some *Ixodid* and *Argasid* ticks acting as vectors. From the wild animals the infection spreads to cattle, sheep and goats. The mode of transmission for humans is by inhalation of infected dust, by handling infected materials and possibly by drinking contaminated raw milk.

The incubation period of Q fever ranges from 15 to 26 days with an average of approximately 19 days. The disease is characterized by fever, malaise, myalgia, headache, weakness, anorexia, loss of weight and interstitial pneumonitis. Case fatality is low but convalescence is prolonged. Complications such as hepatitis, endocarditis, thrombosis, haemorrhages and meningitis may follow. The diagnosis is confirmed by CF tests. Radiological findings resemble those of primary atypical pneumonia. Human cases of Q fever should be treated with tetracyclines or chloramphenicol.

The disease can be prevented by avoiding exposure to infected aerosols. Milk from infected cattle must be boiled or pasteurized. Persons at risk such as dairy workers, butchers, wool sorters, farmers, cowherds and laboratory workers can be protected by immunization with specific vaccines such as those prepared from phase I rickettsiae.

Summary

Rickettsial diseases occur in all parts of the world and are a significant cause of morbidity and mortality. Most rickettsial infections result in zoonotic diseases. Humans are usually accidental hosts and play little role in natural disease

transmission. Rickettsial diseases are usually divided into four groups : Spotted fever group; Typhus group; Scrub typhus (or *Orientia* group); and others. The geographic as well as temporal distribution of rickettsial diseases is largely determined by their vectors. Rickettsia are small (0.3 X 2 μ m) aerobic, obligate intracellular parasites. Groups at risk for exposure to agents of rickettsial diseases are travellers, wood cutters as their occupational or recreational activities bring them in contact with habitats that support the vectors. Rickettsiae are transmitted to humans by the bite of infected ticks and mites and by the contamination of the bite or other skin wounds with the faeces of infected lice and fleas. Most rickettsial diseases are characterized by the classical triad of fever, headache, and rash. Confirmation of diagnosis is done most often by serology. The Weil - Felix test, which uses the *OX* and *K* strains of *Proteus mirabilis*, is still the most widely used diagnostic test in India. Tetracyclines are the antibiotic of choice against rickettsial infections. The essential method of prevention is avoidance of potentially vector infected areas and the use of personal protective measures.

Study Exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of Rickettsial diseases.

Short Notes : (1) Classification of Rickettsial diseases (2) Scrub Typhus (3) Epidemic Typhus

MCQs

- Limited area of intensive transmission of rickettsiae called as (a) Typhus Island (b) Mite islands (c) Rickettsiae Island (d) None of the above
- Agent for Indian Tick Typhus is (a) *Rickettsia typhi* (b) *Rickettsia conorii* (c) *Rickettsia akari* (d) *Rickettsia prowazekii*
- Most commonly reported rickettsial infection in India is (a) Scrub typhus (b) Indian Tick Typhus (c) Epidemic typhus (d) Rickettsial pox
- Epidemic Typhus is transmitted by (a) Tick (b) Mite (c) Human louse (d) Rat flea
- The infection is transmitted to man through the bite of which form of infective mite (a) Larvae (b) Pupa (c) Male adult (d) Female adult

Answers : (1) a; (2) b; (3) a; (4) c; (5) a.

Rajesh Vaidya

Yellow fever was the first viral haemorrhagic fever to be described. It is a mosquito - borne infection endemic to Africa and South America. Its presentation is widely variable ranging from a minimal flulike illness to a fulminant disease characterized by haemorrhage, hepatic failure, renal failure and death. The Yellow Fever virus is an arbovirus, of the family *Flaviviridae* (1). Despite being currently restricted to parts of Africa and South America, Yellow fever has the potential to cause large outbreaks in other areas due to the presence of suitable vectors and climatic conditions (2). Yellow fever has been cited in historic texts dating back to 400 years ago. The "yellow" in the name originates from the jaundice that occurs in seriously ill patients. Although an effective vaccine has been available for 60 years, the number of people infected over the last two decades has increased and the World Health Organization considers Yellow fever to be a serious public health issue again (3). The virus is transmitted by several species of mosquitoes. The *Aedes* is the most important vector while *Haemogogus species* are responsible for the transmission in South America. Mosquito - borne transmission of Yellow fever was first suggested by Carlos Finlay in 1881. In 1900, Walter Reed observed that the infectious agent was transmitted by means of a mosquito bite. Extensive mosquito control measures and widespread vaccination led to the elimination of Yellow fever in the early 20th century from most areas of the world except parts of Africa, South America and the Caribbean.

Epidemiology

Global : Yellow fever is currently confined almost entirely to South and Central America and Africa. The virus is constantly present with low levels of infection in these areas. Periodically this viral presence amplifies into regular epidemics. Over 500 million people live in 33 endemic countries in Africa and are considered to be at risk of suffering from Yellow fever. All these countries lie within a band from 15°N to 10°S of the equator. In South America, Yellow fever is endemic in nine countries and in several Caribbean islands. The countries considered to be at high risk are Bolivia, Brazil, Colombia, Ecuador and Peru. A small number of imported cases also occur in countries free of Yellow fever. Yellow fever has never been reported from Asia. However, WHO considers this region to be at risk because the appropriate primates and vectors are present (3). The global incidence of Yellow fever fluctuates with the occurrence of large epidemics in Africa. The World Health Organization estimates that there are 2,00,000 cases of Yellow fever every year with 30,000 estimated deaths. However, due to underreporting, only a small percentage of these cases are identified (3).

Agent : The viral pathogen is a *Flavivirus* belonging to the family *Togaviridae*. It is a small (40 to 60 nm), single stranded positive sense, enveloped RNA virus. The envelope consists of a lipid bilayer containing an envelope glycoprotein and a matrix protein (4, 5).

Vectors : The virus is transmitted by several different species of the *Aedes* and *Haemogogus* (only in South America). These

mosquitoes may be domestic (breeding close to and around houses), wild (breeding in the jungle) or semi - domestic types. In South America *Haemogogus spegazzinii* is the principal vector for forest transmission. In Africa, the principal vectors for forest transmission are the *Aedes africanus* and *Aedes simpsoni*. In both the continents, the principal urban vector is the *Aedes aegypti*. Female mosquitoes become infected by feeding on an infected host usually during the first to third day of fever. The extrinsic incubation period in the mosquitoes can vary from 4 to 18 days depending on the ambient temperature (6). During subsequent blood meals, the virus is transmitted to a new vertebrate host. In addition, Yellow fever virus can be transmitted transovarially, allowing viral survival in the absence of adult mosquitoes. The principal urban vector *Aedes aegypti*, is an inefficient vector of the Yellow fever virus. However, the anthropophilic nature of the vector and the high densities of the mosquito in urban areas make it an excellent vector for human - to - human transmission (5, 7).

Host : Primates are the only vertebrate hosts for Yellow fever. Humans and monkeys are the principal hosts. The reservoir of urban Yellow fever is sub - clinical human cases. For rural Yellow fever the most important animal reservoir is the monkey. In endemic areas almost 30% monkeys may be infected. Monkey is the only reservoir for jungle Yellow fever (2, 5).

Transmission : Three transmission cycles can be distinguished in Africa - The sylvatic (in jungle areas, mainly affecting the wild monkeys), intermediate (primarily affecting both man and monkeys) and urban (mainly affecting human beings in high population density areas). In South America, only the sylvatic and urban Yellow fever cycles of transmission are seen. In all three cycles, Yellow fever virus is transmitted between primates by diurnally active tree hole-breeding mosquitoes. In all of these cycles, endemic & epidemic disease patterns can occur (4).

The normal low risk to travellers increases with travel to jungle areas in endemic countries and in or near cities during urban outbreaks. Areas where Yellow fever virus is present far exceed those officially reported. The risk of exposure to infection can be reduced by taking measures to prevent mosquito bites (4, 5, 7). The mosquito vectors of Yellow fever are mostly day biters. Although reported cases of human disease are the principal indicator of disease risk, some countries may have no reported cases, either because of a high level of vaccine coverage against Yellow fever in the population or because poor surveillance resulted in no cases being reported. However, the risk of Yellow fever may still persist as the virus, the vector or the animal reservoirs are still present (8 - 10).

Incubation Period : The intrinsic incubation period in human beings is between two and six days. The extrinsic incubation period in a mosquito varies from four to 18 days (average 12 days), with the temperature and humidity. Once the mosquito becomes infective, it remains so for the rest of its life (2).

Period of Communicability : The case is infective to the vector mosquito during the later part of the incubation period and first three clinical days. An infected individual, therefore, can spread infection for about four to six days, starting two to three days after exposure to the infection. It is to prevent the entry of such individuals in India that rigorous rules and regulations are enforced (2).

Clinical Features

The disease presents in two phases. Some infections may be completely asymptomatic. Usually the first “acute” phase is characterized by fever, muscle pain, headache, loss of appetite, nausea and vomiting. The high fever may be paradoxically associated with a slow pulse. After three to four days most patients improve and their symptoms disappear. About 15% of patients enter a “toxic phase” within 24 hours. The patient rapidly develops jaundice and has abdominal pain with vomiting. Bleeding can occur from the mouth, nose, eyes and/or stomach. Blood may appear in the vomit and faeces. Kidney function deteriorates. About half of the patients in the “toxic phase” die within 10 - 14 days. The remaining recover without significant organ damage. Yellow fever is difficult to recognize, especially during the early stages. It can easily be confused with malaria, typhoid, rickettsial diseases, haemorrhagic viral fevers, dengue fever, leptospirosis and viral hepatitis (3).

Diagnosis

Baseline investigations must be carried out in suspected case. Leukopenia with relative neutropenia can occur. Thrombocytopenia can occur as part of a consumptive coagulopathy. Patients are also likely to have an elevated prothrombin time and prolonged clotting times. Renal damage, if present, results in grossly elevated serum creatinine levels and markedly elevated levels of urinary protein. In severe cases liver function tests are grossly deranged. Specific laboratory diagnosis relies on serology or on detection of the virus and viral antigens. Rapid detection methods include the detection of Yellow fever antigen by monoclonal enzyme immunoassay in serum specimens & detection of viral genome sequences in tissue or blood using polymerase chain reaction (PCR). Serologic studies include the Immunoglobulin - M (IgM) antibody - capture enzyme - linked immunosorbent assay (MAC - ELISA) used to detect the specific presence of IgM for Yellow fever. IgM appears 7 - 10 days following infection. A four - fold rise in haemagglutination inhibition, complement fixation, or neutralization of antibodies in acute and convalescent phases is also diagnostic of Yellow fever. The Yellow fever virus can be isolated from viral culture with the intracerebral inoculation of suckling mice or inoculation of mosquito cell cultures (1).

Treatment

As there is no specific treatment for Yellow fever, supportive care is critical. Dehydration and fever must be corrected with oral rehydration salts and anti - pyretics. Any superimposed bacterial infection should be treated with appropriate antibiotics. Intensive supportive care may improve the outcome for seriously ill patients.

Prevention and Control

Vector control and vaccination are the cornerstones of Yellow fever control. Vector control is considered in detail in the Chapter on Entomology.

Yellow Fever Vaccine : During the 1930s, both wild - type Yellow fever virus strains, Asibi and French, were attenuated to derive live vaccines known as 17D and the French neurotropic vaccine, respectively (2). Currently, 17D is the only strain of Yellow fever virus used for vaccination. 17D vaccines are heterogenous mixtures of multiple virus subpopulations (10).

Immune Response : More than 95% of vaccinated people develop neutralizing antibodies within 10 to 14 days of immunization. The International Health Regulations stipulate that the vaccination certificate for Yellow fever is valid for 10 days after administration of 17D vaccine, corresponding to the time at which the majority of vaccinees are demonstrably immune. Immunity following 17D vaccination is remarkably durable and may be lifelong.

Dose, Route of Administration and Preparations : A 17D vaccine dose contains approximately 105 PFU in 0.5 mL and is given subcutaneously, usually in the upper arm. Because there is no preservative in the vaccine and because the vaccine rapidly loses potency after reconstitution, it must be refrigerated at the point of use and held on ice and used soon after reconstitution. Reconstituted vaccines must be discarded within 4 hours. The vaccine is supplied in single and multiple - dose containers.

Vaccine Failure : Rarely, healthy people fail to develop neutralizing antibodies following 17D vaccination. This is not an absolute refractoriness; people who fail to develop antibody after their first vaccination may develop antibody upon revaccination (2, 4, 7).

Precautions and Contraindications : Tolerance of the vaccine is generally good. Less than 5% of vaccine recipients have mild reactions, including myalgia and headache. Contraindications include true allergy to the constituents, cellular immunodeficiency and symptomatic HIV infection. Many industrialized countries administer Yellow fever vaccine to persons with symptomatic HIV infection provided that the CD4 count is at least 200 cells/mm³ (11, 12). Asymptomatic HIV - positive individuals may have a reduced response to the vaccine. There is a theoretical risk of harm to the foetus if the vaccine is given during pregnancy, but this must be weighed against the risk to the mother of remaining unvaccinated and travelling to a high - risk zone. There have been recent reports of a small number of cases of serious disease, including deaths, following Yellow fever vaccination; most of these reactions occurred in elderly persons (12, 13 - 15).

The risk to unvaccinated individuals who visit countries where there may be Yellow fever transmission is far greater than the risk of a vaccine - related adverse event and it remains important for all travellers at risk to be vaccinated. Nonetheless, Yellow fever vaccination should not be prescribed for individuals who are not at risk of exposure to infection (16 - 18). Yellow fever vaccination should be encouraged as a key prevention strategy, but it is important to screen travel itineraries, particularly of older travellers and carefully evaluate the potential risk of systemic illness after Yellow fever vaccination (2, 7, 10, 11).

Mandatory Vaccination : Mandatory vaccination against Yellow fever is carried out to prevent the importation of Yellow fever virus into vulnerable countries. These are countries where Yellow fever does not occur but where the mosquito vector and non - human primate hosts are present. Importation of the virus by an infected traveller could potentially lead to the establishment of infection in mosquitoes and primates, with a consequent risk of infection for the local population. In such cases, vaccination is an entry requirement for all travellers arriving from countries, including airport transit, where there is a risk of Yellow fever transmission. If Yellow fever vaccination

is contraindicated for medical reasons, a medical certificate is required for exemption (19). The international Yellow fever vaccination certificate becomes valid 10 days after vaccination and remains valid for a period of 10 years. Travellers should be aware that the absence of a requirement for vaccination does not imply that there is no risk of exposure to Yellow fever in the country.

Prevention of Entry of Disease in India : In India, *Aedes aegypti* is wide spread and the people possess no immunity against Yellow fever. Yellow fever has not so far entered India due to the stringent regulations and their rigid enforcement. It is, however, interesting to note that Yellow fever never entered India even before these regulations were introduced. May be, this was due to the slow mode of voyage from the African coast to India. Due to faster means of travel the danger of its entry has increased. The details on International Health Regulations are given in a separate chapter.

Summary

Yellow fever was the first viral haemorrhagic fever to be described. The “yellow” in the name originates from the jaundice that occurs in seriously ill patients. Yellow fever is currently confined almost entirely to South and Central America and Africa. All these countries lie within a band from 15°N to 10°S of the equator. WHO considers Asian region to be at risk because the appropriate primates and vectors are present. The viral pathogen is a *Flavivirus* belonging to the family *Togaviridae*. In South America *Haemogogus spegazzinii* is the principal vector for forest transmission. In Africa, the principal vectors for forest transmission are the *Aedes africanus* and *Aedes simpsoni*. In both the continents, the principal urban vector is the *Aedes aegypti*. Humans and monkeys are the principal hosts. The reservoir of urban Yellow fever is sub-clinical human cases. For rural Yellow fever the most important animal reservoir is the monkey. Three transmission cycles can be distinguished in Africa. The sylvatic, intermediate and urban cycle. The intrinsic incubation period in human beings is between two and six days. The extrinsic incubation period in a mosquito varies from four to 18 days (average 12 days). The case is infective to the vector mosquito during the later part of the incubation period and first three clinical days. The disease presents in two phases first “acute” phase is characterized by fever, muscle pain, headache, loss of appetite, nausea and vomiting. About 15% of patients enter a “toxic phase” within 24 hours. The patient rapidly develops jaundice and has abdominal pain with vomiting. About half of the patients in the “toxic phase” die within 10 - 14 days. Complications include Kidney, liver and myocardial damage. Specific laboratory diagnosis relies on serology or on detection of the virus and viral antigens. There is no specific treatment for Yellow fever, supportive care is critical. Vector control and vaccination are the cornerstones of Yellow fever control. Currently, 17D is the only strain of Yellow fever virus used for vaccination. More than 95% of vaccinated people develop neutralizing antibodies within 10 to 14 days of immunization. The international Yellow fever vaccination certificate becomes valid 10 days after vaccination and remains valid for a period of 10 years. Mandatory vaccination against Yellow fever is carried out to prevent the importation of Yellow fever virus into vulnerable countries. These are countries where

Yellow fever does not occur but where the mosquito vector and non-human primate hosts are present.

Study Exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of Yellow fever.

Short Notes : (1) Transmission cycles of Yellow Fever (2) Yellow fever Vaccine (3) Importance of Yellow fever vaccine in International Travel.

MCQs

- All the following are countries considered to be at high risk for yellow fever except (a) Brazil (b) Colombia (c) Hong Kong (d) Peru
- Principal urban vector of Yellow fever is (a) *Aedes aegypti* (b) *Aedes africanus* (c) *Aedes simpsoni* (d) *Aedes vittatus*
- In South America _____ is the principal vector for forest transmission (a) *Aedes simpsoni* (b) *Haemogogus spegazzinii* (c) *Aedes vittatus* (d) *Aedes niveus*
- Strain of Yellow fever virus used for vaccination (a) 16 D (b) 17 D (c) 18 D (d) 19 D
- The international Yellow fever vaccination certificate becomes valid _____ days after vaccination (a) 10 (b) 15 (c) 20 (d) 25

Answers : (1) c; (2) a (3) b; (4) b; (5) a.

Rajesh Vaidya

The word “Jaundice” comes from old french “Jaunice” or “Yalnice”. “Icterus” is a greek word for yellow. Some brightly coloured birds belong to the family “*Icteradae*”. Pliny believed that if a jaundiced patient looked at the icterus or golden oriole, the patient recovered but the bird died. Epidemic jaundice was described by Hippocrates in 400 BC. Outbreaks among armies have been documented in Europe in the 17th and 18th centuries (1). The distinction between ‘infectious’ and ‘serum’ hepatitis was first made by Krugman (2).

The term hepatitis indicates an inflammation of the liver due to any cause. Infection by a number of viruses can cause inflammation of the liver. However, the term ‘Viral Hepatitis’ is used only for disease caused by hepatotropic viruses. There are five viruses which are taxonomically diverse but share the common characteristic of replicating primarily in the liver. These viruses are the Hepatitis A Virus (HAV), Hepatitis B Virus (HBV), Hepatitis C Virus (HCV), Hepatitis D Virus (HDV), and Hepatitis E Virus (HEV). These five viruses are further divided into two groups. The hepatitis A and E viruses are primarily transmitted by the faeco-oral route and result in acute but self limited infection. The hepatitis B, C & D viruses are transmitted by the parenteral route and can cause both acute and chronic infection. Some newer agents have been identified as causes of viral hepatitis but they are not well characterized so far.

Other viruses like Cytomegalovirus, Epstein Barr virus, Yellow Fever virus & Rubella virus can also cause hepatitis. In immunocompromised individuals, herpes simplex virus, varicella virus and adenovirus also result in hepatic dysfunction. However, as the site of primary infection is not the liver in these cases, they are not listed as causes of viral hepatitis.

Hepatitis A

The Hepatitis A Virus (HAV) is the commonest cause of viral hepatitis worldwide (1).

Epidemiology

Global : Endemicity of HAV infection is closely related to sanitary and living condition and other indicators of development, various sero-epidemiological studies show that prevalence of anti-HAV antibodies in the general population varies from 15% to close to 100% in different parts of the world. An estimated 1.5 million clinical cases of hepatitis A occur world-wide each year (4). In areas of low endemicity such as United States, Canada, western Europe, Australia, and other developed countries, hepatitis A usually occurs as single cases (5). However HAV is also known to have potential to cause large outbreaks, one of the worst known outbreaks was seen in 1988 in Shanghai, China, when over 3,00,000 young adults became ill when shellfish contaminated with HAV were sold in the marketplace and subsequently prepared in a traditional manner at temperatures that did not kill the virus (6).

India : In India, limited epidemiological data are available on HAV infection. A few reports suggested that India was

hyperendemic for HAV infection with very high infection rates in the first few years of life and most of the population acquiring antibodies to HAV by 10 yrs of age. Seroprevalence was of anti-HAV was lower (54.5%) in the higher socio-economic group as compared to the lower socio-economic group (85%) (7-9). However recent studies suggest that seroprevalence of anti-HAV vary in different parts of country with some parts showing a gradual shift in the epidemiology of hepatitis A with more cases occurring in adult population (10).

Agent : The HAV is a member of the *Picornavirus* family. It is an icosahedral virus 27 to 32 nm in diameter. The particle is non-enveloped and has single stranded, positive sense RNA (3). Four human genotypes of the virus have been identified. However, they are closely related anti-genically and infection with one genotype results in immunity against the other strains. There is only one serotype. HAV is relatively resistant to destruction.

Host : HAV infection, usually, is common in children and the risk of developing symptomatic illness following HAV infection is directly correlated to age. In children below six years of age, HAV infection is usually asymptomatic, with only 10% developing jaundice. Among older children and adults, infection usually causes clinical disease, with jaundice occurring in more than 70% of cases. However any age group can be affected, if susceptible. For practical purposes, the world can be divided into areas of low, intermediate and high disease endemicity. In areas of low endemicity disease occurs mainly in adolescents and adults in high-risk groups (e.g. homosexual men, injecting-drug users), persons travelling to countries of intermediate and high HAV endemicity. In areas of intermediate endemicity person to person in the general community via faeco-oral route is predominant, most cases occur in late childhood and early adulthood. In areas of high disease endemicity lifetime risk of infection is greater than 90%, most infections occur in early childhood and are asymptomatic (4).

Modes of Transmission : Person-to-person transmission by the faeco-oral route is the predominant mode of HAV transmission. The other less common mode of transmission include blood-borne transmission, sexual transmission in homosexuals and in some rare cases vertical intrauterine transmission has also been demonstrated (11). Secondary attack rates are as high as 30% among household contacts.

Incubation Period : Incubation period ranges from 15 to 50 days with median of about 28 days(12).

Period of Infectivity : 2 weeks before to 1 week after onset of jaundice. Highest concentration of virus is excreted in faeces 2 weeks prior to onset of clinical illness, which rapidly declines with appearance of jaundice (13).

Clinical Features

The clinical course of acute hepatitis A is indistinguishable from other types of acute viral hepatitis. Symptoms typically include fever, malaise, anorexia, nausea and abdominal discomfort, followed by dark urine and jaundice. The severity of disease and mortality increases in older age groups. The convalescence following hepatitis A may be slow, and is characterized by fatigue, nausea and lack of appetite. Complications of hepatitis A include relapsing hepatitis, cholestatic hepatitis and fulminant

hepatitis. Fulminant hepatitis occurs in approximately 0.01% of clinical infections and is characterized by rapid deterioration in liver function and a very high fatality rate. Chronic infection with HAV does not occur.

Diagnosis

Since Hepatitis A is clinically indistinguishable from other forms of hepatitis, diagnosis requires serologic detection of IgM in single acute-phase serum sample. IgM anti-HAV is usually detectable from 5 days prior to the onset of symptoms and declines to undetectable levels within six months after infection. IgG anti-HAV is used to detect previous infection as it usually persists for lifelong after infection. PCR can be used to detect virus in faeces, blood etc. Other biochemical parameters include elevated levels of serum bilirubin and elevated hepatic enzymes (AST, ALT) (14).

Treatment

Treatment primarily comprises of symptomatic management with complete bed rest and low protein diet as no specific antiviral therapy is currently available.

Prevention and Control

As almost all HAV infections are spread by the faeco - oral route, good personal hygiene, high quality standards for public water supplies and proper disposal of sanitary waste are the mainstay of prevention and control of infective hepatitis. Some of the important measures are as follows :

- Water supply should be safeguarded against faecal contamination. Even chlorination may sometimes not kill the virus, unless water is very efficiently chlorinated and a half an hour contact period is ensured. Water should be preferably boiled during an outbreak.
- Sanitation should be kept at a very high level. Methods of proper disposal of human wastes and strict anti-fly measures should be reinforced.
- Personal hygiene must be maintained at an extremely high level. Particularly cooks and housewives must be persuaded to wash their hands with soap and water after defaecation and before handling or consuming food.
- Complete inactivation of HAV in food can be done by heating at 85°C for at least one minute.

Active Immunization : Several inactivated or live attenuated vaccines against hepatitis A have been developed, but only four inactivated hepatitis A vaccines are currently available internationally. All four vaccines are all highly immunogenic. Nearly 100% of adults will develop protective levels of antibody within one month after a single dose of vaccine. Similar results are obtained with children and adolescents in both developing and developed countries. These vaccines are given parenterally (IM), as a two-dose series, 6-18 months apart. The dose of vaccine, vaccination schedule, paediatric and adult formulation varies from manufacturer to manufacturer. Currently no vaccine is available for children less than 1 yr.

A combination vaccine containing inactivated hepatitis A and recombinant hepatitis B vaccines has been licensed since 1996 for use in children aged one year or older in several countries. The combination vaccine is given as a three-dose series, using a 0, 1, 6 month schedule.

WHO recommends that in highly endemic countries where HAV is almost universal before the age of 10 years and is usually a minor public health problem, large-scale immunization efforts against this disease should not be undertaken. In developed countries with low endemicity of hepatitis A and with high rates of disease in specific high-risk populations (injection-drug users, homosexual men, persons travelling to high-risk areas, and certain ethnic or religious groups), vaccination should be given to this high risk population. Recommendations for hepatitis A vaccination in outbreak situations should depend on the epidemiology of hepatitis A in the community, and the feasibility of rapidly implementing a widespread vaccination programme. Hepatitis A vaccination in small, self-contained communities has been found to be very successful in control of the outbreak (15).

Passive Immunization : Passive immunization with IG that contain anti-HAV are more than 85% effective in preventing symptomatic HAV infection if given before, or within two weeks of exposure. With the availability of hepatitis A vaccines, IG is primarily recommended for postexposure prophylaxis for unvaccinated persons who are exposed to HAV. A single IM dose of IG (0.02 mL/kg) should be administered as soon as possible, but not more than two weeks after the last exposure, to unvaccinated household contacts, to persons who have shared illegal drugs with a person with hepatitis A, and to children and staff exposed in day care or certain other institutional settings.

Hepatitis E

Hepatitis E virus (HEV) was first identified in India in 1955 but it was only after development of specific serological test for acute HAV which resulted in the retrospective determination that large outbreaks of hepatitis with faeco-oral mode of transmission were not hepatitis A, but enterically transmitted Non-A Non-B virus (NANB or E-NANB). Hepatitis E was recognized as a distinct human disease in early 1990's (16).

Epidemiology

Global : The highest rates of infection occur in regions where low standards of sanitation promote the transmission of the virus. Hepatitis E is endemic in many parts of the world and always where HAV infection is highly endemic. Epidemics of hepatitis E have been reported in Central and South-East Asia, North and West Africa, and in Mexico, especially where faecal contamination of drinking water is common (19).

India : HEV is responsible for the majority of epidemic and sporadic hepatitis in adults. Epidemics of Hepatitis E have been reported from across the country, one of the largest such epidemic occurred in Delhi during the winter of 1955-56, infecting over 30,000 persons within six weeks (17).

Agent : HEV is a 27-34 nm non-enveloped icosahedral virus with a single-stranded, positive-sense RNA genome. The surface of the viron shows indentation and spikes (17). In morphology it resembles Calcivirus like Norwalk virus hence was wrongly classified into the family *Caliciviridae*, but now has been reclassified to an separate genus of "Hepatitis E like viruses" (18).

Host : The zoonotic origin of HEV is suspected, as monkeys, rats, cattle, sheep, goats, ducks and pigs are susceptible to infection with humans being an end or inadvertent target.

The reservoir of Hepatitis E is unknown. Although asymptomatic infections occur among children, seroprevalence studies in high endemic areas have not identified high rates of infection in this age group. Various studies have shown high attack rate among young adults (20). Hepatitis E has been found to have intriguing relationship with pregnancy. Pregnant women particularly those in the second and the third trimester, are more frequently affected during HEV outbreak. In addition, among pregnant women, especially those infected in the third trimester, the disease is more severe with high mortality (20-40%) (21).

Modes of Transmission : HEV is transmitted via the faeco-oral route. Hepatitis E is a waterborne disease, and contaminated water or food supplies have been implicated in major outbreaks. Consumption of faecally contaminated drinking water has given rise to epidemics, and the ingestion of raw or uncooked shellfish has been the source of sporadic cases in endemic areas. Hepatitis E has been found to be transmitted from infected mothers to their babies with significant perinatal morbidity and mortality (22). However Person-to-person transmission is uncommon with low secondary attack rates ranging from 0.7 to 2.2%. There is no evidence for sexual transmission or for transmission by transfusion.

Incubation Period and Period of Infectivity : The incubation period following exposure to HEV ranges from 3 to 8 weeks, with a mean of 40 days. The period of communicability is unknown. There are no chronic infections reported (23).

Clinical Features

Clinical signs and symptoms are indistinguishable from Hepatitis A. Typical signs and symptoms of hepatitis include jaundice (yellow discoloration of the skin and sclera of the eyes, dark urine and pale stools), anorexia (loss of appetite), an enlarged, tender liver (hepatomegaly), abdominal pain and tenderness, nausea and vomiting, and fever. Most persons with Hepatitis E have self limited disease except in pregnant women in whom high degree of fatality is observed. Infants acquiring infection via vertical transmission have increased risk of fulminant hepatitis (24). Chronic liver disease is not known to occur with HEV infection.

Diagnosis

Hepatitis E are not clinically distinguishable from other types of acute viral hepatitis, diagnosis is made by blood tests which detect elevated antibody levels of specific antibodies to hepatitis E in the body or HEV RNA can be detected in faeces or serum by Reverse Transcriptase Polymerase Chain Reaction (RT-PCR).

Treatment

HEV infections are usually self-limited and available therapy is capable of altering the course of acute infection. Hospitalization is required for fulminant hepatitis and should be considered for infected pregnant women.

Prevention and Control

As almost all HEV infections are spread by the faeco-oral

route, good personal hygiene, high quality standards for public water supplies and proper disposal of sanitary waste is the key for prevention of HEV infection. At present, no commercially available vaccines exist for the prevention of hepatitis E. However, several studies for the development of an effective vaccine against hepatitis E are in progress.

Hepatitis B

HBV is one of the oldest known hepatitis viruses. Even after the advent of an effective vaccine it still continues to be a major public health problem with more than 2 billion people infected worldwide.

Epidemiology

Global : The prevalence of HBV infection varies greatly worldwide. There are more than 2 billion people infected worldwide, and 350 million suffering from chronic HBV infection. HBV infections result in 5,00,000 to 1.2 million deaths per year caused by chronic hepatitis, cirrhosis, and hepatocellular carcinoma. More than one-third of the population has been infected with HBV, and it is estimated that there are 80 million HBV carriers (about 6% of the world population) (27).

India : On meta-analysis, the point prevalence of hepatitis B was found to be 2.1 per cent with a chronic carrier rate of 1.7 per cent (28). Hepatocellular carcinoma is rare in India and constitutes only 1.6 per cent of all cancers. The estimated annual deaths attributable to hepatocellular carcinoma due to hepatitis B was found to be approximately 5000 (29). However certain studies have found higher carrier state ranging from 11% in healthcare worker to 5% in general population (30).

Agent : The Hepatitis B Virus (HBV) is a double-stranded, enveloped virus of the *Hepadnaviridae* family. With a genome of only 3200 base pairs, HBV is one of the smallest DNA viruses known. The complete HBV viron (Dane Particle) is 42nm in diameter and is composed of outer lipoprotein coat containing the Hepatitis B Surface Antigen (HBsAg) and 27nm nucleocapsid core, the Hepatitis B Core Antigen (HBcAg) (17). HbsAg circulates independently in the blood and has four possible subtypes (*adw*, *adr*, *ayw* and *ayr*). Antibodies to the "a" antigen confer immunity to all subtypes (25). A third antigen HBeAg is a soluble protein, which can be detected in serum of patients with acute HBV infection. It acts as a marker of viral replication.

There are eight genotypes of hepatitis B Virus (*A to H*). Genotypes have different geographic distributions like genotype *A* is pandemic whereas genotype *B* and *C* are present in Asia, *D* in Southern Europe and US, *E* in Africa, *F* in the US, *G* in US and France and *H* in Central and South America (26)

Host : There is a direct relationship between the age of the patient and the likelihood to develop symptomatic infection which includes acute (clinically apparent) hepatitis B, chronic HBV infection, cirrhosis and HCC. Acute hepatitis B occurs in approximately 1% of perinatal, 10% of early childhood (1-5 years old) and 30% of late (>5 years old) HBV infections. Fulminant hepatitis develops in 0.1-0.6% of acute hepatitis cases; mortality from fulminant hepatitis B is approximately 70%. However, there is an inverse relationship with age and probability of developing chronic infection. About 90% of infants

infected during the first year of life and 30% to 50% of children infected between 1 to 4 years of age develop chronic infection. Whereas only 2-6% of adults develop chronic infection (31).

Certain occupational categories have been identified as associated with an excess risk of hepatitis B, C & D infection. The categories include dentists, nurses, laboratory technicians and the work areas include haemodialysis units, blood banks and surgical intensive care units.

Modes of Transmission : Humans are the only reservoir of HBV. The virus is highly contagious and is transmitted by percutaneous and permucosal exposure to infected blood and other body fluids (i.e. semen and vaginal fluid). The virus is found in highest concentrations in blood and serous exudates followed by lower concentrations in various body secretions such as saliva, semen and vaginal fluid. Common modes of transmission include mother-to-infant, unsafe injection practices, blood transfusions and sexual contact.

Perinatal Transmission : Perinatal HBV transmission is one of the most efficient modes of infection. Most perinatal HBV infections occur among infants of pregnant women with chronic HBV infection. Risk of transmission from pregnant women who acquire infection during the third trimester is approximately 60%. Perinatal transmission occurs most often at the time of birth, with in utero transmission rarely accounting for infections transmitted from mother to infant. Although HBV can be detected in breast milk, there is no evidence that HBV is transmitted by breast-feeding (32-33).

Sexual Transmission : Presence of HBV in semen and vaginal fluid favours transmission of virus by sexual contact, which is one of the common modes of acquiring the infection. Both heterosexual and homosexual intercourse may transmit HBV. The sexually promiscuous, particularly male homosexuals, are at very high risk of infection with hepatitis B.

Percutaneous Transmission : The risk of acquiring HBV infection through needle stick injury exposure to HBsAg positive blood is approximately 30-60%. This poses a significant risk to health care workers and IV drug abusers.

In highly endemic areas (>8% of the population HBsAg-positive), HBV is most commonly spread from mother to child at birth, or from person to person in early childhood. In countries with low HBV endemicity (<2% of the population HBsAg-positive), sexual transmission and the use of contaminated needles, especially among injecting drug users, are the major routes of infection (34).

Incubation Period and Period of Infectivity : The incubation period ranges from 30 to 180 days with median of 75 days. Period of Infectivity may extend from appearance of HBV in blood (30-60 days following infection) to several months or until disappearance of HBsAg and appearance of surface antibody.

Clinical Features

As mentioned earlier, the chances of development of symptomatic illness is directly related to age. In patients who develop symptomatic infection, the clinical onset of hepatitis B is usually insidious, with malaise, weakness, and anorexia being the most common findings. In 5-10% of patients, a serum

sickness-like syndrome may develop during the prodromal phase that is characterized by arthralgias or arthritis, rash, and angioedema. In patients with icteric hepatitis (30% or more of infected adults), jaundice usually develops within 1-2 weeks after onset of illness, dark urine and clay-colored stools may appear 1-5 days before the onset of clinical jaundice (25). Liver enzyme elevations usually occur prior to onset of jaundice. In most cases it is a self limiting disease and clinical signs and symptoms of acute hepatitis B usually resolve within 1-3 months.

Diagnosis

Acute hepatitis is indistinguishable from other hepatitis by biochemical parameters which include elevated levels of serum bilirubin and elevated hepatic enzymes (AST, ALT). Diagnosis can be made on the basis of serological antigen and antibody markers of HBV infection. HBsAg, IgM anti-HBc, and HBeAg can all be detected in serum as early as 1-2 months after exposure to HBV, but IgM anti-HBc is the only reliable marker of acute infection, as the others can also be detected in persons with chronic HBV infection. IgM anti-HBc usually becomes undetectable within 6-9 months after acute infection, and HBsAg and HBeAg are usually cleared within six months following onset of illness in those who recover from the acute infection. Anti-HBs and anti-HBe develop during the convalescent phase, with anti-HBs being a protective antibody that neutralizes the virus. Presence of anti-HBs following acute infection indicates recovery and immunity from reinfection. And anti-HBs can also be detected in persons who have received hepatitis B vaccine. Detection of anti-HBs is not routinely performed during diagnostic testing of persons with clinical illness but may be used in certain instances to determine a person's immune status following vaccination. In persons who develop chronic HBV infection, HBsAg and total anti-HBc remain detectable, generally for life. Although all persons with detectable HBsAg should be considered infectious, but its presence along with HBeAg and HBV DNA, is more indicative of infectivity (35). In addition Polymerase Chain Reaction (PCR) can be used to detect HBV DNA.

Treatment

In most cases treatment is supportive as the infection is self limiting. Patient is advised to avoid most drugs and bed rest till jaundice is completely resolved. Patients with fulminant viral hepatitis require ICU care with absolute bed rest, low protein diet, enemas to cleanse the bowel and oral neomycin (1 - 1.5g every six hours). Patients with chronic active Hepatitis B may be given specific anti viral therapy in the form of:

- Interferon α : 5 million units / day or 10 million units thrice a week for 16 weeks OR
- Lamivudine: 100 mg OD orally for one year OR
- Adefovir: 10 mg OD orally for 48 weeks

Prevention and Control

General prophylactic measures for HBV prevention include the following:

- Safe sexual practices
- Use of Condoms
- Safe hygiene practices (not sharing shaving blades)

- Safe blood transfusion and injections
- Health care personnel to practice proper “Universal safety precautions” and correct disinfection procedures
- Biomedical waste management as per laid down guidelines

Active Immunization : More than three decades of experience have shown that hepatitis B vaccination is safe and cost effective way of preventing HBV infection. Currently Two types of hepatitis B vaccines are available: plasma derived vaccines and recombinant vaccines are available world wide. The two vaccines show no differences in terms of reactogenicity, efficacy or duration of protection. Plasma-derived vaccines are prepared from purified HBsAg obtained from the plasma of persons with chronic HBV infection and inactivated using formalin. Aluminium phosphate or aluminium hydroxide is added to the vaccine as adjuvant and for multi-dose vials; thiomersal is used as a preservative. The recombinant hepatitis B vaccines (RDNA - Yeast derived vaccine) use HBsAg synthesized in yeast or mammalian cells.

Doses and Schedule : The recommended dose varies by product and with the age of the recipient. In most cases, infants and adolescents receive 50% of the adult dose. The vaccine is administered by intramuscular injection in the anterolateral aspect of the thigh (infants and children aged <2 years) or in the deltoid muscle (older children and adults). Administration in the buttock is not recommended. In case of adults schedule is 0, 1 & 6 months. In case of infants and children there are multiple options for incorporating the hepatitis B vaccine into national immunization programmes (36). The choice of schedule depends on the local epidemiological situation and programmatic considerations. The minimum recommended interval between the doses is four weeks.

Immunogenicity and clinical efficacy : The protective efficacy of hepatitis B vaccination is directly related to the induction of anti-HBs antibodies. An antibody titre of >10 mIU per ml measured 1-3 months after the administration of the last dose of the primary vaccination series is considered a reliable marker of immediate and long-term protection against infection. The complete vaccine series induces protective antibody levels in >95% of infants, children and young adults. After the age of 40 years, protection following the primary vaccination series drops below 90%. However despite the loss of anti-HBs over time, booster doses are not recommended (37,38).

Passive Immunization : Post exposure prophylaxis using HBIG is indicated in the following situation :

- (i) For newborn infants whose mothers are HBsAg-positive
- (ii) Following percutaneous or mucous membrane exposure to HBsAg-positive blood or body fluids
- (iii) Following sexual exposure to an HBsAg-positive person
- (iv) To protect patients from recurrent HBV infection following liver transplantation

HBIG as early as possible (ideally with 6 to 48 hrs). Immunoglobulin (16 % solution) should be given at 0.02 to 0.12 ml per kg of body weight intramuscularly in two doses 30 days apart. As a rule, HBIG should be used as an adjunct to hepatitis B vaccine.

WHO position on hepatitis B vaccine : WHO has called for all countries to add hepatitis B vaccine into their national immunization programmes in 1991. As of March 2004, more than 160 countries had followed the WHO recommendation and had added hepatitis B vaccine as an integral part of their national infant immunization programmes. The need for catch-up vaccination of older age groups, including adolescents and adults, is determined by the baseline epidemiology of HBV infection in the country. In countries of high endemicity, large-scale routine vaccination of infants rapidly reduces infection and transmission of HBV. In this situation, catchup vaccination of older children and adults has relatively little impact because most of them will have already been infected. In countries of intermediate or low hepatitis B endemicity, catch-up strategies targeted at adolescents could be considered as a supplement to routine infant vaccination. Possible additional target groups for catch-up vaccination include persons with risk factors for acquiring HBV infection, such as health care workers who may be exposed to blood or blood products, dialysis patients, persons interned in prisons, injecting drug users, household and sexual contacts of persons with chronic HBV infection, and persons with multiple sexual partners. Catch-up vaccination should be considered only if the continuity of the infant vaccination programme can be ensured (34).

Hepatitis C

Hepatitis C is a viral infection of the liver which was initially referred to as parenterally transmitted “non A, non B hepatitis” until identification of the causative agent in 1989. HCV is one of the major cause of acute hepatitis and chronic liver disease, including cirrhosis and liver cancer and despite extensive global efforts there is still no vaccine available to prevent HCV.

Epidemiology

Global : It is estimated that about 180 million people or 3% of the world’s population, are infected with hepatitis C virus (HCV), 130 million of whom are chronic HCV carriers at risk of developing liver cirrhosis and/or liver cancer. It is estimated that three to four million persons are newly infected each year, 70% of whom will develop chronic hepatitis (40).

India : Hepatitis C virus (HCV) which accounts for one-fourth of all cases of chronic liver disease in India. It is estimated that there are 12.5 million HCV carriers in our country (41). Seroprevalence studies among blood donors in India, have shown a rate varying from 0.48% in Vellore (42) to 1.85% in New Delhi (43).

Agent : HCV is an enveloped virus with an icosahedral capsid that contains a 9.6 kb-long, single-stranded, positive sense genomic RNA. It has been classified into genus *Hepacivirus* in the family *Flaviviridae*. The single translated polyprotein contains structural proteins including the core and two envelope proteins and three nonstructural proteins. Two regions of one of the envelope proteins called the hypervariable regions have extremely high rate of mutation. It is postulated that this rapid evolution of genetic variation facilitates viral persistence in most infected persons. There are 6 HCV genotypes and more than 100 subtypes (39).

Host : Since HBV is transmitted parenterally, certain group of people can be classified as high risk this includes recipients of blood transfusions, healthcare and laboratory personnel, homosexuals, prostitutes, percutaneous drug abuser, infants of HCV carrier mothers.

Modes of Transmission : HCV is transmitted by percutaneous of mucosal exposure to infectious blood and blood derived body fluids. The primary route of transmission is percutaneous exposure to blood. Sexual and perinatal transmission of HCV infection appears to be inefficient, occurring at a frequency lower than that observed for HBV and HIV infection (44).

Percutaneous Transmission: Injection drug use is a major source of HCV transmission in developed countries. Drug users who have injected even once or twice in the past should be considered at high risk of infection, since HCV infection is acquired more rapidly among IDUs than either HBV or HIV infection (45). Transfusion of blood or plasma derived products and transplantation of solid organs from HCV infection donors are highly effective routes for transmitting HCV infection. Nosocomial transmission of HCV infection due to poor infection control practices and aseptic techniques is a common means of transmission in developing countries.

Other modes of transmission such as social, cultural, and behavioural practices using percutaneous procedures (e.g. ear and body piercing, circumcision, tattooing) can occur if inadequately sterilized equipment is used. HCV is not spread by sneezing, hugging, coughing, food or water, sharing eating utensils, or casual contact.

Incubation Period : The incubation period of HCV infection before the onset of clinical symptoms ranges from 15 to 150 days.

Clinical Features

Most persons (60-80%) with newly acquired HCV infection are asymptomatic and only 15-30% become jaundiced. The clinical illness in persons with acute hepatitis C is similar to that observed in hepatitis of other viral etiologies and the diagnosis of hepatitis C can only be made with appropriate serologic testing. The most outstanding feature of HCV infection is that about 80% of newly infected patients progress to develop chronic infection. Cirrhosis develops in about 10% to 20% of persons with chronic infection, and liver cancer develops in 1% to 5% of persons with chronic infection over a period of 20 to 30 years. Most patients suffering from liver cancer who do not have hepatitis B virus infection have evidence of HCV infection. The mechanisms by which HCV infection leads to liver cancer are still unclear (46).

Diagnosis

Diagnostic tests for HCV are used to prevent infection through screening of donor blood and plasma, to establish the clinical diagnosis and to make better decisions regarding medical management of a patient. Diagnostic tests commercially available today are based on Enzyme Immunosorbent Assays (EIA) for the detection of HCV specific antibodies. EIAs can detect more than 95% of chronically infected patients but can detect only 50% to 70% of acute infections. This limitation of diagnosis of recent HCV infection is due to the lack of a

sensitive and specific immunoassay, such as IgM anti-HCV. A Recombinant Immunoblot Assay (RIBA) that identifies antibodies which react with individual HCV antigens is often used as a supplemental test for confirmation of a positive EIA result. PCR can be utilized for confirmation of serological results as well as for assessing the effectiveness of antiviral therapy. A positive result indicates the presence of active infection and a potential for spread of the infection and or/the development of chronic liver disease.

Treatment

Treatment of acute hepatitis is essentially symptomatic and similar to other forms of viral hepatitis. For chronic hepatitis C antiviral drugs such as interferon taken alone or in combination with ribavirin, can be used. Treatment with interferon alone is effective in about 10% to 20% of patients. Interferon combined with ribavirin, is effective in about 30% to 50% of patients. Ribavirin does not appear to be effective when used alone (47).

Prevention and Control

There is no vaccine against HCV. Research is in progress but due to high mutability of the HCV genome, possibility of development of vaccine in the foreseeable future seems remote. Hence in the absence of a vaccine, all precautions to prevent infection must be taken including :

- Screening and testing of blood and organ donors.
- Virus inactivation of plasma derived products.
- Implementation and maintenance of infection control practices in health care settings, including appropriate sterilization of medical and dental equipment.
- Promotion of behaviour change among the general public and health care workers to reduce overuse of injections and to use safe injection practices; and risk reduction counselling for persons with high-risk drug and sexual practices (47).

Hepatitis D

HDV is a defective single-stranded RNA virus that requires the helper function of HBV to replicate. HDV infection can be acquired either as a co-infection with HBV or as a Superinfection of persons with chronic HBV infection.

Epidemiology

Global : In general, the global pattern of HDV infection corresponds to the prevalence of chronic HBV infection; however, several distinct features of the distribution of HDV infection have been identified. The highest prevalences of HDV infection is found in the Amazon basin, parts of Africa, and Romania where 20% of persons with chronic HBV infection and up to 90% of people with HBV-related chronic liver disease have HDV infection. Other countries, including northern Italy, Spain, Turkey, and Egypt, have a moderate prevalence of HDV infection among asymptomatic HBV carriers (10%-19%) and among patients with chronic HBV-related liver disease (30%-50%). In most of Southeast Asia and China, where the prevalence of chronic HBV infection is very high but HDV infection is uncommon (49).

India : The anti-HDV positivity in acute viral hepatitis patients have been reported to vary from 10.7 to as high as >30 per

in various studies conducted across the country. In chronic hepatitis and cirrhosis groups, anti-HDV antibodies have been found to range from 8-21% and 15-19% patients respectively (50).

Agent : The hepatitis delta virus (HDV) is a 1.7kb RNA virus particle containing a circular, single-stranded RNA genome. HDV encodes a single protein, the delta antigen, which is encapsulated with HBsAg, encoded by the hepatitis B virus (HBV). HDV is classified as a satellite virus or subviral agent because it requires HBsAg as a surface protein to replicate (48).

Host : Certain group of people are found to be at high risk of contracting HDV infection these are as follows :

- Intravenous drug users using HDV-contaminated injection needles.
- Promiscuous homosexual and heterosexual groups (although HDV infections are less frequent than HBV or HIV infections).
- People exposed to unscreened blood or blood products such haemophiliacs, persons with clotting factor disorders.

Modes of Transmission : Transmission is similar to that of HBV:

- Bloodborne and sexual.
- Percutaneous (injecting drug use, haemophiliacs).
- Per mucosal (sexual).
- Rare perinatal.

Incubation Period : The incubation is period similar to HBV infection 30 to 180 days.

Clinical Features

An HDV infection absolutely requires an associated HBV infection. The outcome of disease largely depends on whether the two viruses infect simultaneously (*co-infection*), or whether the newly HDV-infected person is a chronically infected HBV carrier (*Superinfection*).

Co-infection : HBV and HDV (simultaneous infection with the two viruses) results in both acute type B and acute type D hepatitis. The incubation period depends on the HBV titre of the infecting inoculum. Depending on the relative titres of HBV and HDV, a single bout or two bouts of hepatitis may be seen. Co-infections of HBV and HDV are usually acute, self-limited infections. The chronic form of hepatitis D is seen in less than 5% of HBV - HDV coinfecting patient (51).

Superinfection : HBV and HDV (HDV infection of a chronically infected HBV carrier) causes a generally severe acute hepatitis with short incubation time that leads to chronic type D hepatitis in up to 80% of cases. Superinfection is associated with fulminant acute hepatitis and severe chronic active hepatitis, often progressive to cirrhosis (52).

Acute hepatitis D occurs after an incubation period of 3 - 7 weeks, and a pre-icteric phase begins with symptoms of fatigue, lethargy, anorexia and nausea, lasting usually 3 to 7 days. The appearance of jaundice is typical at the onset of the icteric phase. Fatigue and nausea persist, clay-colored stools and dark urine appear, and serum bilirubin levels become abnormal. In patients with acute hepatitis, self-limiting infection, convalescence begins with the disappearance of clinical symptoms. Fulminant viral hepatitis is rare, but still

about 10 times more common in hepatitis D than in other types of viral hepatitis.

About 60 to 70% of patients with chronic hepatitis D develop cirrhosis. Progression to cirrhosis usually takes 5 - 10 yrs, but it can appear 2 years after onset of infection. A high proportion of these patients die of hepatic failure.

Diagnosis

The diagnosis of acute hepatitis D is made by serologic tests for detecting anti HDV. One of the major drawbacks is that commercially available Radioimmunoassay (RIA) or Enzyme Immunoassay (EIA) kits can only detect Total anti-HDV and may result in under diagnosis of HDV. HD-ag detection in serum is only available in research laboratories and not very sensitive. Hence method of choice for the diagnosis of ongoing HDV infection if available, should be RT-PCR, which can detect 10 to 100 copies of the HDV genome in infected serum (53).

Treatment

Currently there is no effective antiviral therapy available for treatment of acute or chronic type D hepatitis. In some cases giving massive doses of a-interferon (9 million units three times a week for 12 months or 5 million units daily for up to 12 months) have yielded remissions, but most of the patients have remained unaffected.

Prevention and Control

Since HDV is dependent on HBV for replication, HBV-HDV coinfection can be prevented with either pre- or postexposure prophylaxis for HBV. However, no products exist to prevent HDV superinfection of persons with chronic HBV infection. Thus, prevention of HDV superinfection depends primarily on education to reduce risk behaviours.

Hepatitis G

In 1995, a new virus that causes hepatitis was cloned. The 3 viruses identified were GBV-A, GBV-B, GBV-C. They were together named HGV. Of the three, the third, GBV-C appears to affect man and seems to produce a long standing disease. This hepatitis G virus (HGV) or the GB virus C (GBV-C), is a 30-60 nm. Enveloped, single stranded RNA virus which belongs to the *flavivirus* family. HGV is distinct from hepatitis C virus but has a similar genomic organization. The virus has a global distribution and is reported to be present in 1-3% in volunteer blood donors (54). In India, no formal information is available on the prevalence of HGV in acute viral hepatitis however various studies have reported hepatitis G virus infection in acute viral hepatitis with rates varying from 0 to 34.0%.

Incubation period ranges from 30-120 days. HGV can be transmitted by blood transfusion, sexual contact or vertical transmission from mother to child. It is often detected in patients who received multiple blood transfusion or in hemodialysis patients and intravenous drug users. The virus has a global distribution and is reported to be present in 1-3% in volunteer blood donors. HGV co-infection is observed in 6% of chronic HBV infections and in 10% of chronic HCV infections. HGV has been shown to produce a persistent infection in a high proportion of persons with or without acute hepatitis or hepatitis -related chronic liver disease (55). Since hepatitis G

is a blood-borne infection, prevention relies on avoiding any possible contact with contaminated blood. Drug users should not share needles, syringes, or other equipment. Till date there is no vaccine or treatment of HGV, however it has shown high sensitivity to interferon but most cases relapsed after completion of treatment.

Summary

Viral hepatitis is defined as an infection of the liver caused by hepatotropic virus and is clinically characterized by an acute or sub acute febrile illness associated with nausea, anorexia, abdominal discomfort, dark colored urine, light colored stools and appearance of jaundice in sclera or skin. The known hepatotropic viruses commonly include hepatitis viruses A, B, C, D, E and G. Infections with hepatitis viruses, especially hepatitis virus B and C, have been associated with a wide variety of extra hepatic manifestations. Whether hepatitis G virus (HGV) is pathogenic in humans remains unclear. HAV has a world wide distribution. The risk of infection is inversely proportional to levels of sanitation and personal hygiene. In developing countries with poor environmental hygienic conditions, nearly all children are infected with HAV before the age of 9. HBV also has world wide distribution where 66 percent of the world's population is living in areas where there are high levels of infection. More than 2 billion people in the world had been found to have HDV prevalence rates ranging from 17-90%. Sexual and perinatal transmissions are also described. HEV is transmitted via the faeco-oral route. HEV appears to be endemic in some parts of the lesser-developed countries. Sporadic infections are observed in persons travelling from western countries to these regions. HGV can be transmitted by blood transfusion. HGV co-infection is observed in 6% of chronic HBV infections and in 10% of chronic HCV infections. However, whether HGV is actually pathogenic in humans remains unclear. Maximum infectivity for hepatitis A & E is during the later half of incubation period continuing through early acute phase of infection during the first 1-2 weeks or longer. In hepatitis B, C & D blood remains infective many weeks before the onset of symptoms, through the acute clinical course of the disease and during the chronic carrier state. As almost all HAV & HEV infections are spread by the faeco - oral route, good personal hygiene, high quality standards for public water supplies and proper disposal of sanitary waste are the mainstay of prevention and control of infective hepatitis. Preventive measures for HBV & HCV infection include active and passive immunization & universal precautions in all health care settings.

Study Exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of Viral Hepatitis

Short Notes : (1) Difference between Hepatitis A & B (2) Active and Passive Immunization against Hepatitis A & B

Fill in the blanks

- (1) HBV also has world wide distribution where _____ of the world's population is living in areas where there are high levels of infection.
- (2) HDV prevalence rates ranging from _____
- (3) 350 million are chronic carriers of the virus, which is

- harboured in the _____
 - (4) The virus causes 60-80 per cent of all primary liver cancer, which is one of the three common causes of cancer related death in _____
 - (5) HCV is a _____ with a diameter of 55 nm. It has _____ serotype and multiple genotypes.
 - (6) _____ is the reservoir for all the viruses.
 - (7) Acute hepatitis occurs in approximately _____ of perinatal, _____ of early childhood and about _____ in those above 5 years of age.
 - (8) Maximum infectivity for hepatitis A & E is during the _____ half of incubation period continuing through early acute phase of infection during the first 1-2 weeks or longer.
 - (9) Contacts of HAV may be given normal human immunoglobulin (16 % solution) at _____ ml per kg of body weight intramuscularly as soon as possible after exposure to prevent or attenuate clinical illness.
 - (10) Yeast derived vaccine is as effective in protection but more cost effective than the above vaccine. The schedule is _____ months. Protection is up to _____ years.
 - (11) Needles and syringes used for routine immunization must be autoclaved for twenty minutes or boiled for _____ min.
- Answers :** (1) 66%; (2) 17-90%; (3) liver; (4) East and SEAR, the Pacific Basin and Sub-Saharan Africa; (5) Flavivirus; one (6) Man; (7) 1%, 10%, 30% (8) later; (9) 0.02 to 0.12; (10) 0, 1 & 6, 15; (11) 30

The word "Anthrax" originates from Greek for black or coal because of the black eschar which is characteristic of the cutaneous form of Anthrax infection. It is principally a disease of herbivores but has the potential to infect all mammals and even some birds (1). Anthrax is caused by infection with the bacterium, *Bacillus anthracis*. The spores of the bacteria can survive in the environment for years or decades (2). The disease is endemic in all parts of the world but human cases are not common. Human infection results from direct or indirect exposure to infected animals or occupational exposure to infected or contaminated animal products. Anthrax has been in the news because of the fact that it is a suitable agent for germ warfare and its use as a weapon of bioterrorism in the United States of America (3). Other names for anthrax include "malignant pustule" and "Wool sorter's disease".

Epidemiology

Anthrax incidence among humans is dependent on the level of exposure to affected animals. Anthrax continues to be endemic in many parts of the world. The WHO also reports that the disease is enzootic in most parts of Asia and Africa and sporadic outbreaks among herbivorous animals are reported from other parts of the world (4).

Accurate figures on human anthrax in India are not available. However sporadic outbreaks continue to occur. The three southern states of Tamil Nadu, Andhra Pradesh and Karnataka have recorded at least 200 cases of human anthrax since the 1950s. In the recent past, the National Institute of Communicable Diseases has investigated two outbreaks of human anthrax one in Mysore and the other in Midnapore (5). Animal anthrax remains endemic in India because of inadequate vaccination.

Agent : *Bacillus anthracis* is a large, spore-forming, gram-positive bacillus with a diameter of 1.5 μm and a length of 5 μm . It can easily be cultured on sheep blood agar growing typically "medusa head" colonies. Anthrax can be differentiated from other gram-positive bacilli as it is non-motile and non-haemolytic and typically sensitive to penicillin. The virulence of the organism depends on the bacterial capsule and the toxin complex. The capsule is a poly-D-glutamic acid that protects it against lysis and phagocytosis. There are three anthrax toxins: the Edema Factor (EF), the Lethal Factor (LF) and a protective antigen (2). Only one strain is known.

Under unfavourable conditions which are not conducive to growth and multiplication of the bacilli, they form spores. Sporulation requires the presence of free oxygen. The spores are resistant to drying, heat, ultraviolet light, radiation, and most disinfectants. The spores can survive for many years in the soil. Spores are the predominant form in the environment and it is through the uptake of spores that anthrax is contracted.

Environment : There is clear evidence that anthrax is a seasonal disease. The occurrence of anthrax among animals in any one place is related to temperature and rains. However, the conditions which predispose to outbreaks differ widely from

location to location (4).

Transmission : Anthrax is a zoonosis. Though the bulk of infections occur in herbivores, carnivores are not immune to the disease. Cases among scavengers and other carnivores have been reported with infection occurring due to eating infected carcasses. The precise manner in which grazing animals become infected is not known. It is speculated that infection of the herbivorous animals occurs due to ingestion of the spores while grazing accompanied by minor trauma in the oral mucosa or other parts of the gastrointestinal tract due to chewing rough vegetation.

Human infections occur as a result of contact with diseased animals or animal products. The modes of transmission include direct inoculation of spores through breaks in the skin, inhalation of spores and ingestion of contaminated meat. Human-to-human transmission and laboratory-acquired anthrax are extremely rare (6).

Clinical Features

Anthrax can present in three different forms depending on the route through which the infection was acquired. Cutaneous anthrax occurs when the spores enter through a skin lesion, gastrointestinal tract anthrax is contracted from ingestion of contaminated food, and pulmonary (inhalation) anthrax from breathing in airborne anthrax spores. Another form is Anthrax meningitis.

Cutaneous Anthrax : This is the commonest form of presentation accounting for over 95% of all cases. The incubation period can be as short as 9 hours to as long as two weeks, but usually ranges from two to six days. Over a period of approximately ten days the cutaneous lesion which occurs at the site of entry of the spores, goes through the stages of a papule, ring of vesicles, ulceration and formation of a typical black eschar. The cutaneous lesion is non-purulent and is typically painless. After ten days the eschar begins to resolve. The resolution of the eschar occurs over six weeks and is not hastened by treatment. Cutaneous anthrax is self-limiting and in over 90% of cases resolution of the eschar takes place without complications. However, a small proportion of cases, if untreated, develop systemic anthrax (4, 6).

Pulmonary Anthrax : Inhalational anthrax usually occurring after the inhalation of spores from contaminated animal hides or products. Historical evidence indicates the role of individual susceptibility to infection as only a few cases of inhalational anthrax occurred among workers exposed occupationally to high concentration of viable anthrax spores (6). The onset of illness is usually non-specific with fever, chills, non-productive cough, myalgia and malaise. After one to three days, the disease suddenly becomes hyperacute with dyspnoea, strident cough, cyanosis and disorientation culminating in death. Death may occur within hours of onset of symptoms. Case fatality rate can be over 80% even with aggressive antimicrobial therapy (4, 6, 7).

Gastro-intestinal Anthrax : Gastrointestinal anthrax can present in two clinical forms following ingestion of *Bacillus anthracis* in contaminated food. The incubation period ranges from two to five days following consumption of contaminated meat (8). Intestinal anthrax usually presents with nausea,

vomiting, fever, abdominal pain, haematemesis, diarrhoea and ascites. Overt gastrointestinal tract anthrax cases are often fatal, because they may remain unrecognized until it is too late for effective treatment. Oropharyngeal anthrax is characterized by sore throat, dysphagia, fever, regional lymphadenopathy in the neck and toxemia. These cases are usually milder than the classic gastrointestinal disease and carry a more favourable prognosis.

Anthrax Meningitis : Haematogenous spread of the pathogen can take place from any form of anthrax. Meningitis due to anthrax is a serious development which carries close to 100% mortality. The patient shows clinical signs of meningitis. The meningitis of anthrax is haemorrhagic (9).

Diagnosis

Cutaneous anthrax has the characteristic painless, blackened, necrotic eschar in the late stages of the infection. The early forms of the cutaneous lesion need to be differentiated from other papular lesions that present with lymphadenopathy. A high index of suspicion is required for a clinical diagnosis of gastrointestinal and inhalational anthrax. History of possible occupational exposure or consumption of contaminated meat must be sought.

Confirmation of diagnosis can be done by serology or bacteriological tests. Specific Enzyme - Linked Immunosorbent Assays (ELISAs) are available for anthrax antibodies. Detection indicates past infection or vaccination while a four fold rise in titre indicates recent infection (10, 11). Indirect Hemagglutination tests have also been developed (12, 13).

Blood cultures can also be used to confirm diagnosis. Bacilli can also be cultured from ascitic fluid, pleural fluid, and CSF. In cases of systemic anthrax infection blood cultures are almost always positive but patients often die before blood cultures are obtained. Cultures from skin lesions are not useful diagnostically (14).

Newer molecular techniques including the Polymerase Chain Reaction (PCR) are now available for diagnosis of Anthrax. These rapid methods may be useful because early diagnosis is crucial (15, 16).

Treatment

Prompt and timely antibiotic therapy is essential results in complete recovery of cases of anthrax. *Bacillus anthracis* is highly sensitive to penicillin which is the antibiotic of choice. The pathogen is also sensitive to several other antibiotics including Chloramphenicol, Tetracyclines, Fluoroquinolones and Erythromycin. In most cases particularly inhalational and gastrointestinal anthrax, antibiotics must initially be administered intravenously.

During the bioterrorism attacks of 2001 in the United States, it was found that using two or more antibiotics intravenously improved survival (9). CDC protocols issued after the bioterrorism attacks recommend Ciprofloxacin 400mg BD or Doxycycline 100mg BD for a total of 60 days. The dose of Ciprofloxacin for children is 10 - 15 mg/Kg BD for 60 days (17). The treatment remains the same for pregnant women and immunocompromised individuals.

Prevention and Control

Control of the disease in animals is the key to prevention of anthrax in humans. Vaccination of susceptible animals, correct disposal of carcasses of anthrax cases and proper disinfection, decontamination and disposal of contaminated materials will prevent exposure of humans to anthrax spores. In addition vaccination of persons at risk and chemoprophylaxis of those exposed can also be used for prevention.

Annual immunization of livestock herds is required to be carried out in endemic areas. Decontamination and disinfection of materials and surfaces suspected to be harbouring spores is difficult because the spores are highly resistant to common measures. Autoclaving, dry heat, formaldehyde, ethylene oxide, gamma irradiation and sodium hypochlorite solution can all be used for disinfection. Carcasses of suspected anthrax cases can be disposed by incineration or deep burial. Details pertaining to decontamination and disposal of contaminated material are given in reference 4.

Vaccination : Vaccination among humans should be restricted to those at risk, particularly those at occupational risk. Live spore vaccines are used in China and Russia. In Britain and the United States bacteria free aluminium hydroxide precipitated vaccine is licensed. A complex primary schedule of six vaccinations over an 18 month period is required followed by annual boosters. Newer vaccines including a plasmid DNA vaccine and vaccines for intranasal use are under development (2, 4, 9).

Chemoprophylaxis : The United States Army recommends Ciprofloxacin or Doxycycline for four weeks for unimmunized individuals. A longer duration of chemoprophylaxis is required for complete clearance of spores from the lungs (18).

Summary

The word 'Anthrax' originates from Greek for black or coal because of the black eschar which is characteristic of the cutaneous form of Anthrax infection. Anthrax continues to be endemic in many parts of the world. Accurate figures on human anthrax in India are not available. The three southern states of Tamil Nadu, Andhra Pradesh and Karnataka have recorded at least 200 cases of human anthrax since the 1950s. *Bacillus anthracis* is a large, spore - forming, gram - positive bacillus with a diameter of 1.5 μm and a length of 5 μm . There are three anthrax toxins : the Edema Factor (EF), the Lethal Factor (LF) and a protective antigen. Only one strain is known. Spores are the predominant form in the environment and it is through the uptake of spores that anthrax is contracted. Human infections occur as a result of contact with diseased animals or animal products. The modes of transmission include direct inoculation of spores through breaks in the skin, inhalation of spores and ingestion of contaminated meat. Anthrax can present in three different Cutaneous, Pulmonary and Gastrointestinal Anthrax. Confirmation of diagnosis can be done by serology or bacteriological tests or blood culture. Prompt and timely antibiotic therapy is essential which results in complete recovery of cases of anthrax. Penicillin is the antibiotic of choice. Control of the disease in animals is the key to prevention of anthrax in humans. Vaccination of susceptible animals, correct disposal of carcasses of anthrax cases and proper disinfection,

decontamination and disposal of contaminated materials will prevent exposure of humans to anthrax spores. Vaccination among humans should be restricted to those at risk, particularly those at occupational risk. Chemoprophylaxis recommended in the United States Army is Ciprofloxacin or Doxycycline for four weeks for unimmunized individuals.

Study Exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of Anthrax.

Short Notes : (1) Spectrum of clinical presentation of Anthrax (2) Prevention and control of Anthrax.

MCQs

- All are properties of *Bacillus anthracis* except (a) Gram - positive (b) Spore - forming (c) Non motile (d) Haemolytic
- All are anthrax toxins Except (a) Edema Factor (EF) (b) Swelling Factor (SF) (c) Lethal Factor (LF) (d) Protective antigen
- Bacillus anthracis* is known to have how many strains (a) 1 (EF) (b) 2 (c) 3 (d) 4
- Antibiotic of choice in treatment of Anthrax (a) Penicillin (b) Ciprofloxacin (c) Tetracyclines (d) Chloramphenicol
- Commonest clinical form of presentation of Anthrax is (a) Pulmonary Anthrax (b) Gastrointestinal Anthrax (c) Cutaneous Anthrax (d) Anthrax Meningitis

Answers : (1) d; (2) b; (3)a; (4) a; (5) c.

Rajesh Vaidya

Tetanus is the only non communicable disease that is vaccine preventable (1). It is an infectious disease caused by infection with *Clostridium tetani*. Under favourable anaerobic conditions, the pathogen produces tetanospasmin, which is a potent neurotoxin. This toxin blocks inhibitory neurotransmitters in the central nervous system and causes the muscular stiffness and spasms typical of generalized tetanus (2). Despite a marked decrease in the occurrence of disease following the introduction of vaccination, the disease continues to be an important public health problem in many parts of the world, particularly in developing countries. Infection occurs through

spores of *Clostridium tetani* which are universally present in the soil. The disease can occur at any age but is particularly common and serious in newborn babies in the form of neonatal tetanus (3). Tetanus among adolescents and young adults usually occurs as result of infection through skin injuries.

Epidemiology

The widespread use of a safe and effective vaccine has made the disease rare in the developed world. In developing countries, however, tetanus remains a major public health problem. The WHO estimated that the total number of tetanus deaths worldwide in 2002 was 213,000, of which neonatal tetanus was estimated to cause about 180,000 deaths and maternal tetanus about as 15,000 - 30,000 deaths (4). The global incidence of tetanus is estimated to be one million cases annually or 10 per 100,000 population. Mortality rates can be as high as 28 per 100,000 in developing countries as compared to less than 0.1

per 100,000 in North America (5).

A large majority of tetanus cases are birth - associated and occur in developing countries among newborn babies or in mothers following unclean deliveries and poor postnatal hygiene (4). Neonatal tetanus accounts for more than half of all tetanus cases in developing countries. The WHO aims to eliminate maternal and neonatal tetanus; MNT defined as less than one neonatal tetanus case per 1000 live births at district level per year. 47 countries have not been able to eliminate MNT as of December 2007 (6). In South East Asia, India, Bangladesh, Myanmar and Indonesia are yet to eliminate MNT.

Neonatal tetanus is one of the most under reported notifiable diseases. In 1995, over 5,500 cases of tetanus were reported from Uttar Pradesh, Madhya Pradesh, Rajasthan, Orissa, Bihar and Assam.

Agent : *Clostridium tetani* are gram positive bacilli that are obligate anaerobes. The organisms are sluggishly motile in fresh cultures. On maturity they lose their flagellae and develop a terminal spore which gives the characteristic drumstick appearance. The vegetative forms produce two exotoxins, tetanolysin and tetanospasmin (also called Tetanus Toxin). The role of tetanolysin in the pathogenesis of tetanus is unknown. Tetanospasmin is a neurotoxin and causes the clinical manifestations of tetanus. It diffuses from the wounds to local muscles and can also spread systemically through the blood and lymphatics. Weight for weight, tetanospasmin is one of the most potent toxins known. The estimated human lethal dose is less than 2.5 ng per kg (2).

Tetanus spores are extremely stable and can germinate into vegetative forms even after years. They are highly resistant to heat and most chemical disinfectants including ethanol, phenol, and formalin. They can be destroyed by iodine, glutaraldehyde, and hydrogen peroxide. Autoclaving at 121°C under 15 psi pressure also destroys the spores (1, 5). Tetanus spores are widely distributed in nature. They are found in the soil, human and animal faeces, and even on human skin.

Host : Tetanus can occur at any age. In developed countries tetanus is now largely a disease of the elderly. In the United States, the risk of tetanus increases with age (7). In developing countries, however, a large proportion occur among newborn babies or in mothers following unclean deliveries and poor postnatal hygiene. Tetanus in children and adults following injuries also constitutes a considerable public health problem. Neonatal tetanus in India is reported more in male children. This male preponderance may reflect a male bias for health care seeking rather than an actual male predilection (8). In India, neonatal tetanus shows distinct seasonal variation with the largest number of cases being reported during the monsoons and post - monsoon period.

Transmission : The ubiquitous nature of tetanus spores makes it possible for them to enter the body through any form of injury. Neonatal tetanus results from unclean deliveries and the application of contaminated material on the umbilical stump. In children and adults tetanus can result from both acute wounds and chronic infections. Puncture and deep wounds are more likely to result in tetanus rather than superficial abrasions.

Clinical Features

The incubation from the entry of spores to the onset of clinical manifestations can vary from 3 to 21 days, but is usually between six and eight days. Usually, the further the injury site is from the central nervous system, the longer the incubation period. The severity of disease is inversely related to the duration of the incubation period. The shorter the incubation period, the higher the chance of death. In neonatal tetanus, the average incubation period is about 7 days with a range of 4 - 14 days (1, 9). Tetanus can be classified into four forms based on clinical presentation.

Generalized Tetanus : This is the most common form of presentation. The earliest sign of the disease is usually a spasm of the jaw muscles (lockjaw) and a grimace like appearance of the face (*Risus Sardonius*). As the symptoms progress, there is spasm of the muscles of the abdomen, neck, back and thorax. In severe cases tonic seizures can occur. A characteristic feature is that the patient does not lose consciousness during the spasms. The spasms can be triggered by external stimuli. Patients may also have elevated temperature, sweating, hypertension and tachycardia. Spasms may continue for over three weeks and complete recovery may take months.

Localized Tetanus : This is a less common form of the disease. There is stiffness and rigidity of the muscles around the site of infection. Recovery is usually spontaneous. Only about 1% of cases are fatal. However, at times, localized rigidity may be a prodrome of generalized tetanus.

Cephalic Tetanus : This is a rare form of the localized disease and is generally associated with lesions on the head or face. Involvement of cranial nerves is a characteristic feature of this form of tetanus.

Neonatal Tetanus : This is the form of generalized tetanus occurring in neonates. Generalized weakness followed by an inability to suckle are the common manifestations. WHO considers any neonate with normal ability to suck and cry during the first 2 days of life and who, between 3 and 28 days of age, cannot suck normally and becomes stiff or has spasms (i.e. jerking of the muscles) as a confirmed case of neonatal tetanus (6).

Diagnosis

Diagnosis of tetanus is usually based on history and clinical signs and symptoms rather than laboratory findings. A bedside diagnostic test called the 'Spatula Test' with very high specificity and sensitivity has been proposed from India (10). Isolation of *Clostridium tetani* from can neither confirm nor exclude the diagnosis. The pathogen is often isolated from wounds among patients who do not have the disease and even carefully performed anaerobic cultures are negative even from contaminated wounds. The only condition which mimics tetanus closely is strychnine poisoning. Serology also has little value as antibody levels even in the protective range do not rule out disease (1, 5).

Treatment

Local wound management, supportive therapy particularly airway maintenance and passive immunization are the main

requirements of management of cases of tetanus. All wounds should be cleaned and adequate debridement carried out. The course of the disease, however, is not altered by wound debridement. *Clostridium tetani* is sensitive to several antibiotics including Penicillin, Tetracycline and Metronidazole. Antibiotics may eliminate the organism and consequently prevent further production of toxin. Airway maintenance may require an endotracheal tube or even a tracheostomy. Sedation is the mainstay of symptomatic treatment. Intravenous Diazepam or Lorazepam may be required for control of the spasms.

Immunization : Passive immunization with Human Tetanus Immunoglobulin (HTIG) is required to neutralize unbound tetanus toxin. Doses ranging from 500 units to 3000 - 6000 units have been recommended by various experts (11). Intrathecal HTIG was earlier used for neonatal tetanus, but has now been shown to be ineffective. As the amount of tetanus toxin released during infection is inadequate to produce an effective immune response, all patients of tetanus should also be given active immunization.

Prevention and Control

Active immunization against tetanus is the cornerstone of prevention and control of tetanus. Mass education campaigns and training of birth attendants to ensure hygienic and safe deliveries are also important measures for prevention of neonatal tetanus.

Active Immunization : Tetanus toxin is inactivated by formaldehyde to form tetanus toxoid. The toxoid has been used as a Monovalent Vaccine (TT) to immunize adults, or as a component of combined Diphtheria - Tetanus - Pertussis (DTP) vaccine or Diphtheria - Tetanus (DT) vaccine for immunization of children. Several other combinations like combined Tetanus diphtheria (Td) vaccine for adults and a Tetanus - diphtheria - acellular Pertussis (Tdap) combination are also available. Adsorption of tetanus toxoid onto aluminium salts increases its antigenicity (2). Tetanus toxoid can withstand exposure to temperatures of around 20°C for months and storage at 37°C for a few weeks without significant loss of potency. The vaccine should be stored at 2 - 8°C. Vaccines that have been frozen should not be used (4).

WHO recommends a childhood tetanus immunization schedule of five doses. In India, the primary series of three doses of DTP are given at six, ten and fourteen weeks followed by a booster between 16 and 24 months of age. Another booster of the DT vaccine is given at the school going age, while boosters of TT are given at 10 years and 16 years of age.

Pregnant women with an inadequate or unknown immunization history should always receive 2 doses of tetanus toxoid - containing vaccine : the first dose as early as possible during pregnancy and the second dose at least 4 weeks later (4).

In cases of injury a dose of tetanus toxoid vaccine may be given depending on the severity of the injury and on the reliability of the history of previous tetanus vaccinations. The vaccine should be given if the last dose was administered more than 10 years ago (or 5 years in the case of severe injuries) (4).

Summary

Tetanus is the only non communicable disease that is vaccine preventable. Despite a marked decrease in the occurrence of disease following the introduction of vaccination, the disease continues to be an important public health problem in many parts of the world, particularly in developing countries. The WHO estimated that the total number tetanus deaths worldwide in 2002 were 213,000. The global incidence of tetanus is estimated to be one million cases annually or 10 per 100,000 population. The WHO aims to eliminate maternal and neonatal tetanus; MNT defined as less than one neonatal tetanus case per 1000 live births at district level per year. In South East Asia, India, Bangladesh, Myanmar and Indonesia are yet to eliminate MNT. *Clostridium tetani* are gram positive bacilli that are obligate anaerobes. The vegetative forms produce two exotoxins, tetanolysin and tetanospasmin. The ubiquitous nature of tetanus spores makes it possible for them to enter the body through any form of injury. The incubation from the entry of spores to the onset of clinical manifestations can vary from 3 to 21 days, but is usually between six and eight days. The severity of disease is inversely related to the duration of the incubation period. The shorter the incubation period, the higher the chance of death. Tetanus can be classified into four forms based on clinical presentation they are Generalized Tetanus, Localized Tetanus, Cephalic Tetanus and Neonatal Tetanus. Diagnosis of tetanus is usually based on history and clinical signs and symptoms rather than laboratory findings. A bedside diagnostic test called the 'Spatula Test' has a very high specificity and sensitivity. Local wound management, supportive therapy particularly airway maintenance and passive immunization are the main requirements of management of cases of tetanus. Passive immunization with Human Tetanus Immunoglobulin (HTIG) is required to neutralize unbound tetanus toxin. Active immunization against tetanus is the cornerstone of prevention and control of tetanus.

Study Exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of Tetanus.

Short Notes : (1) Forms of clinical presentation of Tetanus
(2) Active Immunization against Tetanus

MCQs

1. The global incidence of tetanus is estimated to be (a) 1 per 100,000 population (b) 10 per 100,000 population (c) 100 per 100,000 population (d) None of the above
2. In South East Asia, following country has eliminated Maternal and Neonatal Tetanus (a) India (b) Bangladesh (c) Myanmar (d) None of the above
3. In neonatal tetanus, the average incubation period is about (a) 4 days (b) 7 days (c) 11 days (d) 15 days
4. This is the most common form of clinical presentation of tetanus (a) Localized Tetanus (b) Generalized Tetanus (c) Cephalic Tetanus (d) Neonatal Tetanus
5. The only condition which mimics tetanus closely is (a) Strychnine poisoning (b) Botulism Poisoning (c) Rabies (d) None of the above

Answers : (1) b; (2) d; (3) b; (4) b; (5) a.

Rajesh Vaidya

Plague is one of the oldest diseases known to man (1). It is primarily a zoonotic disease that exists in nature between small mammals, usually wild rodents, and the fleas that they harbour (2). Plague is endemic in many parts of the world and exists in many small natural foci. It is widely distributed in the tropics and subtropics and in warmer areas of temperate countries. The causative bacteria, *Yersinia pestis* can also infect humans. It is transmitted between animals and humans by the bite of infected fleas, direct contact, inhalation and rarely, ingestion of infective materials. Untreated plague can be a very serious disease with case fatality rates between 30% and 60% (3). Recent outbreaks have shown that plague may recur in areas that have long remained silent (1).

Plague has been known as a dreaded killer from times immemorial. The first pandemic, also called the *Justinian plague* took place in the sixth century and is reputed to have killed nearly a hundred million victims. The second plague pandemic is known as the "Black Death" of the fourteenth century which caused 50 million deaths. A quarter of the population of Europe is said to have been wiped out by this pandemic. The third pandemic began in Hong Kong in 1894. Within 10 years this pandemic had spread to all the continents. This pandemic resulted in 13 million deaths in India (1, 4). During the third pandemic, the causal agent, *Yersinia pestis* was discovered in 1894.

Epidemiology

Global : The number of cases of human plague reported to the World Health Organization has remained stable in the recent past. The WHO believes that the number of cases officially notified is considerably lower than the actual number (5). Plague exists in natural enzootic cycles involving wild rodents and their fleas in several parts of the world. These natural cycles are usually hidden with no transmission to humans.

Epidemics of plague occasionally occur when the disease spreads from wild rodents to rats that live in close proximity of human habitation.

Between 1989 and 2003, a total of 15 year period, 38, 310 cases with 2845 deaths were recorded in 25 countries. In these 15 years the highest number of human plague cases was reported in 1991 and the lowest number 1989. Eight countries reported human plague almost every year. These countries were the Democratic Republic of the Congo, Madagascar and the United Republic of Tanzania in Africa; Peru and the United States in the Americas, and China, Mongolia and Viet Nam in Asia. An increase in the incidence of human plague has become apparent since the early 1990s, particularly in Africa. Three geographical areas experienced outbreaks of human plague after silent periods of about 30 - 50 years : India in 1994, Indonesia in 1997 and Algeria in 2003 (5 - 7). The total number of human plague cases reported to WHO in 2002 was 1925, of which 177 were fatal. In 2003, nine countries reported 2,118 cases and 182 deaths. 98.7% of those cases and 98.9% of those deaths were reported from Africa. Today the distribution of plague coincides with the geographical distribution of its natural foci (3, 5).

India : India suffered very large number of deaths during the third Plague pandemic. Plague outbreaks continued to occur, but with decreasing frequency during the first half of the 20th century. This is often attributed to the collateral benefit from the extensive insecticide spraying done as a part of the National Malaria Programme. India remained plague free for almost 30 years after the last human case was reported from Karnataka in 1966.

In August - October 1994 human plague was reported in India. During this outbreak, 876 cases with 54 deaths were characterized as presumptive plague. Most cases were reported from Maharashtra (596), 151 from Gujarat, 68 from Delhi, 50 from Karnataka, 12 from Madhya Pradesh, and 10 from Uttar Pradesh. Almost all the deaths were reported from Gujarat. Several reasons have been put forth to explain this outbreak. Rat - fall was first reported from Mamla village in the Beed district of Maharashtra on 5 August 1994. This was followed

by reports of flea nuisance. Three weeks later, suspected cases of bubonic plague were reported from Mamla village followed by reports from other villages in Beed and other districts. Beed has had sylvatic plague in the past. Ecological changes created by the earthquake in September 1993 and large scale storage of foodgrains probably contributed to a gradual growth of the rat population. The resurgence of plague in Surat, Gujarat, was related to a record high rainfall during the September monsoon. Floods in the Tapi river resulted in inundation of large areas. Many rodents were found dead when the water floods receded. Based on the clinical picture and the plague outbreak in neighbouring Maharashtra the outbreak in Surat was declared as pneumonic plague on 21 September 1994 (1, 8 - 12). In February 2002, an outbreak of pneumonic plague (16 cases, 4 deaths) occurred in Hat Koti village, Shimla district, Himachal Pradesh. The outbreak is believed to have started after a person acquired the infection in the forest, which then spread to others through person - to - person contact (5). Since 2002 there has been no confirmed case of plague in India.

Agent: *Yersinia pestis* is a gram - negative coccobacillus. *Yersinia* was formerly classified in the family *Pasteurellaceae*, but has been now reclassified as members of the *Enterobacteriaceae* family. Though there are 11 species in the genus *Yersinia*, only three are considered important human pathogens. The bacteria is small (1.0 to 2.0 μm x 0.5 μm), pleomorphic and is seen as single cells or short chains in direct smears. They are nonmotile, nonsporulating, non - lactose fermenting facultative anaerobes (13 - 15).

Vector: *Yersinia pestis* is most commonly transmitted between animal reservoirs and to humans through the bites of infected fleas. There are more than 1, 500 flea species, of which about 30 are known to be vectors for *Yersinia pestis*. The major flea vectors include the following (15) :

- (a) *Xenopsylla cheopis* (the oriental rat flea; nearly worldwide in moderate climates)
- (b) *Oropsylla montanus* (United States)
- (c) *Nosopsyllus fasciatus* (nearly worldwide in temperate climates)
- (d) *Xenopsylla brasiliensis* (Africa, India, South America)
- (e) *Xenopsylla astia* (Indonesia and Southeast Asia)
- (f) *Xenopsylla vexabilis* (Pacific Islands)

To be an efficient plague vector, the flea must be able to ingest the *Yersinia pestis* with its blood meal. It must also live long enough for the pathogen to multiply in sufficiently large numbers. It must be able to transfer the pathogen to an animal or human host in sufficient concentrations to cause an infection. *Xenopsylla cheopis* is the most important vector of plague. A high incidence of plague infected *Xenopsylla cheopis* in a given focus, greatly increases the risk of transmission to humans (1). *Pulex irritans*, the human flea may be responsible for human to human transmission of Plague (1, 16).

Host Factors: More than 200 mammalian species have been known to be naturally infected with *Yersinia pestis*. However, plague is primarily a disease of rodents. The infection is maintained in natural foci of the disease in wild rodent colonies through transmission between rodents. The animal hosts of plague are classified as enzootic (maintenance) hosts

and epizootic (amplification) hosts (1). Enzootic hosts are characterized by relatively mild illness, and low mortality rates. Voles and mice have been suggested as maintenance hosts. Epizootic rodents are associated with susceptibility and high mortality. Highly susceptible or epizootic plague hosts include various species of mice, rats, voles, gerbils, ground squirrels and marmots. Rats have historically been a primary carrier of plague (1, 15, 17 - 20).

Transmission: The most common mode of transmission of *Yersinia pestis* to humans is by the bite of infectious fleas. Other, less common modes of transmission include direct contact with infectious body fluids or tissues while handling an infected animal or inhaling infectious respiratory droplets (13). The mode of entry of the organism has marked clinical significance.

Clinical Features

Infection by *Yersinia pestis* causes a severe febrile illness characterized by headache, myalgia, malaise, shaking chills, prostration and gastrointestinal symptoms. The three commonest clinical presentations of plague are bubonic, septicaemic and pneumonic (1, 13, 15). Less common forms of plague include pharyngeal and meningial plague.

Bubonic Plague: For bubonic plague the mode of entry of the organism is by a flea bite. The infection spreads via the lymphatics to the regional lymph nodes causing inflammation and swelling in one or several nodes forming the classic buboes. Buboes may occur in any regional lymph node sites including inguinal, axillary and supraclavicular. After an incubation period of two to six days, a patient experiences sudden onset of illness characterized by headache, chills, fever, malaise and pain in the affected regional lymph nodes. Progression of symptoms is usually rapid with the regional lymphadenitis becoming tender and painful. With specific treatment in uncomplicated cases, fever and general clinical symptoms usually resolve over three to five days.

Septicaemic Plague: Septicaemic plague occurs when *Yersinia pestis* invades and continues to multiply in the bloodstream. It can occur secondarily to bubonic plague or can develop without detectable lymphadenopathy. The host response may result in a wide spectrum of pathological events including disseminated intravascular coagulopathy, multiple organ failure and adult respiratory distress syndrome. Complications include plague pneumonia, plague meningitis and hepatic or splenic abscesses.

Pneumonic Plague: Pneumonic plague is the least common but most dangerous and fatal form of the disease. It can develop as a secondary complication of septicaemic plague or result from inhalation of infectious droplets. The incubation period is usually varies from one to three days. There is sudden onset of chills, fever, headache, body pains, weakness and chest discomfort. This progresses rapidly to severe pneumonia accompanied by high fever, dyspnea, and often haemoptysis. If specific antibiotic therapy is not begun within 18 - 24 hours of onset, the patient is unlikely to survive. Pneumonic plague must be considered highly contagious, although person - to - person transmission is most likely in cold humid environments coupled with overcrowding. As the transmission occurs through

infected droplets (and not airborne droplet nuclei), person - to - person transmission requires close contact.

Differential Diagnosis

Differential diagnosis of bubonic plague includes bacterial lymphadenitis, infectious mononucleosis, lymphatic filariasis, tick typhus, tularemia and other causes of acute lymphadenopathy. Involvement of intra - abdominal lymph nodes may mimic appendicitis or acute cholecystitis. Pneumonic plague may be confused with other causes of acute, severe community - acquired pneumonia, such as pneumococcal, streptococcal or *Haemophilus influenzae* pneumonia (1).

Diagnosis

Plague is diagnosed clinically based on exposure history and the symptoms of the patient. Presence of the classical buboes leads to suspicion of plague. Septicaemic plague resembles other gram - negative septicemias and is, therefore more difficult to diagnose on clinical grounds. Pneumonic plague can similarly be mistaken for other pneumonias. If possible, samples for confirmation of plague should be taken before treatment is begun. However, treatment should not be delayed by waiting for the laboratory results (15). Collection and transport of specimens is dealt with in detail in a separate chapter.

Routine blood tests show Leucocytosis with a predominance of neutrophils. Total WBC counts may be as high as 25,000/ml. The degree of leucocytosis is proportional to the severity of illness. Peripheral blood smear may show toxic granulations. Thrombocytopenia is common (21). The laboratory diagnosis of plague is based on bacteriological and/or serological evidence. Diagnostic specimens for smear and culture include whole blood, sputum, aspirates from suspected buboes, pharyngeal swabs and cerebrospinal from suspected plague meningitis cases (1). Smears stained with Gram, Giemsa, Wright, or Wayson stain can provide supportive but not confirmatory evidence of a plague infection in the form of bipolar staining Gram - negative bacilli.

The diagnosis of plague is confirmed by the culture of *Yersinia pestis* from body fluids or tissues. *Yersinia pestis* grows on solid media as grey - white, translucent colonies, usually too small to be seen as individual colonies at 24 hours. After incubation at 37°C for 48 hours, colonies are about 1 - 2mm in diameter. After 48 - 72 hours of incubation colonies are raised and have an irregular appearance. Cultures are definitely identified as *Yersinia pestis* by specific phage lysis (1, 22). Plague can be also be confirmed serologically by a four - fold or greater change in titre to the *Yersinia pestis* F1 antigen by passive haemagglutination testing of paired serum specimens. The specificity of a positive passive haemagglutination test can be confirmed by the F1 antigen haemagglutination - inhibition test. Some patients of plague seroconvert as early as five days after onset of symptoms, most seroconvert between one and two weeks after onset, while a few seroconvert three weeks or more after onset. Less than 5% do not seroconvert. After seroconversion, positive serological titres usually diminish gradually over months to years. Enzyme - Linked ImmunoSorbent Assays (ELISAs) for detecting IgM and IgG antibodies may also be used for diagnosis. Detection of the F1 antigen in tissues or fluids by direct fluorescent antibody testing

provides presumptive evidence of plague (1, 15). In the recent past rapid diagnosis of plague has become available using the F1 antigen diagnostic assays based on dipsticks. These tests make a bedside diagnosis available within 15 minutes using bubo aspirate, serum and urine specimens (23).

Treatment

When a diagnosis of human plague is suspected, appropriate specimens for diagnosis should be taken immediately and the patient should be started on specific antibiotic treatment without waiting for laboratory confirmation. All patients suspected of having bubonic plague should be placed in isolation until 2 days after starting antibiotic treatment. Suspect plague patients with evidence of pneumonia should be placed in isolation and managed under respiratory droplet precautions.

Streptomycin is the drug of choice. The dose of streptomycin is 30 mg/Kg/day (Not more than of 2 g/day) in divided doses given intramuscularly. Streptomycin must be given for a full course of 10 days or until 3 days after the temperature has returned to normal. Chloramphenicol is a suitable alternative. The dose of chloramphenicol is 50 mg/Kg/day administered in divided doses either parenterally or orally for 10 days. Tetracyclines are effective in the primary treatment of patients with uncomplicated plague. An oral loading dose of 15 mg/Kg tetracycline (not to exceed 1 g total) should be followed by 25 - 50 mg/Kg/day (up to a total of 2 g/day) for 10 days. Tetracyclines may also be used adjunctively with other antibiotics. Fluoroquinolones, such as ciprofloxacin are also effective (1, 15, 21).

Prophylaxis

Close contacts of cases with pneumonic plague, or persons suspected to have had direct contact with body fluids or tissues of a *Yersinia pestis* - infected mammal, or exposed during a laboratory accident to known infectious materials should receive prophylactic antibiotics if the exposure was in the previous six days. Tetracycline and chloramphenicol are the antibiotics of choice for prophylaxis (1).

Prevention and Control

Control of transmission is directed at controlling the rodent reservoirs and flea vectors of the disease. Trying to eliminate fleas and wild rodents from the natural environment in plague - infected areas are impractical. However, controlling rodents and their fleas around places where they are in close proximity of human beings is very important. Environmental sanitation and public health education are effective means of achieving these ends. Rodent and flea control measures are discussed in detail in the relevant Chapters in the section on Entomology.

Surveillance : An effective surveillance system to provide early warning can abort epidemics. Effective plague prevention and control programmes require up - to - date information on the incidence and distribution of the disease. The surveillance programme must be designed to collect, analyse, and interpret clinical, epidemiological, and epizootiological data on plague. Surveillance should identify cases and epizootics as quickly as possible so that steps can be taken to control disease spread (1). Surveillance must include reporting of human cases, ecological and environmental observations, and surveillance of rodent populations. Readers may refer to the WHO Plague Manual

(1) for details on human and rodent surveillance including precautions to be observed by health care workers.

Flea Indices : The most basic information obtained from flea and rodent surveys is the number of fleas of different species found on various species of hosts. This raw data can be used to calculate various indices. The important flea indices in use are (1) :

$$\text{Total Flea Index} = \frac{\text{Total number of fleas collected (regardless of species)}}{\text{Total number of host species examined}}$$

$$\text{Specific Flea Index} = \frac{\text{Number of fleas of species 'A' collected from host species}}{\text{Number of individuals of host species examined}}$$

(Multiplication of this index by 100 gives the percentage index).

$$\text{Percentage of hosts infested} = \frac{\text{Number of host species infested with flea species}}{\text{Total number of host species examined}} \times 100$$

$$\text{Burrow (or nest or house) index} = \frac{\text{Number of Flea species collected from burrows (or nest or house) of host species}}{\text{Total number of burrows (or nest or house) of host species examined}}$$

The specific flea index is the most widely used of the above indices. It has been reported that a specific flea index of greater than 1 for *Xenopsylla cheopis* on rats represents a potentially dangerous situation with respect to increased plague risk for humans.

Vaccination : Plague vaccines were widely used in the past but have not proven effective in the control of plague. Both live attenuated and formalin - killed *Yersinia pestis* vaccines have been developed. The vaccines are variably immunogenic and moderately to highly reactogenic. They do not protect against primary pneumonic plague. Vaccination is of little use during human plague outbreaks, since a month or more is required to develop a protective immune response. Vaccines are, therefore, not recommended for immediate protection in outbreak situations. Vaccination is only recommended as a prophylactic measure for high - risk groups like laboratory personnel who are constantly exposed to the risk of contamination (1,16,24).

The killed or inactivated plague vaccine is prepared from *Yersinia pestis* organisms grown in artificial media and then inactivated in formaldehyde. It is administered intramuscularly as a series of three primary doses. The initial dose of 1 ml is followed 1 to 3 months later by a 0.2 ml dose. A third primary injection of 0.2 ml is given 5 to 6 months after the second. Two booster doses of 0.2 ml are administered at 6 - month intervals, and additional boosters may be given every 1 to 2 years (15). Adverse reactions following injection of the first dose of plague vaccine generally are mild, but the frequency and severity of such events can increase with repeated doses. Live *Yersinia*

pestis vaccines composed of presumably avirulent strains also have been developed. However, none of these vaccines is commercially available, and their safety and efficacy have not been adequately tested (13, 25).

Summary

Plague is one of the oldest diseases known to man. The first plague epidemic has been described in the Bible as the outbreak among the Philistines in 1320 BC. The causal agent, *Yersinia pestis* was discovered in 1894. Plague exists in natural enzootic cycles involving wild rodents and their fleas in several parts of the world. These natural cycles are usually hidden with no transmission to humans. Between 1989 and 2003, a total of 15 year period, 38, 310 cases with 2845 deaths were recorded in 25 countries including India. *Yersinia pestis* is nonmotile, nonsporulating, non - lactose fermenting, gram - negative coccobacillus. *Yersinia pestis* is most commonly transmitted between animal reservoirs and to humans through the bites of infected fleas. There are more than 1, 500 flea species, of which about 30 are known to be vectors for *Yersinia pestis*. Plague is primarily a disease of rodents. The infection is maintained in natural foci of the disease in wild rodent colonies through transmission between rodents. The most common mode of transmission of *Yersinia pestis* to humans is by the bite of infectious fleas. The three commonest clinical presentations of plague are bubonic, septicaemic and pneumonic. Plague is diagnosed clinically based on exposure history and the symptoms of the patient. The laboratory diagnosis of plague is based on bacteriological and/or serological evidence. Smears stained with Gram stain can provide supportive but not confirmatory evidence in the form of bipolar staining Gram - negative bacilli. The diagnosis of plague is confirmed by the culture of *Yersinia pestis* from body fluids or tissues. In the recent past rapid diagnosis of plague has become available using the F1 antigen diagnostic assays based on dipsticks. These tests make a bedside diagnosis available within 15 minutes using bubo aspirate, serum and urine specimens. All patients suspected of having bubonic plague should be placed in isolation until 2 days after starting antibiotic treatment. Streptomycin is the drug of choice. The dose of streptomycin is 30 mg/Kg/day (Not more than of 2 g/day) in divided doses given intramuscularly. Close contacts of cases with pneumonic plague should receive prophylactic antibiotics if the exposure was in the previous six days. Tetracycline and chloramphenicol are the antibiotics of choice for prophylaxis. Control of transmission is directed at controlling the rodent reservoirs and flea vectors of the disease. An effective surveillance system to provide early warning can abort epidemics. The surveillance programme must be designed to collect, analyse, and interpret clinical, epidemiological, and epizootiological data on plague. Plague vaccines were widely used in the past but have not proven effective in the control of plague. Vaccines are, therefore, not recommended for immediate protection in outbreak situations.

Study Exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of Plague

Short Notes : (1) Spectrum of clinical presentations of plague (2) Characteristics of efficient plague vector (3) Flea Indices

MCQs

1. *Yersinia pestis* was first discovered in (a) 1893 (b) 1894 (c) 1895 (d) 1896
2. Number of species in the genus *Yersinia* considered important human pathogens (a) 1 (b) 3 (c) 5 (d) 7
3. Human flea responsible for human to human transmission of Plague (a) *Pulex irritans* (b) *Oropsylla montanus* (c) *Nosopsyllus fasciatus* (d) *Xenopsylla vexabilis*
4. Epizootic hosts are all except (a) Amplification hosts (b) Maintenance hosts (c) Highly susceptible (d) Have high mortality
5. _____ Plague is the least common but most dangerous (a) Septicaemic plague (b) Bubonic plague (c) Pneumonic plague (d) None of the above
6. Drug of choice for treatment of plague (a) Tetracyclines (b) Chloramphenicol (c) Ciprofloxacin (d) Streptomycin
7. Antibiotics of choice for prophylaxis (a) Tetracyclines (b) Rifampicin (c) Ciprofloxacin (d) Streptomycin
8. Specific flea index of greater than _____ for *Xenopsylla cheopis* on rats represents a potentially dangerous situation (a) 1 (b) 2 (c) 3 (d) 4

Answers : (1) b; (2) b; (3) a; (4) b; (5) c; (6) d; (7) a; (8) a.

Rajesh Vaidya

The word 'Rabies' has its origin in Sanskrit, "*rabhas*" means "to do violence". The Greek word for rabies, "*lyssa*" derives from the root "*lud*" which means "violent". Rabies is an acute viral disease, which causes encephalomyelitis in virtually all the warm blooded animals, including man. The causative agent is found in domestic and wild animals and is transmitted to

other animals and humans through close contact with their saliva (bites, scratches, licks on broken skin, and mucus membranes).

Epidemiology

Magnitude of the problem : Rabies is enzootic in animal in more than 100 countries with a population of over 3.3 billion. Approximately 55,000 people die from rabies each year, the vast majority of these deaths occurring in Asia and Africa. In Africa, there are estimated at 24,000 (or 4 per 1,00,000 population) deaths annually. More than 10 million people, mostly in Asia, receive post exposure vaccination against rabies every

year (1). In India alone, 20,000 deaths are estimated to occur annually, i.e. 2 per 1,00,000 population. Almost 1.8 million people annually receive post exposure - prophylaxis against rabies. With the exception of Andaman & Nicobar islands and Lakshadweep islands, human cases of rabies are reported from all over the country round the year (2).

Agent : The Rabies viruses belong to the genus *Lyssavirus* of the *Rhabdoviridae* family. Currently, this genus comprises seven genotypes, type 1 of which represents the classic rabies virus. This RNA virus is bullet shaped round at one end and flat at the other measuring 100 - 300 nm in length and 75 nm in diameter. The virus is covered with a lipid envelope having spike like projections.

The rabies virus is highly resistant to cold, and dryness. The virus is highly thermolabile with a half life of approximately 4 hours at 40°C and 35 seconds at 60°C. In brain tissue, it can survive up to 1 - 2 weeks at room temperature (1). The rabies virus remains stable for several days at 0 - 4°C, indefinitely at (-) 70°C and when freeze dried. The virus cannot withstand pH less than 4 or more than 10. It is also susceptible to the action of oxidizing agents, most organic solvents, surface acting agents and quaternary ammonium compounds. Proteolytic enzymes and UV rays rapidly inactivate the rabies virus. Soaps and detergents are effective against rabies virus because of their lipid eliminating property, which destroy the outer covering of the virus (3, 4).

Host factors : Although all age groups are susceptible, rabies is most common in children aged below 15 years, with 30 - 50% of post - exposure prophylaxis given to children aged 5 - 14 years, the majority being male (3).

Transmission : Human infection usually occurs following a transdermal bite or scratch by an infected animal. Transmission may also occur when infectious material, usually saliva, comes into direct contact with the victim's mucosa or with fresh skin lesions. The virus cannot cross intact skin. Very rarely, rabies may occur through inhalation of virus - containing aerosol or via infected organ transplants. In developing countries, dog bites account for over 90% of cases. Wild animals like jackals, fox, or hyena may also be a source of infection. In developed countries, rabies due to domestic animal bites is rare. Most cases are due to contact with wild animals such as raccoons or skunks. Bat rabies is reported from Latin American countries like Brazil, Venezuela and Mexico, Southern United States and parts of Europe including Germany, Denmark, and Holland.

Incubation periods for Rabies have been reported from as short as four days to as long as 19 years. The usual duration is between 20 to 90 days. 95% cases have incubation period less than one year. The duration of the incubation period may depend on the severity of bite, quantity of virus inoculated, innervation of the bitten area and distance from CNS (3).

Pathogenesis

On entering the human body, the virus then either replicates in non - nervous tissues or directly enters peripheral nerves and travels by retrograde axoplasmic flow to the central nervous system (CNS). The estimated speed of virus migration is 15 - 100 mm per day. The virus then moves from the CNS via anterograde axoplasmic flow within peripheral nerves, leading

to infection of some of the adjacent non - nervous tissues like secretory tissues of salivary glands. The virus is widely disseminated throughout the body at the time of clinical onset (4).

Clinical Features

Prodromal symptoms of rabies are non specific and may last for 2 to 10 days. Malaise, headache, anorexia may be present along with fever, cough, chills, and sore throat. Some patients may have gastro - intestinal symptoms like abdominal pain, nausea and diarrhoea (3). The first rabies specific symptom is pain or paraesthesia referred to the site of exposure which is present in about 50% of cases. Major clinical signs are related to the virus - induced encephalomyeloradiculitis. The acute neurological period shows objective signs of CNS involvement. Two major clinical presentations are observed : furious and paralytic forms that cannot be correlated with any specific anatomical localization of rabies virus in the CNS. In furious rabies there is hyperactivity, disorientation, and hallucinations. The patient may have periods of agitation alternating with periods of calm. Attempts at drinking result in spasm of pharynx, larynx, and diaphragm. Similar effects may occur even on seeing water or blowing air on the face (Aerophobia). Eventually there may be abrupt death or paralysis develops. Paralytic rabies is present in about 20% of cases from onset. The paralysis is maximal in bitten extremity, diffuse or symmetric. The final stage of coma almost always begins within 10 days. Death may occur due to respiratory arrest soon after onset of coma. In cases the patient survives for a few days complications like raised ICT, cardiac arrhythmias, hypotension, and renal failure may be seen. Rabies is invariably fatal (3).

Diagnosis

A diagnosis of rabies can be made on clinical grounds if reliable history of exposure is available or specific signs like hydrophobia or aerophobia are present. There are no laboratory tests to diagnose the infection before onset of clinical disease. Fluorescent Antibody detection in skin biopsy (from neck) can be done for confirmation of diagnosis. Post mortem tests include demonstration of 'Negri Bodies' and isolation of virus. It is important to distinguish rabies from treatable conditions to ensure protection of health care workers, prevent rabies hysteria / psychosis. It is also essential to distinguish rabies from post vaccinal encephalomyelitis caused by the nerve tissue vaccine (5, 6, 7).

Treatment

Rabies is invariably fatal once symptoms develop. Treatment discussed later in the chapter focuses on animal exposures where rabies transmission is a possibility.

Prevention and Control

The essential measures required for the control of rabies are eliminating the diseases in domestic animals like dogs and immunoprophylaxis for humans.

Rabies Vaccines

Nerve Tissue Vaccine (NTV) : More than 100 years ago, Louis Pasteur and his colleagues developed the first crude rabies vaccine for post - exposure prophylaxis based on attenuated virus in desiccated nerve tissue. Although continuously

improved over the years, inactivated NTVs produced in the brains of sheep or goats (Semple) or suckling mice (Fuenzalida) are associated with neurological adverse reactions. In about 0.3 - 0.8 individuals per 1000 vaccinees, contaminating neuroproteins present in the vaccine cause severe allergic encephalomyelitis. India and Nepal have successfully phased out production and use of NTVs (1, 3).

Cell Culture Vaccines (CCV) : CCVs consist of virus that has been inactivated following propagation in cell cultures the human diploid cell vaccine was introduced in 1967. The more recently developed, and less expensive, purified chick embryo cell vaccine and purified Vero cell - based vaccines have characteristics comparable to the human diploid cell vaccines. CCVs are based on fixed viruses of genotype 1.

Factors that should be taken into consideration when deciding whether or not to initiate post exposure prophylaxis include the likelihood of the concerned animal being rabid, category of exposure (I - III), clinical features of the animal, as well as its availability for observation and laboratory testing. In most situations in developing countries, the vaccination status of the offending animal should not be taken into consideration to withhold prophylaxis (1, 3).

Rabies Immunoglobulin (RIG) : Rabies immunoglobulin of both equine (ERIG) and human (HRIG) is available. RIG should be administered in all category III exposures and in category II exposures involving immunodeficient individuals. Given its relatively slow clearance, Human Rabies Immunoglobulin (HRIG) is the preferred product, particularly in cases of multiple severe exposures. Where HRIG is not available or affordable, purified Equine Immunoglobulin (ERIG) is used. Most of the new ERIG preparations are potent, highly purified, safe and considerably less expensive than HRIG. The dose for HRIG is 20 IU/kg body weight, and for ERIG is 40 IU/kg body weight. As much of the recommended dose of passive immunization products as is anatomically feasible should be infiltrated into and around the wounds. The remainder should be administered by deep intramuscular injection at an injection site distant from the vaccine injection site. In case of multiple wounds, the RIG should be diluted with normal saline to make sufficient volume to ensure infiltration at all wound sites. RIG for passive immunization should not be injected later than seven days after the initiation of post - exposure vaccination. Several studies of patients with HIV/AIDS have reported that those with very low CD4 counts will mount a significantly lower or no detectable neutralizing antibody response to rabies. In such patients local infiltration of a passive immunization product are of utmost importance (1, 3).

Vaccination

Rabies vaccines are required to be used in three situations : Post exposure prophylaxis, pre exposure prophylaxis, and vaccination in those previously vaccinated.

Post Exposure Prophylaxis

Intramuscular administration : The post exposure vaccination schedule is based on IM doses of 1 ml or 0.5 ml, depending on the manufacturer. The recommended regimen consists of either a 5 - dose or a 4 - dose schedule.

(a) *The 5 - dose regimen (Essen regimen)* : Prescribes 1 dose

injected into the deltoid muscle (or anterolateral thigh in children aged <2 years) on each of days 0, 3, 7, 14 and 28.

(b) *The 4 - dose regimen ("2 - 1 - 1" or Zagreb regimen)* : Prescribes 2 doses on day 0 (1 in each of the 2 deltoid/thigh sites) followed by 1 dose on each of days 7 and 21.

Intradermal Administration : The high cost of CCVs by the volume required for the standard IM route is prohibitive for widespread use in many areas where dog rabies is endemic. For some CCVs, equal immunogenicity has been demonstrated by ID using at least 60% less vaccine than by IM vaccination. Since 1991, WHO has recommended the ID route of administration for rabies pre - and post - exposure prophylaxis. Either the 8 - site or the 2 - site regimen should be used, as recommended by the respective vaccine manufacturer (8, 9).

(a) *The 8 - site ID regimen* : Prescribes on day 0, injections of 0.1 ml given at 8 sites (1 in each upper arm, 1 in each lateral thigh, 1 on each side of the suprascapular region, and 1 on each side of the lower quadrant region of the abdomen) ; on day 7, 1 injection in each upper arm and each lateral thigh; and on each of days 30 and 90, 1 injection in one upper arm. The dose on day 90 may be replaced by 2 ID injections on day 30.

(b) *The 2 - site ID regimen* : Prescribes 1 injection of 0.1 ml at 2 sites on days 0, 3, 7 and 28.

Previously Vaccinated Individuals : For rabies - exposed patients who have previously undergone complete pre - exposure vaccination or post - exposure prophylaxis with a CCV, 2 IM or ID doses of such a vaccine administered on days 0 and 3 are sufficient. RIG is not necessary in such cases. The same rules apply to people vaccinated against rabies who have demonstrated VNA titres of at least 0.5 IU/ml.

Post - exposure prophylaxis of HIV - infected persons and HIV/AIDS patients : Several studies of patients with HIV/AIDS have reported that those with very low CD4 counts will mount a significantly lower or no detectable neutralizing antibody response to rabies. In such patients and those in whom the presence of immunological memory is no longer assured as a result of other causes, proper and thorough wound treatment as described above and antisepsis accompanied by local infiltration of a passive immunization product are of utmost importance. Immunocompromised patients with category II exposures should receive rabies immunoglobulin in addition to a full post - exposure vaccination series as listed above. An infectious disease specialist with expert knowledge of rabies prevention should be consulted.

Pre Exposure Vaccination

Pre exposure vaccination should be offered to :

- People at high risk of exposure such as those working in rabies diagnostic or research laboratories
- Veterinarians, animal handlers (including bat handlers), animal rehabilitators and wildlife officers
- People (especially children) living in or traveling to high - risk areas

Intramuscular Administration : Pre - exposure rabies vaccination requires IM doses of 1 ml or 0.5 ml, depending on the vaccine type, given on days 0, 7 and 28 (day 28 preferable,

but administration may be advanced towards day 21 if time is limited). For adults, the vaccine should always be administered in the deltoid area of the arm; for children aged <2 years, the anterolateral area of the thigh is recommended. Rabies vaccine should not be administered in the gluteal area, where the induction of an adequate immune response may be less reliable.

Intradermal Administration : ID administration of 0.1 ml volumes on days 0, 7, and 28 (day 28 preferable, but administration may be advanced towards day 21 if time is limited) is an acceptable alternative to the standard IM route. However, ID administration is technically more demanding and requires appropriate staff training and qualified supervision.

Booster Injections : Periodic booster injections are recommended only for people whose occupation puts them at continuous or frequent risk of rabies exposure. In such cases, a booster dose should be given at intervals ideally dictated by regular testing for antirabies antibodies (1, 3).

Control of Rabies in Dogs : Canine rabies can be eliminated, as has been demonstrated in North America and Western Europe. However, canine rabies is still widespread, occurring in over 80 countries and territories, which are predominantly in the developing world. In more than 99% of all human rabies cases, the virus is transmitted from dogs. Effective animal vaccines that provide a considerable duration of immunity have been developed and mass parenteral vaccination programmes remain the mainstay of canine rabies control. Dog destruction alone is not effective in rabies control. Canine rabies control programmes should incorporate three basic elements of epidemiological surveillance, mass vaccination, and dog population control. Rabies should be a notifiable disease. Mass

canine vaccination campaigns have been the most effective measure for controlling canine rabies. At least 70% of the dog population in each community should be vaccinated in areas where canine rabies is endemic. Oral vaccination of dogs offers a new approach that may significantly improve dog vaccination coverage (especially of free - roaming and poorly supervised dogs) when applied either exclusively or in combination with parenteral vaccination. There is no evidence that removal of dogs alone has ever had a significant impact on dog population densities or the spread of rabies. However, the targeted and humane removal of unvaccinated, ownerless dogs may be effective when used as a supplementary measure to mass vaccination (10, 11, 12).

Post Exposure Treatment

Local : Elimination of rabies virus at the site of the infection by chemical or physical means is an effective mechanism of protection. It is, therefore, important to have prompt local treatment of all bite wounds and scratches that might be contaminated with rabies virus. Recommended first - aid procedures include immediate and thorough flushing and washing of the wound for a minimum of 15 minutes with soap and water, detergent or povidone iodine. If soap or an antiviral agent is not available, the wound should be thoroughly and extensively washed with water. People who live in rabies - infected areas should be educated in simple local wound treatment and warned not to use procedures that may further contaminate the wounds. Most severe bite wounds are best treated by daily dressing followed by secondary suturing where necessary. If suturing after wound cleansing cannot be avoided, the wound should first be infiltrated with passive rabies immunization products and suturing delayed for several hours. This will allow diffusion of the antibody to occur through the

Table - 1 : Type of contact, exposure and recommended post - exposure prophylaxis

Category	Type of contact with a suspect or confirmed rabid domestic or wild animal, or animal unavailable for testing ^(a)	Type of exposure	Recommended post-exposure prophylaxis
I	<ul style="list-style-type: none"> • Touching or feeding of animals • Licks on intact skin 	None	<ul style="list-style-type: none"> • None, if reliable case history is available
II	<ul style="list-style-type: none"> • Nibbling of uncovered skin • Minor scratches or abrasions without bleeding 	Minor	<ul style="list-style-type: none"> • Administer vaccine Immediately ^(b) • Stop treatment if animal remains healthy throughout an observation period of 10 days ^(c) or if animal is proven to be negative for rabies by a reliable laboratory using appropriate diagnostic techniques
III	<ul style="list-style-type: none"> • Single or multiple transdermal bites or scratches, licks on broken skin • Contamination of mucous membrane with saliva (i.e. licks) • Exposure to bats ^(d) 	Severe	<ul style="list-style-type: none"> • Immunoglobulin and vaccine immediately • Stop treatment if animal remains healthy throughout an observation period of 10 days or if animal is found to be negative for rabies by a reliable laboratory using appropriate diagnostic techniques

(a) Exposure to rodents, rabbits and hares seldom, if ever, requires specific anti-rabies post-exposure prophylaxis.
 (b) If an apparently healthy dog or cat in or from a low-risk area is placed under observation, the situation may warrant delaying initiation of treatment.
 (c) This observation period applies only to dogs and cats. Except in the case of threatened or endangered species, other domestic and wild animals suspected as rabid should be humanely killed and their tissues examined for the presence of rabies antigen using appropriate laboratory techniques.
 (d) Post-exposure prophylaxis should be considered when contact between a human and a bat has occurred unless the exposed person can rule out a bite or scratch, or exposure to a mucous membrane.

tissues before suturing is performed.

Other treatments : Such as the administration of antibiotics and tetanus prophylaxis, should be applied as appropriate for other bite wounds.

Post Exposure Prophylaxis

Table - 1 should serve as a guide for post - exposure prophylaxis. In cases where exposure is questionable or a patient has a concurrent medical condition that may complicate post exposure prophylaxis, an expert in the administration of rabies prophylaxis should be consulted.

Summary

The word 'Rabies' has its origin in Sanskrit, "*rabhas*" means "to do violence". Rabies is an acute viral disease, which causes encephalomyelitis in virtually all the warm blooded animals, including man. Approximately 55,000 people die from rabies each year, the vast majority of these deaths occurring in Asia and Africa. In India alone, 20,000 deaths are estimated to occur annually. The Rabies viruses belong to the genus *Lyssavirus* of the *Rhabdoviridae* family. This RNA virus is bullet shaped round at one end and flat at the other measuring 100 - 300nm in length and 75 nm in diameter. Human infection usually occurs following a transdermal bite or scratch by an infected animal. The virus cannot cross intact skin. Incubation periods for Rabies have been reported from as short as four days to as long as 19 years. The usual duration is between 20 to 90 days. The duration of the incubation period may depend on the severity of bite, quantity of virus inoculated, innervation of the bitten area, and distance from CNS. The first rabies specific symptom is pain or paraesthesia referred to site of exposure which is present in about 50% of cases. Acute neurological period shows objective signs of CNS involvement. Two major clinical presentations are observed : furious and paralytic forms that cannot be correlated with any specific anatomical localization of rabies virus in the CNS. The final stage of Coma almost always begins within 10 days. Death may occur due to respiratory arrest soon after onset of Coma. Rabies is invariably fatal. A diagnosis of rabies can be made on clinical grounds. There are no laboratory tests to diagnose the infection before onset of clinical disease. Fluorescent Antibody detection in skin biopsy (From neck) can be done for confirmation of diagnosis. The essential measures required for the control of rabies are eliminating the diseases in domestic animals like dogs and immunoprophylaxis for humans. Rabies Vaccines (Nerve Tissue Vaccine (NTV), Cell Culture Vaccines (CCV)) are required to be used in three situations : Post exposure prophylaxis, pre exposure prophylaxis, and vaccination in those previously vaccinated. Since 1991, WHO has recommended the ID route of administration for rabies pre - and post - exposure prophylaxis. Rabies Immunoglobulin of both Equine (ERIG) and Human (HRIG) is also available. Effective animal vaccines that provide a considerable duration of immunity have been developed and mass parenteral vaccination programmes remain the mainstay of canine rabies control. Dog destruction alone is not effective in rabies control. Canine rabies control programmes should incorporate three basic elements of epidemiological surveillance, mass vaccination, and dog population control.

Study Exercises

Long Questions : (1) Discuss the epidemiology, treatment, prevention and control of Rabies (2) Describe in detail the measures to be taken in post exposure treatment.

Short Notes : (1) Intradermal regimen in Post Exposure Prophylaxis (2) Zagreb regimen (3) Pre Exposure Vaccination (4) Rabies Immunoglobulin (RIG) (5) Control of Rabies in Dogs.

MCQs

1. Rabies is found in all parts of India except (a) Maharashtra (b) Gujarat (c) Andaman & Nicobar Islands (d) Uttar Pradesh
2. Rabies virus is (a) Bullet shaped (b) Diamond shaped (c) Cone shaped (d) Round shaped
3. Fluorescent Antibody detection test in diagnosis of rabies is done in (a) Blood (b) Urine (c) Skin Biopsy (d) Saliva
4. The dose for Human Rabies Immunoglobulin (HRIG) is (a) 10 IU/Kg body weight (b) 20 IU/Kg body weight (c) 30 IU/Kg body weight (d) 40 IU/Kg body weight
5. The 2 - site ID regimen prescribes 1 injection of 0.1 ml at 2 sites on days (a) 0, 1, 3 and 7 (b) 0, 3, 7 and 28 (c) 0, 3, 9 and 21 (d) 0, 3, 7 and 21

Answers : (1) c; (2) a; (3) a; (4) b; (5) b.

Rajesh Vaidya

Leptospirosis is a zoonosis spread throughout the world. Often under reported, the disease is now a prominent re-emerging infection and surveillance data suggests that it may be the most common zoonosis in the world (1). It is primarily an infection in rodents and several other wild and domesticated animals. Leptospirosis occurs worldwide but is most common in tropical and subtropical areas with high rainfall. The disease is found wherever humans come into contact with the urine of infected animals. Occupational exposure probably accounts for 30 - 50% of human cases (1 - 3). Most human infections are asymptomatic and the disease presentation can vary from extremely mild illness to fatal illness (4). The severe form of the disease was first described by Adolf Weil as a disease entity in four men who had fever, haemorrhage and severe jaundice in 1886 in Heideberg (5). His name is still attached to a serious form of Leptospirosis called Weil's disease. Inada and Ido identified the causal organism in 1916 in Japan.

Epidemiology

Global : Leptospirosis is endemic throughout the world. However, the incidence of the disease is significantly higher in tropical countries as compared to temperate regions. This is attributed to both the favourable climatic conditions in tropical countries as well as the fact that the tropics have a greater proportion of developing countries which provide greater opportunities for exposure of the human population to infected animals. The peak incidence of the disease is in summer or fall in temperate regions, and during rainy seasons in warm - climate regions (6). The number of human cases worldwide is not known precisely. The World Health Organization estimates that incidence ranges from approximately 0.1 - 1 per 1,00,000 per year in temperate climates to 10 - 100 per 1,00,000 in the humid tropics. During outbreaks and in high - exposure risk groups, disease incidence may reach over 100 per 1,00,000 (7). Increased awareness of the disease has led to increased recognition (8).

India : Though Leptospirosis is widespread in India, the true extent of the disease is not known because no large scale serological surveys have been carried out. However, a number of studies have reported outbreaks in different parts of the country since 1930 (9, 10). Several epidemics of Leptospirosis have occurred in Andaman and Nicobar islands and in southern and western parts of India during the past century. For the past 10 years, the city of Mumbai has been witnessing a seasonal increase in the number of cases of Leptospirosis. Large outbreaks have occurred following the monsoon flooding in the city. A post - cyclone outbreak was reported in Orissa, India in 1999.

Agent : *Leptospira icterohaemorrhagiae* is the causal organism for Leptospirosis. It is a slender, closely wound, very actively motile spirochete varying in length from 6μ to 20μ . Before 1989, the genus *Leptospira* was divided into two species.

Leptospira interrogans which were the pathogenic strains and *Leptospira biflexa* which were the saprophytic strains in the environment. Over 12 species with over 250 serologic variants (Serovars) of the pathogen have been identified. Serovars that are antigenically related have traditionally been grouped into serogroups. The serogroups are useful for epidemiological understanding.

Host : A wide variety of animal species, primarily mammals, serve as the animal hosts for the pathogen and are the primary sources for human infection. Small mammal species, notably feral and peridomestic rodents (rats, mice) and insectivores (shrews and hedgehogs) are the most important hosts for maintaining the infection in nature. Domestic animals like cattle, pigs, dogs, sheep and even larger mammals like horses and buffaloes can be infected. Reptiles and amphibians have also been detected to carry *Leptospira*.

Humans are a "dead end" for *Leptospira* as they do not form an infection reservoir. Adult males are most affected due to occupational exposure. Occupations such as livestock farmers, sewer workers and abattoir workers are most affected. The names for some forms of Leptospirosis like rice field fever, cane cutter's disease, swine herd's disease, dairy farm fever, mud fever reflect transmission conditions. Some recreational activities like swimming in natural waters may also result in exposure. Children may acquire infection from dogs. People living in cities may also be exposed to animal hosts notably rats. Outbreaks of Leptospirosis have been reported following natural disasters such as flooding and hurricanes.

Environment : The pathogenic organisms can survive for weeks in soil and water contaminated with urine and faeces of reservoir animals. Poor housing, improper sewage disposal and unsafe water supply increase the risk of transmission. Warm, humid conditions are ideal for survival of the *Leptospira* and consequently the disease shows a seasonal variation in India.

Transmission : The *Leptospira* have the ability to penetrate mucosa but not intact skin. However they can enter the body through broken skin and some researchers have suggested that they can penetrate through waterlogged skin. Human leptospiral infections result primarily from either direct contact with urine or tissue of infected animals or indirect contact through soil, water or vegetation that is contaminated with animal urine. They may occasionally enter the human body via the inhalation of droplets of urine or via drinking - water. They can be transmitted from human to human by sexual intercourse, transplacentally from the mother to the fetus and via breast milk to a child. The urine from a patient suffering from Leptospirosis should be considered infectious (7).

Pathogenesis

On entering the human body, the organisms are carried by blood to all parts of the body. The leptospiremia can spread to any part of the body but particularly affects the liver and kidney. It causes a systemic vasculitis which allows entry of the spirochetes into different organs and tissues which accounts the broad spectrum of clinical presentation. Despite the possibility of severe complications, the disease is mostly self - limited and nonfatal.

Clinical Features

The incubation period is usually between 5 - 14 days but can range from 2 to 30 days. The clinical presentation of the disease can be extremely variable. Most cases present with symptoms of sudden headaches, fevers, nausea and bodyache. 90% of cases have an acute febrile illness with a biphasic course, non-specific signs and symptoms and an excellent prognosis. The first stage is called the septicemic or leptospiremic stage. During this stage, which lasts about 4 - 7 days, the patient develops a nonspecific illness characterized by fever, chills, weakness, and body ache. These symptoms abate during a one to three day period. The fever subsides and the patient may become completely symptom free. The return of fever heralds the onset of the second stage. This stage is called the immune or leptospiruric stage. Disease referable to specific organs is seen. These organs include the meninges, liver, eyes, and kidney. About three fourths of patients complain of headache. Less than 10% of patients suffer from Icteric Leptospirosis or Weil's disease. The presentation includes fever, jaundice, renal failure and haemorrhage. Other organ systems (pulmonary, cardiac, central nervous) also are involved frequently. Weil's disease carries a mortality rate of 5 to 30% (4, 6, 7).

Diagnosis

As the manifestations of Leptospirosis are non specific, laboratory investigations are essential to confirm the diagnosis. Routine blood and biochemical tests also reveal abnormalities that do not confirm the diagnosis. Patients will have raised ESR. Blood counts reveal thrombocytopenia and leucocytosis while biochemical assays may show hyperbilirubinaemia, elevated serum creatinine, elevated creatinine kinase and elevated serum amylase.

Direct visualization, culture and serology have all been used to confirm the diagnosis of Leptospirosis. Samples for culture from blood, CSF or peritoneal fluid should be collected before antibiotic treatment has been started. Cultures take very long as initial growth is very slow, and hence are not a practical means of confirming the diagnosis. The most reliable serological test is the Microscopic Agglutination Test (MAT). A four fold rise in the MAT titre or a single titre of at least 1 : 800 are diagnostic. Other tests include an indirect haemagglutination test and ELISA for specific IgM antibodies. Rapid commercial tests for leptospiral antibodies have recently become available. PCR may be used for molecular diagnosis for epidemiological studies.

Differential Diagnosis

The diseases which should be considered in the differential diagnosis of Leptospirosis are : Influenza; Dengue and Dengue haemorrhagic fever; Yellow fever and other viral haemorrhagic fevers; Rickettsiosis; Borreliosis; Brucellosis; Malaria; Pyelonephritis; Aseptic Meningitis; Chemical poisoning; Food poisoning; Typhoid fever and other enteric fevers; Viral Hepatitis (7).

Treatment

The spirochetes are sensitive to several antibiotics. There is no need to wait for the confirmation of diagnosis before starting antibiotic treatment. Severe cases of Leptospirosis should be treated with high doses of intravenous penicillin. Less severe

cases can be treated with oral antibiotics such as amoxycillin, ampicillin, doxycycline or erythromycin. Third - generation cephalosporins, such as ceftriaxone and cefotaxime, and quinolone antibiotics also appear to be effective. Aggressive supportive care with strict attention to fluid and electrolyte balance is essential. Peritoneal or haemodialysis is indicated in renal failure (2, 3, 7). Doxycycline 200mg orally once a week has been used for chemoprophylaxis. The drug should be given for a few weeks at a time.

Prevention and Control

The control of Leptospirosis in reservoir animals is impossible because of their sheer variety and numbers. Prevention of human cases may be achieved by use of personal protective measures, avoidance of high risk exposure, immunization and chemoprophylaxis. Some degree of reservoir control can be achieved by rodent control and by reducing infection in domestic animals such as dogs or livestock by immunization. Risk of infection is minimized by avoiding contact with animal urine, infected animals or an infected environment. Protective clothing should be worn and wounds covered with waterproof dressings to reduce the chance of infection if occupational or recreational exposure is likely. In case of an outbreak, persons exposed to animal urine (wading through flood waters etc.) may be given doxycycline chemoprophylaxis.

Killed vaccine is available against Leptospirosis. Due to the large number of serovariants, the effectiveness of the vaccine is limited. Protective antibodies are produced only against the serovars present in the particular vaccine used.

Summary

Leptospirosis is a zoonosis and surveillance data suggests that it may be the most common zoonosis in the world. It is primarily an infection in rodents and several other wild and domesticated animals. The World Health Organization estimates that incidences range from approximately 0.1 - 1 per 1,00,000 per year in temperate climates to 10 - 100 per 1,00,000 in the humid tropics. *Leptospira icterohaemorrhagiae* is the causal organism for Leptospirosis. It is a slender, closely wound, very actively motile spirochete. A wide variety of animal species, primarily small mammal species, notably feral and peridomestic rodents (rats, mice) and insectivores (shrews and hedgehogs) are the most important hosts for maintaining the infection in nature. Humans are a "dead end" for Leptospire as they do not form an infection reservoir. Occupations such as livestock farmers, sewer workers and abattoir workers are most affected. The Leptospire has the ability to penetrate mucosa but not intact skin. Human leptospiral infections result primarily from either direct contact with urine or tissue of infected animals or indirect contact through soil, water or vegetation that is contaminated with animal urine. The incubation period is usually between 5 - 14 days but can range from 2 to 30 days. 90% of cases have an acute febrile illness with a biphasic course, non-specific signs and symptoms and an excellent prognosis. Less than 10% of patients suffer from Icteric Leptospirosis or Weil's disease. The presentation includes fever, jaundice, renal failure and haemorrhage. Weil's disease carries a mortality rate of 5 to 30%. Confirm diagnosis can be achieved by direct visualization, culture and serology. Rapid commercial tests for

leptospirosis antibodies have recently become available. PCR may be used for molecular diagnosis for epidemiological studies. Severe cases of Leptospirosis should be treated with high doses of intravenous penicillin. Less severe cases can be treated with oral antibiotics such as amoxicillin, ampicillin, doxycycline or erythromycin. Prevention of human cases may be achieved by use of personal protective measures, avoidance of high risk exposure, immunization and chemoprophylaxis. Some degree of reservoir control can be achieved by rodent control and by reducing infection in domestic animals such as dogs or livestock by immunization. Doxycycline 200mg orally once a week has been used for chemoprophylaxis. Killed vaccine is available against Leptospirosis but due to the large number of serovariants, the effectiveness of the vaccine is limited.

Study Exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of Leptospirosis.

Short Notes : Clinical Features of Leptospirosis

MCQs

- Weil's disease was first described by Adolf Weil in (a) 1884 (b) 1885 (c) 1886 (d) 1887
- Drug used in chemoprophylaxis of Leptospirosis (a) Ciprofloxacin (b) Septran (c) Doxycycline (d) Rifampicin
- Inada and Ido identified the causal organism of Leptospirosis in (a) America (b) Japan (c) S. Korea (d) China

- Humans are (a) Dead end host for Leptospires (b) Intermediate host for Leptospires (c) Amplifying host for Leptospires (d) None of the above.

Answers : (1) c; (2) c; (3) b; (4) a.

Rajesh Vaidya

Brucellosis is a zoonotic infection of domesticated and wild animals, caused by organisms of the genus *Brucella*. It is transmitted from animals to humans by ingestion of infected food products, direct contact with an infected animal, or inhalation of aerosols. It is known by several names like Malta Fever and Undulant Fever. In 1954, *Brucella* was the first bacteria to be weaponised as biological warfare agent because aerosols are a remarkably efficient method of disease transmission. However, its relatively long and variable incubation period and the fact that many infections are asymptomatic, has made it a less desirable agent for biological warfare. Four species of *Brucella* are known to cause human disease. They are *Brucella melitensis*, *Brucella abortus*, *Brucella suis* and *Brucella canis*.

Descriptions of the disease date back to Hippocrates. Brucellosis in humans has a strong association with military medicine (1).

The disease was first described in 1751 by Cleghorn, a British army surgeon stationed on the island of Minorca (2). In 1861, Marston described the clinical characteristics of the disease (3). In 1887, a British army doctor David Bruce, isolated the causative organism from the spleens of five fatal cases (4). The species was named *Brucella* after him. The term Undulant Fever was given by ML Hughes (5). Bang identified *Brucella abortus* as a cause of abortion in cattle in 1895 (6).

Epidemiology

Global : Brucellosis is a worldwide zoonosis. The highest incidence is seen in areas where cattle or other animal rearing is carried out. High rates of disease are observed in the Middle East, Mediterranean region, China, India, Peru and Mexico. Abortus fever occurs sporadically in all parts of the world including India. No epidemics have been reported from any part of the world but upsurge of the sporadic cases occurs in various parts from time to time. With the advent of animal vaccines and improvements in hygiene in animal rearing, the disease has declined in developed countries. However, the global burden of human brucellosis remains large. It is estimated to cause more than 5,00,000 infections per year worldwide. The number

of reported infections is much lower because the diagnosis is often not confirmed.

India : In India, cattle in Maharashtra, Karnataka, Madhya Pradesh, Tamil Nadu and Orissa have been found infected. Very few surveys have been made. A few surveys in dairy farms show low incidence.

Agent : Brucellae are small, nonmotile, nonsporing, nontoxogenic, nonfermenting, aerobic, Gram-negative coccobacilli. The outer cell membrane is similar to that of other Gram - negative bacilli with a dominant lipopolysaccharide (LPS) component and three main groups of proteins. Brucella species do not harbor plasmids naturally although they are known to readily accept broad - host - range plasmids (6, 7, 8). Brucella colonies become visible on suitable solid media in 2 - 3 days (9, 10). Among the four species that cause disease in humans, *Brucella melitensis* is the most virulent and causes the most severe and acute cases. *Brucella suis* infection causes a prolonged course of illness and may be associated with suppurative destructive lesions. Mild-to-moderate sporadic disease, rarely associated with complications is the characteristic of *Brucella abortus*. Infection with *Brucella canis* results in a disease course that is similar to *Brucella abortus* infection. The onset of disease is insidious, marked by frequent relapses and does not commonly cause chronic disease.

Host : Each Brucella species has a specific animal reservoir. The infection in the animal hosts result in chronic disease that persists for life. The organisms tend to localize in the reproductive organs of the animals, causing sterility and abortions. They are shed in large numbers in the urine, milk and placental fluid of the infected animals. This localization is responsible for the efficient spread of infection to workers who come in contact with these liquids. The specific animal reservoirs for the various Brucella species are shown in Table - 1. Human brucellosis is predominantly a disease of adult males. Farmers, shepherds, butchers, abattoirs workers, veterinarians and laboratory workers are particularly at special risk because of occupational exposure.

Organism	Animal reservoir	Geographic distribution
<i>B melitensis</i>	Goats, sheep & camels	Mediterranean, Asia & Latin America
<i>B abortus</i>	Cattle, buffalo & camels	Worldwide (Eliminated in Japan, Israel & several European nations)
<i>B suis</i>	Domestic & feral swine	South America, Asia & mid - western United States
<i>B canis</i>	Canines	Cosmopolitan

Environment : The organism can survive for weeks under favourable conditions. High humidity, overcrowding of herds and poor hygienic conditions of milk and meat production are favourable for the transmission of infection.

Transmission : Animals shed large amounts of Brucella organisms during septic abortion, at the time of slaughter

and in their milk. The incidence of human disease is closely linked to the prevalence of infection in sheep, goats and cattle and to practices that allow exposure of humans to potentially infected animals or their products. Brucellae can gain entry into humans through breaks in the skin, mucous membranes, conjunctiva, respiratory and gastrointestinal tracts. Ingestion of the organisms with milk or other contaminated animal products or by contact with contaminated fingers is the most common route of infection. Inhalation of aerosols containing the bacteria, or aerosol contamination of the conjunctivae, is another route. Percutaneous infection through skin abrasions or by accidental inoculation is a rare mode of transmission of infection.

Pathogenesis

On entry into the human host, Brucellae are rapidly phagocytosed by polymorphonuclear leukocytes. Brucellae possess the ability to survive and multiply within the phagocytic cells. Soon after infection, the organisms become localized in the organs of the reticulo - endothelial system such as the spleen and lymph nodes. In animals the organisms also localize in the reproductive organs. Large granulomas serve as a source for persistent bacteraemia. The specific host defences against brucellae are similar to those against other intracellular bacteria and are both humoral and cell - mediated. Macrophages process brucellar antigen and present this to T lymphocytes which produce lymphokines. T cell - derived lymphokines are also involved in attracting cells to the foci of infection. This leads to granuloma formation.

Clinical Features

The incubation period is extremely variable. Symptoms usually begin insidiously within two to four weeks but may start after as long as 6 months or more. The presentation of brucellosis is characteristically variable. Symptoms of brucellosis are protean in nature. The onset is usually insidious but rarely may be abrupt. Subclinical infections are common. The symptoms are non-specific. Patients develop fever, malaise, headache, loss of appetite. Bodyache may be unusually severe. Sweating, including malodorous sweat and fatigue are common. The leukocyte count may be normal or reduced, with a relative lymphocytosis. Splenomegaly may often be the only clinical finding.

If the disease is not treated, the symptoms may continue for 2 to 4 weeks and a characteristic undulant pattern of fever can be discerned. Many patients will then recover spontaneously but others may suffer a series of exacerbations. Most affected persons recover entirely within 3 to 12 months but some will develop complications marked by involvement of various organs and a few may enter an ill - defined chronic syndrome. Complications include arthritis, often sacroilitis and spondylitis, central nervous system effects including meningitis, uveitis and occasionally, epididymo - orchitis. In contrast to animals, abortion is not a feature of brucellosis in pregnant women (6). Depression, out of proportion to the symptoms has often been reported.

Diagnosis

Cases of Brucellosis are often not diagnosed because of the non specific presentation of the disease. A high index of suspicion

and a detailed history of possible exposure, either occupational or during travel or of ingestion of contaminated foods are essential. However, at times patients can present several years after initial exposure making diagnosis difficult.

Definitive diagnosis is made by isolation of the organism. Blood culture is the method of choice but specimens need to be obtained early in the disease and cultures may need to be incubated for up to four weeks. Despite these precautions, failure to grow the organism is common, especially in cases of *Brucella abortus* infection. Culture from bone marrow and from presenting foci may be successful. Presumptive identification of cultures can be made from morphology and slide agglutination with specific antiserum. Serology is the most commonly used method for confirming the diagnosis. However interpretation of the results should be done carefully. The tube agglutination test, which tests for anti-O-polysaccharide antibody is considered the best. A titer of 1 : 160 or higher of specific IgG and IgM is considered diagnostic. Most patients already have high titers at the time of clinical presentation, so a 4 - fold rise in titer may not occur. The diagnosis of the chronic Brucellosis Syndrome, without specific localization is difficult. If the cultures are negative and the results of serology are equivocal a confident diagnosis may not be possible.

Treatment

The organism is susceptible to a variety of antibiotics. Doxycycline is usually drug of choice. Other antibiotics that may be used are Rifampicin, Gentamycin and Streptomycin. The use of a single drug has been found to have a high relapse rate, so combined regimens should be used whenever possible. A 6 week regimen of doxycycline 200 mg/day administered orally, with the addition of streptomycin 1 g/day administered intramuscularly for the first 2 to 3 weeks is effective therapy for adults with most forms of Brucellosis. The WHO recommended treatment regime is a combination of both rifampicin 600 to 900 mg/day and doxycycline 200 mg/day given orally for six weeks (6). Some workers have reported that treatment with a combination of streptomycin and doxycycline may result in less frequent relapse than treatment with the combination of rifampin and doxycycline. Endocarditis needs longer duration of treatment. Doxycycline along with a combination of two more drugs for six weeks may be required. Central nervous system disease also needs prolonged treatment with drug combinations like rifampicin.

Prevention & Control

Animals : Eradication of the infection from animal reservoirs is the most important means for preventing human brucellosis. Eradication of brucellosis from domestic animals dramatically reduces the threat to humans and has been successful in several countries. Vaccination of animals and improving the hygiene of slaughter houses can markedly reduce the disease in animals. Animal vaccines are available against several strains of *Brucella*. Detection of infected herds and individual animals and their elimination are also important control measures.

Humans : A live vaccine is available only against a particular strain of *Brucella abortus* (Strain 19 BA). Early diagnosis and treatment of cases is important. Protection of dairy products and pasteurization or boiling of milk is also required for control

of transmission. Personal protective measures in the form of wearing impermeable clothing, rubber boots, gloves and face masks, care during handling of carcasses and safe laboratory procedures also help in control.

Summary

Brucellosis is a zoonotic infection of domesticated and wild animals, caused by organisms of the genus *Brucella*. Four species of *Brucella* are known to cause human disease. They are *Brucella melitensis*, *Brucella abortus*, *Brucella suis* and *Brucella canis*. *Brucella melitensis* is the most virulent and causes the most severe and acute cases. Brucellosis is a worldwide zoonosis, it is estimated to cause more than 5,00,000 infections per year worldwide. Brucellae are small, nonmotile, nonsporing, nontoxigenic, nonfermenting, aerobic, Gram-negative coccobacilli. Each *Brucella* species has a specific animal reservoir and the organisms tend to localize in the reproductive organs of these animals, causing sterility and abortions. They are shed in large numbers in the urine, milk and placental fluid of the infected animals. Farmers, shepherds, butchers, abattoir workers, veterinarians and laboratory workers are particularly at special risk. Brucellae can gain entry into humans through breaks in the skin, mucous membranes or ingestion of the organisms with milk or animal products. The incubation period is extremely variable ranging from two to four weeks but may sometimes be as long as 6 months or more. The symptoms are non specific. Patients develop fever, malaise, headache, loss of appetite. Splenomegaly may often be the only clinical finding. Definitive diagnosis is made by isolation of the organism. Blood culture is the method of choice. The WHO recommended treatment regime is a combination of both rifampicin 600 to 900 mg/day & doxycycline 200 mg/day given orally for six weeks. Vaccination of animals and improving the hygiene of slaughter houses can markedly reduce the disease in animals and thus in man. A live vaccine is available only against a particular strain of *Brucella abortus* (Strain 19 BA). Personal protective measures in the form of wearing impermeable clothing, rubber boots, gloves and face masks, care during handling of carcasses and safe laboratory procedures also help in control.

Study Exercises

Long Question : Discuss the epidemiology, treatment and control of *Brucella* infection in man.

Short Notes : (1) Enlist different species of *Brucella* known to cause human disease and also mention animal reservoir of each species (2) Control of *Brucella* in both human beings and animals.

MCQs

1. Brucellae are all except (a) Motile (b) Nonsporing (c) Nontoxogenic (d) Nonfermenting
2. Animal Reservoirs of *Brucella suis* is (a) Buffalo (b) Camels (c) Feral swine (d) Goats
3. Brucellae causes abortion in (a) Animals only (b) Human beings only (c) Both Animals & Human beings (d) None of the above
4. Drug of choice in treatment *Brucella* is (a) Streptomycin (b) Rifampicin (c) Gentamycin (d) Doxycycline

Answers : (1) a; (2) c; (3) a; (4) d.

Mechanism of Air - borne Infections

Rajesh Vaidya

The central aspect of the spread of infectious disease is the transmission of infection, or the various mechanisms by which disease agents reach and infect the human host. This involves escape of the agent from the source, conveyance to the susceptible host, and entry into that host. Transmission may be direct or indirect. A basic classification is shown in Table 1.

Direct	Indirect
Direct Contact	Airborne
Droplet Infection	Vehicle Borne
	Vector Borne

Air - Borne Transmission

All through history man and his ancestors have sought refuge from the elements by taking shelter within caves, tents and wooden structures. Little aware that the common protection they obtained also fostered the exchange and proliferation of airborne pathogens, which would in the coming years form of one of the most dreaded group of organisms.

Airborne infection is defined as "A mechanism of transmission of an infectious agent by particles, dust, or droplet nuclei suspended in the air." Two types of particles are implicated in

the airborne form of spread of infectious agents :

(a) Droplet nuclei (b) Dust

Droplet Nuclei : Droplet nuclei are tiny particles (1-10 microns) that represent the dried residue of droplets. Smaller particles that are less than 3 to 5 microns in diameter may contain one or two micro - organisms which fail to settle due of gravity and remain suspended in the atmosphere for long periods of time. These infectious aerosols are small enough to bypass host defences in the upper respiratory tract and airways. More particles are deposited in small bronchioles and alveoli as particle size decreases below 5 micron. Typical pulmonary infections acquired due inhalation of infectious aerosols include Tuberculosis, Influenza, Legionellosis, Histoplasmosis, Q fever etc. Fig - 1 shows the relationship between particle size and retention in the alveoli. These droplet nuclei may be formed by evaporation of droplets that have been coughed or sneezed into the air, aerolization of infective material in the course of laboratory procedures, and processes for rendering animals in slaughter houses.

General Prevention and Control Measures

Ventilation : Since organisms transmissible through the air can be widely dispersed, specific air ventilation is required to manage their dispersion thus control outbreaks of airborne infections. If resources are available then (especially in healthcare facilities) techniques such as the use of monitored negative airflow ventilation with at least six air changes per hour and filtration of direct exhaust to the outside should be used. In routine areas of work and stay adequacy of ventilation at all times is ensured by provision of at least two windows per room with an area of about 10 percent of the floor space and arranged so as to provide cross ventilation.

Fig. - 1 : Relationship between Particle Size and Retention in Alveoli

Avoid Overcrowding : Other important measure, for preventing airborne infections is prevention of overcrowding. The minimum floor area should be 6 m² per person. Beds must be spaced with an interval of at least two meters between the centres of the

two adjacent beds.

Respiratory Protection Devices : Surgical masks that cover the mouth and nose should be worn by healthcare staff in hospitals and by the patient themselves also. N95 respirator / surgical mask are currently recommended.

Summary

Airborne infection is defined as “A mechanism of transmission of an infectious agent by particles, dust, or droplet nuclei suspended in the air.” Droplet nuclei are tiny particles (1 - 10 microns) that represent the dried residue of droplets. Typical pulmonary infections acquired due to inhalation of infectious aerosols include Tuberculosis, Influenza, Legionellosis, Histoplasmosis, Q fever etc. Prevention and control measures involve ventilation, avoiding overcrowding and respiratory protection devices.

187 Measles

Rajesh Vaidya

Measles, an acute viral exanthematous fever is a leading cause of childhood deaths in developing countries. Measles is one of the most contagious diseases known. Almost all non - immune children contract this respiratory disease if exposed to the virus. It is a human disease not known to occur in animals. Before the development of safe and effective vaccines measles was responsible for approximately six million deaths of infants and children globally every year. As measles vaccination has become more and more widespread, there has been a marked decline in measles particularly in developed countries. Despite these advances, however, an estimated 20 million cases of measles resulted in 242,000 deaths in 2006 (1). The overwhelming majority of measles deaths occur in poor countries.

Epidemiology

Global : Measles is one of the most important infectious diseases of humans. It has been responsible for millions of deaths since its emergence over five thousand years ago (2). Measles is reported from all countries without exception. Prior to the introduction of a safe and effective vaccine measles epidemics would occur every two to five years resulting in an estimated five to eight million deaths every year (2, 3). The introduction and widespread use of the vaccine has brought about a marked decline in measles occurrence and mortality. In 2000, measles was estimated to have killed over 750,000 children. This has been brought down to an estimated 279,006 reported cases and 242,000 measles deaths in 2006. The largest proportional reduction in deaths due to measles has occurred in the African Region accounting for 70% of the global reduction in measles mortality (4). Despite this remarkable reduction in measles mortality, most deaths occur among infants and young children living in Africa and South East Asia. Measles is the leading cause of vaccine - preventable deaths during childhood.

98% of deaths due to measles occur in developing countries. Case - fatality rates in these countries are normally in the range 1 to 5% but may reach as high as 10 to 30% in populations with high levels of malnutrition and poor access to health care (5).

India : Despite the fact that reliable epidemiological data is relatively limited, measles is clearly important cause of sickness and death in India. Before the introduction of measles vaccine as part of the National Immunization Schedule in 1985, an estimated 100,000 cases of measles occurred each year in the country with outbreaks at an interval of about 3 years. After the introduction of measles vaccination, the number of cases has decreased and the interval between outbreaks has also increased to about 5 years. The number of reported cases of measles in India has declined from 162,560 in 1989 to 51,546 in 2004. The problem with this data is the gross under - reporting of measles as shown by the fact that many Indian states did not report any case of measles for 3 years (2001 - 2003). As a result the estimated measles incidence varies from 0 to 142.7 per 100,000 population (6). States with low immunization coverage report the least number of cases indicating a non functional surveillance system in these States (6).

Agent : The measles virus is a member of the genus *Morbillivirus* from the family paramyxoviridae. The virus is a non segmented, enveloped, negative sense single stranded RNA virus. Measles virus particles are pleomorphic spheres with diameter ranging from 100 nm to 250 nm. It is made up of six structural proteins. The measles virus is easily destroyed by drying, exposure to sunlight and acids. It can, however, remain viable in droplets for several hours (7). Humans are the only natural hosts for the virus. However, non - human primates can be infected with the measles virus and develop an illness similar, but milder to measles in humans (2, 3). There is only one serotype.

Host : Susceptibility to infection is universal in those not exposed irrespective of age. However, most infections occur in the age group six months to three years in developing countries. In India, more than 50% of cases were reported in children less than five years of age. The disease takes a more serious form in adults. While the virus exhibits no gender predilection, mortality following acute measles has been observed to be higher in females at all ages (8). Immunity lasts lifelong after natural infection. Nutritional status has an important bearing on the severity of disease. Measles is very severe in malnourished with higher mortality. It can precipitate Kwashiorkor in borderline cases. Persons with malnutrition, especially vitamin A deficiency, or with severe immunological disorders such as advanced HIV infection are at increased risk of developing severe or even fatal measles.

Environment : In India, the peak incidence of measles is in winter and early spring. In temperate countries most cases occur in winter months. Overcrowding favours transmission.

Transmission : Measles is one of the most contagious diseases known with secondary attack rates close to 90%. The mode of transmission is person to person by direct contact. Transmission is through droplets or airborne spread of secretions from the respiratory tract of measles cases. Articles freshly soiled by discharges are also infective. The period of communicability is from one to two days before prodrome to four days after

appearance of rash. Communicability rapidly reduces after appearance of rash (9).

Clinical Features

The incubation period ranges from 8 to 13 days from exposure to fever and is usually 14 days from exposure to appearance of rash. The first sign of infection is high fever.

The fever lasts one to seven days. During the initial stage the patient may develop cough, coryza and conjunctivitis. Koplik's spots, which are considered pathognomonic for measles, appears towards the end of the prodrome. They are small white spots on a red background inside the cheeks. The measles rash usually appears 2 to 4 days after prodromal symptoms. It first appears on the face and upper neck. Over a period of about three days, the rash spreads, to the trunk and extremities. The rash lasts for five to six days and then fades in the order of appearance. Patients normally improve by the third day of rash, and uncomplicated cases recover completely within 7 to 10 days of the onset of disease.

Complications

Measles is often an unpleasant mild or moderately severe illness. However, the disease can take a severe form particularly in poorly nourished young children, those with Vitamin A deficiency, and immunocompromised individuals. Children usually do not die directly of measles, but from its complications. Complications are more common in children under the age of five years or adults over the age of 20 years.

The commonest complications of measles result from involvement of the respiratory tract or the Central Nervous System (CNS). The most serious complications include blindness, encephalitis, severe diarrhoea possibly leading to dehydration, ear infections including otitis media, and severe respiratory infections such as pneumonia, which is the most common cause of death associated with measles. Measles encephalitis, which is considered an autoimmune disorder, occurs once in about 1000 cases. The case fatality rate in developing countries is generally in the range of 1 to 5%, but may be as high as 25% in populations with high levels of malnutrition and poor access to health care. Subacute Sclerosing Panencephalitis (SSPE) occurs at an average of seven years after initial infection.

Special Situations

The presentation of measles can vary from the typical in some situations. The increased severity of measles among the immunocompromised has already been described. Measles during pregnancy is associated with spontaneous abortion and premature delivery. The disease has a more severe presentation during pregnancy but is not known to cause congenital abnormalities. Children born to mothers with measles may suffer from severe measles (10). It has been speculated that depression of cell mediated immunity as a result of infection with the measles virus may aggravate tuberculosis. It may, therefore, be advisable to delay measles vaccination in persons with tuberculosis until after initiation of chemotherapy for tuberculosis (3).

Diagnosis

History of contact with a case and the typical rash provide adequate clues for a clinical diagnosis of measles in endemic

areas. Laboratory confirmation, if required can be through reliable serological tests. IgM antibodies become detectable within 72 hrs and then fall to undetectable after 1 to 2 months. A four fold rise in measles antibody titer in acute or convalescent serum is considered diagnostic for measles. IgG antibodies appear shortly after onset of rash, peak in 2 to 4 weeks and last for the lifetime. Viral particles can be demonstrated using a sensitive RT - PCR.

Treatment

Most patients of measles need no specific treatment. However, severe cases and those with complications should be provided supportive therapy. General nutritional support and treatment of dehydration with oral rehydration solution may be indicated. Antibiotics may also be required for treatment of eye and ear infections as well as pneumonia. However, prophylactic antibiotics are not recommended. Some studies have demonstrated some clinical benefit of the antiviral drug Ribavirin (11). The severity of measles in children can be decreased by oral vitamin A administration (12). All children in developing countries diagnosed with measles should receive two doses of vitamin A supplements given 24 hours apart. This can help prevent eye damage and blindness. Vitamin A supplementation has been shown to reduce the number of deaths from measles by 50%. Supplementary dosage is : Infants 6 - 11 months - 1,00,000 IU; Children 12 months and over - 2,00,000 IU.

Prevention and Control

Active immunization is the primary method of measles prevention. Passive immunization may be resorted to in special circumstances. General measures have little role in the prevention of measles and are included largely for the sake of completion.

General Measures : Outbreaks of measles must be reported to local health authorities. Respiratory isolation may be indicated. Exclusion from school is required for one week from appearance of rash to avoid contact with susceptibles. In hospital strict isolation of cases is essential. Articles soiled by secretions or fluids from vesicles to be incinerated or treated with disinfectants.

Active Immunization : A live attenuated vaccine against measles has been available since 1966. A number of strains like the Edmonston B strain, Schwarz strain and Moraten strain are used in vaccine manufacture. The vaccine is extremely effective and safe.

The age of administration and schedule for the vaccine depends on the risk of contacting measles and the ability of the vaccinee to respond to the vaccine. Programme considerations also determine the number of doses recommended. In India, a single dose of 0.5 ml SC is given at nine months of age. In developed countries two doses are given. The first dose at 12 to 15 months followed by a second dose at 4 to 5 years of age.

Measles vaccination is contraindicated for immunocompromised individuals and during pregnancy. Persons with a history of an anaphylactic reaction to neomycin, gelatin or other components of the vaccine should not be vaccinated. While the vaccine should not be administered if there is high fever

or serious diseases, mild illness is not a contraindication for vaccination.

The WHO position on the vaccine is that immunization against measles is recommended for all susceptible children and adults for whom measles vaccination is not contraindicated (12). Asymptomatic HIV infection is an indication, not a contraindication, for measles vaccination. HIV-infected infants should be given the measles vaccine at 6 months of age, followed by an additional dose at 9 months unless they are severely immunocompromised.

Passive Immunization : Passive immunization involves the administration of normal human immunoglobulin at a dose : 0.25 ml per Kg body weight. The immunoglobulin should ideally be administered within six days of exposure. Passive immunization is indicated for vulnerable susceptible household contacts like immunocompromised children. HIV infected children must also receive passive immunization, even if they have been vaccinated (13, 14).

Summary

Measles is one of the most important infectious diseases of humans. It has been responsible for millions of deaths since its emergence over five thousand years ago. It is a human disease not known to occur in animals. An estimated 20 million cases of measles resulted in 2,42,000 deaths in 2006. Measles is the leading cause of vaccine - preventable deaths during childhood. 98% of deaths due to measles occur in developing countries. The measles virus is a member of the genus *Morbillivirus* from the family paramyxoviridae. The virus is a non segmented, enveloped, negative sense single stranded RNA virus. There is only one serotype. Susceptibility to infection is universal in those not exposed irrespective of age. Immunity lasts lifelong after natural infection. In India the peak incidence of measles is in winter and early spring. The period of communicability is from one to two days before prodrome to four days after appearance of rash. The incubation Period ranges from 8 to 13 days from exposure to fever and is usually 14 days from exposure to appearance of rash. The measles rash usually appears 2 to 4 days after prodromal symptoms. Patients normally improve by the third day of rash, and uncomplicated cases recover completely within 7 to 10 days of the onset of disease. Most serious complications include blindness, encephalitis, severe diarrhoea, Otitis Media, and severe respiratory infections. History of contact with a case and the typical rash provide adequate clues for a clinical diagnosis of measles. Most patients of measles need no specific treatment. Active immunization is the primary method of measles prevention. A live attenuated vaccine against measles has been available since 1966. In India, a single dose of 0.5 ml SC is given at nine months of age. In developed countries two doses are given. The first dose at 12 to 15 months followed by a second dose at 4 to 5 years of age.

Study Exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of Measles.

Short Note : (1) Complications of Measles (2) Measles vaccination

MCQs

1. Most common cause of death associated with measles is (a) Measles encephalitis (b) Pneumonia (c) Subacute Sclerosing Panencephalitis (d) Severe diarrhoea.
2. Measles virus is (a) Single - stranded RNA Virus (b) Double - stranded RNA Virus (c) Single - stranded DNA Virus (d) Double - stranded DNA Virus.
3. Immunity lasts for _____ after natural infection (a) 5 Yrs (b) 10 Yrs (c) Lifelong (d) None of the above.
4. A live attenuated vaccine against measles has been available since (a) 1964 (b) 1965 (c) 1966 (d) 1967.
5. The dose of human immunoglobulin for Passive immunization against measles is (a) 0.25 ml per Kg body weight (b) 0.50 ml per Kg body weight (c) 0.75 ml per Kg body weight (d) 1.00 ml per Kg body weight.

Answers : (1) b; (2) a; (3) c; (4) c; (5) a.

Rajesh Vaidya

Rubella, also called German measles or "three day measles", is viral fever, which occurs worldwide and is normally a mild childhood disease. However, infection during early pregnancy may cause fetal death or the congenital rubella syndrome.

Epidemiology

Rubella has a worldwide distribution. Data from developing countries is sparse. Before the advent of widespread vaccination in developed countries epidemics of rubella occurred every 6 - 9 years and large scale epidemics at intervals of 30 years (1). The World Health Organization (WHO) estimates that more than 1,00,000 cases of congenital rubella syndrome occur each year in developing countries alone (2). Before the introduction of rubella vaccine the incidence of congenital rubella syndrome varied from 0.1 - 0.2 per 1,000 live births. Epidemic rates varied from 1 - 4 per 1,000 live births. In many developed and some developing countries, widespread rubella vaccination during the past decade has markedly reduced rubella and CRS.

A number of serological surveys particularly among women of child bearing age (15-45 years) have been carried out in India to determine the extent of infection. A large study carried out

by the National Institute of Communicable Diseases (NICD) covering a period of 15 years reported that immunity status of women of childbearing age was as low as 49% in 1988. Over the 15 year period it rose to 87% in 2002. The study concluded that approximately 10 to 15 % of women reached childbearing age without developing immunity against rubella virus and were at high risk of contracting infection during pregnancy (3). A more recent study carried out in Tamil Nadu in 2004 reported that 82.2 per cent children in between 1 - 5 years and 13.5 per cent of girls in the 10 - 16 years age groups were seronegative for rubella (4).

Agent : The rubella virus is an enveloped, single - stranded RNA virus of the genus *Rubivirus* from the family *Togaviridae*. Roughly spherical, the virus has a diameter of 60 nm. Humans are the only known reservoir (5). A delicate virus, rubella is easily inactivated by lipid solvents, formalin, ultraviolet light, and extremes of pH and heat (1).

Host : In the pre - vaccine era, the peak age of incidence was in the 5 - 9 years age group. With widespread childhood vaccination in the developed countries, the frequency of rubella has increased in the older age groups.

Environment : The disease exhibits a seasonal pattern. In temperate countries seasonal peaks of the disease are seen in late winter and spring, though infection remains endemic through the year.

Transmission : Rubella virus is transmitted by the respiratory route. The virus is spread by droplets shed from respiratory secretions of infected persons. The virus is highly communicable but less so than measles and varicella. As the disease has a large proportion of sub-clinical cases, they become important factors in disease transmission. Cases are infective from 10 days before to 15 days after onset of rash. Infants with congenital rubella continue to excrete the virus for several months despite high titers of neutralizing antibodies. Natural infection confers lifelong immunity.

Clinical Features

Postnatal Rubella : The incubation period ranges from 12 to 23 days, with an average of 18 days. Viraemia occurs about a week after exposure and leads to viral spread to different organs. A large proportion of cases of postnatal rubella are subclinical. Children suffer from a milder form of the disease as compared to adults. Adults may have prodromal features of fever, malaise and anorexia. Generalized lymphadenopathy and a maculopapular rash are major clinical manifestations. The rash lasts 3 - 5 days. It usually first appears on the face and moves down the body. Complications of rubella are not as common as those following measles. Arthritis or arthralgia can occur in adults, being more common in females. Haemorrhagic manifestations, thrombocytopenia and encephalitis have been reported but are extremely rare complications.

Congenital Rubella : The effects of the rubella virus on the developing foetus are essentially a function of the duration of pregnancy at the time of infection. The risk of congenital defects gradually drops from as high as 65 - 85% in the first two months of pregnancy, to 30 - 35% in the third month, to 10% in the fourth month. The effects of congenital rubella may be temporary (low birth weight), permanent (deafness) and developmental (myopia). The effects of congenital rubella are often not apparent at birth but may be revealed later. More than 50% of infants born with Congenital Rubella Syndrome (CRS) appear normal at birth.

Diagnosis

The mild presentation of the disease makes clinical diagnosis difficult. For postnatal rubella, confirmation of diagnosis can be done serologically. ELISA tests for IgG and IgM antibodies are available. Presence of rubella IgM or demonstration of a significant rise in rubella IgG from paired acute and convalescent sera provide evidence of ongoing or recent rubella infection. For congenital rubella, the diagnosis can be confirmed by RT - PCR or viral isolation from amniotic fluid.

Treatment

Given the mild nature of postnatal rubella, no specific treatment is required. Patients with complications, commonly arthritis require symptomatic treatment.

Prevention

A live attenuated vaccine against rubella has been available since 1966. There are a number of rubella vaccines available, either as single antigen vaccines or combined with either Measles vaccine (MR), Mumps vaccine or Measles and Mumps vaccine (MMR). Most of the currently - licensed vaccines are

based on the live, attenuated RA 27/3 strain of rubella virus. Rubella vaccine is usually administered at age 12 - 15 months. The vaccine has proven to be safe and effective. Seroconversion rates are as high as 95%. The vaccine should not be administered during pregnancy. However, accidental vaccination during pregnancy does not produce any ill effects (6).

WHO Position : The primary purpose of rubella vaccination is to prevent the occurrence of congenital rubella infection. Resource constraints may be an important factor in deciding the mode of use of the rubella vaccine. WHO recommends that countries wishing to prevent CRS should immunize adolescent girls and/or women of childbearing age. The most rapid impact would be achieved by mass campaigns for women of childbearing age (and men preferably). For increased impact even men should be vaccinated (2). The most commonly available rubella vaccine in India is the MMR (Measles, Mumps, and Rubella) vaccine. This vaccine is administered 0.5ml subcutaneously between 15 and 18 months of age.

Summary

Rubella, also called German measles has a worldwide distribution. In many developed and some developing countries, widespread rubella vaccination during the past decade has markedly reduced rubella and CRS. The rubella virus is an enveloped, single - stranded RNA virus of the genus *Rubivirus* from the family *Togaviridae*. The disease exhibits a seasonal pattern. In temperate countries seasonal peaks of the disease are seen in late winter and spring. The virus is spread by droplets shed from respiratory secretions of infected persons. Cases are infective from 10 days before to 15 days after onset of rash. Clinically rubella manifest in two forms. In Postnatal Rubella the incubation period ranges from 12 to 23 days and large proportion of cases are subclinical. Generalized lymphadenopathy and a maculopapular rash are major clinical manifestations. Confirmation of diagnosis can be done serologically. In Congenital Rubella, the effects of the virus on the developing foetus are essentially a function of the duration of pregnancy at the time of infection. The risk of congenital defects gradually drops with progress of pregnancy. The effects of congenital rubella may be temporary (low birth weight), permanent (deafness) and developmental (myopia). The diagnosis can be confirmed by RT - PCR or viral isolation from amniotic fluid. No specific treatment is required in both forms of rubella. A live attenuated vaccine against rubella has been available since 1966. Most of the currently - licensed vaccines are based on the live, attenuated RA 27/3 strain of rubella virus. Rubella vaccine is usually administered at age 12 - 15 months. The most commonly available rubella vaccine in India is the MMR (Measles, Mumps, and Rubella) vaccine, administered subcutaneously 0.5ml between 15 and 18 months of age.

Study Exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of Rubella

Short Notes : (1) Clinical manifestations of Rubella (2) Rubella vaccine

MCQs

1. The rubella virus is from _____ family
(a) Herpesviridae (b) Togaviridae (c) Flaviviridae
(d) Paramyxoviridae.
2. Rubella virus has a diameter of (a) 50 nm (b) 60 nm (c) 70 nm (d) 80 nm.
3. Rubella cases are infective from _____ days before to _____ days after onset of rash respectively (a) 2 & 4 (b) 8 & 10 (c) 10 & 15 (d) 20 & 15
4. Average incubation period of Rubella is (a) 16 days (b) 18 days (c) 20 days (d) 22 days
5. Rubella vaccine in India as MMR is given at (a) 6th month (b) 9th month (c) 15 - 18th month (d) 20 - 24th month

Answers : (1) b; (2) b; (3) c; (4) b; (5) c.

Rajesh Vaidya

Chickenpox and Herpes zoster are distinct diseases but both are caused by the *Varicella zoster* virus. Chickenpox is an acute, highly contagious which occurs mostly in children. Herpes zoster on the other hand affects mostly the elderly and immunocompromised persons. Chickenpox has a worldwide distribution. It results from primary infection by the *Varicella zoster* virus. Like other Herpes viruses the *Varicella zoster* virus is capable of remaining latent in the neural ganglia. Reactivation of the latent virus causes Herpes zoster. While chickenpox is considered a benign disease in most settings, it extracts a high price in terms of absenteeism from school, parental leave and medical costs (1, 2).

Epidemiology

Varicella infection occurs world wide. As the virus is highly contagious, disease rates in temperate countries prior to the introduction of widespread vaccination approached the annual birth rate (3). In temperate countries more than 95% of adults have antibodies against the virus (2). Childhood infection rates are somewhat lower in tropical countries but adult infection rates are higher. Chickenpox occurs in both endemic and epidemic forms in India. There has been a significant decline in the incidence and mortality due to chickenpox in countries with widespread paediatric immunization.

Agent : The *Varicella zoster* virus is a double - stranded DNA virus of the Herpesviridae family (Human α herpes virus 3). It is an enveloped virus 150 to 200 nm in size. Humans are the only known hosts of the virus. Only one serotype is known.

Host : Chicken pox is primarily a disease of childhood particularly in temperate countries where 90% of cases occur before 13 years of age (4, 5). In tropical countries, it is more a disease of young adults. The virus exhibits no gender or ethnic group predilection. Natural infection confers lifelong immunity. However, the virus can remain latent in sensory root ganglia. Any reduction in cell mediated immunity can result in reactivation of the virus which causes Herpes zoster. The disease occurs with greater severity among adults, newborn infants, immunocompromised children and pregnant women (6). Mortality rates in normal young children are estimated to be less than 2 per 100,000. Mortality risk for adults is 15 times higher (3).

Environment : The disease epidemiology varies with ambient temperatures. In temperate countries the disease exhibits distinct seasonal variation with peak incidence in winter and spring (7).

Transmission : The source of infection is almost always a case of chickenpox as subclinical cases are rare (less than 5%). Transmission is through direct contact or air borne spread of infected droplets or droplet nuclei. The vesicle fluid is infective. The portal of entry for the virus is the upper respiratory tract. Patients are infective from one to two days before onset of rash to five days after first appearance of rash. Dry scabs are not infective. The virus is extremely contagious. Secondary attack rates are typically over 90% among susceptible household contacts (8). The virus can cross the placental barrier. Maternal infection in first trimester can give rise to congenital varicella syndrome. Maternal infection just prior to delivery may result in neonatal varicella which carries high mortality.

Clinical Features

The incubation period ranges from one to three weeks, usually 13 to 17 days. It is shortened in the immunocompromised, and prolonged if Varicella Zoster Immune Globulin (VZIG) has been

taken (9). The pre eruptive stage of the disease is characterized by mild to moderate fever, malaise and shivering. This stage usually lasts a day or two but may be longer in adults. The rash which is the hallmark of the disease is distributed centrifugally. It first appears on trunk and face. The rash consisting of maculo - papules, vesicles, and scabs shows rapid evolution and pleomorphism. Early in the disease all stages of the rash can be seen. The rash appears in crops with each exacerbation of fever resulting in a fresh crop of rash. Healing starts within 4 - 5 days and the crusts fall off completely within one to two weeks. Immunocompromised children have a greater number of lesions which take longer to heal.

Complications : Chickenpox is usually a mild self limiting disease. However, complications can occur even in otherwise normal children. Secondary bacterial infection of the lesions is the commonest complication with Staphylococci and Streptococci being the most common pathogens. Rare complications include neurologic complications (Meningo encephalitis) and Reye's syndrome which occurs almost exclusively among children who have been given aspirin during the acute phase. In adults, primary varicella pneumonia or haemorrhagic complications may occur.

Maternal infection during the first trimester of pregnancy could result in the congenital varicella syndrome which is characterized by cicatricial skin scarring, hypoplasia of an extremity, mental retardation and low birth weight. Neonatal varicella occurs as a consequence of maternal infection in late pregnancy. The risk is highest in case of maternal disease five days prior to two days after delivery. These children may remain asymptomatic, or they may develop Herpes zoster at a young age without previous history of primary chickenpox infection.

Diagnosis

The diagnosis of chickenpox is usually based on history of exposure and clinical features such as the characteristic rash. Laboratory confirmation of diagnosis is usually not required except in cases of atypical disease presentation. A Tzanck smear of vesicular fluid, demonstrates multinucleated giant cells and epithelial cells with eosinophilic intranuclear inclusion bodies. The disease can be confirmed by serology but tests usually take very long for diagnosis. Both IgM and IgG tests are available. IgM antibody testing is not considered useful as the tests are neither highly sensitive nor specific. Rising IgG titre from paired acute and convalescent sera are considered evidence of acute infection. Detection of virus, viral antigen or protein can also be done using electron microscopy or PCR. Direct Fluorescent Antibody (DFA) tests give rapid reliable results.

Herpes Zoster

Between 10% and 20% of cases of chicken pox develop by Herpes zoster later in life. The disease is characterized by vesicular eruptions which are typically unilateral and follow a dermatomal distribution. The most commonly involved dermatomes are thoracic and lumbar (3). Most cases of Herpes zoster occur after the age of 50 years or among immunocompromised persons. It is a relatively common complication in HIV - positive persons occurring in 8 - 11% of patients. The disease may rarely result in permanent neurological damage in the form of cranial nerve palsies or visual impairment following Herpes

zoster ophthalmia. Nearly 15% of zoster patients have pain or paraesthesia in the affected dermatome for several weeks and sometimes permanently (postherpetic neuralgia) (10). Disseminated, Herpes zoster may occur in patients suffering from malignancies, AIDS or other immunocompromised states. Transmission of *Varicella zoster* virus from Herpes zoster patients may cause chickenpox in non - immune contacts (1).

Treatment

No antiviral therapy recommended for routine use in uncomplicated varicella. Though the Food and Drug Administration (FDA) approved the use of oral acyclovir for the treatment of varicella in otherwise healthy children in 1992, the American Academy of Paediatric Committee on Infectious Diseases published a statement in 1993 stating that it did not consider administration of acyclovir to healthy children to have clinical benefit sufficient to justify its routine administration (11 - 14). In adults acyclovir is effective in reducing the duration and severity of illness, if the drug is administered within 24 hours of onset of rash (15, 16).

Antiviral therapy is indicated among the immunocompromised. These patients should be administered oral and intravenous acyclovir within 24 hrs of onset of rash. Famciclovir and valacyclovir have better bioavailability. Sorivudine (nucleoside analog) can be used in patients who report late. Foscarnet can be used in patients with acyclovir resistant *Varicella zoster* virus. For patients of Herpes zoster, acyclovir and famciclovir, have been approved by FDA for treating. Treatment reduces the severity of pain and hastens the healing of cutaneous lesions.

Prevention and Control

Chickenpox may be prevented or modified by varicella - zoster immune globulin or treated with antiviral drugs. However, Varicella - zoster immune globulin and antiviral drugs are very expensive. Active immunization appears to be the only measure which can control the dissemination of varicella in a susceptible community. The control of chicken pox can be achieved only by widespread vaccination.

Active Immunization : A live attenuated vaccine based on the OKA strain has been available since 1974. The vaccine is considered safe and effective. A single dose achieves over 95% seroconversion. The vaccine must be given after one year of age. The dose for children from one year to below 13 years is 0.5 ml SC single dose. For those above 13 years of age two doses must be given, 4 - 8 weeks apart. The vaccine is well tolerated and side effects are rare. Contraindications and precautions include pregnancy, allergy to neomycin, immunodeficient state, malignancy, steroids administration and recent administration of blood, plasma, or immune globulin.

WHO Position : The World Health Organization (WHO) recognizes that in most developing countries other vaccine - preventable diseases cause greater morbidity and mortality. As a consequence, varicella vaccine is not a high priority for routine introduction into national immunization programmes. The WHO recommends that routine childhood immunization against varicella may be considered in countries where this disease is a relatively important public health and socioeconomic problem, where the vaccine is affordable, and where high (85% - 90%) and sustained vaccine coverage can be achieved (1).

Passive Immunization : Passive immunization against the *Varicella zoster* virus is available in the form of *Varicella zoster* Immune Globulin (VZIG). It is recommended for used in high risk groups including immunocompromised individuals, susceptible pregnant women, and new born infants. In case of exposure it should be administered as soon as possible after exposure (Within 96 h) at the dose of 125 IU per 10 Kg body weight IM injection.

Control Measures : As the disease is highly contagious prevention of transmission is not very effective. Outbreaks of chickenpox must be notified. Cases need to be isolated till all the lesions have crusted (Six days). Concurrent disinfection of articles soiled from discharges from the nose, throat, and from lesions should be done.

Summary

Chickenpox and Herpes zoster are distinct diseases but both are caused by the *Varicella zoster* virus. As the virus is highly contagious, disease rates in temperate countries prior to the introduction of widespread vaccination approached the annual birth rate. Chickenpox occurs in both endemic and epidemic forms in India. The *Varicella zoster* virus is a double - stranded DNA virus of the Herpesviridae family. Chicken pox is primarily a disease of childhood particularly in temperate countries where 90% of cases occur before 13 years of age. The source of infection is almost always a case of chickenpox. Transmission is through direct contact or air borne spread of infected droplets or droplet nuclei. Secondary attack rates are typically over 90% among susceptible household contacts. The incubation period ranges from one to three weeks, usually 13 to 17 days. The pre eruptive stage of the disease is characterized by mild to moderate fever, malaise and shivering. The rash consisting of maculo - papules, vesicles, and scabs shows rapid evolution and pleomorphism. Healing starts within 4 - 5 days and the crusts fall off completely within one to two weeks. The diagnosis of chickenpox is usually based on history of exposure and clinical features such as the characteristic rash. Laboratory confirmation of diagnosis is usually not required. No antiviral therapy recommended for routine use in uncomplicated varicella. In adults acyclovir is effective in reducing the duration and severity of illness if the drug is administered within 24 hours of onset of rash. Antiviral therapy is indicated among the immunocompromised. Between 10% and 20% of cases of chicken pox develop Herpes zoster later in life. The disease is characterized by vesicular eruptions which are typically unilateral and follow a dermatomal distribution. It is a relatively common complication in HIV - positive persons occurring in 8-11% of patients. A live attenuated vaccine based on the OKA strain has been available since 1974. A single dose achieves over 95% seroconversion. The World Health Organization (WHO) recognizes that in most developing countries other vaccine - preventable diseases cause greater morbidity and mortality. As a consequence, varicella vaccine is not a high priority for routine introduction into national immunization programmes.

Study Exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of Chickenpox

Short Notes : (1) Characteristics of Chickenpox rash (2) Herpes zoster

MCQs

1. Chickenpox occurs in _____ forms in India (a) Endemic forms (b) Epidemic forms (c) Both endemic and epidemic (d) None of the above.
2. The *Varicella zoster* virus is a (a) Single - stranded RNA Virus (b) Double - stranded RNA Virus (c) Single - stranded DNA Virus (d) Double - stranded DNA Virus.
3. Mortality rates in normal young children are estimated to be (a) less than 1 per 100,000 (b) less than 2 per 100,000 (c) less than 3 per 100,000 (d) less than 4 per 100,000.
4. The diagnosis of chickenpox is usually based on (a) Smear of vesicular fluid examination (b) Serology (c) Blood test (d) History of exposure and clinical features.
5. Disseminated Herpes zoster may occur in patients suffering from (a) Malignancies (b) AIDS (c) Immunocompromised states (d) All of the above.

Answers : (1) c; (2) d; (3) b; (4) d; (5) d.

Rajesh Vaidya

Smallpox an acute contagious disease caused by *variola* virus is the only disease to have been eradicated by medical science (1). Smallpox is believed to have originated over 3,000 years ago and was one of the most devastating diseases known to humanity. Epidemics of smallpox had inflicted mankind throughout history, and as recently as 1967, some 10 - 15 million cases were still occurring annually in more than 30 endemic countries (2). No treatment for the disease was ever devised. Despite its eradication over 30 years ago smallpox still evokes fear and dread. A part of this fear stems from the potential use of the smallpox virus as a biological weapon.

Eradication

The story of the eradication of smallpox has been lucidly written by Fenner and Hendersen (2). The demonstration in 1798 by Edward Jenner that pus from a cowpox pustule could protect against smallpox brought the first hope that the disease could be controlled. Over a 150 years after the introduction of the vaccine an estimated 50 million cases of smallpox were still occurring in the world each year. When mass vaccination became widespread, the number of cases dropped to around 10 - 15 million by 1967. In 1967 WHO launched an intensified plan to eradicate smallpox (1).

The last known naturally occurring case of smallpox occurred in Somalia on 26 Oct 1977. Subsequently, two cases due to accidental laboratory infections were reported from England in 1978 (3, 4). A little over two year later smallpox officially was declared eradicated by the World Health Organization in 1980. In 1976, there were 76 laboratories through out the world that officially kept stocks of Smallpox virus. By 1980, the number was reduced to six laboratories. In 1983, the number was down to two; the US Laboratory in Atlanta, Georgia, and the Research Centre of Virology, Koltsovo, Russia, both WHO collaborating centers (5).

The two strategies used for the eradication of smallpox were mass vaccination and surveillance containment of the disease. The development of a stable freeze dried vaccine and the use of the bifurcated needle greatly facilitated mass immunization. However, high levels of immunization alone were not enough to eradicate smallpox. The surveillance - containment strategy was an essential accompaniment to mass vaccination for smallpox eradication to be achieved. Eradication was also facilitated by some epidemiological features of smallpox. The disease has no known animal reservoir. There is no long - term carrier state. Recovery from infection provides stable life long immunity. Detection of cases of smallpox was relatively simple because the rash was so characteristic and occurred on the visible parts of the body. An extremely effective and stable vaccine which provides long term immunity was available.

The Disease

Smallpox is caused by the *variola* virus which is a member of the orthopoxvirus family. Other members of the genus include

cowpox and monkeypox. Transmission of smallpox occurs from person to person by infected aerosols droplets. The disease can also be transmitted by contaminated clothes and bedding. The disease has no animal reservoir. The incubation period of smallpox ranges from 7 - 17 days. Individuals are not infective to other during the incubation period.

The onset of symptoms is sudden with fever, malaise, headache, and body ache. Abdominal pain and vomiting may occur. About three days after the onset of fever, the characteristic rash appears, first on the face, hands and forearms and then after a few days progressing to the trunk. The centrifugal distribution of lesions, more prominent on the face and extremities than on the trunk, is a distinctive diagnostic feature of smallpox. Lesions progress from macules to papules to vesicles to pustules. All lesions in a given area progress together through these stages. 8 to 14 days after the onset of symptoms, the pustules form scabs which leave depressed depigmented scars upon healing. The disease can present in either of two main forms : *variola major* and *variola minor*. The disease followed a milder course in *variola minor*, which had a case - fatality rate of less than 1 per cent. The fatality rate of *variola major* was around 30%. Rare forms of smallpox are haemorrhagic and malignant smallpox both of which carry almost 100% mortality (1).

Is Smallpox a Threat Today?

In 1979, WHO recommended that vaccination against smallpox be stopped in all countries. By 1986, routine vaccination had ceased in all countries. The eradication of smallpox was defined by successive WHO expert groups (WHO Scientific Group on Smallpox Eradication, 1968; WHO Expert Committee on Smallpox Eradication, 1972) as "the elimination of clinical illness caused by *variola* virus". An important corollary of this definition was that it did not involve the extinction of *variola* virus. However, there have been no cases of smallpox from any source for over thirty years. Fears of conversion of animal viruses like monkeypox to the smallpox virus have been discounted. Currently, the only credible sources of the virus are the stocks held in the two WHO Collaborating Centres in the United States and Russia. Therefore, other than the use of the virus as a biological weapon, there appears to be little reason to fear the return of smallpox.

Summary

Smallpox is the only disease to have been eradicated by medical science. Over a 150 years after the introduction of the vaccine an estimated 50 million cases of smallpox were still occurring in the world each year. Hence in 1967 WHO launched an intensified plan to eradicate smallpox. The two strategies used for the eradication of smallpox were mass vaccination and surveillance containment of the disease. Finally smallpox was officially declared eradicated by the World Health Organization in 1980. Smallpox is caused by the *variola* virus which is a member of the orthopoxvirus family. Transmission of smallpox occurs from person to person by infected aerosols droplets. The incubation period of smallpox ranges from 7 - 17 days. The onset of symptoms is sudden with fever, malaise, headache and body ache. Three days after the onset of fever, the characteristic rash appears. Lesions progress from macules to papules to

vesicles to pustules 8 to 14 days after the onset of symptoms, the pustules form scabs which leave depressed depigmented scars upon healing.

Diphtheria

Rajesh Vaidya

Diphtheria has been one of the most feared childhood diseases as, prior to the advent of treatment and vaccination, it carried a very high case fatality rate and occurred in devastating outbreaks (1). The word “diphtheria” originates from Greek “leather” which describes the pharyngeal membrane which is pathognomonic for diphtheria. The disease results from infection with toxigenic strains of *Corynebacterium diphtheriae*. The diphtheria bacillus was first described by Klebs in 1883 and was first cultured by Loeffler in a culture medium of his own design in 1884. It is, therefore, known as the “Klebs - Loeffler” bacillus.

Epidemiology

Global : During the course of the twentieth century diphtheria has moved from being a dreaded childhood killer to a relatively rare disease in large parts of the world. In the United States diphtheria has dropped from 147,000 cases reported in 1920 to an average of two cases every year between 1990 and 2003 (2). In developing countries also, the inclusion of diphtheria vaccination in childhood programmes saw a steady decline in the incidence of the disease. The World Health Organization (WHO) estimates that one million cases of diphtheria including 50,000 - 60,000 deaths occurred each year in developing countries before diphtheria toxoid became easily accessible in the 1980s (1). Despite widespread immunization, diphtheria remains endemic in several parts of the developing world including Africa, India, Bangladesh, Vietnam and Brazil (3-5). 80 - 90% of the global burden of diphtheria cases still comes from developing countries (6). However, over the last decade and a half, the infection has re - emerged in some parts of

the developed world. An ongoing epidemic in the states of the former Soviet Union which began during the 1990s has brought diphtheria back into the list of important public health problems (2). This diphtheria epidemic had caused more than 157,000 cases and 5000 deaths by 1999. A total of 12,735 cases of diphtheria were reported to WHO in 2005 (7).

India : The inclusion of vaccination against diphtheria in the National Immunization Schedule has brought about a marked reduction in the incidence of diphtheria in India. Only 1326 cases of diphtheria were reported in India in 1997. This may represent gross underreporting. Over the last decade the number of reported cases has declined from 5,125 in year 2000 to 3,354 in year 2007 with a peak of 10,231 in year 2005 (8). The disease remains endemic in many parts of the country with the highest number of cases being reported from Andhra Pradesh (9, 10). Sporadic outbreaks have repeatedly been reported from in and around Delhi (11).

Agent : *Corynebacterium diphtheriae* are nonmotile, nonsporulating, unencapsulated gram positive bacilli (12). The word “Coryne” originates from Greek meaning “club” and refers to the club shaped appearance of the bacillus. The species is subdivided into four biotypes : *gravis*, *mitis*, *belfanti* and *intermedius* (1). This division is based on colony characteristics, haemolytic activity, and fermentation reactions. The most important factor determining virulence of *Corynebacterium diphtheriae* is the exotoxin. The production of exotoxin depends on a lysogenic β phage. Diphtheria exotoxin causes both local and systemic cell destruction. In addition to the exotoxin, cell - wall components such as the O and K antigens are important in the pathogenesis of the disease.

Host : Before vaccination became widespread, diphtheria was essentially a disease of children. Even today, in endemic countries, the highest incidence rates for diphtheria are in preschool children and school age children. Childhood immunization programmes have altered the age distribution

of cases. Over 60% of cases and more than three fourths of deaths due to diphtheria in an epidemic that began in 1990 in the Newly Independent States of the former Soviet Union occurred among adults (13, 14). In developed countries, where the incidence of diphtheria has declined markedly, the disease now occurs predominantly in unimmunized adults, homosexual men, intravenous drug abusers, and minority racial groups (3). Studies in India have also demonstrated a rise in proportion of cases of diphtheria over five years of age (15).

Environment : The incidence of diphtheria shows a seasonal variation. In temperate countries most of the cases occur during the winter. In tropical areas, this distinction is blurred with transmission taking place throughout the year (1).

Transmission : The primary modes of transmission are airborne respiratory droplets and direct contact with respiratory secretions or exudates from skin lesions. Transmission can occur through fomites. Contaminated milk has also been implicated in transmission. Humans are the only known reservoir of the disease. Infection can spread from both cases and carriers.

Clinical Features

The incubation period for diphtheria ranges from one to five days. In most cases, transmission of infection to susceptible individuals results in short term pharyngeal carriage rather than in disease. Presentation of diphtheria depends on the portal of entry which may be the respiratory tract or the skin. *Corynebacterium diphtheriae* is not very invasive and usually remains confined to the respiratory mucosa and the skin. Systemic spread of the organism is not common.

Respiratory Tract : Infection can result in an asymptomatic carrier state, particularly in regions where the disease is endemic. The common sites within the respiratory tract are anterior nasal infection, faucial infection, and laryngeal or tracheobronchial infection.

Anterior Nasal : The patient is febrile and has serous or seropurulent nasal discharge. Symptoms are usually mild and toxin effects are uncommon.

Faucial Infection : This is the commonest site for respiratory diphtheria. The patient has fever, malaise and sore throat. The characteristic feature is the development of a membrane on one or both sides. The membrane may be confined to the tonsils or extend over a larger area including the uvula, soft palate, oro - pharynx and naso - pharynx. The extent of the membrane corresponds with the severity of the symptoms. The membrane is white in colour to begin with, but rapidly changes to a grey colour. Attempts to remove the membrane result in bleeding. Cases with severe disease develop marked local edema resulting in a "bull neck" appearance and respiratory stridor.

Laryngeal or tracheobronchial infection : This is the most severe type of respiratory infection. It usually results from a downward spread of pharyngeal infection. Patients present with cough, hoarseness of voice, respiratory stridor and may even have dyspnoea.

Cutaneous Diphtheria : Cutaneous diphtheria is characterized by a chronic non - healing ulcer covered by a dirty gray membrane. The ulcers are usually indolent, non - progressive and superficial. Erythema, tenderness, and pain may be present.

Cutaneous diphtheria can co - exist with other skin infections. These lesions are far more common in tropical countries and may constitute an important reservoir of infection. Infection at other sites is uncommon but otitis externa, purulent or ulcerative conjunctivitis, purulent or ulcerative vulvovaginitis and even pyogenic arthritis are known.

Complications

Death from diphtheria results as a consequence of severe respiratory disease resulting in airway obstruction or from systemic complications due to diphtheria toxin. The extent of toxin absorption depends largely on the extent of the mucosal lesions. The WHO - defined clinical conditions associated with increasing risk of toxin - induced systemic disease are the catarrhal form (erythema of pharynx, no membranes); the follicular form (patches of exudates over pharynx and the tonsils); the spreading form (membranes covering the tonsils and posterior pharynx); and the combined form (more than one anatomical site involved, for example throat and skin). Diphtheria toxin is toxic to all body tissues but the most important complications result from its effects on the heart and the nervous system.

Cardiac Toxicity : The probability of developing cardiac dysfunction is directly correlated with severity of local disease. Myocarditis can begin anytime from the first to the sixth week of clinical illness. The complication is seen in 10 to 25% of patients and carries 50 to 60% mortality. Presentation of myocarditis can extend from heart blocks to congestive failure and circulatory collapse.

Neurologic Toxicity : Peripheral or cranial neuritis can develop one to eight weeks after onset of clinical illness. The occurrence of Neurologic toxicity also correlates well with the severity of local disease. Local paralysis of the soft palate and the posterior pharyngeal wall are the most common presentations. Peripheral neuritis occurs more rarely and takes longer to present. Patients who survive recover completely.

Diagnosis

Prompt treatment greatly improves the prognosis in cases of diphtheria. A high index of suspicion can help in early clinical diagnosis. The presence of hoarseness and stridor along with the characteristic membrane in patients with febrile pharyngitis are adequate to make a diagnosis. Confirmation can be done by culturing smears from the membrane on Loeffler's or tellurite media. Culture specimens should ideally be taken before administration of antibiotics. A PCR test is now available for confirming diphtheria.

Treatment

Diphtheria antitoxin is the cornerstone of definitive treatment. Institution of definitive treatment should not wait for bacteriological confirmation of diagnosis as the antitoxin can neutralize the toxin only before it enters the cells. As the antitoxin is equine in origin and can result in severe anaphylaxis, hypersensitivity testing must be done before use. The dose depends on the duration of and severity of disease. Doses ranging from 20,000 units to 100,000 units have been recommended. Both intravenous (for severe cases) and intramuscular (for moderate cases) routes of administration

are recommended.

Antibiotics are administered to cases of diphtheria for terminating toxin production by eliminating the organism and preventing transmission of disease. A number of antibiotics can be used against *Corynebacterium diphtheriae* including penicillin, erythromycin, azithromycin, tetracycline and rifampicin. Procaine penicillin can be given intramuscularly in the dose of 300,000 units for children below 10 Kg weight and 600,000 units for children weight more than 10 Kg twice daily till the patient is able to swallow comfortably. The dose for erythromycin is 125 mg to 500 mg four times a day for 14 days. Supportive treatment is required particularly in severe cases. Management of complications including airway obstruction must be done energetically. Natural infection does not always confer immunity against the toxin. Patients must, therefore, be given active immunization during convalescence.

Contacts

Household and other close contacts of diphtheria cases should be investigated with culture from nasal swabs. Prophylactic antibiotics, either penicillin or erythromycin should be given for seven days irrespective of immunization status. Contacts with positive cultures should receive active immunization against the disease and repeat cultures two weeks after the course of antibiotics.

Prevention and Control

Active immunization against diphtheria is the mainstay of disease prevention. Diphtheria vaccines are based on diphtheria toxoid, which is a modified bacterial toxin that induces protective antitoxin. The vaccine is available almost always combine with Tetanus toxoid (DT) or tetanus toxoid and Pertussis vaccine (DPT).

The potency of diphtheria toxoid is expressed as flocculation units (Lf) whereas toxoid potency is measured in international units (IU). According to WHO requirements, the potency of diphtheria vaccine used for the immunization of children shall not be less than 30 IU per single human dose. Vaccines of lower potency are used for immunization of children aged above 7 years and adults. This reduction of diphtheria toxoid potency minimizes reactogenicity at the injection site but is still sufficient to provoke an antibody response in older children and adults.

The recommended schedule for childhood immunization in India is three doses of DPT given 0.5 ml intramuscularly (IM) at six, ten and fourteen weeks of age. This primary series is followed by another 0.5 ml IM between 16 and 24 months of age. A booster of DT is given at four to six years of age. For previously un-immunized children aged between one and seven years, WHO recommends two doses of DPT two months apart followed by a third dose after 6 to 12 months. For older children and adolescents a similar schedule should be followed using the DT vaccine.

Vaccines containing diphtheria toxoid should be stored 2 to 8 °C. Vaccines that have been accidentally frozen should not be used. Diphtheria toxoid is one of the safest vaccines available. Severe reactions are extremely rare.

Summary

The word “diphtheria” originates from Greek “leather” which describes the pharyngeal membrane which is pathognomonic for diphtheria. The diphtheria bacillus was first described by Klebs in 1883 and was first cultured by Loeffler in a culture medium of his own design in 1884. A total of 12, 735 cases of diphtheria were reported to WHO in 2005. The inclusion of vaccination against diphtheria in the National Immunization Schedule has brought about a marked reduction in the incidence of diphtheria in India with only 3354 cases in 2007. *Corynebacterium diphtheriae* are nonmotile, nonsporulating, unencapsulated gram positive bacilli. The species is subdivided into four biotypes : *gravis*, *mitis*, *belfanti* and *intermedius*. The most important factor determining virulence of *Corynebacterium diphtheriae* is the exotoxin. The primary modes of transmission are airborne respiratory droplets and direct contact with respiratory secretions or exudates from skin lesions. The incubation period for diphtheria ranges from one to five days. The common sites within the respiratory tract are anterior nasal infection, faucial infection, and laryngeal or tracheobronchial infection. Death from diphtheria results as a consequence of severe respiratory disease resulting in airway obstruction or from systemic complications due to diphtheria toxin. Confirmation of diagnosis can be done by culturing smears from the membrane on Loeffler's or tellurite media. Diphtheria antitoxin is the cornerstone of definitive treatment. Antibiotics are administered to cases of diphtheria for terminating toxin production by eliminating the organism and preventing transmission of disease. Household and other close contacts of diphtheria cases should be given prophylactic antibiotics, either penicillin or erythromycin for seven days irrespective of immunization status. Active immunization against diphtheria is the mainstay of disease prevention. In India, three doses of DPT 0.5 ml intramuscularly (IM) are given at six, ten and fourteen weeks of age.

Study Exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of Diphtheria

Short Notes : (1) Clinical manifestations of Diphtheria
(2) Diphtheria Vaccine

MCQs

1. The diphtheria bacillus was first described by (a) Klebs (b) Loeffler (c) Robert Koch (d) None of the above.
2. The most important factor determining virulence of *Corynebacterium diphtheriae* is (a) Exotoxin (b) Endotoxin (c) O antigens (d) K antigens.
3. This is the commonest site for respiratory diphtheria is (a) Anterior Nasal (b) Faucial Infection (c) Laryngeal or tracheobronchial infection (d) None of the above.
4. This is the most severe type of respiratory infection (a) Anterior Nasal (b) Faucial Infection (c) Laryngeal or tracheobronchial infection (d) None of the above.
5. All are characteristics of *Corynebacterium diphtheriae* except (a) Nonmotile (b) Nonsporulating (c) Encapsulated (d) Gram positive bacilli.

Answers : (1) a; (2) a; (3) b; (4) c; (5) c.

Rajesh Vaidya

The name comes from the British word “to mump”, that is grimace or grin. This results from the appearance of the patient as a result of parotid gland swelling. Mumps is a viral infection primarily affecting the salivary glands. In most instances mumps is a mild childhood disease. However, the mumps virus may also affect adults, among whom complications such as meningitis and orchitis are relatively common. Encephalitis and permanent neurological sequelae are rare complications of mumps.

Epidemiology

Mumps is endemic worldwide. Before the 1960s, mumps was a common infectious disease in all parts of the world, with annual incidences usually ranging from approximately 0.1% to 1%, and up to 6% in certain populations. Currently, in most parts of the world, the annual incidence of mumps is in the range of 100 to 1000 per 100,000 population. In areas without childhood vaccination against mumps, epidemics occur every two to five years (3).

Agent : The mumps virus belongs to the genus rubulavirus and is a part of the paramyxoviridae family. It is an enveloped, non - segmented, negative - sense RNA virus with helical symmetry. It has two major surface glycoproteins : the haemagglutinin - neuraminidase and the fusion protein. Mumps virus is sensitive to heat and ultraviolet light. Only one serotype is known (2).

Host Factors : Humans are the only natural hosts. The disease is rare in children younger than one year of age. Peak incidence

is found among children five to nine years of age (3). However, with increasing vaccination, cases are increasingly being reported among young adults. Natural infection usually results in life long immunity.

Environment : In hot climates the disease is endemic throughout the year, whereas in temperate climates incidence peaks in winter and spring (3).

Transmission : Humans are the only known natural host for mumps virus. The virus is spread via direct contact or by airborne droplets from the upper respiratory tract and requires more intimate contact for transmission than measles or chicken pox. Rarely, transmission can be fomite borne through articles freshly contaminated with saliva. Overcrowding resulting in close contact such as school classrooms, cinema halls, army barracks facilitates transmission. Persons with mumps are infective from about 2 days before the onset of swelling of the salivary glands up to 9 days after the onset of swelling.

Pathogenesis : The primary site of viral replication is the upper respiratory tract or the gastrointestinal tract. The virus spreads rapidly to the local lymphoid tissue and a primary viraemia ensues following which the virus spreads to distant sites in the body. The parotid gland is most commonly involved. However the testis, epididymis, pancreas, ovary and CNS may also be involved. A few days after the onset of illness, virus can again be isolated from the blood, indicating that virus multiplication in target organs leads to a secondary viraemia. The virus is excreted in the urine in infectious form during the two weeks following the onset of clinical illness.

Clinical Features

The incubation time averages 16 to 18 days with a range of 2 to 4 weeks (3). With an overall mortality of only 1 per 10,000 cases, mumps is generally a mild, self limiting disease (3). A

prodromal illness of headache, malaise, myalgia and low grade fever occurs for one or two days before the onset of parotid enlargement. Cases of classic mumps develop enlargement of one parotid gland, followed a few days later by enlargement of the contralateral gland. The patient complains of pain and tenderness in the area of the gland. The sub - mandibular and sublingual glands may occasionally be involved. Parotid swelling develops in 95% of those with clinical illness. Upto 30% of patients may have no or very mild symptoms (sub - clinical cases). Most infections in children below two years of age are subclinical. In a small proportion of patients, the symptoms may resemble mild URTI. The parotid swelling starts to subside after 4 to 7 days and complete recovery usually takes another three days.

Complications

Although the disease is usually mild, up to 10% of patients can develop aseptic meningitis. Encephalitis which can result in death or disability is a less common complication. Permanent deafness, orchitis, and pancreatitis are other untoward effects of mumps. Epididymo - orchitis occurs in about 25% of postpubertal men who contract mumps (4). Testicular atrophy occurs in about one - third of patients with mumps orchitis, but sterility is rare. Mumps orchitis appears to be a risk factor for testicular cancer, though not a major one (5).

Oophoritis can occur in postpubertal women. Among women who acquire mumps during the first 12 weeks of pregnancy, more than a quarter suffer spontaneous abortion. Maternal mumps is not associated with congenital anomalies (6 - 9). Aseptic meningitis occurs in 10% of patients with mumps but as many as 50% show abnormalities in the CSF. Encephalitis is a rare complication of mumps. The incidence of encephalitis is around 1 in 6000 cases of mumps. Deafness is a well - recognized complication of mumps. The incidence of hearing loss is estimated to be in the region of 1 per 15,000 cases. The exact incidence of pancreatitis is hard to determine but is thought to be as high as 4%. There is evidence suggesting that mumps virus can infect human pancreatic beta cells, and may trigger the onset of insulin - dependent diabetes mellitus in some individuals. Arthralgia affecting a large joint may develop 2 weeks after parotitis. Myocarditis can usually only be found on ECG examination in 10 - 15% of patients.

Diagnosis

Cases are commonly diagnosed based on history and clinical presentation; laboratory tests are unnecessary. For specific diagnosis, it is possible to isolate the virus from throat swabs, saliva, urine, and CSF. An assay for the detection of mumps - specific immunoglobulin M antibodies in serum and oral fluid specimens is commercially available. Diagnosis can also be made by significant rise between acute and convalescent phase titers in serum mumps IgG antibody level using any standard serologic assay or positive serologic test for mumps IgM antibody. Interpretation of titer rise may have limitations because of mumps cross - reaction with parainfluenza viruses (1, 2). The presence of mumps virus in a cell culture may be detected by the Haemadsorption Inhibition (HAI) test (3).

Management

Mumps is a mild, self limited disease. No specific anti - viral

therapy is indicated. Treatment is conservative. Analgesics may be given for severe headaches or discomfort due to parotitis. In orchitis, stronger analgesics may be needed. Bed rest is recommended for a faster recovery.

Prevention

Deaths due to mumps are rare. However, the fact that in unvaccinated communities almost every person may get infected and infections are associated with a number of complications imposes a substantial economic burden on society (3). Effective vaccines against mumps and high vaccination coverage reduce the incidence of mumps to insignificant levels. The first vaccine developed against mumps was a killed vaccine which was used in the United States between 1950 and 1978. This vaccine offered low efficacy and short term effectiveness. Since then, live attenuated mumps virus vaccines have been developed based on several different strains. The common ones are the Jeryl - Lynn strains, RIT 4385 strains, Leningrad - 3 strains, L - Zagreb strains, Urabe strains & the Rubini strains (3). The recommended use is the form of a single dose schedule, given at age 12 - 18 months. This is because persistent maternal antibody to mumps virus from previous infection or vaccination interferes with the response to mumps vaccines in young infants. Mumps vaccines are available as monovalent, bivalent Measles - Mumps (MM) and trivalent Measles - Mumps - Rubella (MMR) vaccines. Most of these vaccines contain more than 1,000 cell - CCID50 of attenuated mumps virus per dose. The trivalent MMR vaccine is given as 0.5 ml subcutaneously in the outer aspect of upper arm between 12 to 15 months of age. In India, the MMR vaccine is manufactured by the Serum Institute of India. The strains used are L - Zagreb for mumps, Edmonston Zagreb for measles and Plotkins RA 27/3 for rubella. Being live vaccines, these have exacting storage requirements. They should be protected from heat and light both before and after reconstitution. Reconstituted vaccine must be discarded if not used within 6 hours.

There are very few contraindications to mumps vaccination. Like all other live vaccines the mumps vaccine should not be administered to immunocompromised individuals. MMR vaccine can be given to individuals infected with Human Immunodeficiency Virus (HIV) and who are not severely immunocompromised. Though the vaccine has no known teratogenic effects, the mumps vaccine should not be administered to pregnant women and pregnancy should be avoided for three months after vaccination. The mumps vaccine has proven to be extremely safe, adverse effects are rare and mild. The most common adverse reactions following mumps vaccination are parotitis and low - grade fever. Aseptic meningitis following vaccination has been reported at widely varying frequencies. Vaccine - associated meningitis usually resolves spontaneously in less than a week without any sequelae. Orchitis and sensory - neural deafness have been reported following mumps vaccination. Immunoglobulin has not been demonstrated to be of established value in post exposure prophylaxis and is not recommended.

Control

The World Health Organization (WHO) indicates that mumps can be controlled through high routine coverage with mumps

vaccine administered at age 12 - 18 months. Coverage rates below 70% - 80% may result in an epidemiological shift, as reduced (but not interrupted) circulation of mumps virus in the community may result in an increased number of cases in adults without immunity from natural infection. It considers the addition of mumps vaccine to the measles and rubella vaccination programmes using the MMR combined vaccine as logistically sound, encourages the use of MMR combination where affordable and where vaccine supply is sufficient. The WHO recommends that introduction of mumps vaccine into national childhood immunization programmes should be considered only in countries that have or are establishing adequate vaccination programmes for measles elimination and control of the congenital rubella syndrome (3).

Summary

Mumps is a viral infection primarily affecting the salivary glands. Mumps is endemic worldwide. The annual incidence of mumps is in the range of 100 to 1000 per 100,000 population. The mumps virus belongs to the genus rubulavirus and is a part of the paramyxoviridae family. Humans are the only natural hosts. Peak incidence is found among children five to nine years of age. The virus is spread via direct contact or by airborne droplets from the upper respiratory tract. Persons with mumps are infective from about 2 days before the onset of swelling of the salivary glands up to 9 days after the onset of swelling.

The incubation time averages 16 to 18 days with a range of 2 to 4 weeks. A prodromal illness of headache, malaise, myalgia and low grade fever occurs for one or two days before the onset of parotid enlargement. The parotid swelling starts to subside after 4 to 7 days and complete recovery usually takes another three days. Complications include aseptic meningitis, encephalitis, Permanent deafness, orchitis and pancreatitis. Cases are commonly diagnosed based on history and clinical presentation and laboratory tests are unnecessary. Mumps is a mild, self limited disease. No specific anti - viral therapy is indicated. Treatment is conservative. Analgesics may be given for severe headaches or discomfort due to parotitis. Mumps vaccines are available as monovalent, bivalent Measles - Mumps (MM) and trivalent Measles - Mumps - Rubella (MMR) vaccines. The trivalent MMR vaccine is given as 0.5 ml subcutaneously in the outer aspect of upper arm between 12 to 15 months of

age. The WHO recommends that introduction of mumps vaccine into national childhood immunization programmes should be considered only in countries that have or are establishing adequate vaccination programmes for measles elimination and control of the congenital rubella syndrome.

Study Exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of Mumps.

Short Notes : (1) Complications of Mumps (2) Vaccination against Mumps

MCQs

1. The mumps virus belongs to _____ family
(a) Myxoviridae (b) Paramyxoviridae (c) Flaviviridae (d) Rhabdoviridae.
2. Mumps virus how many known serotype ? (a) 1 (b) 2 (c) 3 (d) 4
3. Average Incubation time of Mumps is ? (a) 10 - 12 (b) 13 - 15 (c) 16 - 18 (d) 19 - 21
4. In India, the MMR vaccine uses which strain for mumps
(a) Rubini strain (b) Urabe strain (c) L - Zagreb strain (d) Jeryl - Lynn strain.

Answers : (1) b; (2) a; (3) c; (4) c.

Rajesh Vaidya

Meningitis, or inflammation of the meninges, can be caused by several different bacterial pathogens. By far, the most important of these pathogens is *Neisseria meningitides* because of its potential to cause epidemics (1).

Epidemiology

Meningococcal meningitis occurs worldwide in both endemic and epidemic forms. It is estimated to be responsible for over 500,000 cases and about 135,000 deaths annually (2). First isolated in 1887, *Neisseria meningitides* is an exclusive human pathogen with the mucosal surfaces of the human nasopharynx being its natural habitat and reservoir (3). In most cases colonization of the human nasopharynx is asymptomatic. However, blood stream invasion by *Neisseria meningitides* can lead to meningitis and septicaemia with serious consequences. Even with adequate chemotherapy, meningococcal meningitis has a fatality rate of about 10% and about 15% of the survivors have residual Central Nervous System (CNS) damage (4).

Worldwide serogroups A, B and C account for most cases of meningococcal disease. The predominant serogroups in Asia and Africa are A and C while serogroups B and C are responsible for the majority of cases in Europe and the Americas. Recent outbreaks among Hajj pilgrims have been attributed to serogroup W135. Epidemic rates of meningococcal disease varies from <1 - 3/100,000 in many developed nations to 10 - 25/100,000 in some developing countries.

The highest level of meningococcal disease occurs in the 'African meningitis belt', which stretches across sub-Saharan Africa from Senegal in the west, to Ethiopia in the east. During epidemics this region has a disease incidence rate of >1,000 cases per 10,000 population. The largest recorded outbreak of meningococcal disease in history occurred in Africa in 1996 where 250,000 cases including 25,000 deaths were reported to the WHO. Major epidemics of meningococcal meningitis have been reported from Asia over the past 35 years. China, Vietnam, Mongolia, Bhutan, and Nepal have all reported large outbreaks with Serogroup B being implicated most often.

Isolated cases of meningococcal meningitis have been reported from many Indian states including Haryana, Uttar Pradesh, Rajasthan, Sikkim, Gujarat, Jammu & Kashmir, West Bengal, Chandigarh, Kerala and Orissa. Serogroup A has been associated with all the repeated outbreaks of meningitis, although serogroup B and C have been detected in a few sporadic cases. Several outbreaks of meningococcal meningitis have been reported from Delhi in 1966, 1985 and 2005.

It is estimated to be responsible for over 500,000 cases and about 135,000 deaths annually (2). First isolated in 1887, *Neisseria meningitides* is an exclusive human pathogen with the mucosal surfaces of the human nasopharynx being its natural habitat and reservoir (3). In most cases colonization of the human nasopharynx is asymptomatic. However, blood stream invasion by *Neisseria meningitides* can lead to

meningitis and septicaemia with serious consequences. Even with adequate chemotherapy, meningococcal meningitis has a fatality rate of about 10% and about 15% of the survivors have residual Central Nervous System (CNS) damage (4).

Agent : *Neisseria meningitides* are bean shaped gram negative, aerobic diplococci. The bacteria are surrounded by an outer membrane of lipids, membrane proteins and lipopolysaccharides. Pathogenic meningococci are enveloped by a polysaccharide capsule (5). The capsular polysaccharide provides the basis for their classification into serogroups (6). They differ in their agglutination reactions to sera directed against polysaccharide antigens. At least 13 serogroups have been described : A, B, C, D, E, H, I, K, L, W - 135, X, Y and Z. Almost all meningococcal infections are caused by five serogroups A, B, C, 29E or W - 135 (7).

Host : Maternal antibodies offer protection against invasive disease till the age of six months. Susceptibility peaks at age 6 - 12 months and decreases again after colonization of closely related nonpathogenic bacteria. Subsequent colonization with *Neisseria meningitides* induces antibodies to the infecting strain, thus reinforcing natural immunity. Invasive disease occurs if no protective bactericidal antibodies are mounted against the infecting strain (7). Those infected with the Human Immunodeficiency Virus are probably also at increased risk for sporadic meningococcal disease (8).

Incidence rates are highest between the age of six months and two years (8). The disease is rarely reported in individuals over 50 years of age. There appears to be no gender predilection, though males account for slightly more than half the reported cases (7). Smoking, both active and passive, antecedent upper respiratory tract infection, underlying chronic illnesses are all associated with increased risk of meningococcal disease (8). Low socioeconomic status with its attendant attributes of poor housing, overcrowding, and inadequate ventilation have been consistently found to be associated with higher risk for meningococcal disease.

Environment : Individuals acquire the infection if they are exposed to virulent bacteria and have no protective bactericidal antibodies. Smoking and concurrent viral infection of the upper respiratory tract diminish the integrity of the respiratory mucosa and increase the likelihood of invasive disease. Crowded living conditions also facilitate disease spread, since individuals from different areas have different strains of meningococci. The risk of invasive disease is higher in the first few days after exposure to a new strain.

Transmission : The main modes of transmission are direct contact and respiratory droplets. Respiratory droplets produced by coughing and sneezing can be transmitted to non immune hosts within a distance of one meter. Close contact like kissing, living in close quarters (like military dormitories) and sharing of utensils enhance the risk of transmission (1).

The average incubation period is 3 - 4 days with a range of 2 to 10 days (1). This is also the period of communicability. The bacteria are rapidly eliminated from the nasopharynx after starting antibiotics, usually within 24 hours. Humans are the only reservoir. Both cases and carriers serve as the source of infection. 5 - 10% adults are asymptomatic nasopharyngeal

carriers during inter - epidemic periods. This figure can, however, rise to 60 - 80% in closed populations like military recruits in camps (7).

Pathophysiology : For invasive disease to occur, a susceptible host must be exposed to a pathogenic strain, be colonized by the pathogenic strain on the naso - oropharyngeal mucosa followed by invasion by the bacteria. Invasion can be subdivided into mucosal penetration followed by invasion of blood stream and finally, invasion of meninges (8). Meningococci overcome host defenses and attach to the microvillous surface of nonciliated columnar mucosal cells of the nasopharynx, where they multiply. In a small proportion of those infected, *Neisseria meningitides* penetrates the mucosa and gains access to the bloodstream, causing systemic disease (6). Systemic disease appears with the development of meningococemia and usually precedes meningitis by 24 to 48 hours. This can lead to systemic infection in the form of bacteremia, involvement of the meninges or severe systemic infection with circulatory collapse and disseminated intravascular coagulation. Meningococemia leads to diffuse vascular injury (7).

Clinical Features

The most common symptoms are acute onset of intense headache, high fever, nausea, vomiting, sensitivity to light (photophobia), and stiff neck. These symptoms can develop over several hours, or they may take 1 - 2 days. Most adult patients have an altered mental state with clinical signs of nuchal rigidity. Less commonly reported symptoms include stupor or coma, which carries a poorer prognosis. A more severe form of meningococcal disease is meningococcal septicaemia which is characterized by a haemorrhagic rash which usually indicates disease progression and rapid circulatory collapse.

In Infants and young children bacterial meningitis usually presents as a subacute infection that progresses over several days. There is a slower onset of signs and symptoms with nonspecific symptoms and neck stiffness may be absent. Irritability and projectile vomiting may be the presenting features in this age group. Seizures occur in 40% of children with meningitis. The Waterhouse - Friderichsen syndrome may develop in 10 - 20% of children with meningococcal infection. This syndrome is characterized by large petechial haemorrhages in the skin & mucous membranes, fever, septic shock & DIC (7). Even when the disease is diagnosed early and adequate therapy instituted, 5% to 10% of patients die, typically within 24 - 48 hours of onset of symptoms. Bacterial meningitis may result in brain damage, hearing loss or learning disability in 10 to 20% of survivors (1).

Diagnosis

The diagnosis of meningococcal meningitis is suspected by the clinical presentation and a lumbar puncture showing a purulent spinal fluid. Typical CSF abnormalities in meningitis include the increased pressure (>180 mm water), WBC counts between 10 and 10,000 cells/ μ L, (predominantly neutrophils), decreased glucose concentration (<45 mg/dL) and increased protein concentration (>45 mg/dL) (7). Bacteriological diagnosis in patients with meningococcal disease can be done by Gram staining, direct antigen detection using latex agglutination, or culture. Blood cultures may not be always revealing and only

CSF samples are generally positive.

Gram staining of cerebrospinal fluid is still considered an important method for rapid detection of *Neisseria meningitides*. Commercially available kits to detect polysaccharide antigen in cerebrospinal fluid, have been used to enhance the laboratory diagnosis. These methods are rapid and specific and can provide a serogroup - specific diagnosis, but false negative results are common.

Management

Meningococcal disease is potentially fatal and should always be viewed as a medical emergency. Management of meningococcal disease requires early recognition of the disease, prompt initial parenteral antibiotic therapy and close monitoring with frequent repeated prognostic evaluations. Admission to a hospital centre is essential. Isolation of the patient is not necessary. Antimicrobial therapy must be commenced as soon as possible after the lumbar puncture has been carried out. Several antibiotics can be used for treatment including penicillin, ampicillin, chloramphenicol and ceftriaxone (1). A single intramuscular dose of an oily suspension of chloramphenicol has been shown to be as effective as a five - day course of crystalline penicillin in the treatment of meningococcal meningitis. During epidemics, this may offer a practical alternative to penicillin or ceftriaxone which require multiple injections.

The adult dose of penicillin is 4 million units IV four times a day. The paediatric dose is 250,000 Units/Kg/day given intravenously in divided doses. For Ceftriaxone, the adult dose is four gram IV per day divided into two doses. Paediatric dose is 50 mg/Kg IV divided into two doses (not to exceed 4 g/d). The use of corticosteroids has not been shown to be effective for meningococcal meningitis and its use remains controversial.

Prevention and Control

Chemoprophylaxis : Chemoprophylaxis is the preferred means of prevention of disease among close contacts of sporadic cases. Household contacts, contacts at day care centres and anyone else directly exposed to an infected patient's oral secretions should be administered chemoprophylaxis as soon as possible (ideally within 24 hours). Chemoprophylaxis has probably limited or no benefit if given more than 14 days after the onset of disease. Antibiotics that can be used for chemoprophylaxis are rifampin, ciprofloxacin, ceftriaxone, minocycline, ofloxacin, and spiramycin. Ciprofloxacin single oral dose of 500 mg, rifampicin 600 mg 12 hourly for two days, or ceftriaxone 250 mg IM single dose are the options for adults. Rifampicin should be avoided during pregnancy. The choices for children include rifampicin 10 mg/Kg 12 hourly for two days (5mg/Kg for infants) or injection ceftriaxone 125 mg IM single dose.

Chemoprophylaxis is not recommended during epidemics because of multiple sources of exposure and prolonged risk of exposure. Logistic problems and high cost also make this an impractical alternative for mass use. It is not an effective means of interrupting transmission during an epidemic. Chemoprophylaxis may prevent secondary cases among close contacts, but since secondary cases comprise less than 2% of all meningococcal disease, chemoprophylaxis is of little value for the control of most endemic and epidemic disease. As

almost 15% of children and young adults carry meningococci in the nasopharynx, control of meningococcal disease based on chemotherapeutic elimination of nasopharyngeal carriage is practically impossible except in small communities. Immunization using safe and effective vaccines is the only rational approach to the control of meningococcal disease.

Meningococcal Vaccines : Invasive disease occurs only in patients without specific bactericidal or opsonizing antibodies and therefore, can be prevented by inducing these antibodies. Of the five common serotypes responsible for more than 90% of meningococcal disease, vaccines are available for group A, C, Y and W - 135. At present two types of meningococcal vaccines are licensed; meningococcal polysaccharide vaccines (bivalent and quadrivalent) and meningococcal conjugated polysaccharide vaccine.

Polysaccharide Vaccines : Bivalent polysaccharide vaccines provide protection against serogroups A and C, while the quadrivalent polysaccharide vaccines provide protection against serogroups A, C, Y and W - 135. The vaccines are purified, heat - stable, lyophilized capsular polysaccharides from meningococci of the respective serogroups. The recommended single dose of the reconstituted vaccine contains 50 µg of each of the individual polysaccharides. The dose for primary vaccination for both adults and children older than two years is a single 0.5 - ml subcutaneous injection. The vaccine can be administered at the same time as other vaccines but should be given at a different anatomic site. The antibody responses to each of the four polysaccharides in the quadrivalent vaccine are serogroup - specific and independent. Protective levels of antibody are usually achieved within 7 - 10 days of vaccination. These unconjugated polysaccharide vaccines confer protection in complement deficient persons also. The serogroup A and C vaccines have good immunogenicity, with clinical efficacy rates of 85% to 100% among children five years of age or older and adults. Serogroup Y and W - 135 polysaccharides are safe and immunogenic in older children and adults. Vaccination does not reduce the transfer of bacteria to non - vaccinated persons and carrier status is unaffected. Vaccination has been highly effective in the control of community outbreaks and epidemics in military centers (8).

The vaccine is extremely safe. Adverse effects are mild, the most frequent reaction being pain and redness at the site of injection, lasting for a couple of days. Severe reactions to polysaccharide meningococcal vaccine are uncommon. The major drawback of the presently available vaccines is the absence of activity against group B meningococci (8).

Conjugated polysaccharide vaccine : A quadrivalent A, C, Y and W - 135 conjugate vaccine has been licensed since January 2005. This vaccine contains 4 µg each of A, C, Y and W - 135 polysaccharide conjugated to 48 µg of diphtheria toxoid. The meningococcal conjugate vaccines induce a T - cell - dependent response, resulting in an improved immune response in infants, priming immunologic memory and leading to a booster response to subsequent doses. These vaccines provide long - lasting immunity even when given as a series in infancy and thus induce herd immunity through protection from nasopharyngeal carriage. Nasopharyngeal carriage rates may also be decreased by use of the conjugate vaccine, reducing

bacterial transmission. The conjugated polysaccharide vaccine is contraindicated in patients with a known hypersensitivity to any component of the vaccine, including diphtheria toxoid and in patients with a history of a severe reaction to any other vaccine containing similar components

Recommendations for use of meningococcal vaccine: Routine childhood vaccination with the meningococcal polysaccharide vaccine is not recommended because of its relative ineffectiveness in young children below two years of age. Large scale coverage with current vaccines does not provide sufficient "herd immunity". Consequently, WHO does not currently recommend meningococcal polysaccharide vaccine as part of routine infant immunization. Routine vaccination with the vaccine is recommended for certain high - risk groups, including persons who have terminal complement component deficiencies and those who have anatomic or functional asplenia. Laboratory personnel and healthcare workers who are exposed routinely to *Neisseria meningitidis* in solutions that may be aerosolized should also be considered for vaccination.

Vaccination with a single dose of polysaccharide vaccine is recommended for travellers above 18 months of age going to an area experiencing an epidemic of meningococcal disease or to areas with a high rate of endemic meningococcal disease. Since the epidemic of meningococcal disease that occurred in 1987 during the Hajj in Mecca, proof of vaccination against meningococcus has been required for the pilgrims to the Hajj or Umra, at their entry in Saudi Arabia. More information concerning geographic areas for which vaccination is recommended can be obtained from internet (<http://www.cdc.gov/travel/>).

Revaccination may be indicated for persons at high risk for infection (living in endemic areas) particularly for children who were first vaccinated when they were less than four years of age; such children should be considered for revaccination after 2 - 3 years if they remain at high risk.

Summary

Meningitis can be caused by several different bacterial pathogens, but most important of these pathogens is *Neisseria meningitidis* because of its potential to cause epidemics. It is estimated to be responsible for over 500,000 cases and about 135,000 deaths annually. Meningococcal meningitis has a fatality rate of about 10% and about 15% of the survivors have residual central nervous system (CNS) damage. *Neisseria meningitidis* are bean shaped, gram negative, aerobic diplococci and at least 13 serogroups have been described: A, B, C, D, E, H, I, K, L, W - 135, X, Y and Z. Almost all meningococcal infections are caused by five serogroups A, B, C, 29E or W - 135. Maternal antibodies known to offer protection against invasive disease till the age of six months. Incidence rates are highest between the age of six months and two years. Worldwide serogroups A, B and C account for most cases of meningococcal disease. The highest level of meningococcal disease occurs in the 'African meningitis belt'. The main modes of transmission are direct contact and respiratory droplets. The average incubation period is 3 - 4 days with a range of 2 to 10 days. Humans are the only reservoir and 5 - 10% adults are asymptomatic nasopharyngeal carriers during inter -

epidemic periods. The diagnosis of meningococcal meningitis is suspected by the clinical presentation and a lumbar puncture showing a purulent spinal fluid. CSF examination shows finding similar to bacterial meningitis. Bacteriological diagnosis is by Gram staining, direct antigen detection using latex agglutination, or culture. Management of meningococcal disease requires early recognition of the disease, prompt initial parenteral antibiotic therapy and close monitoring with frequent repeated prognostic evaluations. Currently, penicillin is the drug of choice for the treatment of meningococcal meningitis and septicemia. Chemoprophylaxis is the preferred means of prevention of disease among close contacts of sporadic cases. Antibiotics that can be used for chemoprophylaxis are rifampin, ciprofloxacin, ceftriaxone, minocycline, ofloxacin and spiramycin. Chemoprophylaxis is not recommended during epidemics because of multiple sources of exposure and prolonged risk of exposure. Immunization using safe and effective vaccines is the only rational approach to the control of meningococcal disease. Vaccines are available for group A, C, Y and W - 135. At present two types of meningococcal vaccines are licensed; meningococcal polysaccharide vaccines (bivalent and quadrivalent) and meningococcal conjugated polysaccharide vaccine.

Tuberculosis (TB) is one the biggest public health challenges facing the world today. It is one of the oldest diseases known to mankind. Its causative organism *Mycobacterium tuberculosis* was one of the first bacterial pathogens to be identified. The etiopathogenesis of the disease is clearly understood. A vaccine against Tuberculosis has been available for close a century. Effective treatment against the disease has been available for

over sixty years. Yet the disease is close to its highest levels ever and the World Health Organization declared TB as a global public health emergency in 1993. It remains a potentially fatal disease which is transmitted by droplet nuclei after close contact with a person who has infectious disease. Treatment requires prolonged multidrug therapy which increases the potential risk of nonadherence by patients. Tuberculosis is a true indicator for social development. An overwhelming majority of cases and practically all deaths due to Tuberculosis take place in developing countries (1 - 4). Tuberculosis is currently second only to AIDS as an infectious cause of death worldwide. The World Health Organization estimates that the disease killed 1.7

million people in 2006 (1). The silver lining is that the number of new cases per capita appears to have been falling globally since 2003 (1).

The organism can infect practically any organ of the body. However, pulmonary tuberculosis accounts for over eighty per cent of the total cases suffering from tuberculosis. The other common forms of tuberculosis are meningeal, bone and joint, renal, genital, abdominal or mesenteric and tubercular lymphadenopathy (1, 2). Tuberculosis is the commonest opportunistic infection in patients suffering from AIDS in large parts of the world. The association with HIV infection has refocused global attention on tuberculosis.

History

Tuberculosis has been known by a number of names through history. The ancient Greeks called it *phthisis* (to waste). The swollen glands of the neck due to tuberculosis were called *scrofula*. TB of the skin was known as *lupus vulgaris*. TB of the bone is known as Pott's disease with characteristic vertebral fusion and deformity of the spine. The most familiar term for TB was consumption, which means to consume or wear away. Among all these names, perhaps the most fitting is 'Captain of the Men of Death'.

Mycobacterium tuberculosis has been present in the human population since antiquity. There is evidence of the disease in fragments of the spinal column from Egyptian mummies from 2400 B.C. which show definite pathological signs of tubercular decay (5). Around 460 B.C., Hippocrates identified *phthisis* as the most widespread disease of the times, and noted that it was almost always fatal. Sylvius was the first to identify actual tubercles in the lungs and other areas of consumptive patients in 1679. He also described their progression to abscesses and cavities. In 1882, Robert Koch discovered a staining technique that enabled him to see *Mycobacterium tuberculosis* (6).

Epidemiology

Global : Tuberculosis has been controlled almost completely in the developed world. Almost all the cases and practically all deaths due to tuberculosis take place in developing countries. Though the absolute numbers of cases and deaths are the largest in Asia, the rates of disease and deaths are the highest in Africa.

The latest WHO report on tuberculosis states that the disease is a major cause of illness and death worldwide, especially in Asia and Africa. A total of 9.2 million new cases (139 per 1,00,000 population) and 1.7 million deaths from TB occurred in 2006, of which 0.7 million cases and 0.2 million deaths were in HIV - positive people. 44% of the new cases were smear positive (1). The increase in the number of cases as compared to the previous year (2005) is attributed to population growth. India, China, Indonesia, South Africa and Nigeria rank first to fifth respectively in terms of absolute numbers of cases. The African Region has the highest incidence rate per capita (363 per 1,00,000 population).

The 2007 estimate is that 8.8 million new TB cases occurred of which 7.4 million occurred in Asia and Sub - Saharan Africa with 1.6 million deaths (7). In 1993, tuberculosis was declared a global public health emergency (2, 8). In Aug 2005

the WHO declared a tuberculosis emergency in Africa (9). One - third of the world's population is already infected with TB. Over the centuries, TB has taken over 1 billion lives. Deaths due to tuberculosis comprise 25% of all avoidable deaths in developing countries. 95% of TB cases and 98% of TB deaths are in developing countries. 75% of TB cases in developing countries are in the economically productive age group of 15 - 50 years (1).

The largest number of cases occurs in South East Asia which accounts for 34% of incident cases globally. In 2007 there were an estimated 5.7 million cases in the region. Every year, 3 million people develop active TB in the region and more than 50,000 die. 80% of the patients are in the age group 15 - 54 years. Bangladesh, India, Indonesia, Myanmar and Thailand account for 95% cases (7). However, the estimated incidence per capita in Sub - Saharan Africa is nearly twice that of South East Asia at 350 cases per 1,00,000 population (2). As with cases of disease, the highest number of estimated deaths due to tuberculosis is in the South - East Asian Region, but the highest mortality per capita is in the African Region, where HIV has led to rapid increases in the incidence of TB and increases the likelihood of dying from TB (1, 2, 7).

Despite these high numbers of cases and deaths the WHO believes that the global incidence of TB per capita peaked around 2003 and appears to have stabilized or begun to decline. Incidence per 1,00,000 population is falling in almost all parts of the world except Eastern Europe where it is stable. The downward trend is most pronounced in Latin America and the Caribbean (3.4% per year, 2001 - 2006). However, the slow decline in incidence is more than offset by the global population growth. This resulted in an increase in the number of new cases from 9.1 million in 2005 to 9.2 million in 2006. While there has been a tremendous decrease in tuberculosis cases in developed countries in the last forty years, there has been an increase in the absolute number of tuberculosis cases in developing countries (1). It is estimated that between 2002 and 2020, approximately 1 billion people will be newly infected, over 150 million will get sick, and 36 million will die of TB, if control is not further strengthened (2).

India : Tuberculosis is the biggest public health problem in the country. With 1.8 million cases occurring annually, India accounts for a fifth of the world's new TB cases and 2/3rd of the cases in South - East Asia. This makes India the highest TB burden country in the world. It has been estimated that for the year 2000 there were about 3.8 million bacteriologically positive TB cases in the country (10). Overall prevalence of infection in India is estimated to be 30% while the annual incidence of infection is estimated to be 1 - 2 %. The prevalence of disease is thought to be 4 per 1000 and the incidence of disease 1.5 per 1000. The prevalence of infection has been found to be increasing with age. The peak age for males is 45 - 54 years and that for females is 35 years. No rural-urban differences in the rate have been found.

Tuberculosis kills more adults than any other infectious disease in India. Because it affects adults, tuberculosis causes enormous social and economic disruption. Prior to 2000, the annual number of deaths due to tuberculosis was estimated to be 5,00,000. This has been revised downwards to 3,70,000

as per WHO estimates in 2004 (mortality rate 30 per 1,00,000 persons). More than 80% of the burden of tuberculosis is due to premature death, as measured in terms of Disability Adjusted Life Years (DALYs) lost. In India, over 70% of the cases occur in the economically productive age group (15 - 54 years). TB causes huge economic loss with about 17 crore workdays lost due to the disease. The annual economic cost of tuberculosis to the Indian economy is at least US\$ 3 billion (more than Rs 13,000 crore) (10). The burden of TB is enormous but is hidden by stigma. TB kills more women in India than any other infectious disease. Women with tuberculosis are often severely stigmatized (11, 12).

Agent : Human tuberculosis is caused by *Mycobacterium tuberculosis* which belongs to the genus *Mycobacterium*, family Mycobacteriaceae and Order Actinomycetales. *Mycobacterium tuberculosis* is Gram positive, non - motile, non - sporing, pleomorphic rod. The bacilli are obligate aerobes growing most successfully in tissues having the highest partial pressure of oxygen, such as lung apices. They are facultative intracellular pathogens, slow - growing with a generation time of 12 to 18 hours. Hence, lesions typically evolve in a sub - acute to chronic course. They are classified as Acid - Fast Bacilli (AFB) because they retain the carbol - fuchsin red dye after washing with acid, alcohol, or both (3, 4). *Mycobacterium bovis* is the etiologic agent of TB in cows and rarely in humans. Both cows and humans can serve as reservoirs. Humans can also be infected by the consumption of unpasteurized milk. *Mycobacterium africanum* can be a rare cause of tuberculosis. Other human pathogens belonging to the genus *Mycobacterium* include *Mycobacterium avium* which causes a TB - like disease especially prevalent in AIDS patients and *Mycobacterium leprae*, the causative agent of leprosy.

Host : Tuberculosis can occur at any age. In India disease prevalence is more in the older age groups. It occurs in both the sexes and it is not a hereditary disease. Man has no inherited immunity against tuberculosis. It is now known that both delayed hypersensitivity and acquired resistance to tuberculosis are cell mediated immune responses. Persons who are undernourished and suffering from silicosis, diabetes, myxoedema, HIV infection or under immuno - suppressive drugs are more susceptible (3, 4). Tuberculosis has often been described as a barometer of social welfare. It strikes poor people and those who do not have access to health care. The highest burden of tuberculosis is in the most impoverished countries. Poor housing and overcrowding are closely associated with transmission of infection.

Transmission : The source of infection is an open (sputum positive) case of pulmonary tuberculosis. *Mycobacterium tuberculosis* is spread by airborne particles, known as droplet nuclei that can be generated when persons with pulmonary or laryngeal tuberculosis sneeze, cough, speak, or sing. It has been estimated that a cough can generate 3000 droplet nuclei. The same number is generated by a person talking for five minutes (13). Persons who share the same airspace with persons with infectious tuberculosis disease are at greatest risk for infection. Infection occurs when a susceptible person inhales droplet nuclei containing tubercle bacilli and these bacilli become established in the alveoli of the lungs and spread

throughout the body. Prolonged household contact with an open case may lead to infection. Fomites do not play any role in transmission of the disease. Ingestion of unpasteurized milk or dairy products may lead to infection by *Mycobacterium bovis*. Direct inoculation through the skin can also lead to infection. However both these modes of transmission probably cause a very small number of cases (3, 7).

Pathogenesis : Primary infection occurs on first exposure to tubercle bacilli. Inhaled droplet nuclei are so small that they avoid the mucous - ciliary defences of the bronchi and lodge in the terminal alveoli of the lungs. Infection begins with multiplication of tubercle bacilli in the lungs. This is the Ghon focus. Lymphatics drain the bacilli to the hilar lymph nodes. The Ghon focus and related hilar lymphadenopathy form the primary complex. Bacilli may spread in the blood from the primary complex throughout the body. The immune response (delayed hypersensitivity and cellular immunity) develops about 4 - 6 weeks after the primary infection. The size of the infecting dose of bacilli and the strength of the immune response determine the course following primary infection. In most cases, the immune response stops the multiplication of bacilli. However, a few dormant bacilli may persist. A positive tuberculin skin test would be the only evidence of infection. The immune response in a few cases is not strong enough to prevent multiplication of bacilli and disease occurs within a few months (14).

Post Primary Tuberculosis : Post - primary TB occurs after a latent period of months or years after primary infection. It may occur either by reactivation or by reinfection. Reactivation means that dormant bacilli persisting in tissues for months or years after primary infection start to multiply. This may be in response to a trigger, such as weakening of the immune system by HIV infection. Reinfection means a repeat infection in a person who has already previously had a primary infection. Post - primary TB usually affects the lungs but can involve any part of the body. The characteristic features of post - primary PTB are extensive lung destruction with cavitation, positive sputum smear, and upper lobe involvement with usually no intrathoracic lymphadenopathy (14). Extra - pulmonary TB can affect the lymph nodes, pleura, bones and joints, the genitourinary tract, the nervous system (meningitis), intestines etc. If untreated, TB leads to death within 2 - 3 years in at least half the patients (15).

Management of Tuberculosis

The source of infection for tuberculosis is almost always a sputum smear positive case of pulmonary tuberculosis. As a consequence, the focus of any public health specialist is concentrated on the management of cases of pulmonary Tuberculosis so that the source of infection can be eliminated from the community. The following description on the management of tuberculosis is, therefore, restricted largely to pulmonary tuberculosis and carries a strong public health bias. In our country, the diagnosis and treatment of cases of tuberculosis is carried out in accordance with the guidelines issued by the Revised National Tuberculosis Control Programme. The following have been extracted from the Technical and Operational Guidelines for Tuberculosis Control issued by Central TB Division, Directorate General of Health Services,

Ministry of Health and Family Welfare, Nirman Bhavan, New Delhi in October 2005 (15).

Diagnosis

Identification of Tuberculosis Suspects : Most patients with TB visit health facilities promptly after symptoms occur. Hence, every adult patient with respiratory symptoms attending the health facility must be asked about symptoms suggestive of tuberculosis. The most common symptom of pulmonary TB is a persistent cough for 2 weeks or more, usually with expectoration. It may be accompanied by one or more of the following symptoms such as weight loss, chest pain, tiredness, shortness of breath, fever, particularly with rise of temperature in the evening. In some cases there will be blood in the sputum, loss of appetite and night sweats. About 2 - 3% of new adult outpatients in a general health facility are expected to have cough for 2 weeks or more and on an average 10% of the suspects are expected to have sputum positive pulmonary TB.

Case Finding tools : The main tools for diagnosing pulmonary TB are sputum smear microscopy, chest X - ray, culture of *Mycobacterium tuberculosis* bacilli. Diagnostic algorithms are as given in Fig. - 1a & b.

Sputum Smear Microscopy : This is the primary tool for diagnosing TB as it is easy to perform at the peripheral laboratories, not expensive and specific with low inter and intra reader variation. It is simple and requires minimum training and can be used for diagnosis, monitoring and defining cure. Therefore, this is the key diagnostic tool used for case detection in RNTCP. If good diagnostic practices are followed, it is expected that at least 50% of the new pulmonary TB patients diagnosed will be smear - positive.

Chest X - Ray : X - ray as a diagnostic tool is sensitive but less specific with large inter and intra reader variations. No shadow is typical of TB. 10 - 15% culture - positive cases remain undiagnosed and 40% patients diagnosed as having TB by X - ray alone may not have active TB disease. It is supportive to microscopy.

Culture : Culture of bacilli *Mycobacterium tuberculosis* is very sensitive and specific but is expensive as it requires a specialized laboratory set - up and results are available only after several weeks. If available, culture of tubercle bacilli may be helpful, although in sputum - negative cases a clinical decision to treat for TB based on X - ray findings and lack of response to broad - spectrum antibiotics would be more practical and also ensure prompt treatment. Culture and sensitivity testing is valuable for diagnosis and management of drug resistant tuberculosis, besides epidemiological surveillance and planning.

Tuberculin Test : Tuberculin test may be useful as an additional tool for diagnosing paediatric TB, in whom a positive test is more likely to reflect recent infection with TB and indicates a much higher risk of developing disease. However, the tuberculin test has no role in diagnosing adult pulmonary TB disease in India.

Diagnosis by Sputum Microscopy : Microscopic examination of sputum is, as a rule, the only way by which the diagnosis of pulmonary TB can be confirmed. Whenever TB is suspected, at least 2 specimens of sputum should be collected over 2 consecutive days and examined by microscopy. Only one

laboratory form needs to be filled for all the three specimens of the patient. The smears are fixed by drying or heating and stained with the Ziehl - Neelsen (ZN) stain & examined under the oil immersion lens of a microscope. The interpretation of the slides is as given in Table - 1.

Examination finding	Result Recorded	Grading	No. of fields examined
>10 AFB per oil immersion field	Positive	3+	20
1 - 10 AFB per oil immersion field	Positive	2+	50
10 - 99 AFB per 100 oil immersion fields	Positive	1+	100
1 - 9 AFB per 100 oil immersion fields	Positive	Scanty	100
No AFB in 100 oil immersion fields	Negative	Negative	100

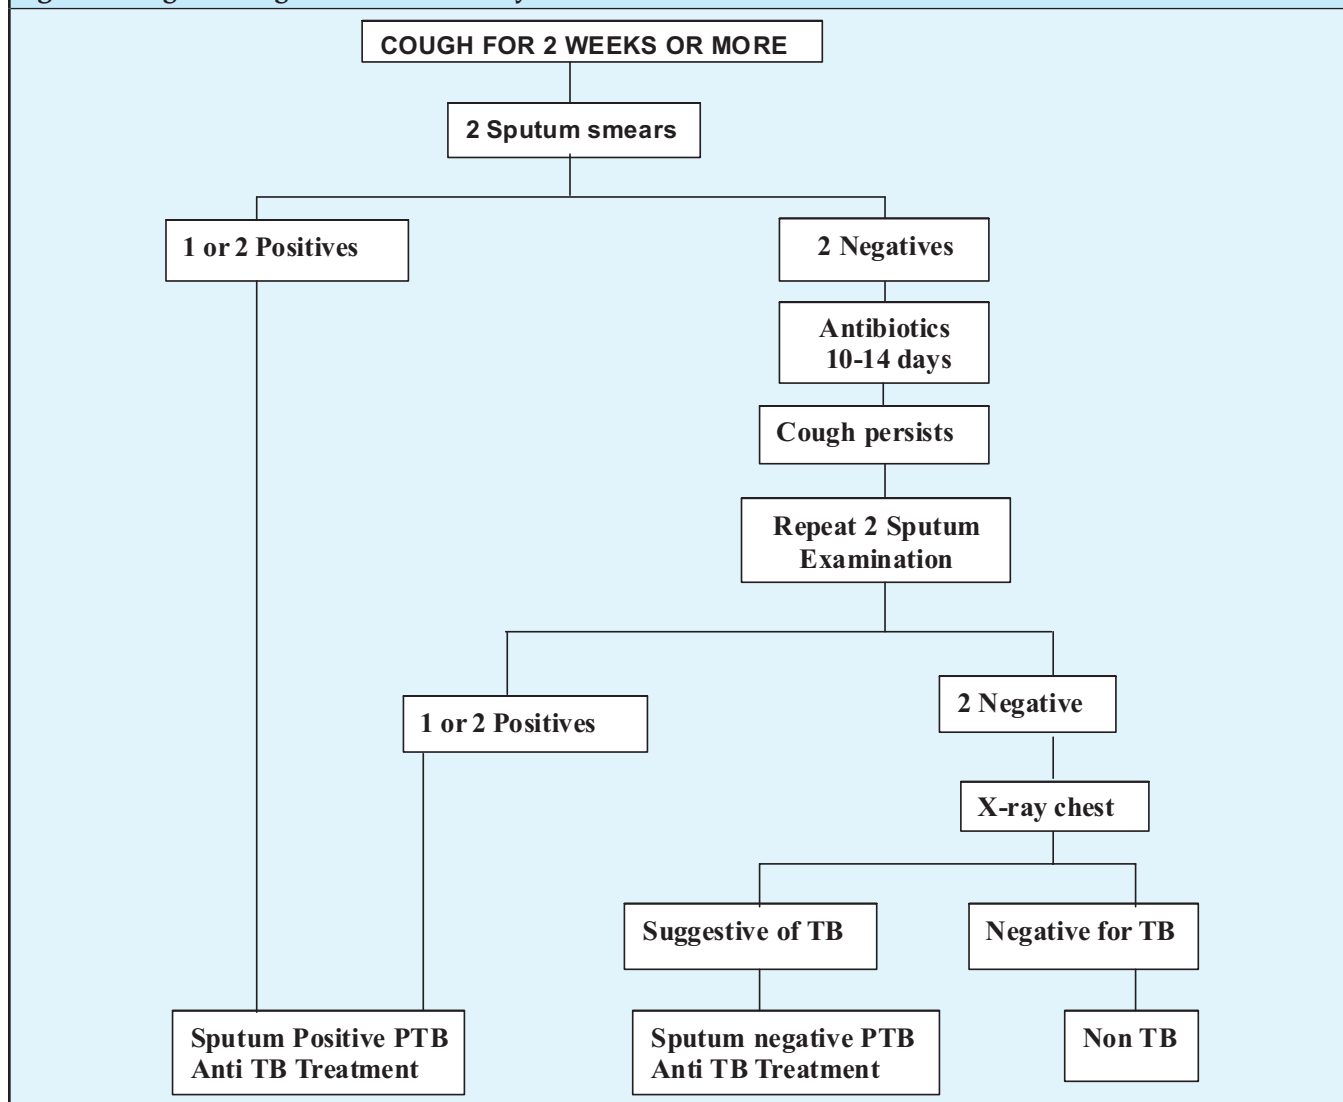

Classification of Tuberculosis cases : The treatment of tuberculosis under the RNTCP is standardized into different categories. It is important to classify a patient into the correct category so that he may receive the correct combination of drugs and duration of treatment. Classification of pulmonary cases should be based on at least 2 sputum smear examinations. Sputum should also be examined for cases of suspected extra - pulmonary TB if pulmonary symptoms are present.

Smear - positive patient : A patient with at least 2 initial sputum smear examinations (direct smear microscopy) positive for Acid - Fast Bacilli (AFB) OR A patient with one sputum examination positive for AFB and radiographic abnormalities consistent with active pulmonary TB as determined by the treating Medical Officer (MO) OR A patient with one sputum specimen positive for AFB and culture positive for *Mycobacterium tuberculosis*.

Smear - negative patient : A patient having symptoms suggestive of TB with at least 2 sputum examinations negative for AFB, and radiographic abnormalities consistent with active pulmonary TB as determined by the treating MO, followed by a decision to treat the patient with a full course of anti - TB therapy OR A patient whose diagnosis is based on culture positive for *Mycobacterium tuberculosis* but sputum smear examinations negative for AFB.

Extra-pulmonary Tuberculosis : Extra-pulmonary Tuberculosis (EPTB) is tuberculosis of organs other than the lungs, such as the pleura (pleurisy), lymph nodes, intestines, genito - urinary tract, skin, joints and bones, and meninges of the brain. Diagnosis should be based on one culture - positive specimen from an extra - pulmonary site, or histological or radiological, or strong clinical evidence consistent with active extra - pulmonary TB followed by the treating MO's decision to treat with a full course of anti - TB therapy. Pleurisy is classified as extra - pulmonary TB. A patient diagnosed with both sputum smear positive pulmonary TB and extra pulmonary TB should be classified as a case of pulmonary TB.

Fig - 1a : Diagnostic Algorithm for Pulmonary TB

Diagnostic Algorithm of RNTCP : Patients with at least two positive smear results are diagnosed by the physician as a case of smear positive TB. They are further classified as new or old cases based on their treatment history, and appropriate therapy is prescribed.

For patients with only one sputum positive result on smear examination, chest X - ray is taken. If findings of the X - ray are consistent with pulmonary tuberculosis patient is diagnosed by the physician as a case of sputum positive pulmonary TB.

Patients in whom all 2 samples are negative on sputum smear examination are prescribed symptomatic treatment and broad spectrum antibiotics (such as cotrimoxazole, doxycycline, and amoxycillin) for 10 - 14 days. In such cases antibiotics such as fluoroquinolones (ciprofloxacin, ofloxacin etc.), rifampicin or streptomycin, which are active against tuberculosis, are not to be used. Most patients are likely to improve with antibiotics if they are not suffering from TB. If the symptoms persist after

a course of broad spectrum antibiotics, repeat sputum smear examination (2 samples) must be done for such patients.

If two or more smears are positive, the patient is diagnosed as having smear positive pulmonary TB. If only one sputum sample is positive, chest X - ray is taken. If findings of the X - ray are consistent with pulmonary tuberculosis, patient is diagnosed by the physician as a case of sputum positive pulmonary TB. If the results for all the three sputum samples of repeat examination are found negative then a chest X - Ray is taken. If findings of the X - ray are consistent with pulmonary tuberculosis, patient is diagnosed by the physician as a case of sputum negative pulmonary TB. The Diagnostic Algorithms are given in Fig - 1a & b. Patients with EPTB who also have cough of any duration, should have 2 sputum samples examined. If the smear result is positive, the patient is classified as pulmonary TB and his/her treatment regimen will be that of a case of smear positive pulmonary TB.

Fig - 1b : Diagnostic Algorithm for Paediatric Pulmonary TB

Treatment

Under the RNTCP, the objectives of tuberculosis treatment are to decrease mortality and morbidity by ensuring cure, minimizing relapses and preventing development of drug resistance; to decrease infections and break the chain of transmission of infection; and to achieve the above whilst minimizing side effects due to drugs. These objectives are achieved in RNTCP through intermittent (thrice weekly) treatment regimens given under direct observation for both pulmonary and extra - pulmonary tuberculosis patients. Treatment regimens for tuberculosis have emerged as a result of controlled clinical trials in India and other parts of the world. It has been proven that thrice - a - week (intermittent) treatment is as effective as daily treatment and produces lesser side effects.

RNTCP provides standardized anti - TB treatment in three categories. Once the patient has been diagnosed as having TB, may be pulmonary or extra - pulmonary, his treatment regimen is decided based on the results of sputum Smear examination, history of previous anti - TB treatment, disease classification (pulmonary/ extra - pulmonary), and severity of illness.

Treatment Regimes : Standardized treatment is given to patients based on their treatment category. The details of treatment are given in Table - 2. The most important drugs used in the treatment of TB are Isoniazid (H), Rifampicin (R), Pyrazinamide (Z), Streptomycin (S) and Ethambutol (E). The dosage of the drugs is shown in Table - 3. Drugs are supplied in Patient - Wise Boxes (PWB) containing the full course of

treatment, and packaged in blister packs. The PWB have a colour code indicating the category (Red for CAT I, Blue for CAT II and Green for CAT III). In each PWB, there are two pouches one for intensive phase (A) and one for continuation phase (B). For the intensive phase, each blister pack contains medicines for one dose. For the continuation phase, each blister pack contains one week's supply of medication. The drugs for extension of the intensive phase (prolongation pouches) are supplied separately. For adults, drugs will be given in the recommended number of pills/capsules irrespective of body weight. However, for patients weighing more than 60 kilograms, an additional capsule of rifampicin 150 mg will be added to the treatment regimen. Patients who are more than 50 years old receive streptomycin 500mg and patients who weigh less than 30 Kg receive drugs as per body weight. For children, the drugs will be given according to body weight. Patient wise boxes for children have been developed.

Medication	Dose (thrice a week)
Isoniazid	600mg
Rifampicin	450mg
Pyrazinamide	1500mg
Ethambutol	1200mg
Streptomycin	0.75 g

Category of Treatment	Type of Patient	Regimen*
Category I	New sputum smear - positive	2H ₃ R ₃ Z ₃ E ₃ / 4H ₃ R ₃
	Seriously ill** new sputum smear - negative	
	Seriously ill** new extra - pulmonary	
Category II	Sputum smear - positive Relapse	2H ₃ R ₃ Z ₃ E ₃ S ₃ / 1H ₃ R ₃ Z ₃ E ₃ / 5H ₃ R ₃ E ₃
	Sputum smear - positive Failure	
	Sputum smear - positive treatment after Default	
	Others***	
Category III	New Sputum smear - negative, not seriously ill	2H ₃ R ₃ Z ₃ /
	New Extra - pulmonary, not seriously ill	4H ₃ R ₃

- * The number before the letters refers to the number of months of treatment. The subscript after the letters refers to the number of doses per week.
- The dosage strengths are as follows : H : Isoniazid (600 mg), R : Rifampicin (450 mg), Z : Pyrazinamide (1500 mg), E : Ethambutol (1200 mg), S : Streptomycin (750 mg). Patients who weigh 60 kg or more receive additional Rifampicin 150 mg. Patients who are more than 50 years old receive Streptomycin 500 mg. Patients who weigh less than 30 kg, receive drugs as per body weight.
- Patients in Categories I & II who have a positive sputum smear at the end of the initial intensive phase receive an additional month of intensive phase treatment.
- ** Seriously ill also includes, any patient, pulmonary or extra - pulmonary who is HIV positive & declares his serostatus to the categorizing/treating medical officer. For the purpose of categorization, HIV testing should not be done.
- *** In rare & exceptional cases, patients who are sputum smear - negative or who have extra - pulmonary disease can have Relapse or Failure. This diagnosis in all such cases should always be made by an MO & should be supported by culture or histological evidence of current, active TB. In these cases, patient should be categorized as 'Others' & given Category II treatment.

Management of Paediatric Tuberculosis under RNTCP : Childhood TB is a reflection of the prevalence of sputum smear - positive Pulmonary Tuberculosis (PTB) and the extent of transmission of TB infection in the community. Children are likely to suffer from more serious forms of TB and are more likely to die if not treated properly. Reliable data on disease incidence and prevalence is however not available due to the difficulties in diagnosis of paediatric TB under field conditions. TB should be suspected among children presenting with fever and / or cough for more than 3 weeks, with or without weight loss or no weight gain; and history of contact with a suspected or diagnosed case of active TB disease within the last 2 years. Diagnosis should be based on a combination of clinical presentation, sputum examination wherever possible, Chest X ray (PA view), Mantoux test (1 TU PPD RT23 with Tween 80, positive if induration >10mm after 48 - 72 hours) and history of contact. Diagnosis should be made by a Medical Officer and the existing RNTCP case definitions be used for all cases diagnosed. Children showing neurological symptoms like irritability, refusal to feed, headache, vomiting or altered sensorium may be suspected to have TB meningitis. Use of currently available scoring systems is not recommended for the diagnosis of TB among children. Where diagnostic difficulties are faced, the child should be referred to a paediatrician for further management. DOTS is the recommended strategy for treatment of TB and all paediatric TB patients should be registered under RNTCP. Intermittent short course chemotherapy given under direct observation should be used in children, as in adults. Recent infection with tubercle bacilli is one of the risk factors for disease development. The younger the child, the higher is the risk of breakdown of infection into disease. Therefore, household contacts of smear - positive TB cases, especially those below 6 years of age, must be screened for symptoms of tuberculosis. In case of symptoms being present, the diagnostic algorithm for paediatric TB should be followed and the child should be given a full course of anti TB treatment if he / she is diagnosed as a TB case. For asymptomatic children under 6 years, chemoprophylaxis with isoniazid (5 mg per kg body wt) should be administered daily for a period of six months. This is regardless of the BCG vaccination status.

Management of Extra - Pulmonary Tuberculosis : Extra - Pulmonary TB (EPTB) comprises about 10% to 15% of all new TB cases in our country. Among them, 75% have lymph node or pleural TB. A person with extra - pulmonary TB may have symptoms related to the organs affected, such as, swelling of lymph nodes, occasionally with discharge of pus; pain and swelling of the joints; headache, fever, stiffness of the neck and mental confusion when the brain or meninges are involved. In addition, the following general symptoms like weight loss, fever, particularly with rise of temperature in the evening and night sweats may be present. Patients with suspected EPTB should be referred to a competent medical practitioner for expert opinion. Diagnosis of such patients may be made by using appropriate diagnostic procedures (such as FNAC/Biopsy/culture from the site of disease) as well as clinical methods. Patients with EPTB who also have cough of any duration, should have 3 sputum samples examined. If the smear result is positive, the patient is classified as pulmonary TB. Intermittent short course

chemotherapy regimens of 6 - 9 months are recommended internationally for all forms of extra - pulmonary TB. In cases of Tubercular Meningitis (TBM), initial hospitalization is recommended. In TBM, ethambutol should be replaced by streptomycin in the intensive phase and continuation phase of the treatment is for 6 - 7 months. Adjunctive steroids may be useful in pericardial & meningeal TB.

Management of Patients with HIV Infection and Tuberculosis: People co-infected with HIV and TB have a higher risk of developing TB disease. Irrespective of HIV status RNTCP diagnostic algorithm should be followed for all TB suspects. Anti - TB treatment is the same for HIV - infected persons as it is for HIV negative TB patients. Hence they should be treated with RNTCP regimens. All new TB cases known to be HIV positive are classified as seriously ill and treated with Category I regimen. The re - treatment cases are to be treated with Category II regimen. It is important to maintain confidentiality regarding HIV status of individuals including TB suspects and patients, in order to prevent stigmatization and discrimination. TB patients should be encouraged to voluntarily share their HIV status with the treating physician for the purpose of taking clinical decisions like categorization for treatment of TB, treatment of other opportunistic infections and provision of ART. The HIV - positive status should not be disclosed by the treating physician to any other staff involved in RNTCP. In addition, the HIV - positive status should not be mentioned in any RNTCP records. TB patients who have other HIV - associated opportunistic infections, or report risk behaviour for HIV, should be offered referral to the nearest Voluntary Counselling and Testing Centre (VCTC) for voluntary counselling and HIV testing. Routine HIV testing of all TB suspects/patients is not the national policy.

Drug Resistance : Drug resistance is more common among patients who show poor compliance, develop TB disease again, after having taken anti tubercular treatment in the past, or come from areas where drug - resistant TB is common.

Multidrug Resistant (MDR) Tuberculosis : Multidrug Resistant TB describes strains of tuberculosis that are resistant to at least the two main first - line TB drugs - isoniazid and rifampicin. Two thirds of all cases of MDR are found in China, India and the Russian Federation. In 2007, the estimated number of cases of MDR - TB were 4, 24,000 and the estimated number of deaths due to MDR - TB were 1,16,000 (17). In India MDR - TB estimates are placed at less than 3.5% of new cases and 12% of retreatment cases. RNTCP advocates using a standardised treatment regimen comprising of six drugs (kanamycin, ofloxacin, ethionamide, pyrazinamide, ethambutol and cycloserine) during 6 - 9 months of the Intensive Phase and 4 drugs (ofloxacin, ethionamide, ethambutol and cycloserine) during the 18 months of the Continuation Phase for cases of MDR - TB.

Extensively Drug Resistant Tuberculosis : Extensive Drug Resistant is MDR - TB that is also resistant to three or more of the six classes of second - line drugs. In 2007 the estimated number of cases were 27,000 and the estimated number of deaths due to XDR TB were 16,000. 28 countries have published cases of XDR - TB and/or reported cases to WHO.

Prevention and Control of Tuberculosis

Early diagnosis and treatment, particularly of sputum smear positive cases is the cornerstone of tuberculosis control. The Revised National Tuberculosis Control Programme has focused on achieving high cure rates. The protective efficacy of BCG has ranged between 0 to 80% in different studies. Details on the vaccine are given in the chapter on Immunization. Further details on the Revised National Tuberculosis Control programme are given in the chapter on National Health Programmes.

The Stop TB Strategy has six major components : DOTS expansion and enhancement; addressing TB/HIV, MDR - TB and other challenges; contributing to health system strengthening; engaging all care providers; empowering patients and communities; and enabling and promoting research (1). It is evident that new tools are urgently needed to improve treatment, detection and prevention of TB. The Stop TB Partnership of WHO has created three specific research working groups devoted to new drugs, diagnosis, and vaccine development, respectively. The need for new rapid and inexpensive diagnostics for diagnosing Tuberculosis and drug resistance is obvious. An effective Tuberculosis vaccine is another urgent need because the BCG vaccine has demonstrated efficacy only in certain populations and only against some forms of the disease.

Summary

Tuberculosis (TB) is one the biggest public health challenges facing the world today. It is one of the oldest diseases known to mankind. *Mycobacterium tuberculosis* was one of the first bacterial pathogens to be identified by Robert Koch who in 1882 discovered a staining technique that enabled him to see *Mycobacterium tuberculosis*. Tuberculosis is currently second only to AIDS as an infectious cause of death worldwide. Almost all the cases and practically all deaths due to Tuberculosis take place in developing countries. A total of 9.2 million new cases (139 per 1,00,000 population) and 1.7 million deaths. India, China, Indonesia, South Africa and Nigeria rank first to fifth respectively in terms of absolute numbers of cases. India accounts for a fifth of the world's new TB cases and 2/3rd of the cases in South - East Asia. The prevalence of disease is thought to be 4 per 1000 and the incidence of disease 1.5 per 1000. Human Tuberculosis is caused by *Mycobacterium tuberculosis* which is Gram positive, non - motile, non - sporing, pleomorphic rod. They are facultative intracellular pathogens, slow - growing with a generation time of 12 to 18 hours. Tuberculosis can occur at any age. In India disease prevalence is more in the older age groups. Persons who are undernourished and suffering from silicosis, diabetes, myxoedema, HIV infection or under immuno - suppressive drugs are more susceptible. The source of infection is an open (sputum positive) case of pulmonary Tuberculosis. *Mycobacterium tuberculosis* is spread by airborne particles, known as droplet nuclei. Pulmonary TB affects the lung and Extra - pulmonary TB can affect the lymph nodes, pleura, bones and joints, the genito - urinary tract, the nervous system (meningitis), intestines etc. The most common symptom of pulmonary TB is a persistent cough for 3 weeks or more. The main tools for diagnosing pulmonary TB are sputum smear microscopy, chest X - ray, and culture of *Mycobacterium tuberculosis* bacilli. Sputum Smear Microscopy is the primary

tool for diagnosing TB under RNTCP. Classification of pulmonary cases should be based on at least 3 sputum smear examinations and are classified as Smear - positive patient, Smear - negative patient and Extra - pulmonary Tuberculosis. RNTCP provides standardized anti - TB treatment in three categories. People co - infected with HIV and TB have a higher risk of developing TB disease. Anti - TB treatment is the same for HIV - infected persons as it is for HIV negative TB patients. Multidrug Resistant TB describes strains of Tuberculosis that are resistant to at least the two main first - line TB drugs - isoniazid and rifampicin. Extensive Drug Resistant is MDR - TB that is also resistant to three or more of the six classes of second - line drugs.

Study Exercises

Long Questions : (1) Discuss the epidemiology, treatment, prevention and control of Tuberculosis (2) Describe the Diagnosis and treatment of TB under RNTCP.

Short Notes : (1) Sputum Microscopy (2) Classification of TB patient based on sputum examination and treatment history (3) Diagnostic Algorithm of RNTCP (4) Treatment Regimens under RNTCP (5) Management of Patients with HIV Infection and Tuberculosis (6) MDR TB.

MCQs

- Which disease is known as 'Captain of the Men of Death'?
(a) Tuberculosis (b) AIDS (c) Plague (d) Cholera.
- Pulmonary Tuberculosis accounts for over _____ per cent of the total cases (a) 50% (b) 60% (c) 70% (d) 80%.
- Commonest opportunistic infection in patients suffering from AIDS (a) Candidiasis (b) Pulmonary Tuberculosis (c) Herpes (d) Scabies.
- The _____ Region has the highest incidence rate per capita (363 per 1,00,000 population) (a) Asian (b) American (c) Indian (d) African.
- _____ is the highest TB burden country in the world (a) Nigeria (b) South Africa (c) India (d) Bangladesh.
- It is estimated that a cough can generate _____ (a) 1000 droplet nuclei (b) 2000 droplet nuclei (c) 3000 droplet nuclei (d) 4000 droplet nuclei.
- Under RNTCP in reporting of Sputum Smears, 1 - 10 AFB per oil immersion field is graded as (a) 1+ (b) 2+ (c) 3+ (d) 4+.
- Category III continuation phase comprises of (a) 4 H₃ R₃ (b) 5 H₃ R₃ E₃ (c) 1 H₃ R₃ Z₃ E₃ (d) None of the above.
- All new TB cases known to be HIV positive are treated with (a) Category I regimen (b) Category II regimen (c) Category III regimen (d) None of the above.
- Multidrug Resistant (MDR) Tuberculosis treatment involves all drugs expect (a) Kanamycin (b) Pyrazinamide (c) Rifampicin (d) Ethambutol.

Answers : (1) a; (2) d; (3) b; (4) d; (5) c; (6) c; (7) b; (8) a; (9) a; (10) c.

Avian Influenza

Rajesh Vaidya

Avian influenza is an infectious disease of birds caused by type A strains of the influenza virus. The disease, which was first identified in Italy more than 100 years ago, occurs worldwide. All birds are thought to be susceptible to infection with avian influenza, though some species are more resistant to infection than others. Migratory waterfowl - most notably wild ducks - are the natural reservoir of avian influenza viruses. Avian influenza viruses do not normally infect species other than birds and pigs. Of the 15 avian influenza virus subtypes, H5N1 is of particular concern for several reasons. H5N1 mutates rapidly and has a documented propensity to acquire genes from viruses infecting other animal species (1, 2).

Epidemiology

Global Situation - Current Outbreak : Some time prior to 1997, the H5N1 strain of avian influenza virus began circulating in the poultry populations of parts of Asia, quietly establishing itself. The virus first erupted in its highly pathogenic form in 1997, but did not appear again. Then, towards the end of 2003, H5N1 suddenly became highly and widely visible. Infection by the H5N1 strain has now been documented in either domestic poultry or migratory birds in over twenty countries spread across Asia and Europe. Over a 140 million birds have been destroyed worldwide in efforts to control the spread of this virus (3). The ability of the H5N1 strain to cause severe disease in humans has now been documented on at least two occasions. The first documented infection of humans with an avian influenza virus occurred in Hong Kong in 1997, when the H5N1 strain caused severe respiratory disease in 18 humans, of whom 6 died (4). In its second documented outbreak, since December 2003, the H5N1 strain has infected at least 387 people and killed 245 in 15 countries, mostly in South East Asia (5).

Lessons from History : An influenza pandemic is a rare but recurrent event. Three pandemics occurred in the previous century : "Spanish influenza" in 1918, "Asian influenza" in 1957, and "Hong Kong influenza" in 1968. The 1918 pandemic killed an estimated 40 - 50 million people worldwide. That pandemic, which was exceptional, is considered one of the deadliest disease events in human history. Subsequent pandemics were much milder, with an estimated 2 million deaths in 1957 and 1 million deaths in 1968. Experts agree that another influenza pandemic is inevitable and possibly imminent. Striking similarities exist between the 1918 virus and the H5N1 strain. The 1918 pandemic is believed by many experts to have begun following adaptive mutation of an avian virus which acquired, following stepwise changes during subsequent human infections, the adaptations needed to sustain efficient human - to - human transmission. Recent publications have suggested other similarities between H5N1 and the 1918 virus in the severity of disease, its concentration in the young & healthy and the occurrence of primary viral pneumonia in the absence of secondary bacterial infection (6, 7).

Host Factors : The categories of persons considered to be at the greatest risk if acquiring infection are workers handling poultry in farms, markets and involved in culling activity, veterinary workers and health workers are at higher risk of acquiring the infection. Even the family members of these workers are at higher risk. Any type of Influenza tends to be more serious in children, elderly persons above 65 years of age and the chronically sick persons.

Transmission

Avian Transmission

Transmission among birds : Infected birds shed the virus in oculo - nasal discharges and faeces, and contaminated drinking water is commonly implicated as the source of infection among birds. Once introduced into a flock, infected birds, contaminated equipment, insects, rodents, and personnel have

all been implicated in the spread of the virus. When birds are in close proximity and air movement is conducive, airborne transmission can occur (7).

Avian to Human Transmission : Direct contact with infected poultry, or surfaces and objects contaminated by their faeces, is presently considered the main route of human infection. To date, most human cases have occurred in rural or peri-urban areas where many households keep small poultry flocks, which often roam freely, sometimes entering homes or sharing outdoor areas where children play. Moreover, because many households in Asia depend on poultry for income and food, many families sell or slaughter and consume birds when signs of illness appear in a flock, and this practice has proved difficult to change. Exposure is considered most likely during slaughter, defeathering, butchering, and preparation of poultry for cooking. There is no evidence that properly cooked poultry or eggs can be a source of infection (7).

Human to Human Transmission : There is no definite evidence of human to human transmission in the current episode. A new virus adapted for efficient human-to-human transmission would spread very rapidly. The respiratory tract is the most likely route of entry.

International Spread : The disease can spread from country to country through international trade in live poultry. Migratory birds, including wild waterfowl, sea birds, and shore birds, can carry the virus for long distances and have, in the past, been implicated in the international spread of highly pathogenic avian influenza. Migratory waterfowl - most notably wild ducks - are the natural reservoir of bird flu viruses, and these birds are also the most resistant to infection. They can carry the virus over great distances, and excrete it in their droppings, yet develop only mild and short-lived illness.

Clinical Features

The incubation time for influenza ranges from 1 - 5 days with an average of 2 days. In most cases, virus is found in specimens from the respiratory tract from 1 - 2 days before to 4 - 5 days after onset of disease, corresponding to the period of communicability. There is no chronic carrier state, but in young children viral shedding tends to last longer than in adults. Clinical onset is characterized by abrupt fever, headache, malaise and myalgias. Systemic symptoms usually last for 3 days. Sore throat, rhinitis and non-productive cough may continue for several days after the systemic symptoms have ceased. Influenza may be misdiagnosed clinically, several infectious agents including respiratory syncytial virus may cause outbreaks of influenza-like disease, illustrating the importance of laboratory based confirmation of the clinical diagnosis (9).

The incubation period of influenza A (H5N1) is currently uncertain. Based on limited experience from 6 cases in Vietnam, the median time between exposure and onset of illness is 3 days (range 2 - 4 days). Cases have been characterized by high fever (above 38°C), cough and shortness of breath. Lower respiratory symptoms or signs developed early and include dyspnoea and auscultatory signs. Clinically apparent pneumonia with chest X-ray changes was seen in all patients, although the X-ray changes were nonspecific and included diffuse, multifocal or

patchy infiltrates, interstitial infiltrates, and segmental or lobular consolidation with air bronchograms. The illness rapidly progressed to respiratory distress and subsequent respiratory failure within 1 week of the onset of symptoms. Most cases have died in spite of ventilatory support. Common laboratory findings were lymphopenia and slightly or moderately raised alanine aminotransferase and aspartate transaminase (10).

Diagnosis

The optimal specimen for influenza A virus detection is a nasopharyngeal aspirate obtained within 3 days of the onset of symptoms, although nasopharyngeal swabs and other specimens can also be used (11). Assays available for the diagnosis of influenza A virus infections include :

(a) Rapid antigen detection : Results can be obtained in 15 - 30 minutes.

(i) Near-patient tests for influenza : These tests are commercially available.

(ii) Immunofluorescence assay : This test is a widely used, sensitive method for diagnosis of Influenza A, B virus infections and other clinically important respiratory viruses.

(iii) Enzyme immunoassay : For Influenza A Nucleoprotein (NP).

(b) Virus Culture : Provides results in 2 - 10 days. Both shell vial and standard cell-culture methods may be used to detect clinically important respiratory viruses. Positive influenza cultures may or may not exhibit cytopathic effects but virus identification by immunofluorescence of cell cultures or Haemagglutination - Inhibition (HI) assay of cell culture medium (supernatant) is required.

(c) Polymerase Chain Reaction and Realtime PCR Assays: Primer sets specific for the Haemagglutinin (HA) gene of currently circulating influenza A/H1N1, A/H3N2 and B viruses are becoming more widely used. Results can be available within a few hours from either clinical swabs or infected cell cultures.

Any specimen with a positive result using the above approaches for influenza A virus and suspected of avian influenza infection should be further tested and verified by a designated WHO H5 Reference Laboratory. Laboratories that lack the capacity to perform specific influenza A subtype identification procedures are requested to forward specimens or virus isolates to a National Influenza Centre or to a WHO H5 Reference Laboratory for further identification or characterization.

Treatment

Two drugs (in the neuraminidase inhibitors class), Oseltamivir (commercially known as Tamiflu) and Zanamivir (commercially known as Relenza) can reduce the severity and duration of illness caused by seasonal influenza. The efficacy of the neuraminidase inhibitors depends on their administration within 48 hours after symptom onset. For cases of human infection with H5N1, the drugs may improve prospects of survival, if administered early, but clinical data are limited. The H5N1 virus is expected to be susceptible to the neuraminidase inhibitors. An older class of antiviral drugs, the M2 inhibitors amantadine and rimantadine, could potentially be used against pandemic influenza, but resistance to these drugs can develop rapidly and this could significantly limit their effectiveness

against pandemic influenza. Some currently circulating H5N1 strains are fully resistant to these the M2 inhibitors. However, should a new virus emerge through reassortment, the M2 inhibitors might be effective.

Prevention and Control

Vaccination and the use of antiviral drugs are two of the most important response measures for reducing morbidity and mortality during a pandemic. On present trends, neither of these interventions will be available in adequate quantities or equitably distributed at the start of a pandemic and for many months thereafter. In such a situation surveillance to provide early warning and health education to reduce human exposure are the most important control measures.

Surveillance : Surveillance (13) is the cornerstone of pandemic preparedness and response. The following events need to be reported to local, state or national health authorities on priority:

- (a) Individuals with, and clusters of, acute respiratory illness on or during admission.
- (b) Unexplained deaths due to acute respiratory illness in the community.
- (c) Unexplained deaths due to acute respiratory illness in health care facilities.
- (d) Monitoring sales of antiviral drugs for influenza A viral infection, antimicrobials commonly used for the treatment of acute respiratory infections, decongestant drugs or antitussive drugs.

For countries and territories where influenza A/H5 viruses have not been identified as a cause of illness in human or animal populations since 1 October 2003, the WHO recommends that the decision on whether to test for influenza A/H5 viruses should be the result of a risk assessment that considers both geographical proximity to countries or territories where HPAI outbreaks are reported in animal populations and the following case - based factors :

- (a) Clinical presentation, including death due to unexplained acute respiratory illness
- (b) Occupational exposure : At-risk occupations such as a domestic fowl or swine farm worker, domestic fowl processing plant worker, domestic fowl culler (catching, bagging, or transporting birds, disposing of dead birds), worker in live animal market, chef working with live or recently killed domestic fowl, dealer or trader in pet birds, worker in a laboratory where specimens are tested for influenza A/H5 viruses, health care worker.
- (c) Living in an area in which there are rumours of deaths of domestic fowl ; (Domestic fowl are birds that are commonly reared for their flesh, eggs, or feathers and are kept in a yard or similar enclosure, including chickens, ducks, geese, turkeys, guinea - fowl).
- (d) History of travel, during the 7 days before the onset of symptoms, to a country or territory with reported HPAI outbreaks due to influenza A (H5N1) in the animal populations AND one or more of the following :
 - Contact (within 1 metre) with live or dead domestic fowl, wild birds, or swine in any setting;
 - Exposure to settings in which domestic fowl or swine were

or had been confined in the previous 6 weeks;

- Contact (within touching or speaking distance) with a confirmed human case of influenza A/H5 infection;
- Contact (within touching or speaking distance) with a person with an unexplained acute respiratory illness that later resulted in death;
- Positive laboratory result for influenza A.

Vaccination : Vaccines are universally regarded as the most important medical intervention for preventing influenza and reducing its health consequences during a pandemic. In the past, however, vaccines have never been available early enough and in sufficient quantities to have an impact on morbidity and mortality during a pandemic. Past problems, related to the special nature of pandemic vaccines and the inadequacy of manufacturing capacity, have endured. Several companies are trying to make an effective vaccine against H5N1. While initial testing of an avian flu vaccine shows promise and trials should be completed by the end of 2005, questions remain about the vaccine's ability to protect large numbers of people. Potential problems include a high initial dose, the requirement of two doses, and requirement of about six weeks for effective immunity to develop. Another major concern is the inability to produce adequate number of doses, once the vaccine is approved (14 - 15).

Chemoprophylaxis : The current recommendation for chemoprophylaxis against H5N1 influenza is one oseltamivir phosphate 75 mg tablet each day for at least 7 days beginning as soon as possible after exposure. Antiviral prophylaxis should begin immediately or at least within 2 days of exposure and may continue for up to 6 weeks (15).

Non Medical Measures : In developing countries, non - medical interventions may be the main line of defence throughout the first wave of a pandemic. Health education to inform the general public especially small poultry farmers is essential to reduce exposure risk. Stringent sanitary measures and appropriate bio - security practices should be applied, including the control of human traffic and introduction of birds of unknown disease status into the flock. Carcasses of suspected and confirmed poultry case of Influenza should preferably be incinerated or buried deep using lime and soil in the ratio of 1 : 3. The H5N1 avian influenza virus is not transmitted to humans through properly cooked food. The virus is sensitive to heat. Normal temperatures used for cooking (so that food reaches 70°C in all parts) will kill the virus. To date, no evidence indicates that any person has become infected with the H5N1 virus following the consumption of properly cooked poultry or poultry products, even in cases where the food item contained the virus prior to cooking. Poultry and poultry products from areas free of the disease can be prepared and consumed as usual, with no fear of acquiring infection with the H5N1 virus. As a standard precaution, WHO recommends that poultry and poultry products should always be prepared following good hygienic practices, and that poultry meat should be properly cooked.

Summary

Avian influenza is an infectious disease of birds caused by type A strains of the influenza virus. Avian influenza viruses do not normally infect species other than birds and pigs. Of

the 15 avian influenza virus subtypes, H5N1 is of particular concern for several reasons. H5N1 mutates rapidly and has a documented propensity to acquire genes from viruses infecting other animal species. The first documented infection of humans with an avian influenza virus occurred in Hong Kong in 1997, when the H5N1 strain caused severe respiratory disease in 18 humans, of whom 6 died. Persons considered to be at the greatest risk if acquiring infection are workers handling poultry in farms, markets & involved in culling activity, veterinary workers. Direct contact with infected poultry, or surfaces and objects contaminated by their faeces, is presently considered the main route of human infection. There is no evidence that properly cooked poultry or eggs can be a source of infection. There is no definite evidence of human to human transmission. The incubation time for influenza ranges from 1 - 5 days with an average of 2 days. Clinical onset is characterized by abrupt fever, headache, malaise and myalgias. Systemic symptoms usually last for 3 days. Influenza A (H5N1) cases have been characterized by high fever, cough shortness of breath and lower respiratory symptoms. The illness rapidly progresses to respiratory distress and subsequent respiratory failure within 1 week of the onset of symptoms. The optimal specimen for influenza A virus detection is a nasopharyngeal aspirate obtained within 3 days of the onset of symptoms. Tests available for the diagnosis of influenza A virus infections include Rapid antigen detection, Virus Culture, Polymerase Chain Reaction and Real - time PCR Assays. Treatment comprises of two drugs oseltamivir (Tamiflu) and zanamivir (Relenza). Surveillance is the cornerstone of pandemic preparedness and response. Vaccination and the use of antiviral drugs are two of the most important response measures for reducing morbidity and mortality during a pandemic if available in adequate quantities. Vaccines are universally regarded as the most important medical intervention for preventing influenza and reducing its health consequences during a pandemic. Potential problems include a high initial dose, the requirement of two doses, and requirement of about six weeks for effective immunity to develop. Another major concern is the inability to produce adequate number of doses. Chemoprophylaxis against H5N1 influenza is one oseltamivir phosphate 75 mg tablet each day for at least 7 days beginning as soon as possible after exposure. In developing countries, non - medical interventions such as health education, stringent sanitary measures and appropriate bio - security practices may be the main line of defence.

Study Exercises

Long Question : Discuss the prevention and control measures during influenza A/H5 viruses outbreak.

Short Notes : (1) Dynamics of Avian Influenza Transmission. (2) Surveillance of Influenza A/H5 infection (3) Non medical measures in combating Avian Influenza spread.

MCQs

1. The first documented infection of humans with an avian influenza virus occurred in (a) Vietnam (b) China (c) Hong Kong (d) Bangladesh
2. Spanish influenza pandemic occurred in the year (a) 1918 (b) 1957 (c) 1968 (d) 1970.
3. The optimal specimen for influenza A virus detection is (a) Blood (b) Urine (c) Stool (d) Nasopharyngeal aspirate.
4. Recommended drug for chemoprophylaxis against H5N1 influenza is (a) Zanamivir (b) Oseltamivir (c) Amantadine (d) Rimantadine
5. Non - medical interventions for defence against influenza pandemic are all except (a) Health education (b) Stringent sanitary measures (c) Vaccination (d) Appropriate bio - security practices.

Answers : (1) c; (2) a; (3) d; (4) b; (5)c.

Rajesh Vaidya

Severe Acute Respiratory Syndrome (SARS) is a new disease which came into notice when a patient was admitted in Hanoi (Vietnam) on 26th Feb 2003 with respiratory illness. Seven health workers who cared for this patient also became ill on 5th March 2003. Since then, the cases have been reported from 29 countries. International travel has facilitated its spread rapidly among six continents. Later on, it was found that the disease initially emerged in China (Guangdong province) in November 2002 from where it spread to other countries (1 - 4).

Epidemiology

Global : The evidence suggests that a newly discovered variant of Corona virus (SARS corona virus) is accountable for this syndrome. Most SARS cases till date have occurred in previously healthy young adults. A few suspected cases have been reported among children. WHO estimates that case fatality ratio ranges from 0% to 50% depending on the age group affected, with an overall estimate of about 15% (1 - 4). As on 15th May 2003, a cumulative total of 7548 probable cases and 573 deaths due to SARS have been reported from 29 countries. The affected areas were : the People's Republic of China (PRC), particularly the Hong Kong Special Administrative Region and the Beijing Municipality, Guangdong, Inner Mongolia, Shanxi, Tianjin, Taiwan Province (China), Toronto (Canada), Singapore (Singapore), India and Manila (Philippines). As of now, China has reported more cases than the rest of the world combined (1 - 7). Currently, there is no known SARS transmission anywhere in the world. The most recent human cases of SARS - CoV infection were reported in China in April 2004 in an outbreak resulting from laboratory - acquired infections. CDC and its partners, including the World Health Organization, continue to monitor the SARS situation globally (1 - 4).

India : As on 14th May, 2003, three probable cases of SARS have been reported from India, one each in West Bengal, Karnataka and Gujarat (1 - 2).

Agent : SARS corona virus is an enveloped RNA virus. The SARS virus has fulfilled the Koch's postulates, and it has been successfully cultivated in vitro (In VERO cell line) as well as in vivo (Experimental infection has been established in monkeys). The genome of the SARS corona virus is somewhat similar to that of other corona viruses, however the detailed sequence data confirm that this SARS corona virus is a previously unrecognized corona virus. The recent studies carried out in the WHO network laboratories have shown that the SARS virus can survive after drying on plastic surfaces for upto 48 hours. The virus can survive in faeces for at least 2 days and in urine for up to 24 hours (1, 2, 5 - 9).

Transmission : SARS virus appears to spread most commonly by close person - to - person contact involving exposure to infectious droplets, and possibly by direct contact with infected body fluids. It is also possible that SARS is transmitting through other unidentified routes. Persons having close contact

with the cases, especially the health care workers and family members are at higher risk.

Clinical Features

The incubation period is usually 2 - 7 days but may extend upto 10 days (1, 2). The illness begins with sudden onset of fever, sometimes associated with chills and rigors and sometimes accompanied by other symptoms e.g. headache, malaise and myalgia. Some people also experience mild respiratory symptoms at the onset. Typically, rash and neurologic findings are absent. Many patients have reported diarrhoea, especially in Hong Kong. After 3 - 7 days a lower respiratory phase begins with the onset of a dry, non - productive cough or dyspnoea that may be accompanied by or progress to hypoxemia. In 10% to 20% of cases, disease may become severe enough to require intubation and mechanical ventilation. The main symptoms of SARS are high fever (more than 38°C or 100.4°F), dry cough, or difficulty in breathing. Changes in X - ray indicative of pneumonia also occur (1, 2, 8 - 10).

Diagnosis

As SARS is currently a diagnosis of exclusion, the status of a reported case may change over time (11 - 14). A case should be excluded if an alternative diagnosis can fully explain the illness after considering the possibility of co - infection. Cases that meet the surveillance case definition for SARS should not be discarded on the basis of a negative laboratory test. A patient should always be managed as clinically appropriate, regardless of their case status. A variety of laboratory tests have been developed and are being validated for diagnosis of SARS. These include :

Virus Detection Test

Molecular Test (PCR) : PCR can detect very minute quantities of the genetic material of the SARS virus in various clinical specimens in the early phase of the disease.

Cell culture : Virus in clinical specimens from SARS patients can also be detected by infecting certain cell lines (VERO cell lines). Once isolated, the virus must be identified as SARS virus with further tests. Cell culture is the only test to indicate the infectivity of a SARS case.

Antibody Detection Test

ELISA test detects antibodies in the serum of SARS patients reliably as from day 21 after the onset of clinical symptoms and signs.

Immunofluorescence Assays (IFA) detect antibodies in serum of SARS patients 10 days after the onset of illness.

Neutralization Test (NT) : This test assesses and quantifies, by means of titration, the ability of patients' sera to neutralize the infectivity of SARS - Co V on cell culture.

The test which has been most widely used so far is PCR test which is supposed to have a high specificity but low sensitivity. The clinical samples from suspect/ probable SARS cases should only be subjected to laboratory tests. Testing of samples from asymptomatic contacts is not recommended.

Treatment

As of now, there is no vaccine or specific treatment available for SARS. However, good supportive treatment has been found

effective in many cases (1, 2, 9 - 12). Ribavirin and steroids have shown to be useful in treating critically ill patients. Ribavirin may be given 8mg/kg every 8 hours intravenously or 1.2g every 12 hours orally, with an oral loading dose of 4g for those with normal renal functions. Administer for 7 - 14 days depending upon the response. Give hydrocortisone 2mg/kg every six hours or 4 mg/kg every 8 hours intravenously. Tail off over one week when there is clinical improvement. For severe and rapidly deteriorating cases give methyl prednisolone 10mg / kg every 24 hours intravenously for two days, and then continue with hydrocortisone as above. Antibiotics treatment (coverage for typical and atypical agents for 7 - 14 days using drugs such as levofloxacin and macrolides) is advocated to prevent superadded infection.

Investigation to exclude other causes of pneumonia should be carried out. Patients who require mechanical ventilation generally fulfill the diagnostic criteria for ARDS with diffuse infiltrates on chest radiography and hypoxaemia without evidence of left ventricular failure. All suspect or probable cases of SARS must be treated in isolation with barrier nursing and universal precautions should be taken by the health care workers to prevent the further spread of disease. All the States/UTs have identified the hospitals where cases of SARS should be referred for treatment. List of such hospitals may be obtained from the respective State Health Authorities. Nebulization should not be done. If patient is on a ventilator, close system suctioning catheter and bacterial filter on expiratory and inspiratory limbs of ventilator circuit should be used.

Following discharge from the hospital, convalescent cases should remain at home for 10 days and keep minimum contact with others. Further confinement may be recommended after clinical assessment. Nevertheless, cases must contact their hospitals from where they were discharged if their condition deteriorates and symptoms reappear at any time.

Prevention and Control

Isolation of suspect and probable cases of SARS and universal precautions taken by the healthcare workers and others who are likely to come in contact with SARS cases would prevent the further spread of disease. WHO recommends that international travellers departing from the places on the affected areas list should be screened for possible SARS at the point of departure. Travellers with one or more symptoms of SARS and having a history of exposure or who appear acutely ill should be assessed by a clinician and may be advised to postpone their trip until they feel better. Under the International Health Regulations all aircraft pilots and masters of ships are required to provide a General Declaration on Health to the Airport/Port authorities and APHOS/PHOs wherein any sickness on board is declared. This needs to be further strengthened by sensitizing all concerned to remain vigilant. Unless absolutely necessary, people should not visit hospitals where the SARS cases have been isolated to avoid any contact with them. Similarly avoid going to the crowded areas, otherwise keep your stay as short as possible.

All persons who come in contact with the suspect and probable cases of SARS should contact the local health authorities if they develop symptoms of SARS within 10 days of exposure.

Temperature should be recorded daily as this is the first symptom which is likely to appear. Contact cases should restrict their movement and remain voluntarily confined to their homes.

All persons disembarking in India are required to fill up a proforma. Any person meeting the criteria of suspect/ probable SARS should be referred to the hospitals identified by Central/ State Governments for further investigations and treatment in isolation. The cases should also be reported to Director, NICD, Delhi, respective State Health Authorities and Director, EMR. Healthy passengers are advised to contact local health authorities if they develop symptoms of SARS in the next 10 days.

Disinfection : In - patient rooms housing SARS patients should be cleaned and disinfected daily and at the time of patient transfer or discharge. Daily cleaning and disinfection should include horizontal surfaces (e.g. over - bed table, night stand), surfaces that are frequently touched by patients and healthcare personnel (e.g. bed rails, phone), and lavatory facilities. Terminal cleaning and disinfection following transfer or discharge should include the type of surfaces described above plus obviously soiled vertical surfaces, frequently touched surfaces (e.g. light cords and switches, door knobs), and durable patient equipment (e.g. bed, night stand, over - bed table, wheel chair, commode etc.). Curtain dividers should also be changed and laundered as appropriate for the curtain fabric. Patient care equipments such as mechanical ventilators, pulse oximeters, blood pressure cuff, should be cleaned and disinfected in accordance with current recommendations and manufacturer's instructions.

Cubicles or rooms in OPD areas where patients with suspected SARS are evaluated should be cleaned and disinfected before another patient is seen or cared for in that environment. Areas that should be specifically targeted for cleaning include the examination table and horizontal surfaces that may have been touched by the patient or healthcare providers. Solutions used for cleaning and disinfection should be discarded after use. Thoroughly rinse and clean housekeeping equipment after use in a SARS room or area and allow the equipment to dry. Launder reusable mop heads and cleaning clothes according to current practice.

Summary

Severe Acute Respiratory Syndrome (SARS) is a new disease which came into notice in Feb. 2003. As on 15th May 2003, a cumulative total of 7548 probable cases and 573 deaths due to SARS have been reported from 29 countries. China has reported more cases than the rest of the world combined. Currently, there is no known SARS transmission anywhere in the world. SARS corona virus is an enveloped RNA virus. SARS virus appears to spread most commonly by close person - to - person contact involving exposure to infectious droplets, and possibly by direct contact with infected body fluids. The incubation period is usually 2 - 7 days but may extend upto 10 days. The illness begins with sudden onset of fever and associated symptoms, after 3 - 7 days a lower respiratory phase begins with the onset of a dry, non - productive cough or dyspnoea. In 10% to 20% of cases, disease may become severe enough

to require intubation and mechanical ventilation. SARS is currently a diagnosis of exclusion. A variety of laboratory tests have been developed and are being validated for diagnosis of SARS. These are PCR, Cell culture, Antibody Detection Test (ELISA, Immunofluorescence assays and Neutralization test). The clinical samples from suspect/ probable SARS cases should only be subjected to laboratory tests. Testing of samples from asymptomatic contacts is not recommended. As of now, there is no vaccine or specific treatment available for SARS. Ribavirin and steroids have shown to be useful in treating critically ill patients. All suspect or probable cases of SARS must be treated in isolation with barrier nursing and universal precautions should be taken by the health care workers to prevent the further spread of disease. All persons who come in contact with the suspect and probable cases of SARS should contact the local health authorities if they develop symptoms of SARS within 10 days of exposure. Disinfection procedures should be strictly followed in all health care centres for SARS.

Study Exercises

Long Question : Discuss the epidemiology, treatment, prevention and control of SARS

Short Notes : (1) Recommendation for International Travel during SARS epidemic (2) Disinfection in SARS care centre

MCQs

- Country which has reported maximum no. of cases of SARS (a) Canada (b) Singapore (c) Hong Kong (d) China.
- All of the following states in India reported probable cases of SARS in 2003 except (a) West Bengal (b) Karnataka (c) Andhra Pradesh (d) Gujarat.
- SARS corona virus is (a) Enveloped RNA virus (b) Non - enveloped RNA virus (c) Enveloped DNA virus (d) Non - enveloped DNA virus.
- SARS virus can survive after drying on plastic surfaces for upto (a) 24 hours (b) 48 hours (c) 72 hours (d) 96 hours.

- Immunofluorescence Assays (IFA) detect antibodies in serum of SARS patients _____ days after the onset of illness (a) 5 (b) 10 (c) 15 (d) 20.

Answers : (1) d; (2) c; (3) a; (4) b; (5) b.

Definition

Gastroenteritis (also known as gastric flu or stomach flu), caused due to infections by a wide variety of micro - organisms including bacteria, virus, protozoa and helminthes or due to toxins produced by them, is an inflammation of gastrointestinal tract, involves both the stomach and small intestine and is characterized by the presence of vomiting and diarrhoea, the

latter being prominent in cases of bacterial origin.

Magnitude of the problem

Acute gastroenteritis is a major cause of morbidity and mortality, especially in children under five. World wide more than a billion cases of gastroenteritis, majority being from developing world, are reported every year. Due to the improved management skills especially the introduction of oral re - hydration therapy and improved sanitation, decadal trend, in the past three decades has shown a steady decline. The mortality rate, estimated as 4.8 million deaths per year prior to 1980, declined to 3.3 million deaths per year during 1980 - 1990 and to 2.6 million deaths per year during 1990 - 2000. In

the year 2001, 1.8 million deaths worldwide were estimated to be because of gastrointestinal infections and these accounted for 3.2% of overall casualties. In India, during the year 2005, about 1.07 million cases of acute diarrhoea with 2040 deaths were reported; though the actual incidence may be manifold.

Epidemiological determinants

Agent factors : A number of infectious agents including virus, bacteria, protozoa and intestinal worms, have been incriminated in the causation of gastroenteritis. Depending on the presence of blood in stool, these agents can be classified as follows :

(a) Causes of acute gastroenteritis without blood in stool

(i) **Viruses** : Rotavirus, Astrovirus, Norwalk group of virus, Enteric adenovirus

(ii) **Bacteria** : Early stages of *Shigella*, *C. jejuni*, *Salmonella* spp infection, Enterotoxigenic *E. coli* (ETEC), Enteropathogenic *E. coli* (EPEC), Enteroaggregative *E. coli* (EAVC), *Staph aureus*, *V. Cholera*, *Clostridium perfringens*, *C. difficile*, *Bacillus cereus* and *B. subtilis*

(iii) **Protozoa** : Giardiasis, Cryptosporidiosis, Cyclospora cayetenesis

(iv) **Helminths** : Strongyloidiasis

(b) Causes of acute gastroenteritis with blood in stool

(i) **Bacteria** : Shigellosis, Enterohaemorrhagic *E.coli*, *Campylobacter jejuni*, *Salmonella* spp, *Yersinia enterocolitis*

(ii) **Protozoa** : *Entamoeba histolytica*, *Balantidium coli* enterocolitis

(iii) **Helminths** : Massive trichuris infection, *Schistosoma mansoni*, *S. japonicum*

Reservoir and source of infection : Man is the principal reservoir of the infections. Mild cases which clinically recover in a few days without going to hospital, constitute one of the chief means by which the reservoir is maintained. Contaminated food or water serves as the principal source of infection.

The causative agents are significantly different from each other as far as the mode of transmission and virulence is concerned. While some like *Vibrio* and *S. typhi* are spread by water, others like *Staph. aureus* and *C. perfringens* are spread by food. Some like salmonella non - typhi, which multiply in food and *V. cholerae* have the potential of causing outbreaks, others like *C. jejuni* and *E. histolytica* produce sporadic diseases. Patients with acute amoebic dysentery pose only limited danger to others because of the fragility of trophozoites. Asymptomatic or mild cases excreting cystic forms of *E. histolytica* on the other hand are important reservoir of infection.

Host factors : Man has no natural immunity against these organisms. Both sexes are equally susceptible. Children and the aged suffer more. Transient immunity develops against the specific strain of some of the organisms like *Shigella*. However, immunity to re - infection has not been clearly demonstrated. Host differences such as race and age have been described as affecting susceptibility of individuals to infection. Intestinal motility plays an important role in providing protection against the infection. Increased gut motility associated with diarrhoea is a highly effective defence mechanism. Oral antibiotic therapy makes the host susceptible to gastrointestinal pathogens.

Diarrhoeal diseases are most common during the first two years of life. Incidence is highest at the time of weaning i.e. between 6 - 11 months. This pattern reflects the combined effects of declining levels of maternally - acquired antibodies, the lack of active immunity in the infant, the introduction of food that may be contaminated with faecal bacteria, and direct contact with human or animal faeces when the infant starts to crawl. Most enteric infections, mainly beyond 2 years of age, are asymptomatic owing to the development of active immunity. Persons with asymptomatic infections play an important role in the spread of many enteric pathogens, especially as they are unaware of their infection, take no special hygienic precautions and move normally from place to place. Under nutrition, recent measles and immunosuppression are associated with increased incidence, severity or duration of diarrhoea.

Environmental factors : Gastrointestinal infections are strongly linked to environmental factors. Non - availability, inadequacy or lack of access to clean drinking water, inadequate disposal of faecal waste and poor hygiene and sanitation increases the likelihood of these diseases. Travellers travelling from developed countries to developing countries usually fall prey to these conditions and develop traveller's diarrhoea.

Diarrhoeal diseases follow a distinct seasonal pattern. In tropical areas, rotavirus diarrhoea tends to occur throughout the year, increasing in frequency during the drier, cool months, whereas bacterial diarrhoeas tend to peak during the warmer, rainy season.

Mode of Transmission : Infection by all organisms of this group of diseases is invariably by ingestion in food or drink i.e. faeco - oral route. Person to person transmission plays an important role in transmission. Individuals primarily responsible for transmission are those with poor personal hygiene and who fail to cleanse contaminated hands and carry organisms under their fingernails after defaecation. Contaminated water is believed to play a major role in the transmission of amoebiasis. The organisms of bacillary dysentery do not thrive in water and are readily killed by chlorination but amoebic cysts are not killed by chlorine in amounts normally added for water disinfection. Water can be rendered free from cyst only by sand filtration. Milk and food are contaminated by infected water or by the hands of a carrier or case or more likely by flies & cockroaches which act as vehicles. Contamination of crockery, cutlery, kitchen utensils by food handlers or by dust containing cysts in case of *Entamoeba histolytica* is a possibility. Vegetables from fields irrigated with polluted water especially those cultivated with raw sewage as practiced in improper sewage farming are liable to carry infection.

Incubation period and Period of communicability : The incubation period varies from few hours as in case of bacillary dysentery to 2 to 4 weeks, but can be prolonged to several months, as in case of amoebic dysentery. Incubation period of some of the common causative organisms are shown in Table-1.

Diarrhoea and bacillary dysentery cases are most infective during the course of clinical illness and a short period thereafter. A case of amoebic dysentery is infective mostly during the non - clinical period between the remissions of clinical attack, because it is the cystic stage of amoeba which is infective and

not the vegetative form.

Causative organisms	Incubation period
<i>C. perfringens</i> , <i>B. cereus</i> (type I & II), <i>B. subtilis</i>	4 - 24 h
<i>S. enteritidis</i> , <i>S. typhimurium</i>	12 - 24 h
<i>Rotavirus</i> , Norwalk gp of virus, <i>V. cholerae</i> , <i>Shigella spp.</i>	1 - 3 days
<i>E. coli</i> (EHEC)	3 - 4 days
<i>E. histolytica</i>	2 - 4 weeks

Clinical Features

Acute gastroenteritis usually presents with diarrhoea, vomiting or occasionally both, abruptly in an otherwise healthy individual. The frequency and consistency of the stool depends on the causative organism and the dose of inoculum and varies from person to person and from day to day.

Conventionally diarrhoea is the passage of 3 or more loose or liquid stools per day, or more frequently than is normal for the individual. Acute diarrhoea is an attack of sudden onset which usually lasts for 3 - 7 days, but may last up to 10 - 14 days. Diarrhoea that starts as an acute episode and lasts for more than 2 weeks is considered persistent or chronic. This definition excludes specific conditions like celiac disease, tropical sprue, or other congenital, biochemical or metabolic disorders. Diarrhoea that is often associated with blood in the faeces is known as dysentery (formerly known as the bloody flux or simply flux). It is, usually, more severe and more likely to result in death than other forms of acute diarrhoea.

Pathophysiologically, diarrhoeal diseases are mainly of 2 types: secretory non - invasive diarrhoea, such as cholera, due to impairment of water absorption mechanisms in the small bowel and inducing watery stools and dehydration; and enteroinvasive diarrhoea, due to alteration of the colonic mucosa, inducing dysentery. Most cases of infectious diarrhoea are acute. Some pathogens, mainly parasites, can induce chronic diarrhoea.

Usually acute gastroenteritis is not associated with constitutional symptoms. But abdominal cramps may be present in some cases especially with dysentery. Fever may be occasionally present especially in salmonella and shigella infections. In some cases, due to excessive loss of fluid, features of dehydration like thirst, restless or irritable behaviour, dry mucosa, decreased skin turgor and sunken eyes, may be present. In severe cases sensorium may be obtunded and the patient may develop hypovolemic shock. Death may follow swiftly, if rehydration is not started immediately.

Laboratory diagnosis

Most uncomplicated cases of acute gastroenteritis can be managed successfully without resorting to any lab investigation. In hospital settings, microscopy and stool cultures may be done for the diagnosis of the causative organisms but, in majority of the cases, patients recover before the culture report is available. In complicated cases, blood sugar and electrolytes

may be required for the management.

Acute Viral Gastroenteritis

Acute viral gastroenteritis is caused by two distinct groups of viruses - the rotavirus and the enteric calicivirus such as Norwalk virus. The rotaviruses primarily infect children while enteric calicivirus affects both children as well as adults. In general these viral enteropathogens affect duodenum and upper jejunum, causing non - inflammatory diarrhoea.

Rotavirus infection occurs worldwide and by the age of three years almost all children suffer from rotavirus infection at least once. The median of peak age of infection in developing countries was found to be between six months to one year while the same for developed countries was over eleven months. World over, rotavirus is estimated to cause 20% of childhood deaths. Rotavirus is a member of Reoviridae family. Several distinct groups (groups A, B, C etc) of rotavirus have been identified so far, but the most common among humans is group A. Children less than 3 years of age are most commonly infected. Both sexes are affected equally. One episode of rotavirus diarrhoea confers good protection against subsequent infection, which are decreasingly less severe with each fresh episode. Protection of neonates against rotavirus infection appears to be due to trans - placental transfer of maternal antibody and due to antibodies present in the breast milk.

The clinical manifestations of rotavirus infection range from sub - clinical infection to fatal dehydrating illness through mild to severe diarrhoea. Vomiting is an early feature and fever is common. Diarrhoea is usually watery and large in volume. Colicky abdominal pain, ill defined tenderness and exaggerated bowel sounds are common. Severe dehydration is not unusual.

Rotavirus infection frequently occurs in conjunction with respiratory tract symptoms. It may rarely be associated with Reye's syndrome, hemolytic uremic syndrome, Henoch Schonlein purpura and polio - like paralysis and encephalitis. It may be severe or even fatal in immuno - compromised children.

Since the virus is shed in large amounts in stool, detection with the help of ELISA and Polymerase Chain Reaction (PCR) is possible, if facilities are available.

A live attenuated oral vaccine effective in reducing the severity of the disease, was developed and marketed but was subsequently withdrawn following reports of intussusception.

Management

Majority of the cases of acute gastroenteritis recover with re - hydration only and do not require anti - biotic therapy. Oral Rehydration Solution (ORS), introduced by WHO, is the single most important measure in the management of acute diarrhoea due to all aetiologies, in all age groups, and in all countries. The composition of reduced osmolarity ORS, as suggested by WHO, is as follows : Sodium Chloride - 2.6 g, Glucose (anhydrous) - 13.5 g, Potassium Chloride - 1.5 g, Trisodium citrate dehydrate - 2.9 g (Total weight of a packet = 20.5 g).

Packets of oral re - hydration mixture are freely available. The contents of the packet are dissolved in 1 litre of drinking water. The prepared solution should be used within 24 h. It should

not be boiled or sterilized otherwise. It alone can correct mild to moderate dehydration. The inclusion of tri - sodium citrate in place of sodium bicarbonate has made the product more stable. Besides, it also results in less stool output especially in high output diarrhoea (e.g. cholera), probably because of a direct effect of trisodium citrate in increasing intestinal absorption of sodium and water.

If these mixtures of salts are not available, simple mixture - Salt and Sugar Solution (SSS) - consisting of table salt 5 gm and sugar 20 gm dissolved in 1 litre of drinking water may safely be used. The child can also be given Home Available Fluids (HAF) like yoghurt drink, lemon drink, rice or pulse based drinks, vegetable soup, green coconut water or plain clean water. The general rule is that patients should be given as much ORS solution as they want, and that signs of dehydration should be checked until they subside. If the child's weight is known, the amount of ORS solutions required for re - hydration during the first four hours may be calculated by setting the deficit at approx 75 ml/kg body weight. Intravenous infusion is usually required only for the initial re - hydration of severely dehydrated patients who are in shock or unable to drink.

Judicious use of antibiotics in selected cases may reduce the severity and duration of the illness. Empirical treatment with quinolone (such as ciprofloxacin) in doses of 500 mg twice a day for 3 to 5 days may be considered in moderate to severe cases. For suspected cases of amoebiasis and giardiasis, treatment with metronidazole (250 mg 6 hrly for 7 days) may be considered.

The guidelines for assessment of dehydration in a patient of

acute gastroenteritis are given in Table - 2.

The guidelines for assessment of fluid deficit in each type of dehydration are given in Table - 3.

The guidelines for fluid replacement, when some dehydration is present, is given in Table - 4.

Note : Use the patient's age only when you do not know the weight. The approximate amount of ORS required (in ml) can also be calculated by multiplying the patient's weight in kg by 75.

- If the patient wants more ORS than shown, give more.
- Encourage the mother to continue breastfeeding her child.
- For infants under 6 months who are not breastfed, if using the old WHO ORS solution containing 90 mmol/L of sodium, also give 100 - 200ml clean water during this period. However, if using the new reduced (low) osmolarity ORS solution containing 75mmol/L of sodium, this is not necessary.
- During the initial stages of therapy, while still dehydrated, adults can consume up to 750 ml per hour, if necessary, and children up to 20 ml per kg body weight per hour.

Guidelines for replacement of fluid in case of severe dehydration are given in Table - 5.

Reassess the patient every 1 - 2 hours. If state of hydration is not improving, give IV fluids more rapidly.

Prevention and control

Constant maintenance of a high standard of waste disposal and environmental sanitation; personal hygiene including food hygiene and habits; wholesome water and milk supply; extermination of flies, and health education are the measures to be relied upon for preventing the infection in community.

Table - 2 : Assessment of diarrhoea patients for dehydration

Sign	Normal (No dehydration)	Some dehydration (any two of the following)	Severe dehydration (any two of the following)
Patient's condition	Conscious, alert, well looking	Restless irritable	Lethargic, unconscious
Eyes	Normal	Sunken	Sunken
Thirst	None	Thirst ++ Drinks eagerly	Drinks poorly, unable to drink
Skin pinch	Goes back immediately	Goes back slowly	Goes back very slowly

Source : IMNCI booklet, Ministry of H& FW, Govt of India (2005)

Table 3 : Assessment of fluid deficit in dehydration

Assessment	Fluid deficit as % of body weight	Fluid deficit in ml/kg body weight
No signs of dehydration	<5%	<50 ml/kg
Some dehydration	5 - 10%	50 - 100 ml/kg
Severe dehydration	>10%	>100 ml/kg

Table 4 : Approximate amount of ORS to be given in the first four hours of treatment when SOME DEHYDRATION is present

Age	Weight (kg)	ORS (ml)
Less than 4 months	Less than 5	200 - 400
4 - 11 months	5 - 8	400 - 600
1 - 2 years	8 - 11	600 - 800
2 - 4 years	11 - 16	800 - 1200
5 - 14 years	16 - 30	1200 - 2200
More than 14 years	More than 30	2200 - 4000

Source : WHO guidelines in Oxford handbook of Tropical Medicine

Table 5 : Approximate amount of IV infusion of Ringer Lactate to be given when SEVERE DEHYDRATION is present

Age	First give	Then give
Less than 12 months	30 ml/ kg in 1 hour	70 ml/ kg in 5 hour
More than 12 months	30 ml/ kg in 30 min	70 ml/ kg in 2.5 hour

Source : WHO guidelines in Oxford handbook of Tropical Medicine

The following measures should be taken for controlling an outbreak :

(a) Isolation : All serious cases should be admitted to hospital and isolated during acute illness with rigid personal precautions by attendants. Fluid and electrolyte replacement is important along with specific drugs. This will break the chain of transmission.

(b) Rehydration : All cases must be given reduced osmolarity ORS liberally. Those requiring parenteral rehydration should be treated in a health care facility.

(c) Breastfeeding : Because of its protective qualities, breastfeeding must be continued for sick children.

(d) Safe drinking water : Water supplies should be scrutinized and adequately chlorinated.

(e) Food safety : Food hygiene should be made stricter. Adequate storage facility for storage of food (both cooked and uncooked) and adequate water for cleaning and cooking must be provided. All crockery and cutlery must be adequately cleaned before use. Milk should be boiled and the food habits of personnel should be improved. WHO guidelines for food safety, as given in Box-1

Box - 1: WHO Golden rules for food safety	
1.	<i>Cook raw foods thoroughly</i> : Thorough cooking will kill the pathogens, which means the temperature of all parts of the food must reach at least 70 °C. Uncooked fruits or vegetables should not be eaten, unless they can be peeled. If milk has not been pasteurized, it should be boiled before use.
2.	<i>Eat cooked food immediately</i> : When cooked foods cool to room temperature, bacteria begin to grow. The longer the wait, the greater the risk. To be on the safe side, eat cooked foods as soon as they come off the heat.
3.	<i>Prepare food for only one meal</i> : Foods should be prepared freshly and for one meal only, as far as possible. If foods have to be prepared in advance, or if there are leftovers, they should be stored cold, i.e. below 5 °C (in a refrigerator or in a cold box), or hot, i.e. above 60 °C. This rule is vitally important when it is planned to store food for more than 4-5 hours. Cooked foods that have been stored must be thoroughly reheated before eating, i.e. all parts reheated to at least 70 °C. Thorough reheating of foods is essential if refrigerators have ceased to operate for some hours due to power cuts.
4.	<i>Avoid contact between raw foods and cooked foods</i> : Safely cooked food can become contaminated through even the slightest contact with raw food. This cross-contamination can be direct, e.g. when raw fish comes into contact with cooked foods. It can also be indirect. For example, preparing raw fish and then using the same unwashed cutting surface and knife to slice cooked food should be avoided, or all the potential risks of illness that were present before cooking may be reintroduced. Cross-contamination may also occur in a freezer when the power has been off for some time and this should be checked for. The juice of raw meat and poultry may drip onto other foods.
5.	<i>Choose foods processed for safety</i> : Many foods, such as fruits and vegetables, are best in their natural state. However, in disasters and emergencies, they may not be safe and should be peeled before consumption if eaten raw. Foods that have been processed (e.g. canned food and packed dried food) may be safer. Dry rations may be easier to keep safe, as they do not need cold-storage, but they do need to be kept dry.
6.	<i>Wash hands repeatedly</i> : Hands should be washed thoroughly before preparing, serving or eating food and after every interruption, especially after use of the toilet or latrine, changing a baby or touching animals. After preparing raw foods, hands should be washed again before handling cooked or ready-to-eat foods.
7.	<i>Keep all food preparation premises meticulously clean</i> : Since foods are so easily contaminated, any surface used for food preparation must be kept absolutely clean. Scraps of food and crumbs are potential reservoirs of germs and can attract insects and animals. The immediate surrounding of the temporary shelter, especially the kitchen and food storage areas should be cleaned and sullage and solid kitchen waste should be disposed of properly. Food should be stored in closed containers to protect it from insects, rodents and other animals. Fly and rat traps should be used if necessary.
8.	<i>Use safe water</i> : Safe water is just as important for food preparation as for drinking. If the supply of safe/potable water has been disrupted, the water intended for drinking or food preparation should be boiled. For example, condensed or powdered milk must be reconstituted with potable water only. Ice made from unsafe water will also be unsafe and may be a source of food contamination.
9.	<i>Be cautious with foods purchased outside</i> : Sometimes food served in restaurants and by street food-vendors is not prepared under hygienic conditions. In times of disasters or emergencies, the risk that such foods are contaminated is greater. Therefore, caution must be exercised in the choice of food: only food that has been thoroughly cooked and is still hot when served should be eaten. Food bought from street food-vendors should be thoroughly cooked in the presence of the customer. Apart from fruits and vegetables that can be peeled, raw or undercooked foods should be avoided. Only water that has been boiled, or disinfected with chlorine or iodine, should be drunk. Beverages such as hot tea or coffee, wine, beer, carbonated water or soft drinks, packaged fruit juices and bottled water are usually safe to drink, if not damaged by the disaster. Ice should be avoided, unless it is made from safe water.
10.	<i>Breast-feed infants and young children</i> : Breast milk is the ideal source of nourishment for infants during their first months of life. It protects infants against diarrhoea through its anti-infective properties, and minimizes their exposure to food borne pathogens. Breast milk will ensure a safe and nutritionally adequate food for infants from birth up to the age of 4-6 months. Continued breast-feeding after this age can also contribute to the prevention of food-borne infections in older infants and young children.

would go a long way in preventing gastroenteritis.

(f) Concurrent Disinfection : All underclothings, soiled linen, bedding, and particularly the excreta should be treated by concurrent disinfection.

(g) Personal Hygiene : Thorough hand washing with soap before handling food must be stressed.

(h) Epidemiological Investigation : For the source of infection and modes of transmission, epidemiological investigation should be carried out and appropriate control measures instituted.

(j) Control of Flies : Control and destruction of flies is the most important method of controlling an outbreak of dysentery. Persistent attention to exterminate breeding places by proper disposal of faeces and manure, ensuring good general sanitation, prohibiting indiscriminate defaecation and the use of insecticides lead to control of flies. Health education of all personnel is very important.

Summary

Gastroenteritis is an inflammation of the intestinal tract caused by a wide variety of micro - organisms including bacteria, virus, protozoa and heminthes. It is a major cause of morbidity and mortality, especially in children under five. A steady decline in the number of cases has been seen after improved sanitation and introduction of oral rehydration therapy.

The infectious agents can be broadly classified as those causing acute gastroenteritis with or without blood in stool. Man is the principal reservoir of the infections. Persons with asymptomatic infections play a major role in spread of the infection as they take no special hygienic precaution. The main source of infection is either contaminated food or water. Man has no natural immunity against these organisms. Both sexes are equally susceptible. Children and the aged suffer more. Increased intestinal motility associated with diarrhoea is an effective defence mechanism. Co - morbid conditions like under nutrition, recent measles and immunosuppression are associated with increased incidence, severity or duration of diarrhoea. Environmental factors like lack of access to clean drinking water, improper disposal of faecal waste and poor hygiene increases the chances of these infections. Mode of disease transmission is by faeco - oral route due to poor personal hygiene. Flies and cockroaches may also act as vehicles for transmission of disease. Adequate chlorination kills some of the disease causing organisms.

Incubation period varies from few hours to a few weeks depending on the infecting organism. It usually presents with diarrhoea, vomiting or occasionally both, abruptly in an otherwise healthy individual. The frequency and consistency of the stool depends on the causative organism and the dose of inoculum and varies from person to person. Diarrhoea less than 2 weeks is known as acute and more than 2 weeks as chronic. Pathophysiologically diarrhoea can be divided as secretory non - invasive and enteroinvasive diarrhoea. Microscopy and stool cultures may be done for the diagnosis of the causative organisms but, in majority of the cases, patients recover before the culture report is available.

Acute viral gastroenteritis is caused by two groups of viruses

- the rotavirus and the enteric calicivirus such as Norwalk virus. The rotaviruses primarily infect children while enteric calicivirus affects both children as well as adults. Children less than 3 years of age are most commonly infected. Both sexes are affected equally. The clinical manifestations of rotavirus infection range from sub - clinical infection to fatal dehydrating illness. Vomiting is an early feature and fever is common. Diarrhoea is usually watery and large in volume.

Majority of the cases of acute gastroenteritis recover with re - hydration only and do not require antibiotic therapy. Oral Rehydration Solution (ORS), introduced by WHO, is the single most important measure in the management of acute diarrhoea due to all aetiologies, in all age groups, and in all countries. Packets of oral re - hydration mixture are freely available. The contents of the packet are dissolved in 1 litre of drinking water. The prepared solution should be used within 24 h. If ORS is not available, then salt and sugar solution (SSS) or home available fluids (HAF) like yoghurt drink, lemon drink, rice or pulse based drinks, vegetable soup, green coconut water or plain water can also be safely given. The patient should be given as much ORS as they want. Intravenous infusion is usually required only for the initial re - hydration of severely dehydrated patients who are in shock or unable to drink. The use of antibiotics in selected cases may reduce the severity and duration of the illness.

A constant maintenance of a high standard of environmental sanitation, personal hygiene, safe water and milk supply, control of flies and health education will be helpful in preventing the infection in community. The measures to be taken during an outbreak are isolation, rehydration, breastfeeding, safe drinking water, food safety, concurrent disinfection, personal hygiene, control of flies and epidemiological investigation for the source of infection and modes of transmission should be carried out and appropriate control measures instituted.

Study Exercises

Long Questions : (1) Discuss the steps to be taken for control of an out break of gastroenteritis (2) Principles of management of cases of dehydration.

Short Notes : (1) Oral rehydration solution (2) WHO golden rules for food safety (3) Discuss briefly the epidemiological factors in Gastroenteritis.

MCQs

1. If ORS is not available which of the following fluids can be given to a case of gastroenteritis (a) Yoghurt drink (b) Vegetable soup (c) Salt and sugar solution (d) All of the above.
2. All cause bloody diarrhoea (dysentery) except (a) Shigella (b) *Campylobacter jejuni* (c) *Entamoeba histolytica* (d) Rotavirus.
3. All are causes of acute gastroenteritis without blood in stool except (a) Rotavirus (b) Shigella (c) Giardiasis (d) Cryptosporidiasis.
4. Which of the following is predominantly transmitted through contaminated food (a) *S. typhi* (b) *V. cholera* (c) *E. histolytica* (d) *S. aureus*.
5. Infection caused by which of the following has an incubation period of 1 - 3 days (a) Rotavirus (b) *V. cholera*

(c) *Shigella* (d) All of the above.

Answers : (1) d; (2) d (3) b; (4) d; (5) d.

Cholera

Rajesh Kunwar

Definition

A serious acute intestinal disease caused by *Vibrio cholerae* O1 (Classical or El Tor) and characterized by sudden onset, profuse, effortless watery stools, vomiting, rapid dehydration, muscular cramps, acidosis and circulatory collapse. Fatality rates in untreated cases may exceed 30 - 40 per cent; inapparent and wholly asymptomatic infections are many times more frequent than clinically recognized cases, especially *Vibrio cholerae* biotype El Tor.

Magnitude of the Problem

For centuries cholera has been one of the most feared diseases. Even today, it remains a global threat to public health and one of the key indicators of social development. While the disease no longer poses a threat to countries where minimum standards of hygiene are met, it remains a challenge in those countries where access to safe water and adequate sanitation can not be guaranteed for all.

Six cholera pandemics, caused by the classical biotype, were reported from South Asia during 19th and early 20th century. The El Tor biotype was first recognized in 1906 but remained localized in Sulawesi in Indonesia. In 1961, an unexpected situation arose. Cholera El tor suddenly became widespread, starting the seventh pandemic. India became involved in 1964. It has since affected more than 80 countries in Asia, Africa & Europe. In India, cholera biotype El Tor has almost completely replaced the age old classical cholera. Currently the large endemic foci of cholera are found in Maharashtra, Tamil Nadu, Karnataka, Delhi, Gujarat & Kerala, which account for 80 percent of the reported incidence in the country.

During the year 2007, a total of 11, 325 cases and 37 deaths were reported from 8 Asian countries. The Indian subcontinent reported 23% of all cases notified from Asia, with India notifying a total of 2635 cases and 3 deaths.

Epidemiological determinants

Agent factors

(a) **Agent** : The causative agent, *Vibrio cholerae* was first isolated in 1883 by Koch from the stools of patients with cholera. It is a Gram - negative, aerobic, comma - shaped rod that is oxidase positive and ferments both sucrose and glucose but not lactose. It is best identified by inoculating stool into taurocholate - tellurite - gelatin (TTG) agar or thiosulfate - citrate - bile salts - sucrose (TCBS) agar. *V. cholerae* colonies are relatively small on TTG agar after 24 hours and are translucent with a dark centre and a cloudy zone surrounding the colonies. On TCBS agar *V. cholerae* are easily recognized as large yellow colonies on a blue - green medium.

The antigenic classification of vibrios depends on the specific somatic (O) antigens. The flagellar antigen (H) is non specific and common to all. The group A vibrios which include both cholera and cholera like vibrios have been divided into six sub groups (I to VI) based on the antigenically different 'O' antigens. Cholera vibrios belong to serological O sub - group I of Gardner and Venkataraman and other serological Sub - group (II to VI) are NAG vibrios (non agglutinable to O group I antisera). The O subgroup I vibrios comprises of classical *V. Cholera* and *V. El Tor* biotype. Based on the O antigenic components, both classical *V. cholerae* and biotype El tor have been divided into 3 serotypes Ogawa, Inaba and Hikojima. The former two are common.

Epidemiologically, cholera due to El Tor biotype differs from classical cholera. In El Tor :

- There is a higher incidence of mild and asymptomatic infection. This implies that the characteristic picture of rice-water stools and other signs of classical cholera described above may not be seen often.
- There are fewer secondary cases in the affected families
- Occurrence of chronic carriers are common
- Since El Tor vibrios are more resistant than classical cholera vibrios, they survive longer in the extra intestinal environment and hence epidemics continue longer.

Classical *Vibrio cholerae* can be distinguished from El Tor by the following tests as shown in Table - 1 :

Table - 1 : Differences between Classical and El Tor *Vibrio Cholerae*

Test	Classical <i>V. cholerae</i>	Biotype El tor
Chick erythrocyte agglutination	Negative	Positive
Polymyxin B sensitivity	Sensitive	Resistant
Cholera phage IV	Sensitive	Resistant
Haemolysis test	Negative	Positive

(b) Resistance : *V. cholerae* O1 is killed by heating at 55°C for 15 mins and by most disinfectants, yet it can survive on a variety of foodstuffs for up to five days at ambient temperature and up to 10 days at 5 - 10 degrees Celsius. The organism can also survive freezing. Low temperatures, however, limit proliferation of the organism and thus may prevent the level of contamination from reaching an infective dose. The cholera vibrio is sensitive to acidity and drying, and commercially prepared acidic (pH 4.5 or less) or dried foods are therefore without risk. Gamma irradiation and temperatures above 70 degrees Celsius also destroy the vibrio.

(c) Toxin production : Vibrios multiply in the lumen of small intestine and produce enterotoxins which act on adenylyl cyclase - cyclic AMP system of mucosal cells and produce diarrhoea.

(d) Reservoir of infection : The only reservoir of infection is man, either a case or a carrier. The ratio of severe cases to mild or inapparent infections has been shown to be about 1 : 5 for classical cholera and 1 : 25 to 1 : 100 for El Tor cholera. Carriers in cholera are of four types viz. incubatory carriers, convalescent carriers, healthy carriers and contact carriers. Duration of carrier period is short, about 4 or 5 days. Chronic carriers who harbour the vibrio for more than 3 months are not common.

(e) Infective material : Stools and vomit of cases and carriers are infectious in nature. However, carriers excrete fewer vibrios as compared to cases.

(f) Period of communicability : A case of cholera is infectious for a period of 7 to 10 days. While convalescent carriers are infectious for 2 - 3 weeks, chronic carrier state may last from one month to 10 years or more.

Host Factors : Cholera usually affects persons belonging to the low socio - economic strata because of poor environmental sanitation. Their standard of personal hygiene is low. When cholera epidemic occurs in non - endemic areas, male adults are more affected. In contrast, in endemic areas, attack rate is equal in both the sexes and it is distinctly higher for children than for adults. This phenomenon is due to development of naturally acquired immunity with increasing age in the endemic areas.

Environmental factors : Contaminated water and food are the most important environmental factors in the causation of cholera. Unusually heavy rains, which have caused flooding, are blamed, at times, for the high incidence of the disease outbreak. Flies may carry *V. cholerae* but are not vectors of proven importance. Social factors responsible for the endemicity of the disease include poor literacy, poor personal hygiene, poor

living standards and unhealthy habits in relation to water and food.

Mode of Transmission : Infection by *V. cholerae* is invariably by ingestion. Most important mode of transmission is through contaminated water. Disease may spread through food contaminated by food handlers and flies. Fruits and vegetables washed with contaminated water may transmit the infection. Person to person contact particularly in overcrowded dwellings without sanitary facilities is very important due to careless handling of human excreta under such conditions.

Incubation Period : It varies from a few hours upto 5 days, but commonly 1 to 2 days. Infectivity of cholera is high, but the disease rate is low; as a rule, although many members of family may be infected, usually one of them falls ill.

Pathogenesis : According to current concepts, the cholera vibrio gets through the mucus which overlies the intestinal epithelium. It probably secretes mucinase, which helps it move rapidly through the mucus. Then it gets attached or adhered to the intestinal epithelial cells, and this it probably does by an adherence factor on its surface. When the vibrio becomes adherent to the mucosa, it produces its enterotoxin which consists of 2 parts - the light or L toxin and the heavy or H toxin. The L toxin combines with substances in the epithelial cell membrane called gangliosides and this binds the vibrio to the cell wall. Binding is irreversible. The mode of action of H toxin is not fully clear. What we know is that there is a substance called "adenylyl cyclase" in the intestinal epithelial cells, and H toxin activates this substance. The activated adenylyl cyclase causes a rise in cAMP. cAMP provides energy which drives fluid and ions into the lumen of the intestine. This fluid is isotonic and is secreted by all segments of small intestine. This increase in fluid is the cause of diarrhoea.

Clinical Features

The severity of cholera is dependent on the rapidity and duration of fluid loss. Epidemiological studies have shown that more than 90 percent of El Tor cholera cases are mild and clinically indistinguishable from other acute diarrhoeas. However, a typical case of cholera shows 3 stages :

(a) Stage of Evacuation : The onset is abrupt with profuse, painless, watery diarrhoea followed by vomiting. The patient may pass as many as 40 stools in a day. The stools may have a "rice water" appearance.

(b) Stage of Collapse : The patient soon passes into a stage of collapse because of dehydration. The classical signs are : sunken eyes, hollow cheeks, scaphoid abdomen, sub - normal temperature, washerman's hands and feet, absent pulse, unrecordable blood pressure, loss of skin elasticity, shallow and quick respiration. The urinary output decreases and may ultimately cease. The patient becomes restless, and complains of intense thirst and cramps in legs and abdomen. Death may occur at this stage, due to dehydration and acidosis resulting from diarrhoea.

(c) Stage of Recovery : If death does not occur, the patient begins to show signs of clinical improvement. The blood pressure begins to rise, the temperature returns to normal and urine output is re - established. If anuria persists, the patient may die of renal failure. The classical form of severe cholera

occurs in only 5 - 10 percent of cases. In the rest, the disease tends to be mild characterised by diarrhoea with or without vomiting or marked dehydration. As a rule, mild cases recover in 1 - 3 days.

Laboratory Diagnosis of Cholera

The diagnosis of cholera can never be made with certainty on clinical grounds alone. Laboratory methods of diagnosis are required to confirm the diagnosis. The details of collection, storage and dispatch, as well as examination under field conditions, of specimens for laboratory diagnosis of cholera have been discussed earlier in the chapter on microbiological procedures in public health and the readers are advised to refer to the same.

Recently developed dipsticks (sensitivity and specificity above 92 and 91%, respectively) for the rapid detection of *Vibrio cholerae* serotypes O1 and O139 from rectal swabs has been successfully used to diagnose cholera. This is likely to improve surveillance for cholera, especially in remote settings.

Management

The successful management of cholera depends on the quick restoration of body fluids and electrolytes with appropriate and adequate fluids. Except in very severe cases or in cases with persistent vomiting, oral fluids are preferred. The volume of replacement depends on the degree of dehydration and the rate of fluid loss. Oral rehydration solution, as recommended by WHO is the most suited solution. In case it is not available, rice - water with sucrose or home available fluids may be used for rehydration.

In case of severe dehydration - characterized by 10% or more loss of body weight, lethargy, obtundation of sensorium and hypovolemic shock - rapid intra - venous infusion with wide - bore needle in both arms aiming to restore normal hydration and electrolyte balance within 2 - 3 hours, will be required. Of this, 50% losses must be restored within half an hour to 45 minutes. After the normal hydration is achieved, the maintenance phase will require replacement of continuing fluid loss in stool. As far as possible, this loss is made up with oral fluids; rare cases may require continuing intra - venous infusion.

Antibiotics, often required in the management of severe cases, have been shown to reduce the volume and duration of diarrhoea. Doxycycline given in a single dose of 300 mg orally or Tetracycline given 500 mg orally QID for three days is the drug of choice for adults (except pregnant women). For children and pregnant women, Co - trimoxazole in a dose of 30 mg/kg given orally in a single dose, has been found useful.

Prevention & Control

Guidelines on prevention and control of cholera are as follows:

(a) Improvement of environmental sanitation : Main aspects of environmental sanitation are adequately chlorinated and protected water supply, proper disposal of night soil/ sewage and safe food supply. Food may be contaminated at the source, at different stages of processing, storing, serving and due to exposure to flies. Health education is important for improvement of personal hygiene.

(b) Immunization : Three types of cholera vaccines are

available

(i) Whole cell killed vaccine : given parenterally, provides protection for 5 months, has significant side effects and efficacy is only 50%.

(ii) B - subunit whole cell killed vaccine : given orally in 2 doses at an interval of 1 to 6 weeks and has an efficacy of 50 - 60%. Appears to provide herd immunity in endemic setting but role during outbreak less well defined. Several mass vaccination trials using Oral Cholera Vaccines (OCV) have been performed with the support of WHO. Based on these, OCVs are now being considered as complements to traditional preventive measures.

(iii) CVD 103 - HgR : It is the only licensed single - dose live attenuated oral cholera vaccine but is not available in the market.

As such, immunization against cholera is not regarded as an effective means of preventing the spread of cholera internationally. Cholera vaccination is not mandatory for international travel. However certain countries still insist on vaccination certificate against cholera. Before undertaking any travel one should consult the booklet issued by WHO every year 'Vaccination Certificate Requirements for International Travel'.

(c) Action on Occurrence of the Disease

(i) Isolation : Even on the slightest of suspicion, the patient must be admitted immediately to the hospital where he must be strictly isolated in a special fly - proofed ward and diagnosis should be confirmed by identifying *V. cholerae* O1 in the stool. Generally several cases occur at the same time; therefore, adequate arrangements for hospitalization of all cases are essential. In a large outbreak a separate hospital in the vicinity of the main hospital may have to be opened.

(ii) Disinfection : Soiled bedding and clothing, which cannot be sterilized, must be burnt. The floors of wards, huts and barracks must be thoroughly scrubbed with 5 per cent cresol (cresoli liquid). The place in which bed pans, urinals and soiled linen are stored should be fly - proofed or carefully covered with a sheet soaked in and kept moist with 5 per cent cresol. The stool and vomit should be poured into a receptacle containing an equal quantity of 5 per cent solution of cresol and left covered for 4 hours before its final disposal. Fresh WSP thoroughly mixed in the proportion of 1.5 g to 1 lit of faeces/vomit may also be used as a disinfectant.

(iii) Notification : Previously, cholera was listed among the three communicable diseases - along with yellow fever and plague - whose notification to WHO was compulsory. Since 15 June 2005, the official notification of cholera is no longer mandatory but countries are required to inform WHO of public health events of international concern.

(iv) Attendants : They should be specially detailed and be isolated from the nursing staff of the main hospital. They should dip their hands in antiseptic solution after washing, after every contact with the patient, his bedding, objects or utensils. They should all be inoculated against cholera beforehand. The consumption of any food or drink by these attendants while in the cholera ward should be strictly prohibited. Gowns should always be worn while on duty.

(v) **Contacts** : They need not be isolated. All persons who are suspected of having partaken of the same infected food or drink as the patient, however remotely, should be kept under daily morning and evening surveillance for 5 days.

(vi) **Food and Drinks** : Control of food and drinks is the most important method of control of an outbreak. The following rules should be followed in the presence of an outbreak in the community :

- Drinking water should be super chlorinated. Washing and bathing water should be chlorinated. Soda water and other drinks should be used only after the most careful investigation of their source of supply. Ice should not be used unless from an authorized source.
- Milk must be boiled. Cream and butter should be obtained only from reliable sources. Consumption of ice cream, unless its origin is absolutely beyond suspicion, should be strictly prohibited.
- Uncooked vegetables and fruits which are customarily eaten unpeeled should be avoided during epidemics. Others should always be washed and then soaked in a solution made by adding 3 scoopsful or 6 g WSP to a bucketful of water, before peeling. Cut fruits exposed for sale should not be eaten.
- All food must be protected against flies. Strict supervision of cookhouses and cooks are necessary to ensure that food is prepared, cooked stored and served under clean conditions. Golden rules for safe food preparation, as suggested by WHO and given in the Box - 1 (WHO Golden rules for food safety) of the previous chapter on gastroenteritis.

A search for mild cases should be carried out by examination of the stools of all those who are suffering from diarrhoea. All diarrhoea cases, however, should be treated with suspicion until proved otherwise.

Summary

It is an acute intestinal disease caused by *Vibrio cholerae* O1 (Classical or El Tor). It is one of the key indicators to social development.

Vibrio cholerae is a gram negative rod shaped organism. The antigenic classification of vibrios depends on the specific somatic (O) antigens. The flagellar antigen (H) is non specific and common to all. The group A vibrios have been divided into six sub groups (I to VI) based on the antigenically different 'O' antigens. The O subgroup I vibrios comprises of classical V. Cholera and V. El Tor biotype. Based on the O antigenic components, both classical *V. cholerae* and biotype El tor have been divided into 3 serotypes Ogawa, Inaba and Hikojima.

The infection caused by V. El tor differs from *V. Cholera* in that the classical signs of cholera might not be seen, few secondary cases, more chronic carriers and since they are more resistant than *V. cholera* the epidemics last longer. The two biotypes can be differentiated by chick erythrocyte agglutination, polymixin B sensitivity and cholera phage IV.

Vibrios multiply in the lumen of small intestine and produce enterotoxins which act on adenyl cyclase - cyclic AMP system of mucosal cells and produce diarrhoea. Either a case or a carrier in man is the reservoir of infection. A case of cholera is infectious for a period of 7 - 10 days. Cholera is seen in

communities where there is poor personal hygiene and low levels of environmental sanitation. The contamination of food and water are the most important factors in the causation of the disease. The incubation period varies from a few hours upto 5 days, but commonly 1 to 2 days.

The severity of cholera depends on rapidity and duration of fluid loss. A typical case of cholera goes through stages of evacuation, collapse and recovery. The diagnosis of cholera can never be made with certainty on clinical grounds alone. Laboratory methods of diagnosis are required to confirm the diagnosis.

The management of cholera depends on restoration of body fluids and electrolytes with appropriate and adequate fluids. Except in very severe cases or in cases with persistent vomiting, oral fluids are preferred. ORS has been recommended for cases with dehydration by WHO. Antibiotics that can be given in severe cases are Doxycycline given in a single dose of 300 mg orally or Tetracycline given 500 mg orally QID for three days for adults (except pregnant women) and for children and pregnant women, Co - trimoxazole in a dose of 30 mg/kg given orally in a single dose.

Guidelines for prevention and control of cholera are improvement in environmental sanitation and immunization. Several mass vaccination trials using Oral Cholera Vaccines (OCV) have been performed with the support of WHO. Based on these, OCVs are now being considered as complements to traditional preventive measures.

On occurrence of epidemic following steps should be taken isolation, disinfection, notification, care of attendants and contacts and food and water safety.

Study Exercises

Long Question : Discuss the steps to be taken during a cholera epidemic.

Short Notes : (1) Outline the preventive and control measures for cholera (2) Cholera vaccine and its importance during an epidemic.

MCQs

1. A case due to V. El tor differs from *V. Cholera* in the following respects except (a) Higher carrier rate (b) Large number of secondary cases (c) Classical signs of cholera not seen (d) Positive chick erythrocyte agglutination.
2. The steps taken during control of an outbreak of cholera would be all except (a) Food safety (b) Super chlorination of water (c) Immunization with whole cell killed parenteral vaccine (d) Proper excreta disposal.
3. Notification to WHO is not required anymore for which of the following diseases (a) Yellow fever (b) Cholera (c) Plague (d) None of the above.
4. What is the correct order of stages in a case of cholera (i) Stage of evacuation (ii) Stage of recovery (iii) stage of collapse (a) iii, ii, i (b) ii, i, iii (c) i, iii, ii (d) None

Answers : (1) b; (2) c; (3) b; (4) c.

Food Poisoning

Rajesh Kunwar, Rajul Gupta

Definition

Food poisoning is an acute gastro - enteritis caused by ingestion of food or drink contaminated with either living bacteria or their toxins or inorganic chemical substances and poisons derived from plants and animals. Food poisoning outbreaks are usually recognized by the sudden occurrences of an illness in a group of people who have consumed common food and have similar signs and symptoms. The food poisoning may occur as a result of eating any of the following :

- Substances containing specific poisons like eating fungi like *Amanita phylloides* instead of edible mushroom or eating sprouting potatoes which contains excess of alkaloid solanine.
- Food contaminated by poisons due to agricultural or industrial activities, fertilizers and pesticides in food or food contaminated with metallic poisons as a result of faulty cooking or storing such as use of cheap enamel dishes or galvanized pans.
- Foods infected with organisms mainly by three bacterial groups - Salmonella, Clostridium and Staphylococcus. This bacterial food poisoning is the commonest form and will be discussed in detail in subsequent paragraphs. Their characteristic features are summarized in Box - 1.

Salmonella Food Poisoning

It is the most common form of food poisoning. The causative organisms belong to Salmonella Group of which several dozens are known to cause food - borne outbreaks. The species most commonly incriminated in human outbreaks is *Salmonella typhimurium*; others are *S. enteritidis*, *S. cholera - suis*. The organisms are natural commensals of rodents, pigs, cattle, poultry, ducks, eggs and also some healthy human carriers. Man acquires the infection from animals and poultry i.e. through contaminated meat, milk and milk products. *S. enteritidis* is present in raw uncooked eggs even if the shell is sound. Most often bacteria is transferred from raw food to processed food by cross contamination. Incubation period usually varies from 12 to 24 hours. On ingestion, the organism multiplies in the intestine and causes acute enteritis and colitis. The onset is generally sudden with chills, fever, nausea, vomiting, abdominal pain and profuse watery diarrhoea. It may be preceded by headache and fever. The illness usually lasts for 2 to 3 days. Mortality is usually low but may be considerably higher in vulnerable groups i.e. very young and elderly. Convalescent carriers are known to occur. Diagnosis is based on the typical history of intake of contaminated food and is confirmed by isolation of the bacteria from faecal samples. Careful rehydration and supportive care is usually sufficient for the management of the case.

Staphylococcal food poisoning

It is as common as food poisoning caused by salmonella. The causative organism is coagulase positive *staphylococcus aureus* which cause the illness by production of heat stable

Box - 1 : Distinctive Features of Common Food Poisoning

Entity	Incriminating food	Incubation period (h)	Clinical features
<i>Salmonella spp</i> food poisoning	Meat, poultry, dairy products	12 - 24	D, V, AP, F
<i>S. aureus</i> food poisoning	Meat, poultry, dairy products	1 - 6	V, D, AP
<i>Cl. Perfringens</i> food poisoning	Cooked meat	6 - 24	D, AP, V
<i>C. botulinum</i> food poisoning	Poorly canned foods, smoked meats	12 - 36	Diplopia, paralysis
<i>C. jejuni</i> food poisoning	Poultry, raw milk, eggs	3 - 5 days	D, AP
<i>B. cereus</i> food poisoning	Type I Fried rice	1 - 6	V
	Type II Soup, sauce	8 - 16	D, AP
<i>E coli</i> O157 food poisoning	Dirty water, raw milk, raw apple juice, ground beef	3 - 4 days	D, V

D = Diarrhoea V = Vomiting F = Fever AP = Abdominal pain

entero - toxins. At least 5 different types of toxins have already been identified, and a sixth one is likely to exist. The toxin resists boiling for 30 minutes. High protein and starch food favour bacterial growth and hence the toxin production. Staphylococcus are ubiquitous in nature and are found in nose, throat and on the skin surface of human beings. They are common agents for pyogenic infections in man and animals. Cows suffering from mastitis have been responsible for the outbreaks. Tinned meat or fish inadequately processed, pickled meats, creams, milk and milk products contaminated with staphylococcus have been incriminated in various outbreaks. Problem occurs most frequently with foods prepared at home or at food service establishments where gross temperature abuse has occurred. The incubation period varies from 1 to 6 hours. The disease manifests as sudden onset of uncontrolled vomiting, due to effect of toxin on the vagus nerve in the stomach, with abdominal cramps and diarrhoea. In severe cases blood and mucous may appear. Fever is uncommon and so is mortality.

Clostridium perfringens food poisoning

Clostridium perfringens (welchii) is found in faeces of man and animals; and in soil, water and air. The spores of the organism are heat resistant and survive cooking, and if the cooked meat and poultry are not cooled enough, the spores germinate and produce a variety of toxins which cause the illness. Outbreaks have resulted from problems in cooling and storage of food cooked in bulk. Generally the implicated meat is cooked, allowed to cool down slowly and then inadequately heated the following day just before the serving. The incubation period varies from 6 to 24 hours. The commonest symptom is explosive diarrhoea with abdominal cramps. Fever, nausea and vomiting are rare. Illness is of short duration. Recovery is fast and mortality is rare.

Botulism

The food borne botulism (the others being wound botulism and infant botulism) is caused by *Clostridium botulinum* - a gram - negative, strict anaerobe, spore forming bacillus whose natural habitat is soil. It produces at least seven types of exotoxins of which type A, B and E are incriminated in food poisoning in humans. The food most frequently responsible are home preserved foods such as smoked or pickled fish, home made cheese and similar low acid foods. The toxin is preformed in food under suitable anaerobic conditions and acts on parasympathetic nervous system. Incubation period is usually 12 to 36 hours. Early symptoms include nausea, vomiting, and occasionally diarrhoea. Other features include dysphagia, diplopia, ptosis, blurring of vision, dysarthria, muscular weakness and even quadriplegia. Gastrointestinal symptoms are very slight, fever is usually absent. Condition is frequently fatal - death occurring 4 to 8 days later due to respiratory or cardiac failure. Non - fatal cases may last for several months.

Campylobacter food poisoning

Three species of Campylobacter - *C. jejuni*, *C. coli*, and *C. laridis* - are known to cause epidemics of food poisoning in nurseries, paediatric wards, and communities in developing countries. *C. jejuni* is the commonest of the three and is most often associated with poultry. Foods linked to outbreak include raw

milk, raw meat and mushrooms. The average incubation period varies from 3 to 5 days. The illness presents as fever, abdominal pain, vomiting and bloody diarrhoea. Headache may be present. Disease is usually self - limiting with complete recovery in 5 - 7 days but the patient may continue to excrete bacteria up to 3 weeks. Relapses and chronic sequelae are known to occur. Guillian - Barre Syndrome and Reiter's Syndrome are rare but serious consequences of campylobacteriosis. Diagnosis depends on Gram stain and dark field microscopy of faecal smear and/or stool culture. In severe cases colonoscopy may be required.

Bacillus Cereus Food Poisoning

Bacillus cereus is an aerobic, spore bearing, motile, gram positive rod. It is ubiquitous in soil, and in raw, dried and processed foods. The spores survive cooking and germinate when the food is held at favourable temperature. It produces 2 types of entero - toxins leading to the causation of the emetic syndrome and the diarrhoeal syndrome. The emetic syndrome (Type I) is similar to *S. aureus* intoxication and has an incubation period of 1 to 6 hours. Symptoms are upper gastrointestinal, including nausea and vomiting, diarrhoea being rare, and usually subside within a day. The causation of this syndrome is linked to the consumption of fried rice, mashed potatoes and pasta. The diarrhoeal syndrome (Type II) is similar to *C. perfringens*, has an incubation period of 8 to 16 hours, and presents with lower intestinal symptoms i.e. watery diarrhoea. Nausea and vomiting is rare and the disease subsides in 12 to 24 hours. The food items commonly incriminated include soup, sauce, meat loaves and gravy, custard and pudding.

E coli O157 Food Poisoning

Food poisoning due to *E coli* O157 - the most common form of Enterohaemorrhagic *E. coli* (EHEC) - has grown to prominence as an emerging public - health hazard since the first cases were reported in the early 1980s. The predominant serotype, incriminated in food poisoning is *E coli* O157 : H7. Far less common than Salmonella and Campylobacter, it can survive for up to 6 months in mud. Vehicles of transmission include ground beef, raw milk, and raw apple juice. The incubation period is 3 to 4 days. The symptoms include bloody diarrhoea associated with severe abdominal pain. Fever is typically absent. While most food - poisoning events are short - lived and resolve without intervention, 2 - 7% of individuals (and up to 15% of children) infected with *E coli* O157 develop haemolytic uraemic syndrome about a week after the onset of diarrhoea. It is characterized by thrombocytopenia, renal failure and CNS involvement. Stool culture is necessary to make the definitive diagnosis. Management includes oral rehydration and supportive care.

Prevention and Control of Food Poisoning

The common measures recommended for the prevention and control of food poisoning have been earlier outlined under the heading "golden rules for food safety" in the chapter on cholera and they will go a long way in preventing food poisoning. The specific actions include the following :

(a) **Eat Freshly cooked and hot food** : The most important measure is the consumption of freshly cooked food while it is still hot. The food which was cooked earlier and cooled, must be reheated adequately, at least up to 60°C, before consumption.

(b) **Meat and Meat products** : Animals should be slaughtered in a hygienic, rat proof, vermin free butchery. Strict supervision should be kept on the whole cycle of meat processing.

(c) **Milk and Milk Products** : Milk should be pasteurized or boiled and every care should be taken against subsequent contamination.

(d) **Protection of Foods** : Adequate precautions should be taken against contamination of food during storage or during processing. The food items should not be left overnight in warm pantries and those not eaten immediately should be kept in cold storage to prevent bacterial multiplication and toxin production.

(e) **Food Handlers** : They should be periodically examined and those suffering from boils, ulcers throat or eye infections and with history of having suffered from enteric fever or diarrhoea in recent past should not be employed as food handlers. A high standard of personal hygiene among food handlers must be maintained. Food handlers should be educated in matters of clean habits and personal hygiene.

Hazard Appraisal and Critical Control Point (HACCP) system

A simple and effective method for preventing food borne illnesses is by undertaking a detailed analysis of the steps in which food items are procured / prepared / stored / served, followed by identification of critical points where hygiene and sanitation can be breached / contamination can be introduced and finally making a check list of these critical control points for taking action for control / preventive action. The system has been recommended by the WHO.

Steps in investigations of an epidemic of food poisoning

The details have been discussed earlier in the chapter on investigations of an epidemic in the section on epidemiology. Distinctive features of common food poisoning are listed in Box - 1.

Summary

Food poisoning is an acute gastro - enteritis caused by ingestion of food or drink contaminated with either living bacteria or their toxins or inorganic chemical substances and poisons derived from plants and animals. Bacterial food poisoning is the commonest form and is caused mainly by three bacterial groups - Salmonella, Clostridium and Staphylococcus.

Salmonella food poisoning is the most common form. The species most commonly incriminated in human outbreaks is *Salmonella typhimurium*; others are *S. enteritidis*, *S. cholerae - suis*. Man acquires infection through meat, eggs, milk and milk products. Incubation period usually varies from 12 to 24 hours. Onset is generally sudden with chills, fever, nausea, vomiting, abdominal pain and profuse watery diarrhoea which lasts for 2 to 3 days. Mortality is usually low.

Staphylococcal food poisoning is as common as food poisoning by Salmonella. It is caused by heat stable enterotoxin of Coagulase positive *Staphylococcus aureus*. Staphylococcus is ubiquitous in nature and usually tinned meat or fish, pickled meats, creams, milk and milk products are incriminated in

outbreaks. Incubation period varies from 1 to 6 hours. The disease manifests as sudden onset of uncontrolled vomiting, abdominal cramps and diarrhoea. Mortality is uncommon.

Clostridium perfringens food poisoning is caused by a variety of toxins produced during germination of spores. Generally the implicated meat is cooked, allowed to cool down slowly and then inadequately heated the following day just before the serving. Incubation period varies from 6 to 24 hours. Common symptom is explosive diarrhoea with abdominal cramps. Mortality is rare.

Food borne botulism is caused by Exotoxins A, B and E of *Clostridium botulinum*. The foods most frequently responsible are home preserved foods. The toxin acts on peripheral nervous system. Incubation period is usually 12 to 36 hours. Symptoms include nausea, vomiting, dysphagia, diplopia, ptosis, blurring of vision, dysarthria, muscular weakness and even quadriplegia. Condition is frequently fatal in 4 to 8 days due to cardiac or respiratory failure.

Campylobacter food poisoning is caused by *C. jejuni*, *C. coli*, *C. laridis*. Foods linked to outbreaks include poultry, raw milk, raw meat and mushrooms. Incubation period averages 3 to 5 days. The illness presents as fever, abdominal pain, vomiting and bloody diarrhoea. Disease is usually self - limiting but relapses and chronic sequelae are known to occur.

Bacillus cereus food poisoning is caused by two types of enterotoxins leading to causation of Emetic syndrome and the diarrhoeal syndrome. The emetic syndrome (Type I) has incubation period of 1 to 6 hours. It is linked to consumption of fried rice, mashed potatoes and pasta. Symptoms are upper gastrointestinal i.e. nausea and vomiting. The diarrhoeal syndrome (Type II) has incubation period of 8 to 16 hours. Symptoms are lower gastrointestinal i.e. diarrhoea. It is linked to consumption of soup, sauce, meat loaves and gravy, custard and pudding.

E. coli O157 food poisoning is the most common form among all Enterohaemorrhagic *E. coli* (EHEC). The predominant serotype is *E. coli* O157 : H7. Vehicles of transmission include ground beef, raw milk, and raw apple juice. The incubation period is 3 to 4 days. The symptoms include bloody diarrhoea associated with severe abdominal pain. While most food poisoning events are short lived and resolve spontaneously, 2 - 7% of individuals develop Haemolytic uraemic syndrome about a week after onset of diarrhoea.

The common measures recommended for prevention and control of food poisoning include consumption of freshly cooked food while it is still hot, cold food should be adequately reheated at least up to 60°C before consumption, strict hygienic measures in whole cycle of meat processing, boiling or pasteurization of milk and periodic examination of food handlers.

Hazard Appraisal and Critical Control Point (HACCP) system is an effective method for preventing food borne illnesses and is recommended by WHO.

Study Exercises

Long Question : Discuss the various types of bacterial food poisonings, their differentiating features and methods of prevention

Short Notes : (1) Botulism (2) Salmonella food poisoning (3) *Bacillus cereus* food poisoning (4) Prevention and control of food poisoning

MCQs

- Salmonella food poisoning is most commonly caused by : (a) *Salmonella typhimurium* (b) *S. enteritidis* (c) *S. cholerae suis* (d) *S. typhi*
- Shortest incubation period of food poisoning is seen with : (a) Salmonella (b) Staphylococcus (c) Clostridium (d) Campylobacter
- A group of people suffer from abdominal cramps, diarrhoea and vomiting two hours after consuming Kheer. The suspected aetiological agent is : (a) Salmonella (b) Clostridium (c) Staphylococcus (d) Campylobacter
- Following food poisonings are due to preformed toxins except : (a) Staphylococcal (b) Botulism (c) Salmonella (d) *Bacillus cereus*
- Which of the following is true about Botulism : (a) Most fatal food poisoning (b) Toxin acts on parasympathetic nervous system (c) Occurs due to consumption of home made cheese (d) All of the above
- All of the following are true of *clostridial perfringens* food poisoning except : (a) Incubation period 6 - 24 hours (b) illness is of short duration with rapid recovery (c) Nausea and vomiting is common (d) Common with intake of meat and poultry
- Following are true of Botulism except : (a) Frequently fatal (b) Bloody diarrhoea (c) Dysphagia (d) Absence of fever
- Following are true of Staphylococcal food poisoning except : (a) High grade fever (b) Due to preformed toxins (c) Death uncommon (d) Abdominal cramps

- Bacillus cereus* causes : (a) Emetic syndrome (b) Diarrhoeal syndrome (c) Both (d) None
- The incubation period of *Bacillus cereus* Type II food poisoning is (a) 1 - 6 hours (b) 8 - 16 hours (c) 12 - 24 hours (d) 3 - 5 days
- Match the Type of food poisoning (A) with correct incubation period (B) :

A		B	
(a)	Salmonella	(I)	6 to 24 hours
(b)	Staphylococcal	(II)	12 to 36 hours
(c)	<i>Clostridium perfringens</i>	(III)	12 to 24 hours
(d)	<i>Clostridium botulinum</i>	(IV)	1 to 6 hours
(e)	Campylobacter	(V)	8 to 16 hours
(f)	<i>E coli</i> O157	(VI)	3 to 5 days
(g)	<i>Bacillus cereus</i> Type II	(VII)	3 to 4 days

Answers : (1) a; (2) b; (3) c; (4) c; (5) d; (6) c; (7) b; (8) a; (9) c; (10) b; (11) a-III; b-IV; c-I; d-II; e-VI; f-VII; g-V.

200 Enteric Group of Fevers

Rajesh Kunwar

Definition

This is a group of clinically similar, but immunologically distinct fevers, caused by *Salmonella spp* and characterized by typical continuous fever for 3 - 4 weeks, relative bradycardia, with involvement of lymphoid tissues and considerable constitutional symptoms. The disease varies in severity, and many mild cases occur. The term 'enteric fever' includes both the typhoid and paratyphoid fevers.

Magnitude of the Problem

Enteric fever, though occurs in all parts of the world, is a serious public - health problem in developing countries. The disease has been virtually eliminated from the industrialized

world because of the provisioning of clean water and good sewage systems. But the under - developed and the developing countries continues to face the brunt. In an outbreak in the Democratic Republic of Congo, between 27 September 2004 and early January 2005, 42,564 cases of typhoid fever were reported, including 214 deaths and 696 cases of peritonitis and intestinal perforations. *S. paratyphi* is becoming predominant in some provinces in China and increasing numbers of cases are being reported from Pakistan.

Few established surveillance systems for typhoid exist in the developing world, especially in community settings, so the true burden is difficult to estimate. According to an estimate of US Centers for Disease Control and Prevention there are 21.6 million typhoid cases annually, with the annual incidence varying from 100 to 1000 cases per 100,000 population. The incidence is highest in the age group of 5 - 19 years but population based studies from South Asia suggest that the incidence is highest in children aged less than 5 years, with

higher rates of complications and hospitalization. The overall ratio of disease caused by *S typhi* to that caused by *S paratyphi* is about 10 to 1 to 4 to 1.

Enteric fevers are not notifiable diseases throughout India and hence the correct incidence is not known. Limited studies in the country reveal more than three lac cases and more than 650 deaths (approx.) annually in our country. Recent population based incidence data demonstrate that the children under 5 years of age are at increased risk of typhoid fever, when compared with school - aged children and adults.

Epidemiological determinants

Agent factors

(a) **Agent** : Typhoid fever is caused by *Salmonella enterica* serovar Typhi (*S typhi*), a Gram negative, flagellated, non - lactose - fermenting bacillus. It is characterized by somatic (O) antigen 9 and 12, and a single flagellar antigen (H). Paratyphoid fever - a similar but often less severe disease - is caused by *S paratyphi* A and, less commonly, by *S paratyphi* B (Schotmulleri) and *S paratyphi* C (Hirschfeldii). The organism survives well in water and sewage but is readily killed by heating at 60°C, drying, pasteurization and common disinfectants.

(b) **Reservoir** : Man is the only reservoir of infection. The case may be mild, moderate or severe and is infectious as long as the bacilli is excreted in stool or urine. The carriers are more important. Convalescent carriers excrete the bacilli for 6 - 8 weeks. Chronic carriers are those who excrete the bacilli for more than one year after clinical attack. A chronic carrier may excrete the bacilli for several years, either continuously or intermittently. *S. typhi* once lodged in human carrier may persist for 20 - 50 years. Faecal carriers are commoner than urinary carriers. The carrier state is commoner in middle aged persons; females predominating over males. The famous case of "Typhoid Mary" who gave rise to more than 1,300 cases is a good example of a chronic carrier. Urinary carriers, though less common, are more dangerous to the community than faecal carriers because of greater chances of contamination of hands during micturation. Detection of carriers is by isolation of organisms from faeces or urine of suspects; agglutination tests are much less reliable.

(c) **Source of Infection** : The sole source of infection is the faeces or urine of cases and carriers. The bacilli are excreted for varying periods in faeces and urine.

Host factors

(a) **Age** : Enteric fever can occur at any age. Highest incidence of this disease occurs in the 5 - 19 years of age group but population based studies from South Asia suggest that the incidence is highest in children aged less than 5 years, with higher rates of complications and hospitalization.

(b) **Sex** : More cases are reported among males probably as a result of increased exposure to infection but carrier rates are more common in females.

(c) **Immunity** : An attack of the disease gives lasting immunity; second attacks however are not uncommon.

(d) **Genetic factors** : Involvement of host genetic factors has also been implicated in the pathogenesis of typhoid fever. HLA - DRB1*12 is associated with protection against complicated

typhoid fever .

Environmental Factors

Enteric fevers are observed all through the year. The peak incidence is reported during July - September. This period coincides with the rainy season and an increase in fly population. Outside the human body, the bacilli are found in water, ice, food, milk and soil for varying periods of time. Typhoid bacilli do not multiply in water; many of them perish within 48 hours, but some may survive for about 7 days. They may survive for over a month in ice and ice-cream and up to 70 days in soil irrigated with sewage under moist winter conditions. Food being a bad conductor of heat, provides shelter to the bacilli in which they may multiply and survive for sometime. Typhoid bacilli grow rapidly in milk without altering its taste or appearance in anyway. Vegetables grown in sewage farms or washed in contaminated water are a definite health hazard. These factors are compounded by such social factors as pollution of drinking water supplies, open air defecation and urination, low standards of food and personal hygiene and health ignorance. Typhoid fever may therefore be regarded as an index of general sanitation in any country.

Incubation Period and Period of Communicability : Incubation period is usually 10 - 14 days but in many cases it may well be outside the range. When the disease is water - borne, the incubation period tends to be longer. The incubation period for paratyphoid is 4 to 5 days. The case is infectious during the later part of incubation period and for a variable period thereafter.

Mode of Transmission : Enteric fever is spread chiefly through the medium of contaminated water, food, milk and vegetables. Flies constitute an important subsidiary vehicle for sporadic incidence. A small proportion of cases may occur due to direct transmission of infection from an actual case/ carrier through contamination of hands, while handling patients or their excreta. The mode of transmission for explosive outbreaks of any considerable size, is, however water, milk or milk products adulterated by contaminated water or handling by carriers.

Clinical features

Typhoid fever is characterized by high grade remittent fever associated with headache and malaise. Non - productive cough and constipation may be present. Diarrhoea is uncommon and vomiting not severe. By the second week, in the absence of treatment, the patient becomes toxic and apathetic, high fever continues and abdomen becomes distended. Relative bradycardia, leucopenia, abdominal tenderness and hepato - splenomegaly are characteristic. Ill defined rose - spots, hardly visible in dark skinned person, may be present. Complications of typhoid fever include confusion, delirium, intestinal perforation, myocarditis and death. Up to 20% of cases relapse after treatment and initial recovery.

Diagnosis

Blood culture done during the first week of illness, is the most common diagnostic test for typhoid. The organism can also be isolated from urine and stool in the second and third week of illness. Bone marrow cultures are frequently positive (90% of cases) and are more likely to yield *s. typhi* than culture from any other site. Widal test which measures the antibody response to

'O' and 'H' antigens, is not definitive and only suggests the diagnosis. A rising titer is more suggestive than a single raised titer of Widal test.

Treatment

Chloramphenicol (1 g 6 hourly) or Amoxicillin (250 - 500 mg 8 hourly) or Co - trimoxazole (2 tabs given twice a day) have been used successfully for the management of typhoid fever. But Fluoroquinolones (Ciprofloxacin) in the dose of 500 - 750 given orally twice a day for 10 to 14 days is the best choice for the empirical treatment of typhoid fever, although resistance to the strains circulating in SE Asia have been reported. Resistance to Chloramphenicol has become widespread including our country.

Prevention & Control

In the endemic areas, the most cost effective strategy for reducing the incidence of enteric fever is the institution of public health measures as enumerated below :

- Provision of protected, clarified and chlorinated water supply
- Efficient pasteurization or boiling of milk
- Proper sanitary disposal of night soil
- Strict anti - fly measures
- Protection and cleanliness of fruits and vegetables
- High standard of food handlers' hygiene
- Personal hygiene and avoidance of unhygienic food habits
- Protective inoculation

Immunization

(a) Heat killed, phenol preserved whole cell *S. typhi* : These were utilized as parenteral vaccines as far back as 1896 in England and Germany, and are still in use in many countries. Efficacy is about 70%.

(b) Vi capsular polysaccharide vaccine : This vaccine is licensed for use in individuals older than 2 years and is given in a single subcutaneous or intramuscular dose. The vaccine is moderately effective for about 3 years after vaccination. Revaccination is recommended every 3 years. The Vi vaccine can be given simultaneously with other vaccines relevant for international travellers such as yellow fever and hepatitis A. Efficacy is approximately 70%.

(c) Live Oral Vaccine : The attenuated *S. typhi* strain Ty21a was generated in Switzerland by chemical mutagenesis of wild - type strain Ty2 and developed as the first live oral typhoid fever vaccine. This live oral vaccine, available in enteric - coated or liquid formulation, is approved for use in people 6 years of age and older. The liquid formulation for younger children is currently marketed in only a few countries. Three doses are recommended each given 2 days apart. Antimicrobials should be avoided for 7 days before or after vaccination. The vaccine is moderately effective for up to about 3 years after vaccination. A booster dose is recommended every 3 years in endemic areas and travellers should be revaccinated annually. The vaccine can be given simultaneously with other vaccines and with anti

- malarial prophylaxis. Efficacy is about 70%.

Summary

Typically continuous fever for 3 - 4 weeks caused by Salmonella spp (*S.typhi*, *S.paratyphi A*, *S.paratyphi B* and *S.paratyphi C*) along with associated relative bradycardia and involvement of lymphoid tissue, occurs through out the world but is a serious public health problem in developing world. The agent is gram negative, flagellated, non lactose fermenting bacillus characterized by somatic O antigen 9 and 12 and a single flagellar H antigen. Human beings are the only reservoir of infection and carriers (convalescent and chronic) are the most important source of infection, fecal carriers being more important than urinary though urinary carriers are more dangerous. Males in age group 5 yrs to 19 yrs are the most susceptible and the subjects with HLA DRB 1*12 are protected from severe complications of typhoid. The peak incidence is in rainy season with favourable conditions for house fly breeding, the medium of transmission being water, food, ice, milk, vegetables and soil. The incubation period is usually 10 to 14 days for fever caused by *S.typhi* and upto 4 - 5 days for *S.paratyphi*. For a proper diagnosis blood culture in 1st week and urine or stool culture in 2nd week are helpful, widal test which measure the antibody titer is only suggestive. Fluoroquinolones are the best choice for the empirical treatment of enteric fever. Institution of public health measures like supply of chlorinated water supply, proper pasteurization of milk, food and personal hygiene and strict fly control measures are the most cost effective control measures. Vi capsular polysaccharide vaccine is licensed for use in individuals older than 2 years and is given in a single subcutaneous or intramuscular dose. Revaccination is recommended every 3 years. The attenuated *S. typhi* strain Ty21a was developed as the first live oral typhoid fever vaccine. This live oral vaccine is approved for use in people 6 years of age and older. Three doses are recommended each given 2 days apart. Antimicrobials should be avoided for 7 days before or after vaccination. A booster dose is recommended every 3 years in endemic areas.

Study Exercises

Short Notes : (1) Typhoid vaccine (2) Epidemiological determinants of enteric fever (3) Clinical features and treatment of enteric fever (4) Prevention and control strategies for enteric fever.

MCQs and Fill in the Blanks :

- _____ is the reservoir of enteric fever.
- The incubation period of typhoid is _____ and the same for paratyphoid is _____
- The most commonly used diagnostic test for confirming typhoid fever in 1st week of illness is _____
- The Typhoral vaccine requires booster every _____ yrs in the endemic region
- Antibiotics should be avoided for the following number of days after vaccination with typhoral vaccine (a) 3 days (b) 5 days (c) 7 days (d) 10 days
- The best antibiotic for the empirical treatment of enteric fever is (a) chloramphenicol (b) ciprofloxacin (c) amoxicillin (d) none

- 7) The somatic antigen is known as _____ antigen and the flagellar antigen is known as _____
- 8) Rose spots are characteristic of the following diseases (a) chicken pox (b) malaria (c) rubella (d) none
- 9) _____ carriers are commoner and _____ carriers are more dangerous in enteric fever.
- 10) Chronic carriers of typhoid are those who excrete the bacilli for more than _____ yrs

Answers : (1) Human beings; (2) 10 to 14 days, 04 to 05 days; (3) Blood culture; (4) three; (5) c; (6) b; (7) O, H; (8) d; (9) faecal, urinary; (10) one

Shigellosis

Rajesh Kunwar

Definition

Shigellosis is a "bacillary dysentery" caused by *Shigella spp* and characterized by diarrhoeal illness with fever, abdominal pain and blood and pus in the stool.

Magnitude of the Problem

Shigellosis is endemic throughout the world. Of the 165 million cases of severe dysentery reported every year, more than 163 million come from developing world. Majority of the affected population includes children below 5 years of age. Approximately 580,000 cases of shigellosis are reported among travellers from industrialized countries. Each year 1.1 million people are estimated to die from *Shigella* infection.

Shigella dysentery is caused by *S. dysenteriae*, *S. sonnei*, *S. flexneri* and *S. boydii*. *S. sonnei* is the causative agent of most shigellosis in industrialized countries where it accounts for 77% of cases (compared to 15% in developing countries), *S. flexneri* is endemic in developing countries (60%) and is the most frequently isolated species worldwide. *S. dysenteriae* (Sd1) is the cause of epidemic dysentery and can cause vicious outbreaks in confined populations, especially refugee camps. A major obstacle to the control of Sd1 is its resistance to antimicrobial drugs.

Since 1969, *S. dysenteriae* have caused extensive outbreaks in many countries. Notable among these being outbreak in Central America in 1969 - 1972; in Zaire, Rwanda and Burundi in 1979 - 1982; in India in 1984; in Burma in 1985; in Bangladesh in 1988; and in Zimbabwe and Zambia in 1992 - 1994. The causative strains in all these outbreaks were resistant to the commonly used antimicrobials.

In India, the outbreak in 1984 was due to multi - resistant strain of *S. dysenteriae* type 1 and the most affected state was

West Bengal. Since then many outbreaks have been reported from various parts of the country.

Epidemiological Determinants

Agent factors

(a) **Agent** : *Shigellae* are aerobic, gram - negative, non - motile, slender bacilli which are lactose negative (except *S. sonnei* which is a late lactose fermenter) and produce acid but not gas from glucose. The 'O' antigens are located on the outer cell wall but the 'H' antigen is typically absent.

(b) **Reservoir** : The primary reservoir of the infection is human being, though it can occasionally infect other primates. The human case may be mild, moderate or severe and is infectious as long as the bacilli is excreted in stool. Asymptomatic carriers up to one year duration have been reported, but prolonged carrier are not known to occur.

(c) **Source of Infection** : *Shigella* are present in the diarrhoeal stools of infected persons while they are sick and for up to a week or two afterwards. *Shigella* species are transmitted by ingestion of contaminated food or water, or by person - to - person contact (i.e. from cases or asymptomatic excretors to susceptible hosts), a most common source of transmission. However, clinically ill persons are more likely to transmit the disease as compared to asymptomatic excretors.

(d) **Infective dose** : The infective dose is very small. For *S. dysenteriae* an inoculum as low as 10 to 100 bacilli is sufficient to cause severe infection in a human being.

Host factors

(a) **Age** : Though the disease can occur in any age group, but it has a predilection for the paediatric age group, majority of the cases occur in children below 10 years of age.

(b) **Sex** : Both the sexes are affected equally.

(c) **Immunity** : Immunity following *Shigella* infection provides short term immunity to the species causing infection. With each subsequent infection with the same serotype, the clinical illness becomes milder and milder and may be absent. This, it is believed, is perhaps because of local gut immunity. Cross

immunity i.e. immunity to the other species of shigella, is not known to exist.

Environmental Factors : Shigellosis is often found in day care centers, nursing homes, refugee camps, and other places where conditions are crowded and sanitation is poor. Shigellosis can also result from drinking or swimming in contaminated water; water may become contaminated if sewage runs into it or if someone with shigellosis swims in it. Lack of safe piped water, inadequate sewage disposal and poor personal hygiene are the conditions which can lead to an outbreak of shigellosis.

Incubation Period : The usual incubation period is about 48 hours but can range from 12 hours to 6 days.

Mode of Transmission : Most Shigella infections are transmitted by oro - faecal route. Food may become contaminated by infected food handlers who forget to wash their hands with soap after using the bathroom. Vegetables can become contaminated if they are harvested from a field with sewage in it. Flies can breed in infected feces and then contaminate food. Water may become contaminated with Shigella bacteria if sewage runs into it, or if someone with shigellosis swims in or plays with it. Shigella infections can then be acquired by drinking, swimming in, or playing with the contaminated water. Outbreaks of shigellosis have also occurred among men who have sex with men.

Clinical features

Although asymptomatic illness can occur, majority of the cases begin with fever, abdominal pain and watery diarrhoea, initially without blood. The fever may be transient and the temperature may rapidly rise up to 40 - 41°C. In young children, the fever may be associated with seizures. The stools are initially watery but with the invasion of colonic mucosa, it become bloody, mucoid or scanty. Dysentery is characterized by frequent passage, usually 10 to 30 times a day, of small volume of stools associated with abdominal cramps and tenesmus. Mild dehydration is common, but severe dehydration is rare. Frequent motion and straining during the act can cause, especially in young children, rectal prolapse. Severe dysentery is most likely in infection with *S. dysenteriae*, occurs less commonly in *S. flexneri* and is least likely in *S. sonnei* infection.

Extra - intestinal manifestations following shigella infection, are rare, but can be of importance. These include convulsions and rectal prolapse (esp in children), post - infectious arthritis and hemolytic - uremic syndrome.

Diagnosis

Shigella is the principal cause of bacterial dysentery and must be considered in all cases of dysentery presenting with fever. Specific diagnosis can be established by culture of shigella from the stool.

Treatment

Persons with mild infections usually recover quickly without antibiotic treatment. Mild to moderate dehydration is corrected by oral rehydration. Antibiotic treatment is required for the management of severe cases. It reduces the duration of illness by a few days and shortens the carriage stage. The antibiotics commonly used for treatment are ampicillin (50 - 100 mg per

kg body weight in children and 2 grams per day in divided doses in adults) and co - trimoxazole (8 mg of trimethoprim per kg body weight per day in children and 2 regular strength tablets twice a day in adults). Fluoroquinolones (Ciprofloxacin) are highly effective, but are costly and are not indicated for treatment of children.

Prevention & Control

The spread of Shigella infection from an infected person to other persons can be prevented by frequent and careful handwashing with soap. Handwashing among children esp those who have not been fully toilet trained, should be frequent and supervised by an adult.

Basic food safety precautions and disinfection of drinking water prevents shigellosis from food and water. People with shigellosis should not prepare food or drinks for others until they have been shown to no longer be carrying the Shigella bacterium, or if they have had no diarrhoea for at least 2 days. At swimming beaches, having enough bathrooms and handwashing stations with soap near the swimming area helps keep the water from becoming contaminated.

Simple precautions like drinking of bottled or boiled water, and eating of only cooked hot foods, taken while travelling to the developing world can prevent shigellosis as well as other types of traveller's diarrhoea.

Some prevention measures in place in most communities help to prevent shigellosis. Making municipal water supplies safe and treating sewage are highly effective prevention measures that have been in place for many years.

Immunization : At present no vaccine is available for protection against shigellosis. Candidate vaccines, both killed and live, are in pre - clinical stage of testing. Definite progress has been made with candidate live oral shigellosis vaccines, but the main problem remains the small margin that exists between under - attenuation responsible for excessive reactogenicity of the strains and over - attenuation leading to poor immunogenicity in human subjects.

Summary

A type of bacillary dysentery presenting with symptoms of fever, abdominal pain and blood and pus in the stool with an average incubation period of 48 hrs. Its endemic throughout the world having caused a number of outbreaks in various countries. Shigellae (*S. dysenteriae*, *S. sonnei*, *S. flexneri*) are aerobic, gram negative and non motile bacilli with 'O' antigen on the outer cell wall but the 'H' antigen is typically absent. Human beings are the main reservoir and the infected, sick person being the main source of infection transmitting the disease agent mainly through oro fecal route. Both sexes and all ages are susceptible with over crowding and poor sanitation being the major contributing factors. Mild cases can be treated with proper oral rehydration but the severe cases will require antibiotics in the form of ampicillin, cotrimaxazole or fluoroquinolones. As no vaccine is available so preventive measure like frequent and careful hand washing, food safety precautions and disinfection of water should be practised.

Study Exercises

Short Notes : (1) Epidemiological determinants of shigellosis
(2) Prevention and control of shigellosis.

MCQs and fill in the blanks

- The causative agent of most cases of shigellosis in industrialized countries is _____
- The average incubation period of shigellosis is _____
- The cause of most vicious outbreaks of shigellosis (a) *S.dysenteriae* (b) *S.sonnei* (c) *S.flexneri* (d) none
- Following is lactose fermenter (a) *S.dysenteriae* (b) *S.sonnei* (c) *S.flexneri* (d) none
- Type of vaccine for *S.sonnei* (a) live attenuated (b) killed (c) both (d) none
- The causative agent of most cases of shigellosis in developing countries is _____
- The infective dose of shigellosis is _____

- The principal cause of bacillary dysentery is _____
- The most common route of transmission of shigella is _____
- The outbreak of shigellosis in India in 1984 was caused by (a) *S.dysenteriae* (b) *S.sonnei* (c) *S.flexneri* (d) none

Answers : (1) *S. sonnei*; (2) 48 hrs; (3) a; (4) *S. sonnei*; (5) d; (6) *S. flexneri*; (7) 10 to 100 bacilli; (8) Shigella; (9) oro faecal; (10) *S. dysenteriae*

Helminthiasis

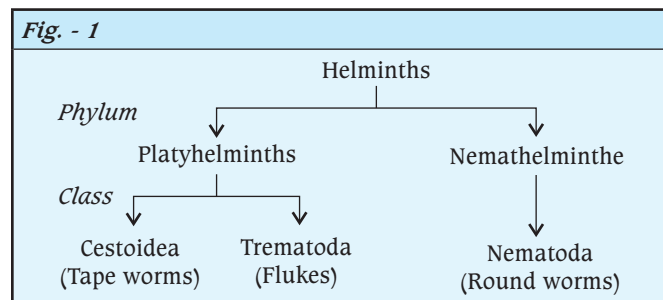

Rajesh Kunwar

Helminths - a word derived from Greek meaning worms - are known to affect the mankind since time immemorial. It is estimated that approximately one - third of the almost three billion people living in the under - developed and developing countries especially the inhabitants of thousands of rural, impoverished villages are infected with one or more helminths. Majority of these are soil transmitted and include round worm (*Ascaris lumbricoides*), whip worm (*Trichuris trichiura*), and hook worm (*Ancylostoma duodenale* and *Necator americanus*). The other category is food borne helminths which include liver flukes (*Clonorchis sinensis*) and intestinal flukes (*Fasciola hepatica* and *Fasciola buski*).

Classification

The helminths of importance to human beings are classified as in Fig. - 1.

Fig. - 1

Based on the mode of transmission, helminths can be classified as follows :

- Soil transmitted helminths e.g. *Ascaris lumbricoides*, *Trichuris trichura*, *Ancylostoma duodenale* and *Necator americanus*.
- Food borne helminths e.g. *Clonorchis sinensis*, *Fasciola hepatica* and *Fasciola buski*.
- Arthropod borne helminths e.g. *Wuchereria bancrofti* and *Brugia malayi*

In the present discussion we will restrict ourselves to the soil transmitted and food borne helminths. Filariasis caused by arthropod borne helminths have been discussed elsewhere.

Soil Transmitted Helminths (STH)

Soil - transmitted helminths commonly known as intestinal worms, are the most common worm infections worldwide. According to an estimate, *A. lumbricoides* infects over 1 billion people, *T. trichiura* 1050 million, and hookworms (*Ancylostoma duodenale* and *Necator americanus*) 1300 million (Table - 1). This is being increasingly recognized as a significant public health problem, particularly in developing countries where poverty, poor nutrition, inadequate sanitation, lack of clean drinking water and minimal health care prevail.

Helminth	No. of Infections (millions)	Morbidity (cases, millions)	Mortality (deaths per year, thousands)
<i>A. lumbricoides</i>	1450	350	60
Hookworms	1300	150	65
<i>T. trichiura</i>	1050	220	10

Source : WHO, TRS 912

Although these helminths can infect all members of a population, the most vulnerable - those who are at most risk and would benefit most from the preventive intervention - are pre - school and school age children, adolescent girls and women of child bearing age. Based on the prevalence and the intensity of the infection, the communities can be classified in to three categories -

(a) **Category I (high) transmission community** : Prevalence greater than 50%, heavy infection more than 10%

(b) **Category II (medium) transmission community** : Prevalence greater than 50%, heavy infection less than 10%

(c) **Category III (low) transmission community** : Prevalence less than 50%, heavy infection less than 10%

Based on their life cycle, STH can be classified into three types:

(a) **Type 1 - Direct** : The Eggs are embryonated. They hatch and reinfect within 2 - 3 hours by direct carriage from anal margin to the mouth. Eggs do not reach the soil, and if they do, do not require a period of development there. Example - *Enterobius vermicularis* (threadworm), *Trichuris trichiura* (whipworm).

(b) **Type 2 - Modified direct** : Eggs are passed in stools and undergo a period of development in soil to become the infective stage, before being ingested. After ingestion, eggs hatch and release larva which penetrate mucous membrane of stomach and enter circulation and pass up the respiratory tract, enter oesophagus, reach intestine and grow into adult. Example - *Ascaris lumbricoides* (roundworm).

(c) **Type 3 - Penetration of the skin** : Eggs are passed in the stool to soil. In soil, eggs hatch into larvae which

undergo development till they are ready to penetrate the skin. The Larvae penetrate the skin, reach circulation and lungs where they penetrate lungs to reach respiratory tract, enter oesophagus, reach small intestine and grow into adult. Example - *Ancylostoma duodenale* (hookworm).

General Measures of Prevention and control of STH : A comprehensive control strategy for helminths infection should include the following :

Chemotherapy : Ensuring wide availability of anthelmintics for soil transmitted infections in all health services in endemic areas; providing regular treatment of all children at risk, including adolescent girls, through school or community based programmes, and treating pregnant women at risk through antenatal care programmes.

Sanitation : Ensuring safe water supply and adequate sanitation facilities in all schools and provisioning and use of safe and adequate water supply at household/ community level

Health education : Promoting good hygiene and sanitation practices (hand washing, use of latrines, use of foot wear etc) among school children and care givers

Community participation : Involving community for planning and execution of the control programme.

Monitoring and evaluation : Monitoring and evaluation of the programme to ensure cost - effectiveness and clearing the road block, if any.

The following important points should be kept in mind in planning a programme for control of helminth infection :

- Long term control can be achieved only if regular treatment of at risk people is accompanied by improvements in hygiene and sanitation.
- Full impact on health can be achieved only if helminth control is implemented as part of a larger maternal and child health strategy, aimed at reducing the burden of anaemia in women, children and adolescent girls

Deworming in schools : The most cost - effective way of deworming the school - age children is through schools because:

- Schools offer a readily available, extensive and sustained infrastructure
- All children including the disadvantaged (such as girls and poor) are available at one place
- Teachers are a skilled workforce that is in close contact with the community
- Teachers need only a few hours training to understand the rationale for deworming
- Teachers can deliver the drug safely

School - based deworming has its full impact when delivered within an integrated school health program which includes the following :

- Health policies that advocate the role of teachers in health promotion and delivery;
- Adequate sanitation and access to safe water to reduce worm transmission
- Skills - based health education that promotes good hygiene to avoid worm infection;

- Basic health and nutrition services that include regular deworming

Do's in school deworming

- Make deworming an integral component of a school health program. Combine deworming with iron and other micronutrient supplements.
- Ensure that teachers and health agents work in unison
- Help teachers understand the benefits of deworming, so that they are supportive
- Make sure that treatment is given regularly and sustained.
- Protect children throughout their development by starting treatment early and continuing treatment throughout primary school.
- Reach out to non - enrolled school aged children.

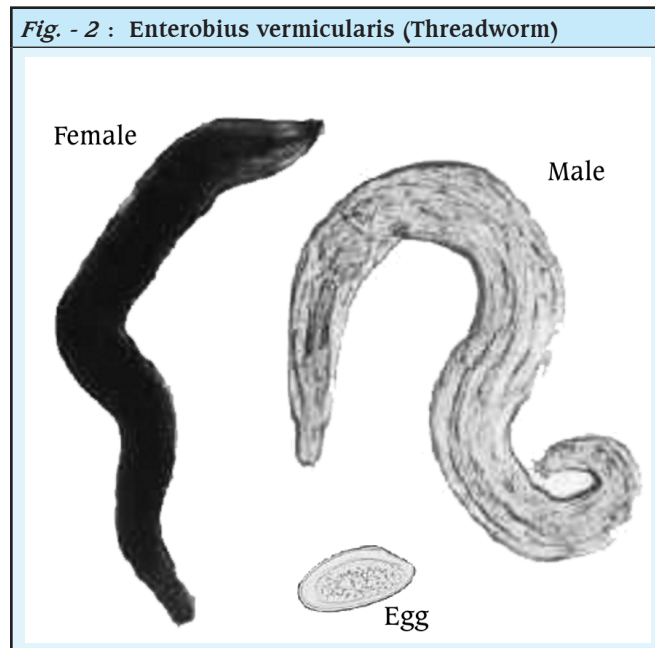

Don'ts in school deworming

- Waste time and resources trying to examine each child. Anthelmintics are safe and can be given to uninfected children over 1 year of age.
- Exclude adolescent girls from systematic treatment. The drugs are safe, even in pregnancy.
- Wait for sanitation to improve before starting deworming - regular treatment will help all children avoid the worst effects of infection.

Enterobius vermicularis (Threadworm)

It is cosmopolitan in distribution and is found all over the world. Essentially an infection of human beings, can affect any age but children are the usual victim. Familial infection is common. Occasional infections in chimpanzees and gibbons have been reported.

Epidemiological Determinants

Agent : The adult worm is small and white in colour. It is more or less like a spindle and resembles a short piece of thread. Male is shorter measuring 2 - 4 mm compared to females which

are 8 - 12 mm in length. Both males and females have a pair of cervical alae (wing like expansion) at the anterior extremity.

The egg is colourless i.e. not bile - stained, plano - convex in shape, surrounded by a transparent shell, contains a coiled tadpole like larva and floats in saturated solution of common salt.

Life cycle : The infection is acquired by ingestion of the eggs. In the stomach, due to gastric juices, egg shells are dissolved and larvae so released, escape to small intestine where they develop into sexually mature worms. There is no multiplication inside the body. After fertilization the male (2.5 mm) dies and the gravid female (9 - 12 mm) migrates to caecum, vermiform appendix and colon and remains there till eggs develop. After this the female worm wanders down the rectum, works its way out of the anus and deposits the eggs, after the patient has retired to bed, on the perianal skin. There, in the presence of oxygen, the eggs complete its development in 24 - 36 hours. No intermediate host is required and the life cycle is completed in 2 - 4 weeks time.

Host : Man is the definitive host. Both sexes are affected equally. Infection is more common in children than in adults.

Environment : Enterobius is soil transmitted and prefers warm moist conditions. The infection is more common in conditions of overcrowding like family groups, asylums and schools.

Mode of transmission : Transmission is effected from one person to another by ingestion of eggs. This can occur by following methods :

- Auto - infection - the patient carries the infection from perianal regions to mouth on his fingernails or soiled night clothes.
- By ingestion of contaminated food or drink
- Air - borne transmission by contaminated dust
- Retrograde infection - the eggs laid on peri - anal skin immediately hatch into infective - stage larvae and migrate through the anus to develop into adult forms in the colon.

Clinical Features

Majority of the cases remain asymptomatic till the eggs are deposited in the peri - anal area. In the peri - anal area, eggs induce pruritus ani which is the most common symptom and varies from mild itching to acute pain especially during the night. On entering the vulva in females, it leads to vulvitis causing mucoid discharge and pruritus vulvi. The general symptoms include insomnia, restlessness, irritability, loss of appetite and weight loss. Very rarely the worm may gain access to abdominal cavity and cause peritonitis.

Diagnosis

Diagnosis is established by :

- Demonstration of adult worms often seen in the peri - anal region at the time of pruritus or in stool after a purge or enema
- Demonstration of eggs on stool microscopy

Treatment

Albendazole given in a single oral dose of 400 mg or 10 - 14 mg/ kg for children, is the drug of choice. Mebendazole given in a single oral dose of 100 mg is a good alternative. Besides the patient, all the members of the family - wherever possible

- should be treated.

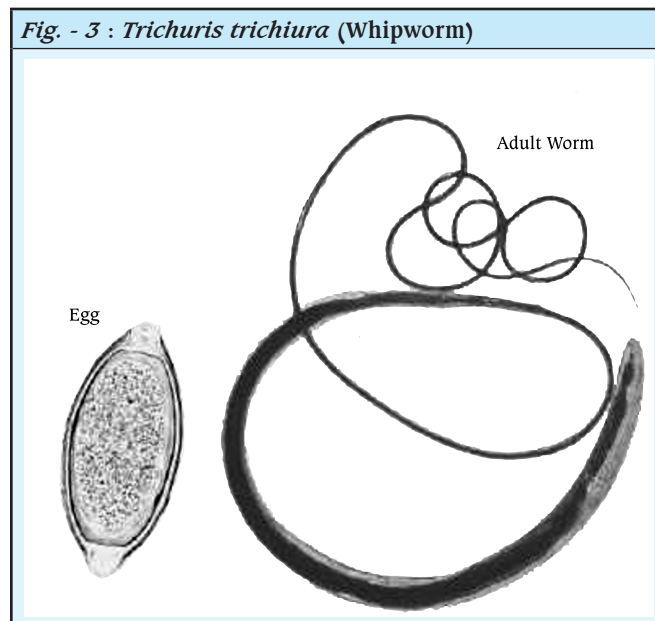

Prevention and control

Prevention and control is as for other soil transmitted helminths. Simple measures as outlined below are the key to preventing re-infection :

- Improving personal hygiene
- Scrubbing children's hands before meals and after defecation
- Keeping finger nails short
- Regular washing of bedclothes

Trichuris trichiura (Whipworm)

Though *T. trichiura* is cosmopolitan in distribution, it is more commonly found in warm moist regions of the world. Recent estimates suggest infection with *T. trichiura* among 795 million people of the world. The infection is often associated with *Ascaris* and *Toxocara* infection.

Agent : The adult worm appears like a whip - the anterior three fifth being very thin and hair like and posterior two fifth being thick and stout like the handle of a whip. The male of the species is 3 - 4 cm long while the female is 4 - 5 cm long. The worm lives in the large intestine with whole of its anterior portion embedded in the mucous membrane. The adult worm survives in humans for many years.

The egg is barrel shaped with a mucous plug at each end. It is bile stained, contains an unsegmented ovum and floats in saturated solution of common salt.

Life cycle : The life cycle is completed in one host, but change of host is necessary for the continuation of the species.

The infection is acquired by ingestion of the eggs. In the stomach, due to gastric juices, egg shells are dissolved and larvae emerges through one of the poles of the egg. The liberated larvae pass down to caecum where it localizes. The worm becomes sexually mature within a month from the time of ingestion of the eggs. After fertilization the gravid female

begins to lay eggs which are passed out in the stool. In water or damp earth, rhabditiform larva develops within the egg in 3 - 4 weeks in tropical climate and in 6 - 12 months in temperate climate. These embryonated eggs are infective to man.

Host : *T. trichiura* is primarily an infection of human beings. All age group can be affected but the most commonly affected are children of primary school age group who pollute the soil around the house and acquire heavy infection. The infection is more common in those who are already infected with *Ascaris* and *Toxocara*.

Environment : The infection is common in areas of high rainfall, high humidity, dense shade, poor sanitation and contaminated soil.

Mode of transmission : Transmission is direct from mature eggs to the mouth via fingers contaminated with infected soil. Infection is also acquired by consumption of food and water contaminated with embryonated eggs.

Clinical Features

Mild infections are generally asymptomatic. But when associated with *Ascaris* or hook worm infection, it produces upper gastro intestinal symptoms like epigastric pain, nausea, vomiting and abdominal distension. Lodged in appendix, it can often mimic acute appendicitis. Anorexia, weight loss, mucous diarrhoea, often streaked with blood can also occur. Prolapse of rectum has often been reported in massive infections with *T. trichiura*.

Diagnosis

The diagnosis is established by the finding of characteristic eggs by a direct microscopical examination of a saline emulsion of stool. An egg count reveals the degree of infection. A count of 30,000 eggs per gram of faeces or more is considered as heavy infection. Adult worms may occasionally be present in stool. Proctoscopy in cases of dysentery due to *T. trichiura* also demonstrates adult worms in abundance.

Treatment

Albendazole and Mebendazole 400 mg and 500 mg respectively as a single dose are highly effective.

Prevention and control

Prevention and control is as for other soil transmitted helminths.

Ascaris lumbricoides (Roundworm)

Ascaris lumbricoides is found worldwide. In human beings, it is one of the most common intestinal worms of tropical and sub-tropical countries and is the cause of worm infestation in up to 10% of the population of the developing world. Worldwide, severe *Ascaris* infections cause approximately 60,000 deaths per year, mainly in children. In endemic areas three distinct patterns have been observed :

- High prevalence (over 60%) in the population above 2 years of age, intensity of infection is lower in adults, transmission of infection takes place through invasive eggs on fingers or in food.
- Moderate prevalence (below 50%) maximum prevalence in pre-school and primary school age children, intensity of

infection in adults low, transmission household or family type

- Low prevalence (below 10%) only focal distribution of infection, seen in association with poor housing and sanitary conditions and unhealthy behavioural practices.

Agent : The adult worm when fresh from the intestine is light brown or pink in colour which gradually changes to white. The worms are cylindrical, rounded and tapers at both ends, the anterior end being thinner than the posterior. While the male of the species measures 15 - 25 cm in length with maximum diameter of 3 - 4 mm, the female measures 25 - 40 cm in length with maximum diameter of 5 mm. The tail end of the male is characteristically curved ventrally in the form of a hook having a conical tip.

The fertilized egg is round in shape, surrounded by thick smooth translucent shell with an outer albuminous coat thrown into rugosities (outer coat is lost in decorticated eggs), contains large unsegmented ovum and has a clear crescentic area at each pole. It is always bile stained and floats in saturated solution of common salt. The unfertilized egg is elliptical in shape, has thinner shell with irregular coating, is bile stained but does not float in saturated salt solution.

Life cycle : The infection is acquired by ingestion of the embryonated eggs which pass down to duodenum where egg shells are dissolved. The newly hatched larvae burrow their way through the mucosa of small intestine and carried by portal circulation, lodge themselves in liver for 3 - 4 days. From here, through the heart, they enter pulmonary circulation. While in lungs, they undergo two moultings and grow bigger in size. Subsequently, in 10 - 15 days, they pass from lung alveoli, bronchi, trachea, larynx, and pharynx and are finally swallowed. Passing down the esophagus to stomach, the larvae localize in upper small intestine - their normal abode - and moult once again. They grow into adult worms and mature sexually in 6 - 10 weeks. The gravid female starts discharging eggs in stool in about two months from the time of infection. Outside the human body and in soil, a rhabditiform larva develops within the egg in 10 - 40 days time. Before hatching, the larva undergoes fourth moulting. The ripe egg containing the coiled up embryo is infective to man.

Host : All age groups are affected. Infection rates are highest in children who are the disseminators of infection. Adult human beings seem to acquire resistance to the infection. A high degree of host - parasite tolerance has been reported.

Environment : The eggs remain viable in the soil for months and years under favourable climatic conditions. Clay soils are

most favourable for the development of eggs. Ecological factors regulating the development of eggs include temperature, humidity, oxygen pressure in the environment and sun light. A low temperature inhibits the development of eggs.

Mode of Transmission : The mode of transmission is essentially oro - faecal. The infection is effected by ingestion of embryonated eggs with raw vegetables on which fecal matter containing eggs has been deposited. Transmission can also occur through recycling of wastewater into crop fields. This is quite common in emerging industrial economies, and poses serious risks for not only local crop sales but also exports of contaminated vegetables. Drinking of water where water supplies are contaminated with ripe eggs, may also transmit infection. Infection may also occur by inhalation of desiccated eggs in the dust reaching pharynx and swallowed. The eggs instead of being swallowed may hatch on moist mucous surface of upper respiratory tract and the larvae may directly penetrate into the blood stream. Transmission from human to human by direct contact is impossible.

Incubation period : The incubation period after swallowing eggs to the first appearance of eggs in the stool is about 2 months.

Clinical features

Individuals with mild infection are usually asymptomatic though a single large worm, when migrate to aberrant sites, can cause diseases like biliary colic, cholecystitis, cholangitis and pancreatitis. During the lung phase of larval migration i.e. 9 to 12 days after egg ingestion, patient may develop irritating non - productive cough and substernal discomfort. Dyspnoea and blood tinged sputum is less common but fever is usual. Eosinophilia develops and chest X-ray may suggest eosinophilic pneumonitis (Löffler's syndrome). In heavy infections, particularly in children, the bolus of worms can cause intestinal obstruction and sometimes perforation.

Diagnosis

Diagnosis of ascariasis is confirmed by demonstration of characteristic eggs on stool microscopy. Adult worm may often be present in the stool which can be identified by its large size and smooth cream coloured surface. In ascariasis with complications, eosinophil count, X-ray chest, X-ray abdomen, ultra sound and endoscopic retrograde cholangiopancreatography (ERCP) may be useful.

Treatment

Ascariasis should always be treated to prevent complication. Albendazole and Mebendazole given in usual dose are effective in uncomplicated cases but are contraindicated in pregnancy and in heavy infections. Pyrantel pamoate given in a single dose of 10 mg per kg body weight is safe as well as effective in pregnancy. Complications are managed conservatively or surgically depending on the nature of the illness.

Prevention and Control

For the prevention and control of ascariasis in the community, following measures should be adopted :

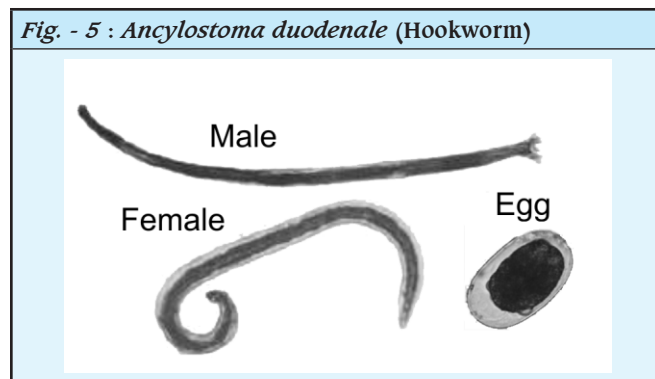

- Sanitary disposal of human excreta to prevent faecal contamination of soil
- Provisioning of safe drinking water availability of water

for use in personal hygiene as well as proper disposal of human faeces

- Health education providing the following messages reduces the number of infected people :
 - avoid contact with soil that may be contaminated with human faeces;
 - wash hands with soap and water before handling food;
 - wash, peel or cook all raw vegetables and fruits;
 - protect food from soil and wash or reheat any food that falls on the floor.
- Where wastewater is used for irrigation, waste stabilization ponds are effective in decreasing transmission due to food grown in contaminated soil.
- Regular repeated mass chemotherapy, especially to school going children, with Albendazole, Mebendazole or Pyrantel pamoate.

Ancylostoma duodenale (Hookworm)

Hookworms are thought to infect 800 million people worldwide. It is an extremely common helminthic infection in human beings and is caused by *Ancylostoma duodenale* and *Necator americanus*. *A. duodenale* predominates in the Middle East, North Africa, India, Japan, China and in southern Europe while *N. americanus* predominates in the Americas, Sub-Saharan Africa, Southeast Asia, China and Indonesia. In India, hookworm infection is widely prevalent with *N. americana* predominantly in South and *A. duodenale* predominantly in North. More than 200 million people are estimated to be infected with hookworms. The most affected states are Bihar, Jharkhand, West Bengal, Assam, Andhra Pradesh, Tamil Nadu, Kerala and Maharashtra. Investigations in rural West Bengal have shown marked aggregation of both hookworm species in individual villagers, with more than 60% of the infections found in less than 10% of the people.

Agent : The adult worm is a small (male measures about 8 mm in size while female measures about 12.5 mm in size), greyish white, cylindrical worm. The anterior end of the worm is bent slightly dorsally in the same direction as the curvature of the body. The buccal capsule is large and conspicuous and is provided with 6 teeth and triangular plates - 4 hook-like on ventral surface and 2 knob-like on dorsal surface. Posterior end is expanded in an umbrella-like fashion in males but it is tapering in females.

The eggs are oval or elliptical in shape, not stained by bile and contain four segmented ovum. It floats in saturated solution of common salt.

Life cycle : The eggs containing 4 blastomeres are passed out in faeces. Within 48 hours in soil, the rhabditiform larva hatches out. It undergoes two moultings on third day and fifth day to develop into filariform larva which is the infective stage of the worm. The filariform larvae gain entrance to the human body by piercing the skin. There it enters the lymphatics and reaches pulmonary alveoli through lympho-vascular system, right heart and pulmonary capillaries. They then migrate upwards the respiratory system and get ultimately swallowed. During its entry to oesophagus, third moulting takes place and a terminal buccal capsule is formed. The growing larvae settle down in small intestine and undergo a fourth moulting to develop into adolescent worms. In three to four weeks time they become sexually mature and following fertilization, the female starts laying eggs. The whole cycle is completed in about six weeks.

Host : Hookworms may reach a considerable intensity in children but commonly remain high throughout adulthood. Whites are much more susceptible than non-whites of similar socio-economic status, suggesting a genetic predisposition. Gender differential in infection has been attributed to difference in habits and exposure. Farmers, gardeners, miners, agriculture workers and individuals working in the fields are more prone to acquire infection as compared to those who are not exposed to such conditions.

Environment : Hookworm larvae live in the upper half inch of the soil. The most favourable conditions for their survival and completion of life cycle include loose, moist, shady, sandy soil with decaying vegetation or improperly treated human faeces. Rainfall is required to provide adequate moisture for the larvae to migrate and reach human skin on grass or other moist surfaces. Temperature is also an important factor for determining the type of infection because *N. americanus* can tolerate higher temperatures as compared to *A. duodenale*. The infective larvae may remain viable in the soil for months during the period of drought or low temperature. Human habits as guided by illiteracy, ignorance, social conditions and low standard of living are important contributing factors for the survival and transmission of hookworm infections.

Mode of transmission : The man acquires the infection when filariform larvae penetrate the skin. The common site of their entry is the skin between toes, the dorsum of the feet, and the inner side of the sole. They may also gain entry through the skin of hands in case of gardeners and miners. Infection can rarely be acquired by drinking contaminated water or ingesting contaminated food materials.

Incubation period : Symptoms usually start appearing 1 to 2 weeks after primary infection. In established infection eggs appear 42nd day onwards after infection.

Clinical features

Most hookworm infections are asymptomatic. A pruritic maculo-papular lesion without any constitutional symptom may develop at the site of entry of the filariform larva.

During migration of larva through lungs, a mild transient pneumonitis, though less severe than that in case of Ascariasis,

can occur. In the early intestinal phase, the infected person may have symptoms of dyspepsia, epigastric pain, vague abdominal symptoms and diarrhoea associated with eosinophilia. The main consequence of chronic hookworm infection is iron deficiency anaemia. Such an infection can result in a daily loss of 1 mg of iron per 10,000 ova per gm of faeces, irrespective of the species. Heavy infection may also lead to malabsorption and hypoproteinemia.

Diagnosis

The diagnosis is clinched by demonstrating characteristic eggs in the stool. Stool concentration may be required for demonstration of eggs in case of mild infection. The blood smear shows hypochromic, microcytic anaemia indicating presence of iron deficiency anaemia. Occasionally eosinophilia may also be present.

Treatment

Albendazole, Mebendazole and Pyrantel pamoate given in usual dose is generally adequate for the treatment. Oral iron supplementation may be required for the management of mild iron deficiency anaemia. Severe hookworm infections with protein loss and malabsorption necessitate nutritional support and iron replacement with deworming.

Prevention and control

The prevention and control of hookworm infection involves, in addition to the general principle as outlined earlier, the following :

- Prevent skin/ soil contact - do not walk bare foot
- Do not defecate out in open, use sanitary latrines
- Do not use human excrement or raw sewage as manure/ fertilizer in agriculture lest it should come in contact with skin
- Iron supplementation for treatment of anaemia and nutritional supplementation in severe hookworm infections leading to hypoproteinemia

Strongyloides stercoralis

S. stercoralis is widely distributed and is endemic in many regions of the world like Vietnam, Cambodia, Papua New Guinea and parts of Africa. High prevalence is reported from some areas of Brazil, Central America and tropical Australia. Knowledge of the geographic distribution of strongyloidiasis is of significance to travellers who may acquire the parasite during their stay in endemic areas.

Agent : The adult worms are small (male measures about 0.9 mm in size while female measures about 2 to 2.5 mm in size) cylindrical worms. Males are distinguished from their female counterparts by two structures : the spicules and gubernaculum. Both genders have a tiny buccal capsule and cylindrical esophagus without a posterior bulb. In the free - living stage, the esophagi of both sexes are rhabditiform. The *Strongyloides* life cycle is of two types :

Free - living cycle : The rhabditiform larvae passed in the stool can molt twice and become infective filariform larvae which penetrate the human host skin to initiate the parasitic cycle. Alternatively the rhabditiform larvae can molt four times and become free living adult males and females that mate and produce eggs from which rhabditiform larvae hatch.

Parasitic cycle : Filariform larvae in contaminated soil penetrate the human skin, and are transported to the lungs. Passing through the bronchial tree and the pharynx, they reach small intestine. In the small intestine they molt twice and become adult female worms. The females by parthenogenesis in the epithelium of the small intestine, produce eggs which yield rhabditiform larvae. The rhabditiform larvae can either be passed in the stool, or can cause autoinfection. In autoinfection, the rhabditiform larvae molts twice to become infective filariform larvae, which can cause internal autoinfection (i.e. penetrate the intestinal mucosa) or external autoinfection (i.e. penetrate the skin of the perianal area).

Host : Strongyloidiasis is less prevalent than infections due to other intestinal nematodes. Travellers and immigrants acquire infection in endemic areas and then harbour the parasite for decades. Risk is highly increased among the residents of mental asylums due to oro - faecal transmission and geophagia. Autoinfection is amplified in immunocompromised hosts.

Environment : *S. stercoralis* has a very low prevalence in societies where fecal contamination of soil or water is rare. Hence, it is more prevalent in rural areas in developing countries, where sanitation standards are poor.

Mode of transmission : The man acquires the infection when filariform larvae penetrate the skin. An unusual feature of *S. stercoralis* is autoinfection. Only one other species in the *Strongyloides* genus, *S. felis*, has the trait of autoinfection. Because of autoinfection, a host once infected with *S. stercoralis*, remains infected life - long unless effective treatment eliminates all adult parasites and migrating autoinfective larvae.

Clinical features

Strongyloidiasis is frequently asymptomatic. Transient pruritus can occur at the site of entry of the filariform larva. Pulmonary symptoms (including Loeffler's syndrome) can occur during pulmonary migration of the larvae. Gastrointestinal symptoms include abdominal pain and diarrhoea. Disseminated strongyloidiasis occurs in immunosuppressed patients. Common predisposing factors include corticosteroid therapy, immunosuppressive chemotherapy, malignancy, tuberculosis and malnutrition. Hyperinfection with *S. stercoralis* can present with abdominal pain, distension, shock, pulmonary and neurologic complications and septicemia, and is potentially fatal. Blood eosinophilia is generally present during the acute and chronic stages, but may be absent with dissemination.

Diagnosis

Diagnosis rests on the microscopic identification of larvae (rhabditiform and occasionally filariform) in the stool or duodenal fluid. Because of the low rate of egg production, examination of serial samples may be necessary. Stool culture for *S. stercoralis* is available at few places only. The duodenal fluid examined using techniques such as the Enterotest string or duodenal aspiration is positive in 90% of the cases. Larvae may be detected in sputum from patients with disseminated strongyloidiasis. Serologic testing may be useful for screening of patients in endemic areas.

Treatment

Ivermectin is the drug of choice, given in a dose of 100

microgram per kg per day for 1 - 2 days is usually sufficient for the management of chronic intestinal strongyloidiasis. For patients with underlying immunodeficiency, the treatment should be repeated at two weeks. Albendazole not as effective as Ivermectin and Thiabendazole, though effective but not well tolerated, have also been used.

Prevention and Control

The prevention and control measures include sanitary disposal of human faeces in endemic areas and wearing of appropriate footwear. Hyperinfection syndromes are prevented by early identification and eradication of strongyloidiasis infection.

Food Borne Helminths

Food borne helminths include a variety of flukes and tapeworms. The notable among these are *Fasciola buski* (intestinal flukes), *Fasciola hepatica* (liver flukes), *Clonorchis sinensis* (liver flukes, Chinese liver fluke, Oriental liver fluke), *Paragonimus westermani* (lung flukes), *Taenia saginata* (beef tapeworm) and *Taenia solium* (Pork tapeworm).

All these worms and flukes are cosmopolitan in nature and are found worldwide but majority of these are found in South East Asia and Western Pacific region. *T. saginata* is common in India but not among Hindu community as they do not eat beef. *F. buski* is common in Bangladesh, China, Indonesia, Malaysia, Taiwan, and Thailand. *Clonorchis sinensis* is common in Southern China, Taiwan, Hong Kong and Vietnam. According to an estimate, Clonorchis infections in China, have more than tripled over the past decade (approximately 15 million people were infected with *C. sinensis* in 2004).

The most important epidemiologic features responsible for transmission of food borne helminths especially flukes include ecologic and environmental factors, behavioural factors, and socioeconomic and cultural factors. Residents living near freshwater bodies have been found to have a 2.15 fold higher

risk of infections than persons living farther from the water. Exponential growth of aquaculture may be the most important risk factor for the emergence of food borne infection with flukes. Socio - economic development, urbanization, adequate food inspection and increased awareness have been found to be associated with a decrease in prevalence of food borne helminths infection. A summary of food borne helminth infection, drug of choice for treatment and its dose is given in Table - 2. The general measures of prevention and control are given subsequently.

General Measures of Prevention and control

Public health interventions that will affect the pool of parasites and will also reduce the prevalence of major food borne helminths infections, are enumerated as under :

- (a) Chemotherapy with antihelminthics in adequate doses for adequate duration
- (b) Sanitation and Hygiene
 - Proper disposal of human and animal wastes to prevent contamination of foods and drinking water sources
 - Sterilization/ composting of night soil before using it as fertilizer.
 - Thorough washing of raw vegetables and fruits may remove eggs of parasites, but it is difficult to adequately clean some leafy vegetables and berries.
 - Control of flies, cockroaches, and other insects may prevent dispersal of infective stages of parasites to foods.
 - Frequent handwashing, use of clean utensils, and measures to prevent cross - contamination during food processing
- (c) Food Inspection and food safety
 - Naked eye inspection can detect parasites in pork, beef, and fish.
 - Soaking of vegetables in a 1.5% bleach solution, potassium permanganate solution (24 mg/L), or saturated salt destroys infective larvae of some food borne helminths

Table - 2 : Food - borne helminth infections and their management

Helminth	Infective form	Food item	Drug of choice	Adult dose and duration
<i>Fasciolopsis buski</i> (intestinal flukes)	Metacercariae encysted in aquatic vegetation	Fruits, raw vegetables	Praziquantel	25 mg/ kg; 3 doses in 1 day
<i>Fasciola hepatica</i> (liver flukes)	Metacercariae encysted in aquatic vegetation	Fruits, raw vegetables	Triclabendazole	10 mg per kg once
<i>Clonorchis sinensis</i> (liver flukes)	Metacercariae in fish flesh	Fish	Praziquantel	25 mg/ kg; 3 doses in 1 day
<i>Paragonimus westermani</i> (lung flukes)	Metacercariae in fish flesh	Crabs, shrimp	Praziquantel	25 mg/ kg; 3 doses per day for 2 days
<i>Taenia saginata</i> (beef tapeworm)	Cysticercus bovis in muscles	Beef	Praziquantel	5 - 10 mg/ kg; single dose
<i>Taenia solium</i> (Pork tapeworm)	Cysticercus cellulosae in muscles	Pork	Praziquantel	5 - 10 mg/ kg; single dose
<i>Diphyllobothrium latum</i> (fish tapeworm)	Plerocercoid larvae in fish flesh	Fish	Praziquantel	5 - 10 mg/ kg; single dose
<i>Trichinella spiralis</i> (trichina worm)	Encysted larvae in muscles	Pork	-	-

- All infective stages of parasites are destroyed by adequate cooking of foods and boiling of water. Microwave cooking does not reliably kill all parasites in meat and fish because heating is uneven and cooler spots may permit survival. It is advisable to cook pork and fish for 10 min at 60°C or 7 min at 70°C.
 - For foods to be eaten raw, such as fish and some meats, freezing for several days can inactivate or kill some parasites. - Fish should be frozen at - 30°C for ≥15 hours in a commercial blast freezer or at - 20°C for ≥7 days in a domestic freezer. Freezing meat at 5°F (- 17°C) for 20 days, - 10°F (- 23.3°C) for 10 days or - 20°F (- 29°C) for 6 days destroys trichinae in pork.
 - Irradiation can destroy parasites on some raw foods. Lower doses of irradiation (0.5 - 0.7 kGy) damage larvae and inhibit infectivity, but larger doses (6 - 7 kGy) are required to kill all the trichinae in meat. Irradiation doses of 0.1 - 0.15 kGy have been reported to kill trematode cysts in fish.
 - Fermentation of meat to produce dry sausages and ham inactivates larvae of parasitic worms. Low pH and low water activity combine to kill parasites.
- (d) IEC activities
- To teach proper cooking methods for fish and other potentially contaminated aquatic foods.
 - To discourage human consumption of raw water plants like watercress and water chestnuts.

Taenia saginata (Beef Tapeworm)

Taenia saginata is widely distributed and is most prevalent in sub-Saharan Africa and Middle Eastern Countries.

Epidemiological Determinants

Taenia saginata lives in small intestine (upper jejunum) of man. The adult worm is white, semi-transparent and measures 5 to 10 meters in length. The body of the worm is divided into scolex, neck and proglottides, the number of which may vary from 1000 to 2000. The life span of the adult worm is more than 10 years.

The eggs are spherical and brown in colour (bile stained), has an outer shell and an inner thick walled, radially striated embryophore, contains three pairs of hooklets, and do not float in saturated solution of common salt.

Life cycle : *Taenia saginata*, in its life cycle, passes through one definitive host (man) and one intermediate hosts (cattle - cow or buffalo)

The eggs or segments are passed out with faeces on ground where they live for months or years till ingested by cattle while grazing. The embryo released after ingestion invades the intestinal wall and is carried to striated muscles where it transforms into a cysticercus. When ingested in raw or undercooked beef, this form infects human beings. After ingestion of cysticercus, it takes 2 months for an adult worm to develop.

Modes of Transmission : Human infection is acquired by eating undercooked beef.

Clinical Features

Majority of individuals with *Taenia saginata* infection are asymptomatic. They become aware of the infection by noting passage of proglottids in stool. Some patients also complain of vague abdominal pain, distension, nausea, anorexia and weight loss may occur.

Diagnosis

Diagnosis is by identification of characteristic eggs or proglottids in stool. Eggs may also be present in perianal area. Eosinophilia and raised IgE may be detected.

Treatment

Treatment is by Praziquantel as given in Table - 2.

Prevention and Control

As outlined above.

Taenia solium (Pork tapeworm)

Taenia solium exists worldwide and is most prevalent in Africa, Latin America, South East Asia and Eastern Europe.

Epidemiological Determinants

Taenia solium lives in small intestine (upper jejunum) of man. The adult worm is white, semi-transparent and measures 2 to 3 meters in length. The body of the worm is divided into scolex, neck and proglottides. As compared to *T. saginata*, the scolex is smaller and the number of proglottids lesser, usually less than 1000. The life span of the adult worm is as much as 25 years. The eggs are similar to those of *T. saginata*.

Life cycle : Life cycle is the same as *T. saginata* except that the intermediate host is pig.

Modes of Transmission : Human infection is acquired by eating undercooked pork. Auto infection may occur if an individual ingests eggs derived from his own faeces.

Clinical features

Intestinal infection with *Taenia solium* may be asymptomatic. Symptoms of vague abdominal pain, distension, nausea, anorexia, and weight loss are infrequent. Extraintestinal manifestations due to cysticercosis which has a predilection for central nervous system are entirely different. Cysticercosis of brain may result in raised intra-cranial pressure, seizures and hydrocephalus. They can also cause chronic meningitis, arachnoiditis and stroke.

Diagnosis

Diagnosis is by identification of characteristic eggs or proglottids in stool. Diagnosis of cysticercosis is difficult. CT scan, MRI and serology may provide useful evidence.

Treatment

Treatment for intestinal infection is by Praziquantel as given in Table - 2. For extra - intestinal manifestation, Praziquantel (50 - 60 mg / kg in 3 divided doses for 15 days) along with suitable surgical or non - surgical intervention may be required.

Prevention and control

As outlined above.

Summary

The word Helminths literally means worms. These are parasitic worms causing diseases of varying magnitude in humans. Nearly 01 billion people worldwide are estimated to be affected with worm infestation. They are divided primarily based on the route of their transmission - soil, food or arthropod borne.

Soil - Transmitted Helminths (STH) can be grouped in various ways, based either on prevalence and the intensity of the infection (into high, medium & low transmission community) or on their life cycle (into direct, modified direct & penetration of skin). They are transmitted by oro - faecal route and produce a wide range of non - specific symptoms which include intestinal manifestations and generalized weakness. Pre - school and school age children, adolescent girls and women of child bearing age are the most vulnerable and afflicted population groups.

Diagnosis of STH infections is established by stool microscopy and identification of characteristic eggs. Treatment of these infections is aimed at improving health; nutrition and overall vocational capability of the target age group population - the drugs used are Albendazole, Mebendazole and Praziquantel. A comprehensive control strategy for helminths infection should include Chemotherapy, Sanitation, Health education, Community participation and Monitoring and evaluation.

The most cost - effective way of deworming the school - age children is through School - based deworming, which has its full impact when delivered within an integrated school health program. While implementing this strategy, it would be prudent to adhere to certain Do's (like making deworming an integral component of a school health program & combining it with iron and other micronutrient supplementation) and Dont's (like excluding adolescent girls from systematic treatment or examining every child).

Enterobius vermicularis (Threadworm) is cosmopolitan in distribution and is found all over the world. The adult worm is like a spindle and the eggs are color - less. Infection is acquired by ingestion of eggs. Man is the definitive host. The infection is more common in conditions of overcrowding. Person - to - person transmission can occur by either Auto - infection, ingestion of contaminated food or drink, air - borne transmission by contaminated dust or by retrograde infection. Majority of the cases remain asymptomatic - in others, pruritus ani is the most common symptom. Diagnosis is by demonstration of adult worms in stool (even naked eye examination) or eggs in stool microscopy. Albendazole or Mebendazole may be used in treatment. Prevention and control includes improving personal hygiene, scrubbing children's hands before meals and after defecation, keeping finger nails short and regular washing of bedclothes.

Trichuris trichiura (Whipworm) is more commonly found in warm moist regions of the world. The adult worm appears like a whip; egg is barrel shaped with a mucous plug at each end. Infection is acquired by ingestion of embryonated eggs. Children and those already infected with *Ascaris* and *Toxocara*. are particularly affected. Transmission is direct, via fingers, food and water. Mild infections are generally asymptomatic, but upper GI symptoms are produced when co - infection with *ascaris* or hookworm takes place. The diagnosis is established by the finding of characteristic eggs by a direct microscopical examination of a saline emulsion of stool. Albendazole and Mebendazole are effective agents. Prevention and control is as for other soil transmitted helminths.

Ascaris lumbricoides (Roundworm) is found worldwide. In human beings, it is one of the most common intestinal worms. Ascariasis could be endemic, epidemic or sporadic. In endemic areas three distinct patterns have been observed - high, moderate & low prevalence. The adult worms are cylindrical, rounded and tapers at both ends. The fertilized egg is round in shape, surrounded by thick smooth translucent shell. The infection is acquired by ingestion of the embryonated eggs . All age groups are affected; nevertheless infection rates are highest in children. The eggs remain viable in the soil for months and years under favourable climatic conditions. Clay soils are most favourable for the development of eggs. The mode of transmission is essentially oro - faecal. Transmission can also occur through recycling of wastewater into crop fields or by inhalation of desiccated eggs in the dust. The incubation period is around 02 months. Clinical features range from asymptomatic to biliary colic, cholecystitis, eosinophilic pneumonitis (Loffler's syndrome), intestinal obstruction or perforation. Diagnosis of *ascaris* infection is confirmed by demonstration of characteristic eggs on stool microscopy. Adult worm may often be present in the stool which can be identified by its large size and smooth cream coloured surface. Treatment comprises of either Albendazole or Mebendazole . Pyrantel pamoate is preferred in cases of pregnant women. Proper sanitation, safe drinking water, health education, setting up of waste stabilization ponds and Regular repeated mass chemotherapy, especially among school children, are essential measures in prevention and control of ascariasis in the community.

Ancylostomiasis is an extremely common helminthic infection in human beings and is caused by *Ancylostoma duodenale* and *Necator americanus*. In India, hookworm infection is widely prevalent with *N. americana* predominantly in South and *A. duodenale* predominantly in North. The adult worm is a small greyish white, cylindrical worm. The life - cycle passes through stages of eggs, rhabditiform larva, filariform larva and adult; the whole cycle is completed in about six weeks. Hookworms may reach a considerable intensity in children. Hookworm larvae live in the upper half inch of the soil. Human habits as guided by illiteracy, ignorance, social conditions and low standard of living are important contributing factors in transmission of hookworm infection; the other ones are moist, shady, sandy soil with decaying vegetation, temperature and humidity. Man acquires the infection when filariform larvae penetrate the skin. Symptoms usually start appearing 1 to 2

weeks after primary infection. Most hookworm infections are asymptomatic; maculo - papular lesion, eosinophilia, anaemia, malabsorption, hypoproteinemia and pneumonitis are the other clinical manifestations. The diagnosis is clinched by demonstrating characteristic eggs in the stool. Albendazole, Mebendazole and Pyrantel pamoate given in usual dose is generally adequate for the treatment. Prevention and control involves among other measures, provision of sanitary latrines and iron supplementation.

Food borne helminths include a variety of flukes and tapeworms; all these worms and flukes are cosmopolitan in nature but majority of these are found in South East Asia and Western Pacific region. The most important epidemiologic features responsible for transmission of food borne helminths especially flukes include ecologic and environmental factors, behavioural factors, and socioeconomic and cultural factors. The transmission of the infection takes place by ingestion of the infective larvae along with raw or uncooked or improperly cooked fish, pork, beef or other food items. Clinical features depend upon the type of helminth and the system involved. The diagnosis is mainly established by demonstration of characteristic ova in stool or sputum (in case of lung fluke infection). The mainstay of treatment is Praziquantel. Essential components of prevention and control include IEC activities, chemotherapy with antihelminthics, maintenance of sanitation and hygiene and ensuring food inspection and food safety .

Taenia saginata (beef tapeworm) is widely distributed globally. The worm lives in small intestine (upper jejunum) of man. The adult worm is white, semi - transparent and measures 5 to 10 meters in length. The eggs are spherical and brown in colour (bile stained), contains three pairs of hooklets. *Taenia saginata*, in its life cycle, passes through one definitive host (man) and one intermediate hosts. Human infection is acquired by eating undercooked beef. Vague abdominal pain, distension, nausea, anorexia, and weight loss are some clinical manifestations. Diagnosis is by identification of characteristic eggs or proglottids in stool. Treatment is by Praziquantel. Preventive and control measures are the same as for food - borne helminthes.

Taenia solium (the Pork tapeworm) exists worldwide. The worm lives in small intestine (upper jejunum) of man. The eggs are similar to those of *T. saginata*. Life cycle is the same as *T. saginata* except that the intermediate host is pig. Human infection is acquired by eating undercooked pork. Auto infection may occur if an individual ingests eggs derived from his own faeces. Symptoms of vague abdominal pain, distension, nausea, anorexia, and weight loss are infrequent. Extraintestinal manifestations due to cysticercosis which has a predilection for central nervous system are entirely different. Diagnosis is by identification of characteristic eggs or proglottids in stool. Treatment for intestinal infection is by Praziquantel. Preventive and control measures are the same as for food - borne helminthes.

Study Exercises

Long question : Discuss food borne helminthes and their control measures.

Short notes : (1) Deworming in schools (2) *Taenia saginata*

MCQs

- In the classification of communities based on prevalence and intensity of infection of soil - transmitted helminthic infections, a high - transmission community is one wherein (a) Prevalence greater than 50%, heavy infection less than 10% (b) Prevalence less than 50%, heavy infection less than 10% (c) prevalence greater than 10%, heavy infection less than 50% (d) Prevalence greater than 50%, heavy infection more than 10%
- All of the following are types of soil - transmitted helminthes based on the life cycle, except : (a) Direct (b) Indirect (c) Penetration of the skin (d) Modified direct
- Anthelminthics are contra - indicated in pregnancy. Yes / No
- All of the following are examples of food borne helminthes examples except (a) *Wuchereria bancrofti* (b) *Clonorchis sinensis* (c) *Fasciola hepatica* (d) *Fasciola buski*.
- Retrograde infection is a significant mode of transmission of (a) Ascariasis (round worm) (b) Paragonimus (lungfluke) (c) Enterobius (thread worm) (d) Ankylostoma (hook worm)
- For whipworm infection to be termed as "heavy infection", the number of eggs per gram of faeces is more than or equal to : (a) 10000 (b) 20000 (c) 30000 (d) 40000
- In areas where Ascariasis is endemic and maximum prevalence is found in pre - school and primary school age children, intensity of infection in adults low, transmission household or family type, the pattern is known as : (a) mild prevalence (b) moderate prevalence (c) intense prevalence (d) high prevalence
- A safe and effective drug in the management of Ascariasis in a pregnant woman is : (a) Praziquantel (b) Mebendazole (c) Albendazole (d) Pyrantel Pamoate
- Diphyllobothrium latum* (fish tapeworm) in its life cycle, passes through : (a) 01 definitive host & 02 intermediate hosts (b) 02 definitive hosts & 01 intermediate host (c) 01 definitive host & 01 intermediate host (d) 02 definitive hosts & 02 intermediate hosts
- Drug of choice in cases of Cysticercosis is : (a) Albendazole (b) Mebendazole (c) Praziquantel (d) Pyrantel pamoate.
- Consumption of raw or incompletely cooked crabs, crayfish and shrimps harbouring metacercariae, leads to infection with : (a) liverfluke (b) lungfluke (c) bloodfluke (d) intestinal fluke.
- Reservoir of infection in man , in cases of Intestinal fluke (*Fasciola hepatica*) is : (a) pig (b) cow (c) snail (d) dog
- Encysted larvae in muscles of pork, when ingested, is the infective form in cases of infection with (a) *Fasciola hepatica* (liver flukes) (b) *Trichinella spiralis* (trichina worm) (c) *Ascaris lumbricoides* (round worm) (d) *Paragonimus westermani* (lung flukes)

14. What amount of iron is approximately lost in cases of chronic hookworm infection, leading to Iron deficiency anaemia : (a) 10 mg of iron per 10,000 ova per gm of faeces (b) 0.1 mg of iron per 10,000 ova per gm of faeces (c) 5 mg of iron per 10,000 ova per gm of faeces (d) 1 mg of iron per 10,000 ova per gm of faeces

Answers : (1) d; (2) b; (3) No; (4) a; (5) c; (6) d; (7) b; (8) d; (9) a; (10) c; (11) b; (12) a; (13) b; (14) d.

Amoebiasis & Giardiasis

Rajesh Kunwar

Amoebiasis

Amoebiasis is an infection caused by a protozoan parasite *Entamoeba histolytica*. The infection is acquired by faeco - oral route and the disease is manifested by intestinal as well as extra - intestinal symptoms.

Magnitude of the Problem

Amoebiasis occurs worldwide but the majority of the cases are reported from developing countries mainly because of poor hygiene and sanitary conditions. These areas include India, Mexico, Central and South America and countries of Africa and Asia in tropical regions. In developed countries, the affected population is mainly constituted by travellers. At anyone time approximately 10% of the world population is affected by Amoebiasis. It is the third commonest cause of death, after schistosomiasis and malaria, from parasitic diseases. In India, the prevalence of Amoebiasis ranges from 3.5% to 45% with an average of about 15%.

Epidemiological Determinants

Agent factors

(a) Agent : Amoebiasis is caused by *Entamoeba histolytica* which, in human, exists in two forms - the vegetative form or trophozoite and the cystic form. The trophozoites are found in large intestine where they multiply and encyst. The cysts are excreted in the stool. On gaining entrance by ingestion, the cysts release trophozoites which colonize in the large bowel which may cause ulceration, mainly in ascending colon and caecum. Some may gain entry in the circulation and cause liver abscess and other extra - intestinal illnesses. Efforts have been made to further classify *Entamoeba histolytica* on the basis of the migration of isoenzymes. More than 10 different zymodenes (similar group of organisms with different movement of one or

more enzymes on electrophoresis) have already been identified. The cyst is the infective form of the organism and survives in soil, water, sewage and faeces for several days. It is not affected by the routine chlorination of the water but is readily killed if dried, frozen or heated to 55°C or more. The trophozoites do not survive outside human body for long and are not important for the transmission of the disease.

(b) Reservoir : Cysts carriers are the main reservoirs of the infection. They discharge up to 1.5×10^7 cysts daily. They are most risky when made responsible for handling food.

(c) Source of Infection : The source of infection is the food and drink contaminated with human faeces. Contamination of water supplies with raw sewage has been reported to cause epidemics.

Host factors

(a) Age : Amoebiasis can occur at any age.

(b) Sex : Both the sexes are affected equally.

(c) High Risk Group : The high risk group includes travellers, migrants, immigrant workers, immunocompromised individuals, prisoners and children in day - care centres. Severe infections occur in very young children, pregnant women, malnourished and people taking corticosteroids. Patients with AIDS do not have an increased risk of severe infection.

(d) Immunity : Immunity following an invasive infection with *E. histolytica* is cell mediated type and is protective against a reinfection. The risk of recurrence is increased if the treatment failed to eradicate the pathogenic form from the colon.

Environmental factors : Amoebiasis is closely associated with poor hygiene and sanitary conditions and low socio - economic status. Prevalence of the infection is found to be higher in places where human faeces are used as fertilizers.

Incubation Period and Period of Communicability : The incubation period is 2 to 4 weeks but may range from few days to several months or years.

Since the infected person may continue to excretes *E. histolytica* cysts for years, the period of communicability could be

prolonged. Asymptomatically infected persons tend to excrete a much higher proportion of cysts and hence are more likely to transmit infection than persons who are acutely ill, who tend to excrete trophozoites.

Mode of Transmission : The disease transmission takes place by faeco - oral route when food and drink get contaminated with human faeces. Viable cyst under finger nails may be directly transmitted from hand to mouth. Sexual transmission can also take place. Transmission through vectors such as flies and cockroaches is possible.

Clinical Features

The clinical spectrum of the disease ranges from asymptomatic carriers to acute colitis, to fulminant colitis and to amoebic liver abscess.

The commonest intestinal manifestation of the disease is abdominal discomfort associated with diarrhoea which subsequently turns into dysentery. Lower abdominal pain and tenesmus is common and tenderness is present over caecum and colon. Patient may pass 10 to 12 stools per day. The stools contain little faecal material and consist mainly blood and mucous. Fever is usually absent (fever is common in bacillary dysentery) in amoebiasis.

Fulminant intestinal infection with severe abdominal pain, high fever and profuse diarrhoea is rare. In such cases patient may develop toxic megacolon.

The most common extra - intestinal manifestation of Amoebiasis is amoebic liver abscess which commonly affects the posterior lobe of the liver and presents as right upper quadrant pain associated with hepatomegaly. Fever is common, jaundice rare. The complications include pleuropulmonary involvement, hepatobronchial fistula and rupture in peritoneum or pericardium. Other extra - intestinal manifestations are cerebral and genito - urinary involvement.

Diagnosis

Diagnosis of amoebic colitis depends upon the demonstration of trophozoites in the stool. ELISA, sigmoidoscopy and colonoscopy are useful in the diagnosis of invasive Amoebiasis. Ultrasound, CAT scan and MRI are useful for the diagnosis of amoebic liver abscess.

Treatment

Metronidazole is the drug of choice for the treatment of both intestinal Amoebiasis and amoebic liver abscess. It is given in a dose of 750 mg orally or IV three times a day for 5 to 10 days. Tinidazole 2g once a day for 3 days is an alternative to metronidazole. In addition to the above, one of the following luminal amoebicides should be prescribed as an adjunctive treatment, either concurrently or sequentially, to destroy *E. histolytica* in the colon :

- Paromomycin 500mg three times a day for 10 days
- Diloxanide furoate 500mg three times a day for 10 days
- Iodoquinol 650mg three times a day for 20 days

Prevention

The preventive measures should aim at :

(a) Community

Sanitation : Safe disposal of human excreta coupled with

elementary sanitation practices like washing of hands with soap and water is the most important measure.

Water Supply : Water supplies must be protected from faecal contamination. Sand filters are quite effective in removing amoebic cysts and hence filtration along with close monitoring of water pipe lines to check faecal contamination is useful. Boiling of water at individual levels are more useful than routine chlorination.

Food Safety : Measures should be taken to protect food and drink from faecal contamination. Foodhandlers with amoebiasis must be excluded from work and should not be permitted back till one stool specimen is negative. In outbreak circumstances, a second consecutive negative stool specimen will be required prior to returning to work.

Health Education : Health education must emphasise the following points;

- Always wash hands thoroughly with soap and water before eating or preparing food, after using the toilet, and after changing diapers.
- After changing diapers, wash the child's hands as well as your own.
- Dispose of faeces in a sanitary manner.
- Avoid sexual practices that may permit fecal - oral transmission.
- Do not eat fruit that already has been peeled or cut.
- Drink only pasteurized milk or dairy products.

(b) Individual : Early diagnosis and treatment - All known cases must be adequately treated with metronidazole or suitable alternative. At present no chemoprophylaxis or vaccination is available.

Giardiasis

Giardiasis is a diarrhoeal illness caused by a protozoan parasite *Giardia lamblia* that commonly inhabits the small intestines of human beings and other mammals. From epidemiological and public health perspective, giardiasis is quite akin to amoebiasis as regards modes of transmission and preventive modalities.

The disease is caused by *Giardia lamblia*, which is a flagellate protozoan parasite of human being. It exists in two forms - the trophozoite which inhabits the duodenum and upper part of jejunum and the cyst which exists outside the host and is the form that transmits the infection. The trophozoite is rounded and broad at the anterior end that tapers to a sharp point at the posterior end. It has a bilaterally symmetrical body with paired organs and four pairs of flagella. The cysts are oval and have four nuclei which may remain clustered at one end or lie in pairs at opposite end. The cysts are resistant to the routine dose of chlorine used for purification of water. It can survive in the environment up to 16 days at a temperature of 8°C.

The disease occurs world - wide. It occurs more commonly in developing countries of Asia, Africa and South & Central America which are poor in resources and where access to clean water and basic sanitation is lacking. The prevalence of giardiasis in such countries varies from 20 to 30% as compared to 2 to 5% in developed countries. It is a disease of young age and nearly all children, especially those of developing countries, do acquire the infection sometime or other during their childhood.

In developed countries, the Giardia infection is associated with ingestion of contaminated water, person - to - person spread, recent foreign travel, and recreational swimming. The infection is common among travellers who travel from developed countries to developing countries. Up to 12% of the traveller's diarrhoea is said to be because of the giardia infection.

Human being, most importantly the asymptomatic carrier, is the main reservoir of Giardia. However, several other mammals like dogs, sheep and cattle are also known to harbour the organism. The source of infection is food and drink contaminated with human faeces.

The preventive modalities are the same as those for amoebiasis. Giardiasis often clears up without treatment. It responds promptly to treatment with metronidazole in a dose of 250 mg orally three times a day.

Summary

Amoebiasis

It is an infection caused by a protozoan parasite *Entamoeba histolytica*. It occurs worldwide but the majority of the cases are reported from developing countries. At anyone time approximately 10% of the world population is affected by amoebiasis. In India the prevalence ranges from 3.5% to 45% with an average of 15%.

E. histolytica exists in humans in two forms - the vegetative trophozoite and the cystic form. On ingestion of the cyst by humans, trophozoites are released which colonize the large bowel mainly ascending colon and caecum. The cyst is the infective form of the organism and survives in soil, water, sewage and faeces for several days. Cyst carriers are the main reservoir of the infection and the source of infection is the food and drink contaminated with human faeces. The high risk group includes travellers, migrants, immigrant workers, immunocompromised individuals, prisoners and children in day - care centres. Severe infection occurs in very young children, pregnant women, malnourished and people taking corticosteroids. It is closely associated with poor hygiene and sanitary conditions and low socio - economic status.

The Incubation period is 2 to 4 weeks but may range from few days to several months or years. Disease transmission mainly takes place through faeco - oral route and sexual transmission or transmission through vectors such as flies may also occur.

Clinical spectrum varies from asymptomatic carriers to acute colitis, to fulminant colitis and to amoebic liver abscess. The commonest intestinal manifestations are abdominal discomfort associated with diarrhoea which subsequently turns into dysentery. Pain and tenesmus are common. The most common extra - intestinal manifestation is amoebic liver abscess which commonly affects the posterior lobe of the liver and presents as right upper quadrant pain with hepatomegaly and fever.

Diagnosis of amoebic colitis depends upon the demonstration of trophozoites in the stool. ELISA, Sigmoidoscopy and colonoscopy are useful in the diagnosis of invasive amoebiasis.

Metronidazole is the drug of choice for the treatment of both intestinal amoebiasis and amoebic liver abscess. Tinidazole is an alternative. In addition one of the luminal amoebicides i.e. Paromomycin or Diloxanide furoate or Iodoquinol should be

prescribed as an adjunct.

Preventive measures should aim at safe disposal of human excreta coupled with elementary sanitation practices, protecting of water supplies from faecal contamination, protection of food and drinks from faecal contamination, stool examination of food handlers and exclusion from work till one stool sample becomes negative, health education and early diagnosis and treatment.

Giardiasis

It is a diarrhoeal illness caused by a flagellate protozoan parasite *Giardia lamblia*. It exists in two forms - the trophozoite which inhabits the duodenum and the cyst which exists outside the host and is the form that transmits the infection. The disease occurs worldwide but is more common in developing countries where access to clean water and basic sanitation is lacking. The prevalence of Giardiasis in such countries varies from 20 to 30% as compared to 2 to 5% in developed countries. Up to 12% of Traveller's diarrhoea is said to be because of the Giardia infection. Human being, most importantly the asymptomatic carrier, is the main reservoir of Giardia. The source of infection is food and drink contaminated with human faeces. The preventive modalities are the same as those for Amoebiasis. It responds promptly to treatment with Metronidazole.

Study Questions

Long Question : Discuss Amoebiasis in details and its prevention and control measures.

Short Notes : (1) Giardiasis (2) Prevention of Amoebiasis (3) Clinical features of Amoebiasis (4) Epidemiological determinants of Amoebiasis

MCQs

1. In India, the prevalence of Amoebiasis is : (a) 5% (b) 10% (c) 15% (d) 20%
2. The form of *E. histolytica* usually infective to man is (a) Trophozoite (b) Merozoite (c) Egg (d) Cyst
3. Reservoir of infection of *E. histolytica* is : (a) Housefly (b) Man (c) Soil (d) Dog
4. *E. histolytica* trophozoite causes ulceration commonly in (a) Rectum (b) Duodenum (c) Transverse and descending colon (d) Caecum and ascending colon
5. All are true of epidemiology of Amoebiasis except (a) No sex difference (b) Does not affect children (c) More among low socio - economic status (d) Incubation period is 2 - 4 weeks
6. Severe infection of *E. histolytica* occurs in all except (a) Very young children (b) Pregnant women (c) Malnourished individuals (d) Patients with AIDS
7. Drug of choice for Amoebic liver abscess is (a) Metronidazole (b) Tinidazole (c) Diloxanide furoate (d) Iodoquinol
8. Worldwide prevalence of Amoebiasis is (a) 5% (b) 10% (c) 15% (d) 20%
9. In outbreak circumstances the number of consecutive negative stool samples required for food handlers to return back to work is/are : (a) 1 (b) 2 (c) 3 (d) 4
10. The trophozoite of *Giardia lamblia* inhabits : (a) Caecum (b) Rectum (c) Ascending and transverse colon (d) Duodenum and upper jejunum

11. What percentage of Traveller's diarrhoea is due to Giardia infections : (a) 8% (b) 12% (c) 16% (d) 20%

Answers : (1) c; (2) d; (3) b; (4) d; (5) b; (6) d; (7) a; (8) b; (9) b; (10) d; (11) b.

204 Sexually Transmitted Infections (STI)

Sunil Agrawal

As a general convention, the term Sexually Transmitted diseases has been replaced by Sexually Transmitted Infections (STI) since 1999 as it better incorporates asymptomatic infections. STI are a group of contagious diseases transmitted predominantly by sexual contact and caused by a wide range of bacteria/viruses, protozoa, fungi and ectoparasites. During the past two decades, STDs have undergone a dramatic transformation like, attention is now given not only to specific diseases but also to clinical syndromes associated with STIs. Most of the recently recognised STIs are now referred to as second generation STIs. AIDS is the most recently recognized STI(1). Sexually Transmitted Infections are among the most common causes of illness in the world and have far reaching health, social and economic consequences for many countries. The emergence and spread of HIV infection and AIDS have

had a major impact on the management and control of STIs. At the same time, resistance of several sexually transmitted pathogens to antimicrobial agents has increased, adding to therapeutic problems (2).

Classification of Sexually Transmitted Infections

This is shown in Table - 1.

Magnitude of the Problem

(a) Global : True incidence of STI's is not known because of stigma involved but the trend in gonorrhoea and primary syphilis is on the increase. The matter of concern is emergence of antimicrobial resistance agents of STI. Second generation STIs are tending to replace the classical bacterial diseases (syphilis, gonorrhoea, chancroid). Minimal estimates of new cases for major STDs are given in Table - 2 :

On an average 9,00,000 people are believed to be infected each day. WHO estimates that worldwide about 340 million new cases of curable STIs occur annually, a large proportion of them among women in the reproductive age (3). Surveys in family planning and antenatal clinics in developing countries indicate that the prevalences of syphilis, gonorrhoea and chlamydial

Table - 1 : Classification of STIs

(a) Bacterial	(b) Viral agents
<ul style="list-style-type: none"> • <i>Neisseria gonorrhoea</i> (Gonorrhoea) • <i>Chlamydia trachomatis</i> (Lympho granuloma Venereum, LGV) • <i>Treponema pallidum</i> (Syphilis) • <i>Haemophilus ducreyi</i> (Chancroid) • <i>Mycoplasma hominis</i> • <i>Ureaplasma urealyticum</i> • <i>Calymmatobacterium granulomatis</i> (Granuloma Inguinale, Donovanosis) • Shigella • Campylobacter • Group B Streptococcus • Bacterial vaginosis related Organism 	<ul style="list-style-type: none"> • Human (alpha) herpes virus 1 and 2 • Human (beta) herpes virus 5 • Hepatitis virus B • Human papilloma virus (genital warts) • <i>Molluscum contagiosum</i> • HIV
	(c) Protozoal agents
	<ul style="list-style-type: none"> • <i>Entamoeba histolytica</i> • <i>Giardia lamblia</i> • <i>Trichomonas vaginalis</i>
(d) Ectoparasites	(e) Fungal agents
<ul style="list-style-type: none"> • <i>Sarcoptes scabiei</i> • <i>Phthirus pubis</i> 	<ul style="list-style-type: none"> • <i>Candida albicans</i>

infections range between 6% and 40%. In many countries, STIs are among the top five conditions for which both men and women seek care, representing a considerable drain on health services. Although infection rates are similar in both men and women, the burden of serious consequences of STIs falls mostly on women and their infants.

STD	Incidence (million/yr)
Gonorrhoea	62 million/yr
Genital chlamydial infection	92 million/yr
Syphilis	12 million/yr
Chancroid	07 million/yr
Genital herpes	20 million/yr
Genital human papilloma infection	30 million/yr

(b) India : In India the yearly incidence of STI's is 4 - 5% which accounts for 40 million cases per year.

(i) Syphilis : Prevalence of 1.4 - 2.4% has been reported in serological surveys. The total number of cases due to Syphilis in 2007 was 47,718 with maximum cases coming from Andhra Pradesh, Karnataka, Maharashtra, Madhya Pradesh, Chattisgarh and Gujarat. The cases are almost equally distributed amongst males (24,181) and females (23,235) (4).

(ii) Gonorrhoea : More widely prevalent than syphilis. The total number of cases due to Gonococcal Infection in 2007 was 1,53,050 with maximum cases coming from Andhra Pradesh, Uttar Pradesh, Madhya Pradesh, Karnataka, Maharashtra, Assam, Jammu and Kashmir and Chattisgarh. There are more cases in females (99,699) than males (51,311).

(iii) Chancroid : Widely prevalent in India.

(iv) LGV : It is more prevalent in southern states of Tamil Nadu, AP, Maharashtra and Karnataka than in northern states. Greater prevalence in coastal areas is found.

Commercial Sex Workers (earlier known as prostitutes) - female and male
Identifiable groups of clients of prostitutes, such as : <ul style="list-style-type: none"> Persons staying away from families due to compulsions of occupation; Long - distance truck drivers; Tourists/businessmen; Migrant workers, refugees, displaced persons; Single men in urban settings.
Men who have sex with men, such as : <ul style="list-style-type: none"> Self - identifying homosexual men; Bisexual and covert homosexual men.
Substance users, e.g. injecting drug users and their sexual partners (particularly of importance where there is a high HIV level amongst injecting drug users and/or where prostitution is used to support a drug habit).
Prisoners, especially where juveniles are mixed with long - stay inmates.
Young people (age 10 - 24 years), especially when out of school and unemployed (e.g. street children). WHO has defined adolescents as persons in the 10 - 19 years age gp, Youth as the 15 - 24 years age gp and Young People as combination of these two overlapping groups covering the range 10 - 24 years.

Vulnerable Groups for STIs

This is shown in Table - 3

Syphilis

Syphilis is a systemic disease from the outset and is caused by the spirochaete, *Treponema pallidum* (*T. pallidum*). The organism is 6 to 15 microns in length to 0.15 micron wide. The incubation period has a mean of 21 days with extremes of 10 to 90 days.

Mode of Transmission : Syphilis is usually acquired by sexual contact. Infants acquire congenital infection by transplacental transmission of *T. pallidum*.

Stages of Syphilis

Both congenital and acquired syphilis are divided into early and late stages. Early stage is one which is diagnosed within two years of infection, while the one which is diagnosed after two years is late syphilis. Early acquired syphilis is further subdivided into an incubation period, primary, secondary and early latent stages. Late syphilis includes the late latent stage, late benign stage (stage of gummas), and stages of cardiovascular & neurosyphilis.

Primary Syphilis : The first clinical manifestation is usually a local lesion at the site of entry. The lesion starts as dull red macule, which rapidly becomes papular and then ulcerate. A small, clean, painless, hard ulcer (Hunterian chancre) appears on the site (See Fig. - 1). The early chancre has a clear red base, but later covers with a gray slough. Untreated, a chancre will persist for 3 to 6 wks and then heal. Regional lymphadenopathy develops within a week and the nodes are painless, nontender, small to moderate in size, rubbery and nonsuppurative.

Secondary Syphilis : *T. pallidum* disseminate widely throughout the body. After 3 - 6 weeks, the disease is seen to be systemic. The more common symptoms include sore throat, malaise, headache, weight loss, fever, musculoskeletal pains. A rash of early secondary stage appears on the back, chest, abdomen,

arms and thighs, and also on the mucous patches in the mouth. Rash characteristically includes the palms and the soles. Rashes can be of follicular, annular or papular type. Papular rashes may become large and raised and may resemble viral warts, but they are characteristically broad and flat so called *Condylomata lata*. Generalised lymphadenopathy is common with moderately enlarged nodes rubbery, discrete and nontender. Even the rash may subside with a little treatment but infective relapses occur with varying intervals of latent periods.

Latent Syphilis : Latent syphilis has no clinical manifestations of treponemal infection. Early latent syphilis is infection of less than two years whereas infection of more than two years is referred as late latent

syphilis. Involvement of other systems occurs in 10 percent of cases or less. After 3 to 4 years, the benign manifestations as gumma in bones, deeper parts of the skin, muscles or liver make their appearance. After about 5 - 10 years or upto even 20 years the vital organs like the brain, heart, nerves and big arteries are affected and the severe signs of cardiovascular and neuro - syphilis may appear. The predominant features of cardiac syphilis are aortic regurgitation, aortic aneurysm, arrhythmias and angina. The neurosyphilis can present in a variety of ways meningovascular syphilis, tabes dorsalis and general paresis (8).

Fig. - 1 : Syphilitic Ulcer

Congenital Syphilis

If the infection is transmitted from mother to child in utero then it is called as congenital syphilis. Prevention of congenital syphilis is feasible by effective screening in pregnant women. Screening for syphilis should be conducted at the first prenatal visit. If the expectant mother has syphilis then giving penicillin during pregnancy can prevent transmission to child. All infants born to seropositive mother should be treated with a single dose of Benzathine benzylpenicillin, 50,000 IU/Kg given I.M. whether or not the mothers were treated during pregnancy (with or without penicillin). Such infants should be examined at birth, at monthly interval for 3 months.

Syphilis and HIV Infection

All patients with syphilis should be encouraged to undergo HIV testing because of high frequency of dual infection and its implication for clinical assessment and management. Conventional syphilis treatment often fails in HIV infected patients. Moreover HIV patients demonstrate accelerated progression to early neuro syphilis. As a result of AIDS epidemic neurosyphilis is becoming more common in young adults. In case of congenital syphilis, the mother should be encouraged to undergo HIV testing. Recommended therapy for early syphilis in HIV infected patients is no different; however, careful follow up is necessary to ensure adequacy of treatment.

Diagnosis

The diagnosis of the primary hard chancre is confirmed by finding of *T. pallidum* on the dark - ground examination of the

discharge from the ulcer. In the late primary or further stages and in congenital infection it is confirmed by the WR, Kahn or VDRL reaction. Skin biopsy may be quiet helpful. Other tests are FTA - ABS (Fluorescent Antibody Absorption Test, MHA - TP (Microhaemagglutination Assay for Antibodies to *T. pallidum*) and HATTS (Haemagglutination Treponemal Test for Syphilis).

Treatment

(a) Early Syphilis

In HIV Negative patients : Benzathine Penicillin 2.4 million IU IM after test dose divided half in each buttock, at a single session or Procaine Penicillin 1.2 million IU IM OD after test dose for 10 days.

In HIV Positive patients : Procaine Penicillin 2.4 million IU IM OD after test dose for 14 days or Crystalline Penicillin 30 lac QID IV for 10 days after test dose.

Penicillin allergic non pregnant patients : Doxycycline 100 mg orally, twice daily for 14 days or Tetracycline, 500 mg orally, 4 times daily for 14 days.

Penicillin allergic pregnant patients : Erythromycin, 500 mg orally, 4 times daily for 14 days.

(b) Late Syphilis

In HIV Negative patients : Benzathine Penicillin 2.4 million IU IM after test dose divided half in each buttock, once weekly for 3 consecutive weeks or Procaine Penicillin 1.2 million IU IM OD after test dose for 14 - 21days.

In HIV Positive patients : Procaine Penicillin 2.4 million IU IM OD after test dose for 14 days or Crystalline Penicillin 20 - 40 lac IU 4 hrly IV for 14 days after test dose.

Penicillin allergic non pregnant patients : Doxycycline 100 mg orally, twice daily for 30 days or Tetracycline, 500 mg orally, 4 times daily for 30 days.

Penicillin allergic pregnant patients : Erythromycin, 500 mg orally, 4 times daily for 30 days.

(c) Neurosyphilis

Recommended regimen : Crystalline Penicillin 12 - 24 million IU IV after test dose administered daily in doses of 2 - 4 million IU IV, every 4 hrs for 14 days.

Alternative regimen : Procaine Penicillin 1.2 million IU IM OD after test dose and probenecid, 500 mg orally, 4 times daily, both for 10 - 14 days.

Penicillin allergic non pregnant patients : Doxycycline 200 mg orally, twice daily for 30 days or Tetracycline, 500 mg orally, 4 times daily for 30 days.

Surveillance

Post hospital surveillance must be carried out to ensure radical cure. All clinics should maintain a STD register. The clinic should ensure that the person reports on due dates to MO who should carry out the treatment or send him to hospital whichever is indicated. The examination and treatment of his wife and, if necessary, of the children should also be arranged.

Gonorrhoea

This is the commonest cause of urethritis in India. Gonorrhoea is caused by *Neisseria gonorrhoeae*, a Gram - negative intracellular diplococcus. In women, the cervix is the most

common site of infection. However, the disease can also spread to the uterus and fallopian tubes, causing pelvic inflammatory disease leading to infertility. Gonorrhoea is most commonly spread during genital contact, but can also be passed from the genitals of one partner to the throat of the other during oral sex. Gonorrhoea of the rectum can occur in people who practice anal intercourse. In pregnant women, gonorrhoea can be passed from an infected woman to her newborn infant during delivery if left untreated.

Although transmission from males to females is easier, in females the infection is often mild, and many women who are infected have no apparent symptoms of the disease. Most patients who report are males only. If symptoms of gonorrhoea develop, they usually appear within 2 to 10 days after sexual contact with an infected partner, although a small percentage of patients may be infected for several months without showing symptoms.

Men are more likely to show symptoms than women. The symptoms in men include burning sensation during urination and yellowish - white discharge from the penis that usually stains the undergarments. The symptoms in women include Painful, Burning sensation when urinating, Yellowish or bloody discharge from the vagina, Bleeding between periods, and Abdominal pain. The complications of Gonorrhoea in males include posterior urethritis, urethral stricture, cystitis, prostatitis, seminal vesiculitis, epididymo - orchitis and urethral fistulae (Watercan Perineum). In females, pelvic inflammatory disease, salpingitis with resultant infertility or ectopic pregnancy are important complications.

Diagnosis is made through detection of bacteria in samples taken from the urethra, cervix, throat or rectum. It is generally more cost effective to treat presumptive chlamydial infection also in all persons with gonorrhoea. The treatment includes single dose Ceftriaxone 125 mg IM or Cefixime 400 mg orally or Ciprofloxacin 500 mg orally or Ofloxacin 400 mg orally along with Doxycycline 100 mg orally twice a day for 7 days.

Granuloma Inguinale (Donovanosis)

Donovanosis is caused by the intracellular Gram Negative bacterium *Klebsiella granulomatis*. The disease present clinically as painless, progressive, ulcerative lesions without regional lymphadenopathy. The lesions are highly vascular and can easily bleed on contact.

Recommended regimen is Azithromycin, 1 gm orally on first day, then 500 mg orally, once a day or Doxycycline, 100 mg orally, twice daily.

Chlamydia

Chlamydia is one of the most common and fastest spreading sexually transmitted disease. It stems from a bacterium, *Chlamydia trachomatis*. Women diagnosed with Chlamydia can also infect their newborn infant during delivery. Symptoms usually appear approximately 7 to 21 days after infection and differ for men, women and children. In men, these are Inflammation of the urethra (the bladder duct within the penis), Stinging feeling when passing urine, Clear discharge from penis and possible itchiness around the opening, Pain or tenderness in the testicles. The usual symptoms in women are Stinging

feeling when passing urine, Unusual vaginal discharge, Pain caused by pelvic inflammation (PID), Pain during intercourse, and, in some cases, bleeding between periods. Among new borns of infected mothers, conjunctivitis is an important occurrence. Treatment consists of antibiotics, and should also be given to the patient's partner. A further swab is recommended once treatment has ended to check whether the infection has cleared. The recommended regimens are : Doxycycline 100 mg orally 2 times a day for 7 days or Azithromycin 1 gm orally, once.

Chancroid

Chancroid is a sexually transmitted ulcerative disease often associated with an inguinal bubo. The infection is common in several parts of the world including Africa, the Caribbean and South East Asia. The causal organism of chancroid is a Gram negative bacillus, *Haemophilus ducreyi*. The incubation period ranges between 3 to 10 days. Men usually present with ulcerative lesion or inguinal tenderness. The chancre begins with tender papule surrounded by erythema and within 2 to 3 days after the infection, sloughing ulcer appears on the penis and goes on increasing until it affects a large portion of the penis. Women often present with less obvious symptoms including pain in voiding, pain on defecation, rectal bleeding, dyspareunia or vaginal discharge. Most lesions in males are on either the external or internal surface of the prepuce, on the frenulum, or in the coronal sulcus. In females, most lesions are at the entrance to the vagina and include lesions on the fourchette, labia, vestibule and clitoris. Diagnosis of chancroid depends on the isolation of *H. ducreyi* from a genital ulcer or bubo. Direct examination by a gram stain reveals gram -ve organisms.

The patients of chancroid who are HIV positive are more likely to have treatment failure. If both pathogens are present they act synergistically with increased infectivity, susceptibility and failure to respond to treatment. Chancroid is one of the major reason for the rapid heterosexual spread of HIV - 1 in eastern and southern Africa. The recommended treatment regimen are Ciprofloxacin, 500 mg orally, twice daily for 3 days; Or, Erythromycin, 500 mg orally, 4 times daily for 7 days; Or Azithromycin, 1 gm orally, as a single dose.

Trichomonas Vaginalis

The flagellate protozoan *T vaginalis*, is almost exclusively sexually transmitted in adults (10). The vaginal discharge is offensive alongwith vulval itching in women and urethritis in man. The infection may be asymptomatic also. Recommended regimens are Metronidazole, 2 g orally, in a single dose or Tinidazole, 2 g orally, in a single dose.

Prevention and Control of STIs

Professional, commercialized and, to some extent, amateur female prostitution provides opportunity for male promiscuity. Various chains and combinations of complex social, economic behavioural, environmental, and other intrinsic and extrinsic factors are at the root of this social evil. Economic distress, lack of security in childhood and adolescence, disharmony in married life, social persecution of or an apathy for abandoned, abducted, waylaid, 'fallen' or forlorn women and failure to rescue and rehabilitate them are some of the important causes

which lead women to take refuge in prostitution. Adolescent delinquency is the next important cause. The aim of the control programme is to prevent infections and the ill health resulting from the above conditions through various interventions. Some studies has demonstrated that STD treatment is an important prevention strategy in HIV infection in a general population. The main aims of STD control are :

- To interrupt the transmission of sexually acquired infections;
- To prevent the development of diseases, complications and sequelae;
- To reduce the risk of HIV infection.

These objectives can be achieved by programmes through primary prevention directed at reducing the incidence of disease, and through secondary prevention directed at reducing prevalence by shortening the duration of disease, thus minimizing the probability of complications or sequelae. The determinants of STD epidemiology are as multifaceted as the approaches to prevention and care should be (11).

Primary prevention

Primary prevention activities will be the responsibility of integrated or coordinated AIDS/STD programmes. In primary prevention the aim is to prevent the acquisition of infection and disease. This can be done by promoting :

- Safer sexual behaviour;
- The use of condoms for penetrative sexual acts.

Health education (HE) : Education should be carried out through lectures, multimedia, flip charts, group or individual discussions and articles in the periodicals/journals/newspapers read by general population. Most of the prevention messages will apply to both HIV and conventional STDs but the educational messages which specifically relate to STDs will include :

- Though not necessarily practical or desirable, abstinence is the only way to completely prevent STIs.
- Avoid sex with many different partners. The less sexual partners a person has, the lower the risk of infection.
- Sexually transmitted diseases can be avoided to a large extent by practicing safe sex (e.g. using condoms).
- Information that symptoms and signs may not be noticed, particularly in women, until complications appear.
- Description of recognizable signs and symptoms.
- A list of places where STD advice may be obtained (i.e. basic health care services) and, where available, categorical STD clinics and voluntary counselling centres.
- Assurance that wherever services are obtained in the public sector privacy, confidentiality and respect are guaranteed.
- Advice on assessing one's personal risk of having acquired an STD, and also that of sexual partner(s). (If the assessment suggests a possibility of STD, attendance for STD advice is indicated).

In order to provide realistic, acceptable and culturally appropriate STD messages it is important to appreciate the knowledge, attitudes and practices of the audience. Simple research will be needed to obtain information from communities including :

- Knowledge and perceptions of the importance of STDs.
- Health care seeking behaviour.
- Constraints to seeking STD care.

Secondary prevention

Secondary prevention entails the provision of treatment and care for infected and affected persons. The activities should include :

- Promotion of health care seeking behaviour directed not only at those with symptoms of STDs, but also at those at increased risk of acquiring STDs, including HIV infection.
- The provision of clinical services that are accessible, acceptable and effective, and which offer diagnosis and effective treatment for both symptomatic and asymptomatic patients with STDs, and their partners.
- Support and counselling services for both STD and HIV patients.

Early Detection & Treatment

Intervention Strategies

1. **Case Detection** : It is an essential part of any control programme. The usual methods of early case detection are :

a) Screening : Screening of special high risk or vulnerable groups is done for early detection of disease.

b) Contact Tracing : The sexual partners of diagnosed patients are identified, located, investigated and treated.

c) Cluster Testing : The patients are asked to name other persons of either sex who move in the same socio - sexual environment.

2. **Effective STD care** : Adequate treatment of patients and their contacts is the mainstay of STD control. Holding patient to ensure complete and adequate treatment is key to effective management. The STI care, should aim to provide the comprehensive case management that includes diagnosis, curative treatment, reduction of risk - taking behaviour and the treatment of sexual partners. The objective of case management of patients with STIs is :

- To make a correct diagnosis;
- To provide effective treatment;
- To reduce/prevent future risk - taking behaviour;
- To advise on treatment compliance;
- To promote and provide condoms;
- To ensure sexual partners are notified and appropriately treated.

3. **Syndromic Management of STI** : Many STIs can be identified and treated on the basis of characteristic symptoms and signs. Some examples of common syndromes are upper respiratory infection, gastroenteritis and vaginal discharge, etc. It is often difficult to know exactly what organism is causing the syndrome, and treatment may need to cover several possible infections. Syndromic management refers to the approach of treating STI symptoms and signs based on the organisms most commonly responsible for such syndrome. Many health care facilities in developing countries lack the equipment and trained personnel required for etiological diagnosis of STIs. More so, laboratory tests require resources, add to the cost of treatment, may require clients to make extra visits to the clinic and almost always result in delays in treatment.

For these reasons, syndromic management guidelines are widely used for syndromes such as lower abdominal pain, urethral discharge and genital ulcer (5), even in developed countries

with advanced laboratory facilities. Comparison of traditional, laboratory assisted approach and syndromic approach is given in Table - 4 . Syndromes of women and men are given in Table 5 & 6 respectively. STD management kits under National AIDS Control Program III are given in Table - 7.

4. Notification of sexual partners : Breaking the cycle of infection is a critical part of STI prevention, and so the client should be encouraged to refer his or her partner(s) for treatment, even when no clinical signs of infection are evident. This is known as '*contact tracing*' and providers should advise clients to notify their partners (including those without symptoms) of their exposure and encourage them to seek treatment. These actions should be carried out with sensitivity and consideration of social and cultural factors to avoid ethical and practical problems such as rejection and violence, particularly against women. Partner notification should be conducted in such a way that all information remains confidential. The process should be voluntary and non coercive. WHO recommends two approaches to contacting sexual partners.

Patient referral : In this option the patient is given the responsibility, after adequate health education and counselling, to contact sexual partners and ask them to present for treatment.

Provider referral : This is the situation where the patient is asked to provide the names and addresses of the partners to the health worker so that members of the health staff can contact the partners. It is a costly exercise and will usually not be successful if it is perceived to threaten patient confidentiality.

Support Components

1. Access to services : The provision of accessible, acceptable and effective services is important for the control of STIs. A balanced and comprehensive programme may require strengthening of public sector, the private sector and the informal sector who are providing STI services. It is recommended that routine STI services be integrated into primary health care. Specialized clinics in urban settings are useful for specific groups such as sex workers and their clients, migrant workers, truckers etc.

2. Training of Health Care Providers : Activities may include:

- On - the - job training;
- Training within basic courses;
- Post - basic courses utilizing venereology expertise concentrated in those specialized clinics selected as referral/reference centres;
- Training of trainers so that the health workers are encouraged to train their colleagues ("cascade" principle);
- Distribution of national guidelines in a form that can be understood and used without special additional training.

3. Healthy Diversions : Provide alternative healthy diversions, incentives and facilities for education and betterment in careers and providing a healthy psychological atmosphere for a tranquil life. Excellent facilities should be provided for indoor and outdoor recreation, organized games, educational and recreational outings, amateur dramas and concerts. The leaders, managers and officers should themselves set an example by always maintaining a high moral and ethical standard.

Table-4: Management of Sexually Transmitted Infections

Traditional clinical approach	Laboratory - assisted approach	Syndromic approach
Interviews patient for symptoms	Interviews patient for symptoms	Interviews patient for symptoms <i>(Picks the relevant flowchart)</i>
Does a clinical examination	Does a clinical examination	Does a clinical examination for finding signs; <i>Uses flowcharts as tools</i>
Uses clinical experience to identify symptoms and signs of a specific STI	Collects samples for testing/refers to laboratory for tests	<i>Syndrome identification</i>
Treats for the specific STI	Treats for STIs identified by the results of the laboratory test	<i>Treats patients for the most common organisms responsible for that syndrome (usually 2-3 STIs)</i>
Educates patients for compliance and prevention, promotes condoms and emphasises the importance of partner management	Educates patients for compliance and prevention, promotes condoms and emphasises the importance of partner management	Educates patients for compliance and prevention, promotes condoms and emphasises the importance of partner management

Table - 5 : RTI/STI syndromes for Women

Symptoms	Syndromes	RTIs/STIs
Vaginal discharge	Vaginal discharge syndrome	Gonorrhoea, Chlamydia, Trichomoniasis, Herpes Simplex Candidiasis, Bacterial Vagionosis Cervicitis
Lower abdominal pain	Lower abdominal pain syndrome	Gonorrhoea, Chlamydia, Mycoplasma Gardnerella, Anaerobic Bacteria (Bacteroids, e.g gram positive cocci)
Genital Ulcers	Genital ulcer syndrome	Syphilis, Chancroid, Genital Herpes, Genital Warts, Molluscum Contagiosum, Pediculosis Pubis, Scabies

Symptoms	Syndromes	RTIs/STIs
Urethral Discharge	Urethral/Vaginal discharge syndrome	Gonorrhoea, Chlamydia, Trichomonas
Genital ulcers	Genital ulcer syndrome	Chancroid, Syphilis, Genital Herpes
Inguinal bubos	Inguinal buno syndrome	Lymphogranuloma venereum, Chancroid
Scrotal swelling	Painful Scrotal Swelling	Gonorrhoea, Chlamydia
Genital skin conditions	Genital skin conditions	Genital Warts, Molluscum Contagiosum, Pediculosis Pubis, Scabies

Kit No.	Syndrome	Colour	Contents
1.	Urethral discharge, Anorectal discharge, Cervicitis	Grey	Tab Azithromycin 1 g (1) and Tab cefixime 400 mg (1)
2.	Vaginitis	Green	Tab Secnidazole 2 g (1) and Tab Fluconazole 150 mg (1)
3.	Genital Ulcer Disease	White	Inj. Benzathaine Penicillin 2.4 MU (1) and Tab Azithromycin 1g a disposable syringe 10 ml with 21 gauge needle (1) and sterile water 10 ml (1)
4.	Genital Ulcer disease	Blue	Tab Doxycycline 100 mg (30) and Tab Azithromycin 1g (1)
5.	Genital Ulcer Disease	Red	Tab Acyclovir 400 mg (21)
6.	Lower Abdominal pain	Yellow	Tab Cefixime 400 mg (1) Tab Metronidazole 400 mg (28) Cap Doxycycline 100 mg (28)
7.	Inguinal Bubo	Black	Tab Doxycycline 100 mg (42) and Tab Azithromycin 1g (1)

Summary

Sexually Transmitted Diseases have been replaced by Sexually Transmitted Infections since 1999. STIs are a group of contagious diseases transmitted predominantly by sexual contact and caused by a wide range of bacteria / viruses, protozoa, fungi and ectoparasites. Classification of sexually transmitted infections is based on their etiological agents. True incidence of STI's is not known because of stigma involved. The matter of concern is emergence of antimicrobial resistant agents of STI. Second generation STIs are tending to replace the classical bacterial diseases (syphilis, gonorrhoea, chancroid). Surveys in family planning and antenatal clinics in developing countries indicate that the prevalence of syphilis, gonorrhoea and chlamydial infections range between 6% and 40%. In India the yearly incidence of STI's is 4 - 5% which accounts for 40 million cases per year. Infection rates are similar in both men and women; the burden of serious consequences of STIs falls mostly on women and their infants. The Vulnerable groups for STIs are : Commercial Sex Workers, Identifiable groups of clients of prostitutes, Men who have sex with men, Substance users, Prisoners & Young people. Important STIs are as follows:

SYPHILIS caused by the spirochaete, *Treponema pallidum*, incubation period has a mean of 21 days with extremes of 10 to 90 days. Both congenital and acquired syphilis are divided into early and late stages. Early stage is one which is diagnosed within two years of infection, while the one which is diagnosed after two years is late syphilis. Early acquired syphilis is further subdivided into an incubation period, primary, secondary

and early latent stages. Late syphilis includes the late latent stage, late benign stage (stage of gummas), and stages of cardiovascular & neurosyphilis. Diagnosis of the primary hard chancre is confirmed by finding of *T. pallidum* on the dark - ground examination of the discharge from the ulcer. In the late primary or further stages and in congenital infection it is confirmed by the WR, Kahn or VDRL reaction, Skin biopsy, FTA - ABS (Fluorescent antibody absorption test, MHA - TP (Microhaemagglutination assay for antibodies to *T. pallidum*) and HATTS (Haemagglutination Treponemal Test for Syphilis). Penicillin is the mainstay of treatment.

GONORRHOEA is the commonest cause of urethritis in India and caused by *Neisseria gonorrhoeae*, a Gram - negative intracellular diplococcus. In women, the cervix is the most common site of infection. If symptoms of gonorrhoea develop, they usually appear within 2 to 10 days after sexual contact with an infected partner. Men are more likely to show symptoms than women. The symptoms in men include burning sensation during urination and yellowish - white discharge from the penis that usually stains the undergarments. The symptoms in women include painful, burning sensation when urinating, yellowish or bloody discharge from the vagina. Diagnosis is made through detection of bacteria in samples taken from the urethra, cervix, throat or rectum The treatment includes single dose Ceftriaxone 125 mg IM or Cefixime 400 mg orally or Ciprofloxacin 500 mg orally or Ofloxacin 400 mg orally along with Doxycycline 100 mg orally twice a day for 7 days.

DONOVANOSIS is caused by the intracellular Gram Negative

bacterium *Klebsiella granulomatis*. The disease present clinically as painless, progressive, ulcerative lesions without regional lymphadenopathy. The lesions are highly vascular and can easily bleed on contact. Recommended regimen is Azithromycin, 1 gm orally on first day, then 500 mg orally, once a day or Doxycycline, 100 mg orally, twice daily.

CHLAMYDIA is one of the most common and fastest spreading sexually transmitted disease. Symptoms usually appear approximately 7 to 21 days after infection and differ for men, women and children. In men, these are inflammation of the urethra, tingling feeling when passing urine, clear discharge from penis and possible itchiness around the opening, pain or tenderness in the testicles. The usual symptoms in women are stinging feeling when passing urine, unusual vaginal discharge, pain caused by pelvic inflammation (PID), Pain during intercourse, and, in some cases, bleeding between periods. Treatment consists of antibiotics, and should also be given to the patient's partner. A further swab is recommended once treatment has ended to check whether the infection has cleared. The recommended regimens are : Doxycycline 100 mg orally 2 times a day for 7 days or Azithromycin 1 gm orally, once.

CHANCROID is a sexually transmitted ulcerative disease often associated with an inguinal bubo. The causal organism is a Gram negative bacillus, *Haemophilus ducreyi*. The incubation period ranges between 3 to 10 days. Men usually present with ulcerative lesion or inguinal tenderness. Women often present with pain in voiding, pain on defecation, rectal bleeding, dyspareunia or vaginal discharge. Diagnosis of chancroid depends on the isolation of *H. ducreyi* from a genital ulcer or bubo. Direct examination by a gram stain reveals gm - ve organisms. The recommended treatment regimen are Ciprofloxacin, 500 mg orally, twice daily for 3 days; Or, Erythromycin, 500 mg orally, 4 times daily for 7 days; Or Azithromycin, 1 gm orally, as a single dose.

TRICHOMONAS is caused by the flagellate protozoan *T. vaginalis*, is almost exclusively sexually transmitted in adults. The vaginal discharge is offensive along with vulval itching in women and urethritis in man. The infection may be asymptomatic also. Recommended regimens are Metronidazole, 2 g orally, in a single dose or Tinidazole, 2 g orally, in a single dose.

Prevention and Control of STIs : The main aims of STD control are: To interrupt the transmission of sexually acquired infections; to prevent the development of diseases, complications and sequelae; to reduce the risk of HIV infection.

These objectives can be achieved by programmes through primary prevention directed at reducing the incidence of disease, safer sexual behaviour by using condoms for penetrative sexual acts & IEC and through secondary prevention directed at reducing prevalence by shortening the duration of disease, thus minimizing the probability of complications or sequelae through the provision of clinical services that are accessible, acceptable and effective, and which offer diagnosis and effective treatment for both symptomatic and asymptomatic patients with STDs, and their partners & support and counselling services for both STD and HIV patients.

Syndromic Management of STI - refers to the approach of treating STI symptoms and signs based on the organisms most commonly responsible for such syndrome. Many health care facilities in developing countries lack the equipment and trained personnel required for etiological diagnosis of STIs. More so, laboratory tests require resources, add to the cost of treatment, may require clients to make extra visits to the clinic and almost always result in delays in treatment. For these reasons, syndromic management guidelines are widely used for syndromes such as lower abdominal pain, urethral discharge and genital ulcer, even in developed countries with advanced laboratory facilities. WHO has developed simple flowcharts to guide health care providers in using the syndromic approach to manage STIs.

Notification of sexual partners : Breaking the cycle of infection is a critical part of STI prevention, and so the client should be encouraged to refer his or her partner(s) for treatment, even when no clinical signs of infection are evident. This is known as 'contact tracing' and providers should advise clients to notify their partners (including those without symptoms) of their exposure and encourage them to seek treatment.

Study Exercises

Long Question : Discuss the epidemiology of STIs and methods of prevention and control of STIs.

Short Notes : (1) Syndromic management of STIs (2) Health education in STIs (3) Prevention and control of STIs

MCQs

1. Main aims of STD control are : (a) To interrupt the transmission of sexually acquired infections; (b) To prevent the development of diseases, complications and sequelae (c) To reduce the risk of HIV infection; (d) All
2. Vulnerable groups for STIs are all except (a) Commercial Sex Workers (b) Men who have sex with men, (c) Couples in monogamous relationship (d) Substance users, Prisoners & Young people
3. Health education for STIs should include educational messages viz : (a) Avoid sex with many different partners (b) Description of treatment for different syndromes (c) Description of recognizable signs and symptoms (d) Advice on assessing one's personal risk of having acquired an STD.
4. The usual methods of early case detection is/ are : (a) Screening (b) Contact Tracing (c) Cluster Testing (d) All .
5. Objective of case management of patients with STIs is/ are : (a) To make a correct diagnosis (b) To provide costly treatment (c) To reduce/prevent future risk - taking behaviour (d) To advise on treatment compliance.
6. Presence of Vaginal discharge in syndromic management could be presentation of : (a) Chlamydia, (b) gonorrhoea, (c) bacterial vaginosis infection, (d) all
7. All of the following are STIs except; (a) *Ureaplasma urealyticum* (b) *Shigella* (c) *Candida albicans* (d) *Staphylococcus*.

True or False

1. Regional lymphadenopathy is common with moderately enlarged nodes rubbery, discrete and non - tender in secondary syphilis. T / F
2. In India the yearly incidence of STI's is 10 % which accounts for 40 million cases per year. T/ F
3. Characteristic lesion of secondary syphilis is condyloma lata. T / F
4. Patients of chancroid who are HIV positive are more likely to have treatment failure T/ F
5. Chancroid is one of major reasons for the rapid heterosexual spread of HIV - 1 in eastern & southern Africa T/ F
6. For Neurosyphilis, recommended regimen is crystalline Penicillin 12 - 24 million IU IV after test dose administered daily in doses of 2 - 4 million IU IV, every 4 hrs for 14 days. T/F

Answers : MCQs : (1) d; (2) c; (3) b; (4) d; (5) b; (6) d; (7) d;

True or False : (1) F; (2) F; (3) T; (4) T; (5) T; (6) T

Yaws : The Story of Successful Elimination

Sunil Agrawal

Yaws is a nonvenereal endemic treponematoses caused by the bacterium *Treponema pallidum*, subspecies *pertenue*, a Gram-negative spirochete. Infection is transmitted by skin-to-skin contact among people with poor hygiene practices living in certain warm and humid tropical areas of Africa, the Americas and Asia. Children aged 2 - 5 years are the most vulnerable to infection, which targets the skin, bones and cartilage, causing destruction of tissue and deformities in the late stages. It is characterised by a primary skin lesion (mother yaw) followed by a generalised eruption and late stage of destructive lesions of the skin and bones. Although highly amenable to eradication epidemiologically (humans are the only reservoir of infection, and the disease is localized to a few endemic areas), technologically (curable by a single injection of penicillin) and in terms of cost effectiveness, the disease has not attracted global attention. Yaws is also known as Pian, Bubas or Framboesia.

Reports suggest that yaws was non-existent in India until 1887, when cases were first noticed among tea plantation labourers in Assam. It later spread to a geographically contiguous and predominantly tribal area in central India.

Epidemiology

Agent Factors : Yaws is caused by *T. pertenue* which measures 20 microns in length and found in the epidermis, lymph glands, spleen and bone marrow. The organism rapidly dies outside the tissues. Man is the only known reservoir of infection which is an infected person. The source of infection is usually the skin lesions and the exudates from early lesions. A case can remain infectious for several years intermittently as moist lesions break out.

Host Factors : Yaws is primarily a disease of childhood and adolescence with greater prevalence in males than females. Man has no natural immunity.

Environmental Factors : Yaws is endemic in warm and humid regions with average rainfall of at least 40 inches. Yaws is endemic in tribal and poor population who wear scanty clothes, poor personal hygiene, overcrowding, bad housing, low standard of living etc. which are important socioeconomic factors favouring transmission.

Mode of Transmission : Yaws is transmitted non venerally by Direct contact; Contact with secretions from infectious lesions; by Fomites, since organism remain alive on fomites in suitable climate long enough to cause infection; through Vectors by small flies and insects feeding on lesions, may transmit infection.

Incubation Period : 3-5 weeks.

Clinical Features

Early Yaws : After inoculation of organism on exposed parts of body, the primary lesions appear after incubatory period. The lesion is extra genital, mainly seen on legs, arms, buttocks or face. A generalised large yellow crusted granulomatous eruptions appear resembling Condylomata lata in secondary syphilis along with lymphadenopathy. During next 5 years skin, mucous membrane, periosteal and bone lesions may develop, subside and relapse at irregular intervals. The early lesions are highly infectious.

Late Yaws : After around 5 years the deforming and destructive lesions appear. The lesions of sole and palms are called '*Crab Yaws*', the lesions of soft palate, hard palate, and nose are called '*Gangosa*' and swelling by the side of the nose due to osteo-periostitis of the superior maxillary bone is called '*Goundu*'.

Yaws Eradication Programme

In 1952, a yaws control programme was started in India with assistance from WHO and UNICEF. From 1952 to 1964, about 0.2 million cases of yaws were detected and treated in endemic states; an estimated 9 million people were at risk for the disease. The campaign reduced the incidence of yaws by 93% and the prevalence fell from 14% to <0.1%. Eradication thus became a distinct possibility. Following this dramatic decline in transmission of the disease, active anti-yaws activities were abandoned in most Indian states, and surveillance and treatment of residual cases were to be undertaken through the general health services. The emphasis was on infectious foci rather than on a re-survey of extinct foci. In 1996, 49 districts in 10 states were endemic for this disease.

The Government formulated strategies and approaches to achieve its elimination and a Yaws Eradication Programme was launched in all endemic areas of the country in Mar 1999 to interrupt disease transmission, with the ultimate goal of eliminating yaws. The National Health Policy of 2002 set a target date of 2005 for eradication of yaws. This date was subsequently revised following cases reported in 2003. It was therefore agreed that elimination status should be achieved and maintained for 3 years before declaring eradication.

Objectives of the Yaws Eradication Programme

The Yaws Eradication Programme had 2 objectives :

- (i) Elimination of yaws, defined as zero reporting of cases based on high-quality case searches validated by independent appraisals.
- (ii) Eradication of yaws, defined as the absence of new cases for a continuous period of 3 years, supported by the absence of evidence of transmission through serosurveys among children aged <5 years, i.e. no seroreactivity to rapid plasma reagin or venereal disease research laboratory tests.

Programme strategy

The Yaws Eradication Programme adopted a 2-pronged strategy:

- (i) Using active case-finding through 6-monthly aggressive search operations, and treatment of cases together with prophylaxis of contacts with long-acting penicillin.

- (ii) Generating awareness and mobilizing the community through Information, Education and Communication (IEC) programmes.

To operationalize the strategy, awareness of yaws was created among health professionals and training was provided. All activities were rigorously monitored, evaluated and supervised.

Programme management

The Yaws Elimination Programme was managed and implemented by 2 agencies :

- The NICD was designated by the Government of India as the main agency for planning, guidance, coordination, and monitoring and evaluation of the Programme.
- The State Health Directorates of yaws-endemic states implemented the Programme by utilizing the existing health-care delivery system in coordination and collaboration with the Department of Tribal Welfare and other related departments and institutions.

Programme implementation

The Yaws Elimination Programme was implemented in 10 steps:

1. Identification of affected areas : Affected areas were identified on the basis of historical data obtained from the literature; reports received from state governments; geographical contiguity and epidemiological evidence. A total of 49 districts in 10 states were identified as affected areas where the Programme needed to become operational.

2. Advocacy : Advocacy was essential for focusing attention on the public health challenge posed by yaws and for resource allocation to the Programme. The following points were emphasized :

- Yaws is eradicable with minimal inputs.
- A cost-effective intervention is available in the form of a single injection of benzathine penicillin.
- The Programme would have collateral advantages such as providing an entry point for primary health care among the most marginalized populations.

Advocacy meetings were organized under the chairmanship of the District Magistrate, inviting representatives from departments such as the Panchayati Raj, Integrated Child Development Services Scheme, Education, Tribal Welfare and Forestry.

3. Piloting and expansion of the project : In accordance with the decision of the Government of India, a pilot project was instituted in the Koraput district of Orissa in 1996 - 1997. Based on the observations of the pilot project, the Programme was expanded to other areas so that all endemic districts were covered by 2000.

4. Staff development : The training of medical officers and paramedical staff was given top priority. The training was conducted at NICD, medical colleges, community or primary health-care centres. The NICD prepared the training materials.

5. Community mobilization through IEC : Before active search campaigns were started for the detection and treatment of cases, community awareness was generated in all areas identified as yaws-endemic in the local language. This promoted

self-reporting and encouraged people to seek treatment free of charge at all health facilities. Weekly markets (or *haats*) in tribal areas provided a good opportunity to disseminate information.

6. Detection and treatment of cases and contacts : Trained paramedical workers and community-level functionaries detected cases by making house-to-house visits in the affected areas at frequent intervals. These cases were then confirmed by the medical officer. Case detection was the most important component of the Programme and was done twice a year (once in the post-monsoon period when cases were common). Cases detected during active searches were treated immediately after detection along with their contacts with an injection of long-acting penicillin (1.2 million units for children aged > 10 years and 0.6 million units for those aged < 10 years).

7. Surveillance : Besides active search campaigns, intersearch surveillance was also done by routine reporting of cases during the visits of health workers to the villages and reporting of cases to the local health facilities. Cross-notification of cases and migratory populations was also carried out. As per the protocol, serosurveys were also undertaken in children aged < 5 years to investigate evidence of transmission.

8. Intersectoral coordination : Close intersectoral coordination was maintained between the health and other departments. Examples of intersectoral coordination included community-oriented activities such as the distribution of rice to cases by the Integrated Tribal Development Agency in Andhra Pradesh to motivate them to receive the injections for treatment.

9. Supportive supervision and monitoring : Programme activities were monitored using monthly reporting of cases; reports of active searches; visits of officers from the NICD and central government hospitals, and state or district programme officers; review meetings of programme officers; and by independent appraisals.

10. Validation and certification : After achieving a zero case status in the country, validation was done by a group of experts consisting of dermatologists and public health professionals who visited the areas and interacted with the programme officers, health personnel and community members. Their observations were examined by a group of experts. This exercise will be undertaken annually for 3 years. If the status is maintained for this period, the process of certification for eradication will be initiated.

Declaration of Yaws Elimination

Following nationwide implementation of the Programme, the number of reported cases fell from 3571 in 1996 to 735 in 1997 to 0 cases in 2004, and India reached zero yaws case status. As per the Programme guidelines, this status had to be validated before yaws elimination could be formally declared. At the third Task Force meeting in 2005, it was decided to incorporate laboratory confirmation of yaws in the case definition to ensure elimination status. In May 2006, the Task Force accepted the recommendation of the expert group that yaws had been eliminated from India. This was formally declared by the Minister of Health of India on 19 September 2006.

Factors Contributing to the Success of the Yaws Elimination Programme in India

The success of any public health programme, particularly a programme aimed at elimination or eradication, depends on high-level political commitment and adequate resources. The 2002 National Health Policy statement regarding the target of achieving yaws eradication by 2005 was an indicator of national commitment to rid India of this disease. This gave an impetus to Programme activities, which were reviewed regularly at the highest level, making it possible to ensure the provision of adequate resources. Periodic advocacy meetings with policy-makers, administrators and stakeholders, focusing on the availability of a cost-effective intervention and the knowledge that the disease is eradicable with marginal inputs, paid rich dividends.

Active case-finding was one of the most important strategies and was vigorously pursued. Every year, at least 1 search was organized in the post-monsoon period. All suspected cases and contacts were treated. An effective monitoring and supervision mechanism to support peripheral-level health workers and review their activities helped to identify constraints and take the necessary corrective measures. The establishment of a high-level Task Force under the chairmanship of the Director General of Health Services was useful for advocacy, resource mobilization, undertaking periodic reviews, monitoring progress and advising on annual Plans of Action. A simplified information system was developed and integrated into general public health services. Prompt action ensured prevention of further spread of infection.

India eliminated Yaws in 2006, showing that this is possible if there is political will, a well-structured delivery system and a modest amount of funding. It now hopes to declare eradication of Yaws in 2010, which will be a remarkable public health success. Following India's example, the WHO South-East Asia Region has set a target of 2012 for the elimination of yaws in the remaining 2 endemic countries - Indonesia and Timor-Leste.

From Elimination to Eradication : The Road Map

India aims to declare eradication of yaws by 2010. The professional commitment of health staff combined with strong policy and administrative support has to be ensured until the goal of eradication is achieved. To overcome the tendency for complacency, a mechanism for supportive supervision and monitoring has been strengthened. The following activities are ongoing to ensure that success is achieved :

- Yearly active case searches and concurrent serosurveillance
- Surveillance and IEC activities
- Verification of reports by the states and districts
- Validation of the zero report through yearly appraisal of the Yaws Elimination Programme by independent experts
- Meeting of State Programme officers
- Verification of cases and investigation of rumoured cases
- Constitution of the National Commission for Certification of Eradication of Yaws from India and validation by international organizations.

Summary

Yaws is a non-venereal endemic treponematosi s caused by the bacterium *Treponema pallidum*, subspecies *pertenue*, a Gram-negative spirochete. Infection is transmitted by skin-to-skin contact among people with poor hygiene practices living in certain warm and humid tropical areas of Africa, the Americas and Asia. Man is the only known reservoir of infection which is an infected person. The source of infection is usually the skin lesions and the exudates from early lesions. Children aged 2 - 5 years are the most vulnerable to infection, which targets the skin, bones and cartilage, causing destruction of tissue and deformities in the late stages. Reports suggest that yaws was non-existent in India until 1887, when cases were first noticed among tea plantation labourers in Assam. It later spread to a geographically contiguous and predominantly tribal area in central India. Yaws is endemic in tribal and poor population who wear scanty clothes, poor personal hygiene, overcrowding, bad housing, low standard of living etc. Yaws is transmitted non venereally by direct contact, contact with secretions from infectious lesions and by fomites. Incubation Period is 3-5 weeks. In 1952, a yaws control programme was started in India with assistance from WHO and UNICEF. The campaign reduced the incidence of yaws by 93% and eradication thus became a distinct possibility. The Government formulated strategies and approaches to achieve its elimination and a Yaws Eradication Programme was launched in all endemic areas of the country in Mar 1999 to interrupt disease transmission. It adopted a 2-pronged strategy : (i) Using active case-finding through 6-monthly aggressive search operations and (ii) Generating awareness and mobilizing the community through Information, Education and Communication (IEC) programmes. The Yaws Elimination Programme was implemented in 10 steps : Identification of affected areas; Advocacy; Piloting and expansion of the project; Staff development; Community mobilization through IEC; Detection and treatment of cases and contacts; Surveillance; Intersectoral coordination; Supportive supervision and monitoring; Validation and Certification. At the third Task Force meeting in 2005, it was decided to incorporate laboratory confirmation of yaws in the case definition to ensure elimination status. In May 2006, the Task Force accepted the recommendation of the expert group that yaws had been eliminated from India. This was formally declared by the Minister of Health of India on 19 September 2006.

Study Exercises

Long Question : Discuss the Yaws eradication programme in India and factors contributing to its success.

MCQs :

1. Factors contributing to the success of the Yaws Elimination Programme in India are (a) high-level political commitment (b) adequate resources (c) active case-finding (d) effective monitoring and supervision (e) all
2. The Yaws Elimination Programme was implemented in following steps, except (a) Community mobilization through IEC (b) Detection and treatment of cases and contacts (c) Passive surveillance (d) Supportive supervision and monitoring validation and certification.
3. Yaws Eradication Programme adopted following strategy (a) using active case-finding through 6-monthly aggressive search operations and treatment of cases together with prophylaxis of contacts with long-acting penicillin (b) generating awareness and mobilizing the community through Information, Education and Communication (IEC) programmes (c) both (d) none
4. Name the agency which is responsible for implementation of Yaws Elimination Programme in our country (a) NICD (b) State Health Directorates of yaws-endemic states (c) WHO (d) a & b
5. Following India's example, the WHO South-East Asia Region has set a target of 2012 for the elimination of yaws in the remaining 2 endemic countries, which are : (a) Indonesia & Timor-Leste, (b) Nepal & Sri Lanka (c) Bangladesh & Bhutan (d) none

Fill in the Blanks

1. The lesions of sole and palms are called _____, the lesions of soft palate, hard palate and nose are called _____ and swelling by the side of the nose due to osteo-periostitis of the superior maxillary bone is called _____.
2. India aims to declare eradication of yaws by _____.
3. In 1952, a yaws control programme was started in India with assistance from _____.
4. The National Health Policy of 2002 set a target date of _____ for eradication of yaws.
5. As per programme document 'elimination of yaws', defined as _____ reporting of cases based on high-quality case searches validated by independent appraisals.
6. In the year _____ India reached zero yaws case status.

Answers : MCQs : (1) e; (2) c; (3) c; (4) d; (5) a.

Fill in the Blanks : (1) Crab Yaws, Gangosa, Gondu; (2) 2010; (3) WHO & UNICEF; (4) 2005; (5) Zero; (6) 2004

Sunil Agrawal

The human immunodeficiency virus (HIV) is a retrovirus that infects cells of the human immune system, destroying or impairing their function. In the early stages of infection, the person has no symptoms. However, as the infection progresses, the immune system becomes weaker, and the person becomes more susceptible to opportunistic infections. The most advanced stage of HIV infection is acquired immunodeficiency syndrome (AIDS). It can take 10-15 years for an HIV-infected person to develop AIDS; antiretroviral drugs can slow down the process even further.

HIV is transmitted through unprotected sexual intercourse (anal or vaginal), transfusion of contaminated blood, through contaminated needles (either due to sharing or iatrogenic) and between a mother and her infant during pregnancy, childbirth and breastfeeding.

AIDS is a severe life threatening clinical condition first recognized as a clinical syndrome in 1981. This syndrome represents the late clinical stage of infection with the human immunodeficiency virus (HIV), which most often results in progressive damages to the immune and other organ systems, including the CNS (1). This means that a person who carries the HIV virus is prone to many different illnesses and may die from diseases that are harmless to healthy people.

Epidemiology

Magnitude of the Problem

Worldwide : HIV/AIDS is one of the most urgent threats to global public health. Global efforts to address the AIDS epidemic, including increased access to effective treatment and prevention programmes have also been commendable. Estimates of the size and course of the HIV epidemic are updated every year by UNAIDS and WHO. In 2007, improved survey data and advances in estimation methodologies led to substantially revised estimates of numbers of people living with HIV, of HIV related deaths and of new infections worldwide (See Box - 1).

The number of people living with HIV was estimated at 33.2 million; these may be as few as 30.6 million or as many as 36.1 million. There were 2.5 million new infections and 2.1 million deaths during 2007. The findings are presented in Table - 1.

Table - 1 : WHO / UNAIDS estimates for year 2007 (numbers in million)

Age group	Living with HIV	Newly infected	Died of HIV
Adults	30.8	2.3	1.8
Children < 15 yrs	2.0	0.37	0.27
Total	33.0	2.7	2.0

Notes : (A) Half, may be slightly more of the adults living with HIV were women. (B) For adults living with HIV, the lowest and highest estimates were 30 and 36 million respectively.

Over 6800 new HIV infections takes place every day out of which more than 96% are in low and middle income countries. About 1200 are in children under 15 years of age and rest about 5600 are in adults aged 15 years and older .

Sub-Saharan Africa continues to bear the brunt of the global epidemic. Two thirds of all adults and children with HIV globally live in this region, a total of 22.5 million. Although other regions are less severely affected, 4 million people in south and south east Asia and 1.6 million in eastern Europe and central Asia were living with HIV/AIDS. Almost 72% of all adult and child deaths due to AIDS in 2006 were in the sub Saharan Africa region. More adult women are now getting infected with HIV, for every 10 adult men there are 14 adult women who are living with HIV. The interaction of HIV/AIDS with other infectious diseases is an increasing public health concern (2, 3, 4).

As of Dec 2007, an estimated 4 Million people are living with HIV in the South and South East Asia region. The number of people who become infected every day (over 6800) is greater than the number who die of the disease (around 6000). On 01st Dec 2003, WHO and UNAIDS announced a detailed plan to reach the "3 by 5 target" of providing antiretroviral treatment (ART) to three million people living with HIV in the developing countries by the end of 2005.

Box - 1 : Understanding the data and downward estimates

HIV infection is detected by testing for HIV antibodies in the blood, although in practice only a small proportion of people ever have an HIV test. For many years, scientists trying to estimate HIV prevalence had to rely on tests carried out on ladies attending Ante-natal care clinic (low risk groups) and certain defined high risk groups (as STD patients). More recently, it has been possible to introduce antibody testing into household surveys that have large samples of the population selected at random. This gives a more unbiased estimate of the overall prevalence of HIV infection, provided survey participation rates are high. It was found that prevalence estimates from these surveys are generally lower than those calculated earlier on the basis of pregnant women or high risk groups. Currently, new infection rates and deaths due to HIV/AIDS are estimated from the application of statistical models using data on:

- HIV prevalence
- Average time between HIV infection and death in the absence of treatment
- Survival rates of people receiving treatment

For the same level of prevalence, this longer average survival period has resulted in lower estimates of new infections and deaths due to AIDS. For the aforesaid reasons, there seems to have been a downward revision in the worldwide and national estimates of HIV infections.

National Scenario : The changing trend in the country indicates that HIV infection is spreading in two ways : From urban to rural areas and from individuals practicing high risk behaviour to the general population called Type 4 pattern, first described in Thailand. Revised estimates at the National level are 2.47 million people living with HIV which was released by National AIDS Control Organization (NACO) in July 2007. In India, 0.28% of adults aged 15-49 are infected with HIV, (including 0.35% in urban and 0.25% in rural areas or 0.36% in males and 0.22% in females). The cumulative number of AIDS cases in the country has risen to 1,99,453 by Dec 2007 (5). Majority of the HIV infections (88.5%) are in the age group of 15-49 years, out of which 31.8% are in the 15-29 years age group. Amongst injecting drug users the infection has spread very rapidly in Manipur with HIV prevalence of more than 70% (6). The estimated prevalence (adults aged 15 to 49 years) in some of the states is shown in Table - 2 :

State	Prevalence rate (%)
Manipur	1.13
Andhra Pradesh	0.97
Karnataka	0.69
Maharashtra	0.62
Tamil Nadu	0.34
Uttar Pradesh	0.07

Source : NFHS - 3, 2007

Agent Factors

Reservoir : The only reservoir are Humans - cases and carriers. Once a person is infected, the virus remains in the body life long. Since symptoms takes years to manifest, the carrier can infect other people for years.

Source of Infection : The virus has been found in greatest concentration from blood, semen and CSF. Lower concentrations in tears, saliva, breast milk, urine, and cervical and vaginal secretions.

Virology : HIV belongs to a class of viruses called retroviruses. Two types have been identified : Type-1 (HIV-1) and Type-2 (HIV-2). Retroviruses are RNA (Ribonucleic Acid) viruses, and in order to replicate (duplicate), they must make a DNA (Deoxyribonucleic Acid) copy of their RNA. It is the DNA genes that allow the virus to replicate. Like all viruses, HIV can replicate only inside cells, commandeering the cell's machinery to reproduce. Only HIV and other retroviruses, however, once inside a cell, use an enzyme called reverse transcriptase to convert their RNA into DNA, which can be incorporated into the host cell's genes (11).

Survival in Nature : HIV is a fragile virus. It cannot live for very long outside the body. As a result, the virus is not transmitted through day-to-day activities such as shaking hands, hugging, or a casual kiss. You cannot become infected from a toilet seat, drinking fountain, doorknob, dishes, drinking glasses, food, or pets. You also cannot get HIV from mosquitoes.

Host Factors

Age : Most cases occur in sexually active persons aged 20-49 yrs. This group represents the productive members of the society, and those responsible for child bearing and child rearing.

Sex : AIDS is still most common among homosexual and bisexual men. However, in more developed countries the disease is becoming more frequent among heterosexuals, especially young people. In the UK, new cases of HIV are now more prevalent among heterosexuals.

High risk groups : Intravenous drug users and people with many sexual partners are particularly at risk from HIV. Higher rate of HIV infection is found in CSWs and their clients, transfusion recipients of blood and blood products, haemophiliacs. Certain persons are at high risk due to the compulsions of their occupation, as truck drivers, military personnel, and migratory labour.

Social factors in Epidemiology : HIV is truly a social disease with medical background. Rapid industrialization, increasing availability of Commercial Sex Workers (CSWs), migration of young persons to urban areas in search of jobs and away from the traditional social control of their families, compulsively staying away from family due to occupational requirements, poverty with consequent resorting to sex for money, trafficking of women and girl children, availability of pornographic literature and visuals which has been further enhanced by internet, are some of the important social causes of the causation and perpetuation of this disease. Lack of knowledge about the causation and prevention and the intense stigma associated with HIV/AIDS further accentuate the problem.

Transmission Dynamics (1, 7)

Incubation period : It is widely variable. Although the time from infection to the development of detectable antibodies is generally 1-3 months, the time from HIV infection to diagnosis of AIDS has an observed range of less than 1 year to 10 years or more. However, it is estimated that 75% of those infected with HIV will develop AIDS by the end of ten years.

Period of Communicability : Presumed to begin early after onset of HIV infection and extend throughout life. Infectiousness increases with increasing immune deficiency; clinical symptoms and other STDs. Recent studies indicate that it may be high during initial period after HIV infection. However patients on ART are less likely to transmit HIV infection to others (12).

Transmission of HIV : HIV can be transmitted from person to person through :

(a) **Sexual contact** : Sexual intercourse is the leading way of transmission of HIV. This form of transmission occurs mainly among high-risk groups, such as men who have sex with men and CSWs. During intercourse, the virus can enter the body through the mucosal linings of the vagina, vulva, penis, or rectum or, rarely, via the mouth and possibly the upper gastrointestinal tract after oral sex. The risk of sexual transmission is in direct relationship with the amount of trauma and laceration of the recipient's genital mucosa. So, receptive anal intercourse provides the greatest risk. The rate of transmission from a man to a woman is greater than the opposite. The likelihood

of transmission is increased by factors that may damage these linings, especially other sexually transmitted infections that cause ulcers or inflammation.

(b) Sharing of HIV contaminated needles and syringes : Users of illicit parenteral drugs continue to account for a large number of infections. Needle-sharing and dilution of drug with blood are common practices, as well as engagement in high-risk sexual practices like exchanging sex for drugs and money.

(c) Transfusion of infected blood or its components (platelets, factor VIII and IX etc.) : The risk of contracting HIV infection from transfusion of a unit of infected blood is estimated to be over 95%. The HIV transmission through blood is dose dependent, hence the risk of getting infected through a contaminated needle, syringe or any other body piercing equipment is very much lower than with transfusion.

(d) Vertical transmission (i.e. from infected mother to foetus) : Vertical (mother to child) transmission is the number one cause of HIV infection in children. It occurs mostly during the perinatal period, and during breastfeeding. The risk of transmission is related to maternal factors (viral load, disease stage and CD4 cell count), obstetric factors, infant prematurity and the extent of breastfeeding. There is no threshold in viral load below which transmission will not occur. The risk of transmission increases in linear fashion with viral load. However, mothers whose viral load has been reduced to <1000 RNA copies per ml are not likely to transmit infection to their babies. From 15% to 30% infants born to HIV-infected mothers are infected before, during, or shortly after birth; treatment of pregnant women results in marked reduction in infant infections.

Factors which increase the risk of transmission are outlined in Table - 3.

Course of HIV infection in Host

Once it enters the body, HIV infects a large number of CD4+ cells and replicates rapidly. During this acute or primary phase of infection, the blood contains many viral particles that spread throughout the body, seeding various organs, particularly the lymphoid organs. Two to 4 weeks after exposure to the virus, up to 70 percent of HIV-infected people suffer flu-like symptoms related to the acute infection, characterized by fever, myalgias, arthralgias, and generalized non-specific lymphadenopathy. Some patients develop a generalized papulomacular rash, and a few develop hepatitis and aseptic meningitis. This illness is known as the acute sero-conversion illness or *acute retroviral syndrome or primary HIV infection*. It is usually a benign, self-limited illness, and few patients seek medical attention. The infection is frequently unrecognized even in those patients who go to their health care provider. The resolution of symptoms coincides with the appearance of specific immunity and seroconversion. Their immune system fights back with killer T cells (CD8+ T cells) and B cell-produced antibodies, which dramatically reduce HIV levels.

Following this initial phase, a person may then remain free of HIV-related symptoms for years despite continuous replication of HIV in the lymphoid organs that had been seeded during the acute phase of infection. These patients are asymptomatic, many don't know they are infected, but they are very infectious

Table-3: Factors Increasing the Risk of Acquisition of HIV	
Common to all transmission categories	
- High Viral Load	- Presence of AIDS
- Lower CD4 cell count	- Seroconversion illness
Vertical transmission	
- Older gestational age	- Prolonged rupture of membranes
- Vaginal delivery (lower in caesarian)	- No peripartum prophylaxis
- Chorioamnionitis	- Lower birth weight
- First born of the twins	
Breast Feeding	
- Longer duration feeding	- Younger age
- Lower parity	- Mastitis
Sexual transmission	
- STIs especially genital ulcers	- Cervical ectopy
- Male to male vs heterosexual sex	- Non circumcised
- Receptive vs insertive anal sex	- Rectal or vaginal trauma
	- Menstruation
	- Increased no. of partners
IV drug use	
- Sharing equipment	- Linked commercial sex
- Intravenous use	- Incarceration
- Frequency of use	- Lower income
- Cocaine use	
Occupational transmission	
- Previous arterial or venous siting	- Deep injury
	- Visible blood on device

and may spread the disease to their sexual and parenteral drug partners, and to their offspring. One reason that HIV is unique, is the fact that despite the body's aggressive immune responses, which are sufficient to clear most viral infections, some HIV invariably escapes. This is due in large part to the high rate of mutations that occur during the process of HIV replication. Finally, the virus may hide within the chromosomes of an infected cell and be shielded from surveillance by the immune system. Such cells can be considered as a latent reservoir of the virus. Because the antiviral agents currently in our therapeutic arsenal attack actively replicating virus, they are not effective against hidden, inactive viral DNA (so-called provirus).

Results from large epidemiologic studies indicate that the median time from infection with HIV to the development of AIDS-related symptoms has been approximately 10 to 12 years in the absence of antiretroviral therapy. However, there is a wide variation in disease progression. Approximately 10 percent of HIV-infected people in these studies have progressed to AIDS within the first 2 to 3 years following infection, while up to 5 percent of individuals in the studies have stable CD4+ T cell counts and no symptoms even after 12 or more years called "*chronic non-progressor*" state, by which a small percentage of

infected patients maintain the integrity of their immune system throughout the years. Cohort studies of HIV infected adults indicate that about 15%-20% develop AIDS within 5 years, about 50% within 7-10 years and close to 70% within 15 years. The case fatality of AIDS is very high and most patients (80-90%) die within 3-5 years after the diagnosis of AIDS is made (7). The presence of either generalized Kaposi sarcoma or cryptococcal meningitis is sufficient for the case definition of AIDS. Patients with AIDS are more likely to acquire a variety of diseases that persons with a stronger immune system would not. At this stage, patients frequently develop a hypercatabolic state due to increased levels of cytokines related to their chronic disease. This leads to weight loss, progressive weakness, and often chronic diarrhoea. They are also prone to develop *Pneumocystis carinii* pneumonia. This predisposition increases as the CD4+ count declines. Patients with a CD4+ count below 50 cells/mm³ are at risk of developing disseminated *Mycobacterium avium* infection, cytomegalovirus disease, and Progressive Multifocal Leukoencephalopathy (PML).

Case Definitions

Expanded WHO case definition for AIDS surveillance :

An adult or adolescent (>12 yrs) is considered to have AIDS if a test for HIV antibody is positive, and one or more of the following criteria are present :

- Weight loss > 10% or cachexia, with diarrhoea or both, intermittent or constant, for > 1 month.
- Tuberculosis with weight loss > 10%, or disseminated, miliary, or extrapulmonary tuberculosis.
- Kaposi's sarcoma.
- Neurologic impairment preventing independent daily activities.
- Oesophageal candidiasis.
- Cryptococcal meningitis.
- Life threatening or recurrent episodes of pneumonia.
- Invasive cervical cancer.

WHO case definition for AIDS surveillance : For the purpose of AIDS surveillance an adult or adolescent (>12 years of age) is considered to have AIDS if at least 2 of the following major

Table - 4 : WHO case definition for AIDS surveillance - Adults	
Major signs	
Weight loss > 10% of body weight	
Chronic diarrhoea for more than 1month	
Prolonged fever for more than 1 month (intermittent or constant)	
Minor signs	
Persistent cough for more than 1 month	
Generalized pruritic dermatitis	
History of herpes zoster	
Oropharyngeal candidiasis	
Chronic progressive or disseminated herpes simplex infection	
Generalized lymphadenopathy	

signs are present in combination with at least 1 of the minor signs listed in Table - 4 & 5, and if these signs are not known to be due to a condition unrelated to HIV infection.

WHO Clinical Staging of HIV/AIDS and Case Definition :

The clinical staging and case definition of HIV for resource-constrained settings were developed by the WHO in 1990 and revised in 2005. Staging is based on clinical findings and does not require a CD4 cell count. This staging system is used in many countries to determine eligibility for antiretroviral therapy. Clinical stages are categorized as 1 through 4, progressing from primary HIV infection to advanced HIV/AIDS. For the purpose of the WHO staging system, adolescents and adults are defined as individuals aged ≥13 years. The details of this staging and case definition is shown in Table - 6.

HIV Testing

Screening tests (HIV Testing) : Once HIV enters the body, the body starts to produce antibodies. Most HIV tests look for these antibodies rather than the virus itself. There are many different kinds of HIV tests, including rapid tests and home test kits. At first a highly sensitive test is used called ELISA, while a second confirmatory test is used to weed out any false positive or to confirm indeterminate results. The confirmatory test, Western Blot is a highly specific test. Alternatively, for confirmation 3 ELISA/rapid/simple tests based on different biological systems may be performed. The "Window Period" is the interval between entry of HIV into the body and appearance of antibodies to it. This period may range between 1- 6 months and during this period the individual may test negative for HIV by conventional tests.

Other tests for HIV infection : There are certain circumstances, such as screening a baby born to an HIV-positive mother, or diagnosing acute retroviral syndrome, or research purposes, in which antibody testing is not reliable. In those situations, the diagnosis should be made by looking for viral particles, such as RNA, pro-viral DNA (RT-PCR or bDNA assays), or proteins (p24 antigen levels), or viral culture and its ability to form syncytium in culture. The viral RNA viz. PCR (Polymerase Chain Reaction) method and the bDNA method (branched chain DNA) can detect the number of viral particles (virions) in blood and are being increasingly used to predict prognosis and monitor efficacy of antiviral therapy.

Table - 5 : WHO case definition for AIDS surveillance - Children	
Major signs	
Weight loss or abnormally slow growth	
Chronic diarrhoea for more than 1month	
Prolonged fever for more than 1 month	
Minor signs	
Recurrent common infections, e.g. ear infection, pharyngitis	
Persistent cough	
Generalized rash	
Oropharyngeal candidiasis	
Generalized lymphadenopathy	

Table - 6 : WHO Clinical Staging of HIV/AIDS for Adults and Adolescents (Interim Definitions)	
Primary HIV Infection	
• Asymptomatic • Acute retroviral syndrome	
Clinical Stage 1	
• Asymptomatic • Persistent generalized lymphadenopathy <i>Performance scale 1 : Asymptomatic, Normal activity</i>	
Clinical Stage 2	
<ul style="list-style-type: none"> • Moderate unexplained weight loss (<10% of presumed or measured body weight) • Recurrent respiratory infections (respiratory tract infections, upper respiratory infections, sinusitis, bronchitis, otitis media, pharyngitis) • Herpes zoster • Minor mucocutaneous manifestations (angular cheilitis, recurrent oral ulcerations, seborrheic dermatitis, prurigo, papular pruritic eruptions, fungal fingernail infections) <i>Performance scale 2 : Symptomatic, Normal activity</i>	
Clinical Stage 3	
<i>(a) Conditions for which a presumptive diagnosis can be made on the basis of clinical signs or simple investigations</i>	
Severe weight loss (>10% of presumed or measured body weight); Unexplained chronic diarrhoea for >1 month; Unexplained persistent fever for >1 month (intermittent or constant); Oral candidiasis (thrush); Oral hairy leukoplakia; Pulmonary tuberculosis within the last 2 years; Severe presumed bacterial infections (e.g. pneumonia, empyema, pyomyositis, bone or joint infection, meningitis, bacteremia); Acute necrotizing ulcerative stomatitis, gingivitis or periodontitis	
<i>(b) Conditions for which confirmatory diagnostic testing is necessary</i>	
Unexplained anaemia (hemoglobin <8 g/dL); Neutropenia (neutrophils <500 cells/ μ L); Thrombocytopenia (platelets <50,000 cells/ μ L) <i>Performance scale 3 : bedridden <50% of the day during the last month</i>	
Clinical Stage 4	
<i>(a) Conditions for which a presumptive diagnosis can be made on the basis of clinical signs or simple investigations</i>	
HIV wasting syndrome; <i>Pneumocystis jiroveci</i> (formerly carinii) pneumonia; Recurrent severe or radiologic bacterial pneumonia; Chronic herpes simplex infection (oral or genital, or anorectal site) for >1 month; Esophageal candidiasis; Extrapulmonary tuberculosis; Kaposi sarcoma; Central nervous system toxoplasmosis; HIV encephalopathy	
<i>(b) Conditions for which a confirmatory diagnostic testing is necessary</i>	
Cryptococcosis, extrapulmonary; Disseminated nontuberculosis Mycobacteria infection; Progressive multifocal leukoencephalopathy; Candida of the trachea, bronchi or lungs; Cryptosporidiosis; Isosporiasis; Visceral herpes simplex infection; cytomegalovirus infection (retinitis or organ other than liver, spleen or lymph node); Any disseminated mycosis (e.g. histoplasmosis, coccidioidomycosis, penicilliosis); Recurrent nontyphoidal Salmonella septicemia; Lymphoma (cerebral or B-cell non-Hodgkin); Invasive cervical carcinoma; Visceral leishmaniasis. <i>Performance scale 4 : Bedridden >50% of the day during the last month</i>	

Several laboratory markers are available to provide prognostic information and guide therapy decisions. The most widely used marker is the absolute CD4 lymphocyte count. As the count decreases, the risk of opportunistic infections increases. People with healthy immune system usually have counts above 950 CD4 cells per cu mm of blood. The number falls over the course of HIV infection. People with AIDS usually have CD4 cell count below 200 per cu mm. The trend of the count is more important than a single reading (9).

Who should be offered the HIV test : It is recommended that the following category of persons should be offered HIV testing, after adequate risk assessment, counselling and after obtaining their informed consent :

- Persons with high-risk behaviour
- Men who have sex with men (MSM)
- Injection drug users
- Persons with multiple sex partners
- Persons who have exchanged money or drugs for sex
- Persons who have had sexual contact with an HIV-positive person or a person at risk for HIV infection
- Persons who request testing, regardless of risk
- Persons with certain medical conditions
 - AIDS-defining illness
 - Oral candidiasis
 - Generalized unexplained lymphadenopathy
 - Symptoms consistent with acute retroviral syndrome
 - Any sexually transmitted disease

- Tuberculosis
- Pregnancy
- Other (e.g. pneumonia, herpes zoster, recurrent vulvovaginal candidiasis, Seborrhoeic dermatitis, new onset psoriasis or oral hairy leukoplakia)
- Persons who have been sexually assaulted
- Persons who have had occupational exposures
- All blood donors (for blood safety)
- All antenatal cases and the husbands/children of the HIV positive cases
- Spouses and dependant children of HIV infected persons
- Patients on dialysis
- Other high risk cases e.g. those who test positive for HbsAg/ HCV/ VDRL etc.
- Duty/travel overseas.

The process of testing a person for HIV involves five steps

1. Risk assessment : The health care provider should elicit information about high-risk sexual behaviour and lifestyle, illicit drug use, and medical conditions that may be associated with an increased incidence of HIV infection. Counselling and testing is then offered as appropriate. All pregnant women should be offered an HIV test. Treatment for her and her baby should be available if the woman tests positive.

2. Pre-test counselling : Pre-test counselling is no longer required, except in the case of a provider who attends a pregnant woman for conditions related to her pregnancy. Pre test counselling should include information about the purpose of the HIV test; the indications for testing (medical and/or high risk); the possible need for retesting; information on how to avoid contracting and transmitting HIV infection; the potential social, medical, and economic effects of a positive test result; and, options for eliminating/reducing risk behaviour.

3. Informed consent : An informed consent must ALWAYS be obtained.

4. Testing : Testing for HIV is performed by looking for HIV-specific antibodies in the patient's blood. The usual screening test is by the ELISA (Enzyme-Linked Immunosorbent Assay) method. Even though it is a very specific method, a positive result must always be confirmed by a second confirmatory test.

5. Post-test counselling : All reasonable efforts must be made to notify the test subject of his or her test result. Post test Counselling should be offered to all test subjects and should be based on the test result and the individual's needs as determined during the risk assessment. Following information should be provided :

- *If test result is negative*
 - Discuss transmission and need for behaviour modification
 - Safer sex
 - Advice second test 3 months after last exposure
- *If test result is positive*
 - Explain significance and implications
 - Organize urgent medical follow up (the availability of appropriate medical and support services)

- Assess coping strategy
- Provide verbal and written information
- Discuss confidentiality issues
- Organize emotional and practical support
- Information on preventing transmission of HIV
- Importance of notifying sex and/or needle-sharing partners

Prevention and Control

Preventing new HIV infections is a priority in any HIV control program. There needs to be a strong political and resource commitment from the government and the community for this purpose. Education, support, access to healthcare and effective treatment all must be included in a successful program. Sexual education is an important component, and should be always provided at an age-appropriate level. Primary care physicians need to teach their patients to avoid high-risk sexual behaviour and promote safe sex practices. Patients who inject illicit drugs should also be taught about the risks of needle-sharing. Healthcare workers and any person with occupational exposure to blood borne pathogens need to be proficient in using standard infection control precautions.

Other components of a prevention program include extensive HIV testing programs and treatment of HIV infection and other STDs in the community. The various strategies of HIV/AIDS prevention includes :

(a) Information, Education and Communication (IEC)

IEC should promote :

- (i) Delay in first sexual encounter (targeting adolescents and young adults)
- (ii) Reduction in number of sexual partners (ideally mutually monogamous relationship)
- (iii) Promoting safe sex through use of condoms.

(b) Prevention of blood-borne HIV transmission

All blood should be screened for HIV before transfusion. All blood banks will transfuse blood only after it has been tested and found negative for HIV 1 & 2, HBSAg, Malaria, Syphilis, and other tests as specified in the National Blood Policy (14). All blood banks should therefore obtain the necessary license. Concerned Medical Officers are advised to acquaint themselves with the provisions of afore-mentioned Govt of India Gazette (15).

Strict sterilization practices should be ensured in hospitals and clinics. Autoclaved syringes and needles and other instruments should be used. Sharing of needles among drug addicts should be eliminated by health education.

(c) Antiretroviral prophylaxis

The prohibitive cost precludes the use of antiretroviral drugs on a mass scale in management of HIV infection in developing countries. Its use at present is limited to prevent perinatal transmission and for post exposure prophylaxis in cases of occupational exposure of Health Care Worker (HCW).

Primary prophylaxis against *P. carinii* pneumonia is indicated when CD4 count falls below 200 cells per cu mm. The regimens available are trimethoprim - sulphamethoxazole, aerosolized pentamidine and dapsone.

(d) Administration of Antiretroviral Therapy

Once diagnosed, HIV-positive patients should be evaluated by a healthcare provider experienced in the care of these patients. The assessment will include establishing the stage of their disease, concomitant conditions like tuberculosis, other sexually transmitted diseases, and hepatitis B and C. A multidisciplinary approach is preferred, with the intervention of psychologists, clinical pharmacists, clinical educators, nutritionists, and social workers. Antiretroviral therapy is available in the form of a multi-drug regimen known as “HAART” (*Highly-Active AntiRetroviral Therapy*). The goals of therapy are to achieve maximal and durable suppression of viral load, restoration or preservation of immunologic function, improvement in quality of life, and reduction of HIV-related morbidity and mortality.

These goals are achieved by maximizing adherence to the antiretroviral regimen and using drug-resistance testing in selected clinical settings. How the available drugs are sequenced and the preservation of future treatment options are also important tools. A typical starting HAART regimen consists of 2 Nucleoside Reverse-Transcriptase Inhibitors (NRTI), and either a Non-Nucleoside Reverse-Transcriptase Inhibitors (NNRTI) or a Protease Inhibitor (PI). Ritonavir is used in certain regimens to boost the serum level of another PI by inhibiting its metabolism by the cytochrome P450 enzyme system. These regimens should be designed by a practitioner experienced in the treatment of patients infected with HIV.

There has been significant discussion about the best time to start HAART in an HIV-positive patient. There is no doubt that HAART is beneficial in patients with AIDS or symptoms related to immunosuppression and these patients should be offered therapy. For asymptomatic patients with CD4+ count greater than 200 cells/mm³, the benefit is less clear. The decision to initiate treatment in these patients should take into account the readiness of the patient for treatment, consideration of the prognosis for disease-free survival as determined by baseline CD4+ T cell count and viral load levels, and assessment of the risk and potential benefits associated with initiating antiretroviral therapy. See Table - 7.

Adherence

Adherence rates >95% are necessary to maximize the effects of ART (17). Good adherence is associated with improved virological, immunological and clinical outcomes. Key to any successful adherence strategy is the education of patients before the initiation of ART to assess their understanding of ART and their treatment readiness as well as regarding the potential side effects of ART.

(e) HIV and the Healthcare Worker

Standard precautions are generally adequate for the care of patients with HIV. They include hand washing before and after each patient contact and the use of gloves. Other personal protective equipment, such as gowns, eye shields and masks, are only necessary when exposure to blood or other body fluids is anticipated. Healthcare workers may occasionally have an accidental parenteral exposure to HIV.

Post - Exposure Prophylaxis (PEP) : An occupational exposure is a percutaneous injury, contact of mucous membrane or contact of skin (when skin is chapped, abraded or afflicted with dermatitis or the contact is prolonged or involving extensive area) with blood, tissue or other body fluids to which universal precautions apply causing considerable risk of HIV infection especially to HCW.

Action to be taken on occurrence of occupational exposure to HIV : On exposure to a needle stick injury, blood and body fluids from a known HIV positive, the individual should go for HIV testing and take Tab Zidovudine (300 mg) and Lamivudine (150 mg) at the earliest (preferably within 24 hours) and continue this twice daily for four weeks. The objective of the PEP is to prevent HIV infection of cells.

When to give PEP?

- (i) *No drugs required*
 - Small volume exposure over intact skin /mucous membrane from a low risk individual.
- (ii) *2 drug regimen*
 - Small volume exposure over non intact skin /mucous membrane from a high risk individual or from a Low risk individual.
 - Large volume exposure over non intact skin /mucous membrane from a low risk individual.
 - Solid needle, superficial (Not severe), exposure from a low risk individual
- (iii) *3 drug regimen*
 - Large volume exposure over non intact skin /mucous membrane from a high risk individual.
 - Severe injury (Large bore, deep injury, visible blood in device, needle in patient artery/vein) from either a low risk or high risk individual.
 - Solid needle, superficial (Not severe), exposure from a high risk individual.

(Small volume = few drops, low risk individual = Asymptomatic HIV or viral load <1,500 c/ml, high risk individual = Symptomatic HIV, AIDS, acute seroconversion, and high viral

Table - 7 : Drugs Used in the Treatment of HIV Infection			
NRTI	NNRTI	Protease Inhibitors	Fusion Inhibitors
Zidovudine (ZDV or AZT) Stavudine (d4T) Tenofovir Lamivudine (3TC) Didanosine (ddI) Emtricitabine Abacavir (ABC) Zalcitabine (ddC)	Efavirenz (EFV) Nevirapine (NVP)	Nelfinavir (NFV) Saquinavir (SQV) Indinavir (IDV) Amprenavir (APV) Fosamprenavir Lopinavir (LPV) Atazanavir Ritonavir (RTV)	Enfuvirtide

load, Large volume exposure = major blood splash)

Monitoring

Testing source : If there is no recent positive or negative serology, a rapid test is preferred, since results should be available in <10 minutes. Standard serologic tests may take 3 to 7 days, but a negative EIA screening assay is usually available in 24 to 48 hours and is adequate for the decision to discontinue PEP.

Testing health care worker : HIV serology should be performed at the time of injury, and repeated at 6 weeks, 3 months, and 6 months. Most health care workers who seroconverted had symptomatic acute HIV syndrome, usually 2 to 6 weeks post exposure.

Caution : The health care worker should be advised to practice safe sex or abstain until serology is negative at 6 months post exposure. The greatest risk is the first 6 to 12 weeks.

Time : PEP should be initiated as quickly as possible, preferably within 1 to 2 hours of exposure and up to 36 hours post exposure.

Side effects : For health care workers who receive PEP, about 74% experience side effects, primarily nausea (58%), fatigue (37%), headache (16%), vomiting (16%), or diarrhoea (14%). About 53% discontinue treatment before completion of the 4-week course due to multiple factors including side effects of drugs. The HCWs should therefore be properly briefed on these aspects to ensure compliance.

(f) Prevention of Parent To Child Transmission (PPTCT)

Good prenatal care, adequate antiretroviral therapy to the mother and child, cesarean section, and exclusive or no breastfeeding are all associated with decreased transmission of HIV. Even in mothers without chronic therapy for HIV and without prenatal care, antiretroviral agents like Zidovudine given through labor and delivery, together with early treatment of the newborn, decrease significantly the risk of transmission. Zidovudine is administered to women during pregnancy, labour and delivery and to their newborns; the rate of HIV transmission is decreased by two third. In addition to the use of ARV drugs, the following obstetric practices will reduce the risk of mother to child transmission :

- Avoidance of early rupture of membranes
- Avoidance of routine episiotomies
- Using non traumatizing suction cups on vacuum extractors where possible
- Avoid fetal scalp puncture

Follow up of the HIV positive Mothers, their Spouses & Children

The Mothers who have tested positive will be followed up every 6 months after their delivery along with their children and spouses.

(g) HIV infected couples/discordant couples

Discordant couples are those in which either the wife or husband is infected while the partner remains HIV negative. HIV infected couples or discordant couples are advised to practice safer sex. However such advise is not likely to be followed if the couple may wish to have child. Such couples should be Counselling for adoption; but should they wish to have their own child, then

the risk of cross infection with potential mutant viruses could be minimized by limiting unprotected intercourse to the most fertile period.

(h) Safer Sex

Safer sex (sex with condom) avoids passing on HIV infection to others and reduces the risk of contracting other sexually transmitted infections, which might harm a person already infected with HIV. It is possible that one partner can reinfect the other with a strain of HIV, which is resistant to some treatments. People with HIV infection who continues to have unprotected sex are likely to develop AIDS sooner and also run the risk of STIs such as Human Papilloma Virus (the wart virus) that can lead to genital cancers.

(j) Nutrition in HIV/AIDS

Nutrition is important to people with HIV infection in two ways:

- HIV positive individual should eat a well balanced diet to ensure that one gets all the essential nutrients that the body needs.
- They should avoid infection that come through contaminated food or drink.

Everyone needs to observe good hygiene when preparing food, avoid raw eggs, avoid partially cooked meat, fish etc. Boiling all water used for cooking or drinking is considered safer than drinking bottled mineral water or filtered tap water.

(k) HIV with TB (18)

In patients with HIV related TB, the priority is to treat TB, especially smear positive Pulmonary Tuberculosis. However, patients with HIV related TB can have ART and anti TB treatment at the same time, if managed carefully. Careful evaluation is necessary in judging when to start ART. Serious patients with disseminated TB and CD4 count less than 200, may require to start ART concomitantly with TB treatment. On the other hand, for a patient with smear +ve PTB with asymptomatic HIV requires to be deferred for ART until initial phase of TB treatment has been completed. This decreases the risk of immune reconstitution syndrome and avoids the risk of drug interaction between Rifampicin and a Protease inhibitor.

(l) Immunisation of HIV infected children

The immunization schedule of HIV infected children is more or less similar to other children. The details are as in Table - 8.

Vaccine	Schedule for HIV +ve children
OPV	Instead of OPV, Inactive Polio Vaccine (IPV) should be given
BCG	Not administered to symptomatic HIV children, but can be given at birth even if mother is HIV +ve
DPT	Can be given as it is
Measles/ MMR	Can be given normally except to those who are severely immunocompromised
Hepatitis B	Can be given as it is
DT/TT	Can be given as it is

(m) HIV Vaccines

Since 1983 the development of a vaccine against diverse strains of HIV has become an urgent global need. There are several approaches to vaccination for prevention of HIV-1 infection (19).

a) Subunit vaccines : These vaccines use HIV-1 surface glycoproteins gp120 or gp160 as immunogens.

b) Recombinant vector vaccines : The viral vectors are genetically engineered to carry HIV-1 genes. These vectors multiply in the body and generate HIV antigens, which are processed by the endogenous pathway and generate cytotoxic T lymphocyte response in the body.

c) DNA vaccines : These vaccines consist of segments of genome or plasmid, and are administered either IM or ID. After injection the DNA plasmids are taken up by the host cells, and the encoded protein antigens are expressed.

A vaccine preparation may be used either alone or in combination with another HIV vaccine. Combination vaccines are used with 'Prime Boost strategy' in which administration of one type is followed by second type of HIV vaccine. However no candidate vaccine has been proved effective till date due to extensive genetic diversity of HIV strains.

Summary

The Human Immunodeficiency Virus (HIV) is a retrovirus that infects cells of the human immune system. Acquired Immuno Deficiency Syndrome (AIDS) is the most advanced stage of HIV infection. It can take 10-15 years for an HIV-infected person to develop AIDS.

In 2007 the number of people living with HIV was estimated at 33.2 million and there were 2.5 million new infections and 2.1 million deaths. Two thirds of all adults and children with HIV globally live in sub-Saharan region (22.5 million). As of Dec 2007, an estimated 4 Million people are living with HIV in the South and South East Asia region. There are 2.47 million people living with HIV in India. Majority of the HIV infections (88.5%) are in the age group of 15-49 years. 0.28% of adults aged 15-49 are infected with HIV. The changing trend in the country indicates that HIV infection is spreading in two ways; from urban to rural areas and from individuals practicing high risk behaviour to the general population (type 4 pattern).

Two types of HIV have been identified type - 1 (HIV-1) and type - 2 (HIV-2). HIV uses an enzyme called *reverse transcriptase* to convert their RNA into DNA. Once a person is infected, the virus remains in the body life long. Humans- cases and carrier are only reservoir. HIV is a fragile virus, cannot live for very long outside the body. The virus has been found in greatest concentration from blood, semen and CSF.

High risk groups are IV drug users, multiple sexual partners (esp. homosexual, bisexual); transfusion recipients of blood and blood products, haemophiliacs. Rapid industrialization, availability of Commercial Sex Workers (CSWs), migration of young persons are some of the important social causes of the causation and perpetuation of this disease.

Disease can be transmitted through sexual contact with infected person, sharing of HIV contaminated needles and

syringes, transfusion of infected blood or its component and vertical transmission from infected mother to fetus. The risk of contracting HIV infection from transfusion of a unit of infected blood is estimated to be over 95% and 15-30% from infected mother to fetus. Inside body HIV infects a large number of CD4+ cells and replicates rapidly and this virus enter into the blood leading to viremia and spread to distant places esp. lymphoid tissue. During this period patient suffers flu like symptoms known as the acute sero-conversion illness which is self limited. After this patient is asymptomatic but infectious. Body immune system is not able to clear HIV infection due to high mutation and incorporation of viral DNA into cell chromosome and forming a latent infection. Cohort study of HIV infected adults indicates that about 15%-20% develop AIDS within 5 years, about 50% within 7-10 years and close to 70% within 15 years. The case fatality of AIDS is very high 80-90%, most die within 3-5 yrs, which is because of opportunistic infections.

An adult or adolescent (>12 yrs) is considered to have AIDS if a test for HIV antibody is positive, and one or more of the following are present : (a) Weight loss > 10% or cachexia, with diarrhoea or both, intermittent or constant, for > 1 month (b) Tuberculosis with weight loss > 10%, or disseminated, miliary, or extrapulmonary tuberculosis (c) Kaposi's sarcoma (d) Neurologic impairment preventing independent daily activities (e) Oesophageal candidiasis (f) Cryptococcal meningitis (g) Life threatening or recurrent episodes of pneumonia (h) Invasive cervical cancer.

For the purpose of AIDS surveillance, an adult or adolescent (>12 years of age) is considered to have AIDS if at least 2 of the following major signs are present in combination with at least 1 of the minor signs listed below, and if these signs are not known to be due to a condition unrelated to HIV infection. In Adults, Major signs are Weight loss > 10% of body weight, chronic diarrhoea for more than 1month, prolonged fever for more than 1 month (intermittent or constant). Minor signs are persistent cough for more than 1 month, generalized pruritic dermatitis, history of herpes zoster, oropharyngeal candidiasis, chronic progressive or disseminated herpes simplex infection, generalized lymphadenopathy. For children, major signs are weight loss or abnormally slow growth, chronic diarrhoea for more than 1month, prolonged fever for more than 1 month and minor signs are Recurrent common infections, e.g. ear infection, pharyngitis, persistent cough, generalized rash, oropharyngeal candidiasis & generalized lymphadenopathy. Clinical staging of HIV/AIDS based on clinical findings (not on CD4 cell count) in which they are categorized as 1 through 4, progressing from primary HIV infection to advanced HIV/AIDS are developed by WHO for resource- constrained settings.

HIV test should be offered to Persons with high-risk behaviour, Persons with AIDS related medical conditions, voluntary basis, Persons who have been sexually assaulted, Persons who have had occupational exposures, All blood donors (for blood safety), All antenatal cases and the husbands/children of the HIV positive cases, Spouses and dependant children of HIV infected persons, Patients on dialysis, Other high risk cases e.g. those who test positive for HbsAg/ HCV/ VDRL etc, Duty/ travel overseas.

A highly sensitive test (ELISA) which detect antibody against HIV is used for screening purposes. A highly specific test, Western Blot is used for confirmation. Alternatively, for confirmation 3 ELISA/rapid/simple tests based on different biological systems may be performed. The individual may test negative for HIV in window period with ELISA. Other test for HIV infection are PCR (Polymerase Chain Reaction) method, the bDNA method (branched chain DNA) etc. Absolute CD4 lymphocyte count is most widely used prognostic marker. Process of testing of HIV is done in five stages, first is risk assessment of the individual, then is pre-test Counselling in which information about all aspects of disease and its subsequent medical, social and economic impact is given, next informed consent of the patient is taken. And then testing for HIV is done and lastly post test Counselling for both negative and positive subjects.

Prevention of new HIV infection should be priority. The various strategies for prevention include Information, Education and Communication (IEC), Prevention of blood-borne HIV transmission, Antiretroviral prophylaxis, Administration of Antiretroviral Therapy, Prevention of Parent To Child Transmission (PPTCT), HIV infected couples/discordant couples, Safer Sex, Nutrition in HIV/AIDS, HIV with TB, Immunization of HIV infected children.

Study Exercises

Long Question : Describe the epidemiology of HIV/AIDS. Enumerate the strategy for its prevention.

Short Notes : (1) Pretest & Post test Counselling (2) HIV vaccines (3) HIV and TB (4) Transmission dynamics of HIV (5) WHO case definition for AIDS surveillance (6) Role of Counselling in HIV (7) PPTCT (8) HIV testing.

MCQs

- The risk of contracting HIV infection from transfusion of a unit of infected blood is estimated to be _____ from infected mother to fetus : (a) 15-30% (b) 30-60% (c) 10-15% (d) 5-15%
- In adults for surveillance of AIDS major signs are all except (a) Weight loss > 10% of body weight (b) Chronic diarrhoea for more than 1 month (c) Prolonged fever for more than 1 month (d) Disseminated TB.
- For children major signs for AIDS surveillance are all except : (a) Weight loss or abnormally slow growth (b) Chronic diarrhoea for more than 1 month (c) Prolonged fever for more than 1 month (d) Persistent cough for more than 1 month.
- Absolute CD4 count in HIV is used as (a) screening test (b) confirmatory test (c) prognostic marker (d) diagnostic marker.
- HIV can be transmitted from person to person through all methods except (a) sexual contact (b) social contact (c) vertical transmission (d) blood transfusion
- Cytomegalovirus disease occurs when CD4 counts fall below (a) 200 per cu mm (b) 50 per cu mm (c) 500 per cu mm (d) 1000 per cu mm
- Efavirenz belongs to (a) NRTI (b) NNRTI (c) PI (d) Fusion inhibitors
- Post exposure prophylaxis should be started (a) preferably within 1-2 hours (b) between 24-48 hrs (c) after 48 hours (d) after 72 hours
- Currently, new infection rates and deaths due to HIV/AIDS are estimated from : (a) HIV prevalence (b) Average time between HIV infection and death in the absence of treatment (c) Survival rates of people receiving treatment (d) All
- Patients with a CD4+ count below 50 cells/mm³ are at risk of developing disseminated (a) *Mycobacterium avium* infection, (b) Cytomegalovirus disease (c) PML (d) All (e) a & b
- Obstetric practices will reduce the risk of mother to child transmission except : (a) avoidance of early rupture of membranes (b) conduct routine episiotomies (c) using non traumatizing suction cups on vacuum extractors where possible (d) avoid foetal scalp puncture.
- Who should be offered the HIV test (a) Persons with high-risk behaviour (b) Persons who request testing, regardless of risk (c) Persons with certain medical conditions (d) All

Fill in the Blanks

- Estimates of the size and course of the HIV epidemic are updated every year by _____ and _____.
- In 2007, the number of people living with HIV was estimated at _____ million with _____ million new infections and about _____ million deaths.
- More adult women are now getting infected with HIV; for every _____ adult men, there are _____ adult women who are living with HIV.
- On 01st Dec 2003, WHO and UNAIDS announced a detailed plan to reach the "3 by 5 target" of providing antiretroviral treatment (ART) to _____ million people living with HIV in the developing countries by the end of _____.
- _____ pattern of HIV transmission i.e. from individuals practicing high risk behaviour to the general population was first described in _____.
- In India approx _____ million people living with HIV was estimated by National AIDS Control Programme (NACO) in July 2007.
- The only reservoir for HIV are _____ cases and carriers.
- HIV infection in children occurs mostly during the _____ and during _____.
- Median time from infection with HIV to the development of AIDS-related symptoms is approximately _____ years in the absence of antiretroviral therapy.
- The case fatality of AIDS is very high and most patients i.e. _____ % die within 3-5 years after the diagnosis of AIDS is made.
- The _____ is the interval between entry of HIV into the body and appearance of antibodies to it. This period may range between _____ months and during this period the individual may test _____ for HIV by conventional tests.
- HAART regimen consists of two _____, and either a Non-Nucleoside Reverse-Transcriptase Inhibitors (NNRTI) or a _____.
- Several approaches to vaccination for prevention of HIV-1 infection available are _____, Recombinant vector vaccines and _____.

Answers : MCQs : (1) a; (2) d; (3) d; (4) c; (5) b; (6) b; (7) b; (8) a; (9) d; (10) d; (11) b; (12) d. **Fill in the Blanks :** (1) UNAIDS; WHO;

(2) 33.2; 2.5; 2.1; (3) 10; 14; (4) 3; 2005; (5) Type 4; Thailand; (6) 2.1; (7) Humans; (8) Perinatal period; breast feeding; (9) 10-15; (10) 80-90%; (11) Window period; 1-6; negative; (12) Nucleoside Reverse Transcriptase Inhibitors (NRTI); protease inhibitor; (13) Subunit vaccines; DNA vaccines.

Leprosy (Hansen's Disease)

Sunil Agrawal

Leprosy is a chronic granulomatous immunological disorder caused by *M. leprae* primarily affecting the peripheral nerves and secondarily involving skin and mucosal membrane etc. It also affects eye, certain internal organs such as the kidney, liver, adrenal glands and in the male, testicles (1). The disease is clinically characterized by one or more of hypopigmented patches or partial/ total loss of sensation in the affected area or presence of thickened nerves or presence of acid fast bacilli in the skin smears.

Epidemiology

Magnitude of the Problem

World : The overall target for the global elimination of leprosy as a public health problem has been attained (2). The fall in prevalence rate is mainly due to an improvement in management of cases, very low rates of relapse, high cure rates, absence of drug resistance and shorter duration of treatment with MDT (3). The WHO estimates for 1994 were 2.4 million cases, a reduction of more than three fourths as compared to the estimated 10.6 million cases in 1976 (4). At the beginning of 2008, the registered prevalence of leprosy globally was 212,802; the number of new cases detected during 2007 was 254,525 (5). The global detection of new cases declined by >11,100 cases (4%) during 2007 compared with 2006 and global prevalence rate of leprosy was below 1 per 10,000 population. About 2.9

lakh cases are newly detected in 2005 which is 27% fall as compared to 2004. No drug resistance to MDT was reported (6). At present the highest burden is concentrated in 6 countries (India, Brazil, Indonesia, DRC, Bangladesh and Nepal). At the beginning of 2008, the Democratic Republic of the Congo and Mozambique reached the leprosy elimination goal however, 3 countries with populations >1 million that have yet to achieve the elimination goal are Brazil, Nepal and Timor - Leste. Together, these 3 countries account for about 17% of the new cases detected during 2007 and 23% of registered cases at the beginning of 2008. Prevalence of leprosy and number of new cases detected, by WHO regions is given in Table - 1.

Table - 1 : Prevalence of leprosy and number of new cases detected, by WHO region, beginning of 2008

WHO Regions	Registered prevalence beginning 2008 (Rate per 10,000)	New cases detected 2007 (Rate per 100,000)
Africa	30,055 (0.47)	31,037 (4.85)
America	49,388 (0.96)	41,978 (8.15)
South - East Asia	1,20,967 (0.72)	1,71,552 (10.22)
Eastern Mediterranean	4,240 (0.09)	4,091 (0.85)
Western Pacific	8,152 (0.05)	5,867 (0.34)
Total	2,12,802	2,54,525

India : In last few years there is marked reduction in cases of Leprosy. As of Mar 2007 the number of reported cases came down to 82,801 giving Prevalence Rate (PR) of 0.72 cases per 10,000 population (7). India achieved elimination level of less than one case per 10,000 population by 31st Dec 2005. The disease shows high prevalence in 6 states (PR of 1 - 2 per 10000 population) viz. Bihar, Chattisgarh, Jharkand, Chandigarh, Dadra and Nagar Haveli and Delhi. These states contribute 67% of the total case load (8). The total cases discharged as cured (151,601) were more than total new cases detected (139,252). Now the focus of attention under national Leprosy Control Programme has shifted from endemic states to high priority districts and blocks. A Focused Leprosy Elimination Plan (FLEP) was carried out in 2005 targeting high endemic districts and blocks which included Block Leprosy Awareness Campaign (BLAC).

Agent : In 1873, Gerhard Armauer Hansen, a Norwegian scientist demonstrated these bacilli in leprosy lesions. Later they are called *Mycobacterium leprae*. The bacilli are acid fast and with ZN stain appear pinkish red resembling the tubercle bacilli morphologically. The bacilli may be arranged in small or large clumps or bundles (called Globi) or may occur singly. The incubation period of the disease is much longer than that of most other infectious diseases. Other than man, it has multiplied in the footpads of mice, in tissues of immunosuppressed rodents and in the nine - banded armadillo.

Reservoir : Man is the only known reservoir. Though natural infection has been reported in Armadillo and certain primates but it is not epidemiologically important. "Active or Open" cases who are shedding the organisms mainly through nasal discharges more so in Lepromatous cases are the chief source of infection.

Host : Infection can take place at any age, to any sex, depending upon the opportunities for exposure in endemic areas. In areas where leprosy is rare, the first contact may not take place early in life and thus the disease may appear late. However, a high incidence of infection among children means the disease is active and spreading. Incidence rates are highest in 10 to 20 yrs of age gp and then fall. In general, leprosy is more commonly seen in men than women due to their greater mobility and increased opportunity to contact the infection. Only a few people exposed to infection develop clinical signs of leprosy, although immunological conversion takes place in large proportions of contacts. It is now recognized that the effective immune response in leprosy is a cell - mediated one. In lepromatous leprosy there is a complete breakdown in the cell mediated immune response.

Diagnosis : The following features assist in the diagnosis of the disease :

(a) Clinical features

- (i) Skin lesions (Infiltration, macules, papules, tubercles and nodules)
- (ii) Paraesthesia (History of numbness and loss of hot and cold sensations in the extremities)
- (iii) Thickening of nerve trunks
- (iv) Anhidrosis

(b) Histamine test : 0.1 ml of 1/1000 solution of histamine

chlorhydrate or phosphate is injected intradermally into the hypopigmented patches. In normal persons it gives rise to wheal surrounded by an erythematous flare (Lewis triple response) within a few minutes. In cases of leprosy where nerve supply is destroyed this response is lost.

(c) Skin smears : The skin smears, nasal smears and nasal scrapings are collected, fixed and stained with ZN method. This is used to distinguish between paucibacillary and multibacillary leprosy. A negative result, which is usual in indeterminate and tuberculoid cases, does not eliminate the diagnosis of leprosy. In certain cases histopathological examination may be necessary.

(d) Immunological Tests

Lepromin Test : The lepromin test, also called Mitsuda reaction, was first described by the Japanese worker, K Mitsuda in 1916. It is an intradermal immunological test employed to detect CMI and classify the type of disease and to find out the prognosis in a given case. Lepromin is a suspension of lepromatous tissue rich in *M.leprae* in an isotonic solution of sodium chlorides sterilized by heating. The test is performed by injecting intradermally 0.1 ml of lepromin or lepra antigen in the forearm of a patient and the reaction is examined at the end of 48 hours and 21 days. The test results in 2 types of reaction.

- (i) **Early reaction (Fernandez reaction)** : If there is erythema and induration measuring more than 10 mm in diameter at the end of 48 hours at the site of injection it is considered positive.
- (ii) **Delayed reaction** : At the end of 21 days, if there is a nodule more than 5 mm in diameter at the site of inoculation, it is said to be positive. This delayed reaction is also known as the classical or Mitsuda reaction. In strongly positive individuals there may be ulceration.

The early positive reaction shows that person has been previously sensitized by exposure to leprosy bacilli. The test is often positive in healthy persons and in those suffering from tuberculoid form of leprosy, and positivity gets weaker as we pass to lepromatous form of disease indicating a failure of CMI. The lepromin test is not a diagnostic test, its value lies in estimating prognosis, positive test indicating good prognosis.

(e) Other tests : These include Lymphocyte Transformation Test (LTT), Leucocyte Migration Inhibition Test (LMIT), Fluorescent Leprosy Antibody Absorption Test (FLA - ABS test), and, ELISA

Reactions in Leprosy : Reactions are acute exacerbations of disease either due to alteration in CMI status (type 1 reaction) or immune complexes (type II or ENL reaction). Clinically there is increase in number and infiltration of lesions, neuritis, associated with constitutional symptoms and involvement of various organs like eyes, bones, testis and viscera. Reactions are best managed in hospital, whereby along with specific antileprosy treatment, anti - inflammatory drugs, steroids or antireactional drugs (Clofazimine, thalidomide) may be administered.

Incubation Period : Leprosy has a long incubation period, an average of 3 - 5 years. Tuberculoid type has shorter incubation period.

Communicability : A patient is infective, if morphologically solid - staining (viable) bacilli are demonstrable.

Mode of Transmission : The exact mechanism of transmission is still unclear (9). The major exit points of *M. Leprae* from untreated lepromatous patients are the nose, mouth, and in some cases abraded skin lesions. As regards mode of entry, most likely sites of entry are skin and nasal mucosa. The bacilli from nasal discharges of infectious patients gain entrance through the skin or respiratory tract. House hold contact is important. Untreated lepromatous patients act as 'source case' or 'pool of infection' in the community. The different mode of transmission are :

(a) **Droplet infection** : This is likely to be the major route. This includes aerosols containing bacilli discharged from Respiratory tract.

(b) **Contact transmission** : Including Direct (skin - to - skin) and Indirect (soil and fomites).

(c) **Other routes (Doubtful)** : These include possibly Breast milk and Tattooing needles.

Classification of Leprosy : Leprosy is a disease of classifications. This is probably a reflection of great variation in individual host resistance to the disease. These classifications are based on clinical, bacteriological, immunological and histological status of patients. The various classification in use are :

- 1) Indian Classification
- 2) Madrid classification
- 3) Ridley and Jopling classification
- 4) WHO operational classification

The Indian classification is the official classification of the Indian Leprosy Association (10) and most widely used in India. It is clinico - bacterial classification and described as under :

(a) **Indeterminate type** : Early cases with one or two vague hypopigmented macules and with and without sensory impairment. Lesions are bacteriologically negative.

(b) **Tuberculoid type** : Cases with one or two well defined lesions which may be flat or raised, hypopigmented or erythematous and are anaesthetic.

(c) **Borderline type** : Cases with four or more lesions which may be flat or raised, well or ill defined, hypopigmented or erythematous and shows sensory impairment or loss. Bacteriological positivity is variable and if left untreated can progress to lepromatous type.

(d) **Lepromatous type** : Cases with diffuse infiltration or numerous flat or raised lesions, symmetrical without any sensory loss.

(e) **Pure neuritic type** : Cases show nerve involvement but do not have any lesion in skin. Cases are bacteriologically negative.

In 1987, WHO study group endorsed that all the patients showing smear positivity should be classified as having multibacillary leprosy for the purpose of MDT treatment. Same study group in 1993 gave clinical classification into two groups:

- (a) Paucibacillary leprosy (1 - 5 skin lesions)
- (b) Multibacillary leprosy (more than 5 skin lesions)

Prevention and Control

(a) **Problem estimation and early diagnosis** : A quick random sample survey is done to collect base line data in the community. Contact surveillance of households with a lepromatous case is recommended for a minimum period of 10 years after case is declared bacteriologically negative, and for 5 years in households with a non - lepromatous case from the time of diagnosis of the index case. Mass surveys are expensive but repeated annual examinations of school children yield better results at relatively low cost (11,12).

(b) **Chemotherapy** : WHO study group has recommended multi - drug therapy for both multi - bacillary and pauci bacillary leprosy (13). Principles of Leprosy Treatment are given in Table - 2.

1. Stop the infection with chemotherapy.
2. Treat infections
3. Educate the patient about leprosy.
4. Prevent disability.
5. Support the patient socially and psychologically.

Objectives of Treatment

- (i) To interrupt transmission of infection in the community by sterilizing infectious patients as rapidly as possible with bactericidal drugs
- (ii) To ensure early detection and treatment of cases, to prevent deformities
- (iii) To prevent drug resistance
- (iv) Curtailing the duration of treatment

Recommended Regimens

(i) **Multibacillary leprosy** : As per the recent recommendations, following groups of patients are to be given MDT :

- All smear positive cases
- Skin lesions more than five in number
- More than one nerve trunk thickening
- All cases of relapse/reactivation and all cases who have been treated with Dapsone monotherapy earlier.

The drugs and dosages are :

Rifampicin : 600mg once monthly, supervised

Dapsone : 100mg daily, self administered

Clofazimine : 300mg once monthly, supervised and 50mg daily, self administered.

(ii) **Paucibacillary leprosy** : The drugs and dose schedule is

Rifampicin 600mg once a month for 6 months supervised

Dapsone 100mg daily for 6 months self administered

MDT is not contraindicated in patients with HIV infection.

Duration of treatment

Multibacillary leprosy : For 12 months, can be extended to 18 months and continued where possible upto smear negativity. Highly bacilliferous LL/BL patients may need 2 - 3 years or more of MDT for achieving bacteriological negativity.

Paucibacillary leprosy : for 6 months.

Follow - up of cases : Follow up of patients after completion of treatment is an important part of MDT. For paucibacillary cases follow up for at least once a year for 2 yrs after completion of treatment and for multibacillary cases at least once a year for 5 yrs.

(c) BCG vaccination : Mycobacterium W vaccine has been released for human use for immuno modulation therapy.

(d) Rehabilitation : It is an important aspect of leprosy control. It means the medical, surgical, social, educational, and vocational restoration as far as possible of treated patients to normal activity so that they resume their place in the home, in society and industry. Early treatment helps in disability limitation.

(e) Health education : The education should be directed towards general public and to patients helping them develop attitudes and behaviour by their own actions and efforts and seeking professional help whenever required. Early recognition of symptoms, prompt diagnosis, health seeking behaviour, personal care, treatment adherence and rehabilitation are important aspects of health education.

Summary

Leprosy is a chronic granulomatous immunological disorder caused by *M. leprae* primarily affecting the peripheral nerves and secondarily involving skin and mucosal membrane etc. The disease is clinically characterized by one or more of hypopigmented patches or partial/ total loss of sensation in the affected area or presence of thickened nerves or presence of acid fast bacilli in the skin smears.

There is a fall in number of new cases detected and prevalence rate due to an improvement in management of cases, very low rates of relapse, high cure rates, and absence of drug resistance and shorter duration of treatment with MDT. At present the highest burden is concentrated in 6 countries (India, Brazil, Indonesia, DRC, Bangladesh and Nepal). 3 countries (Brazil, Nepal and Timor - Leste) are yet to achieve the elimination goal. India has achieved elimination of leprosy in Dec 2005.

Leprosy is caused by *Mycobacterium leprae*. These bacilli are acid fast and with ZN stain appear pink/red, their generation time is around 13 - 14 days. Thus the incubation period is long (3 - 5yrs). Man is the only known reservoir. Lepromatous cases are the chief source of infection. A patient is infective, if morphologically solid - staining (viable) bacilli are demonstrable. Most likely mode of transmission is droplet infection and contact transmission. Only a few people exposed to infection develop clinical signs of leprosy, although immunological conversion takes place in large proportions of contacts. The diagnosis is made on the basis of clinical features, skin smears and immunological test. Clinical features include skin lesions, paraesthesia, thickening of nerve trunks and anhidrosis. The skin smears, nasal smears and nasal scrapings are collected, fixed and stained with ZN method. A negative result does not eliminate the possible diagnosis of leprosy. The lepromin test is an intradermal immunological test. The lepromin test is not a diagnostic test, its value lies in estimating prognosis, positive test indicating good prognosis. Other tests include LTT, LMIT,

FLA - ABS test, ELISA etc.

Reactions are acute exacerbations of disease either due to alteration in CMI status (type1 reaction) or immune complexes (type II or ENL reaction). Reactions are managed in hospital, whereby along with specific anti - leprosy treatment, anti - inflammatory drugs, steroids or anti - reactional drugs (Clofazimine, thalidomide) may be administered. Leprosy can be classified on the basis of clinical, bacteriological, immunological and histological status of patients. There are various classification but Indian classification is the official classification of the Indian Leprosy Association (clinico - bacterial classification). According to this leprosy has been classified into indeterminate type, tuberculoid type, borderline type, lepromatous type and pure neuritic type. In 1987, WHO clinically classified leprosy into two groups : Paucibacillary leprosy (1-5 skin lesions) and Multibacillary leprosy (more than 5 skin lesions).

WHO study group has recommended multi - drug therapy for both multi - bacillary and pauci bacillary leprosy. Three drug (Rifampicin, clofazimine and Dapsone) regimen is used for treatment of multi - bacillary leprosy for duration of 12 - 18 months and two drug regimen (Dapsone and Rifampicin) is used for 06 months for paucibacillary treatment. Follow up of patients after completion of treatment is an important part of MDT. For paucibacillary cases follow up for at least once a year for 2 yrs after completion of treatment and for multibacillary cases at least once a year for 5 yrs. Rehabilitation is an important aspect of leprosy control and it means the medical, surgical, social, educational, and vocational restoration as far as possible of treated patients to normal activity. Health education should be directed towards general public and to patients helping them develop attitudes and behaviour by their own actions and efforts and seeking professional help whenever required.

Study Exercises

Long Question : Discuss the epidemiology of leprosy and principles of its prevention / control.

Short Questions : (1) Lepromin test (2) Principles of leprosy treatment (3) Diagnosis of leprosy case

MCQs

1. Countries which are yet to achieve elimination of leprosy by 2008 includes all except (a) Brazil (b) Nepal (c) Timor - Leste (d) India
2. Leprosy is also known as (a) Hansen's disease (b) Koch's disease (c) Crippling disease (d) Weil's disease
3. Contact surveillance of households in lepromatous case is recommended for the period of _____ yrs (a) 10 (b) 5 (c) 15 (d) 7.
4. Contact surveillance of households in non lepromatous case is recommended for the period of _____ yrs (a) 10 (b) 5 (c) 15 (d) 7.
5. According to WHO clinical classification multibacillary leprosy have (a) 5 or more lesions (b) 6 or more lesions (c) 5 lesions (d) all of the above.
6. Follow up of multi - bacillary cases should be done for _____ yrs (a) 5 (b) 2 (c) 10 (d) 3

- Lepromin test is read at _____ and _____ (a) 24 hrs and 21 days (b) 48 hrs and 21 days (c) 24 hrs and 7 days (d) 48 hrs and 7 days.
- Duration of pauci - bacillary leprosy treatment is (a) 06 months (b) 09 months (c) 12 months (d) 18 months
- Classification into pauci and multi bacillary leprosy is based on _____ features (a) clinical (b) histological (c) bacteriological (d) immunological.
- According to Indian classification Leprosy is classified into _____ types (a) 5 (b) 4 (c) 3 (d) 2.

Match the following

1. Mitsuda reaction	a) Leprosy
2. Fernandez reaction	b) 6 or more lesions
3. Paucibacillary leprosy	c) 21 days
4. Multibacillary leprosy	d) 5 lesions
5. Ridley - Jacob classification	e) 48hrs

True or False

- Highest burden of leprosy is in 6 countries : India, Brazil, Indonesia, Srilanka, Bangladesh and Nepal T/ F
- Generation time of leprosy bacilli is around 13 - 14 days. T/ F
- Following 6 states of India viz. Bihar, Chattisgarh, Jharkand, Chandigarh, Dadra and Nagar Haveli and Delhi have PR of 1 - 2 per 10000 population. T/ F
- Lepromatous cases are the chief source of infection. T/ F

- Lepromin test employed to detect CMI and classify the type of disease T/ F
- Duration of treatment for paucibacillary leprosy is for 12 months, can be extended to 18 months. T/ F

Answers : MCQs : (1) d; (2) a; (3) a; (4) b; (5) b; (6) a; (7) b; (8) a; (9) a; (10) a. **Match the following :** 1 - e; 2 - c; 3 - d; 4 - b; 5 - a. **True or False :** (1) - F; (2) - T; (3) - T; (4) - T; (5) - T; (6) - F.

Sunil Agrawal

The disease is one of the earliest recorded eye afflictions, having been identified in Egypt as early as 15 B.C. Its presence was also recorded in ancient China and Mesopotamia. Trachoma became a problem as people moved in crowded settlements or towns where hygiene was poor. Today, most victims of trachoma live in underdeveloped and poverty-stricken countries in Africa, the Middle East, and Asia. Blindness due to trachoma has been eliminated from the United States.

Definition

Trachoma (Ancient Greek : "rough eye") is an infectious eye disease, and the leading cause of the world's infectious blindness. It is a chronic communicable kerato-conjunctivitis of insidious or abrupt onset, characterized by conjunctival inflammation with lymphoid follicles and papillary hyperplasia associated with vascular invasion of the cornea (pannus) and

in its later stages by conjunctival cicatrization which may lead to gross deformity of the eyelids, progressive visual disability and blindness(1).

Epidemiology

Magnitude of the problem : Trachoma is a major preventable cause of blindness in developing countries. Globally, 84 million people suffer from active infection and nearly 8 million people are visually impaired as a result of this disease. Globally this disease results in an estimated US \$2.9 billion in lost productivity every year. The incidence and prevalence of trachoma has shown a significant decrease in many endemic countries of SEAR during the past few decades. The decrease is due to improved sanitation, water, housing and implementation of control measures but it still remains a problem in parts of Myanmar, western region of Nepal and in few rural areas in India (2). It is estimated to be responsible for 0.2 percent of visual impairment and blindness in India. Blindness due to trachoma is irreversible once it has occurred, but it can be prevented. With the SAFE strategy (described later), the World Health Organization (WHO) and its partners are targeting the Global Elimination of Trachoma (GET) as a cause of blindness

by the year 2020. GET2020 is one element of a broader strategy known as 'VISION 2020: The Right to Sight', which has as its goal the elimination of all avoidable blindness by the same year.

Agent : The infectious agent is *Chlamydia (Bedsonia) trachomatis*, obligatory intracellular bacteria, which includes several antigenic types. Man is the only reservoir. The eyes of infected individuals (especially children from 1 to 15 years of age) are the sources of infection. Trachoma is a disease of low infectivity and only infective when active lesions are present along with ocular discharges and not when cicatrization takes place.

Host : No person is immune. In endemic areas children have active disease more frequently than adults especially from the age of two to five years. At younger age, prevalence is equal in both sexes however, females are more commonly infected in older age group as they remain more close to infected children than males. The severity of the disease often is related to environmental conditions. Lack of water and exposure to dry winds, dust and fine sand may contribute to the severity of the disease.

Environmental factors : The incidence is found high during the month of April-May and July-September. The higher temperature and rainfall favours the increase in eye seeking fly population. Trachoma is a disease of poverty, ignorance, poor personal hygiene, illiteracy, and poor housing. The hygiene and sanitation is inversely proportional to incidence of trachoma cases.

Mode of Transmission : Transmission occurs by close contacts, hands, towels, handkerchief, pillow cases, flies and dust. A dry and hot climate with dust, dirt, squalor and crowding in houses, dormitories, hostels, barracks, swimming pools and general unhygienic conditions leading to fly breeding and midget breeding favour the spread of disease. The use of common family vial of eye cosmetics, such as 'surma' and 'kaja' or towels and wipe clothes is a potent cause of spread in families and close institutions such as schools, hostels and so on. One can, thus, summarize the main environmental risk factors which are involved in the transmission of trachoma as six Ds [Dry, Dusty, Dirty, Dung, Discharge and Density (over-crowding)] or five Fs [Flies, Faeces, Face (eyes), Fingers and Fomites] (3).

Incubation Period : 5 to 12 days, while the period of communicability is very prolonged and starts before the appearance of the follicles and continues until cicatrization has occurred.

Clinical Features

The affected individual experiences symptoms of conjunctivitis, or irritation similar to "pink eye." Trachoma is classified as Blinding and Non-blinding. Trachoma inflammation may undergo spontaneous resolution or may progress to conjunctival scarring which can cause inward deviation of eyelashes (trichiasis) or of the lid margin (entropion). The abrasion of the cornea by eyelashes frequently results in corneal ulceration, followed by scarring and visual loss.

The conjunctival inflammation is called "Active Trachoma" and is usually seen in children, especially pre school children.

It is characterized by white lumps in the undersurface of the upper eye lid (conjunctival follicles or lymphoid germinal centres) and by non-specific inflammation and thickening often associated with papillae. Follicles may also appear at the junction of the cornea and the sclera (limbal follicles). Active trachoma will often be irritating and have a watery discharge. Bacterial secondary infection may occur and cause a purulent discharge.

The later structural changes of trachoma are referred to as "Cicatricial Trachoma". These include scarring in the eye lid (tarsal conjunctiva) that leads to distortion of the eye lid with buckling of the lid (tarsus) so the lashes rub on the eye (trichiasis). These lashes will lead to corneal opacities and scarring and then to blindness. In addition, blood vessels and scar tissue can invade the upper cornea (pannus). Resolved limbal follicles may leave small gaps in pannus (Herbert's Pits). The World Health Organization recommends a simplified grading system for trachoma (Box - 1).

Box-1: The Simplified WHO Grading System for Trachoma	
Trachomatous inflammation, Follicular (TF)	Five or more follicles of >0.5mm on the upper tarsal conjunctiva
Trachomatous inflammation, Intense (TI)	Papillary hypertrophy and inflammatory thickening of the upper tarsal conjunctiva obscuring more than half the deep tarsal vessels
Trachomatous Trichiasis (TT)	At least one ingrown eyelash touching the globe, or evidence of epilation (eyelash removal)
Corneal Opacity (CO)	Corneal opacity blurring part of the pupil margin

The prevalence of TF in children aged 1-9 years is the key index for determining whether an area needs intervention with the A, F and E components of SAFE. The prevalence of TT determines the probable need for surgical services. The prevalence of CO is a (rough) measure of the burden of blindness and visual impairment due to trachoma.

Prognosis

If not treated properly with oral antibiotics, the symptoms may escalate and cause blindness, which is the result of ulceration and consequent scarring of the cornea.

Prevention and Control

The World Health Organization (WHO) has set a goal of eliminating blinding trachoma as a public health concern by 2020, using the SAFE strategy, which includes:

WHO Recommended SAFE Strategy
S-urgery to correct advanced stages of the disease
A-ntibiotics to treat active infection, using Zithromax (azithromycin)
F-acial cleanliness to reduce disease transmission
E-nvironmental change to increase access to clean water and improved sanitation

Surgery : For individuals with trichiasis, a bilamellar tarsal rotation procedure is warranted to direct the lashes away from the globe.

Antibiotic therapy: WHO Guidelines recommend that a region should receive community-based, mass antibiotic treatment when the prevalence of active trachoma among one to nine year-old children is greater than 10 percent (4). Subsequent annual treatment should be administered for three years, at which time the prevalence should be reassessed. Annual treatment should continue until the prevalence drops below five percent. At lower prevalences, antibiotic treatment should be family-based. WHO recommends Azithromycin (single oral dose of 20mg/kg) or topical tetracycline (one percent eye ointment twice a day for six weeks). Azithromycin is preferred because it is used as a single oral dose and can be used in children from the age of six months and in pregnancy.

Facial cleanliness : Children with grossly visible nasal discharge, ocular discharge or flies on their faces are at least twice as likely to have active trachoma as children with clean faces. Intensive community-based health education programs to promote face-washing can significantly reduce the prevalence of active trachoma, especially intense trachoma (TI).

Environmental improvement : Modifications in water use, fly control, latrine use, health education and proximity to domesticated animals have all been proposed to reduce transmission of *C. trachomatis*. These changes pose numerous challenges for implementation. It seems likely that these environmental changes ultimately impact on the transmission of ocular infection by means of lack of facial cleanliness. Particular attention is required for environmental factors that limit clean faces.

Summary

Trachoma (Ancient Greek: “rough eye”) is a chronic communicable kerato-conjunctivitis of insidious or abrupt onset. Trachoma is a major preventable cause of blindness in developing countries. The incidence and prevalence of trachoma has shown a significant decrease in many endemic countries of SEAR during the past few decades due to improved sanitation, water, housing and implementation of control measures. In India, it is responsible for 0.2 percent of visual impairment and blindness. Blindness due to trachoma is irreversible once it has occurred, but it can be prevented. Trachoma is caused by *Chlamydia (Bedsonia) trachomatis*, obligatory intracellular bacteria. Man is the only reservoir. It has low infectivity and spread through eyes of infected person having active lesions. Both sexes are equally affected in younger age group but in older age prevalence is more in females. No person is immune. The incidence is found high during the month of April-May and July-September. It is a disease of poverty and poor environmental condition. The higher temperature and rainfall favours the increase in eye seeking fly population. Transmission occurs by direct or indirect contact with ocular discharges of infected persons or fomites. Incubation period is 5 to 12 days. Communicability Period is very prolonged and starts before the appearance of the follicles and continues until cicatrization has occurred. Conjunctival inflammation is called “active trachoma”. Trachoma is classified as Blinding and non-blinding. Trachoma inflammation may undergo spontaneous

resolution or may progress to corneal scarring and blindness. It is characterized by conjunctival inflammation with lymphoid follicles and papillary hyperplasia associated with vascular invasion of the cornea (pannus) and in its later stages by conjunctival cicatrization which may lead to gross deformity of the eyelids, progressive visual disability and blindness. WHO grading system grade trachoma as Trachomatous Inflammation, Follicular (TF); Trachomatous Inflammation, Intense (TI); Trachomatous Trichiasis (TT); Corneal Opacity (CO). The World Health Organization (WHO) has set a goal of eliminating blinding trachoma as a public health concern by 2020. WHO Recommended SAFE strategy. Surgery for individuals with trichiasis, a bilamellar tarsal rotation procedure is warranted to direct the lashes away from the globe. Antibiotic therapy: Mass antibiotic treatment when the prevalence is more than 10 among 1-9 yrs old children followed by annual treatment till prevalence drop below 5%. At lower prevalences, antibiotic treatment should be family-based. Azithromycin and topical tetracycline are recommended. Intensive community-based health education programs to promote face-washing can significantly reduce the prevalence of active trachoma, especially Intense Trachoma (TI). Environmental changes include improvement in hygiene and sanitation which make transmission of disease difficult.

Study Exercises

Long Question: Describe briefly WHO strategy for elimination of Trachoma.

MCQs

1. Trachoma is responsible for _____ percent of total blindness in India (a) 0.2 (b) 0.5 (c) 0.7 (d) 1
2. Antibiotics of choice in Trachoma is (a) Penicillin (b) Ciprofloxacin (c) Co-trimoxazole (d) Azithromycin
3. In SAFE strategy for elimination of trachoma ‘S’ stands for (a) surgery (b) soiling (c) scarring of conjunctiva and cornea (d) none of the above.
4. Mass antibiotic treatment in trachoma is recommended when the prevalence is more than _____ percent (a) 5 (b) 10 (c) 7 (d) 3
5. WHO grading system grade trachoma as 1) Trachomatous inflammation, Follicular (TF) 2) Trachomatous Trichiasis (TT); 3) Trachomatous inflammation, Intense (TI) 4) Corneal Opacity (CO) arrange the following in order (a) 1,2,3,4 (b) 1,3,2,4 (c) 3,2,1,4 (d) 2,1,3,4

Answers : (1) a; (2) d; (3) a; (4) b; (5) b.

“...The Japanese smoke a lot and suffer fewer heart attacks than Australians or New Zealanders; The French eat a lot of fat and also suffer fewer heart attacks than Australians or New Zealanders; The Italians drink a lot of wine and also suffer fewer heart attacks than Australians or New Zealanders.....”

(Conclusion : Eat, drink, Smoke and enjoy the way Japanese, French and Italians do; Actually it is speaking English that gives so many heart attacks to Australians & New Zealanders!)

With rapid urbanization, industrialization and increasing level of affluence (the so called “modernization”), the price that the society is paying is a tremendous load of “Non - Communicable” diseases, also referred to as “Chronic” diseases” and, often, as “Lifestyle Diseases”. The list of major lifestyle diseases is displayed in the Box - 1. The issue is a global phenomena and not simply restricted to the developed, rich countries. In the context of our country, too, the problem of lifestyle and its consequent diseases needs to be addressed vigorously by all public health care personnel.

Obesity	Heart Disease
Hypertension	Diabetes Mellitus
Oral cancer	Lung cancer
Breast cancer	Colonic cancer
Other cancers	Sexually Transmitted Diseases
HIV & AIDS	Mental Stress and its sequelae
Osteoarthritis	Osteoporosis
Liver Disease	Asthma and Bronchitis
Road accidents	

What is “Lifestyle”

“Lifestyle”, in the context of preventive health care, indicates the behavioural patterns which we routinely adopt and the way we tend to (involuntarily) live our daily life, unless coerced to change by some external stimulus. Lifestyle is thus mainly dependent on psycho - social and environmental factors and, to a smaller extent, on genetic influences. Lifestyle is developed in the form of a set pattern of behaviour, very gradually, over many years, in the way we eat, drink, exercise, use intoxicants, are predisposed to own health care and personal protection, sexual practices and so on. Since these behavioural patterns are acquired very gradually, changing them becomes a difficult proposition and needs a lot of persuasiveness as well as persistent approach on the part of the health care providers

including health educators.

What are the major components of “Lifestyle” : As said earlier, lifestyle is more of attitudes and behaviours, about “predispositions”. Thus, there would be a large number of components of “lifestyle” which affect health, in the form of the way we exercise, to sexual mores to habitual hand washing before eating meals. However, from preventive point of view, the major facets of lifestyle are summarized in Box - 2.

Box - 2 : The Major Components of Unhealthy Lifestyle

- Lack of physical activity
- Faulty dietary habits
- Tobacco use
- Excessive alcohol intake
- Mental Stress
- Disregard to personal safety regarding
 - Accidents
 - Personal hygiene
 - Promiscuous Sex
 - Insect Vectors of Diseases

The National Scenario : India is experiencing a rapid health transition, with large and rising burdens of chronic diseases, which were estimated to account for 53% of all deaths in 2005. Earlier estimates projected that the number of deaths attributable to chronic diseases would rise from 3.78 million in 1990 (40.4% of all deaths) to 7.63 million in 2020 (66.7% of all deaths) (1). Many of these deaths occur at relatively early ages. Compared with all other countries, India suffers the highest loss in potentially productive years of life, due to deaths from cardiovascular disease in people aged 35 - 64 years (9.2 million years lost in 2000). By 2030, this loss is expected to rise to 17.9 million years - 940% greater than the corresponding loss in the USA, which has a population a third the size of India's (2).

The estimated prevalence of coronary heart disease is around 3 - 4% in rural areas and 8 - 10% in urban areas among adults older than 20 years, representing a two - fold rise in rural areas and a six - fold rise in urban areas over the past four decades. About 29.8 million people were estimated to have coronary heart disease in India in 2003; 14.1 million in urban areas and 15.7 million in rural areas (3). The prevalence of stroke is thought to be 203 per 1,00,000 population among people older than 20 years (4).

Data on cancer mortality are available from six centres across the country, which are part of the National Cancer Registry Programme of the Indian Council of Medical Research (ICMR). About 8 Lac new cases of cancer are estimated to occur every year. The age - adjusted incidence rates in men vary from 44 per 1,00,000 in rural Maharashtra to 121 per 1,00,000 in Delhi (5). The major cancers in men are mostly tobacco - related (lung, oral cavity, larynx, oesophagus, and pharynx). In women, the leading cancer sites include those related to tobacco (oral cavity, oesophagus, and lung), and cervix, breast, and ovary cancer.

Lifestyle diseases or “Non-Communicable Diseases” have common risk factors as listed in Box-2. Thus, by becoming physically active, eating a healthy diet, avoiding alcohol and tobacco and by managing mental stress, we will not only prevent IHD; we will prevent IHD, diabetes, hypertension, cancers, road accidents and stroke, since the determinants are common.

India has the largest number of oral cancers in the world, due to the widespread habit of chewing tobacco.

India also has the largest number of people with diabetes in the world, with an estimated 19.3 million in 1995 and projected 57.2 million in 2025 (6). The prevalence of type 2 diabetes in urban Indian adults has been reported to have increased from less than 3.0% in 1970 to about 12.0% in 2000 (7). On the basis of recent surveys, the ICMR estimates the prevalence of diabetes in adults to be 3.8% in rural areas and 11.8% in urban areas. The prevalence of hypertension has been reported to range between 20 - 40% in urban adults and 12 - 17% among rural adults (8). The number of people with hypertension is expected to increase from 118.2 million in 2000 to 213.5 million in 2025, with nearly equal numbers of men and women (9).

These advancing epidemics are propelled by demographic, economic and social factors, of which urbanisation, industrialisation, and globalisation, are the main determinants. The Indian economy is growing at 7% per year. With increasing life expectancy, the proportion of the population older than 35 years is expected to rise from 28% in 1981 to 42% in 2021 (10). During the decade 1991 - 2001, the population grew by 18% in the rural areas and 31% in urban regions (11). Urbanisation and industrialisation are changing the patterns of living in ways that increase behavioural and biological risk factor levels in the population. For these social reasons, the lifestyle epidemic is not simply restricted to non - communicable diseases in our country; the same social changes are leading to other forms of lifestyle diseases, related to sexual lifestyle and have resulted in an HIV - AIDS epidemic that has reached concerning proportions.

An excess risk of death from coronary disease has been observed in men and women of south - Asian origin, by comparison with other ethnic groups, and there is a progressive rise in risk from rural to urban migrant environments (12, 13). The increased risk of cardiovascular problems noted in Indian migrants is a portent of the further rise in risk that Indians are likely to experience alongside the developmental transition of their country. A high frequency of diabetes, central obesity, and other features of the metabolic syndrome (especially the characteristic dyslipidaemia of reduced HDL cholesterol and raised triglycerides) have been reported in migrant and urban Indian population groups (14, 15). The INTERHEART study (16) found that the cluster of nine coronary risk factors identified in the global population was also applicable to south Asians as a group.

In the past few years, two surveillance systems have been established to provide risk factor data from different parts of the country (17). In 2002, ICMR, with technical assistance from WHO, established a community - based surveillance system involving five centres. The prevalence of tobacco use has been estimated in the National Sample Survey and the National Family Health Survey (18). In the Global Youth Tobacco Survey 25.1% of the students aged 13 - 15 years reported that they had ever used tobacco, whereas current use was reported by 17.5% (19). A national survey in 2002, reported that the overall prevalence of current tobacco use in men and boys aged 12 - 60 years was 55.8%, ranging from 21.6% in those aged 12 - 18

years to 71.5% in the 51 - 60 year age group (20). Many cross - sectional surveys have recorded a high urban prevalence of central obesity and overweight (especially when the lower thresholds recommended by WHO for Asian people are used). Though the prevalence of obesity (BMI 30) is usually lower than that observed in the western population, the overweight category (BMI 25) includes almost a third to half the population in every survey. Women and men are equally affected (21, 22). Small birth size, with rebound obesity in early childhood, predicted diabetes and glucose intolerance in adulthood occurs in an Indian cohort (23).

The few available standardised studies of physical activity revealed low levels in urban areas (compared with rural) and in the upper - income and middle - income groups (compared with low - income). Low levels of physical activity have been reported in 61 - 66% of men and 51 - 75% of women, in urban surveys (22, 24). Most surveys have also shown higher mean concentrations of plasma cholesterol in urban population groups (4.6 - 5.2 mmol/L) compared with rural groups (4.3 - 4.6 mmol/L), with a low mean concentration of HDL cholesterol (25). The ICMR surveillance project observed that the prevalence of dyslipidaemia (ratio of total cholesterol to HDL cholesterol 4.5) was 37.5% in individuals aged 15 - 64 years. Even in a relatively young industrial population (20 - 59 years), 62.0% had dyslipidaemia (26). Levels of awareness, treatment, and adequate control are low for hypertension, diabetes, and dyslipidaemia, especially in rural areas (26, 27).

With advancing health transition, the poor are increasingly affected by chronic diseases and their risk factors. Low levels of education and income now predict not only higher levels of tobacco consumption, but also increased risk of coronary heart disease (19, 28). Since India's daily consumption of fruits and vegetables is 130 g per person per day, poor people may also have deficiencies of protective phytonutrients. Urban slums in Delhi have high rates of diabetes and dyslipidaemia (29).

Lack of awareness of risk factors and diseases, and inadequate access to health care, increase the risk of early death or severe disability in such disadvantaged groups. The major socio - economic determinants of unhealthy lifestyle in populations are listed in Box - 3.

World - wide Magnitude of the Problem : Chronic diseases represent a huge proportion of human illness. They include cardiovascular disease (30% of projected total worldwide deaths in 2005), cancer (13%), chronic respiratory diseases (7%), and diabetes (2%). Three risk factors underlying these conditions are key to any population - wide strategy of control - tobacco use, physical inactivity and obesity. These risks and the diseases they engender are not the exclusive preserve of rich nations. An estimated total of 58 million deaths worldwide in a year, heart disease, stroke, cancer, and other chronic diseases will account for 35 million, more than 15 million of which will occur in people younger than 70 years. Approximately four out of five of all deaths from chronic disease now occur in low - income and middle - income countries, and the death rates are highest in middle - aged people in these countries (30).

We shall discuss the major components of healthy lifestyle and the methods of addressing them from the preventive angle.

Box - 3 : What Socio-Environmental Changes have Led to Increasingly Unhealthy Lifestyles in Populations

Rapid Industrialisation / Market economy
Increased global earnings
Materialism / consumerism
Mechanisation
Ad - Driven Competitive Food Industry
TV, Cables, VCDs
Computers, Internet
Increasing market of tobacco and alcohol, more so driven by ads
Academic competitiveness among children
Career Competitiveness
Migration towards urban areas
Loss of traditional "cushion" provided by traditional family life

Lack of Physical Fitness & Physical Inactivity

Substantial progress has been made during the past decades in scientifically substantiating the role of physical exercise and fitness in a number of human diseases and more recently, the role of physical exercise & fitness in positive lifestyle. Indeed, of all the lifestyle factors, physical exercise seems to be one of the most important in relation to health. It has been quite aptly said that physical exercise is the nature's panacea for preventing ill health.

'Physical Activity' and 'Physical Fitness' are two distinct entities. One may be physically active but may still not achieve a high level of fitness. For instance, if a 70 Kg man walks slowly, covering 8 kilometers in 3 hours, he would burn off almost 550 kilocalories (Kcal); however he may not achieve 'fitness' by such activity, since the 'Intensity' is quite low. On the other hand if the same person does a 'Walk and Jog' schedule, overcoming half the distance (4 km) in half an hour, he may burn off only half the numbers of calories, but will achieve a pretty good level of fitness. The point to be noted is that both are important - some work (activity / exercise) needs to be performed to burn off calories and, additionally, such activities / exercises should be undertaken with reasonable amount of intensity (vigorousness) so that, in addition to burning the calories, "fitness" is also achieved. The above point is important since recent research has pointed out that most of the health benefits of physical exercise (as brought out later in a separate section) are actually due to the "Fitness" that results from the exercise and not from simply burning off the calories during such activities (31). For instance, a housewife, during the course of her daily chores, or a person playing golf without carrying the clubs and walking at a slow pace for 2 hours, may burn off substantial amount of calories but may not be able to reap the complete benefits of exercise.

However, for those who are not exercising at all or else cannot exercise at moderate intensity levels even mild exercises will help. For planning a physical exercise program, the dictum

should be 'Any exercise is good; more the better' (32 - 35). In fact, people who have not been exercising for a long time should be encouraged to start with low intensity exercises or even by bringing about "life style changes" so that they become more active. Coaxing them to undertake more strenuous exercises from the very outset could be counter - productive. Subsequently, as they progress, they may be encouraged to gradually increase the level of exercise intensity.

Benefits of Exercise and Diseases Due to Physical Inactivity

It is often thought that physical exercise is a very good way of reducing the body weight and that is all which is good about physical exercise. This notion is correct only to a very small extent which should be emphasised upon the individuals and communities so that they draw the maximum benefits of physical exercise. Alone and by itself physical exercise is not a very efficient method of reducing weight. The major emphasis, if weight reduction is the issue, should be control on diet. Physical exercise can only be a useful adjunct. For example, just one average sized slice of bread will give 65 to 70 Kilocalories (Kcal), to burn off which, one would need to go running for a Kilometer. Just four innocuous looking slices of bread, or a small sized "Samosa" will push in 300 Kcal, which would need 4 kilometers of running/ walking to burn off these calories. If one doesn't do that, these 300 additional Kcal per day will finally result into an extra 1 kg every month or an additional dozen of Kgs at the end of a year. Thus, to reiterate, if the major objective is weight loss or weight maintenance, proper diet should be the mainstay; physical exercise can be used only as a supplementary modality. Notwithstanding the above, there are large number of health benefits of physical exercise and fitness, which are over and above the issue of weight maintenance, as shown in Box - 4.

Epidemiological Evidence - Hazards of Physical Inactivity

WHO estimates indicate that globally, physical inactivity accounts for more than one fifth of the IHD, one tenth each of stroke and breast cancer and one sixth of all colon cancers. Physically inactive lifestyle accounts in 3.3% of all deaths (i.e. 1 death out of every 30 deaths in the world can be attributed to physical inactivity). Physical inactivity also accounts for almost 19 million Disability Adjusted Life Years (DALYs), world - wide. World wide estimates as per a recent WHO report indicate that, on a long term average, *physical inactivity* carries an increased risk (as measured in terms of RR) of 1.05 to 2.63 for IHD, 1.2 to 2.89 for hypertension and stroke, 1.08 to 4.31 times for diabetes type - 2, 1.02 to 2.5 for colonic cancer, 1.02 to as much as 5 times for breast cancer and 1.02 to 1.37 for osteoporosis (36).

In the 1980s and 1990s, various epidemiological studies demonstrated that less intensive physical activity also provides considerable health benefits. The focus has therefore shifted now, to advocate, for the general population at large, to take to moderate intensity exercise by all adults and children, as brisk walking (5-6.5 kmph), recreational cycling and recreational

Box - 4 : Health Benefits of Physical Exercise & Fitness
Helps keeping body weight in check.
Increases the action of insulin hormone, thereby increasing the insulin sensitivity and the peripheral utilization of glucose, thus protecting against Insulin Resistance Syndrome (Syndrome X; Metabolic Syndrome) and NIDDM (Type-2 diabetes), both major risk factors for IHD.
Has a preferential action in mobilizing the fat depots, particularly the “Visceral” (Intra abdominal, peritoneal) fat. By preferentially mobilizing this dangerous type of accumulated fat, physical exercise protects against dyslipidemias, IHD & NIDDM.
Has a specific role in altering the lipid profile in a healthy fashion. Various studies have shown that the HDL levels are much higher while the triglycerides, LDL and Total cholesterol levels are much lower, among those who exercise regularly.
Is associated with lowered levels of systolic and diastolic blood pressure, thereby protecting against hypertension.
Has cardio-protective effect. Besides the improvements in insulin sensitivity, blood pressure, lipid profile and visceral fat deposition, physical exercise exerts its cardio-protective role by opening up the collateral blood vessels; increases the stroke volume and maximal ventilatory capacity; reduces myocardial oxygen demand at a given level of work; reduces fibrinogen levels, platelet aggregation and tendency of thrombus formation.
Brings about a reduction in the level of anxiety and stress and induces a sense of confidence and well-being. To some extent, this effect is believed to be brought about by the release of “beta endorphins “which are natural occurring, opiate-like chemicals.
Tones up muscles and increases flexibility, thus protecting from injuries and falls.
Helps in maintaining adequate bone mass density, thereby protecting from osteoporosis and its complications.
Protective against cancers of colon, prostate and breast.
Is of use in prevention as well as in rehabilitation of low backache.

swimming. In addition, the focus has also shifted to inculcate healthy lifestyle, by increasing activity levels in all the four ‘domains’ of life viz., at workplace, in transport, at home and during recreation time.

Does past physical activity / fitness help ? : This aspect needs to be clearly understood by all medical personnel and explained to the community members. There is enough evidence to indicate that the various health related benefits of physical exercise are always due to “current” physical activity and not “past” activity. Thus, for one to draw the benefits of exercise, one should continue to be active; the benefits will occur only as long as one continues to be active. Physical activity in the past does not seem to help - one may have been an international level athlete during one’s heydays, but that does not protect if one becomes inactive later in life.

Does “Spot - reduction - exercise” works ? : Often, obese people, especially those with abdominal obesity are led to believe that abdominal strengthening exercises (as ‘sit ups’ or equivalent gymnasium gadgets) will “burn off” the fat around the abdomen. It needs to be explained that for burning off the fat “around” (actually inside) the abdomen, one has to burn off overall calories and restrict the diet. Abdominal exercises may only slightly help by ‘toning’ up the abdominal muscles but the energy spent in such exercises will be too little to have any impact on overall weight loss. It needs to be emphasised that ‘sit ups’ do not, by any chance, push away the fat from the abdomen. Vibrator belts and massage systems used over the abdomen are equally unscientific. The best (and generally the only) way to lose fat from the “tummy” is to do brisk aerobic exercise and cut down on dietary calories - this is the only

“tummy trimmer” and there is none else.

The Exercise Program : A physical exercise and fitness schedule should be incorporated into the daily lifestyle. It needs to be emphasized that such program does not include only walking or jogging or only weight - training. An optimum physical fitness program should cater to three major facets of physical fitness, viz, Endurance (Stamina : Cardio - respiratory efficiency); Muscular Strength; and Flexibility.

Endurance : It is the capacity to undertake sustained aerobic physical exercise using a high proportion of maximal oxygen uptake. The ideal means of improving endurance is by undertaking sustained aerobic training at the near maximal level, which a person can tolerate. Gradually, with continued training, at near maximal level, the maximal aerobic capacity increases, i.e. the person increases the ‘Stamina’. Concurrently, with increase in stamina, the level of physical fitness increases and the person starts reaping more and more health benefits of physical exercise, as have been cited earlier. Any endurance training program has three distinct components, viz. :

Frequency : This is measured by the number of sessions per week that are devoted to endurance training. Ideally, there should be 4 to 5 sessions per week; the minimum recommended is 3 per week.

Intensity : Intensity is measured by the ‘strenuousness’ of the exercise. We shall deliberate on the measures of strenuousness a little later in a separate section. In general, it is recommended that to achieve the maximum gains, the physical exercise should be of at least “moderate” intensity. As one becomes more and more fit, one could (and should) aim to undertake

more strenuous (high intensity) exercises.

Duration : This is the time spent on exercise, in a given session. In general, during a session, approximately 60 minutes should be devoted for mild intensity exercises, 40 to 45 minutes for moderate intensity activities, while 20 to 30 minutes and 10 to 15 minutes are adequate for high intensity and very high intensity exercises, respectively. It also needs to be emphasized that the above suggested plans are only recommendations based on overall consensus and evidence. Ultimately, the program has to be tailored to meet the individual / community needs.

Measuring the level of intensity : Out of the 3 components of endurance training, while measuring the duration and frequency is quite straightforward, measuring the various levels of intensity often gets shrouded with confusion, particularly at the level of the user. A summary of various available guidelines to measure intensity of exercises and the overall recommendations are given in the succeeding paragraphs.

Measuring exercise intensity on the basis of heart rate : One of the oldest and quite widely used measure of exercise intensity is based on "Maximum Permissible Heart Rate (MxPHR)". The MxPHR for any individual is calculated as $220 (-) \text{Age in years}$. For example, for a person aged 50 years, the MxPHR will be $220 (-) 50 = 170$ beats per minute. In general, during an exercise session, this limit should not be exceeded. If a person is exercising at 50% to 60% of his MxPHR, it is taken as Low intensity exercise, 60% to 70% is Mild intensity, 70% to 80% is Moderate intensity, while 80% to 90% and 90% to 100% are taken as Severe intensity & Very severe intensity exercises respectively.

For example, the MxPHR for a 50 years old person would be 170. If the heart rate achieved by the person during a session of exercise is 50 to 60% of 170 (i.e. 85 to 102 beats per minute) he is exercising at low intensity level. Accordingly, for this person, the heart rate levels from 103 to 119, 120 - 136, 137 - 153, and 154 to 170 or even more, would qualify for mild, moderate, severe intensity and very severe intensity exercise respectively.

How to measure the heart rate achieved during an exercise session. A practical method is as follows : Immediately on completion of an exercise session and definitely within 5 seconds of completion the individual starts counting the radial pulse, for 10 seconds. The first beat is counted as zero. The number of beats so counted in 10 seconds is multiplied by '6' to obtain the heart rate achieved during exercise.

Measuring Exercise intensity according to Borg's scale of "Rating of Perceived Exertion (RPE)" : The scale has the advantage of simplicity and can be used by anyone in the general community. The scale rates the intensity of exercise, as perceived by the person himself, on a visual analogue scale of

0 to 20, as per Box - 5.

To start with, the exercise should be at a level of '12'score, i.e. the subject feels that the exercise intensity is between "Light" and "Somewhat hard". This level, in most subjects, is approximately equal to 60% of MxPHR. As fitness improves, the subjects should increase the intensity of exercise so that they are finally working at a level of 16 i.e. the perception about the exercise they are undertaking is that it is more than 'hard' but less than 'Very hard'. This level usually represents approximately 85% of MxPHR in most subjects.

Measuring exercise intensity using Metabolic Equivalents (METs) : Recently the concept of METs is being increasingly used to prescribe the level of exercise for individual subjects. 1 MET is actually equal to a level at which a person will spend 1 Kcal energy per kg body weight per hour and this level usually corresponds to the resting stage. This level also corresponds to an oxygen uptake level of 3.5 ml / kg body weight per minute (37). As the level of MET increases, the intensity of exercise increases.

Thus, a person weighting 70 kg at rest, i.e. at activity level of 1 MET will spend 70 K cal per hour while the same person exercising at the level of 6 MET will be spending $6 \times 70 = 420$ K cal in an hour. Moreover, the level of 6 MET will correspond to "moderate" level of exercise intensity. Thus, MET have dual advantage, in that in a single value they gave an indication of both, the amount of energy expenditure as well as the intensity of exercise. According to general agreement, the MET levels corresponding to various intensity levels of exercise are shown in the Box - 6 and the METs for common physical exercises are shown in the Box - 7 (37, 38). For example, let us say a subject weighing 70 kg is exercising by cycling at a speed of 16 km/h. He cycled for 8 km in half an hour. He will be exercising at 7 MET which is the upper limit of 'moderate intensity', rather almost touching the level of high intensity exercise. During this half an hour, he will burn off $(70 \times 7 \times \frac{1}{2}) = 245$ K cal of energy, this will be equivalent to burning off 30 grams of body fat.

Level of exercise Intensity	Usual MET level	
	Men	Women
Rest	1	1
Very low intensity	1 - 1.5	1 - 1.2
Light	1.6 - 3.9	1.2 - 2.7
Moderate	4 - 5.9	2.8 - 4.3
Heavy	6 - 7.9	4.4 - 5.9
Very Heavy	8 - 9.9	6.0 - 7.5
Unduly heavy	>10	> 7.6

0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
Nil	Almost Nil exercise		Very, Very Light			Quite Light			Light		Somewhat Hard		Hard		Very Hard		Excruciatingly Hard			

Box - 7					
Activity		MET level	Activity		MET level
Walking 4.8 km/h (slow pace)		3.0	Badminton leisure		3 - 6
Walking 5.4 Km / h (slow pace)		3.6	Badminton match		7 - 9
Walking 6 km / h (brisk pace)		4.3	Dancing social		3 - 7
Walking 6.4 km/h (brisk pace)		4.6	Dancing aerobic		6 - 9
Walking 7 km / h (very fast pace)		6.0	Circuit weight training		8 - 9
Jogging 8 km/h		8.7	Roller skates		5 - 8
Running 9.6 km/h		10.0	Squash leisure		8 - 10
Running 12 km/h		12.5	Squash match		11 - 12
Bicycling 16 km/h		7.0	Tennis leisure		6 - 8
Swimming 20 mtr from		6.0	Tennis match		9 - 10
Swimming 40 metre from		12.0	Volleyball		3 - 6
Golf, walking		4.0	Basket ball match		7 - 12
Golf, walking carrying bag		5 - 6	Basket ball non game		3 - 9

Recommendations for Physical Exercise

Recommendations based on calorie expenditure : The minimum amounts of calories to be expended in programmed physical exercise by the general population have been recently forwarded by CDC Atlanta and American College of Sports Medicine. These recommendations state that every adult should spend at least 200 Kcal per day (i.e. 1400 k cal in a week) by physical exercise and this should be undertaken on “most days” (Preferably all days of a week) (39). This could be achieved by having a half - hourly session every day of brisk walking. The point to be noted in that these are the minimum recommendations and *more exercise* (in terms of more time or more intensity) *is always better*.

More comprehensive recommendations on adequate calories to be spent have come from large scale studies among Harvard alumni and British civil servants. These recommendations in general suggest that to obtain the maximum health benefits of physical exercise, individuals should spend about 2500 k cal per week through regular, (and at least moderate intensity) exercises. To spend these 2500 calories, an average person weighing about 65 kg will need to walk or jog about 35 kms in a week or roughly 5 kms every day.

Comprehensive Recommendations Based on Intensity, Duration & Frequency : Besides the intensity of exercise and

the calories to be burnt off, the duration (generally to indicate “how long during a given session”) and frequency (to answer “how many times in a week?”) are also equally important. The general guidelines are set out in Box - 8.

The good news is that the above mentioned exercise can be “accumulated” i.e., it is not necessary to undertake a given session of exercise in 60 minutes at a stretch, Rather, 2 session of 30 mts each or even 3 session of 20 mts each over the day may also be good enough. It is generally recommended that for achieving weight loss and subsequently maintaining it, people should accumulate 60 to 80 minutes of moderate intensity exercise every day. Although, to the general public, devoting 60 to 80 mts to exercise may sound a bit too much, even impossible; however, once we emphasize on them that these 60 to 80 mts of exercise can be accumulated by undertaking frequent, short sessions, things seem to become manageable for most individuals.

Most experts agree that the best schedule is to have 4 to 5 sessions per week, of moderate intensity exercises of 5 to 8 MET level, with each session lasting for 45 to 60 minutes. This will provide recesses for recovering, as also improve compliance, since the exercise - off days (2 - 3 per week) leave the participants with ample opportunities for other pursuits and social obligations. The optimum linear distance to be

Box - 8						
Intensity of Exercise			Target Heart rate as % of MxPHR	Kcalorie spent per mt	Recommended Duration (Mts per session)	Recommended Frequency (sessions per week)
<i>By description</i>	<i>By MET level</i>	<i>By Borg's RPE scale</i>				
Low Moderate	4 - 5.9	13	70-80%	5 - 7.4	60 - 75	5 - 6
High Moderate	6 - 7.9	16	80-90%	7.5 - 9.9	45 - 60	4 - 5
Heavy	8 - 9.9	18	90-95%	10 - 12.4	20 - 30	3 - 4

covered by brisk walking or jogging in a week is recommended to be about 32 km (20 miles).

Resistance Training : Weight training and isometrics are often grouped under a general category of “resistance training”. Current opinion is to encourage mild weight training as a part of exercise - fitness program. It is recommended that mild weights (20 - 30 pounds for men and 10 - 20 pounds for women) may be used, exercising all major muscle groups (chest, back, shoulders, arms, forearms, glutei, thighs and legs) keeping about 3 sets for each major muscle group and 10 - 15 repetitions in each set. Two or three weekly sessions of the above schedule are recommended. Care should be specifically taken not to indulge in “Valsalva’s maneuver” (breathing forcefully against closed glottis, as happens while straining at stools), while undertaking resistance training and even while undertaking aerobic exercises.

Flexibility : Gentle stretching exercises as forward bending, side bending and calf stretch are ideal. Yoga exercises are excellent for flexibility. It is best to incorporate flexibility exercises as part of overall exercise plan, during the initial “warming up” for 5 to 10 minutes and the final “Cool down” phase for another 5 to 10 mts.

Progressing on the exercise program : It is generally advisable to progress in three phases. In the first phase the subject starts at a low level of about 3 MET (as walking 4.8 Kms in an hour) and over the next 4 - 6 weeks, gradually working up to a level of 4 - 5 MET (eg., brisk walking at speed of 6.5 to 7 km per hour) for 30 mts in a session, and having 4 - 5 such sessions per week. This level should be maintained for 4 - 6 weeks. Once the subject is comfortable at this level for 4 - 6 weeks (as evidenced

by a reduction of about 5 beats per minute in the exercise heart rate at that intensity level of exercise or by a decreased feeling of exertion on the RPE scale or by ability to undertake higher level of MET exercises), the subject moves to phase - 2, wherein he/she undertakes exercises at MET level of 6 to 7 (see table of MET values, e.g., brisk walk - jogging, covering 7 to 7.5 km in an hour) for about 30 to 45 minutes every session, and maintaining at this level for 4 - 6 weeks. In the last phase, the subject again gradually works up, over 4 - 6 weeks to a level of 8 to 9 MET (Jogging, covering 7.8 to 8.5 km per hour). The overall recommendations are summarised in Box - 9.

Bringing about “Physically Active” Lifestyle Changes

“Structured Physical Activity” programmes, as have been discussed till now, are only one side of inculcating physical activity among individuals and communities. What is equally important is to educate and motivate persons and communities to inculcate a “physically active lifestyle” so that physical activity gets incorporated in each and every action of life. Emphasis should not only be towards incorporating “exercise sessions” in the daily time table or advising gymnasium activities. Equal emphasis should be placed on changing the overall lifestyle from one of luxury and sloth to one of physical activity at every possible moment, integrating physical activity into lifestyle with short, frequent bouts of mild or moderate intensity exercise. This seems to provide the best answer and can be even better than structured exercise programmes. Some examples of positive lifestyle habits are shown in Box - 10.

The principal goal of active lifestyle is to increase energy expenditure without concern for the intensity of activity. The basic principle is that very mild, even inapparent increases

Box - 9 : Key Messages to be Given to Individuals & Communities
There are two clear components : firstly, a formal, structured exercise and fitness programme; secondly, inculcating “physically active lifestyle” as a part of day to day life. Both are equally important.
Structured Program Develop & meticulously follow a structured programme. Include all the three components (Endurance, Strength & Flexibility)
Endurance - <i>Most minimum</i> : Brisk walking at least 2 miles (3.2 Km) every day or at least most days a week, covering 3.2 Km in 30 to 35 mts. - <i>Ideal</i> : Exercise at 6 to 8 MET (e.g. walking / jogging covering 7 to 8 Km in an hour), 45 to 60 mts per day, every day or at least 4 to 5 days a week. - If you can exercise at even higher intensity or longer duration, the better it is. - Instead of walking or jogging, substitute any other aerobic exercise (cycling, swimming, sports, etc.) which makes you happy.
Strength : Advisable to undertake resistance training with light weights (10 to 30 lbs) exercising all major muscle groups 2 or 3 times a week.
Flexibility : Undertake 5 to 10 mts of Yoga or other gentle stretching exercises before and after an exercise session.
Physically Active Lifestyle Develop the attitude to be physically active always. Use stairs instead of lift, walk instead of driving, Remove the remote controls of TV, Fetch a glass of water yourself rather than asking your orderly, walk to your colleague’s office and discuss rather than using the intercom, park your car at the farthest, and so on.
Ensure Compliance Biggest hurdle in structured physical exercise or active lifestyle program is that you tend to lose out on compliance. Watch out.

(as going out for shopping rather than ordering for grocery on telephone) may make much difference. In fact, emphasis should be on promoting low - intensity, leisure pursuits, which are seen as pleasurable (as walking a dog, gardening, etc.) rather than simply stressing on occasional or periodic vigorous exercises. Similarly, “structured exercise” should also be encouraged but should not be presented as one which requires excessive physical effort; target should be on activities that can be easily incorporated in daily schedule.

Box - 10 : Changing the Daily Lifestyle : Examples
Take stairs instead of the lift; make several trips.
Put away the remote control of TV.
Stand while answering the telephone.
After every half an hour of office job, go out and walk in the corridor for 3 minutes.
Park your car at the farthest possible point.
Take a longer way around, to walk to the due destination.
Don't use servants / children for “fetch-it” jobs; do them yourself.
Go out for entertainment (e.g. see a Movie in the theatre) rather than sitting before the TV.
Wash / mop your car yourself.
Clean your house on holidays.

Practice Advocacy rather than Health Education : The effort of all health care professionals, whether in public health or in clinical domains, should be not simply to educate the community / individuals / patients, but rather to socially market the concept of physically active lifestyle. Such advocacy becomes especially important when dealing with high risk groups or with individual persons or patients.

Role of physicians in improving the lifestyle of subject/patient : Physicians may play a catalytic role in improving the lifestyle of people they come in contact with. An initial counselling session of 5 to 7 minutes by the physician followed by periodic telephone calls or personal interview sessions to keep up the motivation have been shown to be quite successful. Some motivational examples to be conveyed to the community members are shown in Box - 11.

Diet & Lifestyle

Detailed deliberations have been made regarding diet, nutrition and lifestyle diseases in the next chapter.

Tobacco & Lifestyle

Tobacco is one of the major causes of deaths and disease in India, accounting for over eight lakh deaths every year. The variety of forms of tobacco use is unique to India. Apart from the smoked forms that include cigarettes, bidis and cigars, a plethora of smokeless forms of consumption exist and they account for about 35 percent of the total tobacco consumption.

According to the National Family Health Survey - 2, the prevalence rate among males for chewing tobacco was 28.3% and for smoking tobacco, 29.4%. For females, the corresponding prevalence rates were 12.4 and 2.5 percent respectively.

Box - 11 : Motivating the Community Members & Subjects : Driving away any Excuses for not Exercising

<p>Lack of time</p> <ul style="list-style-type: none"> • Take several spurts of 10 mts each, of exercise during lunch, tea time & dinner time. • Park farthest away in the parking lot. • Turn off TV/computer for at least 30 minutes and exercise instead.
<p>Bad weather</p> <ul style="list-style-type: none"> • Get a “treadmill” for home. • Try an exercise video at home. • Do stationary jogging / walking.
<p>Holidays</p> <ul style="list-style-type: none"> • Put a lot of effort into cleaning your house. • Wash your car/two wheeler • Go shopping and carry your packets of grocery. • While going for shopping, park your vehicle far off, so that you walk for at least 2 to 3 Kms.
<p>Feeling Fatigued</p> <ul style="list-style-type: none"> • Remind yourself that exercise will give you more energy • Try and “force” yourself for just 10 minutes of walk. Once you start off, chances are that you will continue for longer.

Based on the National Family Health Survey - 2 age specific data, it is estimated that in the thirty plus age group, smoking prevalence among men is 41.2%. Further, 35.4% of men and 18.2% of females use chewing tobacco in this age group.

The prevalence of tobacco use among the youth has been surveyed by the Global Youth Tobacco Survey (GYTS) supported by CDC and WHO. GYTS is a tobacco specific survey to track the prevalence of tobacco use among 13 - 15 year age group school going students. GYTS has been conducted in different states of India in the period 2000 - 2004. As per this survey, 17.5% of 13 - 15 year old students are using tobacco in some form. In many states alarmingly high prevalence of use of tobacco products among the school - going youth has been reported. North Eastern states like Nagaland (63%), Manipur (46.7%), Sikkim (46.1%) have reported highest prevalence of tobacco use among school students.

As a result of collaborative efforts of Ministry of Health and WHO, the National Tobacco Control Cell was set up in February 2001 to provide impetus to the tobacco control efforts and to coordinate these activities at the national level.

The National Tobacco Control Cell assists in development of comprehensive anti - tobacco public awareness plans to provide health education among the masses; capacity building among NGOs working in the field of tobacco control; establishment and strengthening of tobacco cessation centers and providing key technical inputs on research and policy issues related to tobacco. The Cell has been recognized as an innovative approach towards effective tobacco control, which can be replicated by other countries.

Tobacco has been proven, beyond doubt, to be associated with a large number of serious diseases (see Box - 12). In fact, the single most important lifestyle factor as a risk for diseases is tobacco use. Globally, tobacco accounts for 27.8% of all

cardiovascular deaths, 13.6% of all lung cancer deaths, 6.6% of upper aerodigestive cancer deaths, 6.6% of other cancer deaths, 27.2% of deaths due to COPD and 12.8% of other respiratory deaths. Worldwide, tobacco use causes 4.83 million deaths, loss of 59 million DALYs and estimated economic loss of \$ 200 billion per year. The medical recommendations regarding tobacco are very clear - individuals and communities should completely give up use of tobacco. In public health practice, all functionaries should endeavour to educate and motivate individuals and communities regarding the adversities associated with tobacco use and to give up tobacco. In addition to educating and motivating, we must use all possible means to convince the community leaders, peers, politicians, and social groups to exert influence in this regards, with a view to obtain the following ends :

- Make availability difficult (e.g. banning the sale of tobacco products in major markets, near educational institutions, in hotels / restaurants, etc).
- Make the smokers feel that his smoking habit is “undesirable” (e.g. ban smoking in public places, transport systems, auditoria, offices, meetings / gatherings, parties; create separate restricted areas as earmarked smokers rooms for people to smoke).
- Exerting influence through influential socio - political groups
- Setting of personal example by influential persons as doctors, sports and theatre personalities, etc.
- Enforcement of relevant laws.

Box - 12 : Tobacco Related Diseases
IHD (RR 1.28 to 1.78)
Stroke (RR 1.17)
Lung cancer (RR 12 to 24)
Oral cancer (RR 6.95 to 7.87)
Liver Cancer (RR 1.40)
Cancers of upper aerodigestive tract
Peptic Ulcer
COPD
Buerger's Disease
Hypertension
Amblyopia

Alcohol

62.5 million alcohol users are estimated in India. Per capita consumption of alcohol increased by 106.7% over the 15 - year period from 1970 to 1996. Due to its large population, India has been identified as the potentially third largest market for alcoholic beverages in the world which has attracted the attention of multi national liquor companies. Sale of alcohol has been growing steadily at 6% and is estimated to grow at the rate of 8% per year. About 80% of alcohol consumption is in the form of hard liquor or distilled spirits showing that the majority drink beverages with a high concentration of alcohol. Branded liquor accounts for about 40% of alcohol consumption

while the rest is in the form of country liquor. People drink at an earlier age than previously. The mean age of initiation of alcohol use has decreased from 23.36 years in 1950 to 19.45 years in 1980 to 1990. India has a large proportion of lifetime abstainers (89.6%). The female population is largely abstinent with 98.4% as lifetime abstainers. This makes India an attractive business proposition for the liquor industry. Changing social norms, urbanization, increased availability, high intensity mass marketing and relaxation of overseas trade rules along with poor level of awareness related to alcohol has contributed to increased alcohol use. Taxes generated from alcohol production and sale is the major source of revenue in most states (Rs.25,000 crores) and has been cited as a reason for permitting alcohol sale. Four states - Gujarat, Mizoram, Manipur and Nagaland - have enforced prohibition. Profile of clients in addiction treatment centers in 23 states (including states with prohibition) showed that alcohol was the first or second major drug of abuse in all except one state. The annual loss due to alcohol was estimated to be Rs.70,000 to 80,000 million.

Habitual alcohol use is another major lifestyle factor associated with ill health and a large number of serious diseases, as depicted in Box - 13.

Box - 13 : Alcohol Related Diseases
Hypertension & Stroke (RR 1.4 to 4.1, depending on intake)
IHD (mild consumption may be protective (RR = 0.68); heavy consumption carries risk (RR = 1.33)
Road Accidents
Obesity
Diabetes Mellitus type - 2
Cancers : Female Breast Cancer (RR 1.14 to 1.62); Oral Cancer (RR 1.45 to 5.39); Other cancers (aerodigestive tract, stomach, pancreas, kidneys, bladder) (RR 1.8 to 4.93 depending on intake and site)
Liver disease (RR 1.2 to 13 depending on intake) (cirrhosis, increased susceptibility to liver infections)
Pancreatitis
Degenerative neurological diseases
Social and emotional problems
Psychiatric problems and dependence
Lack of efficiency, productivity and organizational issues.

Besides the diseases, alcohol has additional social and emotional problems, and disrupts family and organizational health. A WHO report indicates that alcohol use accounts for 3.2% of all global deaths and 4% of all global burden of diseases; it also accounts for 3.5% of all DALYs lost due to all causes. What is even more concerning is the recent trend wherein lay magazines tend to put across a conveniently distorted version of the medical research findings, which tend to indicate that moderate drinking is good for health. This is, in fact, an issue which all public health persons would need to counter when talking to individuals and communities. While

it is agreed that “moderate” alcohol intake may be associated with lower HDL - cholesterol levels and lower IHD mortality, the fact also remains that continued alcohol intake, even in mild to moderate quantities, is associated with a number of other diseases like road accidents, various cancers, obesity and hypertension. Secondly, it is quite difficult to maintain “moderation” - many of those who are initially moderate may become heavy drinkers gradually. Thirdly, there are various other more healthy methods (as brisk, regular physical exercise) rather than drinking, to increase the HDL levels. All these aspects should be emphasized on the clientele.

The relationship between even mild drinking and obesity (with all the consequent ill health effects of obesity) is quite logical, as depicted in Box - 14. In addition, even two small pegs may raise the blood alcohol level beyond the legally acceptable in India (30 mg %), and may interfere with the protective reflexes, causing road accidents. The hazards of alcohol use should be well communicated to our clientele and they should be motivated to give up alcohol. The recommendations should be:

- There is nothing like medically prescribed or medically encouraged drinking to get good health; with all its well documented resultant diseases, alcohol should not be used.
- However, despite the above exhortation, if somebody still decides to drink, he or she may do so provided there is no other risk factor (Obesity, Diabetes, hypertension) and provided one drinks only in “moderation”. The guidelines for “moderation” are in Box - 15.
- Besides restricting to moderation, adhere to the following principles : firstly, never drive after drinks (even after very mild drinking); secondly, try not to drink on two consecutive days; thirdly, try not to drink in daytime; and, fourthly, drink along with food and not on empty stomach.

Box - 14 : Alcohol even in mild quantities, promotes obesity by :
Providing “blank” calories - each gram gives 7 Kcal; 1 small peg gives 70 Kcal, equal to running 1 Km!
Promotes overeating
Desire to eat rich, fattening food
Reduces desire of physical activity

Box - 15 : Defining “Moderate” Drinking
A “unit” of alcohol is defined as equivalent of 10 grams pure ethanol.
This will be equal to 1 small peg of hard drink or 100 ml of Wine or half a bottle of Beer.
Moderation means maximum of 3 units in a day for men (and 2 units a day for women)

The Principles of Public Health Approach for Preventing Alcohol and Tobacco Use

As would be apparent from the facts mentioned above, tobacco and alcohol use a major cause of diseases, ill health, reduced

quality of life and lowered productivity, the world over. It is therefore a priority area for all public health systems and functionaries to develop and implement programs and strategies to combat these major ill - health issues. The following are the suggested which can be adopted for this purpose.

Tobacco and Alcohol control issues can be considered together from the preventive point of view since both are highly addictive substances, are used by a large proportion of human population, and are liable to cause a wide variety of serious diseases. The preventive strategy should focus on two levels, viz., firstly, the national / large community level and, secondly, at the individual / family level.

Steps at the National / Large Community Level : The approach would include a combination of three strategies, viz. Information, Education and Communication (IEC) steps, Statutory (legal or regulative) steps, and Fiscal steps, as follows :

IEC Steps : These would include the following

Developing a nation wide educational strategy and program : A comprehensive policy and programme should be developed by nations / states for informing the community members regarding the health hazards due to tobacco and alcohol, the seriousness of these diseases and regarding the potential methods of prevention. Educational programs should involve the departments of advertising and audio - visual media and those concerned with information and broadcasting. Educational messages should be adequately pilot tested and should be presented on various channels of mass media, not only on governmental but also private channels as well.

Counter - Advertising (Counter - Marketing) Campaigns : Experience in developed countries has shown that proactively conducted educational and advertising campaigns to highlight the seriousness of consequences of these substances can actually help a lot in increasing the proportion of population who would give up their use and reduce the proportion of persons who take up smoking. The strategy is, in fact, to counter the advertising/ marketing campaigns which are carried out by various liquor/ tobacco companies and under the influence of which a large number of young people actually initiate their smoking habit. It has also been seen that taking the help of prominent public personalities as cine stars and sports - persons may be of further help in this direction.

School and Youth based IEC programs : The persons who are most at risk of initiating the tobacco and alcohol habit are teenagers. It is therefore very logical that educational programs be developed, targeting these adolescents in the schools as well as at other youth forum as youth festivals, sports functions, etc.

Quitlines / Helplines : Experience in developed countries has provided evidence that developing telephonic helplines may be quite helpful in reducing the prevalence of smokers and increasing the duration of cessation. Such telephonic helplines/ quitlines may be part of governmental effort or NGO effort and are designed to provide total assistance to the smoker/ alcoholic who desires to quit smoking, maintain a state of cessation as well as for persons who want education and assistance for not initiating tobacco use habit.

Fiscal Measures : Increasing the prices of tobacco and alcoholic products definitely reduces the proportion of persons who use these substances; particularly, lesser number of adolescents are able to initiate these habits. This has been shown in a number of countries and has been (privately) acknowledged by tobacco companies. Public Health policy makers should suggest to the governments to consider an increase on excise on raw material and increased taxation on finished product.

Legislative and Regulatory Measures : To back up the educational and fiscal steps, the governments and communities would need to develop legal provisions, so as to make availability of tobacco and alcohol difficult to consumers as well as to ensure that users of these substances do not harm the other members of their family / community due to this habit. In general, the legislative measures focus on the following provisions :

- Printing of statutory warnings regarding the fact that alcohol / tobacco is bad for health, on the packets of tobacco/ alcoholic products.
- Clean indoor air laws and smoke free zone policies, including prohibition of use of these substances in public places, as railways, airlines and other transportation systems, offices, common rooms, restaurants, and such other public places.
- Prohibition of sale of these substances to vulnerable groups, especially children and adolescents.
- Ban on advertisements on promotion of tobacco products.

In our country an extensive law has been promulgated starting with the Cigarettes (Regulation of production, supply and distribution) Act of 1975 which specified the printing of statutory warnings on all cigarette packets. Subsequently, the statutory provisions were enlarged with the promulgation of "The cigarettes and other tobacco products (prohibition of advertisement, regulation of trade and commerce, production, supply and distribution) Act 2003. The act declares that it is expedient in public interest that the Union should take control of the tobacco industry. The act prohibits smoking in public places and provision of a separate smoker's room in restaurants having seating capacity of 30 or more and in airports (From 02 Oct, 2008, i.e. the birthday of the father of the nation, the Govt has extended the promulgation by imposing a blanket ban on all public places). The act also lays down a total prohibition on advertisements of cigarettes and other tobacco products. The act prohibits sale of tobacco products to any person aged less than 18 years and lays down restrictions on trade and commerce in and on production, supply and distribution of cigarettes and tobacco products including printing of statutory warnings on the packets of these products, the letter size, language and other specifications of these warnings, and also the powers of searching the premises and confiscation under this act, as well as the punishment and appeal under this act. The detailed rules (2004) for implementation of the act have been published vide Govt of India Gazette No. 200 dated 25 Feb 2004.

As regards alcohol, we do not have such well formulated legislative regulations as we have for tobacco, but the effort of the Government has been, in recent years, to develop a comprehensive policy as well as legislation to reduce alcohol intake among communities. The available statutory provisions

include the following :

- Printing of statutory warnings on bottles of alcoholic drinks
- Promulgation of "dry state" order by certain state wherein consumption of alcohol is totally banned, except for those having permit to drink
- Testing of motor vehicle drivers for breath test and alcohol level in blood. The upper limit for safety in driving, as far as statutory limits in our country are concerned are 30 mg per 100 ml of blood.

Steps at the Family and Individual Level : These are directed to educating, motivating and supporting the individuals and families for, firstly, not initiating the tobacco and alcohol habit and, secondly, to give up the habit. The following steps are documented to be beneficial :

- Educating and motivating the family members, especially the spouse and parents.
- Enrolling "peer groups" as religious teachers, school teachers, etc., in motivating and playing role model for the community.
- Developing support groups as "alcoholics anonymous" groups and informing the community members about their location, ways to contact them and the help that they can provide.
- Pharmaceutical measures as disulfuram for alcohol cessation and nicotine patches / tablets or bupriopion for tobacco cessation. However, these measures should be used under medical supervision.

Summary

With "modernization" there is tremendous increase in "Non - Communicable" diseases referred to as lifestyle diseases and this issue is a global phenomenon. "Lifestyle", in the context of preventive health care, indicates the behavioural patterns which we routinely adopt. The National Scenario estimated chronic diseases to account for 53% of all deaths in 2005. Mortality due to chronic diseases is expected to rise from 40% of all deaths in 1990 to 67% of all deaths in 2020. Prevalence of coronary heart disease is around 3 - 4% in rural areas and 8 - 10% in urban areas among adults older than 20 years. Data on cancer mortality estimates about 8 Lac new cases of cancer every year. The major cancers in men are mostly tobacco - related. In women, the leading cancer sites include those related to tobacco, and cervix, breast and ovary cancer. Further, India also has the largest number of people with diabetes in the world. World - wide estimated deaths due to cardiovascular disease is 30% of projected total worldwide deaths in 2005, cancer (13%), chronic respiratory diseases (7%), and diabetes (2%). Components of healthy lifestyle and addressing them through preventive angle. One of the very important facets of healthy lifestyle is Physical Fitness & Physical activity. Some work (activity / exercise) needs to be performed to burn off calories and additionally, such activities / exercises should be undertaken with reasonable amount of intensity (vigorousness) so that, in addition to burning the calories, "fitness" is also achieved. For planning a physical exercise program, the dictum is 'Any exercise is good; more the better. Physically inactive lifestyle accounts for 3.3% of all deaths, the focus has now shifted to inculcate healthy lifestyle, by increasing activity

levels in all the four 'domains' of life viz. at workplace, in transport, at home and during recreation time. The exercise program should cater to three major facets of physical fitness, viz. Endurance; Muscular Strength; and, Flexibility. Endurance training program has three distinct components, viz. Frequency. (minimum recommended is 3 per week); Intensity, which should be of at least "moderate" intensity; and, Duration, which can be tailored to meet the individual / community needs but is generally recommended to be 30 to 60 minutes on each day on which exercise is undertaken. The easily applicable recommendations are that every adult should spend at least 200 Kcal every day through brisk exercise - this can be achieved by undertaking at least 30 minutes of brisk walking, covering 2 miles (3.2 Kms) in that time, daily or on most days of the week. Measuring the level of intensity can be based on "Maximum Permissible Heart Rate [MxPHR, calculated as $220 - (\text{Age in years})$], Borg's scale of "Rating of Perceived Exertion (RPE), or by Metabolic Equivalents (MET), considering that one MET is equal to a level at which a person will spend 1 Kcal energy per kg body weight per hour and this level corresponds to the resting stage. In addition to a structured physical exercise programme, the lifestyle should be made habitually active. Principal goal of active lifestyle is to increase energy expenditure without concern for the intensity of activity. The basic principle is that very mild, even inapparent increases in physical activity may make much difference.

Proper diet is as important as physical exercise and fitness, in context of lifestyle diseases. A healthy daily diet should provide calories and all nutrients which are actually required by the body, depending on age, sex, existing body weight, amount of physical activity and other physiological requirements of growth, pregnancy, etc. Dietary fats should provide not more than 30% of the total daily energy intake; within this limit, saturated fats should not provide more than 10% of the total dietary energy. Dietary cholesterol should not exceed 300 mg in a day. Total salt intake should not exceed more than 6 grams a day, while sugars should not provide more than 10% of daily dietary energy. Fruits and Vegetables are rich source of Folic acid, antioxidant vitamins and minerals. In one day, an adult should consume about 400 to 500 grams of fresh fruits and vegetables (not including potatoes). Adequate consumption of dietary fiber has been shown to be protective against cardiovascular diseases, diabetes type - 2, obesity, gall bladder disease and certain cancers, particularly colonic cancers. Dietary consumption of fiber should be at least 30 grams per day.

In public health practice, all functionaries should endeavor to educate individuals and communities regarding the adversities associated with tobacco use and motivate them to give up tobacco.

Alcohol intake, even in mild to moderate quantities, is associated with a number of other diseases like road accidents, various cancers, obesity and hypertension in addition to diseases seen in chronic alcoholics like liver diseases, pancreatitis, hypertension and DM, psychiatric & social problems and dependence. Secondly, it is quite difficult to maintain "moderation" - many of those who are initially moderate may become heavy drinkers gradually. Thirdly, there are various other more healthy

methods (as brisk, regular physical exercise) rather than drinking, to increase the HDL levels. All these aspects should be emphasized on the clientele.

Study Exercises

Long Question : What are the disease of lifestyle. Discuss their epidemiology with specific reference to major lifestyle factors.

Short Notes : (1) Community based guidelines for physical exercise (2) Dietary guidelines for prevention of non - communicable diseases (3) Moderation in alcohol intake (4) Health benefits of physical exercise (5) Measures for community prevention and control of tobacco use

MCQs & Exercises

- Enumerate the major components of unhealthy lifestyle?
- Which of the following is not a life style disease?(a) Breast cancer (b) Mental Stress (c) Osteoporosis (d) RHD
- How many new cancer cases are known to occur every year in India? : (a) 1Lac (b) 5 lac (c) 8 lac (d) 10 lac
- What is India's daily consumption of fruits and vegetables per person per day? (a) 250 g (b) 500g (c) 130 g (d) 350g
- If a 70 Kg man walks slowly, covering 8 kilometers in 3 hours, he would burn off how many calories?
- In above question the activity done will be classified as fitness exercise or just an physical activity
- Those who exercise regularly have higher levels of : (a) LDL (b) HDL (c) Triglycerides (d) Total cholesterol
- Physical exercise bring about reduction in the level of anxiety and stress by release of which chemicals
- Effects of physical activity are long lasting - true/false?
- The minimum recommended frequency for endurance training is : (a) 4 - 5/wk (b) 7/wk (c) 3/wk (d) 1 - 2/wk
- How is Maximum Permissible Heart Rate (MxPHR) calculated?
- Rating of Perceived Exertion (RPE) is for rating which of the following : (a) Frequency of exercise (b) Duration of exercise (c) Intensity of exercise
- Match the following

RPE	1Kcal/Kg body wt/hr
MET	220 - Age in years
MxPHR	Visual analogue

- Moderate intensity of exercise level is equivalent to what MET level in men?
- A subject weighing 60 kg is exercising by Running at speed of 12 km/h. He ran 6 km in 30 min (MET level 12.5). Calculate the amount of energy in Kcal expended by the person and the amount of fat burnt off ?
- According to recommendations of CDC Atlanta and American College of Sports Medicine a person should spend how many calories per day by physical exercise?
- Saturated fats should not provide more than what percentage of the total dietary energy?
- What is the daily recommendation of salt intake by a person?
- Globally what percentage of cardiovascular deaths is contributed by tobacco intake?

20. What is the estimated RR of hypertension and stroke due to alcohol intake?

21. A "unit" of alcohol is defined as equivalent of how many grams pure ethanol? (a) 1 g (b) 10g (c) 50g (d) 100g

Answers : (1) Lack of physical activity; Faulty dietary habits; Tobacco use; Excessive alcohol intake; Mental Stress; and Disregard to personal safety (regarding accidents, Personal hygiene, Promiscuous Sex and towards Insect Vectors of Diseases); (2) d; (3) c; (4) c; (5) 550kcal; (6) Physical activity; (7) b; (8) endorphins; (9) False; (10) c; (11) The MxPHR for any individual is calculated as $220 (-) \text{ Age in years}$; (12) c; (13) RPE = visual analogue, MET = 1 Kcal / kg body wt / hour, MxPHR = $220 - \text{Age in years}$; (14) 4 to 5.9; (15) Energy spend is $60 \times 12.5 \times 1/2 = 375$ Kcal i.e 42 gm of fat (1gm fat provides 9 Kcal); (16) 200kcal; (17) 10%; (18) 6 gm; (19) 27.8%; (20) 1.4 to 4.1; (21) b.

“Yuktahar Viharsya Yukt Chestsya Karmsu ; Yukta Swapnav Bodhayasya Yogo Bhavati Dukh Ha.” (Yoga killeth out pain for him who is regulated in eating and amusement, regulated in performing actions, regulated in sleeping and waking”)

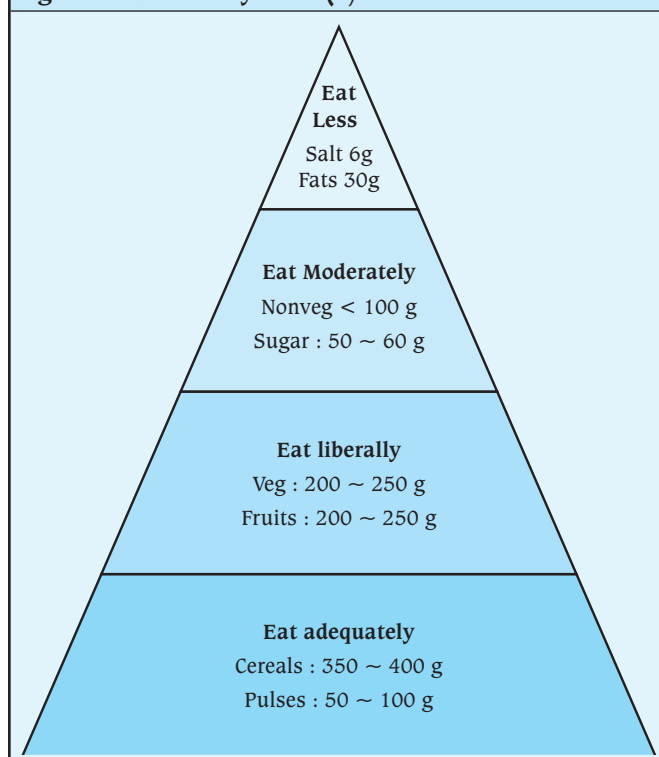

~Shrimad Bhagavad Gita

In an earlier chapter we have seen that a faltered diet, obesity and poor lifestyle puts the human body to a great risk for IHD, diabetes, hypertension and cancers. Many studies indicate that a change in lifestyle can reduce the risk of these conditions (1-5). The practical modifications that should be made in our day to day diet to reduce risk of lifestyle diseases are discussed in this chapter.

The Food Pyramid

The principles of a healthy diet for an average adult (consuming 2500 to 2800 Kcal per day) can be summarized pictorially, through a food pyramid (Fig. - 1) (1). Foods depicted at the bottom of the pyramid (cereals, pulses, vegetables and fruits) are to be consumed in plenty, foods in the middle of the pyramid, meat products and refined sugars, are consumed in moderation and the foods at the top (salt and oils) are sparingly consumed.

Fig. - 1 : The Food Pyramid (1)

In other words, foods which give low calories (and low refined

sugars), enough proteins, low fats and salts but lots of antioxidants, vitamins and natural fibre constitute a healthy diet. Such a diet is contributed to by whole grains, cereals, pulses, milk, low fat foods and plenty of fresh fruits and vegetables, typically depicted at the bottom of the pyramid.

The First Principle of Healthy Diet - It Should Provide the Required Energy, No More and No Less

Besides fulfilling the biological requirement of energy, food caters to the important psychological cue of satiety. So, one eats not only to meet the nutritional requirements, but also because one needs to be psychologically satiated each and every time he sits to dine. Such satiety depends on the “bulk” of food rather than the count of calories. Therefore the quantity of food, besides of course the quality also decides, as to which food is healthy or otherwise. Therefore one may aim to keep the bulk large and the calories low (Box - 1).

Box - 1 : Keeping bulk large and calories low! An example...

One liter of tomato soup and plain rice/dal will give the same level of satiety as one kg of butter chicken, but the former will provide only 500 Kcal while latter 4000 Kcal. Therefore food items which are thin, watery, or made of grains, legumes and pulses provide lesser calories than even much lesser quantities of fats and starchy foods. It is recommended to consume low energy dense items like fresh fruits, vegetables, raw salad or meals cooked with little amount of oil rather than highly energy dense food stuffs like oil dripping butter chicken, mattar paneer or cheese and chocolates!

Low calorie foods : As a general rule, food that is low in calories, but which can fulfill the daily requirements of energy in a balanced manner is considered as healthy. To keep the calories low in the diet the upper limit of calories intake must be limited to the recommended values for sex and activity level. Fats and oils are the most concentrated source of energy so intake of fats and oils must be restricted, as mentioned earlier. Similarly excessive intake of carbohydrates (cereals and starchy foods like potatoes) must also be discouraged. Some low calorie foods are given in Table - 1 (6).

Table - 1 : Some Low Calorie Foods

	Approximate quantity per serving	Calories per serving
Dalia	1 plate	80
Khichri	1 plate	160
Dhokla	2 pieces	100
Poha	1 plate	120
Biscuits	4 numbers	150
Kheer	1 katori	120
Bread	2 slices	125

High calorie fatty foods : High calories are provided by food rich in oils and fats. These foods could be any ‘oil dripping’ preparations or fried foods like the deep fried *puris*, *kachories*,

samosas, pakoras, parathas, matar paneer, malai kofta, cheese balls, meat preparations (mutton curry, butter - chicken) or simply lot of ghee on the *roti/dal*, sweets, cakes and pastries, etc. Table - 2 gives calories provided by one typical serving of these 'unhealthy fatty foods'. The high calories present in these foods increase weight and cause obesity. These foods are high in fats, esp saturated fatty acids and cholesterol, which are strong risk factors for cardiovascular diseases and some cancers. Repeated cooking/frying of these fats (saturated or unsaturated), turns them into a dangerous variety of fats called as the trans - fatty acids (t - fatty acids). The trans - fatty acids are considered as extremely dangerous for the cardiovascular system, as they reduce the HDL - c and increase LDL - c, thereby further augmenting the risk (2, 6).

Table - 2 : Some High Calorie Foods		
	Approximate quantity per serving	Calories per serving
<i>Samosa</i>	1 number	256
<i>Masala Dosa</i>	1 number	360
<i>Kachori</i>	2 numbers	500
<i>Mathri</i>	1 plate	500
<i>Puri</i>	4 numbers	250
<i>Ghee roti</i>	4 numbers	360
<i>Cake</i>	1 small piece	250

Recommendations on Fats - The Preventive Prescription (Box - 2)

Dietary intake of fats, esp the qualitative composition of fats in diet, strongly influences the risk of lifestyle diseases, through effects on blood lipids, thrombosis, blood pressure, endothelial function, arrhythmogenesis and inflammation. The general recommendations for dietary fats are :

- Not more than 20 to 30% of all calories should be obtained from fats.
- Out of this, not more than 7% (of the total energy) should be from saturated fatty acids.
- Adequate intake of Polyunsaturated Fatty Acids (PUFA) : 6 - 10% of daily energy intake, with an optimal balance of n - 6 PUFA (at 5 - 8%) and n - 3 PUFA (1 - 2%) levels of daily energy intake, respectively.
- Intake of Monounsaturated Fatty Acids (MUFA) should make up rest of the daily energy intake.
- Daily cholesterol consumption should be restricted to less than 300mg/day, (preferably < 200 mg) mainly through restriction of dairy fats and red meat.
- The trans - fatty acids intake should be negligible (less than 1%) of daily energy intake.
- Restrict intake of fats from dairy and red meat sources, avoiding use of hydrogenated oils and fats in cooking.

The dietary goals with respect to various kinds of fats can be achieved by limiting the intake of fat from dairy and meat sources, avoiding the use of hydrogenated oils and fats and substituting saturated fats with unsaturated plant oils.

Calculating at a scale of 20 to 30% of energy to be obtained from

fats, (which includes 7 to 10% from saturated fats), for a daily requirement of 2400 Kcal, a sedentary man needs to obtain about 700 Kcal from fats. Half of these come from invisible fats (which are mostly of unsaturated variety) and the other half needs to be provided through apparent dietary sources (350 Calories/day or about 40g of oil/fat per day since 1 gram fat gives 9 Kcal). So in a month, one would need to purchase (40gx30days=1200g) i.e. about 1.25 kg of oil / ghee / butter. Out of this, about one - fourths could come from saturated fats, thus one person needs about 250 grams of ghee / butter and about 1 Kg of edible oil per month.

Different vegetable oils available in the market have varied saturated and unsaturated (PUFA, MUFA) compositions. One must therefore use different oils like mustard, soyabean, groundnut, safflower, sunflower, rice bran, cottonseed, sesame etc. in rotation, to obtain all types of unsaturated fatty acids.

Box 2 : The preventive prescription on fats for lifestyle diseases
One must cater for 1 Kg of vegetable oil and not more than 250 g of butter/ghee per adult in the family per month.
For a family of 4 adults it works out to 4 Kg of vegetable oil and about 1 Kg of butter/ghee per month.
Out of these 4 kgs of oil to be procured in a month, one may purchase different varieties of oils (or rotate the oils over few months) to get an all round benefit.
Regular intake of fish (1-2 times per week) provides PUFA and MUFA, rich in omega-3 fatty acids, beneficial for heart.
Non-frying methods must be resorted to, rather than deep frying and baking with lots of butter/fats.
<i>Puris, parathas</i> rich in oils should be substituted by plain <i>rotis</i> .
Sweets with plenty of ghee and oils must be shunned.
Snacks (<i>kachoris, pakoris, namkeens</i> etc.) which are rich in oils must be avoided.

Cereals

A maximum of 60% of total energy intake i.e. about 1450 Calories should be obtained from carbohydrates for a sedentary male. About 360 g carbohydrates per day would provide these calories. Carbohydrates in excess of this amount would result in accumulation of surplus calories, eventually leading to obesity. Excess intake of starchy food (potato - as vegetables, chips, wafers, French fries, etc.) also provides plenty of 'easy' calories, liable to cause obesity. It is also recommended that different cereals must be consumed in one form or the other. One cereal could be the staple cereal say wheat, but it is advisable to consume one other cereal say rice as the second parallel cereal. In addition to this other cereals e.g. corn, millet (*bajra, ragi*) etc. should be used as snacks.

Fibre : It is recommended that 35 to 40 grams of fibre should be consumed every day (4). Intake of whole grain cereals must be encouraged. Excessive milling of cereals leads to loss of the outer layer of bran and fibre. Thus consumption of whole grains provide adequate fibre. These can be obtained from

brown rice, flour with higher level of bran i.e. coarse *atta*, *dalia* and porridge. To ensure maximum intake of fibre, the flour (*atta*) should not be strained with a thin strainer, so that bran is incorporated in the flour. The bran should not thus be discarded. Pulses, beans and other legumes also provide valuable fibre, so they must be consumed aplenty. The fruits and vegetables contain abundant amount of fibres and must be consumed regularly.

On the other hand, processed products of refined cereals such as refined flour and *maida* e.g. noodles, pasta, cake, white - bread, pizza, macaroni etc. are low in roughage and fibre. Their consumption may cause constipation as compared to a diet that is high in fibre.

Recommendations on salt

Many studies have proved that the amount of sodium in diet is a definite risk factor for hypertension and heart disease. Sodium is present in common salt which is generally consumed without a second thought. The use of sodium should be limited to reduce the risk of lifestyle disease. An upper limit of 6 g of salt is recommended so its use should be restricted to less than this amount (6 g/day). For the preventive prescription on salt, see Box - 3.

Box - 3 : The preventive prescription on salt
At a rate of 6 g/day, for a family of four, salt consumption works out to about (6gX4) = 24 g per day; or about 750 g per month. The following recommendations are made :
For a family of four adults, buy a 1 kg pack of salt and about 1/4 th should be left at the month end, which should either be discarded or included for in the next months 'quota' of 750g.
Avoid foods containing excessive salt like pickles, <i>chutneys</i> , <i>papads</i> , sauce, tinned and preserved food, processed cheese etc.
Consumption of fast foods like burgers, pizza, French fries, <i>chat</i> , <i>bhel-puri</i> which contain high amount of salt must be discouraged.
Remove saltcellars from dining table, to discourage sprinkling of salt on ready to eat food. Avoid sprinkling of salt on fresh salads.

Potassium : Dietary intake of potassium lowers blood pressure and is protective against stroke and cardiac arrhythmias. Potassium intake should be at the level which will keep the sodium potassium ratio close to 1, i.e. at the level of about 5 to 6 g/day. This could be achieved by adequate daily consumption of fruits and vegetables, in the amounts recommended subsequently.

Recommendations for fruits and vegetables

Fruits and vegetables contribute to health through a variety of phytochemicals, antioxidants, flavanoids, potassium and fibre. A variety of seasonal fruits and vegetables should be consumed. Adequate intake of fruits and vegetables (400 - 500 g) (200 to 250 g each of fruits and vegetables) every day is recommended to reduce the risk of lifestyle disease. This recommendation of 400 to 500 g does not include potatoes. A family of 4 should

ideally consume 1.5 Kg fruits & vegetables in a day. Variety is as important as quantity. No single fruit or vegetable provides all the micronutrients needed to be healthy. The key lies in the variety of different fruits that one eats.

An average Indian takes a maximum of just three servings of fruits/ vegetables a day. The earlier dietary guidelines called for about 100 g of fruits to be taken per day. However the guidelines have been changing with the stronger emerging inverse relationship between lifestyle diseases and fruits. Now the American authorities recommend as many as five to thirteen servings of fruits and vegetables a day, depending on one's caloric intake. For a person who needs 2,000 calories a day this translates to nine servings, or about 5 cups/portions per day. This doesn't count potatoes (as potatoes are mostly starch). A typical portion can be defined as

- Melon, Pineapple : Large slice
- Fresh corn on the cob : 1 whole cob
- Apple, banana, orange : 1 fruit
- Small tomatoes : 6 tomatoes
- Grapes, cherries or berries : 1 cupful
- Fresh fruit salad : 2 - 3 heaped tbsps
- Dried fruit - raisins, apricots, dates, figs : 1/2 - 1 heaped tbsps
- Fruit juice : 1 glass (150ml)
- Vegetables, raw, cooked, frozen or canned : 2 heaped tbsps
- Salad : 1 dessert bowlful

Sugary Foods

Such foods contain excessive refined sugar. Chocolates, cakes, candies, *halwa*, *laddoos*, ice creams, soft drinks etc. are some examples of such foods. These foods are also considered unhealthy. These foods have high glycaemic index and their consumption causes sudden spurt in blood glucose levels, which may be deleterious for health. They also contain high calories (e.g. 1 small piece of cake provides 250 Kcal), which leads to an increase in body weight causing obesity and other diseases. In addition to these calorie related drawbacks, since most of these foods are commercial products, they contain chemicals, artificial colours, flavours and preservatives, which are generally unnatural and harmful, many of them being carcinogenic. Moreover, excessively sugary foods are also liable to cause dental caries.

Refined Sugar

Excessive intake of refined sugar is deleterious to health. Therefore its use must also be limited by all in general and by patients of diabetes, hypertension and heart disease in particular. As general guidelines, refined sugars should provide not more than 10% of daily dietary energy; for a sedentary man requiring 2400 Kcal per day, this comes to 240 Kcal i.e. 60 grams of sugar. The following recommendations are made :

- The recommended sugar intake is about 50 - 60g per adult per day.
- For a family of 4 the maximum sugar consumption works out to about (50 to 60gX4) = 200 to 250g per day.
- Thus, for such a family composition, maximum sugar purchase should not be more than 6 to 7.5 kg per month.

Fish

Fish consumption is protective against CVD, stroke etc. For

those who eat fish, 250 to 300 grams of fish (avoiding deep frying) is recommended to be taken twice or thrice a week.

Meat & Eggs

Non vegetarians should prefer lean meat (fish or chicken) rather than mutton and beef (5). Meat contains high amounts of fat so their use must also be limited quantitatively and qualitatively. The following recommendations are made :

- Restrict the consumption of red meat (beef, pork, mutton)
- Preserved meat (ham, bacon, salami, sausages) must also be limited
- Prefer lean meat (chicken and fish) to red meat
- Prefer marinated / baked / grilled dishes to oil dripping fried ones
- Discourage high fat meat / cooked in thick gravies
- Let meat be a part of meal, not the full meal
- Egg yolk too contains high cholesterol so its use should also be restricted. (Yolk of one egg gives 250 mg dietary cholesterol, which is almost upper limit of recommended dietary cholesterol)

Hot foods

Consumption of very hot drinks and foods typically consumed in some cultures probably increase the risk of carcinoma of oral cavity, pharynx and oesophagus. It is recommended not to consume foods/drinks when they are very hot (scalding hot).

Junk foods

Fast foods are served quickly and conveniently at a relatively low cost and so are very popular especially amongst youngsters. Fast food sales have increased dramatically over the past decade, becoming an integral part of our fast paced lifestyle. These include burgers, pizzas, chips, French fries, wafers, colas etc.

Junk food is generally a fast food that is devoid of nutritional value. Regular and consistent 'addiction' to fast foods may therefore be deleterious to health (7). For example burger and cola are nutritionally only refined carbohydrates and sugar. It contains empty calories and hardly any vitamins, minerals or proteins. Some common problems with these foods are :

- Most such menus lack vitamin A, folate, biotin, pantothenic acid and other vitamins
- They are deficient in iron, calcium and copper and other trace elements
- The calorie content of such a meal could be about 900 to 1800 k calories, which is only 33 to 66% of the RDA. Excessive consumption of these is liable to increase weight and cause obesity
- Their sodium content is very high and potassium content low
- Contain chemicals, artificial colours, flavours and preservatives
- The fat content of some of these meals may be as high as 50% of the total daily calories consumed
- The ratio of saturated to unsaturated fatty acids may be unfavourable
- The method of cooking may not be acceptable (deep frying/grilling). Also, the temperature at which food is fried, and if the cooking fat is reused, affects fat quality
- Very costly and less beneficial

Obesity

One of the commonest expressions of unhealthy diet, often combined with lack of physical activity, is obesity. Indeed, we are amidst an epidemic of obesity. Over the past two decades there has been a dramatic rise in the prevalence of obesity throughout the world. It is estimated by the WHO that globally, over 1 billion (16%) adults are overweight and 300 million (5%) are obese. The highest rise in the number of obese is noted in the countries with fast growing economies especially of South East Asia. As many as 250 million people in the third world countries suffer from obesity. In India the prevalence of obesity is 12.6% in women and 9.3% in men (10). In other words, more than a 100 million individuals are obese in India. We are truly in the midst of an obesity epidemic, which has serious health ramifications (11).

Epidemiological Determinants of Obesity

Obesogenic environment : Today the shared environmental factors like affluent lifestyle, rich food, sedentary home environment, vanishing old family traditions (with regards to eating, exercise and outdoor activities), the 'couch - potato' culture etc. substantially contribute to obesity. This environment is moulded towards a very favourable milieu for obesity.

The varied lifestyle and dietary habits of people play an important role in the causation of obesity. In India one important factor, which has ignited the obesity epidemic, is the 'nova - rich' culture. This is marked by a sudden increase in income, having more disposable income at hand, higher purchasing power and being able to spend more on food. Stress, time crunch, sedentary lifestyle and excessive television viewing add fuel to fire. Non - traditional foods and snacks are considered as more and more mainstream. Easy availability of fast foods, falling prey to food fads, pub and junk food culture and aping the west make the problem more complex.

Aggressive advertising, marketing and universal accessibility of chips, wafers and colas have made them not only a household item but a must for any outing or birthday party! These are some of the reasons of urban obesity. Subconsciously we are imparting the same 'unhealthy' eating - behaviour to the children, ensuring that the next generation too falls in the same vicious cycle of no return.

Age : The incidence of obesity increases with age till about 60years. The vulnerability is maximum in the middle age (around 40 years of age), owing to certain hormonal changes, affluence and a more sedentary lifestyle at this age.

Gender : Females are more likely to be obese as compared to males, owing to inherent hormonal differences.

Ethnicity : There are large unexplained variations in the prevalence of obesity in the people from different ethnic groups.

Education levels : It is seen that in the Indian setting, people with a higher education level, are more likely to be obese, as compared to those who are less educated. It is because the educated are likely to be more affluent. In the west, however, the educated might be in a better state of health, as they are more aware and concerned about health issues.

Income : The effect of income too is varied, in India and in the West. Just like education, those with higher income are more likely to be obese in India, but not so in the West.

Marital status : Those who are married are more likely to be obese as compared to those who are not.

Parity : Women with higher parity are more likely to be obese. At an average the woman gains 1kg weight with each pregnancy

Diet : A diet rich in fats, refined sugar and carbohydrates predisposes to obesity. Excessive consumption of sweets, cold drinks, fried food, baked items, pickles and chutneys, fast foods, alcohol etc. is responsible for obesity. Consumption of as little as 100 extra calories per day would increase the weight of an individual by 4 kg in one year. More details on the relationship of diet and obesity are discussed in the subsequent paragraphs.

Smoking : Smoking per se reduces the likelihood of obesity, by virtue of nicotine being an anorexic agent. But this positive effect of smoking can by no means be endorsed for its promotion.

Alcohol : Alcohol provides 7kcal per gm, which is almost double the calorie content of carbohydrates or proteins (4kcal). Such a high calorific value in itself is a risk factor for obesity. The snacks consumed along with an alcoholic drink are invariably nutritionally rich (fried, fatty and oily), which add many more calories and predisposing the individual to obesity.

Physical Inactivity : High physical activity is a vital component that keeps accumulation of fat and obesity under check. One who is undertaking minimal activity and is leading a sedentary life is at a risk of obesity.

Causes of Obesity

Obesity results from an excess of dietary energy intake as compared to energy expenditure and thus both an increase in intake and a decrease in energy expenditure will lead to excess calories being stored as fat and, ultimately to obesity.

Increased energy intake : An increased energy intake due to lifestyle changes and affluence as seen in urban areas seems to be fuelling the obesity epidemic. A detailed discussion follows in the next paragraph.

Passive overeating : The term passive overeating is applied to the practice of eating without a biological need, and not expanding the calories thus gained. Such a situation is commonly seen in the urban setting today where one relishes French fries, wafers and other high calorie snacks while watching TV or using a computer.

Binge eating : It is the practice of overindulging in eating in a short time. This might occur in a party, on a weekend or with drinks. In the binge eating occasions become rather frequent; it certainly is a cause of obesity.

Decreased energy expenditure : There is a rapid decline in energy expenditure i.e. in manual labour resulting from vehicle ownership, availability of labour - saving devices, shunning outdoor sports and watching television and computer use for long hours. These factors contribute to obesity.

Metabolic factors : In some individuals endocrine disorders such as Cushing's syndrome and hypothyroidism, Prader - Willi

syndrome etc. are the cause of obesity.

Genetic factors : Obesity tends to run in families. Obesogenic genes are under study, which alter the metabolism or alter the response to obesity limiting hormones like Leptins etc.

Fetal programming : The Barker's hypothesis proposes that undernutrition during pregnancy may increase the susceptibility of that individual to obesity in adulthood.

Critical Periods for Weight Gain

Weight gained during certain critical periods, usually lead to an increased number of fat cells and makes obesity difficult to treat. It is important to be on guard during these critical periods, with an aim of preventing almost irreversible weight gain (12).

These periods include :

- Age range of 12 to 18 months
- Age range of 12 to 16 years
- Gain of 60% (or more) of his ideal weight by an adult
- Weight gain during pregnancy

Quantifying Obesity

Body Mass Index (BMI) : Overweight is usually determined by the Body Mass Index (BMI), which is a relationship of the person's weight to his height. BMI is computed by taking the body weight in kilograms and dividing it by the square of the height in meters.

$$\text{Body Mass Index (BMI)} = \frac{\text{Weight (Kg)}}{[\text{Height (m)}]^2}$$

BMI does not measure the body fat but relates well with the degree of obesity. The categories of obesity as pronounced by the WHO are depicted in Table - 3. A BMI of 25 - 30 is considered as a warning sign and may warrant intervention, especially in the presence of additional risk factors. A BMI of 30 or higher is generally considered the point at which some form of treatment is required. Obesity Class III i.e. BMI >40 or Morbid obesity, is a medical condition that impairs a person's overall health and therefore requires medical attention.

BMI	Classification	Risk of comorbidities
< 18.5	Underweight	Low
18.5-24.9	Healthy/normal weight	Average
25 - 29.9	Pre-obese (Overweight)	Mildly increased
30 - 34.9	Obesity Class I	Moderate
35 - 39.9	Obesity Class II	Severe
> 40	Obesity Class III	Very severe

The guidelines have been revised lately for Asians, considering the fact that Asians (esp South East Asians including Indians) are more susceptible to metabolic syndrome. These are summarized in Table - 4.

BMI	Classification	Risk of co - morbidities
< 18.5	Underweight	Low
18.5 - 23	Normal weight	Increasing but acceptable
23 - 27.5	Pre - obese	Increased
>27.5	Obese	High

Waist circumference : Measurement of the waist circumference is a practical method to assess obesity, esp. the degree of abdominal adiposity and the cardiovascular disease risk. Waist is measured at mid point of lower border of rib cage and iliac crest (at the level of umbilicus). A measure of less than or equal to 90 cm for men and 80 cm for women is considered healthy.

Waist - Hip Ratio : It is another measure of abdominal adiposity and the cardiovascular disease risk of the individual. A ratio of < 0.9 for men and < 0.8 for women is considered normal.

Types of obesity

Gynoid / 'Pear shaped' : The fat is evenly distributed (globally distributed).

Android/'Apple shaped' : In this type of obesity, the fat is centrally distributed or deposited preferentially in the abdominal region. This expresses the peritoneal (visceral) distribution of fat in the individual. This type of obesity is commonly seen in men of the South East Asian region, including India. Such a distribution is a higher risk factor for coronary artery disease as compared to the global distribution of fat in the body. Higher waist circumference or higher WHR is a good indicator of visceral (peritoneal) deposition of fat.

Hazards of obesity

Obesity is associated with a higher risk of mortality and morbidity. The life expectancy of a morbidly obese individual is about a decade lower than one with normal BMI. Most overweight and obese individuals exhibit certain symptoms like difficulty in walking, heavy breathing while walking, joint pains, snoring, morning headaches and shortness of breath. Some specific clinical consequences are listed below :

Metabolic & Degenerative : Diabetes type 2 (50 to 100 times more common in obese), hyperlipidaemia, ischaemic heart disease, hypertension (5 to 6 times commoner), stroke (2.5 to 6 times commoner), gall stones, breast and colon cancer, infertility (men and women), gout and polycystic ovary syndrome are seen more often in the obese.

Physical : Osteoarthritis, chronic back pain, respiratory problems, limited mobility, higher accidents, sleep apnoea and skin problems.

Psychological : Depression, low self - esteem, social isolation, poor employment status, impaired relationships and discrimination.

Prevention of Obesity

"Most obese people won't enter treatment, most who do won't lose weight and most who lose weight regain it" ~ Stukard

The quotation by Stukard given above, very aptly summarizes, the importance of prevention of obesity vis-a-vis treatment.

Prevention is the the only viable long term strategy for many reasons.

On the other hand, losing 10 kg is associated with :
<ul style="list-style-type: none"> ● A reduction in total mortality by 20% ● A reduction in systolic blood pressure by 10 mmHg ● A reduction in diastolic blood pressure by 20 mmHg ● A reduction in fasting glucose by upto 50% ● A reduction in total cholesterol by 10% ● A beneficial rise of 8% in HDL cholesterol ● An improved self - esteem

Levels of Prevention (9)

1. Universal Prevention : As the name suggests, universal preventive measures are meant for all the individuals in the community, irrespective of their weight status. These measures include healthy lifestyle practices, like consuming a prudent and healthy diet. This includes low consumption of fat and refined carbohydrates. Active physical activity and shunning sedentary lifestyle also forms a part of this strategy. Health and nutritional education is also imparted to everyone in order to create awareness amongst masses for prevention of obesity.

2. Selective Prevention : High risk individuals are targeted under this preventive strategy. The high risk individuals are those who are more likely to gain weight. These include affluent people especially adolescents, pregnant women, middle aged people and those with a rich sedentary lifestyle consuming high energy food (fats) and those under psychological stress. Those with a hormonal disorder, family history of obesity or on certain drugs like Lithium, Sodium valproate, hormones etc. are also at a high risk of obesity.

3. Indicated Prevention : Indicated Prevention or the Secondary preventive measures are to be taken for those with existing problems of overweight and obesity.

How to Reduce Weight?

Nearly 2500 years ago, Socrates had very aptly said : *'Eat only when hungry and drink only when thirsty, and never to leave the table with a feeling of satiety'*.

The aim should be to maintain BMI below 25 kg/m² (preferably below 23.5) and the waist circumference below 90 cm in adult men and < 80 cm in adult women, by a prudent combination of diet and physical activity and avoid weight gain in adulthood. Details are discussed in subsequent sections. It is important to follow the height weight chart so that one could follow his BMI.

Being overweight, a high BMI or an overt obesity is probably the first indication of the fact that our diet is off - course and needs correction. If ignored at this stage other more sinister lifestyle diseases might soon follow. The origin of obesity could however be multifactorial. Many modalities for treatment/prevention of obesity are available. The dietary therapy (commonly known as 'dieting') remains the most practical and effective measure. Other measures are :

- (a) Behaviour therapy
- (b) Drug therapy
- (c) Surgical intervention

(d) Genetic approach.

In the present chapter we shall concentrate only on the dietary therapy.

Reducing weight through dietary therapy (dieting) : The first step to adopt a healthy lifestyle is to get educated on nutritional and health aspects. Understanding the nutritive values of Indian foods is perhaps a good beginning. One must learn about calorie content of different foods, food composition (fats, carbohydrates and proteins), nutrition labels, types of foods to buy and details on cooking procedures. Correct dieting technique involves instructions on how to make safe, sensible and gradual change in eating patterns. Moderate reduction in calorie intake is essential to achieve a slow but steady weight loss. This strategy also helps in maintaining this weight loss.

People should be encouraged to increase the intake of complex carbohydrates (unrefined cereals and sugars, fibre rich foods) and to decrease the intake of fats and simple carbohydrates (refined sugars, excessively milled cereals e.g. white bread, etc). Intake of low calorie and low fat foods must be emphasized. Fruits and vegetables must be made an integral part of the diet.

There are four areas to be considered in the use of dieting and nutritional education in treating obesity. These are :

- Ascertain the activity status : sedentary, moderate or hard worker. Assess the present BMI and the desired BMI (20 to 25 kg/m²). This would indicate the weight (in Kg) to be reduced.

- Set a practical time frame for weight reduction. It has to be achieved at a rate of around 1 to 1.5 kg per month.
- Assess the daily calorie intake from fats, proteins and carbohydrates. The weight to be reduced is then translated to the calorie restriction. These calories are distributed between carbohydrates, protein and fat so as to cut down calories preferably from fats and carbohydrates (in that order). This also helps balance all nutrients.
- Suitable substitutions should be made. The frequency with which the foods are to be eaten and the situation in which the food is ingested is also to be looked into.

An example is illustrated in Box - 4.

Food substitutions that help in weight - loss (14,15) : It is well known that one must try to eat a variety of foods, especially whole - grains and lots of fruits and vegetables. These foods can be filling and satisfying and are lower in calories than foods full of oils or fats. Some times it is not only scientific but easy and more palatable too, to substitute one (set of) food item with other, which is less fattening or healthier. While cooking, try to replace undesirable ingredients with healthier alternatives. Some such examples are given Box - 5.

While these substitutions help in a sustained weight loss, there are some other practical tips that would make the process of weight loss easy, worthy and fun. These tips must be incorporated into our lifestyle and they will help reduce weight in a 'natural' way (Box - 6).

Box - 4 : Reducing weight - An example
Let us take a 1.66 m tall, sedentary male, weighing 80 kg.
<i>Step 1</i> : His present BMI works out to 29 kg/m ² . Let us presume that his desired target BMI is 25 kg/m ² . To achieve this BMI his weight must be about 69 kg i.e. he must reduce 11kg.
<i>Step 2</i> : It is recommended that he reduces 1.5 kg weight per month, i.e. he would be able to reduce 11 kg in about 7 months.
<i>Step 3</i> : Assess his total daily calorie intake. As a rule, generally, a reduction of about 500 Kcal brings about a weight loss of about 500g per week. Conservatively, let us assume that a reduction of say, 1.5 kg per month can be achieved. 500 Kcal per day can be reduced by cutting down 16 g oil (150 Kcal), and about 85 g carbohydrates per day. Suitable modifications must also be made to other lifestyle factors like alcohol, junk foods, parties, snacks, physical activity etc.
<i>Step 4</i> : Make suitable substitutions as applicable (see next Para). For example, replace saturated fats with PUFA/MUFA, replace whole milk with skimmed milk, and refined flour with whole-wheat flour. More fruits and vegetables could be included.

Box-5: Making Some Wise Substitutions - From Fat to Fit
Refined carbohydrates (milled rice, white bread, biscuits) must be replaced with complex carbohydrates e.g. brown rice, whole-wheat <i>atta</i> and whole-wheat bread etc.
High starch foods (potatoes, rice) must be replaced with high fibre ones (whole grains, beans and some vegetables turnips, beet-root and carrots)
Fried nuts with plain nuts
Whole milk with low fat skimmed milk
Substitute mutton and beef with lean meat (e.g. chicken)
Substitute oily meat preparations with non-fried stews, soups
Substitute chips, wafers, burgers, <i>samosa</i> , cutlets with plain toast, fruits, salad and fruit juices
Sweet biscuits with plain ones and nuts
Substitute saturated fats (ghee, butter, t-FA) with vegetable oils : sunflower, safflower, groundnut, linseed or cotton seed oils

Box - 6 : Some more tips on dieting
Do not skip meals to reduce weight
Do not eat left over food after the meals
Eat many small but measured meals
Or eat a minimum of three meals
Do not snack while watching TV or using computer.
It is a myth that some foods can burn fat
Do not shop when hungry as you're likely buy 'junk food'
Reduce stress through relaxation like meditation
Develop a positive attitude and be cheerful
Exercise regularly to burn body fat, strengthen muscles reduce stress
Slow and steady weight loss of about 0.5 -1kg per week is safest

While going through the process of dieting and weight reduction some more precautions must be kept in mind. These cautions are summarized in Box - 7.

Box - 7 : Other cautions on containing weight
Food labels claiming 'low-fat' or 'no-fat' may still have lot of calories
Food labels claiming 'zero cholesterol' may not mean 'zero oil'
Drink enough water each day @ minimum of 8-10 glasses
Alcohol has high calorie content; Snacks taken along with drinks add to calories
Fruits and vegetables are low calorie and source of antioxidants

Fad diets and their role in weight reduction : Fad diets stress either the absence or presence of particular foods or combination of foods. These are commonly aimed at weight reduction. A fad diet is a set of menus advocated generally by people who have little or no knowledge of nutrition or on the basis of inadequate evidence by nutritionist as well. Even though such diets fail to meet the healthy diet specifications, they turn out to be beneficial for a short duration. They are so different from customary foods and are so unpleasant to follow that they are used for a short duration, generally not long enough to cause deficiency. People taking up fad diets skip from one such diet to other, which again saves them from deficiency states. The secret of the short - lived success of such diets is that, weight is rapidly lost, but is regained little later, once the former eating habits are resumed (16).

Commercial 'Weight Reducing' Diets

Either the sheer number of obese and weight conscious people is so large or there is such a glamorization of good physique that today dieting is not only 'commercialized' but dieting and 'slimming centres' have attained industrial proportions. Visiting a well - known slimming centre is considered a prestige symbol for the affluent.

Popular diets have become increasingly prevalent and controversial. More than 1000 diet books are now available, with many popular ones departing substantially from mainstream medical advice. Public interest is being fuelled by cover stories of popular magazines and televised debates.

Out of the thousands of structured commercial diets, probably the more popular ones are the *Atkins diet*, *Ornish diet*, *Weight watchers diet* and *the Zone diet*. These are based on different 'principles' to reduce weight. For example, *Atkins diet*, the most popular of the lot, restricts intake of carbohydrates to less than 30 g a day and permits ad - libitum, the consumption of fats (fatty meat, butter, and other high - fat dairy products). The *Ornish diet* restricts fat, *Weight watcher's* diet restricts portion size and calories, *Zone diet* modulates macronutrient balance and glycemic load (17). Since all these diets are not natural, they have their own associated disadvantages, risks and controversies. Let us take the most popular of these, the Atkins diet for a more detailed discussion.

The *Atkins diet* books have sold more than 45 million copies over 40 years all over the world. In the present obesity epidemic, this diet and accompanying Atkins food products are popular. The diet claims to be effective at producing weight loss despite ad - libitum consumption of fatty meat, butter, and other high - fat dairy products, restricting only the intake of carbohydrates to under 30 g a day.

It eliminates carbohydrates from food without restricting protein and fat intake. Deprived of carbohydrates, the body uses fat for fuel. A small part of metabolized fat is eliminated in the urine as ketone bodies, and this is why such diets are called "ketogenic". In the short run, such diets produce rapid weight loss due to polyuria. The apparent paradox that ad - libitum intake of high - fat foods produces weight loss might be due to

- (i) Severe restriction of carbohydrate depleting glycogen stores
- (ii) This leads to excretion of bound water causing weight loss
- (iii) The ketogenic nature of the diet being appetite suppressing
- (iv) The high protein - content being highly satiating
- (v) High fat / protein diet reduces spontaneous food intake
- (vi) In the absence of carbohydrates the food choices are limited, leading to decreased energy intake

On the other hand in the long run, re - feeding carbohydrates cause water retention and weight gain. The diet decreases appetite : patients eat less without feeling severe hunger and without measuring their food intake. Orthostatic hypotension, fatigue and nausea are frequent. The diet increases plasma cholesterol and uric acid. It may be dangerous in diabetes (anorexia, acidosis) and in heart or kidney disease.

Low - carbohydrate diets have been regarded as fad diets. A systematic review of low - carbohydrate diets found that the weight loss achieved is associated with the duration of the diet and restriction of energy intake, but not with restriction of carbohydrates, per se (18). Perhaps more long - term studies are needed to measure changes in nutritional status and body composition during the low - carbohydrate diet, and to

assess fasting and postprandial cardiovascular risk factors and adverse effects of these diets (19). Without that information, low - carbohydrate diets cannot be recommended as a public health measure for weight reduction.

Study Exercises

Long Questions : (1) Describe the epidemiology of obesity. How would you advise a middle aged man of 90 kg and 170 cms tall to reduce weight? (2) Discuss the principles of a healthy diet in context of lifestyle diseases.

Short Notes : (1) Fad diets (2) Food pyramid (3) BMI (4) Benefits of weight loss

MCQs

- Which is true about substitution for weight reduction : (a) Substitute ghee with butter (b) Substitute buffalo milk with cow milk (c) Substitute groundnut oil with safflower oil (d) Substitute rice with wheat
- To have satiety and also reduce weight (a) Keep bulk large and calories low (b) Keep calories large and bulk low (c) Keep calories low and bulk low (d) Keep calories large and bulk large
- For good health (a) Prefer fish to poultry (b) Prefer poultry to mutton (c) Prefer sprouts to meat (d) All of the above
- A food label reading 'zero - cholesterol' indicates (a) Low cholesterol (b) Low animal fat (c) Low plant fat (d) Low animal and plant fat
- Which of these is not a triggering factor for obesity : (a) Pregnancy (b) Stopping smoking (c) Mental stress (d) Physical stress

Answers : (1) b; (2) a; (3) d; (4) b; (5) d.

Ischaemic Heart Disease (IHD)
Syn: Coronary Heart Disease (CHD);
Coronary Artery Disease (CAD)

RajVir Bhalwar

IHD is the prototype example of the lifestyle diseases. In affluent countries, it is the most devastating disease, often accounting for almost a quarter of all deaths. It has also been the most researched disease in modern times regarding its epidemiology, risk factors, management and prevention. The term Cardio-vascular Diseases (CVD) encompasses a wider spectrum of diseases which include IHD, Heart Diseases other than IHD, Systemic arterial hypertension, Stroke, and,

Peripheral vascular disease (PVD). Within the gamut of the term IHD, we have a wide spectrum of conditions, starting from asymptomatic coronary insufficiency at the mildest end and sudden death at the other; in between we have typical angina, atypical angina and acute Myocardial Infarction, representing increasing severity along the spectrum.

Definition

IHD is defined as a state of lack of supply of oxygen to the myocardium vis-a-vis the demands, due to narrowing of the coronary arteries as a result of the atherosclerotic process.

Magnitude of the problem and Frequency

IHD places a mammoth load of disease and ill health on humanity. In developed countries, half of all deaths are due to CVD and a quarter due to IHD. In developing countries, the

problem is no less; as economic development will occur, IHD may, by the year 2025, become a leading cause of death and disability in our country.

IHD derives its importance for a variety of medical and socio-economic reasons, as follows :

- The magnitude of problem in terms of sheer numbers is very high
- The disease has a very high “killing power” - even in developed countries with well established treatment and ambulance services, 25% of those who suffer from Ac. MI would die within one hour and would never reach the hospital; another 8 to 10% would die in the next 24 hours in the hospital and yet another 10% would die in the next one year.
- Even for those who survive, the quality of life in terms of physical capabilities is compromised, alongwith constant apprehension about the future.
- The treatment is quite costly and available at few selected centres.
- Most of the persons affected with clinical disease are in their middle age, and are in the maximal productive phase of their life; they also have the maximum family and social obligations to fulfill at this age. Getting affected by the disease at this age therefore leads to tremendous loss to the organization and much suffering for the family.
- The silver lining is that a large number of factors which place an individual at high risk of getting affected with IHD (called “coronary Risk factors”) are well known to the medical world and potentially amenable to preventive efforts. IHD thus is very much a preventable issue.

The magnitude of problem has been brought out in the earlier chapter on general principles of healthy lifestyle in this section. Some important findings are as follows :

Global Problem : Of an estimated 58 million deaths globally from all causes in 2005, cardiovascular disease (CVD) accounted for 30%. This proportion is equal to that due to infectious diseases, nutritional deficiencies, and maternal and perinatal conditions combined (1). It is important to recognize that a substantial proportion of these deaths (46%) were of people under 70 years of age, in the more productive period of life; in addition, 79% of the disease burden attributed to cardiovascular disease is in this age group (2). Between 2006 and 2015, deaths due to non-communicable diseases (half of which will be due to cardiovascular disease) are expected to increase by 17%, while deaths from infectious diseases, nutritional deficiencies, and maternal and perinatal conditions combined are projected to decline by 3% (1). Almost half the disease burden in low- and middle-income countries is already due to non-communicable diseases (3).

Indian Scenario : The figures have been extensively summarized by Reddy et al (4) and details have also been presented in the chapter on general principles of healthy lifestyle. Over the past 4 decades, the prevalence of IHD has risen two fold in rural and six fold in urban areas. At present, an estimated 3 to 4% of rural and 8 to 10% of urban adults are likely to be affected by IHD, thus putting the estimated IHD cases in India at 30 million (15 million each in rural and urban areas).

Special Features of IHD among South Asians / Indians :

As is evident from foregoing discussion, IHD has become a major problem among our countrymen and the issue is likely to worsen unless proactive and intensive preventive measures are initiated now onwards. There is another interesting aspect, in that certain risk factors, epidemiology and presentation of IHD seems to be different among Indians / South Asians as compared to the western world. These special features are summarised in the Box - 1.

Box - 1 : Special Features of IHD among South Asians
IHD tends to occur at an earlier age; mean age of onset almost a decade earlier
Proportion of females to males among IHD cases higher as compared to developed countries
Higher case fatality (may be because of either biological differences or due to poor health services)
IHD occurs even in presence of normal or near-normal levels of “conventional” coronary risk factors as BMI, Total cholesterol and smoking; on the other hand high level of “unconventional” risk factors (increased central obesity in the face of normal BMI and low HDL / high triglycerides in the face of normal total cholesterol levels) as occurs in metabolic syndrome ‘X’, may play an important role.

The Determinants (Coronary Risk Factors)

With large scale, world-wide research over the past 60 years, both epidemiological as well as clinical, we are now well aware of various coronary risk factors, which place an individual at high risk of getting affected with IHD (5). It needs to be noted that the search for coronary risk factors is an ongoing one and every year a few more are likely to be added to the list. Broadly, these may be classified as “modifiable” and non-modifiable” risk factors.

Non-Modifiable : As the name suggests, we can not “change” these factors; only thing is that if a person has any of them, he / she needs to be even more careful as regards modifiable factors. The non-modifiable risk factors are :

Age : Age > 45 years for males and > 55 years for females increases the risk.

Sex : Male sex is at a higher risk. However, after menopause, the risk for females increases and equalizes that of males by the age of 50 to 55 years.

Family history : History of definite MI or sudden death in father or 1st degree male relative before 45 years age or in mother or 1st degree female relative before 55 years age indicates high risk.

Race : Some races may be more predisposed. For example, South Asian populations are said to be at higher risk, possibly because of “thrifty gene”; the Finnish population are at a high risk while Japanese are at lower risk. The extent to which these differences are because of genetic factors that differ between races or else due to lifestyle factors peculiar to different races, is still not clear.

Modifiable Coronary Risk factors : These are summarized in Table - 1.

Well Established		Emerging / Being Researched	
<i>Lipid</i>	<i>Non-Lipid</i>	<i>Lipid</i>	<i>Non-Lipid</i>
<ul style="list-style-type: none"> • Raised Total Cholesterol (< 200 mg / dl : desirable; 200 - 239 : Borderline high; >= 240 : High) • Raised LDL - C (< 100 mg/dl : optimal; 100 - 129 : near optimal; 130- 159 : Borderline high; >= 160 : High) • Raised triglycerides (<150 mg/dl : normal; 150 - 199 : Borderline High; >= 200 : High) • Low HDL-C (< 40 mg/dl in men or < 50 in women) • Metabolic Syndrome (Syndrome 'X') - a clustering of low HDL, raised triglycerides, hypertension, impaired glucose tolerance and obesity 	<ul style="list-style-type: none"> • Tobacco use (even small amount of tobacco use increases risk) • Raised Blood Pressure • Diabetes Mellitus - type 2 or Impaired Glucose Tolerance • Obesity (either generalized or central) • Physical Inactivity • Atherogenic diet (high in total calories, Total fat, saturated fats, cholesterol, salt and refined sugar; low in whole grains, cereals, legumes, fruits, vegetables, antioxidant vitamins, folic acid, fibre, and Omega-3 fatty acids) • Mental stress (depression, low job control, suppressed hostility) and personality (type 'A') 	<ul style="list-style-type: none"> • Raised TC : HDL-C ratio (> 4.5) • "Lipid Triad" (concomitant presence of raised triglycerides, small dense LDL particles and low HDL) • Raised Apolipoprotein - B • Low Apolipoprotein A-1 • Small, dense LDL particles • Raised Non-HDL Cholesterol (this is VLDL + LDL and is routinely calculated as TC - HDL) 	<ul style="list-style-type: none"> • Inflammatory markers - Raised Total WBC count - Raised C-reactive Protein • Prothrombotic factors - Platelet- Hyperaggregability - Raised Fibrinogen - Raised Plasminogen Activator Inhibitor (PAI - 1) - Tissue Plasminogen Activator (tPa) • Others - Raised serum Homocysteine - Microalbuminuria - Raised Resting Pulse Rate

A discussion on the major risk factors emphasizing on the benefit achieved by controlling them is reviewed in the subsequent paragraphs.

Dyslipidaemia : Over the past two decades, the focus has shifted from "hypercholesterolaemia" to "dyslipidaemia", giving due consideration to various other fractions of lipid profile. Of course, total serum cholesterol (TC) remains the single most important predictor of CHD risk both on individual as well as population level. The incidence of IHD is high among populations with mean serum TC > 200 mg / dl and low in populations with mean TC levels < 150. It is desirable that on individual level, the TC level should be kept below 200, while on population level, we should strive to keep the mean level below 160 mg.

Besides TC, LDL-Cholesterol levels have assumed importance. The Adult Treatment Panel (ATP-3) of USA's National Cholesterol Education Programme recommends that on individual level, the LDL levels should ideally be < 100; since this may be difficult for most people, levels of < 130 are considered as "near optimal". Levels of > 160 indicate high risk while between 130 to 159 indicate moderately increased risk.

HDL has been acknowledged to be the protective component. HDL levels > 40 mg for males and > 50 mg for females should be aimed. In addition to simply going by TC or HDL levels, the ratio of TC : HDL has been increasingly advocated. Ideally, this ratio should be maintained at < 3; ratio of > 4.5 indicates high risk.

Finally, the role of raised triglycerides (TG) as CHD risk factor has been assuming increasing importance, especially in case of South-Asian populations and in the context of metabolic syndrome (see later). Ideally TG levels should be maintained at < 150 mg/dl; levels of 200 and above indicate high risk.

Needless to say, from the preventive action point of view, dyslipidaemia is only an indicator. It results due to a wide variety of other risk factors especially atherogenic diet, smoking, obesity, and physical inactivity and hence, focus should be to control these risk factors for effectively addressing dyslipidaemia.

Tobacco : There is a large body of evidence from prospective cohort studies regarding the beneficial effect of smoking cessation on coronary heart disease mortality (6). However, the magnitude of the effect and the time required to achieve beneficial results are unclear. Some studies suggest that, about 10 years after stopping smoking, coronary heart disease mortality risk is reduced to that of people who have never smoked. Other reports suggest that a much longer time is required. It has also been shown that cigarette smokers, who change to a pipe or cigar, and those who continue to smoke but reduce the number of cigarettes, have a greater mortality risk than those who quit smoking. A 50-year follow-up of British doctors demonstrated that, among ex-smokers, the age of quitting has a major impact on survival prospects; those who quit between 35 and 44 years of age had the same survival rates as those who had never smoked. The benefits of giving up

other forms of tobacco use are not clearly established. General recommendations are therefore based on the evidence for cigarette smoking. Recent evidence from the Interheart study (7) has highlighted the adverse effects of use of any tobacco product and, importantly, the harm caused by even very low consumption (1-5 cigarettes a day). The benefits of stopping smoking are evident; however, the most effective strategy to encourage smoking cessation is not clearly established. All patients should be asked about their tobacco use and, where relevant, given advice and counselling on quitting, as well as reinforcement at follow-up. There is evidence that advice and counselling on smoking cessation, delivered by health professionals such as physicians, nurses, psychologists, and health counsellors are beneficial and effective. Several systematic reviews have shown that one-time advice from physicians during routine consultation results in 2% of smokers quitting for at least one year. Data from observational studies suggest that passive cigarette smoking produces a small increase in cardiovascular risk (8-10).

Dietary Risk factors

Dietary fat and cholesterol : The relationship between dietary fat and coronary heart disease has been extensively investigated. Saturated fats as a whole have been shown to raise LDL-cholesterol levels. However, individual fatty acids within the group have different effects, with myristic and palmitic acids having the greatest effect on LDL-cholesterol. Saturated fatty acids are not all equally hypercholesterolaemic. The effects of different saturated fatty acids on the distribution of cholesterol over the various lipoproteins are not well known. When substituted for saturated fatty acids in metabolic studies, n-6 polyunsaturated fatty acids (which are abundant in soybean and sunflower oil) and monounsaturated fatty acids (which are abundant in olive oil) lower total cholesterol, LDL cholesterol and triglyceride concentrations. Trans-fatty acids come from both animal and vegetable sources and are produced by partial hydrogenation of unsaturated oils. Dietary intake of trans-fatty acids increases LDL-cholesterol and, at high intakes, lowers HDL cholesterol. Metabolic and epidemiological studies have indicated that trans-fatty acids increase the risk of coronary heart disease.

A high intake of fat (more than one-third of total calories) generally increases intake of saturated fat and is associated with consumption of excess calories and weight gain. A low intake of fats and oils (less than one-fifth of total calories) increases the risk of inadequate intakes of vitamin E and essential fatty acids, and may contribute to unfavourable changes in HDL-cholesterol and triglycerides. It has also been demonstrated that replacing saturated and trans-unsaturated fats with monounsaturated and polyunsaturated fats is more effective in preventing coronary heart disease events than reducing overall fat intake. Current guidelines recommend a diet that provides less than 30% of calories from dietary fat, less than 10% of calories from saturated fats, up to 10% from polyunsaturated fats, and about 15% from monounsaturated fats. Metabolic studies have shown that dietary cholesterol is a determinant of serum cholesterol concentration.

Omega-3 fatty acids, fish and cardiovascular risk : The main dietary sources of omega-3 fatty acids are fish and fish

oils (which contain eicosapentaenoic acid and docosahexaenoic acid), and certain nut and plant oils, such as canola, soybean, flaxseed and walnut (which contain alpha-linoleic acid). Epidemiological studies and clinical trials suggest that people at risk of coronary heart disease benefit from consuming omega-3 fatty acids. The proposed mechanisms for a cardioprotective role include altered lipid profile, reduced thrombotic tendency, and antihypertensive, anti-inflammatory and antiarrhythmic effects. However, further high quality studies are required to confirm suggestions of a protective effect of omega-3 fatty acids on cardiovascular health.

Dietary salt : Population studies have demonstrated that high salt intake is associated with an increased risk of high blood pressure (11). Several observational studies have linked baseline sodium intake, estimated from either 24-hour urinary sodium excretion or dietary intake, to morbidity and mortality. The hazard ratios for coronary heart disease, cardiovascular disease, and all-cause mortality, associated with a 100 mmol increase in 24-h urinary sodium excretion in men and women, have been estimated as 1.51 (95% CI; 1.14 to 2.00), 1.45 (95% CI; 1.14 to 1.84), and 1.26 (95% CI; 1.06 to 1.50), respectively. A prospective study in a Japanese cohort also showed that high dietary salt intake increased the risk of death from stroke. The efficacy of reduced sodium intake in lowering blood pressure is well established. An average reduction of 77 mmol/day (1 gram salt = approximately 1 gram dietary sodium), in dietary intake of sodium has been shown to reduce systolic blood pressure by 1.9 mmHg (95% CI, 1.2 to 2.6 mmHg) and diastolic blood pressure by 1.1 mmHg (95% CI, 0.6 to 1.6 mmHg). Phase 2 of the Trials of Hypertension Prevention. Studies has also documented that a reduced sodium intake can prevent hypertension (12). In a meta-analysis of dietary interventions to alter salt intake, a reduction of 100 mmol (6 g) per day in salt intake was associated with a fall in blood pressure of 7.11 mmHg (systolic) and 3.88 mmHg (diastolic) This information strongly supports other evidence that a modest, long-term reduction in population salt intake would immediately reduce stroke deaths by about 14% and coronary deaths by about 9% in people with hypertension, and by approximately 6% and 4% in those with normal blood pressure. It is clear that intensive interventions, in particular the Dietary Approaches to Stop Hypertension (DASH) (13), are capable of reducing salt intake and lowering blood pressure. On the basis of the above, current recommendations on salt intake [< 5 g (90 mmol) per day] are appropriate (14).

Fruits and vegetables : Fruits and vegetables may promote cardiovascular health through a variety of micronutrients, antioxidants, phytochemicals, flavinoids, fibre and potassium. The evidence on the role of the individual constituents is so far inconclusive.

A review of ecological, case-control and cohort studies examining the association of dietary fruits and vegetables with cardiovascular disease found a significant protective association with consumption of fruits and vegetables or surrogate nutrients. Overall, the results support a protective effect of fruits and vegetables on stroke and coronary heart disease. Joshipura et al evaluated the association between consumption of fruits and vegetables and risk of coronary heart disease in

the Nurses' Health Study and the Health Professionals' Follow-Up Study. After adjustment for standard cardiovascular risk factors, people with fruit and vegetable intake in the highest quintile had a relative risk for coronary heart disease of 0.80 (95% CI; 0.69 to 0.93) compared with those with intake in the lowest quintile. Each increase of one serving per day in intake of fruits or vegetables was associated with a 4% lower risk of coronary heart disease (relative risk 0.96; 95% CI 0.94 to 0.99; $P = 0.01$, test for trend). The relationships between intake of whole grains, refined grains, and fruit and vegetables, and total mortality risk and incidence of coronary artery disease and ischaemic stroke, were also evaluated in the Atherosclerosis Risk in Communities (ARIC) cohort ($n = 15,792$). Over an 11-year follow-up period, whole-grain intake was inversely associated with total mortality and incidence of coronary artery disease. A recent meta-analysis of 10 prospective cohort studies has also shown that the consumption of fibre from cereals and fruits is inversely associated with risk of coronary heart disease. On the basis of the available evidence, a daily intake of at least 400 g of fruit and vegetables is recommended (15).

Physical inactivity : It has been estimated that inadequate physical activity is responsible for about one-third of deaths due to coronary heart disease and type 2 diabetes (16). There is evidence from observational studies that leisure-time physical activity is associated with reduced cardiovascular risk and cardiovascular mortality in both men and women and in middle-aged and older individuals. Several meta-analyses have examined the association between physical activity and cardiovascular disease. Berlin & Colditz found a summary relative risk of death from coronary heart disease of 1.9 (95% CI 1.6 to 2.2) for people with sedentary occupations compared with those with active occupations. A meta-analysis of studies in women showed that physical activity was associated with a reduced risk of overall cardiovascular disease, coronary heart disease and stroke, in a dose-response fashion. Physical activity improves endothelial function, which enhances vasodilatation and vasomotor function in the blood vessels. In addition, physical activity contributes to weight loss, glycaemic control, improved blood pressure, lipid profile and insulin sensitivity. The possible beneficial effects of physical activity on cardiovascular risk may be mediated, at least in part, through these effects on intermediate risk factors. Physical inactivity and low physical fitness are independent predictors of mortality in people with type 2 diabetes, which in turn is a strong risk factor for CHD. Overall, the evidence points to the benefit of continued regular moderate physical activity, which does not need to be strenuous or prolonged, and can include daily leisure activities, such as walking or gardening. Taking up regular light or moderate physical activity in middle or older age significantly reduces CVD and all-cause mortality, and improves the quality of life.

Overweight : Prospective epidemiological studies have shown a relationship between overweight or obesity and cardiovascular morbidity, CVD mortality and total mortality. Obesity is strongly related to major cardiovascular risk factors, such as raised blood pressure, glucose intolerance, type 2 diabetes, and dyslipidaemia. Meta-analyses of RCTs have shown that a weight-reducing diet, combined with exercise, produces

significant weight loss, reduces total cholesterol and LDL-cholesterol, increases HDL-cholesterol, and improves control of blood pressure and diabetes. A meta-analysis of randomized controlled trials found that a net weight reduction of 5.1 kg (95% CI 4.25 to 6.03 kg), reduced systolic blood pressure by 4.44 mmHg (95% CI 2.95 to 5.93 mmHg) and diastolic blood pressure by 3.57 mmHg (95% CI 2.25 to 4.88 mmHg). The long-term benefit of weight reduction on blood pressure control has been confirmed in several studies, including Phase II of the Trials of Hypertension Prevention Collaborative Research Group.

Evidence also suggests that physical exercise and fitness is equally and independently important. In a review of data from 24 prospective observational studies, Blair & Brodney found that regular physical activity attenuated many of the health risks associated with overweight and obesity. Physically active obese individuals have lower morbidity and mortality than individuals of normal weight who are sedentary; physical inactivity and low cardio-respiratory fitness are as important as overweight and obesity as predictors of mortality.

The appropriate upper limits of measures of overweight and obesity have been recently defined by various expert bodies. For South Asian populations, including Indians, the upper limits are (17 - 19) :

- Waist Circumference - 90 cms for males and 80 cms for females
- Waist : Hip ratio (WHR) - 0.90 for males and 0.80 for females
- Body Mass Index (BMI) - 25 and above as overweight and 30 and above as obese. However, recent WHO recommendations tend to recommend an even lower cut-off for Asian populations as 23 and above as overweight and 27.5 and above as obese.

Alcohol : Many studies have shown a U- or J-shaped association between mortality and alcohol consumption, in which people who drink light or moderate amounts have a lower death rate than nondrinkers, while those who drink large amounts have a higher death rate. People who drink heavily have a high mortality from all causes and cardiovascular disease. In addition, they may suffer from psychological, social and other medical problems related to high alcohol consumption. A meta-analysis of 28 cohort studies of alcohol consumption and CHD showed that risk decreased as consumption increased from 0 to 20 g/day (RR = 0.80); there was evidence of a protective effect of alcohol up to 72 g/day (RR = 0.96), and increased risk at consumptions above 89 g/day (RR = 1.05). Smaller protective associations and more harmful effects were found in women. The amount of alcohol associated with the lowest mortality rates was between 10 and 30 g (1-3 units) per day for men and half these quantities for women (1 unit has already been defined in the earlier chapter on general principles of healthy lifestyle). Various mechanisms have been proposed for the protective effect of modest alcohol consumption, including the demonstrated beneficial effects of alcohol on lipid profile, particularly an increase in HDL-cholesterol level, thrombolytic profile, and platelet aggregation (20 - 23). The benefits of alcohol in light to moderate drinkers may be overestimated in observational studies, as a result of confounding because it

is primarily the non-drinking group that causes the U-shaped relationship, and this may contain both life-long abstainers and people who stopped drinking because of ill-health; this could result in a spurious association suggesting that there is a safe level of alcohol intake. A recent meta-analysis of 54 published studies concluded that such lack of precision in the classification of abstainers may invalidate the results of studies showing the benefits of moderate drinking; this would imply that there is no level of alcohol consumption that is beneficial with respect to coronary heart disease; rather, risk increases with increasing consumption in a linear fashion.

Interestingly, earlier, the beneficial effect of hormone replacement therapy (HRT) on HDL-cholesterol convinced many that cohort studies showing a protective effect of HRT on coronary heart disease risk were valid. However, subsequent randomized controlled trials have found either no benefit or a harmful association; the earlier beneficial results were likely to be due to uncontrolled confounding. On the same analogy, it is possible that the protective association between light-to-moderate alcohol consumption and coronary heart disease is also an artefact caused by confounding. Light-to-moderate drinkers may be "light-to-moderate" in other behaviours, such as tobacco use which could be responsible for their lower risk of CHD. It is also important to note that alcohol consumption is associated with a wide range of medical and social problems, including road traffic injuries. Some individuals are also at risk of progression to problem drinking. Other risks associated with moderate drinking include fetal alcohol syndrome, obesity, haemorrhagic stroke, large bowel cancer, and female breast cancer. Consequently, from both the public health and clinical viewpoints, there is no merit in promoting alcohol consumption as a preventive strategy.

Psychosocial factors : Observational studies have indicated that some psychosocial factors, such as depression and anxiety, lack of social support, social isolation, and stressful conditions at work, independently influence the occurrence of major risk factors and the course of coronary heart disease, even after adjusting for confounding factors (24 - 26). Other psychosocial factors, such as hostility and type A behaviour patterns, and anxiety or panic disorders, show an inconsistent association (27, 28). Rugulies, in a meta-analysis of studies of depression as a predictor for coronary heart disease, reported an overall relative risk for the development of coronary heart disease in depressed subjects of 1.64. Other studies have also found a strong association between depression and CHD. Depression was shown to be a predictor for risk of myocardial infarction in the Interheart case-control study (odds ratio 1.55). This finding was consistent across regions, in different ethnic groups, and in men and women. More recent trials have cast doubt on the causal nature of the association between depression and CHD. In a large randomized trial of psychological intervention after myocardial infarction, no impact on recurrence or mortality was found. Another large trial that provided social support and treatment for depression also found no impact. Kivimäki et al, in a 25.6-year prospective cohort study in Finland, found that metal industry employees with high job strain (a combination of high demands at work and low job control) had a cardiovascular mortality risk 2.2 times that of their colleagues with low job

strain. This association between stressful conditions at work and CHD is supported by other studies. There is also some evidence that social isolation and lack of quality social support are independent risk factors for CHD onset and prognosis : the risks are increased 2-3-fold and 3-5-fold, respectively, in both men and women. The association has been demonstrated in subjects in different countries, and in various age groups. While these findings provide some support for a causal interpretation of the associations, it is quite possible that they represent confounding or a form of reporting bias. Well planned trials of interventions are required to elucidate whether there is a true cause-effect relationship and, more importantly, whether intervention reduces cardiovascular risk. In the meantime, physicians and health care providers should consider the whole patient. Early detection, treatment and referral of patients with depression and other emotional and behavioural problems are, in any case, important for reducing suffering and improving the quality of life, independent of any effect on cardiovascular disease.

Raised Blood Pressure : Raised blood pressure is estimated to cause about 7 million premature deaths throughout the world, and 4.5% of the disease burden (64 million disability-adjusted life years (DALYs)) (1 - 3). It is a major risk factor for cerebrovascular disease, coronary heart disease, and cardiac & renal failure. Treating raised blood pressure has been associated with a 35-40% reduction in the risk of stroke and at least a 16% reduction in the risk of myocardial infarction. Raised blood pressure often coexists with other cardiovascular risk factors, such as tobacco use, overweight or obesity, dyslipidaemia and dysglycaemia, which increase the cardiovascular risk attributable to any level of blood pressure. Worldwide, these coexisting risk factors are often inadequately addressed in patients with raised blood pressure, with the result that, even if their blood pressure is lowered, these people still have high cardiovascular morbidity and mortality rates. Almost all clinical trials have confirmed the benefits of antihypertensive treatment at blood pressure levels of 160 mmHg (systolic) and 100 mmHg (diastolic) and above, regardless of the presence of other cardiovascular risk factors. Observational data support lowering of these systolic and diastolic thresholds. Several trials in patients at high cardiovascular risk have confirmed these observational data, showing reductions in cardiovascular morbidity and mortality in people whose blood pressure is reduced to levels significantly below 160 mmHg systolic and 90 mmHg diastolic. These trials support the view that, in patients at high cardiovascular risk, with blood pressures in the range 140-160 mmHg (systolic) and 90-100 mmHg (diastolic), the treatment for such high-risk patients should begin at the lower blood pressure thresholds of even lesser than 160 mm systolic or 90 mm diastolic.

There is also enough evidence that it is not only the diastolic level but that systolic BP level is also independently related to cardiovascular risk; in fact, as age advances, the level of systolic BP may be more important for CV risk than diastolic level.

More details regarding the epidemiology, risk factors and prevention of hypertension are addressed in a subsequent chapter.

Diabetes and Impaired Glucose Tolerance (IGT) / Impaired Fasting Glucose (IFG) : Cardiovascular disease accounts for about 60% of all mortality in people with diabetes. The risk of cardiovascular events is 2-3 times higher in people with type 1 or type 2 diabetes (29, 30) and the risk is disproportionately higher in women (29, 31). Patients with diabetes also have a poorer prognosis after cardiovascular events compared with non-diabetics. Epidemiological evidence also suggests that the association between blood glucose and cardiovascular disease begins before diabetes manifests itself. The cardiovascular risk increases as glucose tolerance becomes impaired and then progresses to diabetes. Further, abnormal glucose regulation tends to occur together with other known cardiovascular risk factors, such as central obesity, elevated blood pressure, low HDL-cholesterol and high triglyceride level. The Diabetes Control and Complications Trial (DCCT), which included 1441 young adults with type 1 diabetes, demonstrated that intensive treatment to ensure good glycaemic control substantially reduced the risks of cardiovascular events, neuropathy, nephropathy and retinopathy. The United Kingdom Prospective Diabetes Study (UKPDS) found that glycaemic control in people with type 2 diabetes reduced the frequency of microvascular complications, such as blindness, amputation, and end-stage renal disease. Each 1% increase in HbA1c level was associated with a 14% increase in the incidence of fatal or nonfatal myocardial infarction. A later study suggested that stringent blood sugar control in people with type 2 diabetes, combined with targeted reductions in blood lipids and blood pressure, reduced macrovascular events in diabetic patients with microalbuminuria. Good glycaemic control should be a key goal of treatment of diabetes, to delay the onset and progression of microvascular and macrovascular disease. The first approach to controlling glycaemia should be through diet alone, combined with physical exercise; if this is not sufficient, oral medication should be given, followed by insulin if necessary. Treatment should aim to achieve a fasting blood glucose level of 4-7 mmol/l (72-126 mg/dl); and an HbA1c level of 6.5% or less.

More details regarding the epidemiology, risk factors and prevention of diabetes type - 2 are addressed in a subsequent chapter.

The Metabolic Syndrome (Syndrome 'X') : In 1988, The noted Diabetologist, Gerald Reaven had postulated that resistance to insulin action would occur mainly due to obesity, central obesity, physical inactivity, and possibly certain genetic reasons. Once insulin resistance develops, the body, in an effort to compensate, releases more and more insulin, resulting into fasting hyperinsulinaemia. Under the influence of this hyperinsulinaemia, there occurs a very unique and specific "clustering" of certain specific cardiovascular risk factors, namely, raised blood pressure, impaired glucose tolerance, and a unique dyslipidaemia manifesting with low HDL and raised triglycerides. This clustering was referred to as "Syndrome X" by Reaven (32) and it was postulated that once such clustering occurs, it is likely to be a major risk factor for development of IHD and Diabetes type -2.

Large number of clinical and epidemiological studies over the past 2 decades have confirmed that the metabolic syndrome is, indeed, a reality. In fact, scientific evidence suggests that

south Asians, especially Indians are likely to be at a high risk of developing this syndrome. There are various defining criteria of this syndrome, of which the WHO criteria and ATP-3 criteria are the most widely used. The *WHO criteria* are (33) : "Diabetes or IFG or IGT or evidence of insulin resistance (either of hyperinsulinaemia or euglycaemic clamp glucose uptake in lowest 25%)" PLUS any two of the following :

- Obesity as defined BMI > 30 or WHR > 0.9 for males or > 0.85 for females (>0.80 for Indian females)
- Hypertension as defined as blood pressure > 140 systolic or > 90 diastolic
- Dyslipidaemia as manifested by triglycerides > 150 mg / dl or HDL < 35 mg / dl for males or < 40 mg / dl for females
- Microalbuminuria defined as albumin excretion > 20 microgram albumin excretion / mt.

Hormone Replacement Therapy (HRT) : On the basis of data from observational studies (34), hormone therapy has been used for prevention of cardiovascular disease, osteoporosis and dementia. This practice has been called into question following publication of the results of several randomized clinical trials, which showed no coronary protection, and the Women's Health Initiative (35), which indicated that long-term use of estrogen plus progestin was associated with increased risks of cancer and cardiovascular disease. A Cochrane systematic review (36) of 15 randomized double-blind trials showed that the only statistically significant benefits of hormone therapy were decreased incidences of fractures and colon cancer with long-term use. In relatively healthy women, combined continuous hormone therapy significantly increased the risk of coronary events and venous thromboembolism (after one year's use), stroke (after 3 years), breast cancer (after 5 years) and gallbladder disease. Long-term estrogen-only hormone therapy also significantly increased the risk of stroke and gallbladder disease. In relatively healthy women over 65 years taking continuous combined hormone therapy, there was an increase in the incidence of dementia.

Thus, HRT is not recommended as a preventive step against IHD, from public health point of view.

The Effect of Multiple Risk Factors : All the leading CHD risk factors described above tend to act in a multiplicative mode when two or more are present (which, quite often, they are). This means that when multiple risk factors are present, their effect on increasing the coronary risk is not simply additive but rather "multiplicative" (in simple corollary, it is not 2+2+2 =6 but rather 2x2x2 = 8). Another aspect which must be kept in mind is that multiple risk factors, even if present in "moderate" quantum, tend to increase the coronary risk quite substantially, compared to when only one factor is present in high quantum. For instance, a person who is marginally obese (e.g. BMI 25.5), smokes 2 or 3 cigarettes a day, has a WHR which is marginally raised (e.g., 0.93), goes for brisk exercise only once a week, and has mild elevation of BP (eg, 150 / 96) would be having much higher overall risk than a person who smokes 10 cigarettes per day but has no other risk factor. This issue is important since we often tend to "condone" who have mild elevations of multiple risk factors thinking that "moderation" is not bad! In fact, as per the widely upheld "continuum of risk theory", if multiple risk factors are present, then IHD risk would start even below

the standard cut-off levels and majority of the events occur at moderate level of risk factors.

Prevention and Control of IHD

As said earlier, IHD is the prototype example of a serious, lifestyle disease. It needs to be addressed in a very concerted manner, by both, the medical functionaries as well as by Commanders / Administrators. The preventive strategies are summarized in Box - 2.

Box - 2 : Preventive Strategies for IHD
Primordial Prevention
Primary prevention (a) Population Strategy - Mass Approach - Targeted Group approach (b) Targeted High Risk Individual Strategy
Secondary Prevention
Tertiary Prevention

Primordial Prevention

The concept may sound “Utopian” to many, but it is a fact that certain countries / communities have been successfully adopting this strategy.

The strategy can be used by those countries / communities where lifestyle has not, as yet, acquired the pattern associated with high CHD incidence and where the average level of critical risk factors is still favourable; however, economic advancements and changing life styles threaten to undermine this favourable situation and in these situations, we could take action to “prevent the very emergence of predisposing conditions, in countries and communities in which they have not yet appeared”. This in essence, is primordial prevention.

Primary prevention

Primary prevention focuses on measures so that the pathological processes of IHD are either not initiated or else do not progress to develop into the disease. There are two mainstays of this approach : firstly, educating & motivating the individuals and communities with a view to achieve positive life style behaviour changes, and, secondly, supplementing these IEC (Information, Education and Communication) efforts by suitable socio-political, legislative and administrative steps. The ultimate objective is that individuals and communities live a healthy lifestyle, free of coronary risk factors.

Primary preventive steps can be undertaken through two broad strategies, viz. the “population approach” which focuses on large population groups, even the entire states or countries, and the “Targeted. individual, high risk strategy” which focuses on individuals who have a high probability of developing IHD, due to the presence of certain risk factors.

Population Strategy

Mass Approach : This focuses on large sections of populations, may be the entire District, state or even the country; in context of armed forces, IEC methods directed to the entire armed forces or a complete Division or Brigade would be an equivalent

example. The strategy adopts a two pronged approach as follows :

- Education and Motivation by various IEC techniques, with a view to informing the community / population and to secure a healthy lifestyle change. The key issues of IEC are summarized in Box - 3.

Box - 3 : Key Messages For I.E.C. : Primary Prevention of IHD
Eat a diet which gives : <ul style="list-style-type: none"> • Just sufficient in calories • Total fats provide < 30% of calorie need • Saturated fats provide < 10% of calorie need • Trans-fatty acids to be eliminated from diet • Most dietary fat should be polyunsaturated (up to 10% of calories) or monounsaturated (10-15% of calories). • Refined sugars provide < 10% of calorie need • Salt consumption (all sources) < 5 gm / day • Cholesterol < 200 mg / day • Low in gravied, fried, creamed and sugared food stuffs • Plenty of whole grains, cereals, legumes, beans & pulses • 400 to 500 grams fresh fruits / vegetables • Low fat dairy produce
Undertake brisk walk every day, covering 2 miles (3.2 Km) in 30 to 35 mts daily; if you can exercise longer or at higher intensity, the better it is
Supplement aerobic exercises (walking, running, cycling, sports) with light weight training and stretching exercises as yoga
NO TOBACCO. If you don't use tobacco, don't start; if you do, stop.
Avoid alcohol. If you must drink, not more than 3 small drinks s day for men (not more than 2 small a day for women); don't drive even after mi,d drinks; try not to drink daily.
Regularly check your body weight and measure your waist and hip circumference; BMI should be kept at < 25 (preferably < 23) and waist < 90 cm or WHR < 0.90 for males (for females, < 80 cm or WHR < 0.80)
Control and manage Mental Stress : <ul style="list-style-type: none"> • Pray, meditate • Spend Quality time with family • Yoga • Manage your finances well • Exercise regularly • Look after health of yourself and family members
Undergo periodic / annual medical examinations seriously; take precautions as told by your Doctor
If you have any symptoms of chest pain, fatiguability. Palpitation or breathlessness, seek medical attention.
<i>See further details in the chapter on healthy lifestyle in this section</i>

- Socio-political, administrative and legal actions to supplement the IEC steps, eg., legislation and coercive steps against tobacco and alcohol; provision of Gymnasia,

playgrounds and walkways; encouragement for produce of fruits and vegetables; subsidy on fruits and vegetables; Administrative disincentives for obese persons; and so on.

Targeted Group Approach : This strategy focuses the educational and motivational efforts, not on entire population or community, but rather on certain selected groups of persons who, due to certain characteristics, are :

- At high risk of developing the coronary risk factors (e.g., “newly rich” persons, executives, bureaucrats, businessmen; in the context of armed forces, JCOs / senior NCOs are an example), or,
- Can be of help in implementing the preventive programmes (e.g., local leaders, policy makers, influential politicians and bureaucrats; in context of armed forces, senior commanders and senior functionaries of Wives Welfare Associations, Army School-Teachers), or,
- Are in a “formative” stage and may develop healthy lifestyle if properly informed / motivated at this stage (e.g., school & college children; in context of armed forces, Recruits, Cadets and school children of Army schools, Sainik Schools, and KVs).

Targeted High Risk Individual Strategy : While population strategy is very effective in gradually bringing down the incidence of IHD in the total population, the process may be slow; secondly it relies on behavioural and lifestyle change by individuals which often may not easily happen, especially permanently. Therefore, the population strategy should be supplemented by the Individual High risk strategy, which aims at identifying those individuals, who have a higher probability of developing IHD, because of presence of certain major risk factors, so that concerted preventive as well as treatment efforts may be directed to these individuals. In the simplest form, when a doctor checks the age, sex, family history of IHD, BP and body weight of each of his adult patient, and educates / treats those who have a few of these risk factors, she is actually practicing the Individual High Risk Strategy.

The recent advancement in this strategy is the development of “Individual Risk Prediction Charts” by the WHO for various regions of the world. (The chart applicable to Indian region is given in Fig. - 1). Use of risk prediction charts to estimate total cardiovascular risk is a major advance on the older practice of identifying and treating individual risk factors, such as raised blood pressure (hypertension) and raised blood cholesterol (hypercholesterolemia). The total risk approach acknowledges that many cardiovascular risk factors tend to appear in clusters; combining risk factors to predict total cardiovascular risk is consequently a logical approach to deciding who should receive treatment. In summary, the great strength of the risk scoring approach is that it provides a rational means of making decisions about intervening in a targeted way, thereby making best use of resources available to reduce cardiovascular risk. Risk scoring moves the focus of treatment from the management of individual risk factors to the best means of reducing an individual's overall risk of disease. It enables the intensity of interventions to be matched to the degree of total risk.

In the chart (Fig. - 1), the subjects are first of all divided into diabetic or non-diabetic. Within each of this category, the

subjects are divided according to tobacco use (users or non users), age and sex. Thereafter, the subject is evaluated as per his / her Systolic BP and Total Cholesterol level, and the level of CHD risk is directly read from the chart. The risk, technically, indicates the probability that the given individual is likely to develop IHD in the next 10 years. In general, < 10% risk is equivalent of low risk (low risk does not mean “NO RISK”); 10 - 20% : moderate risk, 20-30% high risk; and > 30% very high risk.

It may be mentioned that if a person has clear history of having suffered from IHD or has clear family history (as defined in the table of risk factors) then the person is to be taken as “high risk” irrespective of the score obtained in this chart.

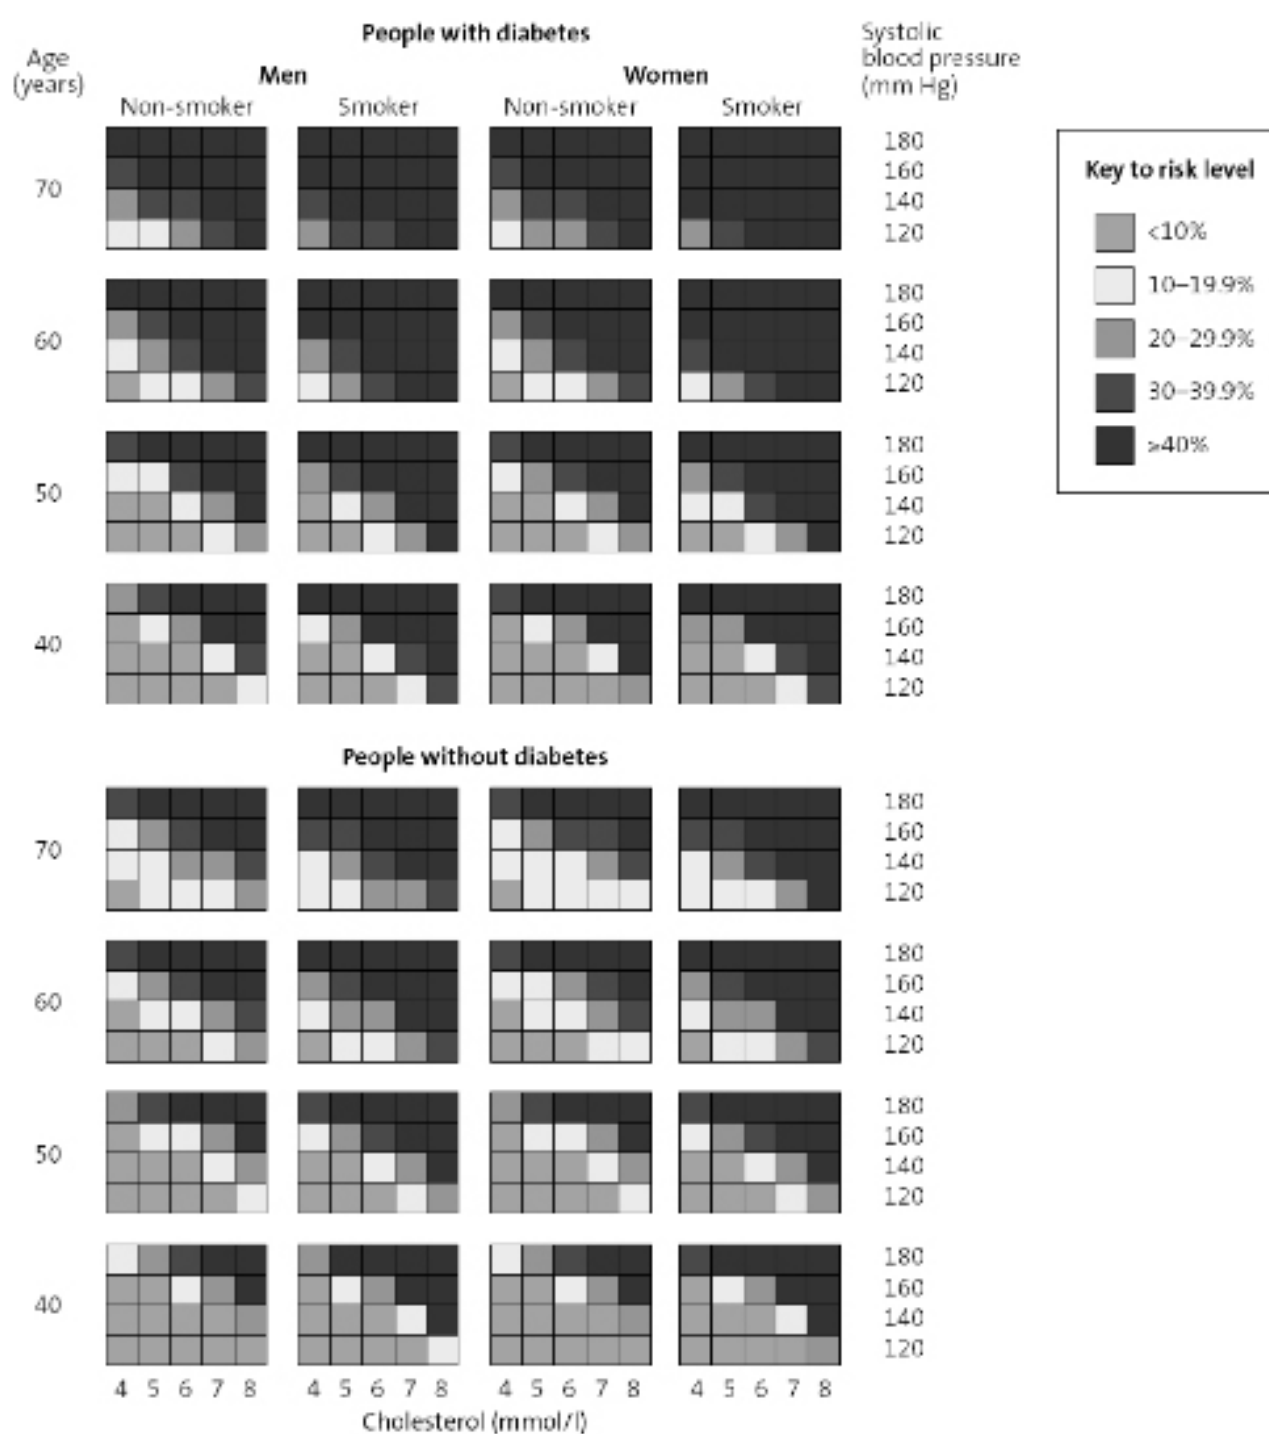

Actions to be taken after evaluation of the person on the risk chart are given in Box - 4.

Box - 4 : Actions to be taken after evaluation of the person on the risk chart
All persons, irrespective of risk category should be educated and motivated for healthy lifestyle changes.
Antihypertensive treatment : Individuals with sustained BP readings > 140 / 90 : if risk category 1 or 2, continue lifestyle changes; if category - 3 give lifestyle changes but if despite lifestyle changes for 4 to 6 months BP is > 140 / 90, give treatment starting with a thiazide like diuretic or ACE inhibitor or calcium channel blocker or beta blocker. Indvls in risk category - 4 with BP > 130 / 90 - start drug treatment alongwith lifestyle changes. All individuals with blood pressure at or above 160/100 mm Hg, or lesser degree of raised blood pressure with target organ damage, irrespective of risk category, should definitely have drug treatment and specific lifestyle advice.
Anti-diabetic drugs : Individuals with persistent hypoglycaemia of fasting > 6 mmol / l (110 mg / dl) should be given hypoglycaemic drugs irrespective of risk category
Lipid lowering treatment (use statin) : Risk category 1 and 2, advise healthy lifestyle; category 3 : If despite lipid lowering diet, TC > 200 or LDL > 120 consider a statin alongwith lifestyle advise; category - 4 along with lipid lowering diet, give statin to lower TC to < 200 and LDL to < 120. If TC > 320, give statin irrespective of risk category.
Antiplatelet drugs : consider low dose aspirin only in case of category - 4.

Secondary Prevention

Early detection of CHD at the incipient stage is quite relevant. The available tools are firstly, resting ECG using Minnesota code criteria for coronary insufficiency, a method which has been used in epidemiological surveys, but has low sensitivity and specificity for individual prediction. Secondly, a combination of Rose questionnaires which taps symptoms of angina on effort and resting ECG can be used. Better predictive values are obtained with exercise ECG, either alone or in conjunction with echocardiography. Exercise ECG however carries some risk and should be undertaken in presence of a physician. All these screening procedures will give better predictive value if

Fig. - 1 : WHO Individual Risk Prediction Chart (For Indian Region)

A person who has diabetes is defined as someone taking insulin or oral hypoglycaemic drugs, or with a fasting plasma glucose concentration above 7.0 mmol/l (126 mg/dl) or a postprandial (approximately 2 hours after a main meal) plasma glucose concentration above 11.0 mmol/l (200 mg/l) on two separate occasions).

Conversion factor for total Cholesterol is 1 mmol / l = 37.5 mg / dl

used in high risk populations, as middle aged, obese, having hypertension or impaired glucose tolerance or dyslipidaemia. The most important practical aspect is to keep a high index of diagnostic suspicion and evaluate any person who presents with coronary risk factors.

Tertiary Prevention

The patients need to be adequately treated and rehabilitated. Personal discussions with the Doctor would go a long way in this process. The patient should be reassured and apprehensions allayed. Advice should be given regards long term drug therapy, physical exercise, reduction of risk profile and gradually getting back into day to day life activities. Follow up, assessment of status at periodic intervals and appropriate advice should be ensured.

Summary

The term IHD is a wide spectrum of conditions, which includes asymptomatic coronary insufficiency, typical angina, atypical angina, acute Myocardial Infarction and sudden death, representing increasing severity along the spectrum. IHD is defined as a state of lack of supply of oxygen to the myocardium vis a vis the demands, due to narrowing of the coronary arteries as a result of the atherosclerotic process. The disease has a high "killing power"; even for those who survive, the quality of life in terms of physical capabilities is compromised, along with constant apprehension about the future; the treatment is quite costly and available at few selected centres; most of the persons affected with clinical disease are in their middle age, and are in the maximal productive phase of their life. The silver lining is that "Coronary Risk Factors" are well known to the medical world and potentially amenable to preventive efforts.

In developed countries, half of all deaths are due to CVD and a quarter due to IHD. Of an estimated 58 million deaths globally from all causes in 2005, cardiovascular disease (CVD) accounted for 30%. In India, over the past 4 decades, the prevalence of IHD has risen two fold in rural and six fold in urban areas. At present, an estimated 3 to 4% of rural and 8 to 10% of urban adults are likely to be affected by IHD, thus putting the estimated IHD cases in India at 30 million (15 million each in rural and urban areas).

The risk factors may be grouped as Non Modifiable and Modifiable. Non Modifiable factors are Increasing Age, male sex, Family history and racial factors (South Asian populations are at a high risk). Modifiable factors are classified as lipid and non-Lipid factors. Lipid factors are Raised Total Cholesterol (< 200 mg / dl : desirable; 200 - 239 : Borderline high; \geq 240 : High) Raised LDL - C (< 100 mg/dl : optimal; 100 - 129 : near optimal; 130- 159 : Borderline high; \geq 160 : High) Raised triglycerides (<150 mg/dl : normal; 150 - 199 : Borderline High; \geq 200 : High) Low HDL-C (< 40 mg/dl in men or < 50 in women), and Metabolic Syndrome. Non-Lipid factors are Tobacco use, Hypertension, Diabetes Mellitus - type 2 or Impaired Glucose Tolerance, Obesity (either generalized or central), Physical Inactivity, Atherogenic diet and Mental stress. All the leading CHD risk factors tend to act in a multiplicative mode. Multiple risk factors, even if present in "moderate" quantum, tend to increase the coronary risk quite substantially, compared to when only one factor is present in high quantum.

The broad strategy for prevention of IHD includes primordial, primary, secondary and tertiary levels of prevention. The strategy of Primordial Prevention can be used by those countries / communities where lifestyle has not, as yet, acquired the pattern associated with high CHD incidence and where the average level of critical risk factors is still favourable. The primary Prevention would basically utilize the IEC strategy in the form of the population strategy, educating both, the general community (mass approach) and specific groups (group approach) and also in the form of "individual high risk strategy", focusing on individuals with "Risk factors". The recent advancement in this strategy is the development of "Individual Risk Prediction Charts" by the WHO for various regions of the world. These IEC (Information, Education and Communication) efforts are supplemented by suitable socio-political, legislative and administrative steps. Secondary Prevention is through early detection of CHD at the incipient stage by using resting ECG, Minnesota code criteria, Rose questionnaires, exercise ECG, either alone or in conjunction with echocardiography and advice regarding lifestyle changes. Tertiary Prevention includes disability limitation through prompt treatment of the condition and its complications and rehabilitation by Follow up, assessment of status at periodic intervals and appropriate advice regarding lifestyle, treatment and counseling on psycho-emotive aspects.

Study Exercises

Long Questions : (1) Describe the recent advances and concepts regarding 'coronary risk factors' (2) Discuss a draft policy for prevention of IHD in our country.

Short Notes : (1) magnitude of problem of IHD in India (2) Special features of IHD among Indians (3) Metabolic syndrome (4) Population versus high risk strategy in IHD prevention.

MCQs & Exercises

1. The estimated deaths due to IHD in industrialized countries is : (a) 25-30% (b) 40-55% (c) 80-90% (d) 10-20%
2. It is estimated that number of IHD cases in India is around (a) 55 million (b) 15 million (c) 30 million (d) 1 million
3. The Desirable, Borderline high and High values of Total Cholesterol are (a) <200, 200 - 239, \geq 240 (b) <160, 160-180, $>$ 180 (c) <200, 200- 249, $>$ 250 (d) <180, 181- 191, $>$ 192
4. The desirable value of HDL Cholesterol : (a) \leq 30 (b) \leq 60 (c) \leq 50 (d) \leq 40
5. The Optimal, Near Optimal, Borderline high, High, Very high values of LDL Cholesterol are : (a) < 100, 100-129, 130 - 159, 160 - 189, $>$ 190 (b) < 120, 120-129, 130 - 159, 160 - 199, $>$ 200 (c) < 130, 130 - 159, 160 - 199, $>$ 200 (d) < 100, 130 - 159, 160 - 189, $>$ 190
6. METABOLIC SYNDROME does not include (a) WHR $>$ 0.9 for males or $>$ 0.85 for females (b) Albumin excretion $<$ 20 microgram (c) Low levels of HDL cholesterol : $<$ 40 mg/dL in men, $<$ 50 mg/dL in women (d) Elevated blood pressure levels : \geq 140 mm Hg SBP or \geq 90 mm Hg DBP
7. Atherogenic diet does not include : (a) high in total calories, total fat, saturated fats and cholesterol (b) high in salt and refined sugar (c) low in whole grains, cereals, legumes,

- fruits, vegetables (d) high in antioxidants
8. Not a Coronary Risk Factor : (a) Raised Non-HDL Cholesterol (b) Raised TC : HDL-C ratio (> 4.5) (c) Low Apolipoprotein A-1 (d) Low Apolipoprotein B
 9. Upper limit of Waist Circumference is 80 cms for males - T/F
 10. Lower cut-off of BMI for overweight as recommended for Asian populations is : (a) >18.5 (b) >20.5 (c) >23 (d) >24.9
 11. One of the following is a mode of Primary prevention: (a) Individual Risk Prediction Charts (b) resting ECG using Minnesota code criteria (c) Rose questionnaires (d) Exercise ECG
 12. There is a U- or J-shaped association between mortality and alcohol consumption - T/F
 13. Early Diagnosis and Treatment of Hypertension is _____ mode of prevention for IHD : (a) Primordial (b) Primary (c) Secondary (d) Tertiary
 14. Early Diagnosis and Treatment of Angina is _____ mode of prevention for IHD : (a) Primordial (b) Primary (c) Secondary (d) Tertiary
 15. Early Diagnosis and Treatment of Dyslipidemia is _____ mode of prevention for IHD : (a) Primordial (b) Primary (c) Secondary (d) Tertiary
 16. Not a Modifiable Coronary Risk Factor : (a) Raised Non-HDL Cholesterol (b) Raised TC : HDL-C ratio (c) Low Apolipoprotein A-1 (d) MI in father before 45 years age

Answers : (1) a; (2) c; (3) a; (4) d; (5) a; (6) b; (7) d; (8) d; (9) F; (10) c; (11) a; (12) T; (13) b; (14) c; (15) b; (16) d

Rajvir Bhalwar

Definition / Identification

Systemic arterial hypertension is defined as a state of chronically elevated arterial blood pressure, as compared to what is normally expected, as per the defined levels given below.

Levels

It needs to be noted that blood pressure is a “continuous” variable and hence it may be scientifically difficult to draw a arbitrary cut-off line to delineate normal and raised blood pressure; e.g., blood pressure level of 130 / 86 mm Hg would carry a higher risk for cardiovascular and other morbidity as compared to 120 / 80 mm Hg, though both would fall in the category of “normotensive”. However, for the purpose of epidemiological, clinical and public health needs, the categorization of hypertension, based on systolic and diastolic levels, is shown in Table - 1. This classification is based on the recent guidelines of WHO & ISH and from JNC - VII (1, 2) :

Table - 1

Grade	Systolic level (mm Hg)		Diastolic level (mm Hg)
Normal	< 120	AND	< 80
Pre-hypertension	120 to 139	OR	80 to 89
Hypertension Grade - I	140 to 159	OR	90 to 99
Hypertension Grade - II	160 to 179	OR	100 to 109
Hypertension grade - III	≥ 180	OR	≥ 110

The above classification is a clear departure from the earlier WHO classification in which Blood pressure levels of 140 / 90 were taken to qualify as hypertension (3), since in this report, even those with levels between 120 to 139 systolic and 80 to 89 diastolic have also been classified as “prehypertensive” thereby emphasizing the importance of concerted “lifestyle” modification and public education efforts for this group also.

Classification

Hypertension can be classified in 3 different ways, as follows :

According to the level of blood pressure : This has been described in Table - 1.

According to identifiable cause, if any : About 5 to 10% of the cases of hypertension will have some identifiable cause for the raised BP. This is called as “Secondary” hypertension. Important causes of secondary hypertension are given in Box-1a. However, 90 to 95% cases will not have any identifiable cause; these are called as “primary” or “essential” hypertension. Certainly, the word “essential” gives an impression that these persons have to have raised BP, which is not correct; there is nothing like “essential” and most of these cases will also

become normotensive with proper lifestyle changes.

According to the extent of target organ damage : The various types of target organ damage that can be caused by raised BP are as per Box - 1b (3, 4).

Box - 1a : Causes of Secondary Hypertension
Induced by exogenous substances or drugs (Hormonal contraceptives, corticosteroids, sympathomimetics, cocaine, Tyramine containing foods & MAO Inhibitors, NSAIDS)
Secondary to Renal Disease (Renal parenchymatous disease, Renovascular hypertension, Renin producing tumours)
Associated with endocrine disorders (Acromegaly, thyroid disease, adrenocortical diseases, carcinoid tumours)
Pregnancy Induced
Coarctation of Aorta
Box - 1b : Target Organ Damage due to Hypertension
Heart : IHD, LVH, Heart Failure
Brain : Stroke, TIC
Chronic kidney disease
Peripheral arterial disease
Retinopathy

Hypertension as a Risk Factor for Diseases

For purposes of public health and preventive medicine, hypertension and stroke are considered together since at the large population level, the major cause of stroke is raised blood pressure and efforts to prevent hypertension will pay a rich dividend for prevention of stroke. At the individualized clinical level, of course, there would be other causes of stroke that naturally, would need consideration.

Hypertension, like diabetes, is often referred to as “silent killer”. During most of its course, it produces hardly any signs/symptoms by itself; however, it damages the end organs substantially (cardiovascular system, Kidneys and Retina). Epidemiological estimates from large scale studies indicate that subjects with DBP of 105 have a ten times increased risk of stroke and five times more risk of IHD compared to subjects having DBP < 80. Prolonged reductions in DBP by 5, 7.5 and 10 mm are respectively associated with at least 34%, 46% and 56% reduction in risk of stroke and at least 21%, 29% and 37% reduction in risk of coronary events (5).

It also needs to be clearly noted that both systolic as well as diastolic are important from the morbidity and mortality point of view. In fact, after 55 years age, SBP may become even more important than DBP from preventive point of view. Raised SBP has been shown to be associated with a higher RR of CHD, stroke, CCF, Renal disease and overall mortality. In the follow up of MRFIT trial, as compared to subjects with SBP < 120 and DBP < 80, the RR of coronary events was 3.23 times higher for those with isolated diastolic hypertension (DBP > 100 with normal systolic, i.e., < 140); the RR was 4.19 times for those with isolated systolic hypertension (SBP > 160 with DBP < 90); and 4.57 times among those who had both, i.e., SBP > 160

and DBP > 100 (6).

Besides stroke and IHD, hypertension also substantially increases the risk of Congestive cardiac failure (CCF) by 2 to 4 times, and of end stage renal disease by 1.65 times (6, 7).

Another important aspect to be remembered is that although raised blood pressure is independently associated with an increased risk of cardiovascular events, the risk is substantially increased by the presence of other risk factors namely smoking, dyslipidaemia and diabetes. Thus, equal blood pressure levels would carry different risks when associated with different combinations of risk factors and that too, at different levels. Therefore, raised blood pressure should not be seen in isolation but as a part of the overall, total cardiovascular risk assessment for the individual (8).

Magnitude of the Problem

World-wide : Hypertension affects approximately 50 million individuals in the United States and approximately 1 billion worldwide. As the population ages, the prevalence of hypertension will increase even further unless broad and effective preventive measures are implemented. Recent data from the Framingham Heart Study suggest that individuals who are normotensive at age 55 have a 90 percent lifetime risk for developing hypertension (9). The crux of the issue is that hypertension is now a major public health problem in all parts of the world (10 - 17). When cut-off values of 160 mm SBP and 95 mm DBP are taken, in most of the adult populations in the world, the prevalence comes to 10% to 20% of the adult population. If cut off levels are lowered to the standard values of 140 SBP and 90 DBP, the prevalence would go up further, possibly to 25% to 30% of adult population (3).

Indian Situation : In our country, prevalence of hypertension has been estimated to be between 20% to 40% in urban adults and 12% to 17% (even upto 20%) in rural adults. The estimated number of Indians with hypertension was 120 million in year 2000, which is likely to expand to 200 million by 2025, with equal numbers among men and women.

Determinants (Risk factors)

As for other lifestyle diseases, the risk factors for hypertension can be grouped as modifiable and non-modifiable.

Non-Modifiable

Age : All studies have demonstrated a positive association between age and blood pressure (18). SBP increases consistently till almost the seventh or eighth decade, while DBP increases till fifth decade, becoming stationary thereafter, leading to an increase of pulse pressure and increased incidence of systolic hypertension in the elderly. However, the age related rise in blood pressure is not an inevitable phenomena of nature since in some isolated populations with very low habitual salt intake, the blood pressure does not increase with age, indicating that with controlled salt intake and physically active lifestyle, the rise of blood pressure can be checked, despite ageing.

Sex : In childhood there is no difference between sexes; from adolescence onwards, the average BP is higher in males. However, this difference narrows down after women attain the age of 50 years, and thereafter, may even get reversed (18).

Heredity : Family history of elevated blood pressure is a strong

risk factor for future development of hypertension.

Genetic factors : The genetic basis of high blood pressure has been well supported by experimental research, and while some monogenic hypertensive disorders in humans have been described (eg, ACE-II and angiotensinogen gene polymorphism), for the most part, hypertension is currently regarded to be a "polygenic" condition.

Ethnicity : Black races have been described to be having higher risk of hypertension; whether this is due to racial factors or else due to socio-cultural differences between black and white races is not clear. More recent research indicates that South Asian populations including Indians, may be more predisposed to developing hypertension and metabolic syndrome.

Modifiable risk factors

Dietary salt : There is substantial and convincing evidence that dietary salt intake over and above the physiological requirements, is a strong risk factor for hypertension. It has been estimated that a 100 mmol per day lower intake of sodium over the lifetime would result in 9 mm smaller rise in SBP between 25 to 55 years of age; this would translate to a reduction in mortality by 16% in IHD, 23% for stroke and 13% deaths from all causes. Well established public health recommendations indicate that dietary salt consumption, from all sources should not exceed 5 to 6 grams a day for an adult (19, 20).

Dietary Potassium : In contrast to sodium, dietary potassium is protective; increasing levels of potassium intake are protective. More precisely, it is the ratio of dietary sodium to potassium which is more relevant. Thus, at a given level of dietary salt intake, blood pressure could be lowered by increasing the potassium intake. The case is therefore quite strong to encourage consumption of fresh fruits and vegetables (400 to 500 grams per day for an adult), which are rich sources of potassium (20, 21).

Other Macro and Micro-nutrients : The role of saturated fats, dietary cholesterol, fibre (protective), antioxidant vitamins (protective), dietary calcium (increased intakes are protective) have all been postulated, though there is still no convincing evidence. However, keeping in view the fact that these nutrients have been shown to have a role in other lifestyle disease as IHD and diabetes, it would be desirable to adhere to the healthy lifestyle recommendations, in totality.

Overweight : There is strong and consistent evidence that overweight / obesity is associated with hypertension, with the RR being 2 to as much as 6 times. The proportion of hypertension attributable to obesity has been estimated to be 30 to 65% in western countries. It is also estimated that for 10 Kg increase in weight (with all other risk factors held constant) the SBP would increase by 2 to 3 mm and DBP by 1 to 3 mm (22). Besides obesity, central obesity due to excessive intra-abdominal (visceral) fat, as measured by waist circumference or WHR has been clearly shown to be a risk factor for hypertension, independent of whether generalized obesity is present or not. Hypertension and obesity / central obesity, in addition, are factors which cluster together in metabolic syndrome.

Lack of Physical Activity : It has also been convincingly demonstrated by epidemiological and clinical data that physical inactivity is an important risk factor for hypertension.

Sedentary and unfit normotensive individuals have 20% to 50% increased risk of developing hypertension in the next few years as compared to their fit and more active peers (23). WHO estimates indicate that the RR for developing hypertension due to physical inactivity is between 1.2 to 2.9, in different research studies.

Alcohol : Alcohol consumption has been consistently related to blood pressure in different epidemiological studies. The risk effects are independent of obesity, central obesity, physical inactivity, age sex and smoking. The RR of alcohol for causing hypertension has been estimated to be 1.4 to as high as 4.1, depending on the quantity and regularity of alcohol consumption (WHO global estimates). When 2 or more drinks are consumed daily, SBP increases by 1 mm and DBP by 0.5 mm on an average; daily drinkers have SBP and DBP levels which are higher by 6.6 mm and 4.7 mm respectively compared to those who drink only once a week (20, 24).

Tobacco use : Tobacco use and hypertension, when present together, interact and greatly increase the cardiovascular risk compared to when either of them would have been alone. The direct risk of tobacco in causing rise in blood pressure is not very clear (some smokers may in fact have lower BP levels, since chronic tobacco use may induce decrease in appetite with consequent low body weight and in turn slight lowering of BP). However, WHO global risk estimates indicate that the RR of hypertension due to tobacco use is 1.17 times higher.

Psychosocial Stress : There is evidence that acute mental stress causes an increase in blood pressure. There is, however, not enough evidence to prove that long term stress causes chronic increase in blood pressure. Overall, the available evidence is insufficient to allow for definite conclusions of causality; methodologically sound research is required in this area. Nonetheless, stress management techniques would be of help in controlling acute stress.

Early Childhood Experiences : The “Barkers Research Group” has undertaken a large amount of research in various settings and strongly hypothesized that foetal malnutrition (as evidenced in form of low birth weight) and malnutrition during infancy and early childhood may be a strong risk factor for subsequent development of hypertension, diabetes, obesity, dyslipidaemia and metabolic syndrome in later adult life (25). While these observations raise interesting possibilities of “foetal programming”, the findings need to be substantiated by prospective studies.

Tracking : The phenomena of “tracking” means that the level of risk factors during childhood and adolescence tends to track into the youth and late adulthood also. Thus, children who have higher levels of body weight, blood pressure, blood glucose and cholesterol, will tend to have the same level of these parameters during adulthood also. For example, in one of the large epidemiological studies, people in their 40’s with elevated BP as a group, had higher blood pressure readings than normal when they were aged 7 years (26).

Other Environmental factors : Exposure to noise, air pollution and water pollution have all been implicated as a risk factor for hypertension, but no concrete epidemiological evidence is still available. Protection of public against environmental hazards

is, in any case, a worthwhile public health measure.

Increased Heart Rate : It has been noted in studies that resting heart rate of hypertensives is higher than normotensives. Whether hypertension leads to raised heart rate, due to haemodynamic adjustments or else, whether increased heart rate is a marker for prediction of hypertension, is not still clear.

Low Socio-economic Status : In a number of populations in developed countries, consistently higher levels of BP and a higher prevalence of hypertension have been noted in lower socio-economic groups. Contrarily, in those countries whose economies are improving, higher prevalence is seen in higher socio-economic groups. Thus, in developing countries, the higher prevalence in higher socioeconomic strata probably represents the initial stages of the epidemic of cardiovascular diseases; as the epidemic advances in these countries, there is likely to be a reversal of the social groups affected.

White Coat Hypertension : Measurement of BP by a Doctor, may raise the concern and lead to a rise in BP in the subject, a phenomenon called as white coat hypertension. It is therefore important to reassure the subject, and record the blood pressure in a relaxed state. White coat hypertension though, by itself may not be truly a “risk factor” for hypertension.

Prevention and Control of Hypertension

Prevention and control of hypertension is addressed as per the same strategies, as has been discussed for IHD and diabetes.

Primary Prevention : This would be by utilizing the mass approach or the group approach. The strategy utilizes the IEC techniques to educate the community (*mass approach*) of the dangers of hypertension and the fact that it is a silent killer and most of the times the patient may not have any outward symptoms but the disease may progress. Education should be provided as regards the risk factors and adoption of healthy lifestyle to prevent the onset or progress of the disease. Education would also be directed towards specific groups (*group approach*) as outlined for prevention of IHD. Similarly, the primary prevention steps would also include the “*individual high risk strategy*”, focusing on individuals who have strong family history of hypertension, who are changing from active to more leisurely lifestyle (as the newly rich, executives, businessmen, etc), are obese, or are likely to physically inactive as office workers.

Secondary Prevention : This would be through early diagnosis and prompt treatment, mainly by way of screening programmes. The strategies could be either “population screening” by screening the entire population or a selected random sample, which is fruitful only if the prevalence of hypertension is very high or else for research or health planning purposes. Secondly, it could be a “selective screening” undertaken in groups of people known to be at high risk, as those with family history, obese persons (BMI > 25), aged more than 40 years in high prevalence populations, or those with diabetes or dyslipidaemia. Thirdly, it could be an “Opportunistic Screening” employed when high risk individuals come in contact with the health care system, e.g. obese persons, diabetics, persons having IHD or risk factors for IHD, those having family history of hypertension, diabetes or IHD, etc, once such a person reports sick. Since

measurement of blood pressure is a very simple, inexpensive and non-invasive procedure, it would be a very fruitful step if all medical persons make it a point to measure the blood pressure of all adult patients who come to them, irrespective of the presenting symptoms.

Tertiary Prevention : The role of Doctors as well as paramedical persons assumes importance in context of tertiary prevention - to follow up the patient, to advocate continuous treatment, to educate the patients about importance of treatment and the various precautions to be taken by them.

Summary

Systemic arterial hypertension is defined as a state of chronically elevated arterial blood pressure, as compared to what is normally expected in context to the age of an individual. Based on the recent guidelines of WHO & ISH and JNC - VII, Hypertension is classified into Pre-Hypertension (Systolic 120-139 or Diastolic 80-89mm Hg), Grade-I (S 140 to 159 or D 90-99), Grade-II (S 160 to 179 or D100 to 109), and Grade III (S \geq 180 or D \geq 110). About 5 to 10% of the cases of hypertension will have some identifiable cause for the raised BP. This is called as "Secondary" hypertension. However, 90 to 95% cases will not have any identifiable cause; these are called as "primary" or "essential" hypertension. The Target organs damaged due to hypertension are Heart (IHD, LVH, Heart Failure), Brain (Stroke, TIC), Chronic kidney disease, Peripheral arterial disease, and Retina (Retinopathy). At the large population level, the major cause of stroke is raised blood pressure and efforts to prevent hypertension will also pay a rich dividend for prevention of stroke. Raised blood pressure should not be seen in isolation but as a part of the overall, total cardiovascular risk assessment for the individual.

Hypertension affects approximately 1 billion worldwide and in our country, it was estimated to affect 120 million in year 2000. In India, the prevalence of hypertension has been estimated to be between 20% to 40% in urban adults and 12% to 17% in rural adults. The risk factors for hypertension can be grouped as modifiable and non-modifiable. Non-Modifiable include increase in Age, Sex (In childhood there is no difference between sexes; from adolescence onwards, the average BP is higher in males. However, this difference narrows down after women attain the age of 50 years, and thereafter, may even get reversed), Positive Family history, Ethnicity (higher among Black races and South Asian populations including Indians). Modifiable risk factors include Diet rich in Sodium (salt exceeding 5 to 6 grams a day for an adult), rich in saturated fats, dietary cholesterol and low in fibre, calcium, potassium and antioxidant vitamins; Obesity especially central obesity; physical inactivity; poor maternal nutrition during pregnancy, and malnutrition during early infancy; psycho-social stress; Alcohol; Tobacco use; Exposure to noise, air pollution and water pollution; and, Low Socio-economic Status. The phenomenon of "tracking" means that the level of risk factors during childhood and adolescence tends to track into the youth and late adulthood also. Thus, children who have higher levels of body weight, blood pressure, blood glucose and cholesterol, will tend to have the same higher level of these parameters during adulthood also.

The broad strategy for prevention and control of hypertension

include primary, secondary and tertiary levels of prevention. The Primary Prevention would basically utilize the IEC strategy in the form of the *population strategy*, educating both, the general community (*mass approach*) and specific groups (*group approach*) and also in the form of "*individual high risk strategy*", focusing on individuals with "Risk factors". Secondary Prevention would be mainly by way of population screening or selective screening or Opportunistic Screening. Tertiary prevention is to follow up the patient, to advocate continuous treatment, and to educate the patient and the family about importance of treatment and the various precautions to be taken by them.

Study Exercises

Long Question : Discuss the epidemiology of hypertension, with special reference to Indian context.

Short Notes : (1) Tracking (2) End organ damage in hypertension (3) Dietary approaches to prevention of hypertension

MCQs & Exercises

1. Following is not a Target organ damaged due to hypertension: (a) Brain (b) Retina (c) Kidney (d) Bladder
2. The systolic BP range of Grade II Hypertension : (a) 140-149 (b) 150-159 (c) 160-179 (d) 170-179
3. The Diastolic BP range of Grade III Hypertension : (a) \geq 100 (b) \geq 150 (c) \geq 110 (d) \geq 120
4. The following Diet is a not a risk factor for Hypertension (a) Rich in Sodium salts (b) Rich in saturated fats (c) Low in fibre (d) High in potassium.
5. In India, the prevalence of hypertension has been estimated to be between (a) 20% - 40% (b) 40 - 60% (c) 60 - 70% (d) $<$ 10%
6. Which mode of prevention does Opportunistic Screening fit in : (a) Primordial (b) Primary (c) Secondary (d) Tertiary.

Answers : (1) d; (2) c; (3) c; (4) d; (5) a; (6) c.

Definition / Identification

Diabetes Mellitus is defined as a metabolic abnormality characterized by hyperglycaemia and disturbances of carbohydrate, fat and protein metabolism that are associated with absolute or relative deficiency in insulin secretion and / or insulin action (1). When fully evolved, it is characterized by fasting hyperglycaemia but it can also be characterized in the less overt stages and before fasting hyperglycaemia appears, most usually by the appearance of glucose intolerance. Most often, it tends to be asymptomatic ("silent killer") in which case the diagnosis depends on biochemical investigations (2).

Classification

Diabetes mellitus consists of a group of metabolic disorders which have been classified by a WHO expert group as shown in Table - 1 (1).

IDDM (now called Type - 1 Diabetes or T1D) : This comprises 5 to 10% of all diabetes. It is due to absolute insulin deficiency as a result of pancreatic beta cell destruction. It is characterized by abrupt onset of severe symptoms, proneness to ketosis, presence of one or more of the classical symptoms (polyuria, polydipsia and polyphagia). The age at clinical onset or diagnosis is usually below 30 years. All patients of this type need exogenous insulin for survival. Blood glucose levels are unequivocally elevated and glucose and ketones are usually present in urine.

NIDDM (now called Type - 2 Diabetes or T2D) : NIDDM forms the majority of the problem from lifestyle and non -

communicable diseases point of view, comprising 85 to 90% of all diabetes cases. For the purpose of this chapter, the focus will be on T2D. The disease takes a very silent course and is quite often detected on a routine, screening urine or blood test, with diagnosis being often made after 40 years age. It has a very strong genetic (family history) component. In addition, obesity is frequently associated with T2D, though in developing countries, many of the subjects with T2D may not be obese if we go simply by weight for height standards.

IGT and IFG : These are progressive stages of the same disease of which T2D represents the most severe form. Both IGT and IFG are themselves strong risk factors for future development of diabetes. Proper lifestyle management (Diet, Exercise and Weight reduction) prevents progression to the later stage. In the natural course, about one - thirds each of IGT subjects will develop diabetes, or remain as IGT or revert back to normal. The microangiopathic complications (Retinal and Renal) which are characteristic of diabetes are rare in IGT; however, there is increased occurrence of atherosclerosis in IGT as compared to normal people.

MRD : In developing countries in the tropics, young people with diabetes may present with a constellation of clinical features including onset usually below 30 years age, average or low body weight (BMI < 30) moderate to severe hyperglycaemia, usually non - proneness to ketoacidosis unless there are precipitating conditions as infections, the requirements of large dose of insulin for metabolic control and frequently a history of malnutrition in infancy and early childhood. The term "MRD" has been assigned to this syndrome.

Diagnostic Criteria

The diagnostic criteria, as enunciated by the American Diabetic association (ADA) and duly agreed by the WHO are shown in Table - 2 (3, 4).

A. Clinical Cases							B. Statistical Risk Classes (Subjects with normal glucose tolerance but substantially increased risk of developing Diabetes)		
I. Diabetes Mellitus				II. Impaired Glucose Tolerance (IGT) and Impaired Fasting Glucose (IFG)		III. Gestational Diabetes Mellitus (GDM)		Previous abnormality of glucose tolerance	Potential abnormality of glucose tolerance
Insulin Dependent Diabetes Mellitus (IDDM, Type - 1)	Non Insulin Dependent Diabetes Mellitus (NIDDM, Type - 2)		Malnutrition Related Diabetes (MRD)	Other Types of Diabetes (associated with certain diseases as pancreatic disease, hormonal, drug induced etc.	Non - Obese	Obese	Associated with certain diseases		
	Non - Obese	Obese							

Diabetes Mellitus		IGT	IFG	
<i>Plasma</i>	<i>Whole Blood</i>	<i>Plasma</i>	<i>Plasma</i>	<i>Whole Blood</i>
Fasting ≥ 126 , OR 2 hrs PP ≥ 200	Fasting ≥ 110 , OR 2 hrs PP ≥ 180	Fasting < 126 AND 2 hrs PP ≥ 140 BUT < 200	Fasting ≥ 110 BUT < 126	Fasting ≥ 100 BUT < 110

Notes :

- All value shown above are in mg / dl
- 2 hrs PP value are after 2 hrs of 75 gms glucose orally in 250 - 300 ml water
- ADA has recently recommended downgrading the criteria of IFG to 100 mg / dl from above mentioned 110 mg. The WHO is reviewing this recommendation and may enunciate their revised recommendations, if any, in near future.

Complications of Diabetes

Diabetes owes its importance to the fact that it is a silent killer. It leads to a large number of serious sequelae which are disabling, besides drastically reducing the quality of life. The complications / sequelae are listed in Table - 3.

It needs to be noted that presence of diabetes carries a very high risk for IHD (RR of 3.5 to 4 times). In addition, diabetes frequently co - exists with other coronary risk factors as hypertension, dyslipidaemia, obesity and metabolic syndrome.

Acute
<ul style="list-style-type: none"> • Hypoglycaemia • Hyperglycaemia and Ketoacidosis • Infections (especially fungal infections of skin and mucous membranes, urinary infections, anaerobic infections of deep tissues, mycobacterial infections).
Chronic
<ul style="list-style-type: none"> • Atherosclerosis, manifesting in cerebrovascular and coronary artery disease. • Diabetic eye disease (Retinopathy, cataract) • Diabetic Kidney Disease • Diabetic Neuropathy (peripheral as well as autonomic neuropathies) • Foot ulceration and infections

Magnitude of the Problem

As per estimates of WHO, the number of people affected worldwide with diabetes were approximately 125 million which are expected to be almost 300 million by 2025. (5). The incidence is peculiarly high among populations living in Nauru islands and among Pima Indians of USA where the prevalence may be as high as 40 to 50%. In developed, industrialized countries, prevalence rates of as high as 10 to 20% may occur (1).

India has the unfortunate privilege of being the "Diabetes capital" of the world, The prevalence rates have been estimated to be 12% in urban areas and 4% in rural areas. More concerning is the fact that diabetes prevalence over the past 4 decades has increased fourfold (6). Another interesting phenomena is that Indians who migrate to affluent countries develop very

high prevalence rates of 10 to 20%, indicating the high racial predisposition that Indians and other South Asian populations have for diabetes, and which gets expressed whenever we get affluent conditions (1).

Determinants - Risk Factors for Diabetes (T2D)

The two most important determinants of diabetes are firstly, genetic background (family history) and secondly, obesity. It has been very aptly said that for diabetes, “genetics loads the cannon and obesity finally fires it”. As for IHD, the risk factors may be grouped as “*Non Modifiable*” (Age, Sex, Genetic and Racial factors) and “*Modifiable*” (Obesity, physical activity, nutritional factors, stress, drugs, infections and chemical toxins, etc).

Genetic Factors : NIDDM shows strong family aggregation. Twin studies and familial studies have provided firm evidence that the role of genetic factors is relatively high. Till now, no specific genetic marker has been identified, though some have been proposed. With the current status of knowledge, it seems that diabetes is a “polygenic” disease and not possibly due to defect in a single gene. History of diabetes among parents, grandparents and first degree relatives predisposes a person to high risk of developing diabetes.

Age : Increasing age increases the risk. Most cases are detected during the middle age.

Sex : There is no clear difference between sexes as regards the risk of diabetes.

Race : Some races are known to be at high risk as Polynesians, Eskimos, Pima Indians, etc. The possibility is also strong that South Asian populations including Indians may be at high risk. One hypothesis is that this may be due to the effect of “*thrifty genes*”. These genes developed as a part of nature’s protective mechanisms, among populations who were for many centuries exposed to starvation, famines and lack of food. The thrifty gene was developed by nature to conserve whatever small amount of energy, which was available to such populations, in the form of body fat stores. However, with economic improvements in such populations, the food supply improves greatly but the protective effect of thrifty gene also continues resulting into excessive levels of obesity and consequent diabetes.

Obesity : Obesity has been proven to be a very strong risk factor for diabetes type 2. The estimates of risk vary from RR of 1.8 to 3.2 in different populations. The role of obesity is independent of racial factors. In addition, central distribution of body fat (referred to as central, abdominal, visceral, apple - shaped or android type of fat distribution and measured in terms of Waist Circumference or Waist Hip ratio) is upheld to be an important risk factor, independent of total body weight. The recommended cut - off levels for BMI, waist circumference and Waist Hip Ratio are given in a previous chapter on nutrition and lifestyle.

Physical inactivity : It has been clearly demonstrated that physical activity increases insulin sensitivity. The risk of diabetes due to physical inactivity has been estimated to be as high an RR of 4.31 in some large scale studies. The protective effect of physical activity is independent of obesity; this means that an obese person who is physically active and fit would have lower risk of diabetes (as well as lower risk of other life

style diseases) than a normal weight person who is physically inactive and unfit. In addition, physical activity will also assist in keeping the body weight under control.

Nutritional Factors : There is increasing evidence from both epidemiological as well as laboratory studies that increased dietary intake of saturated fat and decreased intake of fibre can result in lowered insulin sensitivity and impairment of glucose tolerance. In general, reduction in the overall calories, reduced intake of saturated fats & refined sugars and increased intake of grains, fruits and vegetables would be of utility in preventing diabetes.

Foetal and Early Childhood Influences : There has been increasing evidence (*Barker’s Hypothesis*) that poor maternal nutrition during pregnancy, and malnutrition during early infancy may be associated with insulin resistance, obesity, impaired glucose tolerance, raised blood pressure and occurrence of metabolic syndrome in the same person during his / her adult life. This underlines the value of ensuring adequate nutrition during pregnancy and during early childhood.

Stress : Several states of physical stress and trauma can lead to glucose intolerance through altered hormonal mechanisms but whether they can permanently lead to diabetes is not established. Similarly, the role of mental and social stress as contributory factor in diabetes mellitus has been suggested but remains unproven.

Drugs and Hormones : Phenytoin, diuretics (especially thiazides), beta blockers, corticosteroids and certain contraceptive steroids may, in susceptible persons, induce glucose intolerance or even diabetes, but this usually resolves after withdrawal of the drug.

Prevention and Control

The broad strategy for prevention and control of diabetes will remain the same as that outlined for IHD earlier, including primary, secondary and tertiary levels of prevention.

Primary Prevention : This would basically utilize the Information, education and Communication (IEC) strategy to educate and motivate the community and individuals. The key messages for IEC will remain the same as have been outlined for prevention of IHD in the earlier chapter.

Primary prevention will, as for IHD, include the *population strategy*, educating both, the general community (*mass approach*) and specific groups (*group approach*) as outlined for prevention of IHD. Similarly, the primary prevention steps would also include the “*individual high risk strategy*”, focusing on individuals who have strong family history of diabetes mellitus, who are changing from active to more leisurely lifestyle (as the newly rich), are obese, have evidence of IFG or IGT, have other cardiovascular risk factors as hypertension and dyslipidaemia, and women who have history of Gestational DM or history of giving birth to babies weighing > 4kg. Equally relevant from primary preventive point of view is to create general awareness in the community regarding diabetes, its risk factors and complications and regarding its potential for management, treatment and control. Recent community awareness drives, using prominent personalities, who are themselves diabetics, is a promising trend and should be utilized.

Secondary Prevention : This would be through early diagnosis and prompt treatment, mainly by way of screening programmes. The strategies could be either “population screening” by screening the entire population or a selected random sample, which is fruitful only if the prevalence of diabetes is very high or else for research or health planning purposes. Secondly, it could be a “selective screening” undertaken in groups of people known to be at high risk, as those with family history, obese persons (BMI > 25), aged more than 40 years in high prevalence populations, women giving history of GDM, those with history of IGT / IFG, or those with hypertension or dyslipidaemia. Thirdly, it could be an “Opportunistic Screening” employed when high risk individuals come in contact with the Doctor, e.g. obese person, hypertensive, having IHD, having family history, etc. once such a person reports sick. Similarly, in clinical settings, all opportunities should be utilized to undertake screening for known end organs as ophthalmoscopy, urine testing, etc., to detect any evidence of such end organ damages which could have occurred and may have escaped detection till now.

Tertiary Prevention : The role of Doctors as well as paramedical personnel assumes importance in context of tertiary prevention - to follow up the patient, to advocate continuous treatment, to educate the patient about importance of treatment and the various precautions to be taken by them. The key issues to be kept in mind are outlined in Table - 4. It should also be noted that presence of diabetes is considered to be a major risk factor for development of IHD and other CVD and hence the need to have a tight control on blood sugar levels for prevention of IHD/ CVD. Moreover, the complications of diabetes particularly CVD are much higher if concomitant hypertension is also present and hence the need of monitoring and adequate control of blood pressure in all diabetics as a part of tertiary prevention.

Table - 4 : Key Issues for Tertiary Prevention

Keep a follow up of the patient of diabetes
Reassure about the possibility of leading a near normal life, with proper treatment and precautions
Educate about :
- Do not miss the antidiabetic medicines
- Do not miss the meals
- Diabetic identification card
- Carry some sugar or lozenges for any hypoglycaemic emergency
- Foot care, footwear and daily inspection
- Early identification of complications
- Regular Physical exercise, Diet, No Tobacco, Avoid alcohol

Summary

Diabetes Mellitus is defined as a metabolic abnormality characterized by hyperglycaemia and disturbances of carbohydrate, fat and protein metabolism that are associated with absolute or relative deficiency in insulin secretion and / or insulin action. It has been classified by a WHO expert group as clinical cases and statistical risk classes. Clinical cases are in turn classified as i) diabetes mellitus (Type - 1, Type - 2,

MRD and others) ii) Impaired glucose tolerance and Impaired fasting glucose and iii) Gestational Diabetes Mellitus. Type - 1 Diabetes is due to absolute insulin deficiency as a result of pancreatic beta cell destruction, characterized by abrupt onset of severe symptoms, proneness to ketosis, with onset below 30 years and it comprises 5 to 10% of all diabetes. Type - 2 Diabetes, comprising 85 to 90% of all diabetes cases, takes a very silent course and is quite often detected on a routine, screening urine or blood test, with diagnosis being often made after 40 years age, with a strong genetic (family history) component and association with obesity. IGT and IFG are progressive stages of the same disease of which T2D represents the most severe form. As per the diagnostic criteria, as enunciated by the American Diabetic association (ADA), a person is said to be diabetic when the Plasma Fasting Glucose is more than or equal to 126 mg/dl or Post - prandial Glucose is more than or equal to 200 mg/dl. The *Acute Complications* of DM are Hypoglycaemia, Hyperglycaemia, Ketoacidosis and Infections while the *chronic complications* are Atherosclerosis (CAD, CVA & PVD), Retinopathy, Nephropathy, Neuropathies, Foot Ulcerations and infections.

As per estimates of WHO, approximately 125 million are affected worldwide. In developed, industrialized countries, prevalence rates are as high as 10 to 20%. In India the prevalence rates have been estimated to be 12% in urban areas and 4% in rural areas. The two most important determinants of diabetes are firstly, genetic background (family history) and secondly, obesity. The risk factors may be grouped as “*Non-Modifiable*” (Increasing Age, Genetic factors and Races like Polynesians, Eskimos, Pima Indians and South Asian populations including Indians) and “*Modifiable*” which include Obesity especially central obesity; physical inactivity leading to decreased insulin sensitivity; increased dietary intake of saturated fat and decreased intake of fibre resulting in lowered insulin sensitivity; poor maternal nutrition during pregnancy, and malnutrition during early infancy; physical, mental and social stress; drugs like Phenytoin, diuretics especially thiazides, beta blockers, corticosteroids and certain contraceptive steroids; infections and chemical toxins.

The broad strategy for prevention and control of diabetes includes primary, secondary and tertiary levels of prevention. The primary Prevention would basically utilize the IEC strategy in the form of the *population strategy*, educating both, the general community (*mass approach*) and specific groups (*group approach*) and also in the form of “*individual high risk strategy*”, focusing on individuals with “Risk factors” Secondary Prevention would be mainly by way of population screening or selective screening or Opportunistic Screening. Tertiary prevention is to follow up the patient, to advocate continuous treatment, to educate the patient and the family about importance of treatment and the various precautions to be taken by them.

Study Exercises

Long Question : Give a classification of diabetes mellitus, including diagnostic cut off criteria and deliberate on the available preventive approaches among populations.

Short Notes : (1) Gestational diabetes (2) T2 D as a coronary

risk factor (3) Microvascular and macrovascular complications in NIDDM (4) Rehabilitation of a patient of NIDDM

MCQs & Exercises

1. Type - 1 Diabetes is not characterized by (a) Abrupt onset of severe symptoms (b) Proneness to ketosis (c) onset below 30 years (d) it comprises up to 40% of all diabetes.
2. Type - 2 Diabetes is not characterized by (a) comprising 85 to 90% of all diabetes cases (b) quite often detected on a routine screening tests (c) diagnosis being often made after 40 years age (d) very weak genetic (family history) component.
3. As per the American Diabetic association (ADA), a person is said to be diabetic when the Plasma Fasting Glucose is more than or equal to (in mg/dl) (a) 100 (b) 126 (c) 200 (d) 110
4. As per the American Diabetic association (ADA), a person is said to be diabetic when the Plasma Post prandial Glucose is more than or equal to (in mg/dl) (a) 100 (b) 126 (c) 200 (d) 110

5. Drug induced Diabetes is seen in (a) thiazides (b) beta blockers (c) corticosteroids (d) All of the above.
6. Not a risk factor for Diabetes : (a) increased dietary intake of saturated fat and decreased intake of fibre (b) poor maternal nutrition during pregnancy (c) stress (d) High sodium and Low Potassium intake.

Answers : (1) d; (2) d; (3) b; (4) c; (5) d; (6) d.

RajVir Bhalwar

Definition / Identification

The term cancer encompasses a very wide variety of heterogeneous disorders occurring in different parts of the body, with very different clinical manifestations. However, there is a special reason for grouping such diverse diseases under a single heading. The reason is that cancers, as they are defined, are "Group of heterogeneous disorders characterized by *Clonality* (arise from a single stem cell that clones into carcinomatous cells), *Autonomy* (the cell division and growth is uncontrolled), *Anaplasia* (lack of cell differentiation) and *Metastasis* (distant spread)". It is these common features that bind cancers into a single entity for the purpose of description.

Secondly, various cancers, despite their diversity in clinicopathological manifestations, have some risk factors in common, a phenomenon that again binds them together and can be fruitfully utilized for the purpose of prevention. As we shall see in the course of this chapter, these common risk factors are primarily a reflection of unhealthy lifestyle and hence, the contemporary saying is that cancers are, by and large, diseases of unhealthy lifestyle and are, therefore, potentially preventable.

Magnitude of the Problem

Cancers reflect a major load on human health by way of morbidity, mortality and, above all, human suffering.

Worldwide : Approximately 10 million new cases and more than 6 million deaths (12% of all deaths) occur due to cancers every year. It is estimated that more than 22 million people would be living with cancers, worldwide at any given point of time (1). These figures represent an increase of around 19% in incidence and 18% in mortality since 1990. In terms of incidence, the most common cancers world-wide are those of lung (12.3% of all cancers), breast (10.4%) and colorectum (9.4%). Lung cancer is the largest single cancer in the world (1.1 million annually). The top three causes of death from cancer are those of the lung (17.8% of all cancer deaths), stomach (10.4%) and liver (8.8%). Developing countries contribute to more than half of the total cancer cases worldwide. By 2020, the new cases are expected to reach at least 15 million a year and deaths 10 million. The projection of new cases of cancer per year, for 2020, is 6 million and 9.3 million respectively from developed and developing countries.

India : Approximately 8 lakh new cases of cancers are expected to occur every year. Large majority of these are tobacco related and hence potentially preventable. It has been estimated that 48% of cancers among men and 20% in women are due to tobacco. Cancer incidence in India is estimated to be around 70 - 90 per 100,000 populations with 700,000 - 900,000 new cases of cancer every year. If survival is taken as three years on an average, at any given time there will be about 2,500,000 cancer patients in the country. In the year 2000, five and a half lakh deaths in the country were due to cancer. The commonest cancers in men are those of Lungs, Stomach, Oral cavity and oesophagus, while in women, those of Cervix Uteri, Breast, oral cavity, Ovary, Oesophagus and Stomach are the commonest.

In India, a network of cancer registries was started across the country under the National Cancer Registry Programme (NCRP). There are at present six Population Based Cancer Registries (PBCRs) (five urban and one rural) and five Hospital Based Cancer Registries (HBCRs) generating data on cancer in the country under NCRP. The PBCRs collect information regarding all new cancer cases occurring in a defined population. PBCRs provide data on cancer incidence, survival and mortality. The HBCRs record information on cancer patients attending a specific hospital with focus on clinical care and hospital services. HBCRs provide information on length and quality of survival in relation to site, stage and treatment and help to assess quality of hospital care and cancer services. The details of national cancer registries are given in the section on national health programmes.

The Major Risk Factors for Cancers

Tobacco : Tobacco smoking is the main known cause of human cancer-related deaths, worldwide. An increase in risk of lung cancer (relative to a non-smoker) is consistently evident at the lowest level of daily consumption, and is also proportional to the duration of smoking. In general the relative risk (RR) of lung cancer due to smoking is of the order of 10 to as high as 20 times. Smoking filtered cigarettes probably entails a lower risk for most tobacco-related cancers than unfiltered and high-tar cigarettes. However, it needs to be noted and emphasized that a “safe” cigarette does not exist; all smoking tobacco products entail a carcinogenic risk.

In addition to lung, tobacco also causes cancers of the larynx, oral cavity, pharynx, oesophagus, pancreas, kidney and bladder (2). In non-alcohol drinking male smokers, the risk of developing cancer of the oral cavity is about double that for non-drinking non-smokers. Elevations of ten-fold or more are evident for cancer of the larynx and five-fold or more for oesophageal cancer. A common feature of lung and other smoking-induced cancers is the decreased risk which follows smoking cessation (“quitting”) relative to continuing smoking (2). Despite the clearly established benefit of cessation, the risk for ex-smokers does not decrease to that for “never smokers”.

Other cancer types may be a consequence of smoking. These include cancer of the stomach, liver, nose and myeloid leukemia.

Exposure to environmental smoke (passive smoking) is a definite risk for lung cancer and possibly laryngeal cancer; the relative risk has been estimated at about 1.15-1.20 times.

Smokeless tobacco use (the commonest being tobacco chewing as “quid”) has been associated with increased risk of head and neck cancer, particularly oral cancer. Since chewing of tobacco-containing products is particularly prevalent in southern Asia, especially India, it represents a major carcinogenic hazard in this region.

Alcohol consumption, exposure to asbestos and exposure to ionizing radiations interact with smoking in increasing the risk of cancers. For alcohol drinking and smoking, risk for cancer of the larynx, oesophagus and oral cavity increase multiplicatively in relation to the respective risks generated by either exposure in the absence of the other. For individuals exposed to both asbestos and tobacco smoke (for example,

insulation workers who smoke), risk of lung cancer is also increased multiplicatively.

Alcohol Drinking : Causal association of drinking alcohol has been definitely established in respect of oral, oesophageal, liver and other cancers (3). A causal association is also established in the case of breast cancer and is probable for colon and rectal cancer (3, 4). There have been suggestions of a possible carcinogenic effect of alcohol drinking on other organs, such as the lung, but the evidence is still inconclusive (5). For all cancers caused by drinking alcohol, the risk of cancer increases with the level of consumption, up to an intake of about 80 g of ethanol / day (equal to 8 small pegs of hard drinks as Rum or whisky).

The risk of head and neck cancer is 5-10 times higher in heavy drinkers than in abstainers, the carcinogenic effect of alcohol appearing to be more potent in the oral cavity, pharynx and oesophagus and weaker in the larynx. The relative risk of breast cancer in women with a high consumption of alcohol is approximately two-fold. Alcohol drinking and tobacco smoking show a synergistic interaction in the etiology of cancers of the oral cavity, pharynx, larynx and oesophagus.

Alcohol drinking is estimated to be involved in the etiology of 3% of all cancers (that is, 4% in men, 2% in women). In women, approximately half of the neoplasms attributed to alcohol drinking are breast cancers.

Occupational Exposures : The first reports of associations between risk of cancer and employment in particular occupations appeared during the 18th century (6) and 19th century (bladder cancer in workers exposed to dyes) (7). However, the majority of studies establishing a link between an increased risk of cancer and a particular working environment were published between 1950 and 1975 (8).

At present, 25 chemicals or mixtures, for which exposures are mostly occupational, have been established as human carcinogens, the important ones being asbestos, crystalline silica and heavy metals. Aromatic amines have been shown to increase the risk of Bladder cancer; benzene that of Leukemias and that of myelogenous leukaemia in particular (9); Asbestos and other fibres have been associated with Lung cancer and mesothelioma. Cancer of the lung can be caused by exposure to inorganic arsenic in mining and copper smelting and among workers in chromium plants and chromium alloy workers Nickel refining also carries carcinogenic risk.

Coal tar, coal gas production and iron founding are associated with cancers of the skin and of other sites, including the urinary and respiratory systems. Work in iron and steel founding is also associated with an elevated risk of lung cancer. Nasal Adenocarcinomas are caused by exposures in the furniture and cabinet making industry, mainly among people exposed to wood dust. Similarly, among painters, 40% excess risk of lung cancer has been consistently recorded.

Environmental Pollution : In the present context, “environmental pollution” refers to a specific subset of cancer-causing environmental factors, namely, contaminants of air, water and soil. The carcinogenic pollutants for which most information is available include asbestos (referring here to non-occupational exposure); toxic agents in urban air; pollutants,

chlorination by-products and other contaminants of drinking water. Various studies suggest that environmental pollution accounts of 1-4% of the total burden of cancer in developed countries (10, 11).

Non-occupational exposure to asbestos may occur domestically and as a consequence of localized pollution. Cohabitants of asbestos workers may be exposed to dust brought home on clothes. Exposure to asbestos under domestic circumstances results in an increased risk of mesothelioma. Likewise, non-occupational exposure to asbestos may cause lung cancer, particularly among smokers (12).

Ambient air pollution has been implicated as a cause of lung cancer. It is possible to attribute some carcinogenic risk to particular atmospheric pollutants, including benzopyrene, benzene, some metals, particulate matter (especially fine particles), and possibly ozone. Vehicular exhaust remains a continuing or even increasing problem. Engine consumption products include volatile organic compounds (benzene, toluene, xylenes and acetylene), oxides of nitrogen (NO_x) and fine particulates (carbon, adsorbed organic material and traces of metallic compounds). Some potential carcinogens are also emitted from poorly regulated use of coal, wood and biomass (e.g. animal dung, crop residues) for electricity production and heating.

Drinking water may contain a variety of potentially carcinogenic agents, including chlorination by products and arsenic. Chlorination by products results from the interaction of chlorine with organic chemicals. Among the many halogenated compounds that may be formed, trihalomethanes and chloroform are those commonly found. Studies on bladder cancer have suggested an increased risk associated with consumption of chlorinated drinking water (13). Doubts remain as to whether such associations are causal because of the way in which the studies measured exposure.

Arsenic causes cancer in the skin, lung and other organs. The main source of environmental exposure to arsenic for the general population is through ingestion of contaminated water. High exposure to arsenic from drinking water is found in several areas of Alaska, Argentina, Bangladesh, Chile, India, Mexico, Mongolia, Taiwan and the USA. There is strong evidence of an increased risk of bladder, skin and lung cancers following consumption of water with high arsenic contamination (14, 15).

Food Contaminants : Food may be contaminated by mycotoxins. The most studied are *Aflatoxins*, which occur as food contaminants in hot, humid parts of the world, with diets based upon maize and groundnuts (peanuts). Aflatoxins are products of the aspergillus fungi and particularly accumulate during storage of grains. Together, aflatoxin exposure and HBV infection are the main risk factors accounting for the high incidence of hepatocellular carcinoma in some regions of Africa, Asia and South America (16).

Incidence of oesophageal cancer incidence has been related to the occurrence of another fungus, viz., *F. verticillioides* or its toxins in maize. Similarly, Ochratoxin A, also a fungal metabolite, may contaminate grain and pork / pork products and lead to urinary tract tumours.

Certain organochlorines, including DDT and other pesticides, are resistant to degradation and persist in the environment. They are bioconcentrated in the human food chain. DDT in particular has been associated with increased risk of pancreatic cancer, breast cancer, lymphoma and leukaemia in humans.

Certain heterocyclic amines are formed during cooking of meat and fish at high temperature. Heterocyclic amines are carcinogenic in various organs of mice, rats and non-human primates, although their carcinogenic potential in humans has not yet been established (17). Another group of chemicals, the *Polycyclic Aromatic Hydrocarbons* (PAHs) are generated in meat when it is fried, roasted or cooked over an open flame, and many members of this chemical class are carcinogenic. Finally, N-Nitroso compounds are a wide class of chemicals. Nitrosamines may be formed by chemical reactions in foods containing added nitrates and nitrites, such as salt-processed by smoking and direct fire drying. The use of fertilizers may influence the level of nitrites in food.

Radiation : Ionizing radiations are one of the most intensively studied carcinogens (18 - 20). Exposure to ionizing radiations from natural as well as from industrial, medical and other sources, can cause a variety of neoplasms, including leukaemia, breast cancer and thyroid cancer.

Sunlight is by far the most significant source of ultraviolet irradiation and causes several types of skin cancer, particularly in highly-exposed populations with fair skin, e.g. Australians of Caucasian origin.

Extremely low frequency electromagnetic fields generated by electrical power transmission have been associated with an increased risk of childhood leukaemia, but the findings are not conclusive. IARC has classified extremely low frequency fields as possibly causing cancer in humans (Group 2B), based on childhood leukaemic findings (21).

Mobile telephones are the greatest source of radio frequency exposure for the general public. The evidence of the carcinogenicity of radio frequency fields is not clear. The experimental evidence is also limited, but suggests that radio frequency fields cannot cause DNA mutations. The lack of reproducibility of findings limits the conclusions that can be drawn.

Chronic Infections : Infectious agents are one of the main causes of cancer, accounting for 18% of cases worldwide, and the majority occurring in developing countries. The most frequently affected organ sites are liver (Hepatitis B and C, liver flukes), cervix uteri (Human Papilloma Viruses), lymphoid tissues (Epstein-Barr virus), stomach (*Helicobacter pylori*) and the urinary system (*Schistosoma haematobium*). The mechanism of carcinogenicity by infectious agents may be direct, e.g., mediated by oncogenic proteins produced by the agent (e.g., human papilloma virus) or indirect, through causation of chronic inflammation with tissue necrosis and regeneration. Strategies for prevention include vaccination (Hepatitis B virus), early detection (cervical cancer) and eradication of the infectious agent (*Helicobacter pylori*).

Worldwide, about 2,000 million people have serological evidence of current or past Hepatitis B virus (HBV) infection and about 350 million of them are chronic carries of the virus.

Chronic carriers of HBV, identified by the presence of relevant antibodies in the sera, have around 20 times higher risk of developing liver cancer than non-carriers (22). It has been estimated that 60% of cases of primary liver cancer worldwide and 67% of cases in developing countries can be attributed to chronic persistent infection with HBV. Hepatitis C virus (HCV) is the major causes of parenterally transmitted hepatitis worldwide. Strong associations with relative risks of as high as 20 have been reported in several case-control studies. About 20% of cases of liver cancer in the world are attributed to HCV.

Dozens of molecular epidemiological studies (23 - 25) have consistently shown relative risks for invasive cervical cancer ranging from 20 to over 100. In fact, HPV DNA is found in virtually all invasive cervical cancers, indicating that HPV is a necessary cause (26). Moreover, about 80% of anal cancers and 30% of cancers of the vulva, vagina, penis and oro-pharynx can be attributed to HPV.

HIV infection enhances the risk of Kaposi sarcoma by approximately 1,000-fold, of non-Hodgkin lymphoma by 100-fold, and of Hodgkin disease by 10-fold. Increased risk of cancer of the anus, cervix and conjunctiva has also been observed. In all these cases, the role of HIV is probably as an immunosuppressive agent and hence indirect.

Infection with *Helicobacter pylori* is one of the most common bacterial infections worldwide. In developing countries, the prevalence of *H. pylori* among adults ranges from 80 to 90% whilst in developed areas it is around 50%. *H. pylori* is the main cause of gastritis and peptic ulcer; infection may be lifelong if not treated with antibiotics (27). It is clear that *H. pylori* plays a role in gastric cancer, but other cofactors (e.g. diet) are also contributory.

Diet and Nutrition : A principal environmental factor, now generally recognized as major determinant of cancer incidence, is diet. It is estimated that up to 30% of human cancers are probably related to diet and nutrition. Epidemiological studies suggest that different dietary patterns may be specifically related to higher risk of particular types of cancer. Thus the western diet and lifestyle are generally associated with high incidence of cancers of the colorectum, breast, prostate and endometrium, but with lower incidence of cancers of the stomach, oesophagus, liver and cervix uteri. Based on available evidence, the major factors in diet related to cancers are :

Vegetables and Fruits : The most consistent finding on diet as a determinant of cancer risk is the association between high consumption of vegetables and fruits and reduced risk of several cancers. Adequate consumption of vegetables and fruits is associated with reduced risk of cancers of the pharynx, larynx, lung, oesophagus, stomach and cervix uteri, while only vegetables, but not fruits, seem to protect against cancers of the colon and rectum. Large scale studies confirm these observations, suggesting, for example, that a daily consumption of 500g of fruits and vegetables can decrease incidence of cancer of the digestive tract by as much as 25% (28).

Salt and salt-preserved foods : Several studies have reported increased relative risks of stomach cancer in relation to the increased consumption of salt and salt-preserved foods. Salted,

smoked, pickled and preserved foods (rich in salt, nitrite and preformed N-nitroso compounds) are associated with increased risk of gastric cancer. Such high salt intake, together with *Helicobacter pylori* infection, may contribute to the development of atrophic gastritis and hence gastric cancer. Consumption of Chinese-style salted fish has been specially associated with increased risk of nasopharyngeal cancer in South-East Asia (29).

Meat : Epidemiologic studies on meat consumption and cancer risk support the existence of a specific association with colorectal cancer risk. This association seems to have been found more consistently for consumption of red meat (beef, lamb and pork) and processed meat (ham, salami, bacon etc.) for which consumption of 80 g per day may increase colorectal cancer risk by 25% and 67% respectively (30).

Refined Sugars : Increased consumption of simple sugars (mono- and disaccharides) may be associated with increased colorectal cancer risk, while consumption of complex polysaccharides, non-starch polysaccharides and/or fibre is associated with lower risk.

High Overall fat / Saturated Fat Intake : The hypothesis that high fat intake is a major cancer risk factor of the Western style diet has been at the centre of most epidemiological and laboratory experimental studies. The results are, however far from clear and definitive. The only moderately consistent result seems to be the positive association between consumption of fats of animal origin (except for fish) and risk of colorectal cancer.

Food Additives : Although some animal bioassays have revealed an increased incidence of urinary bladder cancer, there is inadequate evidence for carcinogenicity of saccharin in humans (31). The proportion of dietary-related cancers considered attributable to food additives is very low (32).

Micronutrients : Research on vitamin and cancer in humans has focused mainly on carotenoids and vitamin A (retinol), vitamin E, vitamin C and some of the group of B vitamins (folic acid, B6). The biological basis of the interest in these vitamins is their involvement in either of two metabolic mechanisms commonly called the antioxidant effect (carotenoids, vitamins C and E) and methyl donation (folic acid, B6). Studies have shown quite consistently that individuals with lower carotenoid levels have increased lung cancer risk. Less consistent and weaker protective effects of carotenoids have also been reported for cancer of the oesophagus, stomach, colorectum, breast and cervix. Low dietary intake of vitamin C has been found to be associated with increased risk of cancers of the stomach, mouth, pharynx, oesophagus and, less consistently, with cancers of the lung, pancreas and cervix. Although results on vitamin E and cancer are less strong and consistent than those on carotenoids and vitamin C, several studies have suggested that low vitamin E intake is related to increased risk of cancers of the lung, cervix and colorectum.

There is rising interest in the possible cancer-preventive effect of folic acid; some prospective studies have shown that high dietary intakes and higher blood levels may be associated with reduced risk of cancers and adenomatous polyps of the colorectum. Folate deficiency leads to an accumulation of

homocysteine. High homocysteine levels have recently been found to be strongly associated with death from myocardial infarction, total mortality and colon cancer risk (33). Among other micronutrients, Zinc and selenium deficiency may increase cancer risk (34).

Overweight, Obesity and Reduced Physical Activity : Western type of diet (characterized by high calorie food rich in animal fat and protein), often combined with a sedentary lifestyle and hence energy imbalance and obesity, increases the risk of colon, breast, prostate, endometrial and other cancers. Epidemiological studies have shown, with varying degrees of consistency, that excess body mass is associated with an increased cancer risk. The strongest and most consistent association with body mass has so far been seen for endometrial cancer, the risk of which is increased two-to six-fold in obese compared to lean women, both before and after menopause. Majority of case control and prospective studies have also found that Obesity (related to various alternations in plasma levels of total and bioavailable sex steroids) is a strong risk factor for endometrial cancer, as well as or breast cancer in postmenopausal women.

Genetic Susceptibility : Inherited cancer syndromes (e.g. retinoblastoma, neurofibromatosis etc.), usually involving germline mutation in tumour suppressor or DNA repair genes, may account for up to 4% of all cancers. Inherited mutations of the BRCA 1 gene account for a small proportion of all breast cancers, but affected family members have a greater than 70% lifetime risk of developing breast or ovarian cancer. Environmental factors may modify the cancer risk of individuals affected by inherited cancer syndromes.

Reproductive Factors and Hormones : Female sex hormone metabolism, reproductive factors and menopausal status affects the development of endometrial, ovarian and breast cancer. Use of combined oral contraceptives accounts for a slight increase in risk of breast cancer, but is protective against ovarian and endometrial cancers. Hormone replacement therapy is associated with increases in risk of breast and endometrial cancers.

For breast cancer, incidence rates rise more steeply with age before menopause than after, when ovarian synthesis of estrogen production gradually diminishes. Furthermore, breast cancer risk is increased in women who have early menarche, or who have late menopause, whereas an early age at first full-term pregnancy and high parity are associated with reduced risk of cancers of breast, ovary and endometrium (35). Ovarian cancer risk does not show strong relationship with menstrual history, but is clearly and inversely related to parity (36).

Epidemiology of Common Cancers

Lung Cancer : Lung cancer is the most common tumour worldwide, with 900,000 new cases each year in men and 330,000 in women. It is leading causes of death from cancer. In India also, it is the commonest form of cancer among males. In men more than 80% of lung cancer cases are caused by smoking; in women the attributed risk is less (about 70% in Northern Europe; 45% worldwide). Some occupational exposures and air pollution (including passive tobacco smoke) make a minor contribution to incidence. No population-based screening procedures have been established. No effective treatment is

available; the five-year survival rate for lung cancer patients is less than 15%.

Breast Cancer : Breast cancer is the most common malignancy affecting women, with more than one million cases occurring worldwide annually. Affluent societies carry the greatest risk, with incidence rates of >80 per 100,000 population per year. In India, it is the second commonest cancer among females. Though it can be detected early and treated with effective measures like self / Clinical Breast examination or mammography, in our country, only 15% patients present in the localized stage; in 75% regional lymph nodes are already involved while 10% have distant spread at the time of reporting.

The worldwide breast cancer epidemic has many etiological factors, including *diet and diet related lifestyle factors* including obesity (for post-menopausal breast cancer), western type of high caloric diet, low intake of dietary fibre, physical inactivity, low intake of fruits and vegetables, alcohol use and, tall stature; *hormone related and reproductive factors* (early menarche, late or no pregnancy, late menopause, use of oral contraceptives, and lack of breast feeding); *previous history* (family history of breast cancer; history of benign breast disease); and, exposure to ionizing radiations at the time of development of breasts.

The positive aspect of breast cancer is that it is possible to detect it at an early stage and treat it effectively. In some regions of the world, including North America, Western Europe and Australia, breast cancer mortality rates have started to decline, mainly due to improvements in early detection and treatment (chemotherapy and tamoxifen). Five-year survival rates are higher than 70% in most developed countries. Breast cancer screening trials of mammography have shown that mortality can be reduced by up to 30%. However, there is limited evidence that this can be achieved in population-based countrywide screening programmes.

Cancers of the Female Reproductive Tract : Cervical cancer is the second most common cancer of women worldwide with more than 470,000 new cases per year, of about 230,000 deaths every year. More than 80% occur in developing countries. In India, it is the commonest cancer among females, with more than a lakh new cases being detected and 75000 deaths every year. Sexually transmitted infection with human papilloma virus (HPV) is fundamental to development of carcinoma of the cervix. HPV prevalence increases with multiple sexual partners and poor genital hygiene. Early age at first sexual contact and multiparity are other risk factors.

Population based screening with pap smear has improved early detection and survival. Five-year survival rates are up to 70%. In our country, it is recommended that ideal age at screening should be 35 to 50 years, as chances of detecting pre-cancerous lesions are maximum in this group. Other screening methods being studied for their efficacy in population screening include Unaided Visual inspection (UVI), Visual inspection using 4% acetic acid (VIA) and visual inspection using Lugol's Iodine.

Endometrial cancer mainly affects postmenopausal women in developed countries; worldwide, 188,000 new cases are diagnosed annually and obesity is a major risk factor. About 190,000 cases of ovarian cancer occur each year, predominantly among postmenopausal women in developed countries; five-

year survival rates are about 40%.

Oral and Other Head & Neck Cancers : The most common cancer in the head and neck, namely oral cancer, ranks eleventh worldwide (390,000 new cases per year), while cancers of the pharynx (65,000 cases) and larynx (160,000 cases) are less common. In India, oral cancer is the commonest cancer among males. In India, oral cancer is mainly due to smokeless tobacco (tobacco chewing), which is the single most important risk for oral cancer. Other risk factors include alcohol use, betel nut chewing, and chronic trauma to oral mucosa by sharp teeth or ill-fitting dentures. Multiple primary carcinomas are not uncommon. Oral cancer is eminently suited to early detection and treatment by regular inspection of oral cavity for leukoplakia / erythroplakia or ulcers. Early-stage tumours can be surgically resected. However, in developing countries like ours, many patients present late in the disease. Overall, oral cancer patients have a five-year survival rate of less than 50%.

Stomach Cancer : Cancer of the stomach is among the most common malignancies worldwide, with some 870,000 new cases every year. Mortality from stomach cancer is second only to lung cancer. In India also it is one of the commonest cancers among males, alongwith cancers of lung and oral cavity. Patients are often diagnosed with advanced disease and five-year survival rates are poor, usually less than 30%. Infection with *Helicobacter pylori* causes chronic atrophic and is considered as an important risk factor in the development of stomach cancer.

Incidence is declining worldwide. In most European countries it has fallen by more than 60% during the past 50 years. This trend is mainly due to markedly decreased consumption of salt-preserved food, increasing avoidance of a high-salt diet and availability, in many countries, of fresh fruits and vegetables throughout the year.

Oesophageal Cancer : Cancer of the esophagus is the sixth most common cancer worldwide (more than 400,000 cases per year). Incidence varies markedly, and is highest in western and south-central Asia. Squamous cell carcinoma is the commonest type of oesophageal cancers in developing countries. The major risk factors are tobacco and alcohol abuse. Other risk factors include consumption of very hot beverages and malnutrition. Most cancers of the oesophagus are detected at an advanced stage; five-year survival rates are less than 15%. In developing countries, adenocarcinoma is the commoner variety. Obesity and chronic gastro oesophageal reflux are also known risk factors.

Colorectal Cancer : Cancers of the colon and rectum are rare in developing countries, but are the second most frequent malignancy in affluent societies; over 940,000 cases occur annually worldwide. With increasing industrialization and improving economy with consequent changes in lifestyle in many of the developing countries, the incidence may rise. An important etiological factor is unhealthy lifestyle involving a diet rich in fat, refined carbohydrates and animal protein, combined with low physical activity. Studies suggest that risk can be reduced by decreasing meat consumption and increasing intake of vegetables and fruit. Colonoscopy is the most reliable means for early detection. Progressively improved treatment has resulted in a five-year survival rate of about 50%.

Liver Cancer : About 5,60,000 new cases of liver cancer, usually hepatocellular carcinoma, occur annually, and contribute significantly to cancer mortality worldwide. More than 80% of cases occur in Asia and Africa. The incidence rate is more than twice as high in men as in women. In Africa and Asia, hepatocellular carcinoma is most frequently caused by hepatitis B virus infection; concomitant dietary exposure to aflatoxin multiplies the risk. In Japan, this cancer is predominantly caused by hepatitis C virus infection. In western countries, liver cirrhosis due to chronic alcohol abuse is the major etiological factor. Hepatocellular carcinoma has very poor prognosis, survival from time of diagnosis often being less than six months; only 10% of patients survive five years or more.

Cancers of the Male Reproductive Tract : Prostate cancer accounts for about 200,000 deaths annually worldwide, predominantly afflicting older men in developed countries. Risk factors include high caloric intake and low physical activity. Black men have the highest, white men intermediate and Asian men a lower risk. Recorded incidence is increasing in many countries, partly as a result of screening for elevated serum levels of prostate-specific antigen.

Testicular cancer mainly affects young men, with close to 50,000 new cases each year worldwide. Incidence is increasing in many developed countries; its etiology is largely unknown. The mean five-year survival rate is higher than 95% mainly due to the efficiency of chemotherapy using cisplatin; long-term disease-free survival can even be achieved in cases of metastatic testicular cancer.

Bladder Cancer : Bladder cancer is the ninth most common cancer worldwide, with 330,000 new cases and more than 130,000 deaths per year. Bladder cancer is primarily attributable to smoking, which accounts for 65% of male and 30% of female cases in some developed countries. Other important causes include analgesic abuse (phenacetin), some types of cancer chemotherapy and historically, occupational exposure to chemicals such as 2-naphthylamine. In Egypt and some Asian regions, chronic cystitis caused by *Schistosoma haematobium* infection is a major risk factor. Treatment based on endoscopy, surgery, radiotherapy and cytotoxic drugs often permits long-term survival in developed countries, where 65% of patients live for at least five years after diagnosis.

Leukaemia : Leukaemia is the eleventh most common cancer worldwide with more than 250,000 new cases each year. It typically results from malignant transformation of white blood cells or their precursors. Subtypes are identified on the basis of the cell of origin (lymphocytic or myeloid etc.) and clinical course (acute or chronic). The etiology of leukemia is largely unknown, although a small proportion of cases are attributed to treatment with anticancer drugs or exposure to ionizing radiations. The genetic characteristics of many leukaemias are being elucidated.

Treatment of acute leukemia has made much progress and helped to establish general principles of cancer chemotherapy and management. Survival varies greatly according to type, with acute lymphoblastic leukemia patients having a five-year survival rate of up to 70%, whilst for those with acute myeloid leukemia it is only 20-30%.

Lymphoma : Malignant lymphomas are classified as either Hodgkin's disease or non-Hodgkin's disease or non-Hodgkin lymphoma. Hodgkin's disease affects mainly children and the elderly in developing countries and young adults in developed countries; 62,000 new cases are diagnosed annually. The incidence of malignant Non-Hodgkin lymphomas is increasing worldwide; more than 280,000 new cases occur annually, predominantly in more developed countries. Advances in chemotherapy have led to a five-year survival rate for Hodgkin disease of more than 70% and that for non-Hodgkin lymphomas has increased to 60-70%.

Prevention and Control of Cancers

The modern knowledge is certain that cancers represent serious maladies which have great potential for prevention, as well as early diagnosis and effective treatment in many instances. Prevention of Cancers should be a totalistic approach, targeting all levels of prevention, viz., primary, secondary as well as tertiary levels.

Primary Prevention

Community Education and Motivation : As is evident from the foregoing discussions, the commonest (as also serious) cancers, viz. lung, oral cavity, breast, cervix uteri, stomach, upper aerodigestive tract and colorectum, are greatly related to "unhealthy lifestyle" which has been the discussion of this entire section. Education and motivation of the community to adopt simple healthy lifestyle steps, as depicted in Box-1, will go a long way in preventing not only various serious and common cancers but various other serious diseases also.

Tobacco Control : Tobacco is the single most important modifiable risk factor for cancer. Tobacco usage was estimated to account for an annual death toll of more than three million in 1990. The latest estimates from WHO put the annual number of deaths today at more than four million. If current smoking patterns continue, the total is predicted to increase to more than eight million. Thus, current cigarette smoking will cause about 450 million deaths worldwide in the next 50 years. Tobacco induced death and diseases are preventable; halving current smoking rates would avoid 20-30 million deaths before 2025 and 150 million by 2050. Smoking cessation is very effective in reducing risk of lung cancer even in later life. The greatest saving of life would result if rates of smoking uptake by children and adolescents were decreased.

Comprehensive tobacco control, including implementation of regulatory measures and encouraging personal commitment, requires coordinated involvement of government, professionals and planners. As has already been described earlier, Tobacco control involves health promotion and education, advocacy, support for cessation, community mobilization, taxation and other fiscal measures, livelihood alternatives, regulation, legislation and enforcement. Policy level interventions would include levy of taxes (to raise cost of tobacco products and act as a disincentive for purchase), regulation of tobacco products (for constituents, emissions, health warnings, and misleading health claims) and measures to reduce supply (ban on sale to youth, curbs on smuggling, and programmes to aid tobacco farmers and workers to switch over to alternative livelihoods).

A tobacco control legislation titled "The Cigarettes and Other

Tobacco Products (Prohibition of Advertisement and Regulation of Trade and Commerce, Production, Supply and Distribution) Act 2003" became an Act of Parliament on 18th May 2003. This comprehensive piece of legislation, intended to protect and improve public health, encompasses a wide array of evidence-based strategies to reduce tobacco consumption. This includes provisions for prohibition on direct and indirect advertisements on tobacco products, prohibition on smoking in public places, prohibition on sale of tobacco products to persons less than 18 years age or within 100 yards of an educational institution, and display of statutory health warnings in a conspicuous and legible manner on tobacco products. Each of these provisions is accompanied with corresponding penalties that can be imposed.

Box - 1 : Key Messages - Community Education for Cancer Control
Stop Tobacco in any form today itself; do not start if you are non-user
Stop alcohol; if you cannot stop, drink in moderation
Eat at least half a Kg of fresh, seasonal fruits and vegetables every day
Eat plenty of whole grains, pulses, beans & legumes in diet
Keep salt consumption to < 5 grams a day; avoid food items which are salt-preserved, smoked or cooked in re-heated oils
Exercise briskly : at least 2 miles (3.2 Kms) of brisk walk in 30 minutes every day
Avoid Ghee, butter, deep fried, thick-gravied, creamed and sugary foods
Avoid "Red Meat" (lamb, beef, pork)
Maintain your body weight with proper combination of diet and exercise (BMI at < 25; waist at < 90 for males & < 80 for females)
Avoid sexual promiscuity
Maintain hygiene of genital organs
Take vaccination against hepatitis - B
Do a self examination of oral cavity and breast (females) once a month
Report to the Doctor if you have any "Warning Signs"
Ensure proper protections in occupational settings

Alcohol : Hazards of alcohol use in relation to cancers have already been described earlier. Control of alcohol requires actions similar to those for tobacco control. The action should be targeted towards individuals and communities and include taxation, general public education, encouraging highly vulnerable groups like young people to avoid starting consumption, etc.

Sexual and Reproductive Factors : Sexual and Reproductive Factors are associated with cancer of the uterine cervix and breast, as explained in foregoing paragraphs. Human Papilloma Virus (HPV) has now been identified as the etiological agent responsible for cervical cancer. HPV prevalence increases

with high risk sexual behaviour and poor sexual hygiene. Education regarding sexual hygiene and safe sexual behaviour should be provided for prevention of cancer cervix. Safe sexual behaviour protects women from the risk of cancer by preventing infection with HPV. Breast cancer is not much amenable to primary prevention, to any large extent. Early detection of cancer is the main strategy for improving survival in breast cancer.

Diet, Physical Exercise and Avoidance of Obesity : Proper diet, regular moderate intensity physical exercise and avoidance of obesity are important for prevention of breast, upper aerodigestive tract and intestinal cancers, as has been described in detail earlier. Certain basic measure may help in reducing risk of cancer :

- Avoid being underweight or overweight.
- Engage in regular, brisk physical activity.
- Consumption of alcohol is not recommended.
- Limit consumption of salted, deep fried foods.
- Choose predominantly plant based diets rich in grains, legumes and fruits and vegetables.
- Restrict the intake of red-meat (beef, pork, lamb) and preserved meat.

Occupation : Occupational cancers constitute 5 - 10% of all cancers. Limiting exposure to potentially carcinogenic substances through personal protective gear, rotation of workers and mechanized handling of such chemicals may help reduce cancers from occupational exposures.

Environmental Pollution : Maintaining proper vehicle emission standards, promoting alternative sources of energy instead of biomass fuel, taking measures to reduce the emissions of CFCs and anti-tobacco measures in home / public places will be of help.

Radiation Protection : Personal protective devices and dosimeters by personnel engaged in radiological procedures, avoidance of exposing patients to unnecessary X-rays and adequate safeguards in nuclear facilities should be ensured.

Infection : The important infections in relation to cancer prevention, in Indian context, are HBV and HBC, HPV, and *H pylori*. Vaccination against HBV, use of universal precautions in health care settings, proper sterilization of syringes, needles and other medical equipment, blood safety, safe sexual practices, avoidance of sexual promiscuity, maintenance of genital hygiene, and treating the patients with symptomatic infections of *H pylori* are the mainstays in this regards.

Reduction of Exposure to Ultraviolet Radiation : Encouragement of sun-protective behaviour is the most effective public health measure to reduce incidence of skin cancer in populations, especially in children. Available options include sun avoidance by using shade, wearing protective clothing and using sunscreens. Efficacy is expressed through the “sunscreen protection factor” (SPF). Most commercial preparations are presented as having SPF values of up to 15-20. Sunscreen formulations typically contain UVA absorbers (examples being cinnamates and derivatives of para-aminobenzoic acid) and UVB absorbers (such as the benzophenones).

Chemoprevention : Chemoprevention is defined as reduction of the risk of cancer development through the use of

pharmaceuticals or micronutrients. The breast cancer drug tamoxifen reduces the risk of developing a second cancer in the other breast. A lower risk of colon cancer has been observed following regular use of aspirin and related non-steroidal anti-inflammatory drugs which reduce the risk of recurrence of adenomas. Trials to establish chemo-preventive activity by micronutrients, including carotenoids and retinoids, among people at high risk, have been inconclusive. At present, tamoxifen is the only cancer prophylactic drug being used in medical care, under close supervision of a specialist.

Secondary Prevention : Secondary prevention aims at diagnosing the condition at a very early, preferably asymptomatic stage and effectively treating it. In context of cancer prevention, it takes two forms : firstly by educating the community at large regarding “early danger signs” so that they could report to medical facility for further evaluation, should these signs appear. Secondly, secondary prevention uses certain well established screening procedures for early detection.

Early warning signs : Community should be educated regarding the following signs / symptoms and report to the medical facility should they occur. Certain symptoms and signs may be early indicators of some cancers. These include -

- Unexplained change in bowel or bladder habit.
- A white patch or ulcer in the mouth that does not heal.
- Obvious change in a mole or wart, like rapid increase in size, bleeding or ulceration.
- Bleeding from body’s orifices e.g. - haematuria, bleeding in stools, bleeding PV, haemoptysis, haemetemesis, epistaxis, etc.
- Persistent indigestion / difficulty in swallowing / difficulty in breathing.
- Persistent fever unresponsive to treatment.
- Unexplained loss of weight.
- Chronic cough or hoarseness of voice especially in a smoker.

Screening for Common & Important Cancers in Indian Context

Screening For Breast Cancer : Early diagnosis of breast cancer, by promoting breast awareness among all women and clinical breast examinations for women, preferably in the age group 40-69 years, should be encouraged. Women should be educated and encouraged to inspect and manually examine all quadrants of the breasts with the flat of hand, and the axillae, once a month, ten days after the menstrual period. Every woman should also be made aware of the following signs -

- A change in size
- A nipple that is pulled in or changed in position or shape
- A rash on or around the nipple.
- Discharge from one or both nipples
- Puckering or dimpling of skin
- Lump or thickening in the breast
- Constant pain in the breast or armpit

Breast Examination by a Health Professional : With the flat of the hand, both the breasts are palpated in a circular manner starting from the nipple and areolae in a clockwise manner towards the periphery and the axillary tail of the breast in sitting and lying down position. Then the axillae,

supraclavicular regions and liver are also examined.

Mammography : The epidemic increase in breast cancer incidence has led to the introduction of population-based mammography screening. The analysis of large randomized trials has shown that in women aged 50 to 69 years, mammography screening can reduce mortality from breast cancer by 25-30%. For women in the age group 40-49 years, the screening efficacy is significantly less.

Screening for Cervical Cancer : In most developed countries, cytological screening (Pap test) has led to significant reduction in the incidence of and mortality from cervical cancer in a number of developed countries. Screening should preferably begin at 35 years of age, as at younger ages dysplasia detected through screening rarely progresses to cancer, but adds to programme cost in treatment. Alternative strategies such as visual inspection are being tested for use in low-resource settings where laboratory facilities for cervical cytology are inadequate. There is increasing interest in the use of HPV DNA testing for screening. A very important aspect of cervical cancer screening which should be noted by all medical functionaries is to ensure proper response rates, especially from those who are 'disadvantaged', since they are the ones who are expected to have a higher prevalence. Secondly, it is also equally important to ensure final confirmatory tests and adequate treatment, if required, among those who test positive on screening tests.

Screening for Oral Cancer : Oral cancer and its precancerous lesions, including leukoplakia, can be readily detected by visual inspection of the oral cavity not only by trained health workers and doctors, but to a large extent by the subject himself.

Self Examination of oral cavity : This is important for detecting oral lesions at an early stage. All habitual tobacco users should do it once a month. The following procedure should be followed :

- Rinse the mouth with water and stand before a mirror in adequate light.
- Look in the mirror for any abnormal white or red patch, ulcer or roughened area, or granular area or swelling in the mouth.
- If any such area is seen, the suspicious area should be felt with the fingers (normal oral mucosal is soft and pink).
- Consult a doctor if any abnormal area is found

Examination by a Health Professional : Health care providers should utilize every opportunity to examine the oral cavities of tobacco users. All parts of the oral cavity should be examined; oral cavity includes lip, anterior 2/3 of tongue, floor of mouth, buccal mucosa, gingival mucosa, hard palate and retromolar area.

Population Screening : Population screening for oral cancer results in the diagnosis of large numbers of oral pre-cancers and early stage tumours. However, a reduction in incidence of and mortality from oral cancer resulting from such interventions remains to be demonstrated.

Screening for Other Cancers

Prostatic Cancer : Prostate-specific antigen (PSA) testing is now being widely used in developed countries, for the early detection of prostate cancer. Elevated levels of PSA are closely, but not definitely, associated with prostate cancer.

False positive results may lead to unnecessary treatment. PSA analysis should be combined with a digital rectal examination, the latter providing an assessment of the volume of the gland, since PSA is also released into the bloodstream of patients with benign prostate hyperplasia and other prostatic diseases. The typical cut-off values are : 40-49 years, <2.5 ng/ml; 50-59, <3.5 ng/ml, etc.

Colorectal Cancer : Faecal occult blood test (FOBT) is a very cost-effective and quite applicable screening method available, but its specificity and sensitivity are limited. Endoscopy provides the definitive method for detecting colorectal cancer and its precursor lesions, e.g., polyps. However, its application to population-based screening is limited by cost and availability of qualified specialists.

Tumour Markers : Certain cancers release biological products into the circulation, which can be measured for increasing the level of diagnostic suspicion. The common ones are :

Alpha feto protein (α - FP) : This is increased in Liver cancer and certain tumours of testis and ovary. It is also increased in cirrhosis and hepatitis.

Beta Human Chorionic Gonadotrophin (β - hCG) : Increased in choriocarcinoma and testicular tumours. Also increased in hypogonadism and hydatiform mole.

Carcino Embryonic Antigen (CEA) : Increased in colorectal, breast and stomach cancers and Cholangiocarcinoma. Also raised in liver disease and among smokers.

CA - 125 : Raised in epithelial ovarian cancers. Also raised during pregnancy, menstruation, endometriosis, ascites and pleural effusion.

Prostate Specific Antigen (PSA) : Raised in prostatic cancer as also in prostatitis and BHP.

Tertiary Prevention : Tertiary prevention is also quite important in cancers. It consists of proper treatment of disease, especially advanced disease. The available options are Surgery, Radiotherapy and Chemotherapy. It also involves specialized issues as palliative care, terminal care and pain relief and reassurance / advise to the patient and family.

Summary

Cancers are defined as "Group of heterogeneous disorders characterized by Clonality, Autonomy, Anaplasia and Metastasis". Cancers are, by and large, diseases of unhealthy lifestyle and are, therefore, potentially preventable. Worldwide, approximately 10 million new cases and more than 6 million deaths (12% of all deaths) occur due to cancers every year. In terms of incidence, the most common cancers world-wide are those of lung (12.3% of all cancers), breast (10.4%) and colorectum (9.4%). The top three causes of death from cancer are those of the lung (17.8% of all cancer deaths), stomach (10.4%) and liver (8.8%). Developing countries contribute to more than half of the total cancer cases worldwide. Cancer incidence in India is estimated to be around 70 - 90 per 100,000 populations with 700,000 - 900,000 new cases of cancer every year. The commonest cancers in men are those of Lungs, Stomach, Oral cavity and oesophagus, while in women, those of Cervix Uteri, Breast, oral cavity, Ovary, Oesophagus and Stomach are the commonest. Large majority of these are tobacco related and

hence potentially preventable.

The major risk factors for Cancers are Tobacco use, Alcohol, Occupational hazards, Environmental pollution, Food contaminants, Diet, Obesity & Physical inactivity, radiation, Chronic Infections, Genetic Susceptibility, Reproductive Hormones and many others. Tobacco smoking is the main known cause of human cancer-related deaths, worldwide. Tobacco causes cancers of the Lung (10-20 fold risk), larynx (10-fold), oral cavity (2-fold), oesophagus (5-fold), pancreas, kidney and bladder. Passive smoking is also a definite risk for lung cancer and possibly laryngeal cancer. Causal association of drinking alcohol has been definitely established in respect of oral, oesophageal, liver and breast cancer and is probable for colon and rectal cancer. Occupational exposures like Aromatic amines have been shown to increase the risk of Bladder cancer; benzene that of Leukemias and that of myelogenous leukaemia in particular, Asbestos and other fibres have been associated with Lung cancer and mesothelioma. Cancer of the lung can be caused by exposure to inorganic arsenic in mining and copper smelting and among workers in chromium plants and chromium alloy workers. Nickel refining also carries carcinogenic risk. Coal tar, coal gas production and iron founding are associated with cancers of the skin and of other sites, including the urinary and respiratory systems. Environmental pollution accounts of 1-4% of the total burden of cancer in developed countries. The carcinogenic pollutants include asbestos; Engine consumption products like benzene, toluene, xylenes and acetylene; oxides of nitrogen (NOx) and fine particulates; chlorination by-products and other contaminants of drinking water like Arsenic. Food Contaminants like Aflatoxins cause hepatocellular carcinoma, *F. verticillioides* or its toxins in maize cause oesophageal cancer, Ochratoxin A lead to urinary tract tumors. Bioconcentration of DDT and other pesticides into the food chain; the Polycyclic aromatic hydrocarbons generated in meat when it is fried; Nitrosamines formed by smoking and direct fire drying are all carcinogenic. Exposure to ionizing radiations can cause leukaemia, breast cancer and thyroid cancer. Chronic Infections like Hepatitis B and C, liver flukes, Human papilloma viruses, Epstein-Barr virus, *Helicobacter pylori* and *Schistosoma haematobium*. The western diet and lifestyle are generally associated with high incidence of cancers of the colorectum, breast, prostate and endometrium. A daily consumption of 500g of fruits and vegetables can decrease incidence of cancer of the digestive tract by as much as 25%. Salted, smoked, pickled and preserved foods (rich in salt, nitrite and preformed N-nitroso compounds) are associated with increased risk of gastric cancer. Overweight, Obesity and Reduced Physical Activity increases the risk of colon, breast, prostate, endometrial and other cancers. Cancer syndromes like retinoblastoma, neurofibromatosis etc., breast and ovarian cancers have Genetic Susceptibility. Menopausal status and Hormone replacement therapy are associated with increases in risk of breast and endometrial cancers. Use of combined Oral Contraceptives accounts for a slight increase in risk of breast cancer, but is protective against ovarian and endometrial cancers.

Prevention of Cancers should be a totalistic approach, targeting all levels of prevention, viz. primary, secondary as well as tertiary

levels. Primary prevention includes Education and motivation of the community to adopt healthy lifestyle, Comprehensive tobacco and alcohol control, including implementation of regulatory measures and encouraging personal commitment, requires coordinated involvement of government, professionals and planners. Education regarding sexual hygiene and safe sexual behaviour should be provided for prevention of cancer cervix. Proper diet, regular moderate intensity physical exercise and avoidance of obesity are important for prevention of breast, upper aerodigestive tract and intestinal cancers. Limiting exposure to potentially carcinogenic substances through personal protective gear, rotation of workers and mechanized handling of such chemicals may help reduce cancers from occupational exposures. Maintaining proper vehicle emission standards, promoting alternative sources of energy instead of biomass fuel, taking measures to reduce the emissions of CFCs and anti-tobacco measures in home / public places will be of help. Personal protective devices and dosimeters by personnel engaged in radiological procedures, avoidance of exposing patients to unnecessary X-rays and adequate safeguards in nuclear facilities should be ensured. Vaccination against HBV, use of universal precautions in health care settings, proper sterilization of syringes, needles and other medical equipment, blood safety, safe sexual practices, avoidance of sexual promiscuity, maintenance of genital hygiene, and treating the patients with symptomatic infections of *H. pylori* are important measures. As a part of Chemoprevention, Tamoxifen is the only cancer prophylactic drug being used in medical care, under close supervision of a specialist. Secondary Prevention is firstly by educating the community at large regarding "Early danger signs" and Secondly, by screening procedures for early detection. Screening for Breast Cancer is done by clinical breast examinations for women, preferably in the age group 40-69 years by self or by a health professional or alternatively by Mammography. Screening for Cervical Cancer is by cytological screening (Pap test) or Visual Inspection with Acetic Acid (VIA). Oral cancer and its precancerous lesions, including leukoplakia, can be readily detected by visual inspection of the oral cavity by trained health workers, doctors and by the subject himself. Prostate-specific antigen (PSA) testing is now being widely used in developed countries, for the early detection of Prostate cancer. Colorectal Cancer is screened by Faecal occult blood test (FOBT). Tumour markers like AFP, B - hCG, CEA, CA - 125, PSA are also useful in early detection of some cancers. The options for Tertiary Prevention are Surgery, Radiotherapy and Chemotherapy and it also involves specialized issues as palliative care, terminal care and pain relief and reassurance / advice to the patient and family.

Study Exercises

Long Question : Discuss the epidemiology of common cancers in India and the approach for prevention and control.

Short Notes : (1) Early warning signs of cancer (2) Risk factors in cervical cancer (3) Risk factors in oral cancer (4) Secondary prevention in cancers (5) Tobacco use and cancers (6) Alcohol and cancers

MCQs & Exercises

- Worldwide, the most common cause of death from cancer is that of : (a) Lung (b) Oral cavity (c) Gastric (d) Liver
- Following is not the characteristic of a cancer : (a) clonality (b) metastasis (c) anaplasia (d) all of the above are characteristics
- The most common cancer in Indian women is (a) Breast (b) Cervix (c) Endometrium (d) Oral cavity
- Match the following :

1. Aflatoxin	a. Oesophageal cancer
2. Ochratoxin A	b. Hepatocellular carcinoma
3. <i>F. verticillioides</i> or its toxins	c. Urinary tract cancer
4. Asbestos	d. Lung

- Use of combined Oral Contraceptives accounts for an increase in risk of (a) Breast cancer (b) Ovarian cancer (c) Endometrial cancer (d) None
- Exposure to Benzene causes the following cancer (a) Bladder (b) Lung (c) Prostate (d) Leukemia
- Smoking is NOT a known risk factor for which of the following cancer (a) pancreas (b) kidney (c) bladder (d) prostate
- At present Number of population based cancer registries (PBCRs) in India is : (a) 5 (b) 6 (c) 7 (d) 4
- At present Number of Hospital based cancer registries (HBCRs) in India is : (a) 5 (b) 6 (c) 7 (d) 4
- Match the following cancer with an infection :

1. Cervix uteri	a. <i>Schistosoma haematobium</i>
2. Lymphoid tissues	b. <i>Helicobacter pylori</i>
3. Stomach	c. Epstein-Barr virus
4. Urinary system	d. Human Papilloma virus

- Cancer not having Genetic Susceptibility is (a) Neurofibromatosis (b) Breast (c) Ovarian (d) All of the above have genetic susceptibility
- Visual inspection with Acetic Acid (VIA) is a method of screening for (a) Oral cavity (b) Cervix (c) Gastric (d) Prostate

Answers : (1) a ; (2) d ; (3) b ; (4) 1b,2c,3a,4d ; (5) a ; (6) d ; (7) d ; (8) b ; (9) a ; (10).1-d, 2-c, 3-b, 4-a ; (11) d; (12) b.

Part - 1

Mental Health

Mental health is an important component of the total positive health. Every physical ailment has a mental component and every mental illness has a physical component. The WHO expert committee defines mental health as 'the capacity in an individual to form harmonious relation with others and to participate in or contribute constructively to change in the social environment'. Another definition, forwarded by Ginsburg says "the ability to hold a job, have a family, keep out of trouble with law and enjoy the usual opportunities for pleasure". The comprehensive concept of mental health has thus a four - fold goal before it : to understand and cure the different types of mental disorders and defects; to detect the cases of incipient mental breakdown early; to prevent, or at least to minimize the occurrence of the disorders and defects; and improve the overall mental health of the community (1). A classification of psychiatric disorders is shown in Table - 1. Similarly, the Diagnostic and Statistical Manual for Mental disorders (DSM) has also proved to be of significant value in the diagnosis of mental disorders.

Magnitude of the problem

Worldwide : About 500 million people are believed to be suffering from neurotic, stress related and psychological (somatoform) problems. A further 400 million suffer from anxiety disorders, 340 millions from mood disorders, 60 million from mental retardation and 45 million from schizophrenia. It causes a heavy burden of suffering and economic loss (2). More recent socio - economic estimates by WHO & World Bank, regarding the burden of major psychiatric disorders is presented in Table - 2. Of the entire neuro - psychiatric disease burden, approximately 30 to 40% is comprised of Depression, 6 to 8% is schizophrenia, while Bipolar disorders and panic Disorders comprise 5 to 6% and 2.5 to 3% of all neuropsychiatric disorders, respectively (3).

India : Data forwarded by Reddy and Chandrashekhar (4) on mental morbidity in various parts of the country suggest

Table - 1: Classification of Psychiatric Disorders (ICD-10)

<i>Organic (F10)</i> : Acute e.g. delirium and Chronic e.g. dementia
<i>Psychoactive Substance Use (F1)</i>
<i>Schizophrenia and delusional disorders (F2)</i>
<i>Affective (mood) disorders (F3)</i>
- Depression
- Mania
- Recurrent affective disorders
<i>Neurotic, stress related and somatoform disorders (F4)</i> :
- Anxiety disorders incl Generalised anxiety , Phobic anxiety, and Panic disorder
- Obsessive compulsive disorder
- Reaction to severe stress
- Acute stress disorder incl Post - traumatic stress disorder & adjustment disorder
- Dissociative disorder
- Somatoform disorder
- Neurasthenia
<i>Behavioural disturbances (F5)</i> : Eating disorders, Sleeping disorders, Sexual dysfunction and Puerperal mental disorders
<i>Personality & Behaviour disorders (F6)</i> e.g. thumb sucking, bed wetting, juvenile delinquencies.
<i>Mental Retardation (F7)</i> : Mild, Moderate, Severe & profound retardation.
<i>Disorders of Psychological Development (F8)</i> of speech, language & motor function
<i>Behavioural and emotional disorders with onset during childhood or adolescence (F9)</i>

prevalence rate of 58.2 per 1000. The major psychiatric conditions contributing to this morbidity are Neuroses (20.7 per 1000), Affective Disorders (including Mania, Manic Depression and Depression) 12.3 per 1000, Mental retardation and alcohol & drug addiction (6.9 per 1000 each) and Schizophrenia (2.7 per 1000). It is likely that there may be a load of almost 9 million persons in India suffering from severe incapacitating mental disorders and almost 90 million mildly mentally ill

Table - 2 : Burden of Selected Major Psychiatric Disorders, By World bank Region, per year

Disorder	Worldwide			South Asian region		
	<i>Discounted DALYs (in thousand)</i>	<i>DALYs per million population</i>	<i>% of total disease burden</i>	<i>Discounted DALYs (in thousand)</i>	<i>DALYs per million population</i>	<i>% of total disease burden</i>
Schizophrenia	11643	1894	0.76	2896	2087	0.71
Bipolar disorder	9733	1583	0.63	2237	1612	0.55
Depression	51833	8431	3.37	14054	10507	3.57
Panic Disorder	4550	740	0.30	1081	757	0.26

persons in India (5).

Epidemiology of Major Psychiatric Disorders

Schizophrenia and Non - affective Psychosis : Schizophrenia is a chronic disorder punctuated by episodes of florid psychotic symptoms, especially hallucinations, delusions, negative symptoms and cognitive symptoms. There is a marked gender effect in the age - specific incidence rates of this disorder, in that the cumulative risk of developing schizophrenia is similar in males and females upto the age of 55 years; the risk after that age is almost zero for both the sexes. However, the mean age of onset is higher in females. Socio - cultural environment has an important role in that while incidence rates are similar across various cultures and countries, the course and outcome seems to be more favourable in subjects from developing as compared to developed countries (6). Many schizophrenics also give history of adverse events during foetal life (as obstetric complications in the mother) or during neonatal life.

There are two main categories of epidemiological determinants - heredity and organic brain damage. The risk is high if one parent is a schizophrenic and is greatly increased if both parents are; identical co - twin of a schizophrenic has 50% risk of being affected. Even if a person is blood related to a schizophrenic, the risk rises. In fact heredity seems to have a stronger risk as compared to the type of upbringing that a child receives. Many schizophrenics also show organic brain damage, as enlargement of lateral ventricles. Schizophrenia can also occur in conjunction with a variety of cerebral and physical diseases, of which epilepsy is the commonest.

Bipolar Disorders : These include subjects with history of both depressive and manic episodes (bipolar disorder) and those with only depressive or only manic episodes (unipolar disorder). There is intense emotional drive during an episode, with a tendency to return to pre - morbid functioning as well as a tendency to recur, with multiple episodes during the patient's lifetime. The manic form occurs mainly among the younger age group, while the depressive form is commoner among older age group. Among hospitalized patients, women and those from higher socio - economic status form a higher proportion. Similarly, Bipolar patients are more likely to be married than schizophrenic patients.

Major Depressive Disorders : The core symptom is a disturbance of mood. Sadness is most typical but anger, irritability and loss of interest in usual pursuits and decreased energy or "drive" also occurs. Often the affected person is unable to experience pleasure and may feel hopeless. In most of the developing countries, patients may not complain of these symptoms but rather of physical symptoms as fatigue or aches and are often likely to be misdiagnosed at primary care facilities. Illness usually starts in twenties or thirties although new onsets can be observed across the entire lifespan. In community surveys, there is consistent finding of delayed reporting for treatment and to be associated with substantial impairments in both productive as well as social roles. Drugs in the form of tricyclic antidepressants or the newer selective serotonin inhibitors (SSIs), along with psychosocial therapy are effective in taking care of acute episodes as well as increasing the remission period.

Anxiety Disorders : These include panic disorders and the generalized anxiety disorders, which also includes the Post Traumatic Stress Disorder (PTSD) and Obsessive - Compulsive Disorder). The central feature is the inability to appropriately regulate fear or worry and occasional panic attack, which is a discrete period of intense fear accompanied by typical symptoms as tachycardia, sweating, etc. There are triggering phobia - precursors as travel, crowded places, elevators, etc. and subjects may try to avoid these triggers. These disorders have been consistently found to be associated with decline in productive as well as social roles. Interventions with Benzodiazepines and psycho - social therapy are effective.

Issues of Public Health, Prevention & Control

Patterns of mental health care for Populations : The realization that organizing population based mental health is an achievable goal and that mental health problems can be amenable to primary and secondary prevention (and not only treated when the disease has become apparent and advanced), is a recent one. Many countries, developed as well as developing, are making endeavors to build in mental health care programmes as a part of their public health system, including at the primary level health care level. The general patterns of mental health care services in any country are :

- State supported mental hospitals - This is the oldest pattern. Large hospitals in India include those at Agra, Bareilly and Ranchi and NIMHANS at Bangalore.
- Private Psychiatric Hospitals
- Psychiatric services as a part of general hospitals, as District hospitals.
- Private Practice based psychiatric consultation / treatment
- Mental health services at the primary care level, through trained paramedical workers.
- Preventive & Promotive Mental Health care services as a part of Vertical mental health programs at the national / state level.

Organising Mental Health Care as Part of Public Health Services

Major Issues to be considered : In recent times, there has been a shift from focusing on mental health of individuals, usually in the form of organizing psychiatric treatment for sick individuals, to holistic mental health care, preventive, promotive as well as early curative, and that too, not for individuals but for the entire community. Three important issues which need to be addressed while organizing community mental health services are

- Firstly, to have a clear idea of the prevalence and types of mental health problems by deciding clear cut diagnostic criteria (as DSM - IV) and utilizing the available data from hospitals or by undertaking surveys.
- Clearly deciding as to what will be the appropriate indicator criteria of measuring success being achieved in the mental health program, e.g., number of psychiatric cases who voluntarily reported for treatment or the yearly incidence of suicide cases.
- Setting up of realistic targets as regards these selected indicators.

Needs Assessment : Having decided on the diagnostic criteria and indicators, the needs of the community as regards mental health care should be undertaken. This will involve obtaining data on the major / common psychiatric conditions prevalent in the community, their distribution according to major person, place and time related variables, and identification of risk groups who are in greater need of mental health services. This should also involve making an assessment of the load of mental health problems as per five levels of care, viz. :

Level - 5 : patients who are likely to be requiring admission to psychiatry beds at district hospital or specialized centres.

Level - 4 : patients attending psychiatric services outside the hospitals, as OPD or day care subjects.

Level - 3 : Patients presenting with conspicuous psychiatric morbidity at the Primary health care / CHC level.

Level - 2 : patients who report with “hidden” psychiatric morbidity at the primary care / CHC level. They may be having presentations which may be mixed up with other diseases and need good clinical acumen on the part of the medical person to diagnose them.

Level - 1 : Persons with psychiatric morbidity but who are hidden in the community i.e., have never reported to the health system. Unearthing this load of morbidity will need surveys in the community.

Developing Political Will and Social Climate : Mental illness is often associated with stigma and also tends to get a lower priority from political and bureaucratic echelons. It is therefore imperative that before launching any mental health programme, adequate political will is generated through advocacy.

Reaching out with psychiatric help at grass roots level : One of the major problems with mental illness is that patients do not present voluntarily to the psychiatric services at an early stage. If care could be provided at an earlier stage than at the point of hospital presentation, better care could be given and unnecessary suffering avoided. Similarly, as far as possible, day care / OPD services / follow up domiciliary care would be a better and more cost effective option than hospitalization for most cases.

Developing a graded (tier) system of mental health services : This approach is likely to be of considerable help in establishing community mental health services.

- At the first level, paramedical workers who are in close touch with the community at the village and Health Sub - centre level are adequately trained in recognizing and providing first aid to psychiatric emergencies as well as following up the diagnosed cases in their home environment for ensuring continuity of treatment, for providing basic advice to the patient and family, as well as educating the community members on basic preventive procedures.
- At the second level, the generalist medical officers at the primary health care centre level are adequately trained and equipped to diagnose and treat the common psychiatric illnesses and refer the complicated cases to the next level.
- At the third level, that of the district hospital, a trained psychiatrist deals with the referred cases, as well as provides guidance and training to the persons functioning at the first and second levels. This level also provides

necessary inputs to the district health administration for planning the mental health care services in the district.

- The fourth level is that of super - specialised centres as medical colleges and mental health institutes, to take care to complicated / referred cases as well as to organise epidemiological research and surveys for planning and evaluating the services.

Prevention

Prevention in mental health scenario is more difficult than other branches of medicine because of relatively vague and multifactorial etiologies, stigmata and misconceptions and the general feeling that available (scarce) resources should be directed towards those already affected by these disorders rather than to preventive strategies.

It is usual to consider the principles of prevention according to the traditional approach of primary, secondary and tertiary levels.

Primary prevention : The available strategies are :

- Creating optimum socio - economic environment at the community level, in the form of improved education, improved employment opportunities, optimum nutrition and control of population growth. It needs no emphasis that improved standards of living in a community would reduce the rifts and stresses which often precipitate psychiatric illness.
- Socio - Legal actions in respect of dangerous substances as alcohol and habit - forming drugs / substances.
- Community education regarding common psychiatric illnesses, removing the stigma associated with these diseases and the fact that with the modern armamentarium of drugs, most of the mental illnesses can be stabilized / remission obtained.
- Specific protections as Iodisation of salt to prevent mental handicap associated with cretinism and provision of appropriate diet to children with phenylketonuria; Rubella vaccine before conception to mothers and proper ante - natal care for various vertically transmitted infections; folic acid supplementation for preventing neural tube defects.
- Application of the Science of genetics at the Community level : With advances in clinical genetics, we now know that upto one - third or even more, of the causes of severe mental handicap (Down's syndrome, phenylketonuria, fragile - X syndrome and Tay - sach's disease) are caused by identifiable chromosomal abnormalities and are potentially preventable. As time progresses, these conditions may provide scope for population based screening and identification of carriers in future.
- Community education for adopting measures to reduce personal stress, by stress management techniques (as per details given in the next section of this chapter).

Secondary Prevention : As of today, there are more opportunities for secondary prevention as compared to primary prevention, by way of early detection and intervention among those at risk. This would take the following approaches

- High index of suspicion and good diagnostic acumen by the medical and paramedical personnel, especially

those at the primary or grass root levels to identify the earliest symptoms / expressions of stress and mental illness and early intervention with drug / psycho - therapy, as required. These early symptoms include irritability, changes in behavioural pattern which was otherwise being followed for a long time, mood fluctuations, forgetfulness, suicidal thoughts or tendencies, feeling of exhaustion or worthlessness, and symptoms as changes in appetite, aches and pains which are not explained by available physical findings.

- Certain exposed to high pressure jobs groups as industrial workers and defence personnel.
- Inmates of delinquent homes and prisons.
- Certain clinical groups as immediately post - natal women.
- School children showing learning difficulties.

Tertiary Prevention : Tertiary prevention aims at the prevention of disability and relapse in those who already have a psychiatric disorder. This needs a complete psychiatric rehabilitation team including psychiatrists, clinical psychologists, medico - social workers and counselors, who would need to work in the community with the patients (and families) of patients who have been discharged from psychiatric care, back into their home environment. Firstly, it needs ensuring that patients take their drugs and other treatment as advised without any loss of compliance. This would also include educating the patient and the family about the side effects of the treatment, which is often prolonged in case of psychiatric illnesses. Thirdly, is the requirement of psycho - emotive and vocational / financial support to the patients and this would need advocacy on part of the health care services to create appropriate social conditions to achieve this.

Part - 2

Prevention and Management of Mental Stress

RajVir Bhalwar & VSSR Ryali

In contemporary times, any Doctor engaged in health care of the community should be very well aware about various aspects of stress, so as to educate the clientele and be able to prescribe a road map for its management.

The Stress Response

The term "Stress" is used as an umbrella term to cover all aspects associated with the phenomena. However, what really concerns us is the "Stress Response". This is the sum total of body reaction, both physiological and psychological, in response to a "stressor" i.e., an event occurring outside the body in the external environment. The stress response leads to various "Stress Symptoms" or "Stress diseases".

Biology of the stress response : Nature has built the stress response into our biology and that of all animals for a protective and desirable reason, viz, to gear up the entire body to deal with acute physical emergencies. This quick response is mediated through the autonomic system (ANS), and the endocrine responses mediated through the hypothalamus, pituitary and adrenal glands, consisting of a massive cascade

of instantaneous physiological changes, mainly through hormones like noradrenaline and cortisol. Within milliseconds of their release, they would cause the heart to beat faster and more strongly and the blood pressure to rise (so that more and more blood laden with oxygen and glucose could go to the muscles, to either fight it out or run away). The breathing would become deep and extra glucose would be pumped out into the blood by the liver so that more of sugar and oxygen could be taken by the blood to the active muscles. Kidneys start saving water so that blood volume can increase, digestion reduces and blood from digestive organs is diverted to the active muscles. In addition, the blood clotting mechanism would increase so as to quickly seal off the wounds and minimize blood loss due to bleeding from injuries. All these massive physiological changes occur within the fraction of a second. Their purpose is to prepare us to take instant action against an acute physical stressor, by either fighting it or taking a flight.

However, certainly we don't have to have our body and mind in such a state of alarm, and that too for prolonged periods of hours (may be, weeks or months), to negotiate modern day "stressors" or challenges like having a difficult boss, staying separate from the family, preparing for an important competition, difficulties in career, or lesser difficulties like having a flat tyre while driving on the highway. Unfortunately, even for these small hassles, the body's stress response remains massive or perpetual. The increase in blood pressure and heart rate, increase in blood sugar, increase in blood clotting mechanisms, taut muscles, lowering of the immune defence of the body, reduction in the digestive process continue for long periods and lead to major diseases like hypertension, diabetes, peptic ulcer, infections due to reduced immune defence, muscular and joint pains, just to name a few. It is therefore essential for us to learn ways and means to calm down our reactions to the stressor, and to develop adequate "coping mechanisms" to tackle the stressors of day - to - day living.

The sequence of stress response : The process of stress starts when a "demand" is placed on us. Demands are those requirements placed on us, which are potential stressors. A demand can be something as minor as a wrong telephone call in the night, or as major as reporting of embezzlement of funds in your office. At this point, we are not calling a "demand" as a "stressor", because not every demand may end up becoming a stressor.

Once a demand is placed on us, it does not straightaway lead to stress. There are certain intermediary mechanisms that occur, before we experience stress. The awareness of "demand" is followed by our "appraisal" of the problem. This step is more important, since, as described earlier, the impact of a demand (stressor) is a function of, not only the event, but also the appraisal that we make of our own coping abilities to deal with it. The sequence of appraisal is as follows.

- Firstly, the "primary appraisal", which involves evaluation of the significance of the event. In fact, we ask ourselves "Am I in trouble?"
- After the primary appraisal, comes the secondary appraisal. This involves the question "Can I handle it?"
- Following the primary and secondary appraisal, if we feel that, firstly, we are in trouble, and secondly, we

also feel that the demand (potential stressor situation) would outweigh our available coping resources, we are likely to experience the stress response, with many of its consequent “stress symptoms”. On the other hand, if we appraise the demand as not being difficult, or else we see our “resources” as adequate to cope up with the demand, we experience a “challenge” and also the opportunity to increase our capability of ‘coping”.

The Adverse Effects of Stress

Stress affects our health in a wide variety of ways. The adverse effects are summarized below.

Psycho - somatic : These include IHD, Hypertension, Diabetes Mellitus, Peptic Ulcers, predisposition to certain cancers, lowered immune functioning, arthralgias and myalgias, tension - headaches, etc.

Emotional : These include suppressed hostility, anger, irritability, “burnout”, fatigue, sleep disorders, anxiety, depression, and, suicide / attempted suicide. Inter - personal problems affecting social relationships also occur.

Performance problems : These include difficulties in memory and concentration and impaired ability to take decisions. Physical performance also gets reduced, as evidenced by exhausted feeling and lowered stamina.

Habit problems : Quite often (and very wrongly so), persons under chronic stress get into a tendency to treat it by starting up with self medication with antidepressants or anxiolytics and may even take on to tobacco, alcohol and narcotic drugs as means of relieving stress. Consequently, further health problems result.

Preventing / Pre-empting Stress & Developing “Coping Resources”

This is quite pertinent as the better part of valour is to avoid unnecessary battles. This holds good for potential stressors too. Interestingly, most of these steps are not medical measures but general managerial techniques which are given below.

Learning and practicing decision making techniques : Learning and actually using proper decision making skills when faced with critical situations can prevent much of stress later on. Wise decision making incorporates the sequential steps of firstly, defining the problem at hand, secondly, identifying the various alternative options at hand to tackle the problem, thirdly, deciding on the best option and finally, committing oneself to the selected course of action.

Develop personal financial management skills : Some of the major stressful situations in our lives result from financial crisis. These are often the result of poor financial management. One should write down, on a paper, ones income and expenditure. Having taken a written stock of the credits and potential expenses, one can sensibly match the resources. Secondly, one must avoid excessive desire that could fall in the category of “greed” (rather than essential or desirable for decent life), since, in our drive to fulfill such desire, we add further stress to our lives.

Make Conscious and Deliberate Efforts to Maintain Good Health : Even when one suffers from a disease as minor as common cold, one feels demoralized. Apparently, if one had

to suffer from major diseases like Heart disease, the amount of stress that the person would be subjected to would be tremendous. One should therefore make conscious effort to maintain good health and prevent such diseases. In short, incorporating simple measures for a healthy lifestyle, like regular brisk exercise, giving up tobacco, avoidance of alcohol and eating a healthy diet would go a long way in prevention of some of the most dreaded diseases. One should also deliberately and consciously look after the preventive health care of one’s family members; their good health prevents your stress.

Undertake regular and brisk physical exercise : By now, it has been clearly demonstrated by medical researchers that regular and brisk exercise is a major “stress - buster”. In addition, the resulting physical fitness tends to shape up the psyche and physiology in such a way that we tend to become resistant to developing stress. With regular exercise, the body and mind get used to cope up with this adverse physiological challenge and the resulting high surge of stress hormones.

Spend “Quality time” with your family : Whenever one gets the opportunity, one should make sure that one spends at least a few hours of “QUALITY TIME” with the family members. By quality time we mean that you should get involved with them - play with them, teach them and so on, rather than simply sitting with them and surfing around the TV channels.

Develop Social Support Systems : We, human beings, are social animals. At times of need, we should have social support. This is particularly true when we are faced with difficult and stressful situations. Therefore, it would be a very wise investment to put in some effort to develop some close friends towards whom we can look up for support during stressful situations.

Avoid Ego Struggles : Many stressful encounters with others are, in fact, unnecessary ego struggles. We often argue with our colleagues, superiors, spouse and even children about trivial issues that really don’t matter much. It is best to avoid the tendency to forcefully convince others when it is not so critical to your own health and well - being. Doing so will help you escape a great deal of unnecessary stress.

Adopt traditional cultures : As Indians we have the advantage of a rich and ancient culture. Patanjali advocated Yoga as a means of attaining physical and psychological health 5000 years ago. Our culture has elaborated on the virtues of need based living, sharing, acceptance of good with the bad, and renunciation, which if combined with advantages of modern living will improve the quality of life many fold.

Practice methods to get a good sleep : Good sleep is very important for de - stressing us, as well as in assisting the repair of the physical and the mental breakdown that occurs during the whole day. Accordingly, practicing methods for getting a good sleep is likely to be of much help in both preventing stress as well as negating it’s adverse effects. Some tips for getting good sleep are :

- Associate the bed with sleep only. Don’t eat, read or watch TV while in bed.
- Avoid caffeine containing drinks (Tea, Coffee) or tobacco before retiring.
- Don’t use alcohol to get sleep. It may make us drowsy

and may initiate sleep, but interferes with the rhythm of normal sleep and causes rebound arousal.

- If you have difficulty in falling asleep or tend to have disturbed sleep in the night, then stop sleeping in the afternoons. This is believed to be a useful adjunct in managing stress.
- Carbohydrates in diet tend promote sleep. So, have high carbohydrate items for dinner (chapatti, rice, vegetables, fruits, pudding, etc.).
- Undertake brisk exercise in the morning.
- Keep a regular sleep schedule - go to bed and get up roughly at the same time.
- If, on some odd occasion, despite all the above measures, you are still not able to get sleep, then do not try to “force” sleep by tossing and turning in the bed. Get up, sit down with a light reading and relax till the time you feel like dozing off.

Practice “assertiveness” skills : Assertiveness does not mean being aggressive. The former is a very good quality, while the latter damages the personality and the social support systems. Assertiveness is the honest expression of what you feel and want from others, without trying to force them to give it. Assertive behaviour needs to be developed gradually and carefully. It is particularly useful when dealing with “difficult” people and the consequent stress. So, Speak up for yourself, for your needs and rights, while letting others to speak for themselves; and, protest, maybe politely but definitely, against unfair treatment or unjustified criticism. Also develop the quality of saying “NO”, maybe politely, when you feel that a particular task or favor being asked of you is unjustified or beyond your capabilities.

Practice “Relaxation Techniques” : There are certain proven techniques, which, if practiced for just 15 to 20 minutes a day, will help control stress related tension. These include

Abdominal Breathing (Diaphragmatic breathing) : To undertake abdominal breathing, sit comfortably, with your back upright. Place your left hand on the chest and right hand on the abdomen. Now, breathe in slowly, through the abdomen, so that the abdomen expands, but the chest should not expand. You can come to know of this by noticing your hands - if you are breathing through your abdomen, your right hand will rise but the left hand will move only very little. Now, gently exhale as much air as you can by slowly contracting your abdomen but not your chest. Once again, your left hand should move very little, while the right hand goes down perceptibly. Practice abdominal breathing for 4 to 5 minutes at any fixed time of the day. In addition, try breathing that way when faced with (or immediately after) a stressful situation.

Progressive, Deep Muscular Relaxation : For practicing this technique, you can either lie comfortably on your back, or else, sit in a chair. Begin by taking a slow and deep breath. At the same time, lift your heel a few inches off the ground and extend your legs, pointing your toes towards the knees, thereby tensing your thigh muscles and stretching your calf. Hold in this position for a count of seven. Now inhale deeply. Contract the muscles of your right arm and raise the arm by a few inches. Hold in this raised position for a count of seven, then let it fall down, limp. Relax for a few seconds, then repeat

the same procedure with the left arm. Finally, gently roll your head from side to side and allow your neck to relax. Now inhale and tense up all the muscles of your face, including those of jaws, eyelids, cheeks, lips and forehead. Keep them squeezed for a count of seven, then let them go limp, let the jaw drop down and slowly exhale.

Spiritual Practice and Meditation : Engagement in spiritual practice in various forms has been shown to have a strong role in both, preventing the stress response in an exaggerated fashion, as well as for coping up with a deleterious stressful situation. The important methods of spiritual practice relevant to stress management are :

Praying : Praying, from the stress management point of view, is like “connecting” us to a higher form. It reinforces our confidence and strengthens us with the feeling that we are not alone and that there is some higher power on which we can bank upon. This hope and confidence leads to release of certain hormones / chemicals in our body which strengthen the physiological functioning of various organ systems. It would be worthwhile devoting at least a few minutes once or twice a day for praying.

Meditation : The soothing physiological and psychological benefit of meditation is well known. Meditation essentially means “concentrating or focusing attention on an object and shutting off the mind to all other external thoughts”. Sit down in a comfortable position - in a chair, relaxed, hands on the lap or on the ground, cross - legged. Concentrate on a predecided sound or image and remove any other thought that comes to the mind for the next few minutes that you are practicing meditation.

Yoga : There is enough evidence to indicate that Yoga is a powerful strategy for coping up with stress. An ancient Indian practice, Yoga is essentially a way of life. In general, try to practice Yoga daily or at least on 4 to 5 days in a week. It is not necessary to do complicated stretching exercises but even simple ones like a combination of sarpa - asana (Cobra posture), dhanur - asana (Bow pose), Head rotation, shoulder rotation and shava - asana (Corpse pose) are pretty good.

Emotion Focussed Coping

Our discussion so far has been directed at preventive measures and on development of coping resources. However, in anyone’s life, there are some inevitable difficult situations. Growing old, suffering from chronic diseases, losses in business, etc., are just a few examples of human predicaments that we must learn to live with. These are the situations where it would be wise for us to use the “Emotion Focused Coping” rather than the problem focused approach. The important components of emotion focused approach are listed below.

Accepting the inevitable : Once it appears that the problem is there to stay, it is best to accept the same. For those who have developed adequate coping resources, as faith in God, this becomes easier. One must draw lesson, in such times, from the prayer of St Assisi, which says “God, give me the courage to change what I can, the strength to accept what I can’t and the wisdom to distinguish between the two”.

Don’t discount the importance of hope : Hope is a powerful ally in dealing with stress. The hope that things will improve

goes a long way in reducing stress.

Suppress the distressing thoughts : If you have done what all can be done, then further mental processing of the problem can only make matters worse. In such situations it is better to suppress our thoughts to control the resultant emotional responses.

Discharging painful emotions : We often become unhappy or even sick, due to bottled up emotions. Disclosing our feelings to a near one, or to a Doctor, often provides much relief. Another method is to write a personal diary, often referred to as “therapeutic writing”. Maintaining a stiff upper lip may be a part of the self created “strong personality” for most of us, but it does not seem wise from what we know of the human emotions.

The Early Signs of Stress

Early recognition of stress is important. The first step is being alert to the signals of stress emanating from our body and mind. Quite often your near and dear ones notice them and it would be worthwhile to occasionally ask them if they have noticed such signs in you. The signs of stress are listed below.

- Headache, pain in neck, backache, aches in muscles and joints, fatigue and exhaustion, vague symptoms of indigestion, sleep problems (either difficulty falling asleep or getting up in between sleep)
- Feeling of being distressed / harassed, decreased interest in life and decline in cheerfulness.
- Deterioration of inter - personal relationships, whether at home, workplace or in social circles, increased “tiffs”, frequent bouts of irritability and social withdrawal.
- Deterioration of performance, difficulty in concentration, forgetfulness, increased errors, reduced efficiency and decreased motivation.
- Initiation or increase of substance abuse (alcohol, tobacco etc.).
- Excessive and frequent eating of food / snacks or avoidance of food and gain or loss of body weight in a short span of time.

Medical Officers should emphasize on the clientele that these warning signs are subtle and may be easily missed, unless one is very observant. For noticing them, one will have to search for these signs and deliberately listen to one’s mind and body. One may have to ask your near ones if they noticed these signs in him. If such signals are noticed, they should not be dismissed lightly. Serious action should be taken by bringing all the coping resources (as discussed earlier) into play. Secondly, the clientele should be assured to consider the Doctor as their best friend; to talk to him about their problem. One must realize that stress can occur to anybody. It is no disease to be shy about. It is just a reaction of one’s body to the adversity in the environment. So, even if there is a slight doubt, one should talk to the family members, friends and with the Doctor.

Summary

The WHO expert committee defines mental health as ‘the capacity in an individual to form harmonious relation with others and to participate in or contribute constructively to change in the social environment’. Worldwide, the major

psychiatric conditions are neurotic disorders, stress related and psychological (somatoform) problems followed by anxiety disorders, mood disorders, mental retardation and schizophrenia. In India, mental morbidity in various parts of the country suggest prevalence rate of 58.2 per 1000. The major psychiatric conditions contributing to this morbidity are Neuroses, Affective Disorders (including Mania, Manic Depression and Depression), Mental retardation and alcohol & drug addiction and Schizophrenia.

Epidemiological features of Major Psychiatric disorders include Schizophrenia, which is a chronic disorder with episodes of florid psychotic symptoms. Mean age of onset is higher in females; otherwise rates are equal in both males and females. Schizophrenia also shows definite evidence of organic brain damage. In Bipolar disorders history of both depressive and manic episodes is there; manic form occurs mainly among the younger age group, while the depressive form is commoner among older age group, women and those from higher socio-economic status form a higher proportion of bipolar disorder. In Depressive Disorders, core symptom is a disturbance of mood; illness usually starts in twenties or thirties. Drugs in the form of tricyclic antidepressants, selective serotonin inhibitors (SSIs), along with psychosocial therapy, are effective in acute episodes and in increasing the remission period. Anxiety disorders include Post Traumatic Stress Disorder (PTSD) and Obsessive - Compulsive Disorder; triggers are travel, crowded places, elevators, etc. Interventions with Benzodiazepines and psycho-social therapy are effective for treating the condition.

Issues of Public Health, Prevention & Control include organizing Mental Health care as part of Public Health services i.e. a shift to holistic mental health care, preventive, promotive as well as early curative, and that too, not for individuals but for the entire community. Prevention consists of Primary prevention that includes optimum socio-economic environment, Socio-legal actions, Community education, and Specific protections such as Iodisation of salt, Rubella vaccine, administering folic acid and application of the science of genetics at the community level. Secondary Prevention would comprise of identifying the earliest symptoms / expressions of stress and mental illness and early intervention with drug / psycho-therapy in risk groups like high pressure jobs, inmates of delinquent homes and prisons, post natal women and School children showing learning difficulties. Ensuring that patients take their drugs and other treatment, educating the patient and the family about the side effects of the treatment, and requirement of psycho-emotive and vocational / financial support to the patients would form part of Tertiary Prevention.

Study Exercises

Long Question : Discuss the epidemiology of major mental health problems in India, and the possible approach towards their prevention and control.

Short Notes : (1) Community based mental health programme (2) Graded (tier) system of mental health services (3) Stress management techniques

MCQs & Exercises

1. Out of all cases of Depression, what percentage is formed by neuro - psychiatric illnesses ? (a) 20 - 30% (b) 30 - 40%

- (c) 40 - 50% (d) 10 - 20%
- The Prevalence rate of Mental Morbidity in India is : (a) 25.8 per 1000 (b) 58.2 per 1000 (c) 107.6 per 1000 (d) None of the above
 - All of the following are major symptoms of Schizophrenia except : (a) Obsessions (b) Hallucinations (c) Delusions (d) Cognitive symptoms
 - Mean onset of age for schizophrenia is higher in which sex: (a) Males (b) Females (c) Equal in both sexes
 - Neurotic, stress related and somatoform disorders includes which one of the following : (a) Depression (b) Obsessive compulsive disorder (c) Eating disorder (d) Mental Retardation
 - Which has a higher risk of developing schizophrenia - Hereditary or Upbringing?

Short Questions

- Is Organic damage seen in Schizophrenics?
- Commonest neurological disease that occur in conjunction with schizophrenia?
- Which form of bipolar disorder is more common in younger age group?
- What all interventions can be used in anxiety disorder?
- What are the levels of care for assessment of mental health problem in a community?
- Who forms the first level of graded (tier) system for providing mental health services?
- Ensuring that patients take their drugs and other treatment as advised without any loss of compliance is which level of prevention?

Answers : (1) b; (2) b; (3) a ; (4) b; (5) b; (6) Hereditary ; (7) Yes (Enlargement of lateral ventricles); (8) Epilepsy;

(9) Mania; (10) Benzodiazepines and psycho - social therapy; (11) The levels are : Level - 5 : patients who are likely to be requiring admission to psychiatry beds at district hospital or specialized centres; Level - 4 : patients attending psychiatric services outside the hospitals, as OPD or day care subjects; Level - 3 : Patients presenting with conspicuous psychiatric morbidity at the Primary health care / CHC level; Level - 2 : patients who report with "hidden" psychiatric morbidity at the primary care/ CHC level; Level - 1 : Persons with psychiatric morbidity but who are hidden in the community; (12) Paramedical Workers; (13) - Tertiary Prevention.

R K Khajuria

Injuries have traditionally been defined as damage to a person caused by an acute transfer of energy (Mechanical, Thermal, Electrical, Chemical or Radiation) or by the sudden absence of heat or Oxygen. Unintentional injuries consist of that subset of injuries for which there is no evidence of predetermined intent. The cause-specific intentional injuries for which the World Health Organization routinely analyses & publishes data include road traffic injuries, domestic injuries that include poisonings, falls, burns and drowning (1). Besides these, another major group of injuries, the occupational injuries are not discussed in this chapter. Serious injuries affect more than the individual : They can destroy families and devastate communities as seen in recent earthquakes, hurricanes, and

tsunamis. These events can leave individuals and societies with enormous medical costs, extensive rehabilitation needs, major lifestyle adjustments, and depression losses that cannot easily, if ever, be recouped (2). The WHO Glossary of Health Care Terminology defines accident as - 'An unexpected, unplanned occurrence, which may involve injury'.

Burden of Unintentional Injuries

Worldwide, unintentional injuries accounted for more than 3.5 million deaths in 2001, or about 6 percent of all deaths and 66 percent of all injury deaths. More than 90 percent unintentional injury deaths occurred in low-and middle-income countries, accounting for around 7 percent of all deaths in these countries. More than 90 percent of DALYs that were attributed to unintentional injuries occurred in these countries, accounting for about 8 percent of all DALY in these countries (1).

Worldwide, the number of people killed in road traffic crashes each year is estimated at almost 1.2 million or an average of

3242 people every day, while the number injured could be as high as 50 million - the combined population of five of the world's largest cities (3,4). The road traffic death toll represents only the "tip of the iceberg" of the total waste of human and societal resources from road injuries. In 2004 road traffic crashes, which ranked as the 11th leading cause of death and accounted for 2.1% of all deaths globally but on current trends, by 2020, they are likely to become the third leading cause of disability-adjusted life years lost (5).

India has the second largest highway and road networks with an estimated total road length of 24,56,647 Km. As per the Institute of Road Traffic Education, New Delhi, the total number of registered motor vehicles in 2004 were 67million, while the total number of road traffic accidents that year were estimated to be 4.30 million with 0.92 million fatalities and 4.64 million injured. Over 1,275,000 persons are grievously injured each year and by 2050 there will be an estimated 267 million vehicles on Indian roads, accounting for more than 10% of worldwide road traffic accidents. In economic terms, the cost of road crash injuries is estimated at roughly 1% of Gross National Product (GNP) in low-income countries, 1.5% in middle-income countries and 2% in high-income countries. The direct economic costs of global road crashes have been estimated at US \$ 518 billion, with the costs in low-income countries; estimated at US \$ 65 billion. Road crashes not only place a heavy burden on national and regional economies but also on the number of years lost from premature death with the loss of health from disability (5).

A Causal Model for Injuries

Unintentional injuries and accidents are caused by multiple factors. The traditional epidemiological paradigm of Agent, Host, and Environmental factors that in combination contributes to the incidence of disease best helps to determine & understand the causes of accidents and injuries. This paradigm considers each factor in relation to the time of injury - that is, factors operating before, during, and after the injury or accident (1). While in the traditional epidemiologic causal model for infectious diseases, microbes are the 'agent' of infection and disease; in case of traumatic injury, the '*agent*' of the injury is energy, which could be in many forms including mechanical, electrical, chemical, and thermal. An example of an agent-host interaction in the injury model is a motor vehicle crash in which the energy exerted on the individual is mechanical (2).

The transfer of energy to a host (accident victim) is the necessary and sufficient cause of injury, but this transfer is affected by many other factors. Energy can be transferred to a host through vehicles or 'vectors'. Vectors in this context are animate, such as another human being or an animal. For many injury causes, both vehicles and vectors are involved in energy transfer. For example, when an automobile crash occurs, the vehicles are the automobiles and the vectors are the drivers (2).

The '*environment*' refers to places where energy can be transmitted to a host, and is influenced by many physical, social, economic, demographic, and cultural factors. Modifying the environment can reduce the potential for energy transfer. Characteristics of vehicles and vectors can be modified to reduce the likelihood of causing an injury or to reduce the

amount of energy transmitted. Only energy transmitted beyond the host's tolerance causes an injury, and therefore, not all exposures to energy result in noticeable injury. Humans have natural resistance to energy transfer, which depends on many factors. Intrinsic factors such as age and pre-existing medical conditions can reduce resilience to energy transfer, as can extrinsic factors such as fatigue and alcohol use. Resilience can be increased through the use of protective devices or education to avoid potential injury causing situations; thus the causal model depicts the many potential avenues for intervention (2). The Haddon matrix, which has been discussed later' was initially developed to address the problem of RTIs only but it is also applicable for understanding multitudes of factors that may play role in any causal injury pathway (1).

Causes of Injuries

As described above in the causal model for Injuries, unintentional injuries and accidents may be caused by multiple factors and the etiological factors causing accidents may be summarized under the following headings :

- Human Factors
- Environmental Factors
- Vehicular Factors

Human Factors : Some of the important human factors which may influence road traffic injuries include, age, sex, medical conditions, fatigue, inadequate personal protection and psychological factors. Over 50% of the global mortality due to road traffic injury occurs among young adults aged between 15 and 44 years. In 2002, males accounted for 73% of all road traffic deaths, with an overall rate almost three times that of females. Fatigue, chronic sleepiness of the drivers, long work hours, and exhaustion all contributes to increase the risk (1). Failure to use helmets, use of non-standard helmets or improperly secured helmets is a factor seen in number of Asian countries, including India. This is also a risk factor for increased injury severity among bicyclists, but still there are no stringent laws in most developing countries towards this. Failure to use seat belts is too a significant risk factor associated with increased injury severity among vehicle occupants, still many low-middle income countries do not have such legal requirements (8).

The following psychosocial factors may also play an important role :

- Risk Taking behaviour
- Lack of Experience
- Impulsiveness
- Defective Judgment
- Delay in Decisions
- Aggression
- Poor Perception
- Alcohol intake

Environmental Factors : The environmental factors may be vehicle related factors, road related factors, and bad weather. The hallmark of transportation systems seen in many developed countries which are technical aspects of planning, highway design, traffic engineering & traffic management required for a level of heterogeneity in traffic are absent in most of the low middle income countries (1). Road and vehicle-related factors like traffic passing through residential areas, conflict between

pedestrians and vehicle, schools located on busy roads, lack of median barriers are also important risk factors for causing road traffic accidents and injuries. Roadside hazards like trees, poles, and road signs may contribute to between 18 to 42 percent of road crashes and increase the injury severity (1). Some of the road related risk factors are as under :

- Inattention to safety in planning and designing
- Lack of remedial action at high-risk crash sites
- Safety defects in existing roads
- Poor lighting
- Transport, land use and road network planning

Vehicle Factors : The increasing volume of traffic is one of the main factors contributing increase in RTIs in low middle-income countries. In some of these countries, this growth has been led by an unprecedented increase in motorized two wheeled vehicles, one of the least safe forms of travel. The rapid growth in motor vehicles in many of these countries has not been accompanied by improvements in facilities for these road users or by facilities that respond to the continued predominance of non-motorized traffic. Important risk factors in relation to vehicles are as under :

Vehicle Speed : There is a strong relationship between the increase in vehicle speeds and increased risk of crash and injuries, both for motor vehicle occupants & for vulnerable road users, specially pedestrians, a relationship which is particularly true in low middle income countries, where speed is listed as the leading cause of road traffic crashes, accounting for upto 50 percent of all crashes. Increase in speed of 1 km per hour is associated with 3 percent higher risk of crash. In a crash with an impact speed of 80 km per hour, the likelihood of death is twenty times as compared to a speed of 32 km per hour (6).

Pedestrians : They have a 90 percent chance of surviving car crashes at vehicle speeds of 30 km per hour or below and less than 50 per cent at vehicle speed of more than 45 km per hour. The vehicle related factors may be summarized as under :

- Motorized two-wheeled vehicles
- Mixing of Motorized and Non-motorized traffic
- Over Speeding
- Pedestrians and cyclists
- Lack of in-vehicle crash protection
- Non-use of crash helmets by two-wheeled vehicle users
- Non-use of seat belts and child restraints in motor vehicles
- Roadside objects
- Poor maintenance of vehicles
- Increasing vehicle crowd on roads
- Overloaded vehicle
- Rapid motorization

Precipitating Factors : Following are some of the important precipitating factors for RTIs :

Alcohol Consumption : The role of alcohol consumption by the drivers has been confirmed unequivocally in increasing the risk of road accidents (1). It is an important factor influencing both - the risk of an accident and the severity of injuries due to it.

Data from some of the low-middle income countries has confirmed that drivers had consumed alcohol in 33 to 69 percent of crashes in which drivers were fatally injured and in

8 to 29 percent of crashes in which they sustained non-fatal injuries (7). Alcohol leads to poor judgment, slowed reaction time, loss of concentration and impaired vision.

Blood Alcohol Concentration (BAC) of 80 mg/dl doubles the risk of crash while BAC 100 mg/dl increases the risk of crash to three times. Recent analyses suggest that the risks associated with the blood alcohol levels of 80 mg/dl are higher than that was originally thought. This has led many countries to reduce legal blood alcohol content limits to 50mg/dl (5).

Hand-Held Mobile Telephones : Use of hand - held mobiles telephones, and inadequate visibility of vulnerable road users, all of which are equally likely increase the risk of road accidents in both the developed & developing countries (8). Hand-held mobile telephones increase the driver's reaction time by 0.5-1.5 seconds. Drivers who use mobile telephones while driving face a risk of a crash four times higher than those who do not use them (5).

Social Pressure : Social pressure like traveling in groups especially among the young who have risk taking behaviours may act as a precipitating factors and use of stolen vehicles are also known risk factors for road crashes (5).

Demographic factors : Some of the precipitating risk factors influencing exposure to risk, which may be categorized as demographic factors are enumerated below :

- Increased need for travel
- Choice of less safe forms of travel
- Young drivers and riders
- Alcohol Medicinal and recreational drugs
- Driver fatigue
- Hand-held mobile telephones
- Inadequate visibility
- Pre-hospital factors
- Hospital care factors

Unintentional Injuries Other Than RTIs

Fall Related Injuries : The risk factors for fall-related injuries, in most of the low and middle income countries, especially hip fractures are consistent with the risk factors identified in the developed countries, which include low bone density; poor nutritional status and low body mass index; low calcium intake; co morbid conditions like hypertension and diabetes; low levels of physical activity; poor cognitive function and vision; environmental factors affecting balance or gait; family history of hip fracture and alcohol consumption. Falls usually in and around the home, with significant proportion being associated with fall from heights including rooftops and trees are common in younger people in developing countries. However falls other than from heights predominate, and are frequently related to engagement in vigorous levels of physical activity (1).

Burn Related Injuries : Despite focus of most available WHO's data is on burn related injuries to fires, many surveys suggest that scalds from hot water may be equally or even more important causes of burn-related injuries. However in China and particularly India, fire related injuries clearly outweigh scald-related injuries. Overall women are at greater risk of fire related injuries than men. Environmental risk factors that have been identified include lack of water supply, storage of

inflammable substances at home, cooking equipments in kitchen in the reach of children, and housing that is located in slums and congested areas. Protective factors include presence of a living room, better maternal education (1).

Risk Factors for Drowning : Most drowning incidents in low middle income countries are associated with every day activities near water bodies, including rivers, wells, and ponds; as against drowning incidents in developing countries being commonly associated with recreation or leisure activities. Men account for a higher proportion of drowning incidents than women, and children aged one to four and young people appear to be at greater risk. Surveys also indicate that those living in rural areas are at a greater risk than their urban counterparts, probably indicating greater exposure to unprotected water surfaces. Most adult drowning incidents also appear to be associated with positive blood alcohol tests. Socio-demographic risk factors & risk factors associated with proximity to water bodies have been seen to cause a higher incidence of drowning in younger children. The risk of drowning in children having a well at their home was seven times higher as against those without one at their homes (1)

Prevention and Control

Injuries and the Public Health Approach

Injury prevention is well suited to the public health model, which advocates the following :

- A cycle of surveillance
- Risk factor identification
- Intervention implementation
- Evaluation.

Injury surveillance provides an understanding of the incidence, trends, and magnitude of injuries, identifies specific populations that have a higher incidence of injuries. Surveillance can help identify injuries on which to focus prevention efforts. Priority can be given to the most prevalent injury causes, those that show an increasing incidence, or those that affect a population of special interest, such as children.

The process of risk factor assessment helps identify individual or community factors that increase the risk for injury. Risk factors can be intrinsic, such as age or gender; behavioural, such as drinking and driving; or environmental, such as a poorly maintained roadway. Injury events are usually influenced by many risk factors. An intervention strategy is defined following careful surveillance and risk factor assessment. However, many interventions are implemented in the absence of such information.

An evaluation of the intervention strategy should accompany its implementation. A comprehensive evaluation should identify whether the program was implemented completely (process evaluation), determine if the intervention led to the desired change (impact evaluation), and finally, determine if the injury outcome of interest was achieved (outcome evaluation) (2).

Approaches to Injury Control

Unlike many chronic diseases, the agent of injury is usually known, and the mechanism of energy transfer from reservoir to host can be described with great detail. With the exception of some poisonings and burns, injuries usually occur immediately

after exposure and have very short 'latent' periods. Within the framework of the public health model (Fig. 1), the primary focus of injury control is to identify sources of energy forces, which cause injury, to define mechanisms of human exposure, and to identify precisely where interventions (countermeasures) may be introduced in the 'natural history' of injury. Public health has defined three levels of prevention.

- Primary prevention
- Secondary prevention
- Tertiary prevention

Primary prevention aims to prevent the event, which causes injury by eliminating the mechanisms of energy transfer or exposure. Traffic safety laws, which prevent automobile crashes, fences around swimming pools, which prevent submersion and drowning, locking devices on guns, and safety caps on poisonous substances are all examples of primary prevention, which reduce or eliminate the chance of exposure. The goal of **secondary prevention** is to eliminate injuries or reduce injury severity once a potential injury-producing exposure has occurred. Motorcycle and bicycle helmets, seat belts, life vests, and bulletproof vests are examples of secondary prevention. **Tertiary prevention** acknowledges that an injury has occurred, and aims to reduce the consequences of the injury. These efforts can include emergency response, trauma care, social work, and physical, occupational, and speech therapy.

Specific injury prevention strategies can be divided into following two very broad groups based on need for host actions.

- Passive intervention
- Active intervention

Passive intervention requires no input or action by the host and is usually accomplished by modifying the agent, vehicle, vector, or environment. Modifications in car design to improve brakes or increase energy absorption by the vehicle frame are two examples. **Active intervention** requires that the host take some type of action for the intervention to work. Seat belts and helmets are examples of active intervention.

One framework for conceptualizing the many approaches to injury prevention is termed the "4Es," which consist of the following :

- Education
- Environmental modification
- Enforcement
- Engineering

Education refers to efforts using educational messages to increase safe behaviour among the intended audience. Of the four approaches, education is perhaps the most difficult to implement. Successful educational messages must be clear, appropriate for the audience, and must be periodically repeated to maintain behaviour change.

The effectiveness of environmental modification has been demonstrated through reduction in motor vehicle crashes following changes in the driving environment. Examples include skid-free road surfaces, cross slopes on curved roadways in areas with heavy rainfall, and separation barriers on freeways and two-way roads. Environmental modifications as simple as removing trees and adding guardrails can reduce

traffic crashes in some areas by as much as 75%. Another example of successful environmental modification includes the introduction of pool-fencing barriers.

Enforcement refers to legislative regulations and the enforcement of these activities. The introduction of a mandatory helmet use law in California in 1992 led to a decrease in motorcycle fatalities of over 35% and a decrease in severe head injuries among injured motorcycle riders of over 50%. Another example of successful legislation has been the implementation of blood alcohol limits for drivers.

Engineering advancements have been highly successful in reducing injuries. The most notable examples are the seat belt and airbag, which have been attributed with decreasing injuries in frontal collisions by over 50%. Many effective prevention measures have been introduced to motor vehicles without the consumer's knowledge, including improvements in brakes, collapsible steering columns, and stronger head rests.

The Haddon Matrix : One of the most successful theoretical approaches to injury prevention is the Haddon Matrix (Table - 1), developed by Dr William Haddon in the 1970s. The Haddon Matrix identifies three phases in an injury event and links approaches to prevent or reduce injury in each phase. This matrix was developed for application to countermeasures for highway safety but continues to be a useful theoretical framework for many types of injuries. The Haddon Matrix divides the timing of the injury event into three phases : pre-injury, injury, and post injury. In the pre-injury phase, the goal is primary prevention to eliminate any energy transfer to the host. Additional examples include fences around swimming pools, which prevent submersion; trigger locks on guns, and safety caps on poisonous substances.

In the injury phase, which represents secondary prevention, the goal is to eliminate or reduce the amount of energy absorbed by the host once an energy transfer has occurred. Post-injury interventions, also called tertiary prevention, reduce the consequences of the injury once an injury producing energy transfer has occurred. The Haddon Matrix categorizes interventions in each injury phase into those that affect the host, the vehicles or vectors in the causal pathway, and the environment. The environment is often separated into physical and socioeconomic components.

The third dimension introduces value criteria to consider when choosing an intervention strategy, and includes such elements as anticipated effectiveness, cost, freedom, equity, stigmatization, preferences, and feasibility. These value criteria can be applied to interventions in each cell of the original

Haddon Matrix to determine which approach is best suited for the specific problem. The principles of injury prevention based on the Haddons Matrix are :

- To reduce exposure to risk
- To prevent road traffic crashes from occurring
- To reduce the severity of injury in the event of crash
- To reduce the consequences of injury through improved post-collision care

Public Health Issues in Prevention of Road Traffic Injuries

The motto-‘Safer Roads, Safer Vehicles, and Safer Systems’ is popular with many of those who are working to reduce RTIs. A recent augmentation to this motto is ‘appropriate transport and land-use policies in managing exposure to risk of an RTI (8). Managing exposure to risk involves strategies aimed at reducing motor vehicle traffic; making greater use of safer modes of transport; minimizing exposure to high risk situations like giving priority to higher occupancy vehicles or to vulnerable road users, speed restrictions, increasing the legal age for operating motorized two wheeler from 16 to 18 years and use of graduated drivers license system to be strictly enforced (1).

Safer Roads : Traffic calming measures are among the strategies recommended for incorporating safety features into road design. Safety awareness in planning road networks, safety features in road design, and remedial action in high risk crash sites like making provision for slow moving traffic and vulnerable road uses, median barriers, street lighting. Speed bumps, use of speed cameras and automated speed enforcements virtually eliminate speeding (1,9).

Safer Vehicles : Improving the visibility of vehicles, providing automatic daytime running lights and incorporating crash protective design into vehicles, including installing seat belts help to reduce RTIs (1). Simple strategies like ensuring regular maintenance of older vehicles, removal of vehicles in poor condition from the roads, as well as vehicle licensing and inspection are very cost effective measures (1, 8).

Safer People : Intervention strategies aimed at improving road user behaviour focusing on introduction and enforcement of relevant legislations, like increasing fines and suspending driver's license can help to reduce RTIs and deaths (1). Setting and enforcing speed limits reduces RTIs by almost 34 percent. It is also seen that setting and enforcing legal blood alcohol limits and minimum drinking-age laws, using alcohol check points, and running mass media campaigns aimed at reducing drinking and driving also gives very gratifying results.

Phase	Human	Vector (Vehicles)	Physical Environ	Socioeconomic Environ
Pre-Injury	Alcohol Intoxication	Instability in utility vehicles	Poor visibility of road hazards	Lack of knowledge regarding injury risks
Injury	Low resistance to energy	Sharp or pointed edges/surfaces	Flammable building materials	Lack of enforcement of safety belt legislation
Post-Injury	Conditions affecting energy tolerance	Rapidity of energy reduction	Emergency medical response	Lack of funding for emergency medical Services and rehabilitation services

Mandatory seat belts and child restraint laws reduce vehicle occupant deaths and injuries by almost 25 percent (8). Both bicycle and motorcycle helmet use reduces head injuries among riders by upto 85 percent. Though education may be effective in increasing helmet use, the effect is greater when combined with legislation and enforcement (1).

Exposure to risk can be minimized by reducing the volume of motor vehicle traffic; encouraging use of safer modes of travel; minimizing exposure to high-risk scenarios; and placing restrictions. Salient points, under each heading, are summarized as follows :

Reducing the volume of motor vehicle traffic may be achieved by :

- Efficient land use
- Providing shorter & safer routes
- Trip reduction measures
- Providing better public transport facilities
- Pooling of vehicles
- Providing no private vehicle zones.

Encouraging use of safer modes of travel :

- Promotion of public transport
- Walking and cycling
- 'PARK & RIDE' facilities
- Higher fuel taxes to discourage private car use
- Financial incentives.

Minimizing exposure to high-risk scenarios :

- Restricting access to different parts of the road network
- Priority to higher occupancy vehicles
- Safe crossing facilities to pedestrians like under/ over passes

Placing Restrictions :

- Restrictions on speed
- Restrictions on engine capacity
- Increasing legal age
- Graduated driver licensing system

Legislations

The important legislations on the subject in India are as under:

- Motor Vehicles Act, 1988 (59 of 1988)
- Central Motor Vehicles Rules, 1989
- The Carriers Act, 1865 (3 of 1865)

Motor Vehicles Act, 1988 (59 of 1988) : This Act governs the regulation of motor vehicular traffic through out the country; however the implementation of various provisions of this Act rests with the State Governments. This Act was last amended in the year 2001. This act includes the definition of the various categories of motor vehicles, tightening of norms for drivers transporting dangerous or hazardous goods, encouraging use of battery, CNG and solar energy as an auto fuel, bars alterations made in transport vehicle without prior approval of the Registering Authority. Vehicle safety standards are specified in Rules 93 to 127, year 2000. This act includes. The amendment made in the year 2001 brought the buses plying on CNG within the purview of State Transport Authority.

Central Motor Vehicles Rules, 1989 : Central Motor Vehicles Rules, 1989 have been framed so as to have the guidelines for smooth flow of vehicular traffic. It has been frequently

amended keeping in view the changing requirements.

The amendments notified include, norms for construction, updating of specifications for various components of motor vehicles, provision of wearing of seat belts by passengers occupying the rear seats, norms relating to conversion of diesel vehicle to LPG mode.

Poisonings

Suggested interventions to reduce exposure to occupational poisonings include better storage of poisons in terms of both the location and the nature of the storage vessels used. Specific interventions include storing poisons out side the home and above children's head height and reducing the use of secondhand household containers for example soda bottles along with introducing and enforcing legislation to prohibit the sale of poisons in such containers. The efficacy of child-resistant containers in preventing access to poisons has been demonstrated, and free distribution of child resistant containers is a highly effective means of preventing poisoning in children (1).

Fall Related Injuries

Interventions proven effective for preventing falls in older people in developed countries include muscle strengthening and balance retraining that is individually prescribed at home by a trained health professional; home hazard assessment and modification that is professionally prescribed for older people with a history of falling; and multidisciplinary, multi-factorial health and environment risk factor screening and intervention programs, both for community dwelling older people in general and for older people with known risk factors. In relation to fall related injuries among young children, increased supervision of children and the importance of height reductions and appropriate ground surfacing to prevent playground injuries are effective and relevant (1).

Burn Related Injuries

These interventions include separating cooking areas from living areas, including efforts to reduce the use of indoor fires for cooking, ensuring that cooking surfaces are at heights, reducing the storage of flammable substances in households, and supervising young children more effectively. The introduction, monitoring, and enforcement of standards and codes for and the wearing of fire retardant garments have also been proposed. Finally interventions directed at increasing awareness of burn prevention have been proposed, largely because of the success of safe community interventions involving a multitude of strategies (1).

Drowning

Fencing domestic swimming pools, covering wells with grills, fencing nearby lakes or riverbanks, and building flood control embankments might be effective in reducing the risks of drowning.

Implementation of Prevention and Control Strategies

Investments in the health sector to address specific problems are a critical indicator of political commitment, sectoral efforts, and priorities at the national and international levels. In some cases, investments are so low that they provide a useful reference point for assessing the returns on additional investments in the

future. Investments in preventing RTIs, which are responsible for the majority of the burden of unintentional injuries and about which much is known regarding effective interventions, even though such interventions have not been examined in the context of rigorously controlled studies in low -middle income countries, definitely need to be significantly enhanced (1).

Despite the global burden of RTIs, the levels of investment are pitifully small, largely because of a lack of awareness of the scale of the problem and a lack of awareness that interventions can prevent and reduce the levels of harm. As a consequence, the WHO document 'World report on road traffic injury prevention' of 2004, directs a number of recommendations at governments and communities in the hope that they will enable countries, particularly the low and middle-income countries, to begin a sustainable process that will eventually lead to the adaptation and implementation of effective preventive strategies. The recommendations include the following :

- Identify a lead government agency to guide the national road safety effort.
- Assess the problems, policies, and institutional settings relating to RTIs and the capacity or preventing RTIs in each country.
- Prepare a national road safety strategy and plan of action.
- Allocate financial and human resources to address the problem.
- Implement specific actions to prevent crashes, minimize injuries and their consequences, and evaluate the effect of those actions.
- Support the development of national capacity and international cooperation(5).

Summary

Injuries have traditionally been defined as damage to a person caused by an acute transfer of energy (Mechanical, thermal, electrical, Chemical or reduction) or by the sudden absence of heat or Oxygen. Unintentional injuries consist of that subset of injuries for which there is no evidence of predetermined intent. The cause-specific intentional injuries for which the World Health Organization routinely analyses & publishes data include road traffic injuries, domestic injuries that include poisonings, falls, burns and drowning. The WHO Glossary of Health Care Terminology defines accident as - 'An unexpected, unplanned occurrence, which may involve injury'.

Worldwide, unintentional injuries accounted for more than 3.5 million deaths in 2001, or about 6 percent of all deaths and 66 percent of all injury deaths. Worldwide, the number of people killed in road traffic crashes each year is estimated at almost 1.2 million, or an average of 3242 people every day, while the number injured could be as high as 50 million. In 2004 road traffic crashes, which ranked as the 11th leading cause of death and accounted for 2.1% of all deaths globally but on current trends, by 2020, they are likely to become the third leading cause of disability-adjusted life years lost. In India in 2004, the total number of road traffic accidents that were estimated were 4.30 million with 0.92 million fatalities.

Unintentional injuries and accidents are caused by multiple factors. The 'agent' factor of the injury is energy, which could be in many forms including mechanical, electrical, chemical,

and thermal. Human factors include Fatigue, Chronic sleepiness of the drivers, long work hours and exhaustion, failure to use helmets, use of non-standard helmets or improperly secured helmets and psychosocial factors like risk taking behaviour, lack of experience, impulsiveness, defective judgment, delay in decisions, aggression, poor perception, alcohol intake etc. The environmental factors may be vehicle related factors, road related factors, and bad weather. The precipitating factors are alcohol consumption, hand-held mobile telephones, social pressure, and demographic factors like increased need for travel, choice of less safe forms of travel, young drivers and riders etc.

Injury prevention includes a cycle of surveillance, Risk factor identification, Intervention implementation and Evaluation. Injury surveillance provides an understanding of the incidence, trends, and magnitude of injuries, identifies specific populations that have a higher incidence of injuries. Surveillance can help identify injuries on which to focus prevention efforts. The process of risk factor assessment helps identify individual or community factors that increase the risk for injury. An intervention strategy is defined following careful surveillance and risk factor assessment. However, many interventions are implemented in the absence of such information. An evaluation of the intervention strategy should accompany its implementation. A comprehensive evaluation should identify whether the program was implemented completely (process evaluation), determine if the intervention led to the desired change (impact evaluation), and finally, determine if the injury outcome of interest was achieved (outcome evaluation).

Primary prevention includes Traffic safety laws, which prevent automobile crashes, fences around swimming pools, which prevent submersion and drowning, locking devices on guns, and safety caps on poisonous substances. The secondary prevention includes Motorcycle and bicycle helmets, seat belts, life vests, and bulletproof vests. Tertiary prevention includes emergency response, trauma care, social work, and physical, occupational, and speech therapy. Specific injury prevention strategies can be divided into Passive and Active interventions. Passive intervention requires no input or action by the host and is usually accomplished by modifying the agent, vehicle, vector, or environment. Modifications in car design to improve brakes or increase energy absorption by the vehicle frame are two examples. Active intervention requires that the host take some type of action for the intervention to work. Seat belts and helmets are examples of active intervention. One framework for conceptualizing the many approaches to injury prevention is termed the "4Es," Education, Environmental modification, Enforcement and Engineering.

The Haddon matrix was initially developed to address the problem of RTIs only but it is also applicable for understanding multitudes of factors that may play role in any causal injury pathway. It identifies three phases in an injury event and links approaches to prevent or reduce injury in each phase.

Study Exercises

Long Question : Describe the various epidemiological factors causing Injuries and Accidents, and discuss the strategies for

Prevention and control of RTAs.

Short Notes : (1) Human factors causing Accident (2) Environmental factors causing Accident (3) Primary prevention for RTAs (4) Haddon Matrix

MCQs :

1. Worldwide, the number of people killed in road traffic crashes each year is estimated at almost (a) 0.2 million (b) 1.2 million (c) 2.2 million (d) 4.2 million
2. In India in 2004, the total number of fatalities in road traffic accidents were estimated to be (In million) (a) 0.02 (b) 0.92 (c) 2.92 (d) 4
3. The following is not a Precipitating Factor for causing RTAs (a) Alcohol Consumption (b) Hand-Held Mobile telephones (c) Social Pressure (d) none of the above
4. The legal blood alcohol content limit while driving is (a) 50mg/dl (b) 75mg/dl (c) 100mg/dl (d) 150mg/dl
5. The important legislation related to Accidents in India are (a) Motor Vehicles Act, 1988 (b) Central Motor Vehicles Rules, 1989 (c) The Carriers Act, 1865 (d) all of the above

Answers : (1) b; (2) b; (3) d; (4) a; (5) d.

Intentional Injuries (Including Inter-Personal and Domestic Violence)

RajVir Bhalwar

Injuries, with their resultant mortality, morbidity, disability and reduced quality of life are a major public health issue the world over. Very broadly, injuries can be classified into two broad groups, viz. "un-intentional" (accidental) injuries, in which there is no premeditation of the act causing the injury; these have been covered in detail in an earlier chapter in this section. The second group is "intentional" injuries which are due to pre-meditated and intended acts. Such intentional injuries, which are the subject for this chapter, can be further divided into the following categories (1) :

- Self directed violence in which the perpetrator is the victim (as, suicide).
- Inter-personal violence, which means violence inflicted on a person by another person or by a small group of individuals.
- Domestic (family) violence is a special type of inter-personal violence in which the perpetrators as well as the victim are members of the same family. Family violence

can be further subdivided into 3 groups, namely child violence, intimate partner violence (synonymous with couple violence) and elderly directed violence. The serious and extreme forms of couple violence are also referred to as "intimate terrorism" by some workers. In general, especially in context of developing countries, it is the female partner who is subjected to violence.

- Collective violence which is committed by larger groups as terrorists, militia groups, local political groups and communal frenzies.
- War related in which the defense personnel are subjected to violence due to declared war between states.

Violence has been defined by the WHO as "*The intentional use of physical force or power, threatened or actual, against oneself, another person or against a group or community that either results in or has a high likelihood of resulting in injury, death, psychological harm, mal-development or deprivation.*" (The word "intentional" as italicized in the definition discriminates violence from unintended injuries and accidents).

Sources of Information Regarding Inter-personal Violence

It is important to obtain data which is complete as well as accurate, when addressing the public health concerns directed towards violence. This is quite a difficult proposition as compared to other disease conditions as IHD, TB or AIDS. One

would need to resort to multiple sources of information when addressing the public health issues related to violence.

The most widely used sources are from the health and criminal justice sectors. Coroner and mortuary reports, police records, death certificates and vital statistics records may be useful in this field of epidemiology. Health sector records may provide data regarding medical details of injuries, and the circumstances surrounding the attack. In developing countries, population based surveys, though costly and logistically difficult, may provide more comprehensive information regarding the epidemiology of violence, especially those cases which may not be reported to the health, police or legal sector.

Estimates based for the year 2001 indicate that approximately 1.65 million died globally due to violence. These included 1.5 million from developing and 0.15 million from developed countries. Out of these 1.65 million, 53.3% were due to suicide, 34% due to homicide and 12.7% were war related fatalities.

Risk factors for becoming a Victim or Perpetrator of Violence : Violence is an outcome of complex interactions among many factors. To explain this complex relationship of risk factors, Dahlberg and Krug (1) have proposed a model which classifies risk factors for violence at four levels : individual level, intimate relationship level, community, and societal levels, as follows :

Individual Level : (Biological and personal history factors that influence as how individuals behave). These include :

- Early psychosocial developmental experiences
- Demographic factors (young age, male sex, poor education, poor socio-economic status, and large family)
- Being a victim of childhood abuse and neglect
- Personality disorders / psychological problems
- Ill health / physical disabilities
- Alcohol or substance abuse problems
- Ownership of a weapon (legal or illegal)

Relationship Level : Relationship Level (among family members, intimate partners, friends and peers) - These include marital conflicts, association with friends who engage in violent or delinquent behaviour, poor parenting practices, conflicts among parents, and poverty in the household.

Community Level : Community Level (among neighborhood, schools and workplaces) - These include factors as high residential mobility, high unemployment levels, high population density, proximity to drug and substance trade, and inadequate victim care services.

Societal Level : These include broad factors that reduce inhibitions against violence, viz. rapid social changes, economic inequality, gender inequality, norms that encourage male dominance over females or of parents over children, poor

Table - 1 : Preventive Steps at Individual Level

Developmental stage			
<i>Age upto 3 years</i>	<i>Age 4 to 11 years</i>	<i>Age 12 to 19 years (Adolescence)</i>	<i>Adulthood (Age 20 years and above)</i>
<ul style="list-style-type: none"> • Reduction in unintended pregnancies • Access to prenatal and post natal services • Treatment programmes for child witnesses of violence and victims of maltreatment 	<ul style="list-style-type: none"> • Programmes against drug abuse • School based programs to prevent child maltreatment • Community based prevention of child sexual abuse • Training in safe handling of firearms / weapons 	<ul style="list-style-type: none"> • Programmes against drug abuse • Educational incentives for at risk, disadvantaged students • Individual counseling • Academic enrichment programs • Residential programs in psychiatric or correctional institutions • School / college based violence prevention programs 	<ul style="list-style-type: none"> • Incentives for post-secondary or vocational training • Services for adults abused during their childhood • Strict scrutiny and waiting period for weapon licensing / purchases • Treatment for child and intimate partner abuse offenders

Table - 2 : Preventive Steps at "Relationships' Level

Developmental stage			
<i>Age upto 3 years</i>	<i>Age 4 to 11 years</i>	<i>Age 12 to 19 years (Adolescence)</i>	<i>Adulthood (Age 20 years and above)</i>
<ul style="list-style-type: none"> • Home visit services • Therapeutic foster care 	<ul style="list-style-type: none"> • Partnership programs between homes and schools to promote parental involvement 	<ul style="list-style-type: none"> • Peer mediation and counseling • Temporary foster care programs for serious and chronic delinquents • Psychosocial counseling at familial level 	<ul style="list-style-type: none"> • Programs to strengthen ties within families • Programs to strengthen ties to job • Relationship education and therapy

Table - 3 : Preventive Steps at Community Level	
Developmental stage	
<i>Children aged < 11 years</i>	<i>Adolescents and adults aged 12 years and above</i>
<ul style="list-style-type: none"> • Community policing • Emergency responses and trauma care improvements • Health care providers trained in detection and reporting of child maltreatment • Secure means of transportation of children to and from schools • Child protection service programs • Educational campaigns to increase awareness of child maltreatment 	<ul style="list-style-type: none"> • Health care professionals trained in identification and referral of high risk youth and victims of sexual violence • Improvements in emergency response, trauma care and access to health services • Shelters and crisis centres for battered women and victims of elder abuse • Mandatory arrest policies and strict laws for people indulging in intimate partner violence, child abuse and elder abuse; possibly public shaming of such persons • Community policing • Disruption of illegal weapons trade • Coordinated community interventions and educational campaigns against interpersonal violence

Table - 4 : Preventive Steps at Societal Level	
Developmental stage	
<i>Children aged < 11 years</i>	<i>Adolescents and adults aged 12 years and above</i>
<ul style="list-style-type: none"> • Reduce violent content of movies, televisions, video games and internet sites • Launch public information campaigns to promote pro-social norms • Strengthen police and judicial system • De-concentrate poverty 	<ul style="list-style-type: none"> • Enforce strict weapons licencing policies to inhibit easy acquiring of weapons by people • Reduce violent content of movies, televisions, video games and internet sites • Create job opportunities for youth • Reduce violent content of movies, televisions, video games and internet sites • Launch public information campaigns to promote pro-social norms • Strengthen police and judicial system • De-concentrate poverty

law and order situations and poor governance, societal norms that support the use of excessive violence by police personnel against civilian citizens, socio-religio-cultural norms that support violence, availability of weapons among civilian population, and conflict-like situations.

Preventive Strategies

Based on the ecological model of risk factors at four levels, as explained above, a model has been developed for violence prevention, which recommends preventive steps at the above mentioned four levels and according to the stage of developmental of individuals (1, 2) are shown in Table - 1, 2, 3 and 4 :

Summary

Violence has been defined by the WHO as “The intentional use of physical force or power, threatened or actual, against oneself, another person or against a group or community that either results in or has a high likelihood of resulting in injury, death, psychological harm, mal-development or deprivation.” Injuries can be classified into two broad groups, viz., “un-intentional” (accidental) injuries and “intentional” injuries. Intentional injuries can be further divided into Self directed

violence, Inter-personal violence, Domestic (family) violence, Collective violence and War- related violence. The most widely used sources of information when addressing the public health issues related to violence are from the health and criminal justice sectors. Estimates based for the year 2001 indicate that approximately 1.65 million died globally due to violence. To explain the complex relationship of risk factors for becoming a Victim or Perpetrator of Violence, Dahlberg and Krug have proposed a model which classifies risk factors for violence at four levels : individual level, intimate relationship level, community, and societal levels. Based on the ecological model of risk factors at four levels, a model has been developed for violence prevention.

Preventive Steps at Individual Level includes Access to prenatal and post natal services, Community based prevention of child sexual abuse, Individual counseling and Treatment for child and intimate partner abuse offenders. Preventive Steps at “Relationships’ Level includes Therapeutic foster care and Relationship education and therapy. Preventive Steps at Community Level Community policing and Child protection service programs. Preventive Steps at Societal Level include reduction violent content of movies, televisions, video games and internet sites and steps to De-concentrate poverty.

Study Exercises

MCQs

1. A model which classifies risk factors for violence at four levels has been proposed by : (a) Watson & Crick (b) Mcmohan & Pugh (c) Ramazzini (d) Dahlberg and Krug
2. All of the following are preventive steps that can be taken to prevent violence at Societal Level, except (a) De-concentrate poverty (b) Create job opportunities for youth (c) Therapeutic foster care (d) Reduce violent content of movies, televisions, video games and internet sites
3. Violence which is committed by larger groups as terrorists, militia groups, local political groups is known as (a) Collective violence (b) Domestic violence (c) Inter-personal violence (d) Self-inflicted violence

4. High residential mobility, high unemployment levels, high population density, proximity to drug and substance trade are a few risk factors leading to violence on a (a) Individual level (b) Community level (c) Societal level (d) Relationship level

Answers : (1) d; (2) c; (3) a; (4) b.

Chronic Obstructive Pulmonary Diseases

R K Khajuria

Chronic Obstructive Pulmonary Disease (COPD) is a major cause of chronic morbidity and mortality throughout the world. Many people suffer from this disease for years and die prematurely from it or its complications (1). COPD is the fourth leading cause of death in the world, and further increases in its prevalence and mortality has been predicted in the coming decades (2,3). Furthermore, although COPD has received increasing attention from the medical community in recent years, it is still relatively unknown or ignored by the public as well as public health and government officials (4). COPD and asthma are the two chronic diseases with very different diagnoses and causes. However the treatments for these two different chronic respiratory diseases share similarities (1).

Definition

Chronic Obstructive Pulmonary Disease (COPD) is the internationally preferred term encompassing chronic bronchitis and emphysema. By definition, COPD is a chronic, slowly progressive disorder characterized by airflow obstruction, which is often assessed by reduced pulmonary function as measured by simple spirometry and the presence of reduced ratio of the forced expiratory volume in one second (FEV1) divided by the vital capacity (VC). FEV1 less than 80% of the predicted value and FEV1/VC ratio below 70%, which does not change markedly over several months, is the recommended objective criteria for the same. Historically, the term 'Chronic bronchitis' was used to define any patient who coughed sputum on most days of at least 3 consecutive months for more than

2 successive years, provided other causes of cough have been excluded; while 'Emphysema' refers to the pathological process of a permanent destructive enlargement of airspaces distal to the terminal bronchioles. Although pure forms of these two conditions do exist, there is a considerable overlap in the vast majority of patients (5). Based on the current knowledge, a working definition of COPD is : 'Chronic Obstructive Pulmonary Disease (COPD) is a preventable and treatable disease with some significant *extra pulmonary* effects that may contribute to the severity in individual patients. Its pulmonary component is characterized by *airflow limitation that is not fully reversible*. The airflow limitation is usually progressive and associated with an abnormal inflammatory response of the lung to noxious particles or gases' (4).

Asthma is characterized by chronic airway inflammation and increased airway responsiveness resulting in symptoms of wheeze, cough, chest tightness & dyspnoea. It is characterized functionally by the presence of airflow obstruction, which is variable over short periods of time or is reversible with treatment. It is not a uniform disease but rather a dynamic clinical syndrome, which has a number of clinical patterns. Patients with well-controlled asthma, who are asymptomatic, may have normal lung function tests between exacerbations but may have evidence of chronic airway inflammation and hyper responsiveness. By contrast, in some patients with chronic asthma, the asthma progresses, leading to irreversible obstruction of airways (5).

Spiro Metric Classification of Severity

Spirometry is essential for diagnosis and provides a useful description of the severity of pathological changes in COPD. Specific spirometric cut-points are used for purposes of simplicity. A simple spirometric classification of disease severity into four stages is given below (4).

Stage I : Mild COPD- Characterized by mild airflow limitation (FEV1/FVC < 0.70; FEV1 > 80 % predicted). Symptoms of chronic cough and sputum production may be present, but not always. At this stage, the individual is usually unaware that his or her lung function is abnormal.

Stage II : Moderate COPD- Characterized by worsening airflow limitation (FEV1/FVC < 0.70; FEV1 < 80% predicted), with shortness of breath typically developing on exertion and cough and sputum production sometimes also present. This is the stage at which patients typically seek medical attention because of chronic respiratory symptoms or an exacerbation of their disease.

Stage III : Severe COPD- Characterized by further worsening of airflow limitation (FEV1/FVC < 0.70; FEV1 < 50% predicted), greater shortness of breath, reduced exercise capacity, fatigue, and repeated exacerbations that almost always have an impact on patient's quality of life.

Stage IV : Very Severe COPD- Characterized by severe airflow limitation (FEV1/FVC < 0.70; FEV1 < 30% predicted or FEV1 < 50% predicted plus the presence of chronic respiratory failure).

(*Note* : FEV1 : Forced Expiratory Volume in one second; FVC: Forced Vital Capacity; respiratory failure : arterial Partial pressure of Oxygen (PaO₂) less than 8.0 kPa (60 mm Hg) with or without arterial Partial pressure of CO₂ (PaCO₂) greater than 6.7 kPa (50 mm Hg) while breathing air at sea level).

Natural History

COPD has a variable natural history and not all individuals follow the same course. However, COPD is generally a progressive disease, especially if a patient's exposure to noxious agents continues. Stopping exposure to these agents, even when significant airflow limitation is present, may result in some improvement in lung function and slow or even halt progression of the disease. However, once developed, COPD and its co morbidities cannot be cured and thus must be treated continuously. COPD treatment can reduce symptoms, improve quality of life, reduce exacerbations, and possibly reduce mortality (4).

Magnitude of the Problem

COPD is a leading cause of morbidity and mortality worldwide and results in an economic and social burden that is both substantial and increasing. COPD prevalence, morbidity, and mortality vary across countries and across different groups within countries but, in general, are directly related to the identified COPD risk factors like prevalence of tobacco smoking, air pollution resulting from the burning of wood and other biomass fuels. Existing COPD prevalence data show remarkable variation due to differences in survey methods, diagnostic criteria, and analytic approaches.

The lowest estimates of prevalence are usually those based on self-reporting of a doctor's diagnosis of COPD or equivalent condition. Most national data show that less than 6% of the population has been told that they have COPD which reflects the widespread under recognition and under diagnosis of COPD as well as the fact that those with Mild COPD may have no symptoms, or else symptoms that are not perceived by individuals or their health care providers as abnormal

and possibly indicative of early COPD. By contrast, data from prevalence surveys carried out using standardized methods and including spirometry, it is estimated that up to about one-quarter of adults aged 40 years and older may have airflow limitation classified as mild to moderate COPD. The incidence of COPD in India is high. Over 13 million people are estimated to be suffering from it out of which 62 percent are estimated to be males (6).

The prevalence and burden of COPD are projected to increase in the coming decades due to continued exposure to COPD risk factors and the changing age structure of the world's population, with more people living longer, and thus reaching the age at which COPD normally develops (4). Despite the problems with the accuracy of the COPD mortality data, it is clear that COPD is one of the most important causes of death in most countries. The Global Burden of Disease Study has projected that COPD, which ranked sixth as the cause of death in 1990, will become the third leading cause of death worldwide by 2020. This increased mortality is driven by the expanding epidemic of smoking and the changing demographics in most countries, with more of the population living longer (7,8).

Economic and Social Burden of COPD

COPD is a costly disease with both direct costs and indirect costs. The presence of COPD greatly increases the total cost of care for patients, especially when inpatient costs and professional medical care in their homes are considered. Since human capital is often the most important national asset for developing countries, the indirect costs of COPD may represent a serious threat to their economies (4).

In 1990, COPD was the twelfth leading cause of DALYs lost in the world, responsible for 2.1% of the total. Presently on a worldwide basis COPD dominates all other chronic respiratory diseases in adults accounting for 2 percent to more than 10 percent of lost disability adjusted life years (DALYs). According to the projections, COPD will be the fifth leading cause of DALYs lost worldwide in 2020, behind ischemic heart disease, major depression, traffic accidents, and cerebro-vascular disease. This substantial increase in the global burden of COPD projected over the next twenty years reflects, in large part, the continued high use of tobacco in many countries and the changing age structure of populations in developing countries (1,7,8).

As compared to the developing world, data from the developing countries is much scarcer. It is estimated that the burden of respiratory diseases in India that is attributable to indoor air pollution is between 1.6 million to 2 billion sick days per year(1).

Risk Factors

As the understanding of the importance of risk factors for COPD has grown, so has the recognition that essentially all risk for COPD results from a gene- environment interaction. The salient risk factors of COPD are discussed as under (4).

Tobacco Smoke : Worldwide, cigarette smoking is the most commonly encountered risk factor for COPD. Cigarette smokers have a higher prevalence of respiratory symptoms and lung function abnormalities, and a greater COPD mortality rate than nonsmokers. The risk for COPD in smokers is dose-related. Age

at starting to smoke, total pack-years smoked, and current smoking status are predictive of COPD mortality. Passive exposure to cigarette smoke (also known as environmental tobacco smoke or ETS) may also contribute to respiratory symptoms (4). Smoking cessation has been associated with reduced morbidity from COPD. Within a few years of stopping smoking, the smoker's rate of decline of pulmonary function (FEV1) returns to the rate found in non-smokers, although little of the lost pulmonary function is regained (1). Some recent studies have also emphasized the strong familial risks associated with the development of COPD, with the incidence of disease in an individual who smokes and also has an affected sibling, being 4.7 times than that of the matched control (1,5).

Indoor Air Pollution : Wood, animal dung, crop residues, and coal, typically burnt in open fires or poorly functioning stoves, lead to very high levels of indoor air pollution. Almost 3 billion people worldwide use biomass and coal as their main source of energy for cooking, heating, and other household needs. Biomass fuels used by women for cooking account for the high prevalence of COPD among nonsmoking women in developing countries in parts of Asia, the Middle East and Africa. Indoor air pollution resulting from the burning of wood and other biomass fuels is estimated to kill two million women and children each year (1,4,5).

Gender : Most of the earlier studies showed that COPD prevalence and mortality were greater among men than women. Studies from developed countries show that the prevalence of the disease is now almost equal in men and women, which probably reflects changing patterns of tobacco smoking (4).

Genetic Factors : COPD is a polygenic disease and a classic example of gene-environment interaction. The genetic risk factor that is best documented is a severe hereditary deficiency of alpha-1 antitrypsin- 4 (4).

Inhalational Exposures : An individual may be exposed to a variety of different types of inhaled particles over their lifetime, which may contribute to the risk of COPD; but only tobacco smoke and occupational dusts and chemicals (vapours, irritants, and fumes) are known to cause COPD on their own. Tobacco smoke and occupational exposures also appear to act additively to increase the risk of developing COPD (4).

Occupational Dusts and Chemicals : Occupational exposures are an under appreciated risk factor for COPD. These exposures include organic and inorganic dusts and chemical agents and fumes (4).

Outdoor Air Pollution : The role of outdoor air pollution in causing COPD appears to be small when compared with that of cigarette smoking. However, air pollution from fossil fuel combustion, primarily from motor vehicle emissions in cities, is associated with decrements of respiratory function (4).

Infections : Repeated infections, viral and bacterial, may contribute to the pathogenesis and progression of COPD, and may also play a significant role in acute exacerbations. Newer infections as HIV infection has been shown to accelerate the onset of smoking-related emphysema (4).

Nutrition : Malnutrition and weight loss can reduce respiratory muscle strength and endurance, apparently by reducing both respiratory muscle mass and the strength of the remaining

muscle fibers. But the role of nutrition as an independent risk factor for the development of COPD is unclear (4).

Prevention and Control

1. Primary Prevention

- (a) Population education on causes and risk factors, and symptomatology, with particular focus on tobacco smoking and indoor/outdoor air-pollution, using all possible media.
- (b) Comprehensive public health actions focused on reducing tobacco use including health education, legislative and legal measures, fiscal measures and social action. These would also include measures to protect against passive smoking.
- (c) Legislative, legal as well as social measures to reduce outdoor air pollution especially from automobiles and industries.
- (d) Educational, fiscal and promotive measures to reduce the use of biomass as fuel in domestic settings and converting to environmental friendly fuel as LPG.
- (e) Specific protective measures in occupational settings as discussed in detail in the section on occupational health.
- (f) General improvements in nutrition at the population level, particularly disadvantaged groups as the elderly, children, women and the low socio economic groups.

2. Secondary Prevention

- (a) Training and retraining of health care workers especially at the primary care level for keeping a high diagnostic suspicion and diagnosing the disease at the earliest.
- (b) Provision of diagnostic (especially spirometry) facilities at the PHC/CHC level and definitely at District Hospital Level.
- (c) Equipping the primary health care level with required drugs and equipment, namely bronchodilators for long term management and inhaled bronchodilators, corticosteroids, antibiotics and oxygen for acute exacerbations.
- (d) Surveys to find out magnitude of the problem.
- (e) Periodic health examination especially among the individual worker and the elderly.
- (f) **Early diagnosis and Management of COPD** : Management of Mild to Moderate COPD involves the avoidance of risk factors to prevent disease progression and pharmacotherapy as needed to control symptoms. Severe and Very Severe COPD often require the integration of several different disciplines, a variety of treatment approaches, and a commitment of the clinician to the continued support of the patient as the illness progresses. In addition to patient education, health advice, and pharmacotherapy, COPD patients may require specific counseling about smoking cessation, instruction in physical exercise, nutritional advice, and continued nursing support. An effective COPD management plan includes four components; (1) Assess and Monitor Disease (2) Reduce Risk Factors (3) Manage Stable COPD and (4) Manage Exacerbations.

Assess and Monitor Disease : The Key Points in assessment and monitoring of COPD in a patient are :

- A clinical diagnosis of COPD should be considered in any patient who has dyspnoea, chronic cough or sputum production, and/or a history of exposure to risk factors

for the disease. The diagnosis should be confirmed by spirometry.

- For the diagnosis and assessment of COPD, spirometry is the gold standard as it is the most reproducible, standardized, and objective way of measuring airflow limitation. The presence of a post-bronchodilator FEV1/FVC < 0.70 and FEV1 < 80% predicted confirms the presence of airflow limitation that is not fully reversible.
- COPD is usually a progressive disease and lung function can be expected to worsen over time, even with the best available care. Symptoms and objective measures of airflow limitation should be monitored to determine when to modify therapy and to identify any complications that may develop.
- Co-morbidities are common in COPD and should be actively identified. Co-morbidities often complicate the management of COPD, and vice versa.

Reduce Risk Factors : The Key Points in to achieve reduction of risk factors are as under :

- Reduction of total personal exposure to tobacco smoke, occupational dusts and chemicals, and indoor and outdoor air pollutants are important goals to prevent the onset and progression of COPD.
- Smoking cessation is the single most effective-and cost effective-intervention in most people to reduce the risk of developing COPD and stop its progression. Comprehensive tobacco control policies and programs with clear, consistent, and repeated nonsmoking messages should be delivered through every feasible channel. Efforts to reduce smoking through public health initiatives should also focus on passive smoking to minimize risks for nonsmokers.
- Many occupationally induced respiratory disorders can be reduced or controlled through a variety of strategies aimed at reducing the burden of inhaled particles and gases.
- Reducing the risk from indoor and outdoor air pollution is feasible and requires a combination of public policy and protective steps taken by individual patients.

Managing Stable COPD and Acute Exacerbations of COPD

- For patients with COPD, health education plays an important role in smoking cessation and can also play a role in improving skills, ability to cope with illness and health status.
- None of the existing medications for COPD have been shown to modify the long-term decline in lung function that is the hallmark of this disease. Therefore, pharmacotherapy for COPD is used to decrease symptoms and/or complications.
- Bronchodilator medications are central to the symptomatic management of COPD. They are given on an as-needed basis or on a regular basis to prevent or reduce symptoms and exacerbations.
- Regular treatment with long-acting bronchodilators is more effective and convenient than treatment with short-acting bronchodilators.
- All COPD patients benefit from exercise training programs, improving with respect to both exercise tolerance and symptoms of dyspnoea and fatigue.
- An exacerbation of COPD is defined as an event in the natural course of the disease characterized by a change

in the patient's baseline dyspnoea, cough, and/or sputum that is beyond normal day-to-day variations, is acute in onset, and may warrant a change in regular medication in a patient with underlying COPD. The most common causes of an exacerbation are infection of the tracheo-bronchial tree and air pollution, but the cause of about one-third of severe exacerbations cannot be identified. Inhaled bronchodilators (particularly inhaled Beta-2- agonists with or without anticholinergics) and oral gluco-corticosteroids are effective treatments for exacerbations of COPD.

- Patients experiencing COPD exacerbations with clinical signs of airway infection (e.g. increased sputum purulence) may benefit from antibiotic treatment.
- Medications and education to help prevent future exacerbations should be considered as part of follow-up, as exacerbations affect the quality of life and prognosis of patients with COPD.

3. Tertiary Intervention

- (a) Establishment of referral centers at each district level.
- (b) Establishment of apex institute for chest diseases in each region preferably one in each state.
- (c) Training of patients in self management programmes.

Summary

Chronic Obstructive Pulmonary Disease (COPD) is a major cause of chronic morbidity and mortality throughout the world and it is the fourth leading cause of death in the world. It is the internationally preferred term encompassing chronic bronchitis and emphysema and by definition, COPD is a chronic, slowly progressive disorder characterized by airflow obstruction, which is often assessed by reduced pulmonary function as measured by simple spirometry (FEV1 less than 80% of the predicted value and FEV1/VC ratio below 70%). Asthma is characterized by chronic airway inflammation and increased airway responsiveness resulting in symptoms of wheeze, cough, chest tightness & dyspnoea and it is characterized functionally by the presence of airflow obstruction, which is variable over short periods of time or is reversible with treatment.

Based on Spirometry, Stage I : Mild COPD- (FEV1/FVC < 0.70; FEV1 > 80 % predicted), Symptoms of chronic cough and sputum production may be present, but not always. Stage II: Moderate COPD- (FEV1/FVC < 0.70; FEV 1 < 80% predicted), with shortness of breath typically developing on exertion and cough and sputum production sometimes also present. Stage III : Severe COPD- (FEV1/FVC < 0.70; FEV1 < 50% predicted), greater shortness of breath, reduced exercise capacity, fatigue, and repeated exacerbations that almost always have an impact on patient's quality of life. Stage IV : Very Severe COPD- (FEV1/ FVC < 0.70; FEV1 < 30% predicted or FEV1 < 50% predicted plus the presence of chronic respiratory failure.

The prevalence, morbidity, and mortality of COPD vary across countries and within countries mostly as a result of differences in survey methods, diagnostic criteria, and analytic approaches. It is estimated that about one-quarter of adults aged 40 years and older may have airflow limitation. The incidence of COPD in India is high and over 13 million people are estimated to be suffering from it out of which 62 percent are estimated to be males. The cost of management of patients with COPD is high,

hence it adds to the economic burden of a country in addition to causing loss of DALY's.

The salient risk factors of COPD are tobacco smoke , Indoor air pollution, genetic factors, inhalational exposures of which tobacco smoke and occupational dusts and chemicals (vapors, irritants, and fumes), outdoor air pollution, repeated viral and bacterial infections, malnutrition and weight loss.

COPD management includes assessment and monitoring of the disease, reducing the associated risk factors mainly exposure to tobacco smoke, occupational dusts and chemicals, and indoor and outdoor air pollutants, pharmacological management of stable patients and exacerbations if any. Spirometry is the gold standard for diagnosis and monitoring of COPD. Regular monitoring is essential in order to determine when to modify therapy and to identify any complications and other comorbidities. Since none of the medications modify the long term reduction in lung functions, *primary preventive* strategies like health education of the patient and general population, legislative measures to keep check on tobacco smoking and indoor/outdoor air-pollution play a very vital role in improving the quality of life of the patient. *Secondary prevention* strategies include regular treatment with long-acting bronchodilators and inhaled bronchodilators and oral gluco-corticosteroids, antibiotics and oxygen for treating exacerbations of COPD , training of staff at periphery to recognize symptoms of COPD as well as provision of diagnostic facilities and drugs and equipments for the long term management of symptomatic cases as also to prevent exacerbations. *Tertiary intervention* requires establishment of referral centers at each district level and working out the feasibility of establishing an apex institute for chest diseases preferably in every state as well as training of patients in self management programmes.

Study Exercises

Long Question : Discuss the risk factors involved in the development of COPD and the strategies for prevention and control of the same.

Short Notes : (1) Risk factors of COPD (2) Diagnosis and classification of COPD (3) Preventive strategies for COPD

MCQs

1. Which of the following is a diagnostic criteria for COPD: (a) FEV1 less than 80% of the predicted value (b) FEV1 less than 90% of the predicted value (c) FEV1 less than 85% of the predicted value (d) FEV1 less than 94% of the predicted value
2. Mild COPD is characterized by : (a) FEV1 less than 80% predicted (b) FEV1 more than 80% predicted (c) FEV1 less than 50 % predicted (d) FEV1 less than 60% predicted
3. Very severe COPD is characterized by : (a) FEV1 less than 80% predicted (b) FEV1 more than 80% predicted (c) FEV1 less than 30 % predicted (d) FEV1 less than 60% predicted
4. The gold standard for diagnosis and assessment of COPD is (a) Chest X Ray (b) Spirometry (c) Clinical examination (d) none of the above
5. Most important pharmacotherapy for the management of COPD is (a) Bronchodilators (b) Glucocorticosteroids (c) Anticholinergics (d) None of the above
6. The most cost effective-intervention to reduce the risk of developing COPD and stop its progression is (a) Pharmacotherapy (b) Better nutrition (c) Reducing indoor air pollution (d) Cessation of smoking

Answers : (1) a; (2) b; (3) c; (4) b; (5) a; (6) d.

219 Visual Impairment & Blindness

RajVir Bhalwar

Impairment or loss of vision leads to a substantial reduction in the quality of life, besides being an important cause of comorbidities among the affected persons. It also contributes to early death. The importance of this condition, from the public health point of view is further increased keeping in view the considerable size of the problem in terms of disease frequency particularly in the developing world, as well as the fact that 80% of these conditions are potentially amenable to either primary prevention (trachoma, Vitamin A deficiency, injuries, glaucoma, diabetic retinopathy) or by early diagnosis and specific treatment (cataract, glaucoma, refractive errors).

Definitions

<i>The defining criteria for visual impairment and blindness as per WHO (ICD - 10) (4)</i>		
Degree of Impairment	Definition	Visual impairment category
Low Vision	Visual acuity of less than 6 / 18 (Snellen 20 / 70) in worse eye but equal to or better than 3 / 60 (Snellen 20 / 400) in the better eye with best possible correction.	1 & 2
Blindness	Visual acuity of less than 3 / 60 (Snellen 20 / 400) or corresponding visual field loss of less than 10 degrees in the better eye with best possible correction	3, 4 & 5
Visual impairment	Blindness as well as low vision	1 to 5

Magnitude of the problem

It is estimated that 35 - 45 million people are blind and an additional 110 - 135 million suffer from low vision conditions. The total number of "visually impaired" worldwide is thus estimated to be approximately at least 161 million. The estimated number of blind persons in the world, as per the conditions causing blindness are : cataract (17.6 million), glaucoma (4.5 m), age related macular degeneration (3.2m), corneal opacity (1.9m), diabetic retinopathy (1.8m), childhood blindness (1.4m), Trachoma (1.3m), Onchocerciasis (0.3 m) and other causes (4.8m) (2, 3). Worldwide, in percentages, the major contributors are cataract (47.8%), glaucoma (12.3%), macular degeneration (8.3%), diabetic retinopathy (4.8%) and trachoma (3.6%). These conditions together account for more than 75% of the blindness.

The socioeconomic impact of these conditions is tremendous. According to World Bank estimates, the DALYs (in thousands), worldwide were 23,898 for cataract, 3,493 for glaucoma and

2,211 for trachoma; the corresponding DALYs for South Asia for these 3 conditions were 10259, 566, and 226 respectively.

As per the global statistics on Blindness 1998, India has approximately 10 million blind persons requiring services. The estimated incidence of blindness in India is 2.13 million per year (1). The common causes of blindness and visual impairment in India are : Cataract, Glaucoma, Corneal ulcer, Xerophthalmia and other forms of vitamin A deficiency, Conjunctivitis, Retinal detachment, Albinism, Astigmatism, Nystagmus, Optic atrophy, Retinitis pigmentosa, Trachoma. The percentage wise distribution of causes of visual impairment in India is cataract (81%), refractive errors (7%), corneal opacity (3%), glaucoma (2%), trachoma (0.2%), malnutrition related blindness (0.04%) and other causes put together (6.76%). The magnitude of blindness in India has multifarious dimensions with most of them having preventable background.

Risk factors

1. Age : It is estimated that almost 82% of the blind people are aged above 50 years, mainly because the major contributors to blindness are cataract, glaucoma and diabetes which are all advanced age - related. However, childhood visual impairment though representing only about 4 to 5 % of all visual impairment, is also quite important since it contributes to a very large number of DALYs and also since it has defined and preventable reasons as Vit A deficiency and injuries.

2. Gender : The number of women with visual impairment is higher than men, even after adjustment for age. The female to male ratio of visually impaired, worldwide, has been estimated as 1.5 to 2.2 women for 1 male. The main reason is probably the reduced access of women to eye care services.

3. Diabetes : Diabetics have much higher risk of developing retinopathy as well as higher risk of cataract.

4. Tobacco smoking : The risk of macular degeneration and possibly of cataract is higher among tobacco users.

5. Occupation : Various occupations, especially if proper personal protective measures are not used, are prone to eye injuries, as welders, agriculturists, soldiers.

6. Cultural factors : Festivals during which use of crackers is widespread pose a risk for eye injuries, especially among children.

7. Poor Socio-Economic Status : Poor socio - economic status plays an important role in many ways. Major pathways are poor nutritional status (Vitamin A deficiency blindness), inadequate water supply and poor general hygiene (trachoma), poor personal protection especially in occupational settings (eye injuries) and poor access to general health care and eye care services (cataract, glaucoma, diabetic retinopathy).

8. Genetic factors : Retinitis Pigmentosa is an example of genetically determined (X linked recessive) disease.

9. HIV Infection and the eye : The frequency of HIV / AIDS has reached epidemic proportions. 40 to 70% of all AIDS patients show evidence of some ocular disease. AIDS may involve the eye directly by causing a microangiopathy, or anterior segmental manifestations as molluscum contagiosum and kaposi's sarcoma; or, posterior segmental opportunistic

infections, mainly by Cytomegalovirus causing CMV retinitis.

Prevention, Control and Public Health Issues

Prevention and control of visual impairment needs a coordinated approach and actions at all levels of prevention - primary, secondary and tertiary, as follows :

Primary Prevention : The steps will include the following :

- Health Education of the community regarding eye care, hygiene and sanitation and frequent washing of eyes in trachoma endemic areas, regarding proper nutrition especially in context of vitamin A rich foods, and regarding availability of eye care services.
- Upliftment of socio - economic status, general standards of living and general education.
- Nutritional supplementation programmes, especially with vitamin A. The details are dealt with in the chapter on national programme for prevention of visual impairment and blindness.
- Immunization of children against common diseases, particularly measles, since measles aggravates the effects of an existing vitamin A deficiency state.
- Provision of eye care services as a part of general health services. The approach in our country is to provide ophthalmic services as a part of the primary health care system.
- Personal protection : personal protection using goggles / eye shields in high risk occupations should be ensured. Details are discussed in the section on occupational health.
- Social actions during fairs and festivals by keeping children at a safe distance from places where crackers are being burst.

Secondary Prevention : Secondary prevention, by way of early diagnosis and treatment is the mainstay of programmes for prevention and control of blindness. As said earlier, eye care services should be provided as a part of general health services at the grass root level, through the medical officers at PHC, assisted by ophthalmic assistants and optometrists. The major conditions which would be resolved by this approach are cataract, glaucoma, trachoma, refractive errors and diabetic eye complications, besides providing early emergency treatment for injuries.

Cataract : Surgical removal of the opacified lens followed by either intraocular lens implantation or else provision of spectacles is the only way of tackling cataract. Early diagnosis at PHCs or using the community outreach approach and provision of surgery using eye camp approach is the cornerstone. The details are discussed in the chapter on national programme for visual impairment and blindness.

Trachoma : The “SAFE” strategy (Surgery, Antibiotics to control infection, Facial cleanliness and Environmental improvements) has been recommended by the WHO. The details are discussed in an exclusive chapter on trachoma in the section on infectious diseases.

Glaucoma : Early diagnosis and treatment should be addressed at the PHC level and referral to the District ophthalmologist / apex ophthalmic institutes if required.

Diabetic Eye Complications : Early detection of diabetes, including detailed ophthalmologic assessment of diabetics

should be aimed at the PHC level. All diabetics as well as their family members should be educated regarding eye care, control of blood sugar levels and warning signs of diabetic eye complications.

Refractive Errors : Medical officers / optometrists working at the primary health care level should be equipped to undertake refraction and provide glasses to those who need them. This should ideally be a part of the general health services, with facilities for refraction being made available at PHC level.

Health Examinations : Health examinations should be utilized for ophthalmologic assessment and vision / refraction. The potential groups include school children and occupational workers. Proper corrective glasses and advise should be provided to those requiring glasses.

Special Screening Examinations : Retinopathy of Prematurity (ROP) and Retinitis Pigmentosa (RP) are important conditions in which screening during early childhood may be helpful. However, at present the scope of such screening, at public health level in developing countries may be limited.

Tertiary Prevention : The community should cater for specialized treatment of complicated cases and research as well as cater to social action and security for rehabilitation of visually impaired.

Disability Limitation : At the District level, there should be an ophthalmologist along with the ophthalmic team to cater to any referred cases. Similarly the medical colleges and apex ophthalmic institutions need to be developed for management of difficult cases as well as for research purposes.

Rehabilitation : Social security and rehabilitation programmes should be developed as a part of community action to ensure that visually impaired persons lead a fulfilling life and become productive members of the society. Details of social security and rehabilitation facilities in our country are discussed in detail in the chapter on “rehabilitation process in India”.

Summary

Impairment or loss of vision leads to a substantial reduction in the quality of life, besides being an important cause of co - morbidities among the affected persons. It also contributes to early death as the fact that 80% of these conditions are potentially amenable to either primary prevention (trachoma, Vitamin A deficiency, injuries, glaucoma, diabetic retinopathy) or by early diagnosis and specific treatment (cataract, glaucoma, refractive errors). The total number of visually impaired world wide are estimated to be approximately at least 161 million, of which the major contributors are cataract (17.6 million), glaucoma (4.5 m), age related macular degeneration (3.2m). India has approximately 10 million blind persons requiring services. The estimated incidence of blindness in India is 2.13 million per year. Age above 50 years, female gender, co - morbidities like Diabetes, Tobacco smoking, poor Socio - economic Status and HIV Infection are some of the risk factors. Primary Prevention consists mainly of Health Education of the community, upliftment of socio - economic status, Nutritional supplementation programmes (especially Vitamin A), and Immunization and Personal protection. Provision of eye care as part of general health services should be the aim.

Secondary prevention, by way of early diagnosis and treatment is the mainstay of programmes aimed at prevention/ control of cataract, Trachoma, Glaucoma, Diabetic eye complications and Refractive errors. Health examinations and Special Screening Examinations form part of this strategy. Tertiary prevention consists of Disability Limitation, wherein, at the District level, there should be an ophthalmologist along with the ophthalmic team; and Rehabilitation as a part of community action to ensure that visually impaired persons lead a fulfilling life and become productive member of society.

Study Exercise

MCQs

1. Diabetics have much higher risk of developing retinopathy as well as higher risk of cataract. Yes/ No
2. What percentage of of all AIDS patients show evidence of some ocular disease (a) 10 - 20% (b) 30 - 40% (c) 40 - 70% (d) 80 - 100%

3. Visual impairment category 3, 4 & 5 is termed as (a) Low vision (b) Blindness (c) Both (d) Neither
4. Immunization against which particular disease is part of specific protection measures aimed at preventing Blindness (a) Mumps (b) Measles (c) Rubella (d) Chickenpox

Answers : (1) Yes; (2) c; (3) b; (4) b.

Hearing Impairment & Deafness

RajVir Bhalwar

Hearing loss is a chronic and often lifelong disability that causes profound damage to the development of speech, language and cognitive skills in children, especially if commencing pre - lingually. Such damage greatly affects the child's progress in school and later his or her ability to obtain and execute an occupation. Besides, it causes, for all ages and both genders, difficulties in inter - personal communication and leads to significant individual social problems, especially isolation and stigmatization. All these difficulties are much magnified in developing countries which have limited services, little equipment, facilities and trained personnel, and little awareness about how to deal with these difficulties.

General Definitions

Normal human being hears at an intensity of 20 decibels (dB). The term "hearing loss" is used to denote any of the following four levels of hearing difficulty, viz., mild (26 to 40 decibel hearing level, dBHL), moderate (41 to 60 dBHL), severe (61 to 80 dBHL) and profound (81 dBHL or above). Out of these four levels, profound hearing impairment (81 dBHL and above) is taken to be equivalent of "deafness" (1, 2). *Disabling hearing impairment* in adults is defined as "permanent unaided hearing threshold level for the better ear of 41 dB or greater; for this purpose, the hearing threshold level is to be taken as the better ear average hearing threshold level for the four frequencies, viz., 0.5, 1, 2, and 4 kHz.

From the disease classification point of view, hearing loss is

divided into three categories in ICD - 10, viz. conductive hearing loss, sensori - neural hearing loss and other hearing losses.

Magnitude of the Problem

It has been estimated that worldwide, in 2002, almost 255 million people had disabling hearing loss (as per above definition of moderate or worse hearing loss i.e. 41 dB or above, in the better ear). This represents more than 4% of the world population. These 255 m include 192 million with adult onset loss (age 20 years and above) and 62 m with childhood onset loss (3). Estimates also indicate that another one and a half times more persons, i.e. another approximately 400 m would be there with mild hearing loss.

In our country, the NSSO estimated in 1991, that there are 3 million persons with hearing impairment in India. The age wise distribution per 1000 persons with hearing impairment was :

Age Group (years)	Hearing Impairment	
	Rural	Urban
0 - 4	NA	NA
5 - 14	85	80
15 - 59	387	377
60 & above	526	541

WHO in 1980 summarised the main causes of hearing impairment in India as infections, neglect and ignorance.

Causes and Risk Factors

The main causes of hearing loss according to the proportion that these contribute to the total burden of hearing loss are as follows (5) :

Causes contributing to high proportion of hearing loss : Genetic causes, Otitis Media, Presbycusis.

Causes contributing to moderate proportion of hearing loss: Excessive noise, Ototoxic drugs and chemicals, Prenatal and Perinatal problems, Infectious causes, wax and foreign bodies.

Causes contributing to low proportion of hearing loss: Nutritionally related (as iodine deficiency disorders and cretinism), Trauma related, Meniere's disease, Tumours and Cerebrovascular disease.

The Important Risk Factors Include

Age and Sex : The prevalence of hearing loss increases with increasing age groups apparently due to age-related hearing loss (presbycusis). The incidence is higher among males possibly because of occupational related hearing loss.

Genetic Risk Factors : A large proportion of childhood deafness is likely to be congenital and having genetic background. Consanguinity, and history of congenital deafness among blood relatives are important risk factors and need to be addressed from genetic counselling / testing point of view.

Intranatal Risk Factors : Transplacentally transmitted infections as TORCHES, especially Rubella, are well known risk factors for congenital hearing loss.

Environmental Noise : Noise induced hearing loss (NIHL) is a well documented entity. The adverse effects of noise can be in occupational settings (occupational hearing loss), which has been discussed in detail in the section on occupational diseases. In the citizen life settings too, noise can play a hazardous role, as loud speakers used during fairs and festivals, personal stereos, music systems, firecrackers and noisy toys. High noise traffic on highways can affect residents staying in houses besides these streets.

Infections : Exposure to conditions facilitating the transmission of bacterial and viral infections causing Upper respiratory tract infections / otitis media is an important risk factor. In addition, measles and meningococcal infections are also documented.

Trauma : Inserting sharp or even blunt objects into the ear, as is quite common practice in developing world, for cleaning the ear, is a definite risk factor for otitis media.

Poor Socio - Economic Conditions : Poverty, poor environmental and domestic hygiene, overcrowding and poor access to health care services are all risk factors that lead to upper respiratory infections, otitis media and other infections that can lead to hearing loss (as measles and meningitis).

Nutrition : Cretinism and even mild varieties of Iodine Deficiency disorders may present with hearing loss.

Other Risk Factors : Ototoxic medications, low birth weight and low apgar score have been cited by certain workers as risk factors.

Prevention, Control and Public Health Issues

It has been estimated that at least 50% of the burden of hearing loss, worldwide, can be prevented by primary, secondary and tertiary preventive measures (1, 4).

Primary Prevention

Improvement in socioeconomic and living conditions : Improved general hygiene and sanitation, housing standards and prevention of domestic overcrowding will go a long way in preventing infections which cause URTI, otitis media and other infections that may lead to hearing loss as measles and meningitis.

Improvements in health care services : Health care services would need to be improved in respect of the following aspects:

Improvements in facilities : this would include availability of drugs and equipment for early detection and treatment of URTI and otitis media, as well as providing specialized equipment as facilities for audiometry for early detection, at places as near to the community as possible.

Improvements in trained manpower : At present, developing countries have a definite shortage of ENT trained doctors as well as paramedical staff trained in ENT issues, as audiologists and speech therapists. The need is to increase the availability of such trained manpower and position them at places as near to the community as possible, after adequately equipping them with required equipment and drugs.

Improvements in accessibility and affordability : Even if trained manpower and facilities are available, they are clustered in larger cities, far away from the majority of the population. The need would be to make these services as accessible as possible as well as to ensure that the community can afford these services.

Promotive & Preventive Genetics : A substantial proportion of hearing loss is due to genetic background. All efforts should be made towards genetic counselling and, if required, genetic intervention in the form of prenatal diagnostics, in this regards, as already detailed in the chapter on genetic aspects of public health. The target individuals and communities include those where consanguineous marriages are common and family history of childhood hearing loss among blood relatives.

Prevention of noise pollution : Noise pollution would need to be addressed at two echelons. Firstly, in the occupational settings, as has been discussed in detail in the section on occupational health. Secondly, at the societal level, by individual and community education, backed up by legal provisions to prevent noise pollution at public places.

Immunization : Against measles, meningitis, and various other diseases as provided under the national immunization programme and of potential mothers against Rubella, will be of definite help in reducing the problem.

Nutrition : Implementation of various steps for control of iodine deficiency diseases as enumerated in the sections on nutrition and on national health programmes should be undertaken.

Secondary Prevention

Early detection and prompt management

- **Community Education regarding the importance of early detection :** This is a very important issue, particularly in developing countries, especially in context of congenital/ childhood hearing loss. The fact is that if a child with hearing loss can be detected as early as 6 months of age and provided with audiometric assistance, most of these

children can live a normal or near normal life. If this detection and provision of hearing aids is delayed to even 3 years of age, much preventable loss would occur. However, in developing countries, most parents keep waiting till about 3 to 5 years of age, thinking that their child may be one who is probably developing delayed speech or may be having “tongue - tie”. It must be remembered by all medical personnel, and conveyed to the community that any child who is not speaking is most probably the one who is not hearing and hence needs to be evaluated. Therefore, any child who has delayed socio - developmental milestones as delayed social smile, delay in speaking 2 or 3 syllables, or any child who has history of childhood hearing loss among another member of the family should be subjected to special evaluation.

- Early detection of Upper respiratory tract infections, otitis media (both acute and chronic) and other infections that can cause hearing loss, by organizing adequately staffed, equipped and accessible health care services, as described above.
- Early detection of hearing loss : This is a very important, as has been already outlined above. The children / adults falling under these criteria of suspicion should be subjected to an evaluation by an ENT surgeon / trained audiologist. The most commonly used screening technique is audiometry. Childhood audiometry is possible for children even as young as 3 to 4 months of age. More advanced techniques as Brainstem Evoked Response Audiometry (BERA) are available at specialized centers only.
Among Adults : The groups which need to be subjected to preventive audiometry include Occupational workers exposed to high noise and old people.
Among Children : Detailed risk factors and indicators have been developed for neonates and infants who should be subjected to hearing evaluation. These include children who suffered from conditions which should have required admission to neonatal ICU, stigmata of syndromes causing hearing loss, positive family history of hearing loss, craniofacial anomalies, certain in - utero and post-natal infections (TORCHES and meningitis), hyper - bilirubinaemia, conditions requiring prolonged mechanical ventilation, or effusion, persistent discharge for ear, and infants who do not achieve developmental milestones in time.
- *Adequate Treatment* : Prompt treatment of infections by suitable antibiotics and supportive measures; and, surgical intervention including tympanoplasty for relevant cases of chronic otitis media. For hearing impairment, the correct hearing aid / cochlear implant should be provide after detailed audiometric and clinical evaluation by an ENT surgeon. It must be remembered that parents / patients should be advised that for a given patient, the correct hearing aid has to be worked out and not that they should go to the market and buy any hearing aid, as is often done. Secondly, hearing aids, once given should be followed up with proper evaluation by the ENT surgeon as well as speech and educational rehabilitation programmes.

Tertiary Prevention : Tertiary prevention would include the following :

Speech Therapy : A number of patients provided hearing aid, especially childhood cases will need assistance for developing proper speech. In community and public health context, it needs to be noted that the best speech therapists are the motivated parents and every opportunity should be taken to educate the parents in bringing about speech rehabilitation of their affected child.

Vocational and Educational Training : Very large proportion of children with childhood hearing loss if detected and treated early with appropriate hearing aids, will live a near normal life. Children should be sent to normal schools as far as possible unless there are indications that the child has to be sent to special school for hearing challenged. For adults, those who are not able to cope up with the fine requirements of occupation even after provision of hearing aids, the employers should consider alternative areas of work.

Follow up : Cases who have been provided hearing aid, or have undergone surgical correction for otitis media should be followed up as prescribed.

Social Actions : Suitable facilities need to be created for education and vocation of the hearing challenged. Various provisions including reservations in education and jobs, travel facilities and economic relaxations are available in our country for this group, the details of which have already been provided in the chapter on rehabilitation process in India.

Specialized Training, Research and Referral : Efforts should be made to develop apex centres for undertaking training of ENT surgeons in specialized hearing problems and of support manpower as audiologists. These institutions should also cater to research and referral support for specialized cases. In our country, such specialized centers are available at Mysore and Mumbai.

Summary

Hearing loss is a chronic and often lifelong disability that causes profound damage to the development of speech, language and cognitive skills in children. The term “hearing loss” is used to denote any of the following four levels of hearing difficulty, viz., mild (26 to 40 decibel hearing level, dBHL), moderate (41 to 60 dBHL), severe (61 to 80 dBHL) and profound (81 dBHL or above). It has been estimated that worldwide, in 2002, almost 255 million people had disabling hearing loss. The NSSO estimated in 1991, that there are 3 million persons with hearing impairment in India. Among the main causes of hearing loss are Genetic causes, Excessive noise and Trauma related. The important risk factors include increasing age, Genetic factors, trans - placentally transmitted infections as TORCHES, Noise - induced hearing loss, Infections, Trauma, Ototoxic medications and Poor Socio - economic conditions. Important among the measures of Primary Prevention include improvement in socioeconomic and living conditions, improvements in health care services, genetic counseling, prevention of noise pollution, Immunization towards specific diseases and Nutrition. Secondary Prevention measures include Community Education regarding the importance of early detection, particularly in

developing countries, early detection of Upper respiratory tract infections that can cause hearing loss, early detection of hearing loss using tests like Brainstem Evoked Response Audiometry (BERA) and Adequate Treatment. Speech therapy, Vocational and Educational training, Follow up, Social Actions, Specialized training, Research and Referral all form part of Tertiary Prevention.

Study Exercises

MCQs

1. Childhood audiometry is possible for children even as young as (a) From birth (b) 1 - 2 months of age (c) 3 - 4 months of age (d) 01 year of age
2. Age related hearing loss is known as (a) Presbycusis (b) Presbyopia (c) Otitis Media (d) NIHL
3. All of the following are measures of tertiary prevention of hearing loss, except (a) Speech therapy (b) Using tests like Brainstem Evoked Response Audiometry (BERA) (c) Specialized training (d) Follow up

4. Moderate hearing difficulty refers to that which includes the range of (a) 41 - 60 dB (b) 61 - 80 dB (c) 81 - 100 dB (d) 101 - 120 dB
5. It has been estimated that at least what percentage of the burden of hearing loss, worldwide, can be prevented by primary, secondary and tertiary preventive measures (a) 20% (b) 30% (c) 40% (d) 50%

Answers : (1) c; (2) a; (3) b; (4) a; (5) d.

Dental and Oral Health

Ramen Sinha

During the past few decades, oral health authorities in the fields of epidemiology, education, services, health education and disease prevention have given special attention to the highly prevalent oral health problems like dental caries and periodontal diseases. With these approaches, dramatic improvement in scientific knowledge and technology has taken place in the field of oral health.

Structure of the Tooth

The teeth are hard-calcified structures set firmly in bone sockets in the maxilla and mandible by means of a root or roots. The part visible in the oral cavity is the crown, which is separated from the roots by a narrow portion called the neck or cervical portion of the tooth. The crown is covered with hard shiny enamel. The tissue covering the root is the cementum. The ivory-like structure that forms the bulk of the tooth is the dentine. Enamel lacks the capacity for self-repair since it contains no cells. It resists wear only through its extreme degree of hardness. Dentine is capable of repair, but it is less hard and resistant than enamel. Investing between the roots of teeth and socket wall formed by alveolar bone is the thin periodontal ligament, the fibre-bundles of which help to suspend and anchor the teeth in place. Its cushioning effect also helps in

protecting periapical tissues from likely compression during mastication. The dental pulp occupies hollow pulp chambers and pulp canals in the crown and roots of teeth. It contains a plexus formed by connective tissue fibers, nerve endings, blood vessels, tissue cells and lymphatics which communicate with their major source of supply through apical foramina in the roots ends (Fig. - 1).

The gingival, periodontal ligament, alveolar bone and cementum which support the teeth are collectively termed as periodontium.

Dentition

The first dentition brings forth the deciduous or “Milk teeth”. There are twenty teeth in this set; ten in each jaw. The tooth buds begin to form about the sixth week of prenatal life and calcification starts about the sixteenth week of prenatal life. The position of the first permanent molar determine to a great extent, the position of the other teeth. Therefore, early examination and care will help to ensure their retention throughout life. Deciduous teeth are shed about the 7th year onwards, when the permanent teeth follow. There are 32 teeth in the permanent set; 16 in each jaw. Calcification of permanent teeth begins in the jaws about the time of birth. The last four teeth to erupt are the third permanent molars, or “wisdom teeth”. They do not erupt until about the age of 18 years or later and may even never erupt. Sometimes they become “impacted” below the gum surface necessitating extraction to preserve the health of the adjacent teeth. Dentition schedule is shown in Table-1.

Tooth Numbering

The system which is recommended for use is as per Federation Dentaire International system is Modified Palmer System. In this two-digit system, the first digit indicates the quadrant and the second digit a particular tooth in that quadrant. Quadrants are allotted the digit 1 to 4 for the permanent and 5 to 8 for the deciduous teeth in a clockwise sequence, starting at the upper right side; permanent teeth within the same quadrant are allotted the digits 1 to 8 whereas deciduous teeth (1 to 5) from the mid-line backwards. The digits should be pronounced separately : thus the permanent canines are teeth one-three, two three, three-three and four three. Numbering system is as follows :

<i>Permanent teeth</i>	
(Upper right)	(Upper left)
18 17 16 15 14 13 12 11	21 22 23 24 25 26 27 28
48 47 46 45 44 43 42 41	31 32 33 34 35 36 37 38
(Lower right)	(Lower left)
<i>Deciduous teeth</i>	
(Upper right)	(Upper left)
55 54 53 52 51	61 62 63 64 65
85 84 83 82 81	71 72 73 74 75
(Lower right)	(Lower left)

Functions of Teeth

Besides mastication, the teeth help in phonetics and also contribute towards aesthetics. The process of mastication involves incision and grinding of food. The incisors serve to incise the food and the premolars and molars do the grinding. The food is broken into smaller portions and is thoroughly mixed with saliva before it is swallowed. For efficient performance of their function the teeth must be correctly aligned in arches and meet in normal occlusion. Occlusion means a contact relationship of the teeth when the jaws are closed. Normally mastication is done at one side only at a time. Chewing ability depends upon the soundness of teeth, firmness of their embedment, hardness of enamel, uniformity of occlusion and strength of the jaws. Chewing the fibrous foods such as meat, radish, celery, carrots, and apples and so on develops the jaws and at the same time keeps the gums in proper tone by stimulating blood circulation through them. Children should be taught to chew their food thoroughly, but not to crack nuts or very hard items, less it may damage the

Table - 1 : Dentition Schedule

	Maxillary			Mandibular		
	<i>Formation Begins</i>	<i>Eruption</i>	<i>Shedding</i>	<i>Formation Begins</i>	<i>Eruption</i>	<i>Shedding</i>
(A) Deciduous Teeth	Intra Uterine	Postnatal				
Central incisors	4 months	7 months	7 years	4 months	6 months	7 years
Lateral incisors	4½ months	9 months	8 years	4 months	7 months	7-8 years
Canines	5 months	18 months	11-12 years	5 months	16 months	10-12 years
First molar	5 months	14 months	9 - 10 years	5 months	12 months	8-9 years
Second molar	6 months	24 months	11-12 years	6 months	20 months	10-11 years
(B) Permanent Teeth	Postnatal					
Central incisors	3-4 months	7-8 years		3-4 years	6-7 years	
Lateral incisors	10-12 months	8-9 years		3-4 years	7-8 years	
Canine	4-5 months	11-12 years		4-5 years	9-10 years	
First pre molar	1½ years	10-11 years	No definite schedule	1½-2 years	10-12 years	No definite schedule
Second pre molar	2-3 years	10-12 years		2 - 2½ years	11-12 years	
First molar	At birth	6-7 years		At birth	6-7 years	
Second molar	2½ -3 years	12-13 years		2½ - 3 years	11-13 years	
Third molar	7-9 years	17-21 years		8-10 years	17-21 years	

enamel, so that the teeth and the supporting structures develop properly as a well functioning organ. Teeth that are properly aligned and occlude normally help in proper pronunciation of words. Facial appearance, beauty, and symmetry depend upon well-developed jaws and a full compliment of teeth developed in proper alignment. If the teeth are mal-aligned or have spaces between them or a few teeth are missing, the speech becomes faulty and lacks clarity. The unpleasing expression due to irregular or missing teeth may cause self-consciousness, which leads to inferiority complex that may ultimately, result in social maladjustment. Teeth and their supporting structures thus considerably influence and affect the personality.

It has always been commonly believed that with the advancing age the loss of teeth should be considered a natural and inevitable occurrence. However, it is now recognised to be a direct result of pathological process. It was earlier inferred, although rather incorrectly, that below the age of 35, the tooth loss was the result of dental caries, where as beyond the age of 35 it results from 'pyorrhoea'. However, from the epidemiological studies world over, it has been established that diseases of four different supporting structures of the teeth (termed collectively as 'periodontium') can have their origin even amongst the school going children. Such global surveys therefore indicate, that although drastic and damaging results might be discernable in a majority of population, beyond the age of 35 or more, the damaging influences on the periodontal tissues can be traced to have commenced even as early as 12-15 years of age. The universal axiom that "prevention is better than cure" still holds true, and to be more effective, this too must therefore commence during the school-going age.

Dental Plaque

Dental plaque is thin, tenacious, firmly adherent and well organized biofilm adhering to the tooth surface, restorations and dentures. It is different from other deposits on the tooth surface such as materia alba and calculus. Materia alba refers to soft accumulations of bacteria and tissue cells that lack organized structure of dental plaque and are easily displaced with water spray. Calculus is a hard deposit that forms by mineralization of dental plaque and is always covered by a layer of unmineralized plaque. Dental plaque is composed primarily of more than 325 different bacterial species and one gram of plaque contains approximately 2×10^{11} bacteria (14). The dental plaque may be cariogenic, causing dental caries or calculogenic, causing periodontal diseases.

Dental Caries

Dental caries (commonly referred as "tooth decay" in layman's language) is a public health problem worldwide. As per official reports, it is the single most common chronic childhood disease in the USA. Epidemiological data for large number of countries is available on the Who site <http://www.whocollab.od.mah.se/index.html> and interested readers are advised to refer to the same.

Dental caries is found not only in children and young adults but also in other age groups. The elderly, particularly those with exposed tooth root surfaces constitute a special risk population. There is evidence that persons aged 50 years and above are also a caries active group, experiencing new caries at

a rate comparable to that of adolescents.

Epidemiological Measurements of the Load of Dental Caries: Caries prevalence of permanent teeth in a community is generally assessed by an index known as "Decayed Missing and Filled teeth (DMFT)". It is calculated by counting the number of DMFT of each individual and then calculating the mean for the group examined. A very common age group used for international comparisons of DMFT is the 12-year age group. The WHO also recommends this age group, and the WHO goal was to achieve "3 or less DMFT" among 12 year old children" by the year 2000. According to estimates, 70% of the countries, representing 85% of the world population had achieved this goal by 2001; however, several developing countries have reported a trend towards higher level of dental caries.

Another parameter for measuring the load of caries is "Significant caries (SiC)" index. This is calculated by calculating the mean DMFT of the one-third of the group having the highest DMFT in that population (i.e., in the upper teeth). This is because the distribution of DMFT among children in a population often tends to be skewed, with a proportion of children showing high or very high number of DMFT while the remaining showing low number or none. Expressing caries prevalence as mean DMFT may therefore not accurately describe the disease level in populations with such skewed distributions.

Pathophysiology and Clinical Features : Dental Caries develops due to localized dissolution of hard tissues of the tooth, caused by acids that are produced by the bacteria (mainly streptococci), in the "biofilms" (dental plaque) which form on the teeth and eventually lead to "cavities". The destructive acids are produced when fermentable carbohydrates come in contact with these biofilms, each episode resulting in tooth damage, which manifests clinically as an 'episode'. If this process does not occur frequently, then the natural capacity of the body (through saliva) to remineralize will prevent formation of a cavity. Thus the main risk factors are presence of "carioenic" biofilm, frequent consumption of fermentable carbohydrates and conditions in which saliva production is decreased. The protective factors against caries include exposure to fluorides in optimum concentration (as through drinking water or fluoridated toothpastes) and normal saliva flow.

Untreated caries can give rise to infection of tooth pulp, causing pain and destruction of the tooth. The infection can spread to the supporting tissues and the jaws, culminating in advanced disease conditions.

Diagnosis : Although bacteria on the teeth are the direct cause of dental caries, a large number of microbiological, environmental and host factors interact to determine whether or not an individual will be affected and if affected, how and to what extent. Dental caries is therefore a multifactorial disease (Fig. - 2).

In the past, diagnosis of dental caries involved the use of a mouth mirror, an explorer and perhaps bites wing radiographs. "Tug back" or a feeling of resistance when the explorer was moved on the tooth surface led to an almost confirmed diagnosis of caries. Treatment of dental caries as per Black's "Extension for prevention" necessitated considerable loss of tooth substance beyond the actual carious lesion. The modern

approach to diagnosis and treatment based on a series of important advances differs from Black's rules in almost all respects. The diagnostic process does not focus only on the presence of lesions but is expanded to include identification of factors that lead to the formation of lesions.

Fig. - 2 : Dental Caries is a Multifactorial Infectious Disease

Prevention

The multi-factorial nature of caries allows scope for a number of different approaches for prevention of this disease. It should also be recognized that certain etiological factors have vastly different consequences, depending on the total mix of factors. For example, the consequence of a diet rich in sucrose is quite different for a person who is frequently exposed to fluorides than for one who has very little exposure.

(a) Proper Brushing

Fig. - 3 : Proper Brushing

1. Place the brush at an angle against the tooth, making certain that the bristles are at the gumline. Gently brush the surface of each tooth using a short, gentle vibrating motion.
2. Brush the outer surface of each tooth, upper and lower, keeping the bristles angled against the gumline. Repeat the same method on the inner surface of the teeth as well.

3. To clean the inside surfaces of the front teeth, tilt the brush vertically and make the several gentle up and down strokes using the front half of the brush.
4. Scrub the chewing surface of the teeth using a short back and forth movement. Brushing the tongue will remove bacteria and freshen your breath.

(b) Diet : The contribution of sucrose to implantation, colonization and metabolic activities of cariogenic bacteria has been clearly established and has led to search of sucrose substitutes.

(c) Dental Flossing

- When flossing your teeth, start off by breaking about 18 inches of dental floss from your floss dispenser. Take each end of the floss and begin to wrap it around the middle two fingers of each of your hands. Wrap most of the floss on the fingers of one hand while wrapping just enough on the other hand that the dental floss is easily held. Continue to wrap the floss until just a small length (3 to 4 inches) is left stretching between your hands (Fig. - 4a).

Fig. - 4a : Dental Flossing

- The floss will be held by the middle fingers while some combination of each hand's index finger and thumb will be used to manipulate the dental floss between your teeth. There should be about 1/2 to 1 1/2 inches of dental floss stretched between your pinch hold on the floss. This is the section of the dental floss that will be worked between your teeth and used to clean away the accumulated food debris and dental plaque.
- To floss a particular location you will need to work the dental floss past the contact point where the two teeth touch. If the contact between the teeth is very tight you may need to use a slight back and forth sawing motion to get the floss to go. You might also need to use a small amount of pressure to help to guide the floss through the contact point. But don't use so much force that the dental floss snaps past the contact and traumatizes your gums. *Work the dental floss up and down the side of each tooth. Always keep the pressure of the dental floss against the tooth's surface* (Fig. - 4b).

Fig. - 4b : Dental Flossing

- Once you have finished cleaning the side of this first tooth you will need to bring the floss back above the gum line, pull it up against the side of the other tooth, and then clean this second tooth just like you did the first one.
- Don't forget to floss the back side of the last teeth in your mouth and the sides of any teeth that face spaces where teeth have been removed.
- Using dental floss once a day should be often enough to keep you in good oral health.
- You should floss your teeth first and then brush afterwards.

(c) Fluoride : Recent reports from Australia and United States have confirmed the safety and efficacy of fluoride in preventing dental caries. The United States has set a limit of 4 mg / litre as the maximum allowable level in drinking water and recommends a level of 0.7 to 1.2 mg / litre. During decreases in the pH of the dental plaque free fluoride is available and helps in remineralization process. Moreover fluoride used on a regular basis becomes concentrated in dental plaque and appears to interfere with enzymes used by the bacteria in metabolizing sugars. Fluoridated toothpaste, rinses, gels and tablets are important delivery system. Water, salt and milk are highly cost effective vehicles and should be implemented wherever technically feasible.

Fluorides supplements are available as

(i) Systemic fluorides : e.g. Water fluoridation, various food products

(ii) Topical fluorides : Available in the form of gels, mouthwashes, solutions and toothpastes

(d) Sealant : The use of dental sealant is an effective way to prevent pit and fissure caries. One of the barriers to increased use, however is the fact that successful placement and retention of sealant are highly dependent on technique and the availability of appropriate equipment.

(e) Antimicrobials : Infants acquire the bacteria that colonize the oral cavity and digestive tract usually through normal handling by their mothers or other care givers. Investigators have found that it is possible to interfere with the process of transmission of mutans streptococci by treating mothers and other close family members with antimicrobials like

chlorhexidine gluconate 0.2 or 0.12%.

Immunization

An improved understanding of genetics of oral bacteria is also leading to new approaches to development of safe and effective oral vaccines. The possibility of creating a polyvalent vaccine effective against caries, as well as measles, poliomyelitis and other serious infections is under consideration. With successful programme to reduce the effects of etiological agents & increase host resistance, a new approach to treatment of the caries lesion can therefore be outlined as follows :

(a) Incipient Lesion

- (i) Remineralization using topical fluoride therapy.
- (ii) Counselling on dietary and other risk factors.

(b) Initial Cavitation

- (i) Application of a sealant.
- (ii) Restoration with preventive materials after minimal excavation and preparation with hand or rotating instruments if necessary.

(c) Moderately Sized Lesion : Restoration conserving maximum amount of tooth substance

(d) Deep Lesion

- (i) Restoration, conserving maximum amount of tooth substance.
- (ii) Endodontic therapy, if necessary.

This new approach can also be applied to retreatment using same steps and repairing physical defects only if symptoms are evident in the teeth or supporting tissues.

Periodontal Diseases

The inflammatory diseases, viz., gingivitis and periodontitis are quite common (Fig. - 5).

Fig. 5 : Periodontal Diseases

Gingivitis : While caries has been linked strongly with only a few organisms, the development of gingivitis appears to be caused by nonspecific bacterial plaque flora, which changes over time from predominantly gram positive to more gram negative. In gingivitis the gums become spongy, red, swollen, bleed when brushed or touched, stand away from teeth, often causing little pain and discomfort. Gingivitis therefore is often neglected until it has reached an advanced stage. Gingivitis does not necessarily develop into periodontitis. However, periodontitis is always preceded by gingivitis. The disease can spread to involve deeper supporting tissues viz. periodontal ligament, cementum and alveolar bone. Due to apical migration of junctional epithelium there is formation of a gap between teeth and gums known as the periodontal pocket. Such pockets harbour dental plaque and calculus which, if untreated, ultimately leads to alveolar bone resorption, mobility of teeth and exfoliation.

Diagnosis : Traditional approaches to periodontal diagnosis include assessment of gingival health and measure of pocket depth, alveolar bone height and loss of periodontal attachment. In addition, the presence or absence of dental plaque and supra and sub gingival calculus is recorded. Assessment of gingival health continues to rely on visual evaluation of the tissues and the extent to which gingival gentle probing can provoke bleeding. The height of alveolar bone is assessed from radiographs. A complete assessment of the periodontal situation should include quantification of the loss of attachment around the teeth (pocket depth and gingival recession as measured from the cemento - enamel junction or some fixed points). It is important to note that pocket depth, bone height and periodontal attachment, represents only the cumulative results of past pathological events and do not reflect the rate of progression of lesions unless measurements of radiographic assessments are made at short time intervals. Many diagnostic tests aimed at detecting early events in the disease process such as bacterial cultures, DNA probes, immunofluorescent assays, specific antibody determinations and the measurements of hydrolytic enzymes, break down products and cytokines are currently being studied. Markers of host defence mechanisms, such as chemotactic responses and phagocytic capability of polymorphonuclear leucocytes have also been investigated.

There is no single organism that is pathognomonic of a change from gingivitis to adult periodontitis. Several species like *Porphyromonas gingivalis*, *Prevotella intermedia*, *Eikenella corrodens*, *Wolinella recta*, *Treponema denticola* and *Capnocytophaga* are present in various combinations in patients with adult periodontitis. The association between a gram-negative anaerobic microflora and periodontitis has been extensively demonstrated and elimination / control of this flora will reduce risk of periodontitis.

Treatment : Epidemiological studies from many countries show that severe periodontal destruction is less prevalent than it was thought to be 10 to 15 years ago. Improvements in oral hygiene are believed to be the primary factor in this change. Due to increased life expectancy, periodontal care will also be needed by many elderly people who are medically compromised, have physical and mental handicaps, or take medications with potentially harmful side effects.

At present, the prevention of periodontitis is based on mechanical removal of plaque, plus antimicrobial and antiseptic mouthwashes, if necessary. Where Oral hygiene levels are generally high, fewer than 10% of adult population develops advanced periodontal destruction. However, treatment of gingival inflammation (gingivitis) and maintenance of gingival health depend on adequate plaque control through self-care. Instruction in good oral hygiene and constant practice early in life may lead to good habits, which will help to prevent the formation of calculus. Regular examinations and frequent removal of calculus are also beneficial. Regular brushing of teeth, using proper brush and correct technique needs no emphasis. Rubbing and cleaning with finger and rinsing the mouth vigorously with water, after eating, also help.

Moderate or advanced periodontitis can be treated by elimination of bacterial infection and establishment of effective plaque control. It has been conclusively demonstrated that the large majority of periodontal problems can be treated using non-surgical, conservative approaches. With a better understanding of the biology of connective tissue and of the regenerative potential of periodontal tissues, guided tissue regenerative procedures have been shown to enhance formation of new alveolar bone. This approach has great potential value for individual teeth but can not be applied as a general public health measure.

A rare condition, Juvenile periodontitis, seems to be familial and is characterized clinically by inflammation and rapid progression of periodontal lesion. Presence of *Actinobacillus actinomycetemcomitans* may be an early marker of this disease.

Dental Implants

In the recent past, dental implants have been successfully used for replacing missing teeth without unnecessarily damaging adjacent tissues or compromising function. The principle of osseo-integration of dental implants using high biocompatible materials and appropriate prosthetic concepts has provided the oral health profession with opportunities that transcend the original concept of tissue restitution. During the past decade, implementation of this principle in the treatment of total and partial edentulousness has contributed to a rapid increase in replacing removable dental prosthesis with fixed restorations.

Other Oral Lesions

Oral Sub Mucous Fibrosis (OSMF)

It was initially described in 1966 by Pindborg and Sirsat as an insidious, precancerous, chronic disease that may affect the entire oral cavity and that sometimes extends to the pharynx. Although it is occasionally preceded by the formation of vesicles, OSF is always associated with a subepithelial inflammatory reaction followed by fibroelastic changes of the lamina propria, accompanied by epithelial atrophy. Various factors have been implicated in the development of OSF, the most common of which is chewing areca nut. Associations with tobacco use and vitamin deficiency have also been reported. Symptoms of OSF include the following : Trismus due to oral fibrosis and scarring, pain and a burning sensation upon consumption of spicy food stuffs, increased salivation, change of gustatory sensation, hearing loss due to stenosis of the eustachian tubes, dryness of the mouth, nasal tonality to the voice, dysphagia

to solids, impaired mouth movements (e.g. eating, whistling, blowing, sucking).

Group classification system for the surgical management of trismus.

Group I : earliest stage, interincisal distance of greater than 35 mm.

Group II : interincisal distance of 26-35 mm.

Group III : Moderately advanced cases, interincisal distance of 15-26 mm Fibrotic bands are visible at the soft palate, and pterygomandibular raphe and anterior pillars of fauces are present.

Group IVA : Trismus is severe, with an interincisal distance of less than 15 mm and extensive fibrosis of all the oral mucosa.

Group IVB : Disease is most advanced, with premalignant and malignant changes throughout the mucosa.

The medical management in moderate cases involves : Cessation of the habit followed by use of Steroids, Placental extracts, Hyaluronidase. Surgical management in severe cases : excision of the fibrous bands, buccal pad of fat grafting or Split-thickness skin grafting following bilateral coronoidectomy..

Aphthous Stomatitis

This most common oral condition has been usually associated with stress, nutritional deficiencies and malabsorption syndrome. Various symptomatic treatment options have been proposed but improvements seen are considered to be due to placebo effect.

Lichen Planus

It is a common oral mucosal disease of unknown etiology, which often occurs without simultaneous skin lesions. In the ulcerated form, the disease often presents significant therapeutic problems. Occasionally, patients may present with lesions called lichenoid reactions, which are sometimes related to drugs and / or graft versus host reactions.

Oral Manifestations of HIV Infections and AIDS

In most of the countries, HIV epidemic is spreading with alarming speed. The WHO prediction for the year 2001 is 10 million AIDS cases and 40 million HIV seropositive individuals. In many cases, oral lesions are the first signs of HIV infection and members of the oral health profession should therefore be well trained in recognizing these lesions. The common oral conditions reported to occur in HIV infected patients are Candidiasis; Erythematous, hyperplastic, pseudomembranous hairy leukoplakia; HIV - gingivitis; HIV - Necrotizing gingivitis; HIV - Periodontitis; Kaposi's sarcoma; and, Non Hodgkin's Lymphomas.

In patients with AIDS, treatment of oral Candidiasis should follow general recommended guidelines; use of a triazol drug or Fluconazole may be required. Necrotizing gingivitis and Stomatitis are also frequently encountered. Good oral hygiene is essential, supplemented with antibiotic treatment if necessary. The drug of choice is often Metronidazole. For Kaposi's sarcoma various treatments are used including radiotherapy, surgery and intralesional cytotoxic drugs such as Vinblastine, Vincristine and Bleomycin. Like Candidiasis, hairy leukoplakia is a strong predictor of AIDS.

Impacted Tooth

The definition of an impacted tooth is "tooth that can not, or will not, erupt into its normal functioning position, and is, therefore, pathologic and requires treatment.

Mandibular and maxillary third molars, followed by maxillary canine are the teeth most commonly impacted. Failure of teeth to erupt into their normal position in the arch may result in problems that include pericoronitis, pericoronal abscess, periodontal disease, caries, and root resorption of adjacent teeth, dentigerous cysts or odontogenic tumors.

Clinical features include : redness, swelling and tenderness of the gingiva around the impacted tooth, unpleasant taste when biting down on or near the area, halitosis, pain radiating to ear, trismus, and palpable lymph nodes of submandibular region.

Treatment of mandibular third molars involves surgical extraction of the teeth by the dental surgeon under local anesthesia

Take home message

- Brush your teeth after every meal, at least twice daily.
- Stop deleterious habits like chewing tobacco, *pan masala*, etc. and smoking
- Visit your dentist at least after every six months for regular check ups.
- Visit the nearest dental centre, immediately without any delay if you experience severe pain or any discomfort rather than taking any indigenous domestic remedies.

Summary

During the past few decades, oral health authorities in the fields of epidemiology, education, services, health education and disease prevention have given special attention to the highly prevalent oral health problems like dental caries and periodontal diseases.

Dental plaque is thin, tenacious, firmly adherent and well organized biofilm adhering to the tooth surface, restorations and dentures. The dental plaque may be cariogenic, causing dental caries or calculogenic, causing periodontal diseases. Dental caries (commonly referred as "tooth decay" in layman's language) is a public health problem worldwide. Caries prevalence of permanent teeth in a community is generally assessed by an index known as "Decayed Missing and Filled teeth (DMFT)". The WHO goal was to achieve "3 or less DMFT" among 12 year old children" by the year 2000. According to estimates, 70% of the countries, representing 85% of the world population had achieved this goal by 2001; however, several developing countries have reported a trend towards higher level of dental caries. Another parameter for measuring the load of caries is "Significant caries (SiC)" index. Dental caries is a multifactorial disease. "Tug back" or a feeling of resistance when the explorer was moved on the tooth surface led to an almost confirmed diagnosis of caries. Treatment of dental caries as per Black's "Extension for prevention" necessitated considerable loss of tooth substance beyond the actual carious lesion. It can be prevented by proper brushing, Diet, Flossing, fluorides (Systemic or topical), sealant, antimicrobials like chlorhexidine gluconate 0.2 or 0.12%. The possibility of creating a polyvalent vaccine effective against caries, as well

as measles, poliomyelitis and other serious infections is under consideration.

Periodontal Diseases are the inflammatory diseases, viz., gingivitis and periodontitis and are quite common. While caries has been linked strongly with only a few organisms, the development of gingivitis appears to be caused by nonspecific bacterial plaque flora, which changes over time from predominantly gram positive to more gram negative. In gingivitis the gums become spongy, red, swollen, bleed when brushed or touched, stand away from teeth, often causing little pain and discomfort. Gingivitis therefore is often neglected until it has reached an advanced stage. Gingivitis does not necessarily develop into periodontitis. However, periodontitis is always preceded by gingivitis. The disease can spread to involve deeper supporting tissues viz. periodontal ligament, cementum and alveolar bone. At present, the prevention of periodontitis is based on mechanical removal of plaque, plus antimicrobial and antiseptic mouthwashes, if necessary. Moderate or advanced periodontitis can be treated by elimination of bacterial infection and establishment of effective plaque control. It has been conclusively demonstrated that the large majority of periodontal problems can be treated using non-surgical, conservative approaches. In the recent past, dental implants have been successfully used for replacing missing teeth without unnecessarily damaging adjacent tissues or compromising function.

Oral submucous fibrosis (OSMF) is always associated with a subepithelial inflammatory reaction followed by fibroelastic changes of the lamina propria, accompanied by epithelial atrophy. Various factors have been implicated in the development of OSF, the most common of which is chewing areca nut. Associations with tobacco use and vitamin deficiency have also been reported. Symptoms of OSF include Trismus, pain and a burning sensation upon consumption of spicy food stuffs, increased salivation, change of gustatory sensation, hearing loss, dryness of the mouth, nasal tonality to the voice, dysphagia to solids, impaired mouth movements. The medical management in moderate cases involves Cessation of the habit followed by use of Steroids, Placental extracts, Hyaluronidase. Surgical management in severe cases include excision of the fibrous bands, buccal pad of fat grafting or Split-thickness skin grafting following bilateral coronoidectomy.

Aphthous Stomatitis is associated with stress, nutritional deficiencies and malabsorption syndrome. Lichen Planus is a common oral mucosal disease of unknown etiology, which often occurs without simultaneous skin lesions. In the ulcerated form, the disease often presents significant therapeutic problems. The common oral conditions reported to occur in HIV infected patients are Candidiasis; Erythematous, hyperplastic, pseudomembranous hairy leukoplakia; HIV - gingivitis; HIV - Necrotizing gingivitis; HIV - Periodontitis; Kaposi's sarcoma; and, Non Hodgkin's Lymphomas.

Brushing teeth after every meal, at least twice daily, Stopping deleterious habits like chewing tobacco, pan masala, etc. and smoking, Visiting dentist at least after every six months for regular check ups are the most important preventive measures for Oral and Dental Diseases.

Ashok K Verma

Rheumatic fever is a febrile disease affecting connective tissues particularly in the heart and joints initiated by infection of the throat by group A beta haemolytic streptococci. Rheumatic fever often leads to Rheumatic Heart Disease (RHD), which is a crippling disease.

RF and RHD remain significant causes of cardiovascular diseases in the world today. Despite a documented decrease in the incidence of acute RF and a similar documented decrease in the prevalence of RHD in industrialized countries during the past five decades, nonsuppurative cardiovascular sequel of group A streptococcal pharyngitis remain medical and public health problems in both developed and developing countries even at the beginning of the 21st century. The most devastating effects are on children and young adults in their most productive years (1-6).

Magnitude of the Problem

The reported prevalence rates among school-age children in various parts of the world range from very low of about 0.2 per 1000 in Havana to as high as 77.8 cases per 1000 in Samoa (7). It has been estimated that RF is the most common cause of heart disease in the 5-30 year age group throughout the world. Based on hospital data, RHD accounts for 12-65 percent of hospital admissions related to cardiovascular disease.

Epidemiological Factors

Agent Factors : Rheumatic Fever (RF) and Rheumatic Heart Disease (RHD) are nonsuppurative complications of Group A streptococcal pharyngitis due to a delayed immune response (8,9). All strains of Group A streptococci are not implicated in causation of Rheumatic Fever but the serotype which has attracted the most attention in M type 5(10).

Carriers of Group A streptococci are responsible for the subclinical infections in the community. These carriers can be convalescent, transient and chronic. The carrier stages make the disease difficult for eradication (11).

Host Factors : The host factors are as follows :

- Age- Rheumatic Fever is commonly a disease of childhood and adolescent age group (5-15 years).
- Sex-Affects both sexes equally.

Environmental Factors : Rheumatic fever is more commonly seen among individuals of low socio-economic status. Poverty, overcrowding and poor ventilation/housing conditions are important precipitating factors.

Clinical Features

Fever and polyarthrititis are the cardinal features of Rheumatic Fever. Fever is normally acute in onset lasting for 12 weeks or longer. Large joints like ankles, knees, elbows and wrists are more commonly involved than smaller joints. Carditis occurs in 60-70% of cases, which manifests clinically in the form of cardiac murmurs, pericarditis, myocarditis, endocarditis, heart enlargement and heart failure. First degree AV block is the most common ECG finding.

Appearance of small, painless and non tender subcutaneous nodules 4 weeks after onset of Rheumatic Fever may also be seen. These are self limiting and disappear with no residual damage. Other clinical features could be skin rashes and chorea.

Diagnosis

The 2002-2003 WHO criteria (Table - 1) (7) for the diagnosis of RF and RHD are based on revised Jones criteria and facilitate the diagnosis of :

- A primary episode of RF.
- Recurrent attacks of RF in patients without RHD.
- Recurrent attacks of RF in patients with RHD.

Table - 1 : The diagnostic criteria	
Primary episode of RF	Two major* or one major and two minor** manifestations <i>plus</i> evidence of a preceding group A streptococcal infection***
Recurrent attack of RF in a patient without established rheumatic heart disease	Two major or one major and two minor manifestations <i>plus</i> . evidence of a preceding group A streptococcal infection.
Recurrent attack of RF in a patient with established rheumatic heart disease	Two minor manifestations <i>plus</i> evidence of a preceding group A. Streptococcal infection. c
*Major manifestations	Carditis
	Polyarthrititis
	Chorea
	Erythema marginatum
	Subcutaneous nodules
**Minor manifestations	Fever, polyarthralgia
	Laboratory; elevated acute phase reactants (erythrocyte sedimentation rate or leukocyte count).
***Supporting evidence of a preceding streptococcal infection within the last 45 days	Prolonged P-R interval
	Elevated or rising antistreptolysin-O or other streptococcal antibody OR
	A positive throat culture OR
	Rapid antigen test for group A streptococci OR
	Recent scarlet fever.

Prevention of Rheumatic Fever and Rheumatic Heart Disease

Primary Prevention : The primary prevention of Rheumatic Fever (RF) is defined as the adequate antibiotic therapy of group A streptococcal Upper Respiratory Tract (URT) infections to prevent an initial attack of acute RF (12, 13, 14, 15). Primary prevention is administered only when there is group A streptococcal URT infection while approach is theoretically

simple, but it may not be practically feasible. In order to prevent a single case of RHD, several thousand cases of streptococcal throat infection will need to be identified and treated.

A more practical and viable approach is to concentrate on “high risk” group such as school children and to treat a sore throat with penicillin empirically even without the throat swab culture. The recommended treatment regimes for streptococcal pharyngitis for primary prevention of Rheumatic Fever are as given in Table - 2.

Secondary Prevention : Secondary prevention of Rheumatic Fever (RF) is defined as the continuous administration of specific antibiotics to patients with a previous attack of RF, or a well-documented Rheumatic Heart Disease (RHD). The purpose is to prevent colonization or infection of the Upper Respiratory Tract (URT) with group A beta-hemolytic streptococci and the development of recurrent attacks of RF. Secondary prophylaxis is mandatory for all patients, who have had an attack of RF, whether or not they have residual rheumatic valvular heart disease.

The antibiotics used in secondary prophylaxis of Rheumatic

Fever are as given in Table - 3.

Other Preventive Measures : Non-medical measures for the prevention/control of RF are related to improving living conditions, and breaking the poverty-disease-poverty cycle. Improvements in socio-economic conditions (particularly better housing) will in the long term reduce the incidence of RF.

Planning and Implementation of National Programme for the Prevention and Control of Rheumatic Fever and RHD

The establishment of a national prevention programme is essential in countries where Rheumatic Fever (RF) and Rheumatic Heart Disease (RHD) remain significant health problems. Both primary and secondary prevention of RF and RHD have been proven to be safe, feasible and effective in both developed and developing countries. The overall goal of a national programme should be to reduce morbidity, disabilities and mortality from RF and RHD.

The main components of a national programme would be :

- (a) Secondary prevention activities aimed at preventing the

Table - 2 : Treatment regimes for streptococcal pharyngitis for primary prevention of Rheumatic Fever

Antibiotic	Administration	Dose	Comments
Benzathine Benzylpenicillin	Single intramuscular injection	1200 000 units intramuscularly; 600000 units for children weighing <27kg.	Preferable to oral penicillin G because of patient adherence problems.
Phenoxymethyl penicillin (Penicillin V)	Orally 2-4times/day for 10 full days	Children: 250mg bid or tid. Adolescents or adults:250mg tid or qid, or 500mg bid	Penicillin G resistance by group A streptococci has never been reported.
Amoxicillin	Orally 2-3 times/day for 10 full days	25-50mg/kg/day in three doses. Total adult dose is 750-1500mg/day.	Acceptable alternative to oral penicillin G because of the taste.
First-generation Cephalosporins	Orally 2-3 times/day for 10 full days	Varies with agent	Acceptable alternative for oral penicillin.
Erythromycin Ethylsuccinate	Orally 4 times/day for 10 full days	Varies with formulation. Available as the stearate, ethylsuccinate, estolate or base.	Alternative drug for patients allergic to penicillin. Should not be used in areas where group A streptococci have high rates of macrolide resistance.

Table - 3 : Antibiotics used in secondary prophylaxis of Rheumatic Fever

Antibiotic	Mode of administration	Dose
Benzathine Benzylpenicillin	Single intramuscular Injection every 3-4 weeks	For adults and children >30kg in weight: 1200000 units. For children<30kg in weight: 600 000 units.
Penicillin V	Oral	250mg twice daily. For adults and children >30kg in weight
Sulfonamide (e.g. sulfadiazine sulfadoxine, sulfisoazole)	Oral	1 gram daily
Erythromycin	Oral	For children <30kg in weight: 500mg daily. 250mg twice daily

- recurrence of acute RF and severe RHD;
- (b) Primary prevention activities aimed at preventing the first attack of acute RF;
 - (c) Health education activities;
 - (d) Training of health-care providers;
 - (e) Epidemiological surveillance;
 - (f) Community involvement.

Although proven inexpensive cost-effective strategies for the prevention and control of streptococcal infections and their non-suppurative sequelae, acute Rheumatic Fever and Rheumatic Heart Disease, are available, these diseases remain significant public health problems in the world today, particularly in developing countries.

Primary prevention of Rheumatic Fever consists of the effective treatment of group A beta-hemolytic streptococcal pharyngitis, with the goal of preventing the first attack of Rheumatic Fever. While it is not always feasible to implement broad-based primary prevention programs in most developing countries, a provision for the prompt diagnosis and effective therapy of streptococcal pharyngitis should be integrated into the existing healthcare facilities.

Definition

'Occupational health should aim at the promotion and maintenance of the highest degree of physical, mental and social well being of workers in all occupations; the prevention amongst workers of departures from health caused by their working conditions; the protection of workers in their employment from risks resulting from factors adverse to health; placing and maintenance of the worker in an occupational environment adapted to his physiological and psychological equipment and to summarize : the adaptation of work to man and of each man to his job'.

- Joint Committee of WHO and ILO, 1950

Health Hazards in Industry

Hazards in the industry can be due to physical, chemical, biological, mechanical and psychosocial causes. Table - 1 gives

the physical hazards and their adverse health effects due to them.

Chemical Hazards : Almost all the occupations in industry have scope of exposure to some chemical substance or the other. These substances may be solids, liquids or gases, vapours, fumes, dusts, smoke, mist, fog or smogs.

Biological Hazards : Viruses, rickettsiae, bacteria, fungi, protozoa and helminthes may be transmitted in certain occupations.

Mechanical Hazards : Mechanical factors of importance in illness and injury in industry are defective design of machinery, defective procedures, unguarded machinery, protruding and moving parts, falling heavy objects and poor ergonomics.

Psychosocial Hazards : Factors responsible for psychosocial illness are frustration due to type of work, risks involved in work, monotony, long working hours, lack of recognition, lack of job satisfaction, poor remuneration, poor man management, lack of welfare activities and tensions at home and place of work. The indicators for psychosocial group of are chronic absenteeism, mass leave lock outs, strikes and unexplained reduction in production.

Table - 1 : Physical Hazards in an industry

Hazard	Occupation	Health Effects
Heat	Foundry, glass, heavy metal industries, underground mines, vulcanization of rubber, spinning room of textile industry	Heat stroke, heat hyperpyrexia, heat exhaustion, heat syncope, heat cramps
Cold	Armed forces, food processing and preservation industry	Chill blains, frost bite, trench foot, erythrocyanosis
Light	Mines, driving	Eye strain, eye fatigue, nystagmus, headache
Noise	Machinery in factories producing loud noise	<i>Auditory</i> : Auditory fatigue, permanent hearing loss; <i>Non auditory</i> : Nervousness, fatigue, decreased efficacy, annoyance, raised blood pressure, loss of sleep
Vibration	Pneumatic drill users	Vibration induced white fingers due to Raynaud's phenomenon, osteoarthritis of wrists, elbows, shoulders.
UV radiation	Arc welding	Glare and dazzle, pain and gritty feeling in the eyes
Ionizing radiation	Radiography, radioisotope use, processing of plastics, food preservation, industrial radiography, industrial hydrology, chemical industry and medical research	Cancer, leukemia, aplastic anemia, pancytopenia

Ashok K. Jindal & Puja Dudeja

Health Hazards in Foundry Work

Founding consists of pouring molten metal into a mould which is made to the outside shape of a pattern of the article required and contains, in some case a core which will determine the dimensions of any internal cavity. The basic principles of foundry work have hardly changed over the years though a lot of modernization has come, making plants more mechanized and automatic. Molten metal is introduced into the mould. After cooling occurs, the mould is subjected to a 'shakeout' procedure, which releases the casting and removes the core. The casting is then cleaned and any extraneous metal is removed from it.

Process

The various processes involved in foundries include Moulding & pattern making, Core making, Melting & pouring, Shakeout (Knockout) and Dressing & cleaning.

The various process outlined in the preceding section give rise to heat, molten metal splashes, dusts, noise, gases and vapours in the foundry environment. If these hazards are not controlled or contained, serious health effects in exposed workers can result. Foundry work also involves various manual operations which carry a risk of physical injury. The occupational health and safety issues are encountered during foundry activities include Physical hazards, Radiation hazards, Respiratory hazards, Electrical hazards, Noise exposure, Burial hazards, and Fire & explosions. The common and important ones are as follows :

Silicosis : Silica dust presents a prominent hazard of silicosis. This dust is generated during mixing, moulding, shakeout and dressing operations, and during sand conditioning for re - use. The dust arises from quartz in the sand, and the concentration of free silica in the air varies with the handling process, the efficiency of dust control, the chemical composition of the sand and the physical state of the sand, that is, whether the sand is screened or un-screened, wet or dry and is either dumped or re-milled, with water and binder added before it is re - used. The amount of respirable dust is increased by such re - use. Sand is dry at the mixing or 'mulling stage prior to mould making', and at the shakeout stage; this dry sand is potentially more hazardous than wet sand. Screened sand does not produce as much silica dust as un-screened sand and pure quartz sand is more hazardous than olivine sand. Abrasive blasting processes may involve the use of sand containing high concentrations of free silica.

Irritation, Allergy, Asthma, Metal Fume Fever, Malignancy:

In addition to dusts, the air in foundries may contain the potential irritants like formaldehyde, various amines and phenol. These contaminants are generated primarily by the core making and moulding processes, and may irritate the eyes and the respiratory tract. Some hardwoods used in

pattern making can release products which may cause asthma in exposed workers. Vapours from various resins can initiate severe allergic reactions. Carbon monoxide gas is produced in substantial amounts by a variety of furnaces. Exposure to concentrations of 500 to 1000 ppm for approximately 30 minutes may precipitate headache, accelerated breathing, nausea, dizziness and mental confusion. Thus a possible secondary effect of exposure is an increased risk of accident and injury to the worker. Various metal fumes may be generated during founding processes, especially during melting and pouring operations. Lead, magnesium, zinc, copper, aluminum, cadmium, antimony, tin and beryllium fumes are commonly present in non - ferrous foundries. Iron oxide is the major fume generated in iron and steel operations. 'Metal fume fever' may result from exposure to these contaminants. This is an acute illness of short duration which commences some hours after inhalation of the metallic fumes. The initial symptoms are flu - like; nausea, headache, dry throat and coughing, and muscular pains, chills and sweating may occur later. Recovery is usual within 24 hours after removal from exposure. The lead hazard in furnace cleaning, dross disposal and the fettling of lead alloys deserves particular attention. Besides dusts & fumes in foundries are known to have carcinogenic properties.

Occupational Dermatitis : Formaldehyde, isocyanates, various resin products associated with pattern making and core making processes can irritate the skin and may precipitate allergic skin reactions.

Noise Induced Hearing Loss and Related Effects : The foundry process generates noise from various sources, including scrap handling, furnace charging and EAF melting, fuel burners, shakeout and mould / core shooting, and transportation and ventilation systems. Some fettling workers have been shown to be exposed to levels of noise over 100 db; shakeout and knockout processes are typically associated with readings of 90 - 110 db. Mechanical sand mixing processes and forced draught furnaces may produce noise levels of 90 - 100 db. Extraction fans, die - casting machines, core - making and shell - making equipment may also be sources of excessive noise.

Vibration : Pneumatic grinding and chipping tools used in dressing the cooled castings may cause vibration induced health effects in operators. Hazardous vibration equipment may also be utilized in shakeout and core removal operations.

Heat and Heat Stress : Radiant heat is the major contributor to the heat load imposed on the worker by the environment. Convective heat transfer adds to this radiant heat. Protective clothing is worn for protection against the heat radiating from the heat sources and against contact with molten metals. Such clothing greatly restricts the potential for body heat loss via evaporation. The effects of heat range from decreased concentration to painful cramps, fainting, heat exhaustion and heatstroke. Heat stress can also aggravate the effects of exposure to other agents such as noise and carbon monoxide.

Accidents & Injuries : Serious burns may result from splashes of molten metal in the melting and pouring areas of foundries. Frequent, unprotected viewing of white - hot metals in furnaces and pouring areas may cause eye cataracts. Eye injuries from molten metal or fragments of metal may occur in pouring and

dressing areas, during continuous casting processes, non-ferrous molten metals, such as copper and aluminum, may explode violently if they contact water. Injuries related to the manual handling of materials, and injuries due to falls, may occur. Grinding wheels used for dressing small articles may result in hand injuries.

Preventive Measures

Monitoring & Evaluation of Exposure : Monitoring of the work environment, personal monitoring and biological monitoring should be undertaken. In some cases, biological monitoring may be required to supplement static or personal monitoring. When developing a monitoring programme in foundries, due consideration should be given to the hazards in the foundry. In the control of health hazards due to specific contaminant, where it has been demonstrated that the exposure of the employee to the contaminant is approaching the relevant exposure standard, or where biological monitoring indicates that an unacceptable exposure is occurring, immediate action must be taken to reduce the health hazard and intensive monitoring should continue. Worker exposure to dusts, gases and vapours should be kept as low as workable. Exposures should be well below the exposure standards recommended in the Factories Act 1948.

Engineering Control Measures

- (a) **Elimination/substitution and process modification** viz. quartz sand can be substituted by olivine sand in 'sand blasting' as it is less hazardous. Silica-based polishing pastes should not be used in metal cleaning operations.
- (b) **Engineering controls** like local exhaust ventilation should be provided at the mixing or mulling stage as the sand is dry. It is a means of controlling carbon monoxide emissions at their source. Total enclosure of abrasive and cleaning operations should be provided. Potentially irritant vapours or fumes generated in core making or moulding processes should be collected by exhaust ventilation at the point of emission.
- (c) The **reduction of noise at the source** or in the transmission path should be achieved wherever workable.

Preventing Physical Injuries

- (a) **Mechanically propelled vehicles or machinery** should be inspected regularly. Contact between molten metal and water must be avoided. All ladles and other equipment used for handling metal should be completely dry before contacting molten metal.
- (b) **Good house keeping practices** are to be followed.
- (c) **Floors around furnaces** should be of slip-resistant, non-combustible material, kept free of obstructions and cleaned regularly.
- (d) Persons would be prohibited from **entering furnace areas** when the temperature exceeds 50°C.
- (e) Foundries should be **equipped with safety blankets, automatic emergency showers or hoses** to extinguish burning clothing.
- (f) **Self-contained breathing apparatus** must be used in emergencies when high carbon monoxide concentrations are suspected.

Minimizing the Risk of Heat Illness : People who have any history of heat intolerance or a circulatory disorder, anyone

recovering from a fever, and any dehydrated worker must be regarded as being in a high-risk category for heat illness. Unacclimatised persons must be given time to acclimatize to work in the heat. Planned job rotation can assist in reducing exposure to heat. Cool water should always be available in close proximity to hot working areas and encouragement be given for the use of these facilities. The exposure of workers to radiant heat can be reduced by the strategic positioning of shields between workstations and heat sources. Clothing should be carefully selected so that a balance between protection and facilitation of heat loss through evaporation is achieved.

Personal Protective Equipment : Personal protective equipment such as goggles, padded gloves, ear muffs must be used by the workers. If the mechanical ventilation in the foundry is not adequate in removing the dust at all points of contamination, the wearing of personal respiratory protective equipment, such as a face mask/respirator, is a complementary preventive measure together with local exhaust ventilation. If operators are required to work inside the enclosure, a continuous-flow, air-line respirator must be worn.

Education and Training : All employees working with foundry hazards must be informed of the hazards and the precautions necessary to prevent damage to their health. Employees exposed to contamination hazards should be educated in the need for, and proper use of, facilities, clothing and equipment and thereby maintain a high standard of personal cleanliness.

Health Assessment : Pre-placement examination and periodic medical examination of all worker should be done annually for early identification of health effects and for documentation for compensation claims.

Noise Management Techniques :

- Enclose the process buildings and / or insulate them
- Cover and enclose scrap storage and handling areas, as well as shake out and fettling processes
- Enclose fans, insulate ventilation pipes and use dampers
- Implement management controls, including limitation of scrap handling and transport during night time. Noise abatement measures should achieve the ambient noise levels

Health Problems of Agricultural Workers

Agriculture is art/practice of cultivating land. WHO defines it as an industry comprising of all forms of activities connected with growing, harvesting and primary processing of all types of crops. It also includes activities related to breeding, raising caring for animals in the farms and tending gardens and nurseries. Any person engaged either temporarily/ permanent in activities related to agriculture is called as agricultural labour. Agricultural sector occupies a key position in our country. It provides employment to about 65 per cent of the working population of India (5). It is the major source of income for about three-fourths of India's populations who live in villages. Agricultural workers constitute by far the largest segment in the unorganized sector. Most of them are listed as cultivators (large, medium and small) of whom approximately 50% belong to the category of small and marginal farmers. A significant number of them are engaged in livestock, forestry, fishing, orchards and allied activities. Agricultural workers constitute

the most neglected class in Indian rural structure. Their income is low and irregular. They do not possess any skill or training and have no alternative employment opportunities. Socially, a large number of agricultural workers belong to scheduled castes and scheduled tribes. Therefore, they are a suppressed class. They are not organized and they cannot fight for their rights (6). Occupational hazards of agriculture sector are given in Table - 1 (7).

The various types of respiratory diseases in agriculture are highlighted in Table - 2.

Agent	Disease
Saw dust	Carcinoma nasal septum
Sugar cane dust	Bagassosis
Cotton, flax, sisal or hemp	Byssinosis
Husk with thermophilic actinomycis (<i>Micropolyspora faeni</i>)	Farmer's lung
Tobacco dust	Tobaccosis
Dusts of grains, rice, coconut fibres, tea	Asthama, COPD
Cocoa bean handling	Respiratory allergy

Others : Agriculture being labour intensive activity musculo - skeletal disorders are the leading cause of the occupational ill health (8). This risk of musculo - skeletal disorders is higher in agricultural workers because of the longer working hours, practice of lifting heavy weights and inconvenient work posture. There is poor application of ergonomics principle to agricultural tools. There are no legislations related to health, safety and welfare of agricultural workers. There is no social security for agricultural workers other than crop insurance. There is no act to provide welfare to the workers. Living condition of these people, low educational status, lack of medical facilities in rural areas aggravate there problems. Being in close proximity to animals agricultural labour also faces hazards of zoonosis.

Women in Agriculture

Women in India are the major work force in agriculture and perform almost all the agricultural activities. Since agriculture by its nature is an unorganized sector and in case of women, their contribution is generally unrecognized. In fact some economist have use the term 'Labour for Love' while describing the status of Indian women who is married with farmer'. A significant proportion of women work force in rural areas is dependent for their livelihood (8). The lives of these women are plagued by high levels of occupational, poverty - induced diseases and reproductive health problems. Abortions, premature delivery, and still birth are outcomes of their deprived socio - economic,

Exposure	Health Effect	Remarks
Weather, Climate	Dehydration, heat cramps, heat exhaustion, heat stroke, skin cancer	Most agriculture occupations are performed outdoors
Snakes, insects	Fatal or injurious bites and stings	Close proximity in high incidence
Sharp tools, farm equipment	Injuries ranging from cuts to fatalities, hearing impairment from loud machinery	Most farm operations require variety of skills for which workers have little formal training and there are few hazard controls on tool equipment
Physical labour carrying loads	Numerous types of (largely unreported) musculoskeletal disorders, particularly soft - tissue disorders, e.g. back pain	Agricultural work involves awkward and uncomfortable conditions and sustained carrying of excessive loads
Pesticides	Acute poisonings, chronic effects such as neurotoxicity, reproductive effects and cancer	More hazardous products are used in developing countries with minimal Personal Protective Equipment (PPE)
Dusts, fumes, gases, particulates	Irritation of the eyes and respiratory tract, allergic reactions, respiratory diseases such as Byssinosis, bagassosis, asthma, chronic obstructive pulmonary disease and hypersensitivity pneumonitis	Agricultural workers are exposed to a wide range of dusts and gases from decomposition of organic materials in environments with few exposure controls and limited use of PPE use in hot climates.
Biological agents and vectors of disease	Skin diseases such as fungal infections, allergic reactions and dermatoses	Workers are in direct contact with environmental pathogens, fungi, infected animals and allergenic plants
	Parasitic diseases such as schistosomiasis, malaria, sleeping sickness, leishmaniasis, ascariasis and hookworm	Workers are in direct contact with environmental pathogens, fungi, infected animals and allergenic plants
	Animal - related diseases or zoonoses such as anthrax, bovine tuberculosis and rabies (at least 40 of the 250 zoonoses are occupational diseases in agriculture)	Workers have ongoing, close contact with animals through raising, sheltering, and slaughtering exposed to a mix of biological agents, pesticides, and diesel fumes, all linked with cancer

cultural, and political conditions and gender inequities (9). The socio - cultural norms and practices that endanger the women's health are reflected in their low age at marriage and low age at first childbirth. Women working in fields shoulder the double burden of work - within home and outside home - and stretch themselves beyond their physical capabilities to procure adequate economic security for their families. They bear the brunt of the deprivation due to the gender inequities. The low nourishment and the resultant general under - nourishment lead to illnesses, which prevent them from translating their labour endowments into economic resources. In short, the poverty of the women agricultural workers encompasses a wide range of unmet needs and gender - specific inequities including lack of adequate access to education, employment, resources as well a range of violence, relative powerlessness, and feelings of hurt, low self - esteem and denial of identity.

Legislations

Though agriculture is the major occupation in India and gives not only employment but is also responsible for providing food security to the nation but unfortunately only lip service has been paid in providing social security for the welfare of the workers engaged in this class. As a result they can go into penury due to floods, droughts, extensive loans under taken

from money lenders to buy costly fertilizers and pesticides. The general public health system of the country is also in a poor state and has very little to offer as preventive, promotive and curative care to this class. This is evident from the large number of suicides that have taken place among farmers. There is a definite need to take case for social security for this sector. In this connection government has come out with National Policy for Farmers 2007(10). The objective of the policy is to improve the economic viability of farming through substantially improving net income of farmers. The policy emphasis on increased productivity, profitability, institutional support, and improvement of land, water and support services apart from provisions of appropriate price policy, risk mitigation measures and so on. Government of India has recently taken several initiatives such as the National Horticulture Mission, the National Bamboo Mission, reforms in agricultural marketing, the revitalization of cooperative credit structure and setting up of the National Fisheries Development Board and the National Rainfed Area Authority. More recently, the National Food Security Mission and the *Rashtriya Krishi Vikas Yojana* (Additional Central Assistance Scheme) have been approved to substantially enhance investment in agriculture and increase production and productivity.

Organ / System Diseases Peculiar to Occupational Settings

Leo S Vaz, Ashok K. Jindal & Puja Dudeja

Occupational Lung Disease

An occupational lung disease is a lung condition that develops as a result of a person inhaling harmful substances at his or her place of work. Occupational lung diseases are the most common work - related illness but fortunately many are preventable or controllable with proper treatment. Occupational lung diseases are classified into two major groups : pneumoconiosis, caused by dust that gets into the lungs, and hypersensitivity diseases, such as asthma, that are caused by the lungs' overreaction to airborne pollutants. Table - 1 depicts important features of various lung diseases.

Pneumoconiosis

By ILO definition it is the accumulation of dust in the lung and tissue reaction to its presence. The concept of using the term pneumoconiosis has undergone a change. Earlier this term was used to describe all lung related problems caused by any kind of dust (17). However the term should be used

for all dust damage to the alveolar part of lung including the airways which do not have mucociliary lining (18). Therefore the term does not include bronchitis, asthma or cancers. In other words the inorganic dusts like silica, asbestos and coal cause pneumoconiosis where as organic dust like cotton and cane sugar cause bronchitic changes and do not qualify to be called pneumoconiosis.

Body Defence Mechanism : Dust is an aerosol consisting of finely divided particulate matter, size 1μ - 150μ , organic or inorganic, generally inanimate and produced by attrition of solid matter by processes such as cutting, sawing, crushing, grinding, blasting etc. Dust particles 10μ or more in size are released in size settle down on the floor due to effect of gravity. The dust particles of such larger size which are inhaled are mostly arrested by the upper airway filter of hairs in the nostrils and by the folds of mucosa over the turbinates and carried down in the mucus and swallowed over airway filter, carried in the mucus back to the larynx and swallowed. Irritant particles are thrown out by reflex acts of coughing and sneezing. Of smaller particles those are inhaled in size of $3 - 10\mu$ are tackled by the mucociliary lining of lower airway, filter, carried in the mucus back to the larynx and are swallowed. Particles $0.5\mu - 3\mu$ in size reaches the alveoli and get deposited causing damage to the lungs, producing various types of pneumoconiosis. Particles less than 0.5μ in size have a slim chance of settling down in

	Silicosis	Anthracosis	Asbestosis	Byssinosis	Bagassosis	Farmers' lung	Siderosis
Type	Major	Major	Major	Major	Major	Major	Major
Occupational exposure	Silica dust mines, tunnels : quarries, foundries; potteries and soap	Coal miners and handlers : carbon electrode manufacturing	Asbestos industry; brake and fire resistant product manufacturing	Exposure to cotton dust released during cording, spinning and weaving	Fibrous residue of sugar cane in cardboard and paper industry	Agricultural workers	Foundry workers, grinders and welders
Initiating stimulus	Chemical	Unknown	Mechanical	Allergy	Infection	Infection	Absent
Pathogenesis	Fibrosis initiated by silicic acid leading to nodular fibrosis, emphysema and right heart failure. Pulmonary TB in 50% cases	Two distinct stages - simple CWP and PMF. Average time taken is 12 years	Asbestos fibres initiate fibrosis of pulmonary tissue, emphysema and its associated complication	Cotton dust inhalation produces allergic reaction leading to broncho - spasm, emphysema and its complications	Fungal infection leading to acute bronchitis and broncho - pneumonia	Fungal infection leading to bronchitis and broncho - pneumonia	No tissue reaction or functional impairment though lungs are loaded with iron dust.

the lungs and are mostly breathed out in the expiratory air.

Silicosis : Silicosis is a disease caused by breathing air containing silica in its free state, as quartz (SiO₂). The pathological result is a generalized fibrotic change and development of miliary nodules of variable sizes in both lungs. The clinical manifestations are shortness of breath, decreased chest expansion, a lessened capacity for work and chronic bronchitis with the absence of fever and characteristic X - ray findings. There is an increased susceptibility to tuberculosis. The diagnosis of the disease mainly depends upon occupational history symptom complex and the radiological findings. The pathological process starts only when the dust particles, which contain silica in a free state such as quartz (SiO₂), reach the alveoli. Most of the dust inhaled is expelled by the ciliated epithelium and some part is eliminated by phagocytosis, which brings up the particles and discharges them to the ciliated epithelium and the cough mechanism expels them. However, when the fine particles are present in the atmosphere in a large quantity, some find way to the finer air passages. They first cause the inflammation of the ciliated epithelial cells with their subsequent destruction, reducing the first line of defense. Epithelial cells crowded with silica dust get aggregated into definite clumps around which fibrosis occurs. This damage produced in the lung is permanent. It is liable to activate the preexisting tubercular focus and develop tuberculosis. The disease finally produces emphysema and corpulmonale.

Very little can be done once the disease has set in and therefore, prevention is most important, pre - placement & periodic health examinations of the worker are important. Chest X Ray is to

be taken to see if the individual has pulmonary tuberculosis or any other lung disease. Basic lung function tests should be carried out, including measurement of the Vital Capacity & Forced Expiratory Volume in one second. Dust control is the most important engineering procedure to reduce risk. If a significant number of workers develop silicosis within 20 - 25 years of first employment, the dust control measures should be suitably revised.

Asbestosis : Asbestos is a fibrous material. These are silicates; silica combined with bases like magnesium, iron, calcium, sodium and aluminum. These are of two types - serpentine and amphibole. However, 90% of production is of serpentine variety. Asbestos used in the manufacture of asbestos cement, fireproof textiles, roof tiling, brake lining, gaskets, and such other items. Asbestos fibres are inhaled and fine dust gets deposited in the alveoli. These are insoluble and cause chronic irritation resulting in pulmonary fibrosis of lungs. It can also cause carcinoma of bronchus and mesothelioma of pleura and peritoneum (more due to amphibole variety). These possibilities are more when exposure is coupled with smoking. The disease appears after an exposure of 5 to 10 years. The fibrosis is peribronchial, diffuse and more near the bases in contrast to fibrosis due to silicosis. Clinically, patient gets cough, pain in chest and dyspnoea disproportionate to the clinical signs in lungs. In advanced cases, there may be clubbing of fingers, cardiac failure and cyanosis. Sputum show asbestos fibres coated with fibrin called "asbestos bodies". X - ray chest shows a ground glass appearance in lower parts of lungs. Disease is progressive even after removal from exposure. Preventive

measures include :

- Adopt all measures for dust control. The legal exposure limit in India is 23 fibres/ml of air. Fig.-1 shows various methods of dust control.
- Substitute it with safer materials like glass fibres, calcium silicate, plastic foam etc. where feasible.
- Use safer varieties of asbestos (chrysotile and amosite).
- Periodic medical examination of workers and elimination of susceptible from workforce.
- Use of personal protective measures.
- Good housekeeping & the use of vacuum cleaners.
- Use of respirators & protective clothing is to be encouraged.
- Health education of the workers.
- Continuing research to find out safer substitutes (19-24).

Anthracosis or Coal Worker's Pneumoconiosis : (Synonyms: Anthracosis, Coalminer's consumption, phthisis melanotica, black spit). The diseases due to inhalation of dust in coal mines are simple coal - worker's pneumoconiosis (CWP) and complicated coal - worker's pneumoconiosis. Simple CWP is due to chronic exposure to coal dust with a low level of other mineral dust contamination. In this condition, the progression of small rounded opacities may be associated with only a slight loss of ventilation, which is insufficient to produce any disability. It can be very difficult to differentiate these effects from those of aging and cigarette smoking. Complicated CWP is one in which CWP is complicated by the additional pathology of large masses of solid tissue within the lung parenchyma. The condition usually occurs after 20 - 30 years in the occupation.

It is associated with breathlessness, clubbing, bronchitis, emphysema and right heart failure. This condition may be due to quartz, coal mine dust plus rheumatoid arthritis (as seen by Dr. A Caplan in 1953 in New South Wales Coal mines). Progressive massive fibrosis is characterized by formation of a mass 3 - 10 cm or more in length in the lung tissue and lying parallel to the pleura : this may cavitate after many years releasing large quantities of black necrotic tissue and dust which is coughed out as an expectorant resembling black ink (melanoptysis). Control measures centre on dust control and early detection of the disease.

In X - rays, 3 stages are seen in simple CWP **First stage** - Generalized mottling of the lung through which exaggerated lung markings are seen. **Second stage** - Mottling becomes very dense and exaggerated lung marking cannot be seen through them. **Third stage** - Very dense reticulated opacities seen all over the lung. The reticular markings indicate coal dust foci around the tips of the bronchioles. A person suffering from silicosis is both breathless and ill but a person with CWP is breathless but does not look ill. It has been seen that there is a negligible risk of developing CWP over a working lifetime with a dust level below 2mg/cu.m. The basic lesion of CWP is the local macule. Air spaces adjacent to the macule get enlarged, consistent with focal emphysema. A small percentage of miners develop complicated CWP or PMF diagnosed radiologically by the appearance of a density 1 cm or greater. Recent studies suggest that superoxide anion generation by alveolar macrophages may play a role in the lung injury of CWP. The introduction of improved ventilation, water spraying

Fig. - 1 : Methods of Dust Control

and mechanized equipment has greatly reduced dust levels in the mines. Medical surveillance is the second most important measure to prevent disabling CWP.

Other Lung Diseases

Byssinosis : Bronchopulmonary diseases caused by exposure to airborne dust of cotton, flax & soft hemp leads to Byssinosis. It is a chronic respiratory disease characterized by tightness of the chest & breathlessness at work after the weekend or other absence. It is also called 'Monday Fever'. This is probably due to a histamine releasing substance. In addition to histamine release, exposure to cotton dust causes irritation in the upper respiratory tracts & bronchi, which after prolonged exposures slowly progresses to chronic obstructive pulmonary disease. In early stages there may be decline in FEV1, which may be symptomless in some workers. Within, one or two days, most symptoms tend to disappear except for irritation in the upper respiratory tract. As the disease progresses, the chest tightness is accompanied by breathlessness, the symptoms becoming worse & persisting for a longer time. In its late stages the diseases resembles chronic bronchitis & emphysema, except for the history of chest tightness & decline in ventilatory capacity, characteristically worse at the beginning of the work week. Chest X - rays do not show any specific changes. Prevention includes Pre - placement examination, which should include Chest X ray, VC and FEV1. Periodic medical examination is recommended every year. In groups of workers, a drop of more than 10% in FEV1 during the work shift on the day after the weekend holiday may provide advance warning that workers are liable to develop Byssinosis.

Occupational Asthma : Occupational asthma is a form of lung disease in which the breathing passages shrink, swell, or become inflamed or congested as a result of exposure to irritants in the workplace. Occupational asthma is a lung disorder characterized by attacks of breathing difficulty, wheezing, prolonged exhalation, and cough, which is caused by various agents found in the work place.

Hypersensitivity Pneumonitis : Hypersensitivity pneumonitis is an inflammation of the lung (usually of the very small airways) caused by the body's immune reaction to small air - borne particles. These particles can be bacteria, mould, fungi, or even inorganic. Hypersensitivity pneumonitis is usually an occupational disease in which exposure to organic dusts, fungus, or moulds leads to acute and over time, chronic lung disease.

Berylliosis : Berylliosis (or beryllium disease) is caused by the inhalation of beryllium particles, dust or fumes. Its symptoms include coughing, shortness of breath, fatigue, weight loss or loss of appetite, fever and sweating. Medical tests may reveal abnormal lung sounds, lung scars, decreased pulmonary function, granulomas (a nodular form of chronic inflammation) and an allergy to beryllium.

Occupational Cancers

Occupational cancer is any malignancy wholly or partly caused by exposures at the workplace or in occupation. Such exposure may be to a particular chemical (such as β - naphthylamine), a physical agent (such as ionising radiation or a fibre like

asbestos), a biological agent (such as hepatitis B virus), or an industrial process in which the specific carcinogen may elude precise definition (such as coke production) (13). Common occupational carcinogens include Benzidine, 2 - naphthylamine, Arsenic, Beryllium, Cadmium, Chromium, Nickel, Asbestos, Silica, Talc containing asbestiform fibres, Wood dust, Benzene, Trichloroethylene (TCE), Polychlorinated Biphenyls (PCBs) and Ethylene oxide.

Prevention

Occupational cancers have two characteristic features namely they are preventable (14) and most occupational carcinogens have first been recognized by clinicians (15).

Primary Prevention

- Recognising presence of hazards and risks
- Educating management and workforce
- Eliminating exposure by substitution and automation
- Reducing exposure by engineering controls (such as local exhaust ventilation and enclosure), changes in handling, and altering physical form in processing
- Monitoring exposure and maintaining plant
- Protecting workers by means of personal protective equipment
- Limiting access
- Providing adequate facilities for showering, washing, and changing
- Legislative provisions

Secondary Prevention : A secondary approach to prevention consists of detection at an early stage to prevent the further progression of diseases and increased survival by institution of treatment. Screening tests and medical surveillance - for example, exfoliative urinary cytology and skin inspections.

Occupational Dermatoses

An occupational dermatitis is one where the inflammatory reaction is caused entirely by occupational contact factors or where such agents are partly responsible by contributing to the reaction on compromised skin. The commonest site is hands followed by forearms. In case of airborne contact dermatitis face may be the prime site on inflammation. Contact dermatitis accounts for at least 60% of occupational skin disease, which, in turn, account for 40 - 70 % of occupationally acquired illness.

Causes

1. Physical agents : Heat, Low Humidity, High Humidity, Cold, Pressure, Vibrations, Friction (Coal Mines, Construction Workers) and Occlusion, Presence of Sharp Particles (Fibre Glass), Damage from Minor Lacerations of the Skin, Solar Radiation, Ultraviolet Radiation, Ionizing Radiation.

2. Biological Agents : Bacteria, Viruses, Fungi (Confectioners - Monilia, Sewage Workers, Doctors), Parasites (Miners and Workers in tea gardens - Ankylostomiasis).

3. Chemical Agents : These account for 70% of all occupational dermatoses and include :

- *Acids* : HCl, HNO₃, H₂SO₄
- *Alkalis* : Hydroxides, Carbonates of Sodium, Potassium and Ammonium
- *Chlorides* : Sulphuryl Chloride, Arsenic Chloride, Stannous Chloride

Some examples of substances causing occupational dermatitis are :

- Rubber accelerating chemicals, such as Thiurams and Carbamates
- Biocides - such as Formaldehyde
- Hairdressing chemicals - such as Thioglycolates, Phenylethylamine
- Epoxy resin monomers
- Chromates
- Plant allergens - such as Sesquiterpene Lactones found in Chrysanthemum

Diagnostic Criteria

1. Disease appears during a period of occupational exposure or within a reasonable period of time after the exposure ceases
2. Occurs first on the exposed part
3. Disease has not been present previously
4. Disease improves after the termination of exposure
5. Disease recurs after exposure
6. Morphology of the disease is similar to the well known cases resulting from similar exposure and other fellows with similar exposure similarly affected.

Types

Occupational dermatitis is commonly of two types Irritant contact or Allergic contact Dermatitis. Others are contact urticaria, rubber latex protein sensitivity and photo contact dermatitis.

Management

1. Detailed occupational history
2. Evaluation of contact factors
3. Patch test followed by recommendation on reducing or stopping exposure to the offending agent and similar ones.
4. Chemical analysis of environmental materials to determine whether they contain a substance to which the patient is patch test positive.

Prevention

1. Primary prevention is aimed at providing appropriate information and protection.

2. Employer and employee should be aware of the potential risks of exposure
3. Education of need for good occupational hygiene
4. Adequate provision of suitable and effective means of reducing exposure
5. Awareness of limitations of personal protection devices
6. Engineering or environmental control. Few examples are given below :
 - Substitution of mineral oil by vegetable oils
 - Segregation and mechanical handling of radioactive substances
 - Local exhaust ventilation - chromium plating
 - Good general ventilation
 - Good housekeeping - mercury and its compounds
 - Safe design of the plants
 - Provision of adequate bathing and washing facilities
 - Provision of protective clothing
 - Periodic environmental survey to ascertain TLV
 - Wet methods

7. Medical methods

(i) Pre - placement medical examination : careful and detailed history to exclude allergic tendencies such as eczema/ asthma. Such people may not be employed in occupations with sensitizers.

(ii) Standardized Patch Test

- a) Test substances appropriately diluted. Standardized kits available.
- b) Apply the patch to the upper or mid back.
- c) Leave the patch in place and keep dry for 2 days before removing.
- d) Read tests :
 - The same day that patches are removed
 - One additional reading 3, 4, or 7 days after test initially applied
- e) Grade test reactions according to intensity : 0 = no reaction to 3+ = small blisters

Relate relevance of positive reactions to clinical dermatitis cautiously. Careful history and review of skin exposures must establish significance.

(iii) Treatment : Treatment with barrier / moisturizing creams, topical steroids, oral steroids and antibiotics if required.

Ashok K. Jindal, Leo S. Vaz, Puja Dudeja

The most important industrial hazard due to machinery is the accidental injury. A detailed account of the prevention of industrial accidents is outside the scope of this book. Box - 1 depicts epidemiology of industrial accidents, while Fig. - 1 shows methods of accident prevention.

The first step in any accident prevention programme is elimination of various hazards whilst designing the process. If this is not possible, the next best step would be to control the physical, mechanical and chemical hazards in work environment by suitable engineering design. But when this also is not possible or is not able to give full protection to workers the third line of defence has to be resorted i.e., the personal protective equipments. These protective equipments cannot eliminate hazard or stop an accident taking place. These equipments merely set up a barrier against the hazards thereby preventing or minimizing an injury.

In selection of these equipments, the following points are to be borne in mind :

- Type of hazard to be faced
- Selection of right type of personal protective equipment
- Availability of correct equipment in good condition at the work spot
- Training of workers to use the equipment
- Convincing the workers that the equipment is used will protect them from hazard
- Making it a habit with the worker to use the equipment,
- Degree of protection needed

- East and comfort with which it can be used and freedom of movement with equipment which should not hamper performance of the worker
- Maintenance of these equipment
- Periodical check up
- Good earthing

Safety Audit

Objectives

- Critically evaluate the safety programme
- Evaluate the systems to identify and control hazards
- Check that the above system meets the statutory standards and codes of practice

Benefits

- Strengthening of the Organization safety standard and programme.
- Improve the skill and performance of employee and managers.
- Helps to create group and self awareness and provides motivation.
- Identifies specific deficiencies in the safety programme.
- Provides timely information before any injury producing incident occurs.

Mechanism

Safety audit shall be carried out at three levels

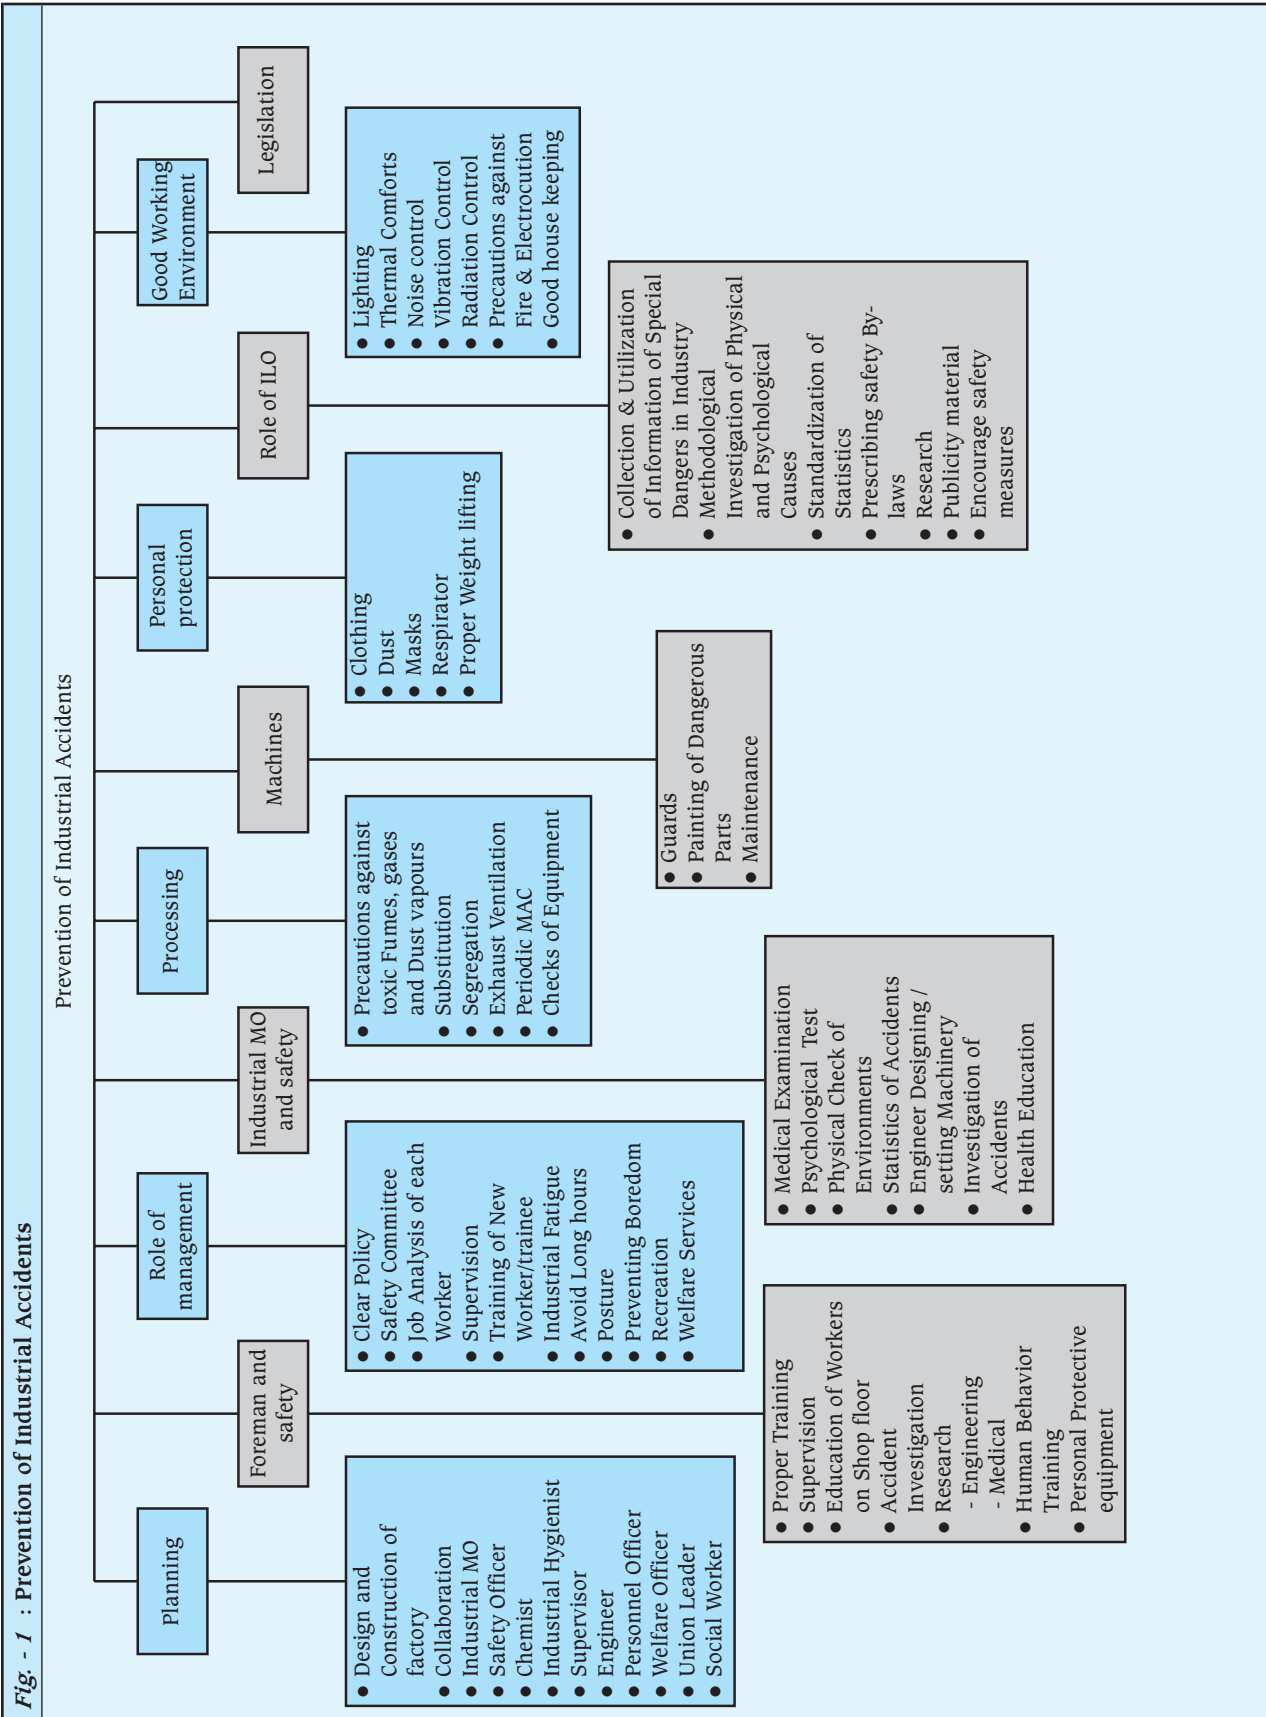

(i) Level - I : Internal Audit inspection by Safety Officers from within the factory once in every three months.

(ii) Level - II : Audit inspection by a group comprising of 3 officers of the factories in the concerned group, once in a period of six months.

(iii) Level - III : Annual Audit inspection by the Regional Controller of Safety / O.F. Board.

Box - 1 : Epidemiology of Industrial Accidents

Host factors	Agent factors	Environment factors
<ul style="list-style-type: none"> ● Age ● Sex ● Experience and education ● Concomitant disease ● Psychological factors ● Personality Traits/ Emotional stability ● Wearing unsuitable shoes ● Carrying improper loads ● Faulty stepping ● Not using personal Protective measures ● Physical defects 	<ul style="list-style-type: none"> ● Improper planning and construction of factories ● Machines ● Faulty design ● Lack of maintenance ● Entanglement of loose clothes and hair ● Transmission of Machinery ● Speed of Work Processes ● Faulty planning ● Boiler explosion ● Dust explosion ● Corrosive materials ● Molten metal and Hot liquids ● Flying solid particles ● Metal grinding ● Stone dressing ● Riveting ● Chipping metal ● Electricity ● Gassing 	<p><i>Physical</i></p> <ul style="list-style-type: none"> ● Overcrowding ● Defective lighting ● Temperature ● Ventilation ● Humidity ● Radiations from surroundings ● Pressure ● Noise ● Vibrations ● Ionizing Radiation ● Slippery Floors ● Uncovered drains <p><i>Social</i></p> <ul style="list-style-type: none"> ● At work place ● Domestic ● Relationship between workers and management ● Lack of Safety Policy

Scope

The Audit is necessarily very wide ranging in scope and covers all aspects of a company's operations. Some of the broad areas to be covered for Safety Audit are to study, in detail, the Safety Policy, Process Safety, Fire Safety, Hazards in the processes and their control, Pollution control, Machine guarding, Housekeeping, Material Handling system, Training of workers/supervisory staff and Management personnel, Accident reporting, investigation & analysis, Emergency preparedness and availability of Health, First Aid, Periodical Medical examination.

Accident Investigation : All accidents should be investigated by the concerned Heads of Sections and an unambiguous report sent in Form No. 14. Safety section shall investigate selected accidents involving plants/machineries/chemicals

where accidents are due to unsafe conditions. In case of all serious accidents, a Board of Enquiry to investigate in to the accident shall start investigation immediately on receipt of intimation by visiting the accident spot so that the evidence is not tampered. Photographs may be taken if necessary. The investigations should be towards fact finding and not fault finding. The concerned sections shall not disturb the site until it is cleared by the board of Enquiry of Safety Officer.

Accident Returns & Analysis : The accident statistics indicating details of accidents, man days lost, man hours worked are compiled quarterly. A monthly report on the accidents taking place during the preceding month is also compiled. Any accident taking place in the factory shall be analyzed by Safety Section.

Ashok K. Jindal & Puja Dudeja

Industry uses and manufactures wide variety of substances, which are either known or suspected to cause toxic effects in the persons working with them. Industrial toxicology is concerned with the study of various substances used in industry either as media for processing some other materials or as raw materials or the finished product. The *Permissible Exposure Limit* (PEL) to a substance is defined as exposure to a maximum time weighed average (TWA) of concentration of a toxicant for an 8 - hour work. The *Threshold Limit Value* (TLV) is that limit in an environment of a toxic agent or the substance or the deleterious material which when inhaled by a worker for a duration of 8 hours per day for indefinite periods will not cause any harmful effects.

Details of industrial toxicology in respect of common and important toxic substances are being described in this chapter. The general measures of prevention and control are dealt with subsequently.

Lead

Lead is ubiquitous in industry and poisoning due to absorption of lead and its compounds is still common. Lead is the most commonly used metal in industries because of anticorrosive property. Hazardous process are lead smelting, burning and making paint, painting, welding riveting, battery manufacture, and lead baths connected with heat treatment of metals, specially when carried out in confined spaces. Inhalation of lead dust and fumes is the chief route of poisoning, the next common route is ingestion, cutaneous absorption is rare. It is rapidly absorbed into general circulation when inhaled

and produces ill effects much more rapidly and probably in a more severe form than when ingested. Young persons are more prone to lead poisoning than adult. Lead concentration in the working atmosphere should be kept below 2.0 mg per 10 cu m of air (25 - 31).

Symptoms : The commonest manifestations of lead poisoning are blood changes and lead palsy. Lead makes the RBC fragile and causes haemolysis, which results in anaemia with compensatory stimulation of the bone marrow. So immature RBC or reticulocytes appear in the blood. The RBC count is generally below 3 million with haemoglobin under 70 percent (Sahli). In 'Lead palsy' there is a typical degenerative neuritis and subsequent fibrosis. In acute lead encephalopathy, there is involvement of the meninges with oedema and increased intracranial pressure. There may be some capillary damage as well. The lead line showing blue discoloration of the margins of the gums is a classical sign. A diagnosis of lead poisoning should be based on clinical finding, biochemical evidence of excessive lead absorption and by evidence of unusual exposure (See Table - 1 and 2).

Prevention : It depends on good housekeeping, personal protection and education of workers and medical supervision for the detection of hazards the occurrence of poisoning followed by its rectification.

- (i) Exhaust ventilation measures so arranged that whatsoever position the worker assumes the lead dust and fumes are drawn away from his face.
- (ii) Strict periodical inspection of the exhaust system : All ducts and their angles should be cleaned periodically.
- (iii) Avoidance of crowding in the workrooms where metallic lead is heated.
- (iv) The floor should be impervious to water, and smooth so that no lead dust can accumulate.
- (v) The floor should be constantly kept wet & swept before

System	Evidence of absorption	Evidence of incipient poisoning	Evidence of definite poisoning
General appearance	Restive, moody, easily excited, emotional, lead line	Pallor, Leadline, Jaundice	Anemia, Leadline, Jaundice, Emaciation, "Premature ageing"
Digestive System	Persistent Metallic taste, slight anorexia slight constipation	Metallic taste, definite anorexia, slight colic, constipation	Metallic taste, increasing anorexia, nausea and vomiting, marked colic, rigid abdomen marked constipation, blood in stool
Nervous System	Irritability, uncooperativeness	Slight headache, insomnia, slight dizziness, palpitation, increased irritability, increased reflex	Severe headache, increased insomnia, increased dizziness ataxia, confusion, marked reflex changes, tremor, fibrillary twitching, neuritis, visual disturbances, encephalopathy hallucinations, convulsions, coma paralysis.
Miscellaneous	-	Muscle soreness, easily fatigued	General weakness, arthralgia, hypertension
Urine examination	Abnormal lead content	Abnormal lead content, Albumin, Casts	Abnormal lead content, Albumin, Casts, Porphyrinuria, Haematuria
Blood changes	Polycythemia, polychromatophilia, increase platelets, reticulocytosis, abnormal blood lead	Normal red cell count and haemoglobin, reticulocytosis 50 - 100 stippled cells per 100,000 RBC, abnormal blood lead	Decrease in haemoglobin, decrease in RBC, increase in cells showing basophilia, anisocytosis and poikilocytosis, decreased platelets, increase in blood lead

Test	Normal Population	Acceptable absorption in occupation	Excessive absorption occupation with signs & symptoms
Blood lead	10µg/dl	75 µg/dl	> 80µg/dl
Urinary lead	10-65µg/g Cr	Upto-150 µg/g Cr	> 150 µg/g Cr
Zinc protoporphyrin	16-35 µg/dl	Upto 100µg/dl	> 100 µg/dl
Urinary delta aminolaevulinic acid	5 mg/g Cr	6-20 mg/g Cr	> 20mg/g cr

and after the day's work with a vacuum cleaner.

- (vi) Workers should wear special work clothes which should be removed before leaving the factory and deposited in specially provided lockers in order to ensure the prevention of contamination of private clothes.
- (vii) Suitable respirators against lead dust and fumes should be use and inspected regularly.
- (viii) No food, drink and tobacco should be taken in a place where there is a risk of lead poisoning - special rooms should be provided for this in factories.
- (ix) Personal cleanliness should be ensured by providing bathing and washing facilities.
- (x) Health education to avoid dusts and fumes of lead being inhaled or ingested.
- (xi) *Medical surveillance* : Pre-employment medical scrutiny of the prospective workers in the hazardous process should include the history of previous exposure to lead and elimination of those with a positive history of symptoms of lead poisoning. Quarterly medical examination during employment with attention paid to the loss of weight, gastrointestinal symptoms, weakness of wrist muscles and blood picture, removal from exposure should be followed

by active treatment.

Treatment : When lead poisoning is diagnosed, the further exposure should be discontinued, the use of penicillamine and Ca - EDTA, chelating agents, help in bringing down the blood lead levels by promoting lead excretion in urine. A saline purge will help to remove unabsorbed lead from the gut and also will relieve constipation.

Tetraethyl Lead

Exposure to high concentrations of vapour of leaded petrol, especially in hot weather, is responsible for an acute form of lead poisoning (lead encephalopathy). In industry this hazard occurs by spillage in petrol filling sheds/holds/barges with inadequate ventilation, inhalation from clothing saturated with petrol from spillage and splashing and absorption through the skin, which is relatively sight. In some cases a chronic form of lead poisoning occurs. Proper ventilation of the shed is important. The operation of filling should be carried out in the open air. Exhausted fans may be necessary. Special precautions must be adopted when containers are loaded in the holds of the barges. Only containers in sound condition should be accepted for loading and care should be taken in the

storage of the containers. The holds of the barges /tanks should be provided with adequate ventilation. Short shifts at frequent intervals during the work and overall turnover of the labour, so that each man is employed for one week in four on this work, are essential preventive measures. Other precautions are the same as have been described under lead poisoning with the current trend on use of unleaded petrol; it is presumed that toxicity due to this cause will be on the decline.

Phosphorous

White Phosphorus (WP)

White phosphorus (WP) is being used in smoke producing ammunition. After white phosphorus exposure burnt skin is washed with 5 % sodium bicarbonate and 3 % copper sulphate in 1 % hydroxy ethyl cellulose. Phosphorus particulars become coated with black cupric phosphide allowing easy identification. Copper sulphate also decreases rate of underlying tissue. Since blackened particles continue to elicit tissue injury, they can be removed. Of late, copper sulphate is found to be toxic and systemic copper poisoning can manifest as vomiting, diarrhea, oliguria, haematuria, hepatic necrosis and cardio - pulmonary collapse.

Mercury

Mercury Fulminate

It is a brownish yellow, heavy, crystalline solid prepared by the action of alcohol on mercuric nitrate. The chief hazard is dermatitis affecting those who are employed in filling operations where a fine dust is raised, which comes in contact with the naked skin. The susceptibility of some individuals may not enable them to withstand exposure even for a day. The exposed parts of the body become erythematous accompanied by violent itching, swelling and oedema of the face, eye - lids, ears, neck and forearms. Teeth become black owing to the formation of mercuric sulphide. Cleanliness of the plant is important. All precautions as for a lead factory should be taken. Exhaust ventilation with fitting overalls, aprons, rubber gloves, and if necessary respirators as well. Additional hand washing facilities should be provided (26 - 31).

Chromium

Chromic Acid and bichromates of sodium and potassium are used in chromium plating of metals, manufacture of explosives and for tanning of leather, characteristic chrome ulcers occur on nail beds and the nasal septum. They are small, deep ulcers varying in size from the head of a matchstick to the end of a lead pencil. The tissues around the ulcers are heaped up and are covered by crusts. They may cause perforation of the nasal septum. The ulcers are as rule not painful but heal very slowly (25 - 31).

Prevention

Mechanical lateral exhaust ventilation should be provided for the removal of the vapour and spray at the point of origin. The floor of rooms containing chrome baths should be impervious, maintained in good condition and flushed out daily. Suitable rubber gloves, aprons and other protective clothing should be provided and maintained properly. Water taps should be installed in workplaces, to enable the workers to wash hands

frequently. Shower bath and a change of clothing should follow the day's work. All cuts, abrasions and other injuries on hand and forearm should be protected by adhesive strapping before starting work. The forearm should be inspected twice a week and any breach of continuity of the skin should be immediately reported to the factory doctor. A protective ointment should be applied in the nostrils.

Metal Fume Fever

It is a transient illness and is commonly known as 'Brass Founders Ague' 'Zinc Fever' or 'Metal Chill'. It follows the inhalation of high concentrations of finely dispersed zinc or brass fumes, usually in the form of oxides. After heavy exposure, the nose and throat feel dry and sore giving rise to a dry cough. In a few hours, the symptoms appear. There is shivering which may last for some time and this is followed by profuse perspiration, the picture simulating that of an attack of malaria. Considerable prostration follows the attack, but by the next morning recovery is almost complete. Some degree of insusceptibility is produced by low - grade inhalation but is lost in 48 hours. Workers therefore, are likely to suffer more on Monday morning; Metal fumes should be eliminated by proper exhaust ventilation. When conducting replacement or transfer medical examinations, cases with a history of chronic bronchitis, asthma or any other respiratory trouble should be withheld.

Mineral Oils

Mineral oils are insoluble and soluble. The insoluble ones are used mainly as lubricants for cutting tools and the soluble ones are used as cooling agents. Cutting oils have the property of defatting the skin. They also plug the pores of the skin and form comedones. After some days of use they may contain steel slivers, which may injure the skin and thus start dermatitis affecting the forearm and thigh, small blackheads due to blocking of the sebaceous glands appear in these areas.

Prevention

Cleanliness of persons, their clothes and machines should be ensured by the provision of adequate washing and shower bath facilities. Suitable industrial cleaners should be placed at convenient location in the washroom. Clean rags or cotton waste free from silver should be provided. Time should be allowed for workers to carry out thorough cleansing, change of clothes and dressing. Those who give a previous history of dermatitis should be excluded by pre placement examination. Persons suffering from seborrhea, acne and excessive sweating should be prohibited from employment appear, the person should be temporarily withdrawn from the process and re - employed when the skin condition clears up.

Treatment

The treatment is usually by soothing lotions or cream like calamine. Barrier creams may help in getting the skin of the beginners slowly conditioned to the contact with cutting oils but cannot serve as a permanent protective measure for persons whose skins are excessively sensitive.

Benzene

This is colourless aromatic hydrocarbon with a characteristic

pleasant smell. It is extensively used as a solvent and a starting material in the synthesis of numerous chemicals (25, 26, 32 - 36).

Acute Poisoning

Clinically, acute poisoning is of three general types, depending upon the severity of its anaesthetic effects on brain centers. Very high concentrations of benzene inhalation may result in unconsciousness, followed by death from respiratory failure. With somewhat lower concentrations, there may be dizziness, weakness, apprehension, collapse and unconsciousness. Death may occur from respiratory failure.

Chronic Poisoning

The haemopoetic system is mostly affected but degenerative changes are also observed in the kidneys and heart. There is weakness, dizziness, rapid pulse, persistent headache, malaise, loss of appetite, shortness of breath, undue fatigue, decreased resistance to infections, and ulcers in the throat. Due to decrease in platelets, there is bleeding from the mucous membrane and haemorrhage in tissues. Macrocytic anaemia gives more reliable indication of the poisoning than leucopenia, especially in the early part of the disease.

Prevention

The ventilation of the workroom should be improved by mechanical exhaust ventilation. A monthly examination of the employees should be carried out including a complete blood count, and findings recorded in a special register. There should be a rotation in duties of the personnel. Worker's showing an altered blood picture should be removed from exposure. They should report for medical examination, if bleeding from the nose, gums or other mucous membranes is noticed. Toluene, Xylene, Cyclohexane or trichloroethylene can be used as comparatively safer and satisfactory substitutes for benzene.

Trichloroethylene (Trilene)

It is colourless liquid with chloroform like odour. It is largely used in the metal industry as a degreaser. When the exposure is sudden, the worker may die and the post - mortem examination may reveal oedema of the lungs and petechial haemorrhages. Fatty degeneration of the liver, kidneys and heart is present if death is delayed. Repeated exposure affects the central nervous system leading to paralysis of the hypoglossal nerve, sensory fibres of the fifth nerve, second cranial nerve and polyneuritis in the limbs. Mild poisoning may cause various grades of unconsciousness as occurred in the past in laundry workers. Trichloroethylene should be used only in closed systems or in rooms with a downward exhaust ventilation system. Workmen with dry and fissured skin should not be permitted to handle the chemical. Inhalation of a mixture of 95 percent carbon dioxide is of great value in the treatment of poisoning. Artificial respiration may be necessary (25,26,31,32).

Carbon - Monoxide

It is a colorless and odourless gas formed from the incomplete combustion of materials containing carbon. It is encountered in various industries such as foundries, gasworks, ovens, blast furnaces and in automobile garages. It is a chemical asphyxiant. It forms a relatively stable compound, carboxyhaemoglobin

when it combines with haemoglobin, as its affinity for the haemoglobin is about 300 times that of oxygen (25,26).

Symptoms

Acute poisoning causes a sudden onset of unconsciousness, rapidly developing cyanosis and death. Initial symptoms of sub acute carbon monoxide poisoning, which are more likely to be encountered in industry than the acute poisoning are shortness of breath palpitation on exertion accompanied by slight headaches which tend to increase in severity. With the increased concentration of this gas in the blood, judgment becomes fogged and the affected individual may not realise his own danger. If the exposure continues, mental aberration is followed by unconsciousness resulting in death from respiratory failure. Chronic poisoning shows all these symptoms coming on gradually and then continuing for longer periods.

Prevention

Minimising its leakage by ensuring efficient ventilation, and finally by observing the rules of personal protection can prevent carbon monoxide poisoning. No person should be allowed to work single handed in a place where there is a danger of production of this deadly gas. No workman should enter or approach a place until the gas has been flushed out by fresh air and a suitable breathing apparatus issued. Safety posters in common languages should be displayed at strategic points explaining the deadly nature of symptoms of poisoning and means of rescue and first aid. Workmen should be given practice drill in rescue operation, artificial respiration and resuscitation. A cylinder containing a mixture of 95 percent oxygen and 5 percent carbon dioxide with a close fitting mask, should be available at all times for immediate use.

Treatment

The victim should be removed immediately into fresh air and should not be made to walk even if he is conscious. The oxygen and carbon dioxide mixture should be administered or oxygen should be administered under positive pressure if available. If the breathing has stopped or is shallow, artificial respiration must be started and continued until normal breathing returns. If the heart has stopped beating, cardiac massage and stimulants should be given. Absolute rest in bed and warmth are essential. A close vigil should be maintained because of the tendency to relapse. Artificial respiration, administration of oxygen - CO₂ mixture and cardiac massage should not be stopped until it is quite certain that heartbeat can not be revived.

Hydrogen Cyanide

It is colourless gas with a penetrating bitter almond odour, Sodium and potassium cyanide baths used in the heat treatment of steel and iron are potential health hazards (25, 26).

Symptoms

Hydrogen cyanide like carbon monoxide is a chemical asphyxiant and prevents the tissue from using the oxygen carried in the blood. When inhaled in high concentration it caused sudden collapse and almost immediate death. In lower concentration symptoms are delayed; the patient complains of headache, dizziness, vomiting, general weakness; slow and irregular respiration and pulse is almost imperceptible. There

is a smell of bitter almonds in the breath, and if inhalation continues for some time coma supervenes, followed by death from respiratory failure.

Prevention

Efficient plenum and exhaust ventilation, respiratory devices, protective hood and respirators ensure safety.

Treatment

Immediate first aid measure comprises of removing the patient to fresh air, keeping the patient warm and at rest and removing contaminated clothing. Contaminated skin is washed well with water. Treatment consists of inhalation of amyl nitrite for 15 - 20 secs every 2 - 3 mins along with oxygen inhalation and artificial respiration. If patient is comatose or becomes drowsy then Dicobalt edetate (300 mg in 20 ml glucose sol) should be given by slow IV injection over 3 - 4 mins. If there is no return to consciousness then give sodium thiosulphate (12.5 gm in 25 ml of 50 % sol) IV over 5 - 6 mins. If the symptoms reappear or persist, half the dose of the antidotes should be repeated one hour later. If cyanide has been swallowed, gastric lavage is essential.

Nitrous Fumes

The chief constituent of nitrous fumes are nitrous oxide, nitric acid and two forms of nitrogen dioxide, NO_2 , N_2O_4 ; the last two lend a brown colour to the fumes. Nitrous fumes are present in industries where sulphuric & nitric acids and explosives are manufactured. The fumes are also a hazard in certain operations e.g. welding, metal cleaning and electroplating. Toxicologically nitrogen dioxide NO_2 is the most important of the oxides of nitrogen (25, 26).

Symptoms

The fumes should be controlled at the point of origin by efficient general ventilation and by local exhaust ventilation. Isolation of the offending operation is helpful where the process does not yield readily to the above measure of control. Respiration protective devices such as chemical filter respirator are justified as a last resort when all other measures of control have proved ineffective. These masks need periodical examination and proper maintenance. The education of the worker in the use of the respirator is of utmost importance.

Prevention

The fumes should be controlled at the point of origin by efficient general ventilation and by local exhaust ventilation. Isolation of the offending operation is helpful where the process does not yield readily to the above measure of control. Respiratory protective devices such as chemical filter respirators are justified as a last resort when all other measure of control has proved ineffective. These masks need periodical examination and proper maintenance. The education of the worker in the use of the respirator is of utmost importance.

Alkalies

The alkalies used in industry are chiefly ammonia, potassium and sodium hydrates. The industrial hazard from ammonia is invariably due to the accidental escape of the liquid or gas. It is very irritating to the upper respiratory passages and

may give rise to pulmonary edema. Burns may follow the splashing of ammonia and other alkalies, especially in the eyes. Prevention is achieved by taking precautions to obviate the except of ammonia and the use of goggles or eye shields. If splashing occurs, frequent irrigation of eyes by a 4 percent solution of ammonium chloride should be ensured to reduce the fixed alkalies. Penicillin droops or ointment should follow irrigation.

Acids

The common acids used in industry are sulphuric, nitric and hydrochloric acids. When splashed into the eyes they cause severe burns of the cornea and conjunctiva. Prevention of splashing by protective devices, training of workers in work methods and personal protection are important precautions. Tubs full of water 'plunge baths' should be kept in the sections which involve the risk of chemical burns so that the affected individual can immediately plunge into it for washing the chemical without vigorous rubbing. In cold weather, the water bath should be kept at 38°C (about the body temperature) during working hours. A number of ointments containing 3 percent boric acid solution should be placed in strategic places and workmen should be taught how to irrigate the eyes immediately. Splashing clean water into the eyes is also helpful. Arrangements should be made for the mechanical transport of carboys containing acids covered with baskets and handled as little as possible.

General Measures for Prevention / Reduction of Hazards : Industrial Toxicology

Engineering Measures

General rules for prevention/reduction of hazards from dangerous and obnoxious substances are as under :

(a) **Substitution** : Wherever practicable the use of offending substances should be prohibited. Failing that, a harmless substance should be substituted for the harmful one e.g. the use of yellow phosphorus substituted by phosphorus sesquisulphide in the match industry, sand - blasting may be substituted by shot blasting, and acetone may be issued in place of benzol as solvent.

(b) **Total enclosure** : Through airtight enclosure, personal contact with harmful substances such as dusts, fibres, fumes, gases, mists or vapours can be prevented.

(c) **Local exhaust Ventilation** : Where an airtight apparatus cannot be used, the harmful products should be removed at or near their point of origin by means of fume chambers or suction hoods properly connected to efficient exhaust systems.

(d) **Dust Suppression** : Where practicable the material should be used in a moist or wet state to prevent the evolution of dust e.g. lead

(e) **Duration of Exposure** : Limitation of the duration of exposure or employment should be compulsory in certain trades e.g. in radioactive processes.

(f) **Segregation** : Segregation of process involving toxic agents i.e radioactive material is segregated. Segregation is also coupled with mechanical handling.

(g) **Use of wet methods** : Dry processes lead to cloud of dust. Wet methods can prevent this.

i. **Wetting basic material** : when painters scrap the lead paint, repeatedly wetting sand paper in water.

ii. **Periodic environmental sprays** : for humidification in mines and mills

iii. **Use of hydraulic mills in mines**

(h) **Good housekeeping** : The golden rule is that there is a place for everything and everything has a place.

(j) **Good general ventilation** : It dilutes the substance in work environment.

(k) **Provisioning of control equipment** : Equipment like continuous carbon monoxide detectors and carbon monoxide detection tubes.

(l) **Periodic environmental surveys** : These will help in detection of any leak at an early stage. Threshold limit value of a substance should not be exceeded.

(m) **Safe plant design** : Safety engineers should be involved in the construction of the plant.

Personal control measures

(a) **Protective clothing** : It includes the following -

- i. Helmets
- ii. Goggles
- iii. Earplugs
- iv. Gowns and aprons
- v. Shoes
- vi. Personal monitoring equipment like dosimeter
- vii. Respirators

Medical control measures

(a) **Medical examination**

- i. Pre placement medical examination - before one is employed in a particular job.
- ii. Periodical medical examination.
- iii. Medical examination of susceptible groups - young people, old age, people with anaemia, malnutrition, females.
- iv. Medical examination before leaving the job or work.
- v. Medical examination of persons joining after a periods of sickness.
- vi. Medical examination for early detection of cases and treatment.

(b) **Good record keeping** : It helps both in early detection and research.

(c) **Periodic environmental surveys** : Done by medical and safety personnel.

(d) **Health education** : By far the most important safety factor is the cooperation of the worker in obeying the given safety orders and instructions. Too often the safety notices / posters are couched in purely negative terms; the worker is exhorted not to perform one or other action and is left in doubt as to the reason for prohibition. A positive approach has been found to be more effective. If the notices give an indication of the hazard to which the workman would be exposing himself, there could be less temptation for disobeying the restrictions.

Legislative Measures

(a) **Restriction of Employment** : Children below 14 years are not permitted to work in any industry. Women and young persons between 15 - 18 years are prohibited from working in hazardous industries. Women are prohibited from working underground in a mine.

(b) **The Factories act, 1948** modified in 1987 lists diseases which are notifiable.

Ashok K. Jindal & Puja Dudeja

Measures of Prevention and Control of occupational diseases are shown in Fig. - 1.

Engineering measures

General rules for prevention/reduction of hazards from dangerous and obnoxious substances have been discussed under the heading of safe design of building. However other

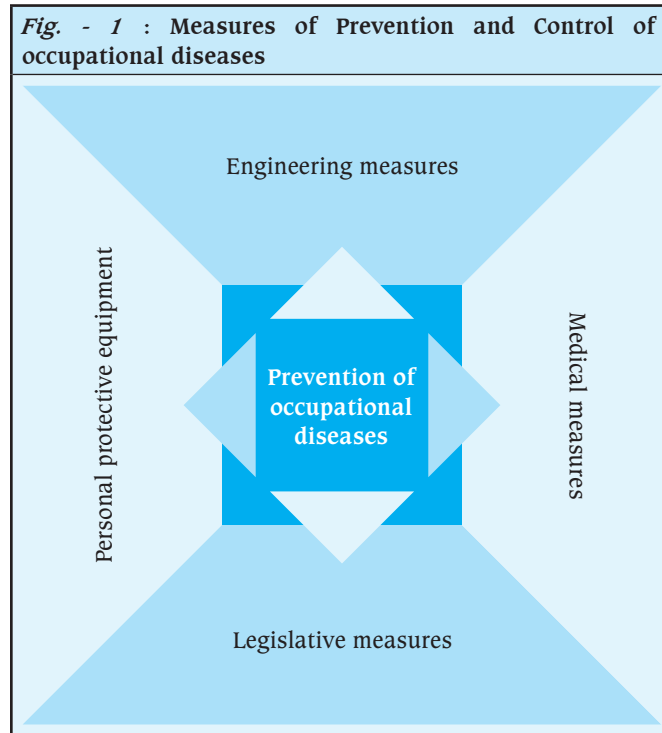

methods for prevention of occupational hazards are given as under :

Substitution : Wherever practicable the use of offending substances should be prohibited. Failing that, a harmless substance should be substituted for the harmful one e.g. the use of yellow phosphorus substituted by phosphorus sesquisulphide in the match industry, sand - blasting may be substituted by shot blasting, and acetone may be used in place of benzol as solvent.

Total enclosure : Through airtight enclosure, personal contact with harmful substances such as dusts, fibres, fumes, gases, mists or vapours can be prevented.

Local exhaust Ventilation : Where an airtight apparatus cannot be used, the harmful products should be removed at or

near their point of origin by means of fume chambers or suction hoods properly connected to efficient exhaust systems.

Dust Suppression : Where practicable the material should be used in a moist or wet state to prevent the evolution of dust e.g. lead.

Duration of Exposure : Limitation of the duration of exposure or employment should be compulsory in certain trades e.g. in radioactive processes.

Segregation : Segregation of process involving toxic agents i.e. radioactive material is segregated. Segregation is also coupled with mechanical handling.

Use of wet methods : Dry processes lead to cloud of dust. Wet methods can prevent this.

- i. Wetting basic material : when painters scrap the lead paint, repeatedly wetting sand paper in water.
- ii. Periodic environmental sprays : for humidification in mines and mills.
- iii. Use of hydraulic mills in mines.

Good housekeeping : The golden rule is that there is a place for everything and everything has a place.

Good general ventilation : It dilutes the substance in work environment.

Provisioning of control equipment : e.g. continuous carbon monoxide detectors and carbon-monoxide detection tubes.

Periodic environmental surveys : These will help in detection of any leak at an early stage. Threshold limit value of a substance should not be exceeded.

Safe plant design : Safety engineers should be involved in the construction of the plant. A positive approach has been found to be more effective. If the notices give an indication of the

hazard to which the workman would be exposing himself, there could be less temptation for disobeying the restrictions.

Medical Control Measures

Medical examination

Pre placement medical examination : It is done before one is employed in a particular job i.e. at the time of entry into an employment and includes a detailed history followed by complete physical examination and laboratory/ radiological investigations of the individual. It helps in rejecting the individuals who are unfit and also helps in placement of the worker to the right job so that there is maximum productivity and at the same time it is less detrimental to worker's health. It also gives a baseline for various parameters which can be used for future comparisons.

Periodical medical examination : This involves checkup of workers at periodic intervals for early detection and treatment of cases. The frequency and content of this examination depends upon the occupational exposure. Ordinarily the workers are examined once a year. However, monthly examination is recommended in case workers are exposed to toxic substances as lead, radium etc.

- *Medical examination of susceptible groups - young people, old age, people with anemia, malnutrition, females.*
- *Medical examination before leaving the job or work.*
- *Medical examination of persons joining after a period of sickness.*
- *Medical examination for early detection of cases and treatment.*

Good Record Keeping : It helps both in early detection and research. Records also play an important role in planning, development and efficient operation of an occupational health service. It also helps in planning of preventive services in an industry.

Periodic Environmental Surveys : This includes survey of the working environment in form of temperature, lighting, ventilation, humidity, noise, cubic space, air pollution and sanitation which have an important role in the health of the worker. It is done by medical and safety personnel. These surveys also include study of raw materials, the process and manufactured products.

Health Education : Health education about the process, handling of raw material, correct use of protective devices has a lot of impact in prevention of occupational diseases. The aim is to assist the worker in his process of adjustment to the working, home and community environment. It also includes guiding the worker about various legislations available and social security schemes existing for the benefit of workers.

Personal Protective Equipment (PPE)

Personal protective equipment is designed to protect the worker from health and safety hazards that cannot practically be removed from work area. Personal protective equipment protects many parts of body including eyes, face, head, hands, feet, and ears.

Head Protection : Helmets /Hard hats protect from impact and penetration caused by objects hitting head. They also give you

limited protection from electrical shock or burns.

Eye Protection : Goggles give eye protection when working with : molten metals, liquid chemicals, hazardous gases or flying particles.

Ear Protection : Ear protection consists of earplugs and earmuffs. These should be used when the sounds in work area are irritating, sound levels reach 85 decibels or higher for an 8 - hour time period or there are short bursts of sound that can cause hearing damage.

Hand Protection : Gloves give protection against severe cuts or lacerations, severe abrasions, punctures, chemical burns, thermal burns, and harmful temperature extremes.

Foot Protection : Foot protection is important to prevent injuries in case a heavy or sharp object falls on foot or when the worker can step on an object that could pierce his shoe.

Respiratory Protection : Masks (filter/gas/ air purifying respirator) should be used to prevent inhalation of toxic gases into the lungs.

Legislative Measures

Labour protection for the working people in India is available under various laws enacted by the Parliament as well as the State Legislatures. The Preamble of the Constitution of India guarantees its citizens justice - social, economic and political; liberty of thought, expression, belief, faith and worship; equality of status and opportunities and fraternity, dignity of individual and dignity of nation. The organized sector workers which constitute about 7% of the total workforce of about 400 million in the country are covered under various legislations providing social security to these workers. The major legislations providing social security to these workers are : the Employees' State Insurance Act, 1948 and the Employees' Provident Fund & Miscellaneous Provisions Act, 1952 etc. These two legislations provide for medical and health insurance and provident fund & pension to the workers respectively. The Factories act and ESI act have been dealt in detail under social security.

Ergonomics

Leo S Vaz

'Ergonomics' is derived from two Greek words 'Ergon' meaning work and 'Nomos' meaning principles or laws. *Ergonomics is the Science of Work*. Ergonomics is essentially fitting the workplace to the worker. The better the fit the higher the level of safety and worker efficiency. It takes account of the worker's capabilities and limitations in seeking to ensure that tasks, equipment, information and the environment suit each worker. The anticipated benefits of good ergonomics are :

- Improved health and safety by reducing work - related injuries and disorders;
- Improved comfort, morale and job satisfaction;
- Improved productivity and reduced workers' compensation costs and employee turnover.

Basic Ergonomic Principles

To assess the fit between a person and their work, ergonomists consider :

- The job being done and the demands on the worker;
- The equipment used (its size, shape, and how appropriate it is for the task);
- The information used (how it is presented, accessed, and changed).

Currently, the focus of ergonomics is to minimize work stressors, both physical and environmental to reduce the potential for bodily harm. The basic work stressors that promote repetitive

or cumulative injuries include excessive repetition, forceful movements, and awkward movements and postures. General ergonomic principles help us to control these work stressors.

- a) **Repetitive tasks** may not require much muscular effort, but the velocity and range of the movements can cause muscles to fatigue quickly as the muscle never completely relaxes and never completely contracts. With insufficient rest time, recovery of micro - trauma to the muscles, tendons and joints is not complete. Gradually, injury builds until swelling and pain begin to limit activity.
- b) **Forceful movements** require excessive tension or pressure on the tissues of the body, increasing muscular effort, reducing circulation to the body's tissues, and causing muscles to rapidly fatigue.
- c) **Awkward movements and postures** place biomechanical stresses on the joints, muscles and tendons, causing friction and inflammation at the stressed sites, reducing the body's ability to perform work efficiently and comfortably.

Work - Related Musculoskeletal Disorders (WMSDs)

These are MSDs that are caused or made worse by work methods and environment. They occur when the physical capabilities of the worker do not match the physical requirements of the job. Common MSDs are Tendonitis, Epicondylitis (Tennis or Golfer's Elbow), Bursitis, Trigger Finger, Carpal Tunnel Syndrome, and Back Strain. Work - related MSDs are also known as Repetitive Strain or Stress Injury (RSI) Repetitive Motion Injury (RMI), Cumulative Trauma Disorder (CTD), Overuse Syndrome or Activity - related Pain Syndrome.

Causes of MSDs : The characteristics of a job which put a worker at risk for MSDs are :

(a) **Repetition** : Performing the same motion or group of motions excessively.

(b) **Awkward Postures or Postures outside of neutral** : Neutral is the optimal position of each joint that provides the most strength and control.

(c) **Static Postures** : Holding the same position or using the same muscles for extended periods of time.

(d) **Cold Temperatures** : Working in environments below 68°F can cause nerve damage.

(e) **Forceful exertions** : A strong physical exertion produces tension by muscles and is transmitted through tendons.

(f) **Vibration** : Single Point Hand and Arm exposure results from vibrating objects such as power tools.

Whole Body exposure to vibration results from vehicles such as forklifts, cranes, trucks, buses subways and aircraft.

(g) **Compression** : Soft tissue is compressed between the bone and a hard or sharp object.

(h) **Poor work-Station design** : It is a risk factor for the development of upper limb disorders. The computer mouse is one of several input devices used with today's IT, usually with a standard keyboard. Several reports have appeared in the literature of upper limb disorders such as tenosynovitis, lateral epicondylitis and myofascial syndrome resulting from mouse use. The use of mouse results in abduction and flexion at the shoulder, flexion of the elbow and resting of the wrist on the mat along with ulnar deviation for standard tasks. The prevention of problems involves ensuring that the user handles the mouse within his or her normal zone of comfort.

Signs and Symptoms of MSDs : Common Signs and Symptoms of MSDs are Painful aching joints, muscles, tingling or numbness, fingers or toes turning white, Shooting or stabbing pains, Swelling or inflammation, Stiffness or difficulty moving, Burning sensation or Pain during the night.

Carpal Tunnel Syndrome : Carpal tunnel syndrome is associated with exposure to some workplace hazards. Clinically diagnosed carpal tunnel syndrome has been reported to occur in textile and other industrial workers. Pressure on the median nerve as it passes under the flexor retinaculum may lead to the development of a clinical picture compromising pain and paraesthesiae in the thumb, index and middle fingers, which is often worse at night. Wasting of the small muscles of the hand supplied by the median nerve may occur if the condition remains untreated for some time. Nerve conduction studies are often used to assist the diagnosis. Probably the main occupational hazard is repetitive movements of the wrist, although exposure to hand - arm vibration is also thought to be important. Surgery to decompress the median nerve may be required to relieve symptoms or preserve function in the hand.

Pre - Patellar Bursitis : Occupational disorders due to repetitive strain are not new. Coal miners, for example, suffered from 'beat' conditions. Repeated kneeling and crawling could lead to the development of inflamed pre - patellar and pre - tibial bursae. Beat knee is a combination of haemorrhagic bursitis and pyogenic infection. This condition arises as a result of manual labour causing excessive pressure or friction in the area of the knee. Workers who have to kneel repeatedly in their

jobs may suffer from bursitis at the knee.

Back Pain and Work : Low back pain is common in the general population, and is a common symptom in workers whose jobs involve manual handling. Although the aetiology of back pain is complex, studies have shown that repetitive overuse and postural factors resulting from systems of work are associated with increased prevalence rates. It is not merely a requirement to lift heavy loads in jobs that leads to an increased risk of back pain; the prolonged maintenance of abnormal postures also causes marked increases in pressures on the spine because of the protective responses of the supporting muscles. Consequently, guidelines on manual handling should not merely focus on weights to be lifted, but should also include an assessment of the associated ergonomics.

The handling of load may involve pushing and pulling as well as lifting. Risks of injury to the back or upper limbs are dependent not only on the weight lifted, but also on the posture needed for the lift. Lifting with the back outside of its normal range of movement places stresses on the soft and bony tissues of the spine. The majority of injuries to the back are due to damage to the soft tissues rather than the intervertebral discs, but the symptoms of pain, restriction of movement and disability are the same. Prevention of injury involves eliminating or modifying tasks, and providing lifting aids and training in safe lifting techniques.

Employers should minimize the risks to workers by avoiding lifting and handling manoeuvres except where they are unavoidable. The use of lifting aids and the provision of training are both important risk - reducing measures. There is increasing evidence that psychological risk factors are also important with respect to both the development of low back pain and the occurrence of chronic low back pain. The identification of these risk factors is a necessary component of a holistic risk assessment.

Pregnancy and Ergonomics : A number of studies have looked at the risk to the mother and foetus from physically tiring work and strenuous exercise. The former has a reported association with amenorrhoea, and the latter may lead to an increased risk of abortion, stillbirth and foetal growth retardation. The ergonomic aspects of the developing pregnancy and the resulting reduced flexibility and movement also need to be taken into account when assessing the job, and different recommendations may be appropriate at different stages of the pregnancy.

Prevention of MSDs : The principles involved in prevention of MSDs lies in good Ergonomics and the motto '*Work Smarter, Not Harder!*' This can be achieved by the following principles :

- Work in neutral postures
- Reduce excessive force & repetition
- Keep everything in easy reach and at proper heights
- Keep warm
- Minimize static unsupported postures and pressure points

Methods of Reducing Repetition are :

- a) Break up the repetitive components of a job.
- b) Switch frequently between tasks.
- c) Find a different tool that makes the job easier.
- d) Let the tool or automation do the work instead of the

body.

- e) Introduce leisure activities that have different physical demands than work activities.

Methods of Reducing Force : To reduce the force or exertion required to perform specific activities, use the appropriate tool for the job and maintain tools in good working order. For example, blades should be kept sharp; use longer handles for better leverage; use clamps to hold parts instead of holding with the other hand. A slippery surface requires extra grip strength to hold the object; Avoid sudden impact, jerking, or sudden start - stop movements; when lifting or moving objects, keep them close to your body; push rather than pull.

Methods of Reducing Awkward Positioning & Improving Posture : Proper posture ensures that one keeps reaching to a minimum. This can be done by assuring proper fit of the chair. There should be support for the lower back. Height should be adjustable in relationship to the work surface so that the shoulders are relaxed and the elbows are positioned at the side of the body (in - line with the shoulders). The work should be positioned at a height that allows the elbows to be open slightly greater than 90 degrees. A foot - rest should used when necessary. The work should be positioned directly in front of the body to avoid excessive reaching or turning. Frequently used items should be within an easy reach. Tools that fit the hand well and/or are shaped to help maintain the neutral wrist position should be used. One of the best ways to prevent injuries is to keep a relaxed and neutral posture while working. For those who work at a desk or on a computer, the forward head and rounded shoulder posture is prevalent. However the following are recommended :

- The head should be upright with the neck relaxed.
- The monitor should be at a height that allows you to view it directly in front of you, not looking up or looking down or to one side or the other.

- Use a copy holder if you work input information from hard copies.
- The ears, shoulders and elbows should be in vertical alignment.
- The shoulders should be relaxed, not elevated.
- Arm rests are optional. If you do use arm rests, position them at a height that does not push your shoulders towards your ears.
- The keyboard and mouse should be positioned at a level just slightly below elbow level. However, depending on the type of work, this may need to be adjusted.
- The wrists should be in the neutral position flat and straight. They should not be bent forward or back, or angled to one side or the other.
- The fingers should be relaxed. Do not pound on the keyboard. Use the lightest touch possible to activate the keys or any tool control.

Seating in the Workplace : Ideally, seats should be personal to the individual worker and move with him or her where necessary, but where this is not possible, adjustable seating should be provided at every workstation. The lumbar region needs to be supported to decrease disc pressure. Providing both a seat back that inclines backwards and has a lumbar support is critical to prevent excessive low back pressures. The combination which minimizes pressure on the lower back is having a backrest inclination of 120 degrees and a lumbar support of 5 cm. The 120 degrees inclination means the angle between the seat and the backrest should be 120 degrees. The lumbar support of 5 cm means the chair backrest supports the lumbar by sticking out 5 cm in the lower back area. Another key to reducing lumbar disc pressure is the use of armrests. They help by putting the force of your body not entirely on the seat and back rest, but putting some of this pressure on the armrests. Armrest needs to be adjustable in height to assure shoulders are not overstressed.

Noise

High levels of occupational noise remain a problem in all regions of the world. Although noise is associated with almost every work activity, some activities are associated with particularly high levels of noise, the most important of which are working with impact processes, handling certain types of materials, and flying commercial jets. Occupations at highest risk for NIHL include those in manufacturing, transportation, mining,

construction, agriculture and the military. The review of the literature indicates that noise has a series of health effects, in addition to hearing impairment. Some of these, such as sleep deprivation, are important in the context of environmental noise, but are less likely to be associated with noise in the workplace. Other consequences of workplace noise, such as annoyance, hypertension, disturbance of psychosocial well - being, and psychiatric disorders have also been described. For occupational noise, the best characterized health outcome is hearing impairment.

Effects of Noise

The first effects of exposure to excess noise are typically an increase in the threshold of hearing (threshold shift), as assessed by audiometry. This is defined as a change in hearing

thresholds of an average 10 dB or more at 2000, 3000 and 4000 Hz in either ear (poorer hearing). NIHL is measured by comparing the threshold of hearing at a specified frequency with a specified standard of normal hearing, and is reported in units of decibel hearing loss (dBHL). Threshold shift is the precursor of NIHL, the main outcome of occupational noise. It corresponds to a permanent increase in the threshold of hearing that may be accompanied by tinnitus. Because hearing impairment is usually gradual, the affected worker will not notice changes in hearing ability until a large threshold shift has occurred. Noise - induced hearing impairment occurs predominantly at higher frequencies (3000–6000 Hz), with the largest effect at 4000 Hz. It is irreversible and increases in severity with continued exposure.

The consequences of NIHL include :

- a) Social isolation
- b) Impaired communication with coworkers and family
- c) Decreased ability to monitor the work environment (warning signals, equipment sounds)
- d) Increased injuries from impaired communication and isolation
- e) Anxiety, irritability, decreased self - esteem
- f) Lost productivity
- g) Expenses for workers' compensation and hearing aids.

For a detailed account on noise pollution and control kindly refer to chapter on environmental pollution.

Vibration

Increased mechanization and industrialization has introduced a number of tools which produce variable quantities of vibration. In today's world, vibration induced illness is common in Foundry workers, Shipyard workers including workers in the ship breaking industry, Chain saw operators, Grinders and drivers of various vehicles which vibrate. What has been observed is that the number of affected people increases as the intensity and duration of vibration exposure increases. This type of exposure - response relationship indicates a possible link between health effects and the total amount of vibration energy entering the hands or body. Depending on the intensity of exposure, the symptoms may appear months or years after the start of the exposure.

Three important factors affect the health effects that can result from exposure to vibration :

- *The threshold value* or the amount of vibration exposure that results in no adverse health effects In other words, it is the maximum intensity of vibration to which workers can be exposed every workday for their entire full - time employment without developing numbness, paleness or chill of fingers.
- *The dose - response relationship* (how the severity of the ill health effects is related to the amount of exposure): What has been observed is that the number of affected people increases as the intensity and duration of vibration exposure increases.
- *Latent period* (time from first exposure to appearance of symptoms) : The higher the intensity, the shorter the latent period.

Effects of Vibration

Hand - Arm Vibration Syndrome (HAVS) & Vibration - induced white finger (VWF) : It is the most common condition among the operators of hand - held vibrating tools. Vibration can cause changes in tendons, muscles, bones and joints, and can affect the nervous system. Collectively, these effects are known as *Hand - Arm Vibration Syndrome* (HAVS). The symptoms of VWF are aggravated when the hands are exposed to cold.

Hand-arm vibration syndrome is also known as Raynaud's phenomenon of occupational origin. Vibration is just one cause of Raynaud's phenomenon. Other causes are connective tissue diseases, tissue injury, diseases of the blood vessels in the fingers, exposure to vinyl chloride, and the use of certain drugs. The resulting reduced blood flow can produce white fingers in cold environments.

Workers affected by HAVS commonly report :

- Attacks of whitening (blanching) of one or more fingers when exposed to cold
- Tingling and loss of sensation in the fingers
- Loss of light touch
- Pain and cold sensations between periodic white finger attacks
- Loss of grip strength
- Bone cysts in fingers and wrists

The development of HAVS is gradual and increases in severity over time. It may take a few months to several years for the symptoms of HAVS to become noticeable. Hand - arm vibration exposure affects the blood flow (vascular effect) and causes loss of touch sensation (neurological effect) in fingers.

The severity of hand - arm vibration syndrome depends on several other factors, such as Protective practices and equipment including gloves, boots, work - rest periods, duration of exposure each workday, Years of employment involving vibration exposure, State of tool maintenance, acceleration of vibration, frequency of vibration, the characteristics of vibration exposure, work practice, personal history and habits.

Whole - Body Vibration : Whole - body vibration can cause fatigue, insomnia, headache and "shakiness" shortly after or during exposure. The symptoms are similar to those that many people experience after a long car or boat trip. After daily exposure over a number of years, whole - body vibration can affect the entire body and result in a number of health disorders. Sea, air or land vehicles cause motion sickness when the vibration exposure occurs in the 0.1 to 0.6 Hz frequency range. Studies of bus and truck drivers found that occupational exposure to whole - body vibration could have contributed to a number of circulatory, bowel, respiratory, muscular and back disorders. The combined effects of body posture, postural fatigue, dietary habits and whole - body vibration are the possible causes for these disorders.

Studies show that whole - body vibration can increase heart rate, oxygen uptake and respiratory rate, and can produce changes in blood and urine. Researchers have noted that exposure to whole - body vibration can produce an overall ill feeling which they call "*vibration sickness*." Many studies have reported decreased performance in workers exposed to whole

- body vibration. As in all occupational exposures, individual sensitivity to vibration varies from person to person.

Vibration and Noise : Since most vibrating machines and tools produce noise, a vibration - exposed worker is likely to be exposed to noise at the same time. Studies of hearing loss among lumberjacks revealed that, for equal noise exposure, those with Vibration-induced White Finger (VWF) had greater hearing loss than those without VWF. The reason for this effect is not clear. Studies of the effect of separate and simultaneous exposure to noise and whole - body vibration have concluded that whole - body vibration alone does not cause hearing loss. However, simultaneous exposure to noise and vibration produces greater temporary hearing loss than noise alone.

Prevention & Control of hazards Due to Physical Environment

Personal Protective Equipment

The main danger for employees working in hazardous industries lie in working with chemicals, machinery and tools, noise and vibrations. Therefore, health and safety measurements focus on chemical handling, dust formation, safety of machines and tools and noise and vibrations. An employer must meet specific requirements concerning "personal protective equipment" (PPE), such as gloves, goggles, hard hats, face shields and ear muffs.

Responsibilities of an Employer : It is the responsibility of an employer to :

- a) Survey the workplace to identify hazards, (this survey must be in writing and must be available to workers or their representatives upon request),
- b) Determine whether any hazard requires PPE,
- c) Pay special attention to working conditions or processes that can produce the following hazards :
 - Falling objects
 - Objects that could puncture the skin
 - Objects that could roll over workers' feet
 - Toxic chemicals
 - Heat
 - Harmful dust
 - Radiation

In order to avoid accidents and unhealthy environments, managers give high priority to :

- Reducing the frequency of accidents by good plant design and good operational control; Good - housekeeping measures are general measures within the company organising issues as occupational health and safety and also environment. These measures often are not very complex, but rather basic and therefore important. Good - housekeeping is about reducing and preventing accidents and injuries by organising the company, especially the work floor. Measures will vary from training employees on possible hazards associated with the materials they work with, handling machines, using adequate protective gear, reducing spillages by putting down working procedures to keeping the work floor clean and tidy.
- Minimising the consequences if they occur by appropriate

plant design and procedures, but in addition a predetermined set of emergency plans for personnel.

- Be aware of the possible origin of accidents.

Reassess hazards whenever necessary, especially when new equipment is installed or following accidents. The employer must ensure that all PPE used is the right kind of equipment for the job, and that it is maintained properly, even when workers are using their own equipment. Every employer must ensure that :

- a) PPE provides a level of protection above the minimum required to protect the worker,
- b) All PPE fits properly,
- c) No defective or damaged PPE is used,
- d) All PPE is properly cleaned and maintained on a regular basis.

Employers must train all workers who use personal protective equipment. Training must cover : when and which PPE is necessary, how to know if it fits properly, how to put on, remove, adjust and wear PPE, how to dispose of PPE and the limitations of using PPE. Training must be given whenever working conditions change, or when new or different PPE is used, or if a worker does not understand or remember any topic in the training. Employers must certify in writing that each worker has received and has understood the training. Workers should know how to inspect all PPE to make sure that it is not damaged. Defective PPE should be replaced as soon as the defect occurs.

It is always preferable for the employer to remove or minimize hazards. The provision of PPEs does not enable an individual to take liberties against the hazard, as it is not foolproof. Hence, emphasis should be directed at prevention of hazards by making the system foolproof. Wearing PPE can be uncomfortable (especially in hot weather) or awkward, and many people complain that it gets in the way of doing the job. Although PPE cannot usually completely protect the wearer, people often get a false sense of security when they use it. Also, PPE protects only the person wearing it and many people may not be able to wear PPE due to certain types of medical conditions. Problems such as incorrect fit, use of the wrong PPE for the job, use of damaged or poorly maintained PPE or inconsistent PPE use can all result in less than adequate protection.

The material and shape of special protective overalls should vary with the substances involved e.g. liquid proof or gas proof against corrosive and irritant liquids / gases; asbestos suits complete with a helmet, gloves and boots against risks of excessive heat and fire; against radio - active substances, washable material so designed as to cover other clothing at the neck and wrists. Washing of working clothing is necessary at least once a week as prevention against contamination of other clothing.

Types of Personal Protective Equipment

Eye and face protection : Goggles and face protection must be used when workers are at risk from flying particles, liquid chemicals, acids or caustic liquids, chemical gases or vapours. Workers must also be protected from radiation during welding, torching, soldering, and brazing, or other operations that emit light. Goggles and face protection must meet certain design

criteria for safety. Workers with errors of refraction should have the error corrected. Glasses or transparent plastic materials for goggles and windows of protectors should be free from striae and air bubbles. All goggles intended for mechanical protection should be splinter proof. Goggles and shields for workers engaged in welding, furnace work or any other operation where their eyes are exposed to glare should have filter lenses or windows of standard absorption value against ultraviolet and heat rays. Nonflammable, transparent visors, free of scratches should be provided for protection against glare and sparks. Goggles, when not in use should be kept in special closed containers protecting them from mechanical damage and should be inspected at regular intervals once a month and all defective parts should be replaced immediately.

Head protection : Hard hats/Helmets must be worn where there is a danger of falling objects. Specialized hard hats are required to reduce electrical shock hazards. Well fitting helmets made of aluminium; fibreglass or steel should be worn as a protection against falling or flying objects and blow on the head. For protection of hair from overhead moving belt, well fitting caps of washable and non - inflammable material should be used.

Foot protection : Safety shoes with impact protection are required in work areas where heavy objects or tools could be accidentally dropped on the feet. Safety shoes with compression protection must be worn where objects could roll over workers' feet, and in operations involving skid trucks, hand trucks, dollies, etc. Safety shoes with puncture protection are required when working around nails, wire, tacks, scrap metal, and other objects that could pierce the feet. Leggings for workers handling molten metals should be made of asbestos or other suitable heat resisting material, extending to the knee. At the lower end they should also cover eyelets of footwear. Metal toe guards or safety boots or shoes should be worn in operations where heavy objects are handled. Footwear for workers handling corrosive liquids should be of rubber, specially treated leather, wood or other suitable corrosion resisting material. Footwear for electrical workers should have nonconductive soles.

Hand Protection : Gloves are required to protect workers from cuts, scrapes, punctures, burns, chemical absorption, or temperature extremes. It is crucial that the type of glove being used is the right one for the job since incorrect gloves may provide no protection. This is a particular problem with chemical absorption where incorrect gloves may allow certain chemicals to reach the skin. Gloves for workers handling sharp edged or abrasive objects should be made of tough material and where necessary provided with special reinforcements of leather pieces or even a metal piece over the palm. Gloves should also be made of steel mesh for use in cutting process. Gloves and sleeves for workers handling hot metals could be made of asbestos or other heat - resisting material. Gloves with sleeves made of rubber capable of withstanding voltage of 10000 or more should be used for electrical workers. Gauntlets made of natural synthetic rubber or pliable plastic material should be used when handling corrosive liquids. Close fitting gloves should be used for avoiding exposure to toxic fumes and infectious agents. Barrier creams prevents penetration of irritant substance into the skin. Ideally a barrier cream should be non - irritating, nonsensitising, insoluble in substance

against which being used, easily removable and cosmetically agreeable.

Hearing Protection : Appropriate ear muffs or ear plugs must be made available as a last resort if it is not possible to make the workplace less noisy. Employers must ensure that workers are exposed to less than 90 decibels of noise over an 8 - hour day. If noise levels reach 85 decibels over an 8 - hour day, the employer must develop a hearing conservation program. If no other method of eliminating or reducing the noise exposure is found, the employer must supply PPE. These reduce the sound level exposure by about 20 dB each.

Respirators : Appropriate respirators must be worn as a last resort, if it is not possible to ventilate the work area properly. The following are a few types of respirators used in various industrial processes and environments. These should all be inspected and tested at regular intervals by responsible trained persons.

A mechanical filter respirator can only filter the suspended atmospheric impurities. A wide variety of impressive patterns and designs are available. None afford protection against solvent vapours, injurious gases or in atmospheres deficient in oxygen, and are essentially dust and fume filters in an otherwise healthy atmosphere. The simplest example of such type of respirator is the common surgical gauze mask. By introducing a thin layer of wet cotton wool in between the layers of gauze, it may be worn as a protection against coarse particles, such as fibres or sawdust. Their efficiency against fine particulate, such as those of silica dust, will depend upon the quality of the filtering medium. In course of time, these filters become clogged and there is increased resistance to breathing. The filters should then be washed or changed. Everybody should be supplied with a personal mask.

Chemical cartridge respirators and canister masks ensure the purification of air, which passes through the canisters containing specific neutralisers against specific toxic gases. The canisters have a particular coloured design painted on them indicating the specific toxic gases against which they afford protection; e.g. an orange coloured canister indicates that it is meant to be used against nitrous fumes. The user has to depend upon the oxygen content of the atmosphere, therefore, such respirators should not be worn in confined or poorly ventilated places or where the concentration of the offending gases is high.

The term 'supplied - air - respirators' means a respirator equipped with a hose line, through which fresh air is supplied under positive pressure whereas through hose masks the wearer can inhale air at atmospheric pressure. These are also used when the canister for cartridge respirator cannot be used due to high concentration of dangerous gases or fumes.

A self-generated oxygen mask is an oxygen breathing apparatus consists of a face piece with a corrugated tube connecting it to an oxygen tank or cylinder. This is used by workers engaged in fire fighting, rescue or repair work in atmospheres containing high concentrations of gases or which is deficient in oxygen or sufficient pure air supply. A self - generated oxygen mask is a new type of oxygen breathing apparatus fitted with a small canister containing a chemical. Moisture from the inhaled air starts a chemical reaction, which liberates oxygen.

Safe Work Environment

Design of Building : All buildings, permanent or temporary should be structurally safe and sound to withstand the stress and strain of machinery. Single storey construction is the usual rule as it allows flexibility of layout. Any intensity of natural light can be obtained in it by a combination of wall and roof lighting and it is easier to manage natural ventilation. By careful orientation, direct exposure to the tropical sun can be avoided. Protection from conducted heat can be achieved by a choice of suitable material. Asbestos lining of the walls and ceilings will reduce the noise of machines by controlling the reverberation, resonance and sympathetic vibrations. This will also make the building fireproof.

Space Requirement : A floor area of 3.8 sq.m and 14.2 cu.m of space per worker should be provided. The height of the work rooms should not be less than 3 m. In calculating the space, no deduction need be made for furniture, machines and material, but a height above 4.2 meters should be excluded. The floor should, however, not be crowded with machinery. Individual machines or process units should have sufficient space around them to permit safe operation.

Lighting : Workrooms should be adequately provided with natural and /or artificial lighting. Any special type of work should have special, extra or sport lighting suitable for the operations. In all places where persons work or pass through, enough diffuse background lighting should be ensured. Natural lighting is ensured by the provision of skylights and windows located and spaced with devices to avoid glare. Artificial lighting should be provided where the daylight illumination is insufficient. It should be uniform and free from sharp and contrast shadows and direct or reflected glare. Supplementary lighting specifically designed for particular visual task should be so arranged as to avoid glare, flicker or after - image. Emergency lighting should be provided in all important stairway exits and passages, to and from work places and windowless buildings. The fluorescent tube in strip lighting is being increasingly used. Their efficiency is high and running costs are low. They give uniform illumination and there is low heat formation with absence of shadows. However, in course of time when the tube gets exhausted it develops a flicker, which is irksome to the eyes and also produces a stroboscopic effect.

Ventilation : Modern concept of ventilation requires replacement of vitiated air by supply of fresh outdoor air, the quality of the incoming air should be such that its temperature, humidity and purity are conducive for healthful working. Clean fresh air should be supplied to enclosed work places and it is recommended that in work rooms and assemblies there should be 4 to 6 air changes in one hour. If the air is changed more frequently, i.e. more than 6 times in one hour, it is likely to produce a draught which should be avoided. Where an adequate supply of fresh air cannot be obtained by natural ventilation, mechanical ventilation should be provided. All dust, fumes, gases, vapours or mists generated and released in industrial processes should be removed by local exhaust ventilation at their point of origin.

Thermal Comfort : Temperature and humidity should be maintained in enclosed work places suitable to the kind or

work performed. In localities subject to high or low seasonal temperatures appropriate means such as heat insulation of roofs, walls and floors, and even of doors and windows should be adopted. All employees should be protected against radiant heat and excessive temperature from heated machines or hot processes by heat insulation of the equipment and / or by suitable protective clothing. In industries involving exposure of workers to high or low temperatures, 'transition rooms' should be provided so that the workers can gradually adjust themselves to the external climatic environments. Roof - shelters and windbreakers should be provided for yard - workers where necessary.

Working Comfort : Seats and Workbenches of suitable shape and height should be provided for workers. The seats should be so placed that working material can be reached easily without strain or having to bend forward unduly. Seats should also be provided for all workers who have to work in a standing position, for rest during occasional short interruptions in their work.

Sanitary Conveniences : These should be conveniently located.

(a) **Latrines** : Scales of latrine accommodation is 4 for the first 100 workers and 2 for subsequent 100 workers or part thereof.

(b) **Urinals** : Two urinals for every 100 workers upto 500 and there after one for 100 workers are to be provided. For female workers separates sanitary conveniences are to be provided.

(c) **Wash Basins** : Adequate hand washing facilities should be provided for persons whose work involves contact with any injurious substances, there should be at least one tap for every 15 workers.

(d) **Bath - rooms** : Adequate number of bathrooms for bathing and washing of clothes should be provided.

(e) **Spittoons** : Sufficient number of spittoons should be placed at convenient places.

(f) **Cloak Rooms** : Well - ventilated rooms with individual lockers should be provided for dressing purposes and storage of personal clothing.

Drinking Water : An adequate supply of cool and safe drinking water should be provided in a readily accessible place. Water coolers are ideal and most hygienic. Proper precautions to prevent contamination of water in tanks, pails and other containers must be enforced, section 18 of the factories Act lays down that every factory having more than 250 workers will provide cool drinking water during hot weather.

House-Keeping : It implies general cleanliness and orderliness of the plants, the tools and the products. Cleaning and sweeping should be done during non - working hours; vacuum cleaning or wet mopping should be adopted. Effective drainage should be maintained where wet processing is carried out. False floors, platforms, mats or other dry standing places along with suitable footwear should be provided in oily and greasy places. However, 'house - keeping' means much more than merely keeping the working places clean. "*There is a place for everything and everything in its right place*" is a tried and true axiom of industrial safety. Stumbling and tripping

due to improper house - keeping is another potential cause of accidents.

Miscellaneous Requirements

Infestation with rodents, insects and vermin should be eliminated by suitable measures. Workrooms and work places should not be used as living or sleeping quarters. No food, drink, betel nut or leaves or tobacco should be consumed or

brought by any worker into any workroom in which dangerous and obnoxious materials, particularly lead and radioactive substances, are in use. Any one suffering from communicable diseases should be at once isolated and preventive and control measures instituted.

231

Social Security and Labour Laws

Ashok K. Jindal, Puja Dudeja

Rapid industrialisation of the country has led to a sharp increase in the Labour force in the twentieth century. The expansion of the workforce has taken place more in the unorganised sector. Today a staggering 92.5% of the Indian Labour is employed in this sector. It comprises largely the needy small and marginal farmers, the contract labourers and the agricultural workers. The organised sector, considered better off, employs 280 lacs employees. Out of these, 195 lacs are in the public sector and 85 lacs in private sector.

The earliest legislation in the field of Social Security in India was the "Fatal Accident Act" of 1855 that provided compensation to workers who died as a result of an industrial accident. However, the law remained merely on paper, as it was left to the heirs of the deceased to prove that the accident occurred due to the personal negligence of the factory owner, which was a Herculean task. The powerful Indian Bourgeoisie had thus ensured by getting this clause inserted, that Social Security for the working class remained a non starter. The easy availability of cheap labour and the capital might of the Indian industrialist ensured that it took a long time for the Indian labour force to get organized and fight for their rights. History has shown that legislation and Social Security in industry has come about not due to growth in knowledge or due to a philanthropic attitude of the employers or Government but due to a continuous struggle by the working class. The constant pressure from the workers, trade unions and the ILO forced the Indian Government to enact legislations in the realm of Social Security and Labour Welfare. These were the Workmen's Compensation Act 1923, the ESI Act 1948 and the Factories Act 1948. While the first two dealt with primarily compensation of occupational diseases and injuries, the Factories Act provided for enforcing Safety and Health measures on the factory floor.

The Workmen's Compensation Act 1923 was based on the principle of employer's liability to compensate the worker. This legislation provided for compensation of a personal injury from an industrial accident or an occupational disease and also led

to the setting up of special machinery to deal with claims of compensation under the Act. The Workmen's Compensation Act became an important means in the system of social security for labour in India till independence. It provided for compensation in case of death, total disability, permanent partial disability and temporary disability. However, this Act was criticized as being inadequate to provide compensation to workers in case of Employment Injury or Occupational Disease as the worker had to undergo protracted litigation against the employer to get his legitimate dues. In the name of collective responsibility and functioning of the state, the employer and the employee; and with the assistance of liberal intellectuals and administrators, a compulsory contributory Health Insurance Scheme for Industrial workers was framed giving birth to the ESI Act 1948, which replaced the Workmen's Compensation Act in respect of employees covered by the former.

Under the Constitution of India, Labour is a subject in the Concurrent List where both the Central & State Governments are competent to enact legislation subject to certain matters being reserved for the Centre. Table - 1 gives the responsibilities under union and concurrent list.

Union List	Concurrent List
Regulation of labour & safety in mines and oil fields	Trade Unions; industrial and labour disputes
Industrial disputes concerning Union employees	Social Security and insurance, employment and unemployment
Union agencies & institutions for "Vocational training"	Welfare of labour including conditions of work, provident funds, employers' invalidity and old age pension and maternity benefit

List of Acts Related to Labour

- The Child Labour (Prohibition and Regulation) Act 1986
- The E.P.F. and Miscellaneous Provisions Act, 1952
- Industrial Disputes Act, 1947
- The Maternity Benefit Act, 1961

- Minimum Wages Act, 1948
- Payment of Bonus Act, 1965
- Payment of Gratuity Act, 1972
- Payment of Wages Act, 1936
- Payment of wages (Amendment) Act 2005
- Public Provident Fund Act, 1968
- Workmen's Compensation Act, 1923
- Factories Act, 1948
- ESI Act , 1948 (Employees State Insurance Act, 1948)

The Child Labour Act 1986

The problem of child labour is a big challenge before the nation. Government has been taking various pro - active measures to tackle this issue (33). This quandry will require concerted efforts from all sections of the society. This problem is intimately related to poverty. Based on the recommendations of Gurupadaswamy Committee, the *Child Labour (Prohibition & Regulation) Act* was enacted in 1986. The Act prohibits employment of children in certain specified hazardous occupations and processes and regulates the working conditions in others. The list of hazardous occupations and processes is progressively being expanded on the recommendation of Child Labour Technical Advisory Committee constituted under the Act. *National Policy on Child Labour* was formulated in 1987. The Policy seeks to adopt a gradual & sequential approach with a focus on rehabilitation of children working in hazardous occupations & processes in the first instance. The Action Plan in the Policy for tackling this problem is as follows :

- Legislative Action Plan for strict enforcement of *Child Labour Act* and other labour laws to ensure that children are not employed in hazardous employments, and that the working conditions of children working in non - hazardous areas are regulated in accordance with the provisions of the Child Labour Act.
- Focusing of General Developmental Programmes for Benefiting Child Labour.
- Project Based Plan of Action envisages starting of projects in areas of high concentration of child labour. Pursuant to this, in 1988, the *National Child Labour Project (NCLP)* Scheme was launched in 9 districts of high child labour endemicity in the country.

The Factories Act 1948

The factories Act was enacted by the parliament of India in 1948, and since then it has been revised and amended from time to time (34), the latest being the factories (Amendment) Act, 1987. The amendment in 1987 was elaborated following the Bhopal Gas Tragedy. This land mark amendment of 1987, in the factories Act - 1948, in effect means that the affair of the Company cannot be entrusted to a managing agent, and the owners or directors of the factories will be deemed to be the 'occupier' of the factory. This makes the factory owners directly responsible for ensuring Safe and Healthy working conditions in their factory.

Scope of the Act : The Act defines "factory" as an establishment employing 10 or more workers where power is used, and 20 or more workers where power is not used. The term 'worker' includes within its meaning contract labour employed in the manufacturing process. The Act applies to the whole of India except the State of Jammu & Kashmir, under the provisions

of the Act, the State Governments are authorized to appoint besides the Chief Inspector of Factories as many Additional Chief Inspector of Factories, joint Chief Inspectors, Deputy Chief Inspectors and Inspectors as they think fit to enforce the provisions of the law. The system of enforcement of Factories Act, 1948 is established on two tier basis. At the Central level, the Director General Factory Advisory Services & Labour Institutes (DGFASLI) has an advisory role. It coordinates the activities of the factory Inspectorates and provides training and advisory services to the inspectors. In addition it also assists the Ministry in drafting amendments to the Act and the Model Rules. The latter are recommended to the State Governments for adaptation with necessary modifications to suit local conditions. The Factory Inspectorates under the State Government and Union Territories carry out the enforcement functions (35).

General Duties of Employer : The Act specifically directs the employer to ensure the Health, Safety and Welfare of all workers while they are at work in the factory. His duties include ensuring Proper maintenance of plant and systems of work in the factory; Ensuring safety in connection with the use, handling, storage and transport of articles and substances; Provision of information, instruction, training and supervision necessary to ensure the health and safety of all workers at work; Provision and maintenance of risk free and safe means of access, and egress from, all places in the factory; and, Provision, maintenance and monitoring of working environment in the factory so that the same is risk free and safe.

The Inspecting Staff : The state government is empowered to appoint inspectors/Additional Chief Inspector of Factories and as many officers, it thinks fit to ensure that provisions of the Act are complied with (36), these inspectors are empowered to enter any factory or any place which he believes is being used as a factory and undertake inspections.

Certifying Surgeons : The State Government is empowered to appoint qualified medical practitioner to be certifying surgeons for the purposes of the Factories Act.

Health and Safety : Elaborate provisions have been made in the Act under chapter III, IV and IV A, with regard to health and safety of workers, These chapters deal with laws pertaining to such matters as cleanliness, lighting, ventilation. treatment of workers, effluents and their disposal, elimination of dusts and fumes in the workplace, provision of spittoons, control of temperature, supply of cool drinking water and for the employment of cleaner to keep the water closets clean. A minimum of 350 cu feet of space for each worker for factories installed before 1948 and 500 cu feet for factories installed after 1948 has been prescribed by the govt not taking into account space more than 14 feet above ground level. The Act also prescribes in detail provisions relating to the safety of workers. Section 40B provides for the appointment of "Safety Officers" in every factory wherein 1000 or more workers are ordinarily employed. The state Government is empowered to prescribe maximum weights, which may be lifted or carried by men, women and children. Some of the other safety provisions relate to caring of machinery, devices for cutting off power, hoists and lifts, protection of eyes and precautions against dangerous fumes, explosives and inflammable materials.

Welfare : Chapter V of the Act relates to welfare measure for the worker. The Act specified that wherein more than 250 workers are ordinarily employed, a canteen shall be provided. In every factory, wherein 30 or more women workers are ordinarily employed, a crèche should be provided. Provisions have been made under the Act to ensure adequate washing facilities, appliances, shelters, rest rooms and lunchrooms. There should be a welfare officer for every factory employing more than 500 workers.

Employment in Hazardous Processes : Chapter IV A, incorporate by the Factories (Amendment) Act, 1987, relates to hazardous processes. A site appraisal Committee is to be constituted to submit recommendations on the siting of factories using hazardous processes. Provisions have been made for workers, participation in safety management in industries involving hazardous processes.

Hours of Work : The Act has prescribed a maximum of 56 hrs of work (60 hrs including overtime) per week with maximum spread over of work upto 12 hrs per day (including rest interval of ½ hr after every 5 hrs of work). For adolescents, the maximum hours of work per day have been restricted 4 ½ hours.

Employment of Young Persons and Women : The Act prohibits employment of children below 14 years of age. Persons between the ages of 15 and 18 years are to be duly certified as adolescents by “Certifying Surgeons” and also deemed thus fit to work. Adolescent employees and Women are restricted from employment in certain dangerous occupations and hazardous processes and are allowed to work between 6 A.M and 7 P.M.

Leave with Wages : The Act lays down that besides weekly holidays, every worker will be entitled to leave with wages after 12 months of continuous work at the rate of one day for every 20 days of work for adults and one day for every 15 days of work for adolescents.

Notifiable Occupational Diseases : The Act gives a schedule of Notifiable disease (see 3rd schedule of the Act). It is obligatory on the part of the factory management to give information regarding specified accidents, which cause death or serious bodily injury and regarding occupational diseases. Provisions have also been made for safety and occupational health surveys in the factories.

Social Security Schemes

Social Security is a wide term and it is difficult to have a standard uniform definition of the term. The international Labour organization (ILO) defines it as “the Security that society furnishes through appropriate organization against certain risk to which its members are exposed. It is social because it represents a collective effort by society. The security is provided in an organized form and therefore is not haphazard. Examples of Social security schemes in India are :

1. Employees Provident Fund Organization
2. Central Government Health Scheme (CGHS)
3. Central Maternity Benefit Act 1961
4. Workmen's Compensation Act 1923
5. Employees State insurance Act 1948
6. The Family Pension Scheme 1971
7. Various insurance Schemes of LIC, private insurers

The Employees State Insurance Act 1948

The ESI scheme is hailed as the largest Social Security Scheme of its kind in Asia. The ESI Act 1948 was enacted to “provide for certain benefits to employees in case of sickness and employment injury and to make provision for certain other matters in relation thereto. It has undergone amendments several times. The ESI Act, at present, applies in the first instance to non - seasonal factories using power in the manufacturing process and employing 10 or more persons and non power using factories employing 20 or more persons for wages. A factory or an establishment to which this Act applies shall continue to be governed by this Act, notwithstanding that the number of persons employed there at any time falls below the limit specified by or under this Act or the manufacturing process therein ceases to be carried on with the aid of power.

The Act contains an enabling provision under which the ‘appropriate government’ is empowered to extend the provisions of the Act to other classes of establishment. Under these provisions most of the state governments have extended provisions of the Act to certain additional establishments, viz., Shops, hotels, restaurants, cinemas including preview theatres, road motor transport agencies, newspaper establishments, employing 20 or more persons; Beedi manufacturing establishments employing 10 or more persons in the implemented area; and, State pencil manufacturing establishments employing one or more persons (37).

All factories or establishment to which the Act applies are required to register themselves in the Local office of the ESI Corporation. The Act empowers the Central Government, the State Government and the Corporation to frame rules for the running of the scheme. For carrying out its functions a statutory body called the ESI Corporation has been set up with the Minister of Labour as its Chairman, It has representatives of the Central and State Governments, Employers, employees, medical professionals and members of Parliament. The Chief Executive of the Corporation is the director General ESI who is assisted by an insurance Commissioner, a Medical Commissioner, a Finance Commissioner and an Actuary. The DGESI and the Finance Commissioner are appointed by the Central government. The other executives get promoted through ESI departmental channels. The Corporation has one Regional office each, in all the States who have local offices under them in all areas covered by the Act. There is a Medical Benefit Council, which decides medical care polices, headed by the DGHS who is assisted by the Medical Commissioner. The other members of the Medical Benefit Council include Dy DGHS, State ESI medical heads, and representatives of employers, employees and medical professionals. The latter are nominated by the Indian Medical Association.

The medical care component called the Kingpin of the scheme is to provide full preventive, curative and occupational health services to its beneficiaries (38, 39, 40). Through it the Scheme provides Out - patient treatment, Domiciliary treatment, Specialist Consultation, In - patient treatment, Free supply of drugs, dressing, artificial limbs, aids and appliances, X - ray and laboratory investigations, Vaccination and preventive inoculations, Antenatal care, confinement and postnatal care, Ambulance service or conveyance charges for

going to hospitals, diagnostic centres, etc. where admissible, Family welfare services and other national health programme services, Medical certification, Special provisions including super - specialist services, and, early detection and diagnosis of occupational diseases.

Initially the medical care was provided only to workers in active employment. It has subsequently been extended to families of workers. In 1989, the Act was amended to include provision of medical care to an IP who ceases to be in insurable employment on account of permanent disablement, subject to payment of contribution, till the date on which he would have been superannuated had he not sustained such permanent disablement. It also brought under the 'medical care umbrella' retired workers and their spouses subject to payment of nominal contribution of Rs 10 only by a subsequent amendment. This Scheme is run by the State Governments under the guidance of the Corporation except in Delhi and NOIDA where it is run directly by the Corporation. The State Government bears 1/8th of the cost of medical care and the balance is met by the Corporation. For budgetary calculations the ceiling for the total cost on medical care benefit has been fixed at Rs 500 per IP annually. These benefits are provided free of cost including hospitalization in case of sickness, employment injury and maternity related causes. Medical care is provided either directly through the exclusive ESI hospitals and Dispensaries or indirectly through a panel of private medical practitioners (Panel System). All industrial Centres having large concentration of insured persons have the direct pattern of medical care, and the indirect pattern if restricted to areas having less concentration of insured persons where providing exclusive ESI services is not considered cost effective. It has its own referral chain and patients requiring super specialty treatment can be referred to the zone level ESI hospitals cum occupational Centres. In addition patients can be sent to specialized non ESI hospitals also at the expense of the ESI Corporation. Besides, the ESI Scheme provides the following major benefits :

Sickness Benefit : This consists of periodical cash payment to an insured person if his sickness is duly certified by an ESI/ insurance Medical Practitioner. The benefit is payable for a variable period of time depending on the type of illness and subject to the individual remaining under medical treatment provided under the Act. The insured person is protected from dismissal or discharge from service by the employer during the period of sickness.

Maternity Benefit : The benefit is payable in cash for an insured Woman for confinement/miscarriage or sickness arising out of pregnancy/confinement or premature birth of child or miscarriage. For confinement the duration of benefit is 12 weeks, for miscarriage 6 weeks and for sickness arising out of confinement 30 days. The benefit is allowed at about full wages.

Disablement Benefit : The Act provides for periodic cash payment, besides free medical treatment, in the event of a temporary or permanent disablement as a result of employment injury as well as occupational disease.

Dependent Benefit : In case of death, as a result of employment injury, the dependents of an insured person are eligible for periodical payments.

Funeral Benefit : Funeral expenses are in the nature of lump sum payment up to a maximum of Rs 1500 made to defray the expenditure on the funeral of a deceased insured person. This payment is to be made to the eldest surviving member of the family of the deceased.

Unemployment Allowance : This benefit has been introduced from 10 Apr 2005 & provides for an unemployment allowance to an individual for a maximum period of 6 months on account of closure of factory or establishment, retrenchment or permanent invalidity arising out of non employment injury, after being in insurable employment for five or more years.

Leo S Vaz

Keeping in view the problems likely to be encountered by workers in various industries it is essential that the Occupational health physician put in place a detailed surveillance system which would be effective and provide predictive guidelines for prevention of diseases due to occupation. These evaluations explore the physical demands and environmental hazards of a worker's position. The Occupational Medical Services health care provider reviews the individual's personal medical and

immunization history to determine whether the worker can assume/continue the duties. The staff provides work - related health and safety advice, administers appropriate vaccines, and enrolls the individual in applicable surveillance programs.

Preassignment (Pre-placement)

Some companies require pre - placement testing as a means to determine if the applicant has the capacities to accomplish the specific duties of the job, based upon the physical, environmental and psychological demands of the position. Pre - placement medical evaluations are recommended for individuals whose work involves:

- Hazardous industries
- Strenuous activity

- Animal contact
- Patient contact,
- Possible exposure to human body fluids
- Potential contact with human pathogens, or
- Work in an area that is used for clinical care.

As per factories Act, all workers should undergo a medical examination before entering industrial employment for the first time (engagement or preplacement examination) or within 15 days of employment. The focus of these exams is to avoid potential work - related accidents by detecting medical conditions early. Diagnosis made on these medical examinations should be strictly confidential. Persons suffering from unsafe traits, such as, 'accident - proneness' should not be employed near hazardous jobs.

Periodic Medical Surveillance

Medical surveillance is a valuable tool for assuring and maintaining a healthful workplace environment. Medical surveillance is the periodic testing of employees exposed to potentially hazardous materials or other risks in the workplace. The purpose of medical surveillance is to detect early signs of work - related illness so that appropriate action can be taken to eliminate the underlying exposures. The Factories Act requires companies to conduct Periodical medical examination at regular intervals (monthly, quarterly, yearly) depending upon the hazard to which a worker is exposed. For instance, medical surveillance is required to detect illnesses caused by materials such as asbestos, lead, formaldehyde, benzene, and hazardous waste. The clinical examination should be supplemented by special investigations where indicated. Date and results of such examination should be recorded in special registers maintained for this purpose.

Post - Illness or Injury (return - to - work)

An employee's health status may be reevaluated following prolonged absence from work due to illness or injury. This exam is conducted to ensure that an employee has sufficiently recovered from an illness or injury to perform the job without harm to himself/herself or to others. In addition medical examination of workers should be carried out on their returning from sick leave and those seeking change of employment.

Pre Retirement / Change of Job

An employee's status requires to be evaluated prior to his retirement or change of job so that it can be assessed as to whether he has suffered from disability/ disease due to the job. This is also beneficial to the employer as the employee cannot make subsequent claims.

Components of Tests

Physical testing is composed of several distinct tests. Exam components may vary based upon the protocols required by

your company. In general, an occupational health test may include:

- Physical exam
- Vision
- Audiometry Tests
- Pulmonary Function (PFT)
- ECG
- Blood tests
- Chest X - ray

(a) Physical Exam : The physical exam is conducted by an occupational health physician, and is designed to provide an assessment of health as it relates to the specific occupation. The evaluation usually consists of a thorough physical exam: review of systems (head/neck, heart/lungs, gastrointestinal, genitourinary, skin and soft tissue, musculoskeletal, neurological). A physician will usually inquire further on any positive responses in the medical history questionnaire to help determine physical ability to work.

(b) Vision Screening : This test screens for visual acuity (both near and far visual fields, depth perception) or colour (if required on job). A glaucoma screen may also be performed under certain circumstances.

(c) Audiometric Tests : This testing is part designed to protect workers with significant occupational noise exposure from suffering material hearing impairment.

(d) Pulmonary Function Test : Pulmonary function testing (PFT), or lung function testing, is carried out in workers working in industries which are likely to have adverse affects in pulmonary function.

(e) ECG

(f) Blood Tests : as considered essential by the physician.

(g) Chest X-Ray : A chest X-ray is usually done for the evaluation of lungs, heart and surrounding anatomy.

Report

The physician must send his report to the third party/employer who requested the assessment. He may discharge the mandate entrusted to him by giving his opinion in the report. This opinion may take any of the following forms:

- Unconditional acceptance of the applicant;
- Acceptance despite the presence of limitations not entirely incompatible with the job, accompanied by a description of these limitations;
- Acceptance conditional upon accommodations made to the job because of incompatible limitations;
- Refusal because of impairments resulting in total incompatibility.

Leo S Vaz, Ashok K. Jindal & Puja Dudeja

Burden of Occupational Disease and Injuries

There are 100 million occupational injuries causing 0.1 million deaths in the world according to WHO. It is also estimated that in India, 17 million occupational non-fatal injuries (17% of the world) and 45,000 fatal injuries (45% of the total deaths due to occupational injuries in the world) occur each year. Out of 11 million cases of occupational diseases in the world 1.9 million cases (17%) are contributed by India and out of 0.7 million deaths in the world 0.12 (17%) is contributed by India. National Institute of Occupational Safety & Health (NIOSH) has developed a priority list of 10 leading work-related illnesses and injuries. Three criteria were used to develop the list: (a) The frequency of occurrence of the illness or injury (b) Its severity in individual cases and (c) Its potential for prevention. Occupational lung disease is first on the list. Silicosis, asbestosis and byssinosis are still prevalent in many parts of the world. The prevalence of Occupational Asthma varies from 10% to nearly all of the workers in certain high-risk occupations. NIOSH considers occupational cancer to be the second leading work-related disease, followed by cardio-vascular diseases; disorder of reproduction, neurotoxicity, noise induced hearing loss, dermatological conditions, and psychological disorders.

Global Strategy for Occupational Health

The first WHO programme on occupational health was designed in 1950, just two years after the Organization was established. WHO joined with ILO to form the Joint ILO/WHO Committee on Industrial Hygiene. In the 1960s and most of the 1970s, the WHO occupational health strategy focused on the scientific and technical aspects of occupational health services, including the early diagnosis of occupational diseases, and training and education in occupational health. A new strategy for the further development of occupational health services was adopted in 1979, with the World Health Assembly Resolution WHA32.14 on the proposed comprehensive workers' health programme, stressing the need to organize primary health care services "as close as possible to where people live and work". To mitigate the adverse health impact of work-related risk factors, the WHO Programme on Occupational Health set up a new agenda in the 1990s with the adoption of a new resolution in 1996 (WHA 49.12) which led to the development of the WHO Global Strategy for Occupational Health for All.

The global strategy for achieving occupational health for all (WHO-SEARO 1999) includes the following ten major areas for action (41):

1. Strengthening of international and national policies for health at work and developing the necessary policy tools.
2. Development of healthy work environment.
3. Development of healthy work practices and promotion of health at work.
4. Strengthening of occupational health services (OHS).
5. Establishment of support services for occupational health.
6. Development of occupational health standards based on scientific risk assessment.
7. Development of human resources for occupational health.
8. Establishment of registration and data systems, development of information services for experts, effective transmission of data and raising of public awareness through public information.
9. Strengthening of research.
10. Development of collaboration in occupational health and with other activities and services.

National Programme

Occupational health was one of the components of the National Health Policy 1983 and now also included in National Health Policy 2002, but very little attention has been paid to mitigate the effect of occupational disease through proper programme. Ministry of Health & Family Welfare, Govt. of India has launched a scheme entitled "National Programme for Control & Treatment of Occupational Diseases" in 1998-99. The National Institute of Occupational Health, Ahmedabad (ICMR) has been identified as the nodal agency for the same (42).

Following research projects has been proposed to be initiated by the Government :

1. Prevention, control and treatment of silicosis and silico-tuberculosis in Agate Industry.
2. Occupational health problems of tobacco harvesters and their prevention.
3. Hazardous process and chemicals, database generation, documentation, and information dissemination.
4. Capacity building to promote research, education, training at National Institute of Occupational Disease.
5. Health Risk Assessment and development of intervention programme in cottage industries with high risk of silicosis.
6. Prevention and control of Occupational Health Hazards among salt workers in the remote desert areas of Gujarat and Western Rajasthan.

Study Exercises (For Section 11)

MCQs

1. Father of occupational medicine is (a) Bernardino Ramazzini (b) Karl Marx (c) Donald Hunter (d) John Simon
2. First Industrial Health nurse (a) Philippa Howerday (b) Mother Teresa (c) None of the above
3. Which of the following is not an agricultural hazard (a) Musculoskeletal disorders (b) Bagassosis (c) Byssinosis (d) Silicosis
4. Which is not true of occupational cancer (a) History of exposure to carcinogen is present (b) Danger of getting cancer even after exposure has ceased (c) Location and histological pattern are quite common in most occupations (d) Short latent period
5. Exposure to vinyl chloride leads to (a) Angiosarcoma of the liver (b) Laryngeal tumour (c) Nasal cancer (d) None of the above
6. Aromatic amines lead to carcinoma of (a) Bladder (b) Lung (c) Nasal Septum (d) All of above
7. By ILO definition, Pneumoconiosis is _____ (a) accumulation of dust in the lung (b) Tissue reaction to its presence. (c) a & b (d) Any damage to lung
8. Which is not true of silicosis (a) Clinical manifestations are shortness of breath (b) The dust must contain silica in a free state as quartz (SiO₂) and the particles must be of respirable size. (c) No X ray changes (d) Wet processes carry less risk or none at all but dry processes are definitely dangerous
9. "Asbestos bodies" are seen in (a) Sputum (b) X-ray (c) Clinical examination (d) None of the above
10. Ground glass appearance on X ray is seen in (a) Asbestosis (b) Silicosis (c) Anthracosis (d) Berylliosis
11. Caplan's syndrome is seen in (a) Asbestosis (b) Silicosis (c) Anthracosis (d) Berylliosis
12. Byssinosis is caused by exposure to (a) Cotton dust (b) Sugarcane dust (c) Tobacco (d) All of above
13. Level I safety audit is done (a) Once in a month (b) Once in two months (c) Once in three months (d) Fortnightly
14. Asbestosis causes all except (a) Mesothelioma (b) Calcified pleural plaque (c) Pneumoconiosis (d) Farmer's lung
15. Farmer's lung results from exposure to :- (a) Sugarcane dust (b) Cotton fibre dust (c) Grain dust (d) Tobacco
16. *Micropolyspora faeni* is the main cause for (a) Byssinosis (b) Bagassosis (c) Anthracosis (d) Farmer's lung
17. Lead is the most used metal commonly in the industries because of : (a) Low boiling point (b) Anticorrosive (c) Least toxic (d) Easily mixes with other metals
18. Acceptable blood lead levels are: (a) 25 µg/100ml (b) 50 µg/100ml (c) 75 µg/100ml (d) 100 µg/100ml
19. Lead poisoning in industries commonly occurs by: (a) Inhalation (b) Ingestion (c) Skin absorption (d) Conjunctival route
20. Size of respirable dust is below (a) 0.1 micron (b) 1 micron (c) 5 micron (d) 10 micron
21. Toxic effects of inorganic lead exposure include all except: (a) Abdominal colic (b) Blue line on gums (c) Wrist drop (d) Mental confusion (e) Stippling of RBC
22. Safer Alternatives for benzene are (a) Toluene (b) Xylene (c) Trichloroethylene (d) Cyclohexane (e) All the above
23. Smell of 'Bitter Almonds' in the breath is seen in poisoning of (a) Hydrogen cyanide (b) Nitrous Fumes (c) Carbon – Monoxide (d) Trichloroethylene (Trilene)
24. Which one of the following is not the direct effect of heat exposure in an industry : (a) Heat exhaustion (b) Heat stroke (c) Erythrocyanosis (d) Burns
25. Canteen for workers as a welfare measure under Factories Act is a must when the strength of the workers is more than (a) 200 (b) 100 (c) 250 (d) 500
26. Which of the following statement is Not true for ESI (a) Funeral benefit up to a maximum of Rs 2500 (b) In result of employment injury, the dependents of an insured person are eligible for periodical payments (c) Disablement benefit @ 80% of wages (d) Maternity benefit for 12 weeks for confinement.
27. Which of the following is not a benefit to the employer in ESIC (a) No responsibility for the employee's health (b) Exemption from applicability of Workmen's Compensation Act 1923 (c) Healthy work force (d) Rebate under Income tax act
28. All of the following are notified under Factories act except (a) Asbestos (b) Nickel (c) Coal tar (d) Silica
29. Which of the following disease may be encountered as occupational hazard (a) Leptospirosis (b) Brucellosis (c) Anthrax (d) All of the above
30. All the following are pneumoconiosis except : (a) Siderosis (b) Bagoasosis (c) Farmers's lung (d) Psittacosis
31. Pneumoconiosis is caused by all except (a) Coal dust (b) Silica (c) Chromium (d) Asbestos
32. The ESI Act came into being in : (a) 1948 (b) 1952 (c) 1962 (d) 1975
33. ESI corporation works under:- (a) Ministry of Labour (b) Ministry of Health (c) As autonomous body (d) Respective state government.

Answers : (1) a; (2) a; (3) d; (4) d; (5) a; (6) a; (7) c; (8) c; (9) a; (10) a; (11) c; (12) a; (13) c; (14) d; (15) c; (16) d; (17) b; (18) c; (19) a; (20) c; (21) d; (22) e; (23) a; (24) a; (25) c; (26) b; (27) a; (28) b; (29) d; (30) d; (31) c; (32) c; (33) c.
