From The Chief Editor's Desk

There is widespread recognition of the fact that the health status of the population at large in our country leaves much to be desired, despite having a well-developed administrative system, good technical skills in many fields, and an extensive network of public health institutions for research, training, and diagnostics. The acceptance of this yawning gap between our capabilities and the actual reality of the health situation in India has focused the attention of governmental and non – governmental bodies on the twin disciplines of Community Medicine and Public Health.

As a consequence, Community Medicine and Public health are expanding rapidly in India. After relative inactivity for several years, they have now moved to the centre stage of health related activities. The emergence of new infections like HIV/ AIDS, re-emergence of a number of infections like pandemic influenza and dengue fever, and enormous increases in lifestyle related diseases in India have refocused the limelight on preventive rather than curative medicine. A number of large scale government initiatives like the National Rural Health Mission are a direct offshoot of the inequities in health care delivery.

This increased attention on public health in the country has brought out the stark reality of a massive shortage of public health professionals in the country. Running the Public Health agenda of our country needs not only medical doctors, but professionals from diverse fields, particularly various Biomedical disciplines, management and finance. Public health professionals try to prevent problems from happening or re-occurring through implementing educational programs, developing policies, administering services, and conducting research. It is also a field that is concerned with limiting health disparities and a large part of public health is the fight for health care equity, quality, and accessibility. Overall, Community Medicine and Public Health are concerned with protecting the health of entire populations. These populations can be as small as a village, or as large as an entire country.

To fulfill the enormous demand for health professionals in the field of Community Medicine, in addition to the academic departments of Community Medicine / PSM in various medical colleges, a number of public health schools have opened across the country with several more in the pipeline. These schools offer degrees of varying names and with varied course content. Most of these courses including several Masters of Public Health (MPH) courses are still not recognized by any statutory academic body. The curriculum of these courses is not standardized. There is no prescribed course book for these courses. Most of these schools of public health accept medical as well as non-medical personnel as students. Different schools have courses of different durations (One / two years) and appear to follow varied syllabi.

The currently available textbooks in our country, on undergraduate (or even postgraduate) teaching in public health and preventive medicine are aimed only at medical professionals. Against this backdrop, this textbook has been developed with a view to address a wide variety of target audience. The selection of topics covered, the depth and extent of coverage, and the structure of the book have been designed for three categories of users. This book should, firstly, fulfill the needs of undergraduate and postgraduate students of Community Medicine. Secondly, it should be able to be used by students undergoing MPH courses, whether they are medical doctors or non medical professionals. Thirdly, this book should be able to provide guidance to both medical and non medical professionals who are active in the field of public health in India. The book is also intended to be prescribed reading for training courses. Towards this end, each chapter has been provided with a summary, self assessment Multiple Choice Questions (MCQs) and short and long questions.

Any effort can be improved upon. This first edition of the book will, without doubt, have errors and shortcomings. We intend to improve the book as it evolves over the years. Feedback from the readers is the most important instrument for improvement and we earnestly solicit it from all our readers.

FOREWORD

The need for a comprehensive textbook covering the vast and closely related subjects of Public Health and Community Medicine in the Indian context has been felt by all concerned in the medical field in India. The health scenario in our country is rapidly changing, both in terms of the public health challenges that we face as well as our response to these challenges. As India becomes more and more developed and we have greater means at our disposal, our response to our health challenges must reflect our changing health and socio-economic status. It is, indeed, time for a quality textbook to clearly bring before our scientists and health practitioners, the actual health situation in our country and guide their responses to these challenges.

It gives me immense pleasure to learn that the Department of Community Medicine, Armed Forces Medical College, Pune has endeavored to author a textbook on 'Public Health & Community Medicine' to encompass the rapid changes in the field of Public Health and Community Medicine, while preserving the basic contents of the subject, for the benefit of medical students and the practitioners of public health.

The book is comprehensive and complete in its content and aims to reflect the current medical knowledge on the topics presented. A unique feature of this book is that several new chapters have been included which would be difficult to find in any standard textbook at one place. Besides, all chapters have been provided with summary and relevant questions to make learning more comprehensive. All chapters in the book have detailed references and suggested readings which will guide readers towards further reading, thereby making it an ideal resource book for students undergoing training in the speciality of Community Medicine / Public Health, including those preparing for entry into these specialities.

This textbook will indeed occupy a niche in the shelves of library of graduate and post-graduate medical students, practitioners of public health, as well as various Institutes of Public Health and Community Medicine in our country. I implore all to ensure that this book is updated at regular intervals.

I acknowledge and appreciate the perseverance and dedication shown by the team of Authors and Editors led by Col Rajvir Bhalwar, Professor & Head and the faculty at the Department of Community Medicine, Armed Forces Medical College. I congratulate them all for this commendable effort and wish them all success.

New Delhi

(Yogendra Singh)
Lieutenant General

MESSAGE

Today, public health is poised at a critical juncture in terms of its further development in India. There exists a need to review the current medical education curricula and provide a meaningful public health orientation. Public health training requires to be re-gearred to address the needs of the community. There is a need to broaden the concept of public health to include community-focused health services. While institutional care is necessary, community public health problems cannot be addressed only by health care facilities. An important challenge today, is to link institutional service delivery with national public health programmes and community-oriented services.

Concurrently, globally, there is a widespread recognition of the complex social determinants of health. Influences on human health have acquired a global dimension. In face of rapid global ization, emerging global health threats, and environmental challenges, greater integration of public health with other disciplines is needed. Multi-sectoral actions and multi-disciplinary approaches are required to achieve public health goals.

Public health is a diverse and growing field of study in India. While education in public health is vital, there needs to be equal emphasis on public health practice, with a clear vision of reaching the un-reached. In this context, the preparation of this document titled 'Textbook of Public Health and Community Medicine' is an important input to the field of public health in India. This document is a timely and valuable resource for public health practitioners, experts, and programme managers. We hope that the textbook would provide major inputs to students pursuing studies in public health.

The WHO is pleased to support this commendable initiative undertaken by the Armed Forces Medical College (AFMC), Pune. It is hoped that this comprehensive work would contribute towards further development of public health education and practice in India.

Dr S. J. Habayeb
WHO Representative to India

Contents			
Section 1 : Introduction and General Concepts in Public Health, Community Medicine & Preventive Medicine			
1	Introduction, Definitions & General Concepts in Public Health & Community Medicine	RajVir Bhalwar, Mandeep Singh, J Jayaram	1

RajVir Bhalwar, Mandeep Singh, J Jayaram

The last two decades of the 20th century saw a renewal of the world population's interest in public health, in disease prevention, communicable and chronic disease control, health protection and health promotion. Not that public health is a new concept; great public health movements had already started in mid-nineteenth century by Edwin Chadwick in UK (report on an inquiry into the sanitary conditions of the labouring population in great Britain, 1842) and around the same time in USA in 1850 by Lemuel Shattuck (Report of the sanitary commission of Massachusetts) (1,2). These two reports initiated that brilliant movement - now known as public health, of which preventive medicine is an essential component and which has been responsible for saving billions of human lives and reducing human suffering during the last 100 years. The recent increasing interest in public health shown by nearly all governments, whether from developed or developing countries has been, therefore, due to the realization of the fact that continued investment in clinical care brings diminishing returns, while the gains can be maximized by resorting to methods of health promotion and disease prevention among populations at large.

The handicap that public health and preventive medicine always face is that its predominant focus on prevention makes it more abstract than curative medicine and its achievements are therefore more difficult to recognize. The doctor who cures a patient has achieved a real, recognizable benefit and the patient, as well as her near ones and even the community members, are all grateful. On the other hand, public health cannot point to the people who have been spared of illness by its efforts. As the famous quote goes "---- If we had but the gift of second sight to transmute abstract figures into flesh and blood, so that as we walk along the street, we could say, "that man would have been dead of typhoid fever", "that woman would have succumbed to anaemia of pregnancy", "that rosy infant would have been in its coffin because of diarrhoea and dehydration", -then only would we have a faint conception of the silent victories of public health----". In fact, it is this "silence" that accounts, in large part, for the lack of attention paid to public health by those who are in a position to mobilize community opinion or take public decisions. In developing countries not even one percent of the total national budget is spent on public health; the situation, even in the developed countries is no better. For example, even in USA, just about 1% of the nation's total health spendings go towards public health. In 1992, when the average cost of medical treatment was \$3,007 for each American, the amount spent on public health was only \$ 34 per person (3) !

Despite the above-mentioned difficulties that public health including preventive medicine, as a concept and as a science, is faced with, it has undoubtedly been a major force in furthering the cause of human health and development. Indeed, during

the 20th century, many times more lives have been saved and diseases prevented by simple public health measures as safe water supply, sanitary excreta disposal, vaccination and insect-vector-control measures, than would have been saved by all the dazzling advancements of curatives and diagnostics put together! For instance, as per a report, the life expectancy in USA increased from 45 years in beginning of 20th century to over 75 years in the next 100 years and only 5 out of these 30 years increase can be attributed to the work of curative medical care system, while the large majority of this gain has come from improvements in public health, broadly defined to include better housing, nutrition, sanitation, immunization and occupational safety (4).

Definitions & Basic Concepts

At the outset it would be worth-while to review the meanings of some terms in common use in the disciplines of public health, preventive medicine & community medicine. In fact, meanings change with time. Terms which have been long in use acquire extended meanings (a case in point is the term "Preventive Medicine" itself), while new terms are coined to signal a new emphasis. The meanings of some terms may overlap and different shades of meanings may be associated with use of the same term. In fact, Public Health, Preventive Medicine and Community Medicine contain very overlapping ideas as would be evident throughout this book; accordingly, their definitions are quite likely to overlap.

Health

There are many views as to what constitutes "health". One view puts it as "absence of disease", i.e. there are no impediments to an individual's functioning or survival. This view is reflected by Oxford English Dictionary (5) which defines health as the state of being free from illness or injury. Implicit in this view is a set of abilities that favours growth and development and the efficient performance of bodily function in the face of changing environmental conditions, a capability known as "adaptability". As a corollary, disease corresponds to failures or disturbances in growth, development, function and adjustments of the organism, as a whole or any of its systems (6).

The problem inherent in the "absence of disease" definition is that it focuses only on disease. However, there is, in every disease, a long phase of transition from actual health to the overt disease process, as will be appreciated when one goes through the chapter on "natural history of disease and levels of prevention" in this book. Hence, health is something much more than the mere absence of disease.

The above ethos is echoed in the widely used definition of health by WHO, which states "Health is a state of complete physical, mental and social well being and not merely the absence of disease or infirmity (7). This definition is commonly seen as the statement of an "ideal" towards which nations should aspire, rather than as a practical working definition. For this reason, an "operational" definition of health, one drawn from the above "ideal" definition, has been forwarded, by a technical study group of WHO (8). According to this definition, the concept of health is viewed as being of two orders - first, in a broad sense, health can be seen as a condition or quality of the human organism in given conditions : genetic and

environmental. Secondly, in a narrow sense, more useful for working purposes, health means :

There is no obvious evidence of diseases and that the person is functioning “normally”, i.e. conforming within normal limits of variations to the standards of health criteria, generally accepted for one’s age, sex, community and geographic region and,

That various organs of the body are functioning adequately in themselves and in relation to one another, which implies a kind of equilibrium or homeostasis.

Medicine

The noted medical historian Henry Sigerist (9) defined medicine as “Medicine, by providing health and preventing illness, endeavours to keep individuals adjusted to their environment as useful and contented members of society; or by restoring health and rehabilitating the former patient, it endeavours to readjust individuals to their environment.

It is clear from the above-mentioned, widely accepted definition, that “Medicine” as a discipline, has two clear components - firstly the “promotive and preventive” component, which is mainly the purview of preventive medicine; and the other, a “restorative and rehabilitative” component, which is the main purview of curative medicine. However, there is no such sacrosanct dividing line in practice, since very often, a clinician may also adopt ways and means of primary and secondary prevention, while a preventive medicine practitioner may very often focus on basic clinical care or rehabilitation. Finally, public health, as a discipline, keeps a focus on both the components, i.e. health promotive / preventive as well as restorative / rehabilitative, but distinguishes itself from curative or specific preventive medicine in two very special facets - that in public health, the focus is on the “Public” (i.e. a community or a population) and not on any individual and that the approach utilizes “organised community efforts”, as we shall appreciate a little later.

Preventive Medicine

Preventive Medicine is that branch of medicine which deals with promoting health and preventing disease. The cardinal goal of preventive medicine is to avert the occurrence of disease. Achievement of this goal requires that actions be directed at the earliest stage of the natural history of disease, i.e. stage of susceptibility, using the methods of health promotion and specific protection; and to some extent, methods of secondary prevention by early detection of disease when it may be otherwise not detected using usual methods of diagnosis, often by screening followed by appropriate intervention. However, in a broader sense, preventive medicine refers to “limiting” the progression of disease at any stage of its course. Thus, when a clinician, using the approach of curative medicine, diagnosis and treats a patient of pulmonary tuberculosis, she is practicing preventive medicine too, since she is “preventing” the progress of the disease from the mild / uncomplicated phase to one of complications and more disability. Similarly, when we “treat” a patient of Colle’s fracture, by closed reduction and plaster cast, we are actually limiting the progress of a disease to a more severe form which would have complications like mal-union; thus we are practicing preventive medicine (preventing disability).

To understand as to what preventive medicine has come to represent as a movement within medical theory and practice, it is necessary to follow historically the application of the concept and its interaction with other movements. As said earlier, preventive medicine, in its modern form, is not the same as the older discipline of public health, although the principles and techniques of prevention are also widely applied by public health professionals. Initially, preventive medicine was identified with its most outstanding activity, i.e. contributing to the control of communicable diseases. In fact, in its early years, preventive medicine was equated with infectious disease control. Subsequently, by applying specific measures, as demonstrated by the continuing emergence of “Epidemiology” (one of the most important tools of preventive medicine & public health), the preventability of non-communicable diseases was demonstrated as well, with health education and counselling for behaviour change being added on to the armamentarium of preventive medicine.

Public Health

The perspective of public health is captured in statements contained in the report on “Higher Education for Public Health” of the Milbank memorial commission (10). In public health, problems are named within the context of the community as a whole rather than occurring in a series of individuals. This view leads to the establishment of priorities and permits rational choices on the use of resources. From this view also comes a commitment that is communal rather than personal, one in favour of solving problems for the benefit of the health of the population as a whole. Over the years, the unique feature of public health has been acknowledged to be “Organized Community Effort” and “Systematic Social Action” and the classical definition of public health, which has stood the test of time, is the one forwarded by CEA Winslow (11) as :

“The science and art of preventing disease, prolonging life and promoting physical health and efficiency through organized community efforts for the sanitation of the environment, the control of community infections, the education of the individual in principles of personal hygiene, the organization of medical and nursing services for the early diagnosis and preventive treatment of diseases and the development of social machinery which will ensure to every individual, in the community, a standard of living adequate for maintenance of health”.

Thus public health is best identified as a social movement concerned with protecting and promoting the collective health of the community. This is its origin and this is its accomplishment. Thus, the province of public health is by no means limited to prevention. While mostly public health activities are funded and regulated by the Governments (National or State), the work of voluntary health agencies is also very much part of public health activities since they represent an organized community effort and systematic social action. In fact, even a small movement by a small village to purify their drinking water source or to stop alcohol drinking is also very much a public health activity. As has been very aptly stated by Mustard “A health problem becomes a public health responsibility if, or when, it is of such character or extent as to be amenable to solution only through systematized social action” (12).

Preventive Medicine versus Public Health

The dividing line between preventive medicine and public health is actually a very thin, rather hazy one. Preventive medicine is an overall science, public health is an approach within this science. When preventive medicine starts focusing on population groups rather than individuals and utilises the approach of "organised community efforts" it takes the shape of public health.

The other approach of using preventive medicine is the "individualized" preventive medicine, for instance, immunising an otherwise healthy child, or the "clinical" preventive medicine, which can be very effectively practiced in clinical settings; for example, a doctor who educates her ante-natal case about breast feeding or a doctor who takes a pap smear from her patients who are attending a family planning clinic is actually practicing individualized or clinical preventive medicine, but, may be, not public health. On the other hand when the government or even a Non Governmental Organization (NGO) working with community members in a village, organises a health education program in breast feeding for expectant mothers, or organises a cervical cancer screening camp, the approach becomes that of public health.

Social Medicine

The concepts of social medicine were formulated by some very eminent physicians like Rudolph Virchow, Grotjahn and Rene Sand, besides others. The fact that man is a social animal, it is apparent that any effort at preventing or curing the disease or making an assessment of the health problems has to take social factors into account. This is, in essence, the concept of social medicine. Subsequently, the concepts of social medicine merged with preventive medicine, to form the specialty of preventive & social medicine (see later).

Preventive & Social Medicine

Beginning from somewhere around the mid twentieth century, it was realized that the art and science of preventive disease and promoting health should be taught as an independent subject in the curricula of medical schools. Till then, most of the medical colleges were conducting such training for graduate level students under the subject nomenclature "Hygiene" usually as a part of General Medicine curriculum. It was also realized that every human disease has deep rooted social causes and not simply a result of an infectious agent. For example, everybody does not get infected with tubercle bacilli; and even out of those who get infected, only a small proportion develop the actual disease. Who gets the infection and who gets the disease is actually decided by a wide array of social factors as poverty, ignorance, overcrowding, malnutrition and so on. The considered decision was that preventive medicine should essentially combine the social aspects of health and disease in its theory, practice and teaching. This led to the birth of academic departments and the specialty of Preventive & Social Medicine (PSM) or Social & Preventive Medicine (SPM).

Socialized Medicine

Socialized Medicine is different from Social Medicine. It refers to the policy of providing complete medical care, preventive and curative, to all members of a society (usually a nation) as

a governmental commitment and out of governmental (public) finances, as is the policy in Russia.

Community Medicine

As a professional movement, Community medicine (or Community Health) is the most recent of the three fields to emerge in medical education and medical practice. As a discipline, it is defined as that branch of medicine, which addresses certain selected aspects of health promotion, disease prevention, health restoration (by curative steps) and rehabilitation of the former patients, in the community, usually, from an "Institutional Community Base" which is usually either an Academic Department in a medical college or through a curative centre. Community medicine, as an approach, has borrowed heavily from the concepts, methods and approaches of its two elder sisters, viz. public health and preventive medicine.

Community medicine is one pathway for representing an institution's commitment to improving health of its immediate (or adopted) community - generally a medical college, hospital or a clinical department serve as the base. The health task is to define the health problems, propose solutions, maintain surveillance, evaluate progress and monitor the use of resources. The approaches employed range from tools of epidemiology to the social skills, necessary for involvement with the community. Central to the approach of community medicine, whether in academia or in practice, is the promise that the main factors that determine a community's health are to be found within the community itself - in its social, cultural or biological features, or in its environment - natural and man made.

An understanding of the ways in which these factors interact to cause disease or promote health in different communities, is basic to the decisions to be made in the care and protection of the community (13). For these reasons, community medicine must be concerned with and relate to, the community behaviour and its environment and not solely restrict itself to the health services, which, very frequently, is otherwise the principal interest of the Institutional unit responsible.

As a professional movement, in USA, community medicine first appeared when some medical schools began to establish a new department (or rename an existing Dept of Preventive Medicine) and to charge it with functions of defining the health problems of a community (in the vicinity of the college, or an adopted community) and to suggest solutions, maintain surveillance and monitor progress. Many hospitals also established department of community medicine to bring together responsibility for the professional direction and coordination of a range of ambulatory programs in OPD and emergency, personal health, outreach satellite elements and other services. In UK, community medicine essentially includes Epidemiology and Medical Administration and has been seen as a successor to public health, providing information and advise on the health status and the services to the community and to the local Self Govt / community organizations, as well as performing other planning and management functions. Thus, in UK, the community medicine specialist is trained to function as Medical Officer of Health (MOH).

Evolution of Contemporary Public Health

From Shattuck and Chadwick in Mid-Nineteenth Century to Twenty-First Century (14, 15)

In the late nineteenth and early twentieth century, concern with control of epidemics was at the centre of medical and public attention. Measures for protection of the community through “environmental health” appeared first and with the establishment of effective sanitary services, the modern era of public health was born. Later, towards end of nineteenth century, microbiology expanded greatly and laid down new and scientific basis of infectious disease control. When it became clear that an “organized effort” to apply these sanitary and bacteriologic techniques was needed, the responsibility of governmental health departments, to control the communicable diseases, was given the status of law; and since treatment of infected individuals was also a part of control of infectious diseases, this also became a responsibility of public health. Later public health responsibility was further extended for organized maternal and child health services, thus extending public responsibility into the realm of personal care of individuals. As a result, organized “programs” for prevention (usually public funded but often by voluntary, non govt. organizations) become more visibly identified.

In the first half of the 20th century, personal preventive services in large numbers began to be publicly financed, while the personal curative services, for the most part, remained privately supported. As a result the personal health services become compartmentalized into two different medical practice settings - one largely preventive and the other largely curative. However, later on, as the concept of “comprehensive health care” came in, the traditional dichotomy between preventive and curative medicine become less and less differentiable.

One way of coping with the compartmentalization of activities into the two practice settings (preventive & curative) is to rationalize their inter-relationships. For example, the concept of prevention has been, in recent times, extended into curative settings in the form of “secondary prevention”, as one form of response to the rising frequency of chronic, non-communicable diseases and diseases of special groups (mothers, children, old people and industrial workers). Under this new strategy, clinicians are being urged to think more regularly about preventive management in diseases and to incorporate more of a preventive outlook in their daily practice. Similarly, public health physicians are being invited to move from their preoccupation with primary prevention, to undertake administrative involvement in health care systems. By doing so, they could relate to the total range of health care and take part in the planning, operation and evaluation of any or all of the health services. In fact, according to one of the contemporary views, “Medical Care Administration” has been advocated as a legitimate concern of public health authorities. While mostly public health activities are funded and regulated by the Govt. (National or State) the work of voluntary health agencies is also very much part of public health activities since they represent an organized community effort and systematic social action.

Contemporary Views on the Definition, Role, Principles, Core Activities and Components of Public Health

Definition : The Definition of Public health, as enunciated by Winslow (11) and which has been presented earlier, though more than 80 years old now, has stood the test of time and is very well accepted among the public health fraternity as the most standard definition. Another definition given by the Institute of Medicine (USA) also echoes the same ethos : “Public Health is a mission for the fulfillment of society’s interest in assuring the conditions in which people can be healthy, through organised community efforts aimed at the prevention of disease and the promotion of health, using activities undertaken within the formal structure of government as well as the associated efforts of private and voluntary organizations and individuals” (16).

Role of Public Health (16) : As per international consensus, the role of public health is to contribute to the health of the public (community) through :

Assessment of Health Status & Health Needs : For making assessments of health status and health needs and to reach a “community diagnosis”, with the ultimate objective of formulating health policies and planning appropriate health services, public health specialists draw heavily from the “quantitative sciences” (Epidemiology, Research Methodology, Bio-statistics, Information Technology); from “Environmental Sciences”; from “Socio-Behavioural & Communication Sciences”; and, from “Bio-Medical Sciences”.

Development of Health Policies : For this purpose the public health specialist will need a good knowledge of Quantitative Sciences; Managerial Sciences; and of Socio-Behavioural & Communication Sciences.

Assurance of the Availability and Quality of Health Services: To fulfill this role, sound knowledge of Basic Clinical Skills, Managerial Sciences, Bio-Medical Sciences and Quantitative Sciences would be an essential requirement.

In fact, the present text-book has been organized addressing, in a section-wise manner, the various core-competencies as enlisted above. These major sciences required for the practice of public health can be grouped into five major core competency areas, viz. Quantitative Sciences, Environmental Sciences, Socio-Behavioural and Communication Sciences, Biological Sciences and Managerial Sciences. The details of these core areas are given in Table - 1.

Core Principles Underlying Public health Practice: Contemporary thinking indicates that the principles underpinning the concepts of public health are as follows and the public health specialist must develop the mental attitude to adopt these core principles in her activities (17) :

- The emphasis on collective responsibility for health.
- An envisaged major role of the state in protecting and promoting the public’s health.
- A focus on whole populations and not on individuals.
- An emphasis on prevention, especially primary prevention, while not losing track of the importance of curative medicine also.

Table - 1 : Core-Competency Areas in Public Health Training & Practice

(a) Quantitative and Analytical Sciences
<ul style="list-style-type: none"> ● General Epidemiology ● Field Epidemiology, including outbreak investigations and public health surveillance systems ● Bio-statistics including statistical software ● Health Research Methodology ● Database Management and other core issues of Information Technology
(b) Environmental Sciences
<ul style="list-style-type: none"> ● Water and Food Safety ● Sanitation and Disposal of Wastes ● Environmental heat, cold & altitude and related aspects of shelter & clothing ● Air, Soil and Noise Pollution ● Nuclear & Chemical Pollution
(c) Socio-Behavioural & Communication Sciences
<ul style="list-style-type: none"> ● Sociology in Health ● Life Style & diseases of the lifestyle ● Health Education, Information, Education & Communication (IEC)
(d) Biological Sciences
<ul style="list-style-type: none"> ● Clinical Sciences (basic diagnostics and therapeutics for common and important health problems in the Community) ● Microbiology & Pathology ● Infectious and Non-Communicable Diseases : Epidemiology, prevention and Control ● Entomology
(e) Managerial Sciences
<ul style="list-style-type: none"> ● General Principles of Management & application in Health care ● Health policies & programmes, including policy / programme management ● Legal issues in Health care ● Health systems and Organization of health care delivery at various levels ● Personnel, Financial and Equipment Management ● Management of Hospitals & other Health Care Facilities ● Medical Care Administration at Primary, Secondary & Tertiary level ● Management of Health Care for Special Groups (Women, Children, Workers, old people, the “challenged” and the socio-economically disadvantaged) ● Health Care Management during Disasters

- A concern for underlying socio-economic determinants of health and disease as well as more proximal determinants, such as health care.
- A multi-disciplinary basis; the readiness to work, in a team, with different and diverging disciplines concerned with human health and development.
- Attitude to incorporate qualitative and quantitative methods, as appropriate, in the area of work.

- Readiness to undertake partnership with populations being served.

The “Dozen” Core Activities of Public Health : In 1995, the US Health and Human Services department identified ten core activities of public health (18). In our national context, we can think of the “One Dozen” core activities of public health, as follows :

- 1) Protecting the environment, food and water.
- 2) Promoting healthy behaviour through information, education and communication.
- 3) Assessing needs, making community diagnosis and monitoring the health status of the population/ community being served.
- 4) Leading to the development of sound health policy and planning.
- 5) Health programme management and management of other medical & health care systems (health care system includes the triad of personal medical care, public health care and other inter-sectoral initiatives related to health).
- 6) Preventing and investigating epidemics and maintaining surveillance on important diseases, to provide early warning.
- 7) Promoting the health and efficiency of the “workers” and protecting the “work-environment”.
- 8) Effectively responding to disasters.
- 9) Mobilizing community action.
- 10) Research to develop new insights and innovative solutions for relevant community health problems.
- 11) Reaching out to link the health services with the high risk, disadvantaged and hard to reach people (socio-economically weaker sections, hilly, tribal and inaccessible areas), or those requiring special attention (women, children and old people).
- 12) Assuring the availability, accessibility, quality and accountability of medical care.

Bridging the Gap between Theory and Practice in Public Health and Community Medicine

A very peculiar situation which all specialists in public health and community medicine realize after just a few years of practice, is the wide gap between “theory” and actual “practice” in this specialty. Such gaps occur in all other medical specialties too, but only to a limited extent - a patient of typhoid or one with ante-partum haemorrhage will show variations as regards clinical presentation and response to treatment when compared to what is written in the standard textbooks, but only to a limited, understandable extent. In public health practice, the practitioner is faced, everyday, with challenging situations, for addressing which she has to work out innovative solutions, which may not be at all described in her standard textbooks (in fact, that is why it is difficult to have a “standard textbook” in public health; one could only have guidelines!). The reason is that in community medicine and public health, we do not deal with a patient; we rather deal with human groups, who are apparently healthy (at least that is the way they feel themselves to be). Human groups or communities have their own attitudes and practices and their own diverse ways of assessing and responding to situations.

For the aforesaid reasons, the author would, based on own

experience and the shared experience with colleagues, like to narrate, certain “rules of the game”, which are otherwise not formally written down in any textbook. It is felt that putting these guiding principles into day to day practice may help bridging the gap between theory and practice, thereby deriving more satisfaction out of our specialty work. A dozen of such guiding principles are as follows :

1. Learn how to take insults, be tenacious : Remember that public health/ community medicine with its focus on prevention, is more abstract than curative medicine and its achievements are therefore more difficult to recognize. The Doctor who cures such a person has achieved a real, recognizable benefit and the patient is grateful; public health cannot point to the people who have been spared illness by its efforts. Public health and preventive medicine lead to silent, unrecognized victories. This “silence” accounts in large parts, for the relative lack of attention paid to public health by decision makers and the general public (in comparison to the attention paid to medical care).

So, remember, that while Public health may not be as glamorous a specialty as Cardiac Surgery or Imaging, it has tremendous potential to improve the quality of life of innumerable human beings - to give you a proof, the major improvements in health and quality of human life during the last one century have actually come from clean food and water, sanitary housing and immunization rather than all the other “glamorous” medical specialties put together. Despite this, preventive medicine and public health is often at the receiving end of insults as “Sewer drain doctors” “insect catchers” or “people who could never make it to the clinical world”. You have to learn how to bear with such humiliations, but do not lose heart - be tenacious, keep moving forward - you have indeed selected the most humane specialty.

2. Stick to the facts - preferably based on quantitative evidence : Public health, with its very important tools of epidemiology and statistics, is an evidence based specialty and is dependant on collecting, analyzing and interpreting the data in a valid manner and making use of good quantitative and qualitative evidence. Good public health practitioners should collect good knowledge about topics they are dealing with, whether it is the incidence of ARI among children in their area of jurisdiction or it is concerning the amount of risk that tobacco carries for IHD. Good amount of reading into latest journals, reports or text books and discussion with experts is a must for public health practitioners.

3. Develop the art of communicating : Remember that unless “data” are turned into “stories” which are understood by all, people would not show concern for your reasoning. Having command on communication skills, both verbal and written, is an art which is a compulsory requirement for public health practitioners and this art should be developed very diligently and methodically.

4. Walk well and talk well : A successful public health specialist is one who changes shoes every month or two, since constant walking, seeing for herself and making assessments of environment and the community’s conditions, tears off the shoe - sole very fast. This is the typical shoe - leather epidemiology. So keep moving in your area, talk to the community members

about their health problems and make assessment of their behaviours, beliefs, lifestyle and the environment they live in.

5. Develop “Multi - Disciplinary Team” approach : Always remember that in public health, you have to build an effective team, comprising of people from various disciplines - Statisticians, Clinicians, Social Scientists, Entomologists, Pathologists, Civil Engineers, Management experts, Administrators, Politicians and so on. No public health specialist can be successful by working in isolation. Learn how to form an effective team; have respect for others, listen to their advice and take decisions in consultation with them after logical reasoning and not by arguing or bulldozing. In fact, be proactive in seeking out allies from these various specialties / walks of life.

6. Always prepare very well before you meet people : Whenever you go to attend a conference, be it of administrators and specialists from allied specialties, or else a focus group discussion with school - teachers, make sure to always read the agenda and its details very well. Apply your thought to the issues under discussion, think what do you want to achieve and how you will be best placed to do so, with those present.

7. Focus on “long term” but take action on “short term” also : The objectives of public health (whether through an immunization program or purification of community water supply, etc.) are achieved over the longer time period of decades or generations. However, Governments are generally reluctant to think further ahead of the 5 year term of parliament / assembly. They would, naturally, like to demonstrate some results within the limited span of a couple of years. Hence, in public health practice, while gaining support for achieving the long term goals should be definitely an objective, it is equally essential to have some very readily identifiable strategies to demonstrate progress towards these long term goals, in a shorter period of time - the so called strategy of “Early Victories”.

8. Understand the “Politics” : Very often we find public health specialists talking about ways of influencing “Policy Makers”. This means getting to know your chief administrative boss (and other influential people) and how he or she works. When you are, as a public health management manager, affronted to a one of senior politicians or bureaucrat, the first things you should do is to set to know what makes him or her “tick” and do things in a way that merges with his / her line of thinking.

Public health specialists should also keep themselves well aware of the “political climate” - not only international and national but, also the “local” politics and even the political climate in their own office. It is essential, in public health, to have good political antennae. Moreover, in any organization or office, it is essential to understand as to who wields the power - this may not only be the chief executive, but may be some lower level staff officer also. It is also very paying to have good relationships with colleagues.

9. Don’t take on too much : Failure to deliver is one of the biggest potential risks for public health and you should remember that one important reason for landing in this pitfall is when you take on too many jobs, well beyond your capabilities. You should learn how to say “No” to tasks which you feel are getting on too much; or else, if it is something that has to be done, then decide what is going to be dropped off your agenda.

Next, once you take on a job, then keep track of its progress.

10. Develop Your Staff : A clinician may still do well without improving his staff and without delegating; conversely, in public health practice you must constantly endeavour to develop your staff and subordinates as regards their technical and managerial competence. Secondly, analyze their capabilities and learn how to delegate responsibilities / tasks to your subordinates. If you try to do everything yourself, in public health practice, you will get bogged down and become inefficient pretty soon.

11. Always Know of Specialists who can do the Jobs : The wide activity of public health inevitably means that you will not be able to retain all the necessary skills at any one time, though you may have been trained to some extent in all these disciplines (as entomology, epidemiology, statistics, database management, etc.). Therefore, maintaining networks with others who have the skills & expertise in that area, is vital.

12. Always Be There : Though stated in the last, this twelfth golden principle is one of the most important. Remember that the world is run by people who are physically there at the place of action; the first rule of politics is to “be there”. It is surprising how scant attention is paid to this very simple dictum. So, for being a successful public health specialist, never miss a meeting, a workshop, any function, a sports meet or even any street play to which you have been invited.

And, finally, keep the highest regards for your specialty - it is the biggest asset you have in the changing fortunes of time; Keep perseverance and faith alive, for, despite all it's drudgery and sham, it is still a beautiful world -----.

Summary

The last two decades of the 20th century saw a renewal of the world population's interest in public health, in disease prevention, communicable and chronic disease control, health protection and health promotion. The two reports in mid-nineteenth century by Edwin Chadwick in UK & Lemuel Shattuck in USA initiated the genesis of public health & preventive medicine. During the 20th century, many lives have been saved and diseases prevented by simple public health measures as safe water supply, sanitary excreta disposal, vaccination and insect-vector-control measures.

Widely used definition of health by WHO states that “Health is a state of complete physical, mental and social well being and not merely the absence of disease or infirmity. This definition is commonly seen as the statement of an “ideal” towards which nations should aspire. “Operational” definition of health, one drawn from the above “ideal” definition, has been forwarded, by a technical study group of WHO. This concept of health is viewed as being of two orders - first, in a broad sense, health can be seen as a condition or quality of the human organism in given conditions : Genetic and environmental. Secondly, in a narrow sense, more useful for working purposes which includes no obvious evidence of diseases and that the person is functioning “normally” & various organs of the body are functioning adequately in themselves and in relation to one another.

A widely accepted definition of medicine by Henry Sigerist defines medicine as “Medicine, by providing health and

preventing illness, endeavours to keep individuals adjusted to their environment as useful and contented members of society; or by restoring health and rehabilitating the former patient, it endeavours to readjust individuals to their environment”. Preventive Medicine is that branch of medicine which deals with promoting health and preventing disease. The cardinal goal of preventive medicine is to avert the occurrence of disease. The field of Epidemiology has emerged as one of the most important tools in preventive medicine & public health. CEA Winslow gave the most comprehensive & widely accepted definition for public health which states as “The science and art of preventing disease, prolonging life and promoting physical health and efficiency through organized community efforts for the sanitation of the environment, the control of community infections, the education of the individual in principles of personal hygiene, the organization of medical and nursing services for the early diagnosis and preventive treatment of diseases and the development of social machinery which will ensure to every individual, in the community, a standard of living adequate for maintenance of health”. The two unique feature of public health are acknowledged as “Organized Community Effort” and “Systematic Social Action”. Preventive Medicine is a branch of medicine which deals with promoting health and preventing disease. When preventive medicine starts focusing on population groups rather than individuals and utilises the approach of “organised community efforts” it takes the shape of public health. The integration of the social aspects of health and disease in theory, practice and teaching led to the birth of Preventive & Social Medicine (PSM) or Social & Preventive Medicine (SPM). Community Medicine is a branch of medicine, which addresses certain selected aspects of health promotion, disease prevention, health restoration (by curative steps) and rehabilitation of the former patients, in the community, usually, from an “Institutional Community Base” which is usually either an Academic Department in a medical college or through a curative centre.

Public health plays a very important role in contributing to the health of the public (community) through assessment of Health Status & Health Needs, development of Health Policies, assurance of the availability and quality of Health Services. Major sciences required for the practice of public health can be grouped into five major core competency areas, viz. Quantitative Sciences, Environmental Sciences, Socio-Behavioural and Communication Sciences, Biological Sciences and Managerial Sciences.

Core Activities of Public Health include protecting the environment, food and water, promoting healthy behaviour through IEC, assessing needs, making community diagnosis and monitoring the health status of the community being served, development of sound health policy and planning, health programme management and management of other medical & health care systems, preventing and investigating epidemics and maintaining surveillance on important diseases, to provide early warning, promoting the health and efficiency of the “workers” and protecting the “work-environment”, effectively responding to disasters, mobilizing community action, research to develop new insights and innovative solutions for relevant community health problems, reaching out to link the health services with the high risk, disadvantaged and hard to reach

people, or those requiring special attention, assuring the availability, accessibility, quality and accountability of medical care.

Study Exercises

Short Notes : (1) Definition of health (2) Definition of public health (3) Community Medicine - definition and scope (4) Core activities of public health

MCQs & Exercises

Fill in the Blanks

1. Movement - now known as public health were initiated in nineteenth century by ----- &----- in their reports on sanitary conditions of the labouring population in Great Britain & sanitary commission of Massachusetts.
2. Health is a state of complete -----, ----- and ----- well being and not merely the absence of ----- or ----- . This was the definition given by -----.
3. "Operational" definition of health view's health as being ----- in broader sense & -----, ----- in narrower sense.
4. Two unique features of public health are ----- and -----.
5. When preventive medicine starts focusing on population groups rather than individuals and utilises the approach of ----- it takes the shape of-----.
6. ----- is the branch of medicine which deals with promoting health and preventing disease.

Match the Following

- | | |
|--------------------|---|
| 1. CEA Winslow | a. Sanitary commission of Massachusetts |
| 2. Henry Sigerist | b. Social medicine |
| 3. Rudolph Virchow | c. Definition of Medicine |
| 4. Grotjahn | d. Definition of Public health |
| 5. Lemuel Shattuck | e. Virchows triad |

Answers :

Fill in the Blanks : (1) Edwin Chadwick; Lemuel Shattuck (2) Physical; Mental ; Social; Disease; Infirmity; WHO

(3) Condition or quality of the human organism in given conditions : genetic and environmental; Within normal limits of variations to the standards of health criteria; various organs of the body in a state of equilibrium or homeostasis (4) Organized Community Effort; Systematic Social Action (5) Organised community efforts; Public health (6) Preventive Medicine.

Match the Following : 1-d; 2-c; 3-e; 4-b; 5-a.

History of Public Health

Leo S. Vaz

During the ancient Egyptian period developments such as toilets and bathing were introduced, but this was on a private level. While Egyptian religious beliefs encouraged washing the body, thereby improving the health of the population, this was not part of a public health programme. The Greeks encouraged

healthy living and pursued regimens of exercise and hygiene such as those prescribed by Hippocrates in his Regimen and Regimen in Acute Diseases (4th century BC). Patients visiting the temples of the god of healing, Aesculapius, were encouraged to take part in exercise, but the temples were, again, not part of a public health system. There was some development of public health by the Minoans, a Mediterranean civilization that flourished on Crete about 3000-1050 BC. The Minoans built baths and constructed channels to supply clean water and remove waste. However, these facilities were lost when the Minoan civilization collapsed and their palaces and towns

were destroyed by natural disasters and invading Greek forces. Aqueducts (bridges carrying water) were also constructed; one of the first great aqueducts was built in 691 BC to carry water for 80km to Ninevah, capital of the ancient Assyrian Empire. However, the scale of the public health system introduced by the Roman Empire from around 300 BC was without precedent in the Western world.

Ancient India and Public Health

Ancient Indian thoughts, philosophy developed on concepts of spirituality. Ayurveda is the ancient science of life. It lays down the principles of management in health and disease and the code of conduct for the physician. Charaka has described the objective of medicine as two fold; preservation of good health and combating disease. Ayurveda emphasised the need for healthy lifestyle, including cleanliness and purity, good diet, proper behaviour and mental and physical discipline. Purity and cleanliness were to be observed in everything : jalasuddi (pure water), aharasuddi (clean food), dehasuddi (clean body), manasuddi (pure mind) and desasuddi (clean environment).

Ayurveda calls upon the physician to treat the patient as a whole: '*Dividho jayate vyadhih, Sariro manasasthatha, Parasparranz tavorjanma, Nirdvadvam nopalahhyate*'. Diseases occur both physically and mentally and even though each part might be dominant, they cannot be compartmentalized. Ayurveda treats man as a whole body, mind and what is beyond mind. The earliest protagonists of Indian Medicine, such as Atreya, Kashyapa, Bhela, Charaka and Susruta have based their writings on the foundations of spiritual philosophy and ethics. Charaka Samhita prescribes an elaborate code of conduct.

The ruins of ancient civilizations like Mohenjadaro and Harrappa show intricate water and sullage disposal systems. It can hence be assumed that sanitation played a major part in planning of these cities.

Greco-Roman Era

This period focused on personal hygiene. Governmental public health practices were effected to augment the prevailing religious attitude. Medical care hospitals, staffed with public physicians and programs in environmental sanitation (water supply and sewage) were developed. These measures which placed a high priority on a clean mind and body were developed for the upper classes. The Romans were able to implement public health measures as they had an organized, centralized government and the money to pay for the work. Such a vast system of public health was unprecedented in history and made the Romans a much healthier people. The Romans did not know about bacteria and the true causes of disease, but they observed that swamps caused illness and that a lack of fresh water was damaging to health. By the end of the Roman Empire in AD 476, the Roman public health system was more advanced than any system of public health would be in Europe for the next 1,400 years or so.

Middle Ages

This is considered as a period identified as an era of paganism, barbarism and anti-intellectualism. When Christianity became the official religion of the Roman Empire, the poor and afflicted were given status and recognition. Society was given an obligatory responsibility for care and treatment of the sick.

During the Middle Ages (5th-15th centuries) in Europe, public health systems collapsed and became virtually non-existent, particularly during the period known as the Dark Ages (around 500-1000 AD). The towns and cities of the Romans were often abandoned and the aqueducts, sewers and baths were allowed to fall into disrepair. Medieval governments and wealthy people in society no longer felt the responsibility or need to provide public health. Money was not spent on providing fresh, clean water or removing waste, but on more pressing concerns, such as the provision of armies and defences for the almost continuous wars that raged throughout the period. Various diseases (leprosy, consumption, typhoid fever and the black death) fatally affected approximately one-third of the population living in middle and southern Europe. In the Middle Ages, commerce and industry developed which were based on economic theory involving exchange of goods and services. Through the accumulation of wealth, individuals and nations became powerful. Because of such affluence, concern developed for labour as it related to productivity.

Streets were often used as dumping grounds for slaughterhouse waste or the contents of chamber pots from people's houses. Action was only taken during outbreaks of disease such as the Black Death, an epidemic of bubonic plague that swept across Europe in the mid-14th century, killing between one-third and half of the population. When the plague arrived in England in 1348, Edward III ordered the lord mayor of London to clean up the streets of the capital and keep animals and slaughterhouses out of the city. Public toilets were to be introduced and the dumping of waste in the streets was forbidden. The improvements continued until the end of the 14th century, but the measures were often poorly enforced and had little effect on the overcrowding and lack of cleanliness that was rife in the larger towns and cities. Few hospitals existed and doctors were far too expensive for the poor to consult, so ill health and disease were unchecked and spread rapidly.

18th-19th Centuries (Europe)

This was the period of the industrial revolution and cholera epidemics. The industrial revolution brought about the need for increased manpower and massive use of labouring classes. The life expectancy rate based on social class was : gentry, 35 years; tradesmen, 22 years; and labourers, 15 years. Approximately one-half of the children of the working classes died before age of five.

William Farr, the keeper of abstracts at the Registrar General Office in 1836 was convinced that mortality increased with density of population. From 1839 William Farr collected statistics from parish registers on births and deaths. He was able to show the impact of poor living conditions on life expectancy and the differences between different areas. The Victorian middle class believed that the overcrowding resulted in immorality, drunkenness, crime, incest and destroyed the sanctity of homes. This resulted in moralistic theories being projected all over Britain & Europe as a cure of most evils including disease.

The poor engaged in agriculture went through a series of bad harvests at the end of the eighteenth century and by 1795 the farmers had fewer & fewer resources to pay their labourers. An allowance system was then started and administrated

through the Poor Law. A study of Poverty was carried out by two assistants of Central Poor Law Commission an economist and lawyer Nassau Senior and upwardly mobile lawyer Edwin Chadwick. They concluded that the allowance system was a threat to the free market economy. The Poor Law Amendment 1834 which Chadwick wrote deprived the paupers of his liberty and put them into workhouses.

The cholera Epidemic of 1832 highlighted the problem of disease. In 1837 Chadwick appointed doctors to investigate the London districts with high typhus mortality. The report highlighted the squalor of the inhabitants and the insanitary conditions. Chadwick compiled a survey of "Sanitary condition of labouring classes of great Briton" in 1842 in which he recommended the "Sanitary Idea" with creation of a public health authority to provide drainage, potable water, sanitation, regulation of buildings etc. He believed in the 'miasmatic' theory of disease origin where gaseous contamination of atmosphere due to putrefaction of organic matter was the cause of disease.

The first British Public health Act was passed in 1848 creating a General Body of health with Southwood Smith as its medical advisor and Chadwick its only salaried member. The city of London also had its own private Sewers Act 1848. Internal conflicts in the Metropolitan Sewers Commission resulted in removal of Chadwick in 1849.

A shift from "Sanitary idea" to medical managed took place when Chadwick was succeeded as Britain's chief health administrator by Dr John Simon. The new concept was of "State Medicine" He had been credited to having laid the foundation of subsequent British health policy. He followed a comprehensive approach to disease prevention and set up investigations into a wide range of issues from regulation of food contamination & drug adulteration to hygiene standards of environmental planning. Simon's most significant legislation was the Sanitary Act 1866. In 1856 Dr Henry Rumsey published a series of "Essays on state Medicine". He claimed that medical prevention would cover a broad range of causes of disease resulting in their elimination. In 1875 the Public Health Act was codified including all existing sanitary legislation. The prevailing social conditions in England resulted in an illustrative national survey, known as the Edwin Chadwick Report, which focused on the health of the labouring classes. The Chadwick Report affected sweeping reforms, such as the establishment of a National Board of Health, advances in environmental sanitation and hygiene, new legislation regulating factory management; child labour and welfare and care for the aged and mentally ill.

In 1864 the first contagious Disease Acts was passed which provided for compulsory examination of women believed to be "Common prostitutes" who were to be locked up for up to one year without right to habeas corpus if they were diagnosed to have sexually transmitted disease. The Act was approved by a large number of people including John Simon. The Act was repealed in 1886.

Free vaccination were made available through the Poor Law Medical Services in 1840. In 1853 vaccination was made compulsory for all children with the first year of life. In 1867 the new Vaccination Act imposed penalties on parents not vaccinating their children. A drive against compulsory

vaccination was started by John Gibbs which ultimately culminated in its modification in 1907.

Public Health in the United States

In the 17th - 18th Centuries in Colonial America, life expectancy was less than in Central Europe. Towns and cities were generally unsanitary, contagious diseases were rampant and most physicians were self-designated and itinerant. In America the first colonist had found healthy land, clean water and fertile soil. However newer arrivals brought in scurvy, smallpox, cholera, measles, typhoid diphtheria and influenza. Small pox and measles contributed in large part to mortality. In the eighteenth century quarantine laws were passed in all major towns and pest-houses built for immigrants arriving on infected ships.

During the civil war a large number of soldiers died of Typhoid, Malaria, camp Diarrhoea and camp Measles. However, wherever the sanitary commission improved sanitary conditions, disease rates were found to be lower. Due to the industrial revolution cities grew and there was increase in number of disease. Due to a dedicated band of reformers, the Metropolitan Health Bill of 1866 was passed. In 1879 a large yellow fever epidemic swept Mississippi and New Orleans, resulting in the creation of the National Board of Health.

The Lemuel Shattuck Report encouraged social reform, including documentation of disease conditions and collection of vital statistics. Some pertinent recommendations of the Shattuck Report were establishment of sanitary inspection system, the collection and analysis of vital statistics, the promotion of health care, establishment of regulations to expose and eliminate quackery. Port cities such as Boston, Baltimore, New York and their respective states sought ordinances and legislation to reduce mortality, establish medical services for seamen and raise the professional status of physicians.

Sanitary Theory

The theory of miasma, which said that disease is due to causes contained in bad air including the cosmic radiations, found much support during the 18th and 19th century. It made sense to the English Sanitary reformers of the mid-nineteenth century. Miasma explained why cholera and other diseases were epidemic in places where the water was un-drained and very foul-smelling. The theory led to improvements in the sanitation systems, which led to decreased episodes of cholera, which helped to support the theory. Even though the miasmatic theory has been dis-proven by the knowledge of viruses and bacteria, it made the connection between dirtiness and diseases. This caused public health reforms and encouraged cleanliness, even though some doctors still did not wash their hands between patients. They believed that the miasmata were only airborne and would not be stuck on the doctors' hands.

Chadwick has generally been considered to be the person who defined prevention of disease in " Sanitary" terms. However Edmund Parkes, the first British Professor of hygiene who was appointed to the Army Medical School at Netley believed that future of prevention lay in discovery of specific causes of individual diseases.

A shift in public health took place during the Edwardian period when individuals began to be categorized into "Risk

populations". These were on the basis of analysis of disease by Edmund Parkes. Soon thereafter came the germ theory which was based on the concept that specific microbes caused specific diseases. Developments in Bacteriology in 1880's were embraced by the preventive profession. A model was developed in which one agent was related to one disease (Robert Koch). This is discussed in subsequent chapters.

Contemporary (19th and Early 20th Centuries) Public Health

During the 19th Century and the first half of the 20th century, the perception of public health was limited to prevention of communicable diseases through environmental sanitation. For example, a dramatic increase in industrialization in the late 19th century, coupled with urbanization, had profound effects on urban water supplies. There was pollution from human wastes from homes and the workplace disposed in the waterways. Effluents containing organic and inorganic toxic and non-toxic material were dumped into the same waterways. During this time medical theories were limited to bacteriological paradigms.

In 1898 when US sent troops into Cuba they lost 968 men in battle and 5438 due to infectious diseases. When yellow fever threatened troops in Cuba in 1900 an army commission under Walter Reed confirmed that the disease was transmitted by mosquito and eliminated the disease from Havana. The US Army in Philippines had to battle with malaria, dengue, dysentery and beriberi to continue to remain in the region.

The French attempt to build a canal across Panama was abandoned due to disease. The American attempt succeeded due to an intensive campaign against mosquitoes and hence reduction of yellow fever and malaria so as to prevent malaria in America troops. During World war II the Public Health service established the control of Malaria in war areas. After the war the organisation was converted into the Centres for Disease Control and Prevention.

In 1907 preventive medicine practitioners and town planners got together to bring about housing reforms. Simultaneously legislations were passed for free school meals, medical inspection of school children and antenatal care. These concerns were clubbed by society into "Endowment of motherhood" movement which included targeting of malnutrition and breaking habits of inefficient and unhygienic motherhood. A great emphasis was placed on health education. It was emphasised that infant mortality was not a "Weeding Out" process of eugenic value as was earlier considered, but a preventable wastage of child life. Newsholm in 1910 introduced the concept of "Causal attack" upon disease after redefining the environment from a "Social Standpoint".

In Germany, Pettenkofer first calculated the financial returns on public health investments to prove the value of sanitary improvement in reducing death from typhoid.

Bacteriological analysis was used to determine the presence of coliform bacteria in municipal water supplies. Since coliform bacteria are present in great numbers in humans and animals but are not typical water organisms, their presence served as an indicator of fecal pollution and possible pathogenic organisms. Since industrial wastes did not contain these coliform

organisms, it was concluded that water sanitary hazards at industrial sites were generally remote with the exception of anthrax from tanneries and wool scouring facilities.

Current Public Health

Classical infectious disease rates have declined while increased rates of so-called modern diseases (heart disease, cancer and immune deficiency diseases) are now being observed in epidemic proportions throughout the world. Classical public health organizations and systems are now in a state of flux because these structures were erected for classical communicable disease control. New problem-solving systems are needed in areas such as health care financing, medical care for the aged, environmental health protection and health care planning and administration.

Founders of Modern Public Health, Community Medicine & Preventive Medicine

Edward Jenner(1749-1823)

Edward Jenner was born on May 17, 1749 in the small village

in Gloucestershire. He had always been fascinated by the rural old wives tale that milkmaids could not get smallpox. He believed that there was a connection between the fact that milkmaids only got a weak version of smallpox - the non-life threatening cowpox - but did not get smallpox itself. Jenner decided to try out a theory he had developed. Jenner was given the opportunity on the 14 May 1796, when a young milkmaid

called Sarah Nelmes came to see him with sores on her hands like blisters. He took some pus from cowpox blisters found on the hand of Sarah. She had milked a cow called Blossom and had developed the tell-tale blisters. Jenner 'injected' some of the pus into a young boy, James Phipps. This process he repeated over a number of days gradually increasing the amount of pus he put into the boy. He then deliberately injected Phipps with smallpox. James became ill but after a few days made a full recovery with no side effects. Jenner found a great deal of scepticism to his ideas and was subject to much ridicule. However, what he had discovered could not be denied and eventually his discovery had to be accepted - a discovery that was to eventually change the world. So successful was Jenner's discovery, that in 1840 the government of the day banned any other treatment for smallpox other than Jenner's. Jenner died in Berkeley on January 26, 1823 aged 74. The word vaccination comes from the Latin 'vacca' which means cow - in honour of the part played by Blossom and Sarah in Jenner's research. However, from the point of Jenner's demonstrations, it took the humanity almost two centuries to conquer small pox - In 1980, the World Health Organisation declared that smallpox was extinct throughout the world.

John Snow (1813 - 1858)

Snow was a British physician and also one of the founder fathers of the discipline of anaesthesiology, is also considered one of the founders of epidemiology for his work identifying the source of a cholera outbreak in 1854. He was born into a labourer's family on 15 March 1813 in York and at 14 was

apprenticed to a surgeon. At the time, it was assumed that cholera was airborne. However, Snow did not accept this 'miasma' (bad air) theory, arguing that in fact entered the body through the mouth.

He published his ideas in an essay 'On the Mode of Communication of Cholera' in 1849. A few years later, Snow was able to prove his theory in dramatic circumstances. In August 1854 a cholera outbreak occurred in Soho. It was common at the time to have a cesspit under most homes. Most families tried to have their raw sewage collected and dumped in the Thames to prevent their cesspit from filling faster than the sewage could decompose into

the soil. After careful investigation, including plotting cases of cholera on a map of the area, Snow was able to identify a water pump in Broad (now Broadwick) Street as the source of the disease. He had the handle of the pump removed and cases of cholera immediately began to diminish. Snow later used a spot map to illustrate how cases of cholera were centred around the pump. He showed that companies taking water from sewage-polluted sections of the Thames delivered water to homes with an increased incidence of cholera. Snow's study was a major event in the history of public health and can be regarded as the founding event of the science of epidemiology.

Snow was also a pioneer in the field of anaesthetics. In 1853 and 1857, he was responsible for giving chloroform to Queen Victoria at the birth of her son Leopold and daughter Beatrice. Snow died of a stroke on 16 June 1858.

James Lind (1716 - 1794)

Lind was a Scottish doctor, a pioneer of naval hygiene and expert on the treatment of scurvy. James Lind was born in Edinburgh in 1716. In 1747, while serving as surgeon on HMS Salisbury, he carried out experiments to discover the cause of scurvy, the symptoms of which included loose teeth, bleeding gums and haemorrhages.

Lind selected 12 men from the ship, all suffering from scurvy and divided them into six pairs, giving each group different additions to their basic diet. Some were given cider, others seawater, others a mixture of garlic, mustard and horseradish. Another group of two were given spoonfuls of vinegar and the last two oranges and lemons. Those fed citrus fruits experienced a remarkable recovery. While there was nothing new about his discovery - the benefits of lime juice had been known for centuries - Lind had definitively established the superiority of citrus fruits above all other 'remedies'. In 1753, he published 'A Treatise of the Scurvy' and in 1757 'An Essay on the Most Effectual Means of Preserving the Health of Seamen in the Royal Navy', which threw much light on the appalling living conditions and diet of seamen. In 1763, Lind published work on typhus fever in ships and in the 1768 publication 'An Essay on Diseases Incidental to Europeans in Hot Climates' he summarised the prevalent diseases in each colony and gave advice on avoiding tropical

infections. Lind died in 1794 in Gosport.

Robert Koch (1843 - 1910)

The French parasitologist Casimir-Joseph Davaine inspired by the work of the French microbiologist Louis Pasteur had showed, in 1863, that anthrax in sheep was due to the presence of rod-like bodies in the blood. Koch announced that he had isolated and grown, the tubercle bacillus to the Physiological Society of Berlin on 24 March 1882. He believed this to be the cause of all forms of tuberculosis.

The outbreak of cholera in Egypt and the danger of it finding its way to Europe, caused Koch, as a member of the German government commission, to go to Egypt to investigate the disease. Although he was frustrated by the cessation of the epidemic, he was able to study the disease long enough to suspect a particular comma-shaped bacillus. Whilst there, however he was able to discover the cause of amoebic dysentery and the bacilli of two varieties of Egyptian conjunctivitis. He was able to complete his work on cholera by proceeding to India. He discovered the cholera organism and its transmission via drinking water, food and clothing. When he returned to Berlin Koch advised regular checks on the water supplies and recommendations regarding sewage disposal. He also organised courses in the recognition of cholera. Koch investigated the effect an injection of dead bacilli would have on a person who subsequently received a dose of living ones. He concluded that the local reaction produced might provide the means by which the disease could not only be diagnosed but, in the early stages, perhaps even cured. He used as the active agent a sterile liquid produced from cultures of the bacillus. As the liquid (tuberculin, 1890) proved disappointing as a curative agent its importance as a means of detecting a present or past tubercular state was not immediately recognised.

The result of Koch investigations into a bubonic plague epidemic in Calcutta in 1897 showed that rats were vectors of the disease. He also demonstrated that sleeping sickness is transmitted by the tsetse fly. Other studies by Koch included leprosy, surra, rinderpest, Texas fever and malaria. In 1905 Koch won the Nobel Prize for Physiology or Medicine for investigation and discoveries in relation to tuberculosis.

Joseph Lister (1827-1912)

By the middle of the nineteenth century, post-operative sepsis infection accounted for the death of almost half of the patients undergoing major surgery. A common report by surgeons was 'operation successful but the patient died'. Sepsis was considered as a kind of combustion caused by exposing moist body tissue to oxygen. It was therefore considered that the best prevention was to keep air away from wounds by means of plasters, collodion or resins.

Joseph Lister, a British surgeon, considered that infection was not due to bad air alone and that 'wound sepsis' was a form

of decomposition. In August 1861 he was appointed surgeon at the Glasgow Royal Infirmary and put in charge of its new surgical building. Lister reported that between 45 and 50 percent of his amputation cases died from sepsis between 1861 and 1865 in his Male Accident Ward. It was in this ward that Lister began his experimental work with antiseptics. Having tried methods to encourage clean healing, with little, or no success, He discarded the popular concept of direct infection by bad air and postulated that sepsis might be caused by a 'pollen-like dust'. When, In 1865, Louis Pasteur suggested that decay was caused by living organisms in the air, which on entering matter caused it to ferment, Lister made the connection with wound sepsis. He considered that microbes in the air were likely causing the putrefaction and had to be destroyed before they entered the wound. Lister had heard that 'carbolic acid' was being used to treat sewage in Carlisle and that fields treated with the effluent were freed of a parasite causing disease in cattle. Lister now began to clean wounds and dress them using a solution of carbolic acid. In 1867, he announced that his wards at the Glasgow Royal Infirmary had remained clear of sepsis for nine months. In 1870 Lister's antiseptic methods were used, by Germany, during the Franco-Prussian war saving many Prussian soldier's lives. Lister saw the culmination of his emphasis on the principle of preventive medicine with the opening of the Institute of Preventive Medicine in 1891. He died on the 10 February 1912 in Walmer, Kent.

John Simon (1816-1904)

An English physician, was appointed surgeon. He trained as a surgeon and lecturer in pathology at St. Thomas's Hospital in London in 1847. He was elected a Fellow of the Royal Society for his work on the comparative anatomy of the thyroid gland at the age of 29. When Parliament implemented the recommendations of the Royal Sanitary Commission and amalgamated the Poor Law Board, the Local Government Act Office and the Medical Department of the Privy Council to form the Local Government Board, Simon was appointed first Medical Officer of Health for London in 1848.

He soon discovered that, instead of his being given the free hand that he had expected, the Medical Department was subordinate to the Poor Law officers. His reports on the health problems of the city and the steps taken to deal with these problems, are regarded as models of preventive medicine and the administration of public health services. In 1858, Simon became medical officer to the Privy Council. Simon had overall responsibility for the organization and administration of national public health services. He oversaw the passage of the Public Health Act of 1875, but resigned the following year because of disagreements about implementing policies he advocated.

Simon's major achievements was his supervision of measures taken in 1866 to enhance public sanitation, including the provision of clean drinking water and safe sanitary disposal. He also established the General Medical Council, the licensing body for medical practitioners in the United Kingdom. His work on sanitary science and public health practice made Britain

the European (and world) leader in public health in the late nineteenth century. His books include two classics of public health, *Public Health Reports* (1887) and *English Sanitary Institutions* (1890). Simon was awarded a knighthood in 1897.

Lemuel Shattuck(1793-1859)

He was born in 1793 in Ashby, Massachusetts and he died in 1859 in Boston. He came to believe that he could enhance the ability of government to respond to social ills through the collection of statistics. In 1835, he gained attention for writing *A History of the Town of Concord*, which included a statistical analysis based on church and municipal records.

He became a bookseller and helped form the American Statistical Association.

After being elected to the Boston City Council in 1837, Shattuck was asked to create a report analyzing Boston's vital statistics from 1810 to 1841. In addition to his findings, which were published in the *American Journal of Medical Sciences*, Shattuck outlined a method for the systematic gathering of vital statistics and a plan for analyzing that data. Based on his suggestions, Massachusetts passed the Registration Act of 1842. Shattuck was also renowned for his 1850 survey of sanitary conditions throughout the state, the *Report of the Sanitary Conditions of Massachusetts*, which was commissioned by the state legislature. In this report, Shattuck proposed the creation of a permanent statewide public health infrastructure and he recommended establishing health offices at the state and local levels in order to gather statistical information on public health conditions. Although the legislature did not adopt his comprehensive plan, his specific proposals became routine public health activities over the course of the twentieth century.

Edwin Chadwick(1800-1890)

The son of a successful businessman, was born in Manchester on 24th January, 1800. Chadwick's father had progressive political views and encouraged his son to read books by radicals. In 1832, the Prime Minister, Earl Grey, initiated a Royal Commission of Enquiry on the Poor Laws. Chadwick was appointed as one of the assistant commissioners responsible for collecting information on the subject.

Edwin Chadwick soon emerged as one of the most important members of the investigation and he was eventually responsible for writing nearly a third of the published report. In the report published in 1834, the Commission made several recommendations to Parliament. As a result of the report, the Poor Law Amendment Act was passed. One of the suggestions accepted by Grey's government was that there should be a three man Central Poor Law Commission that would be responsible for supervising the working of the legislation. Chadwick was not appointed as a Commissioner but was offered the post as Secretary, with a promise that he would have the

power to make further recommendations on administering the Poor Law. During the economic depression of 1837, many working people were forced to enter the workhouse. Chadwick was identified as the man responsible for abolishing outdoor relief and during the 1837 General Election there were public demonstrations against him. After the influenza and typhoid epidemics in 1837 and 1838, Edwin Chadwick was asked by the government to carry out a new enquiry into sanitation. His report, *The Sanitary Conditions of the Labouring Population* was published in 1842. In the report Chadwick argued that disease was directly related to living conditions and that there was a desperate need for public health reform. However, it was only after the 1847 General Election, that new legislation was introduced. In 1848 Parliament passed a Public Health Act that provided for the formation of a Central Board of Health. This new body had powers to create local boards to oversee street cleansing, refuse collection, water supply and sewerage systems. Chadwick, who was appointed Sanitation Commissioner, had several ideas on how public health could be improved. This included a constant supply of fresh clean water, water closets in every house and a system of carrying sewage to outlying farms, where it would provide a cheap source of fertilizer. Attempts to introduce public health reforms were resisted successfully by people with vested interests, for example, landlords and water companies, in maintaining the present system.

In 1854 Chadwick was so unpopular it would be impossible to persuade the House of Commons to renew the powers of the Board of Health while he remained in charge of the organisation. In order to preserve the reforms that he had achieved, Chadwick agreed to resign. Although officially retired on a £1,000 a year pension, Chadwick continued to campaign for changes in the law. This included the reform of sanitation, education and transportation. Edwin Chadwick died on 6th July, 1890.

Sir Ronald Ross (1857 -1932)

Ronald Ross was born in Almora, India. At the age of ten, Ross was sent to England for his education. Ross commenced his study of medicine at St. Bartholomew's Hospital in London and joined the Indian Medical Service in 1881. His first posting was in Madras. Ross studied malaria between 1881 and 1899. He worked on malaria in Calcutta at the Presidency General Hospital. In 1883, Ross was posted as the Acting Garrison Surgeon at Bangalore during which time he noticed the possibility of controlling mosquitoes by controlling their access to water. In 1897, Ross was posted in Ooty and fell ill with malaria. After this he was transferred to Secunderabad, he discovered the presence of the malarial parasite within a specific species of mosquito, the *Anopheles*. He initially called them dapple-wings and following the hypothesis of Sir Patrick Manson that the agent that causes malaria was spread by the mosquito, he was able to find the malaria parasite in a mosquito that he artificially fed on a malaria patient named Hussain Khan. Later using birds that were sick with malaria, he was soon able to ascertain the entire life cycle of the malarial parasite, including its presence in the mosquito's salivary glands. He demonstrated that malaria is

transmitted from infected birds to healthy ones by the bite of a mosquito, a finding that suggested the disease's mode of transmission to humans. In 1902, Ross was awarded the Nobel Prize in Physiology / Medicine for his remarkable work on malaria.

During his active career Ross advocated the task of prevention of malaria in different countries. He also initiated organizations, which have proved to be well established, for the prevention of malaria within the planting industries of India and Ceylon. He made many contributions to the epidemiology of malaria and to methods of its survey and assessment, but perhaps his greatest contribution was the development of mathematical models for the study of its epidemiology, initiated in his report on Mauritius in 1908, elaborated in his *Prevention of malaria* in 1911.

William Farr (1807-1883)

Farr was born in the village of Kenley, Shropshire, on 30 November 1807, the son of parents of modest means. At the age of two he went to live with Joseph Pryce, a local squire noted for his charitable works.

Pryce effectively adopted Farr and paid for his education. On his death in 1828 Pryce left Farr a legacy of 500 pounds which enabled him to pursue his studies in Paris and Switzerland.

He studied further at University College London, where he became a licentiate of the Society of Apothecaries, the only medical qualification he ever gained by study. In 1833 he set up as a practicing apothecary in Bloomsbury, London. From 1835 his earnings were supplemented by writings in early issues of the *Lancet*. In 1837, Farr contributed an article on "Vital statistics" for a volume entitled McCulloch's *Account of the British Empire*. Farr recognized that "Diseases are more easily prevented than cured and the first step to their prevention is the discovery of their exciting causes" and he set about establishing a firm foundation for his statistical work. He undertook a study of the bills of mortality, tabulating causes of death according to categories.

In 1838, the Office of the Registrar-General was established with the task of registering births, marriages and deaths. The dominant figure in the new service was William Farr, who was appointed as the first "compiler of abstracts" (chief statistician) to the new office. Farr remained in the post until his retirement in 1880 and used his position to become one of the leading figures in the sanitary movement, which campaigned for better sanitary conditions, especially in urban areas. Farr is often referred to as the father of modern epidemiological surveillance.

Sir Joseph William Bore (1878-1960)

This Indian Civil Servant was responsible for the initial concepts of comprehensive health care. Bore committee was set up by the Government of India in 1943 to investigate and recommend improvements to the Indian Public Health system. Under the chairmanship of Sir Joseph William Bore the committee made many landmark recommendations in its final report in 1946.

The committee was instrumental in bringing about the public health reforms related to primary health centres in India. It said "If it were possible to evaluate the loss, which this country annually suffers through the avoidable waste of valuable human material and the lowering of human efficiency through malnutrition and preventable morbidity, we feel that the result would be so startling that the whole country would be aroused and

would not rest until a radical change had been brought about". Though most of the recommendations of the committee were not implemented at the time, the committee was a trigger to the reforms that followed. Even today, the primary health care infrastructure of our country is based on what the Bhore committee had recommended more than 60 years ago. Sir Bhore can be very rightly said to be the man who envisioned the primary health care component of public health in our country.

Dr Sushila Nayyar (1914-2000)

Dr Sushila Nayyar, was the younger sister of Pyarelal Nayyar, personal secretary to Mahatma Gandhi. She was born in 1914 in Kunjah, Punjab now in Pakistan and came to Delhi in her youth to study medicine at Lady Hardinge Medical College. In 1939 she came to Sevagram to join her brother and quickly became a close associate of Mahatma Gandhi.

Shortly after her arrival, cholera broke out in Wardha and the young medical graduate tackled the outbreak almost single-handedly. Gandhiji praised her fortitude and dedication to service and appointed her his personal physician. In 1942 she was awarded an MD and returned once more to Mahatma Gandhi's side, to take part in the Quit India Movement that was sweeping the country. That year she was imprisoned along with other prominent Gandhians at the Aga Khan's Palace. In 1944 she set up a small dispensary at Sevagram, but this soon grew so large that it disturbed the peace of the ashram and she shifted it to a guesthouse donated by the Birlas, in Wardha. In 1945 this clinic formally became the Kasturba Gandhi Memorial Hospital. After Mahatma Gandhi's assassination in 1948, Dr Sushila Nayyar went to the USA where she took two degrees in public health (M.PH. and Dr PH) from Johns Hopkins University. Returning in 1950, she set up a tuberculosis sanatorium in Faridabad, the model township on the outskirts of Delhi. Dr. Nayyar also headed the Gandhi Memorial Leprosy Foundation.

Dr. Sushila Nayyar was deeply influenced by the Gandhian philosophy of hard work and abstinence. She felt strongly about the need for prohibition and linked this to the domestic concerns of poor women whose lives were often blighted by alcoholism in their husbands. She was also a staunch campaigner for family planning, once again seeing this as essential empowerment for women, especially poor women. She also believed, like Mahatma Gandhi that there was no

such thing as a dirty job and that medicine required hands-on involvement with patients and their ailments, regardless of feminine delicacy or upper caste squeamishness. In 1952 she entered politics and was elected to the Delhi State Assembly. From 1952 to 1955 she served as Health Minister in Pandit Nehru's cabinet. She was Speaker of the Delhi Vidhan Sabha from 1955 to 1956. In 1957 she was elected to the Lok Sabha and served till 1971. She was Union Health Minister again from 1962 to 1967. She retired from politics to devote herself to the Gandhian ideals. She had set up the Mahatma Gandhi Institute of Medical Sciences in Wardha, in 1969 and remained committed to confine her energies to developing and extending it. She passed away towards the end of 2000. Dr Nayyar has been very appropriately hailed as the leading light in the discipline of Community Medicine in our country.

Alexander Duncan Langmuir(1910-1993)

Alexander Duncan Langmuir was born on Sept. 22, 1910, in Santa Monica, California and grew up in New Jersey, died at the age of 83 in Baltimore of kidney cancer. He went to medical school, receiving a degree from Cornell and interning at the Boston City Hospital. His math training and a flair for statistics helped him earn a degree in public health from Johns Hopkins University.

His academic training led him into public health and he gained field experience working as a public health officer in New York State and as a member of the Armed Forces Epidemiological Board. He taught for three years at the Johns Hopkins University School of Hygiene and Public Health. In 1949, Dr. Langmuir created a corps of epidemiologists at the Federal Centers for Disease Control and Prevention in Atlanta. The corps was ready to fly anywhere immediately to investigate reports of an epidemic or an unusual cluster of cases. Known as the Epidemic Intelligence Service, the program played a crucial role in turning what was then an obscure and fledgling operation into a large Federal agency. From 1949 to 1970, Dr. Langmuir was the disease centers' chief epidemiologist. As the Government's chief disease detective, he created the concept of surveillance for infectious diseases. The agency used it to track dozens of diseases and to analyze patterns to take steps to prevent clusters and outbreaks from becoming epidemics. The agency also responded to requests from state health departments to investigate unusual cases and clusters. When the possibility of biological warfare was raised during the Korean War, scientists looked to epidemiology as the first line of defense. Dr. Langmuir seized the opportunity to strengthen disease surveillance and his program. Dr. Langmuir taught what he called "shoe leather epidemiology," stressing that investigators go into the field to collect their own data and view directly the locale of the public health problem they were investigating. His graduates wore lapel pins of a shoe with a hole in the sole. Upon retirement from the CDC, Langmuir served as a visiting professor at both the Harvard University School of Public Health and Johns Hopkins. He is rightly known as the founder of 20th century epidemiological and public health surveillance.

Summary

The History of Public health dates back to Greeco-Roman Era period, when Romans were able to implement public health measures and by the end of the Roman Empire in AD 476, the Roman public health system was well advanced comparatively in Europe. During the Middle Ages (5th-15th centuries) in Europe, public health systems collapsed, particularly during the period known as the Dark Ages (around 500-1000 AD). Action was only taken during outbreaks of disease such as the Black Death, an epidemic of bubonic plague that swept across Europe in the mid-14th century, killing between one-third and half of the population. Public toilets were to be introduced and the dumping of waste in the streets was forbidden.

In 1836, William Farr showed the impact of poor living conditions on life expectancy and the differences between different areas. In 1837 Chadwick compiled a survey of "Sanitary condition of labouring classes of Great Britain". In 1842 he recommended the "Sanitary Idea" with creation of a public health authority to provide drainage, potable water, sanitation, regulation of buildings etc. The first British Public health Act was passed in 1848. Chadwick then shifted the "Sanitary idea" to a new concept "State Medicine". He laid the foundation of subsequent British health policy and followed a comprehensive approach to disease prevention. In 1875 the Public Health Act was codified including all existing sanitary legislation.

In 1864 the first contagious Disease Acts was passed which provided for compulsory examination of women believed to be "Common prostitutes". Free vaccination was made available through the Poor Law Medical Services in 1840. In 1853 vaccination was made compulsory for all children with the first year of life. The Lemuel Shattuck Report encouraged social reform, including documentation of disease conditions and collection of vital statistics. The theory of miasma, which said that disease is due to causes contained in bad air, led to improvements in the sanitation systems, which led to decreased episodes of cholera. This caused public health reforms and encouraged cleanliness.

During the 19th Century and the first half of the 20th century, the perception of public health was limited to prevention of communicable diseases through environmental sanitation. During World war II the Public Health service established the control of Malaria in war areas. In 1907 preventive medicine practitioners and town planners got together to bring about housing reforms. Simultaneously legislations were passed for free school meals, medical inspection of school children and antenatal care.

In Germany, Pettenkofer first calculated the financial returns on public health investments to prove the value of sanitary

improvement in reducing death from typhoid. Bacteriological analysis was used to determine the presence of coliform bacteria in municipal water supplies. Currently, Classical infectious disease rates have declined while increased rates of non communicable diseases are now being observed in epidemic proportions throughout the world. New problem-solving systems are needed in areas such as health care financing, medical care for the aged, environmental health protection and health care planning and administration. Some of the pioneers and founders of Modern Public Health, Community Medicine & Preventive Medicine are Edward Jenner, John Snow, James Lind, Robert Koch, Joseph Lister, John Simmon, Lemuel Shattuck, Edwin Chadwick, Sir Ronald Ross, Sir Joseph William Bhome, Alexander Duncan Langmuir and Dr Sushila Nayyar.

Study Exercises

Short Notes : (1) John Snow (2) Edwin Chadwick (3) Sir Ronald Ross (4) Public Health evolution

MCQs & Exercises :

- (1) The "Sanitary Idea", with creation of a public health authority to provide drainage, potable water, sanitation, regulation of buildings, was first recommended by (a) William Farr (b) John Snow (c) Edwin Chadwick (d) Pettenkofer.
- (2) 'On the Mode of Communication of Cholera' in 1849 was written by (a) William Farr (b) John Snow (c) Edwin Chadwick (d) Pettenkofer.
- (3) 'A Treatise of the Scurvy' and 'An Essay on the Most Effectual Means of Preserving the Health of Seamen in the Royal Navy' were published by (a) William Farr (b) James Lind (c) Edwin Chadwick (d) Pettenkofer.
- (4) The father of modern epidemiological surveillance is (a) William Farr (b) James Lind (c) Edwin Chadwick (d) Pettenkofer.
- (5) The founder of 20th century epidemiological and public health surveillance is (a) Langmuir (b) James Lind (c) Edwin Chadwick (d) Pettenkofer.

Answers : (1) c; (2) b; (3) b; (4) a; (5) a.

Theories of Disease Causation

Since the primitive ages, man has been always concerned with disease and its possible determinants like etiology, risk factors, preventive, diagnostic and therapeutic measures. As a result, various theoretical models to explain the causation of human disease have evolved.

Theories in Primitive and Middle Ages

Since disease has always been a constant accompaniment of man, right from the pre-historic times onwards, he has been trying to find out the causes of disease. The various theories prevalent in different civilizations were “supernatural causes” (e.g. being possessed by evil spirits, wrath of gods, punishment for evil deeds during previous births and so on). Subsequently, as the middle ages came up, attempts were made to relate the human disease to “bad air” or to various forms of close contacts with diseased person (contagion theory). Even illustrious epidemiologists like William Farr were very inclined to the “miasma” theory which postulated that human diseases are due to bad clouds which are more dense at lower altitudes and hence diseases are more common among people who live nearer to the earth or sea level; in fact Farr tried to prove this by data taken from London cholera epidemic during mid-nineteenth century. These various theories had staunch supporters and backed up by strong religious and political sanctions to the extent that refuting such contemporary theories could mean facing severe forms of punishment.

Germ Theory

It was in the second half of the 19th century that the golden era of medicine was heralded by the pioneering discoveries of bacteria as a cause of human disease, by Robert Koch and Louis Pasteur. The contributions of these discoveries to human health cannot be questioned. So tremendous was the impact that a tendency developed to relate every human disease to a specific microbe or “germ”, to the extent that the germ theory of the human disease emphasized that each and every human disease has to be caused by a microbe or germ, which is specific for that disease and one must be able to isolate the microbe from the diseased human being. This was the central philosophy of the famous Koch’s postulates, formulated by Robert Koch (now also known as Henle-Koch postulates) :

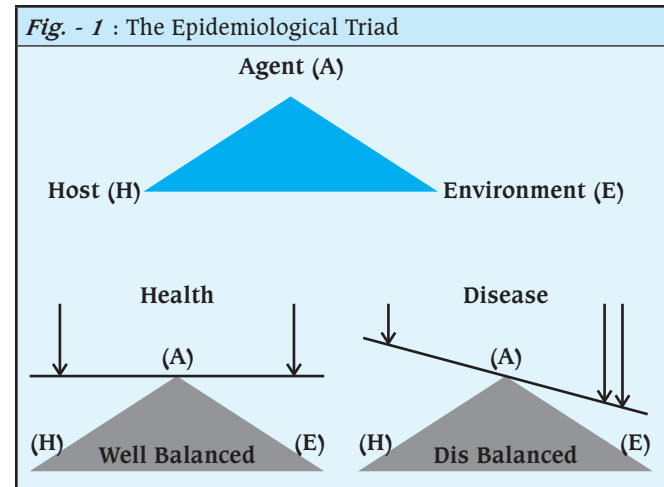

- 1) The disease agent occurs in every case of that disease and under circumstances which can account for the pathological changes and clinical course of the disease.
- 2) It occurs in no other disease as a non-pathogenic parasite.
- 3) After being fully isolated from the body and repeatedly grown in pure culture, it can induce the disease anew.

As the 20th century started rolling, it was realized that the germ theory really could not fully explain the causation of

human disease. The occurrence of tuberculosis in Western world fell down dramatically even without the availability of a specific vaccine (to specifically prevent infection) or a specific treatment (to specifically kill the tuberculosis “germ”). Simple facts like disease does not necessarily occur in everybody who has the tuberculosis germ in the body (i.e. infection does not necessarily lead to disease in Tuberculosis) started putting a question mark on the ability of the germ theory and Koch’s postulates, in completely explaining the causation of human disease.

The Epidemiological Triad

Not refuting the importance of germ theory, thought processes were started to explain the role of other factors in accentuating or attenuating the effect of the “germ” or “agent” of disease. This finally culminated into an extremely important and widely used theory to explain causation of human disease-the “Epidemiological triad” (see Fig. - 1).

The epidemiological triad theory hypothesizes that there are 3 important determinants of the state of health or disease in a human being, namely :

The agent factors : Related to the various characteristics of the “agent” which causes the disease.

The host factors : Which relate to various characteristics of the human being himself.

The environmental factors : Which relate to the various characteristics of the environment in which the human being is living.

As per the theory, as long as a state of fine balance or equilibrium is maintained between the various agent, host and environmental factors, the person stays in a state of health. (Health has been defined by the World Health Organization as a state of perfect physical, mental and social well being and not merely an absence of disease or infirmity). On the other hand, the moment this fine balance is disturbed due to change in any one or more of the agent, host and environment related factors, a departure from the state of health occurs (though evidence of disease may still not occur because manifest evidence of disease may take sometime to develop; thus, the importance of the definition of health given by the WHO in that health is not simply absence of disease. This aspect will be explained

further, later in this chapter when we discuss the process of natural history of disease and levels of prevention).

To give an example, a person may have infection with *M tuberculosis* but may be perfectly healthy in terms of physical, mental and social well being (most of us in the developing countries are that way). He remains in the state of health because the agent, host and environmental factors are well balanced with each other. Now, let us say, some of the host factors change, e.g. the person because grossly malnourished due to severe measles; or becomes immuno-compromised due to HIV infection; or the environmental conditions lead to gross poverty, consequent to wars and famines. Any one or more of these changes will lead to a disturbance in the equilibrium that

was earlier maintained, thus leading to departure from the state of health.

The various factors related to agent, host and environment can fall into the following categories :

Agent Factors

Physical Agents : (as heat, cold, vibrations, electricity, mechanical forces etc.).

Chemical Agents : (as acids, alkalies, heavy metals, allergens, etc.).

Biological Agents : (as viruses, bacteria, parasites, etc.).

Nutritional agents : These are truly a part of chemical agents but often described as a separate category because of the

exclusive importance that nutrition has in human health. Both deficiencies as well as excess of nutrients cause diseases; in addition, specific food toxins cause a variety of diseases, which will be dealt with in the section on nutrition.

Host Factors

Socio-demographic Factors : Such as age, sex, occupation, education, marital status, etc.

Psycho-social Factors : Such as attitudes, practices, behavioural patterns, life style, etc.

Intrinsic Characteristics : Intrinsic Characteristics or the “biological, Immunological and Genetic factors” in a human being - e.g. genetic factors, HLA types, biochemical and physiological characteristics, etc.

Environmental Factors

Physical Environment : Such as seasons, climate, altitude, rainfall, etc.

Biological Environment : e.g. arthropod vectors of diseases like mosquitoes, animal reservoirs like canines and rodents, etc.

Social Environment : e.g. community attitudes, beliefs, practices and cultural factors affecting disease; level of socio-economic development; availability of health services, etc.

The “BEINGS” Model of Disease Causation

Another recent concept postulates that human disease and its consequences are caused by a complex interplay of nine different factors - *Biological factors* innate in a human being, *Behavioural factors* concerned with individual lifestyles, *Environmental factors* as physical, chemical and biological aspects of environment, *Immunological factors*, *Nutritional factors*, *Genetic factors*, *Social factors*, *Spiritual factors* and *Services factors*, related to the various aspects of health care services.

The Theory of “Web of Causation”

The “epidemiological triad theory” was very effectively used by Leavel and Clark in explaining the natural history of disease and levels of prevention for obviating such departures from the state of health, which have formed the basis of public health activities. However, difficulties come up when an attempt is made to explain the causation of non communicable diseases like IHD or road accidents on the basis of epidemiological triad. For example, no single agent can be ascribed for IHD; a wide variety of interacting factors like Hypercholesterolemia, hypertension, tobacco, obesity, physical inactivity, genetic background, age, sex, just to name a few, interact in various ways to finally lead to the pre-pathogenic changes of “plaque” formation, which finally progress to the pathogenic phase of full blown disease.

For explaining the causation of such non communicable diseases in particular, McMahon and Colleagues (McMahon and Pugh T. *Epidemiology : Principle and methods* 1st Ed, 1970) forwarded the theory of “epidemiological web of causation”, wherein the various factors (e.g. hypercholesterolemia, smoking, hypertension and so on) are like an interacting web of a spider. Each factor has its own relative importance in causing the final departure from the state of health, as well as

interacts with others, modifying the effect of each other. The web theory also postulates that for preventing a disease, it is not necessary to take action against all the factors - if we could identify a few “weakest links” in the inter-lacing webs, actions directed to these weakest links may be of considerable value in prevention.

Epidemiological Wheel Theory

As medical knowledge has advanced, the additional aspect which has been exciting interest is the comparative role of “genetic” and the “environmental” (i.e. extrinsic factors outside the host) factors in causation of disease. The “triad” as well as the “web” theory does not adequately cover up this differential. To explain such relative contribution of genetic and environmental factors, the “wheel” theory has been postulated. A graphical presentation of this theory is given in Fig. - 2.

The theory visualizes human disease in the form of a wheel, which has a central hub representing the genetic components and the peripheral portion representing the environmental component. Like any wheel, the outer part (environmental component) has spokes (3 in this model) and the environmental component is thus divided into 3 sub components, representing the social, biological and physical components of the environment. For every disease, the genetic, social, biological and physical environmental components take different sizes, which we shall clarify with three examples, depicted in Fig. 2.

For a disease like Diabetes Mellitus, the genetic as well as the overall environmental component have an equal contribution; and within the environmental component, the maximum role is of social environment (behavioural patterns related to diet, physical exercise, smoking and drinking and availability of health services). On the other hand, biological component has quite a small role (certain viruses like Mumps or Coxsackie’s being implicated) while physical environmental has hardly any contribution. The relative sizes of these various components are kept in proportion to their contribution to the disease of interest, as shown in Fig. - 2. For a disease like phenylketonuria the major role is played by the genetic factors and hence a large central part, while out of the three environmental factors, represented by the smaller peripheral part, the social component plays an important part, since, if the parents can be educated regarding the proper diet (and, of course, if they can economically afford it), still the symptoms of the disease can be prevented, despite the genetic background. Finally, in malaria, genetic factors have a small role and hence a small central hub, while out of the environmental factors, all the three components have a major and equal role (physical environment by way of producing malariogenic conditions by rainfall, humidity and water logging; biologic environment by way of affecting the breeding and bionomics of mosquitoes and the social environment by way of overall socio-economic development, housing conditions, availability of health services affecting the treatment and preventive programmes.) Thus, all the 3 components of environment are shown with equal share in the figure.

The Theory of “Necessary” and “Sufficient” cause

Way back, John Stuart Mill had defined “cause” as “The cause, then, philosophically speaking, is the sum total of the

conditions, positive and negative, taken together, the whole of the contingencies, of every description, which being realized, the consequent invariably follows". Thus, the "cause" of a particular human disease is like the constellation of various factors and when all of them come into play in an *optimum* combination, the pathological process which finally produces the disease gets initiated. The definition clearly underlines the "multifactorial" causation of disease rather than "unifactorial" causation that was thought of in the germ theory. Modern epidemiology therefore proceeds to identify "a cause" or "some of the causes" of a disease (rather than "the cause") and directs preventive action towards the one or few of the various factors which may form part of the contingency.

To explain in very general terms, if the "disease" was like the sweet melody which flows out of a concert, the various contingencies that combine to produce it are the violin, guitar, drums, accordion, musicians, electricity, etc. Once all these various contingencies come together in an *optimum* mix, the final melody flows out. Now for preventing the melody, it is not necessary to identify and take action against all the contingencies. Just cut off the electric wires of the guitar or make a hole in the drum and the melody is prevented! The definition of Mill was further expanded to the concept of web of causation by McMahon and colleagues. Subsequently, Rothman further dilated on this aspect and forwarded the concepts of "necessary" and "sufficient" cause. For example, there could be 3 different contingencies, all of which when present together in an "optimum mix" lead to Tubercular disease. In the first contingency, presence of infection with *M tuberculosis* (A) along with optimum amounts of overcrowding (B), poverty (C), malnutrition (D) and lack of BCG vaccination (E) will lead to tubercular disease. In the next situation, presence of infection (A), even in absence of B, C, D and E but in the presence of other factors, viz attack of severe measles (F) and possible racial or genetic predisposition (G) will also finally lead to disease. In the last situation, the presence of infection (A) simply along with HIV infection (H) would also cause the disease.

Interestingly, then, *M tuberculosis* (A) has to be present in all the contingencies for the tubercular disease to finally occur but alone, by itself, it will not necessarily cause the disease. Thus, *M tuberculosis* is a "necessary" cause of tubercular disease but NOT a "sufficient cause". On the other hand, (A, B, C, D, E) or (A, F, G) or (A, H) when they come together in "optimum mix" become "sufficient cause" for the disease to occur. Thus, a necessary cause is one whose presence is essential for disease causation, but which alone, by itself may or may not be able to finally cause the disease. Thus, disease may or may not occur in its presence but will not occur in its absence. At times, the necessary cause may by itself be a sufficient cause for the disease (e.g. infection with HIV is a "necessary" as well "sufficient" cause for AIDS). More often, however, in most of the infectious diseases, the necessary cause by itself may not be a sufficient cause (example of Tubercular disease given earlier). Finally in most of the non-communicable diseases one may not be able to identify any "necessary" cause at all; what is important in these diseases is whether the optimum mix of various factors has occurred in a way to produce the "sufficient cause". For example, for a non-communicable disease, like IHD, different factors may combine to form different "constellations"

of sufficient cause, e.g. :

(Genetic predisposition+smoking+middle age) >>>> IHD
 (Hypertension+central obesity+suppressed hostility) >> IHD
 (Hypercholesterolemia+DM+physical inactivity) >>>> IHD

Induction and Latent Periods

The concept of "sufficient" cause has also brought about the interesting terms "Induction period" and "Latent period" in respect of non - communicable diseases.

A = Sufficient cause becomes operative.

B = Disease process (pathological changes) start in the human body.

C = Earliest point of detection of disease by available diagnostic methods.

Thus, induction period is the time interval that elapses between the point when "sufficient cause" becomes operative to the point when the first pathological changes of disease start in the body. On the other hand latent period is the time period that elapses between the initiation of pathological change till the point when the earliest diagnosis of the disease is possible with the currently available clinical and diagnostic armamentarium. The counterpart in infectious disease epidemiology is the "incubation period" which refers to the time period that elapses between the entry of the infectious agent into the body till the point the earliest manifestation of the disease are evident. The "generation time" on the other hand refers to the time between entry of the infectious agent into the body and the maximum infectivity of the human host.

Predisposing, Enabling, Precipitating, Reinforcing and Risk Factors in Disease Causation

It is apparent from the foregoing discussion that in a "sufficient cause", besides the necessary cause, a large number of other factors are also present, based on whose optimum permutation and combination, the "sufficient cause" finally emerges. Experts have classified such factors into the following four types :

- a) *Predisposing factors* are factors which create a state of susceptibility, so that the host becomes vulnerable to the agent or to necessary cause, e.g. age, sex, previous illness.
- b) *Enabling factors* are those which assist in the development of (or in recovery from) the disease; e.g. housing conditions, socio-economic status.
- c) *Precipitating factors* are those which are associated with immediate exposure to the disease agent or onset of disease, e.g. drinking contaminated water, close contact with open case of pulmonary TB.
- d) *Reinforcing factors* are those which aggravate an already existing disease, e.g. malnutrition, repeated, exposures, etc.
- e) *Risk factors* : A risk factor is defined as a condition, quality or attribute, the presence of which increases the chances of an individual to have, develop or be adversely affected by a disease process. A risk factor is thus not necessarily the cause of a disease but does increase the probability

that a person exposed to the factor may get the disease. For example, smoking is a risk factor for IHD; it increases the risk of developing IHD by about two times although it may not be an essential cause because many smokers may never develop IHD while many non-smokers may develop the same. Broadly, in public health approach, risk factors are classified as either modifiable or non-modifiable. The former includes those which cannot be changed, as age, sex, genetic background and racial background. The modifiable factors are those which can be modified or stopped, as smoking, lack of physical activity, dietary indiscretion, etc. While the non-modifiable factors cannot be changed, they are still quite important since if a person is having one or more non-modifiable factors, there is an even greater need for him or her to give up the modifiable risk factors.

- f) *Risk Marker* : There is a fine difference between a risk factor and a risk marker. A risk factor, once established by epidemiological studies, is directly involved in the chain of causation of the disease; any manipulation in the risk factor will also change the level of the disease. For example, if smoking is a risk factor for lung cancer, decrease or stoppage of smoking will decrease the chances of suffering from lung cancer and vice versa. However, a risk marker, on the other hand, is only a surrogate or a proxy indicator of the risk of the disease, mostly because of its association with another risk factor. For example, development of a transverse crease on the ear lobe has been shown, in many studies, to indicate an increased risk for IHD. However, even if we correct the ear lobe crease by a plastic surgery procedure, the risk of IHD will not reduce! However, risk markers are important in preventive and public health care, since one should get alert and vigorously enforce preventive procedures in those who have the risk marker.
- g) *Risk Groups and Risk Approach* : One of the important strategies in modern day public health is the “high risk approach”. A high risk group can be defined as a group of people or a subsection of the population, who, by virtue of certain characteristics, are likely to have a higher probability of suffering from one or more diseases or from general ill health. Such characteristics may be
- Innate, non-modifiable characteristic as age (infants and young children are more at risk for respiratory and gastro-intestinal infections), sex (males are more susceptible to IHD), or genetic background (children of both diabetic parents), or blood groups.
 - Modifiable Biological characteristics as obese people are at higher risk of developing IHD, hypertension and diabetes mellitus.
 - Socio-demographic and environmental characteristics: as low income, low education groups, slum dwellers, gender (females are more susceptible to complications of pregnancy, sexual exploitation and domestic violence) or geographical characteristics (people living in rural and remote hilly areas) or occupation (soldiers are more susceptible to injuries and adverse effects of hot, cold and high altitude environment).

Accordingly, the “high risk approach” has developed as an important strategy in public health. This is defined as a health care management strategy which endeavours to provide special care to those who are at higher risk of being affected by adverse health conditions, due to some identified characteristics, while, at the same time, providing optimum care to all other members of the community. Thus, the risk approach conceptualizes providing some basic level of care to all the members of the community and, in addition, providing special care to those who are more in need, being identified as being high risk. Risk approach has been most convincingly used in the field of mother and child health care, the details of which will be presented in the section of maternal and child health.

Natural History of Disease

Next to searching and explaining the “causes” of diseases, another area which has been of great inquisitiveness to humans, is to study the “natural history” of diseases. This is defined as the “natural course that a disease would take when it has not been affected by any treatment or any other intervention. It is of much importance for all of us to understand the natural course of human diseases, since, as we shall see later in this chapter, the various modalities of disease prevention and control are dependant on such knowledge.

Let us take the example of a common disease like typhoid fever. After the infecting organism enters our body by way of food or drinks, there is an incubation period of about 14 days, after which we have clinical manifestations in the form of headache, remittent fever which rises in a step ladder pattern and initial constipation followed by pea-soup stools. The spleen is palpable and rash appears in the second week. Most of the individuals recover by the third week, though variable feeling of weakness may persist for a longer time. However, some patients may develop complications in the third week in the form of intestinal haemorrhage, perforation and peritonitis, with high mortality. Another small percentage may pass on to a chronic carrier state after an apparent clinical recovery.

Have you ever paused to think as to how the various textbooks describe the course of various human diseases? In fact, this is all based on the knowledge of epidemiology, as we shall describe later in the chapter on definition and uses of epidemiology.

Let's continue with our example of typhoid fever. If we ask you as to what is the cause of typhoid fever, you would be sure enough to reply “*Salmonella typhi*”. Very fine. But, is it the only cause? For example, if I gulp down a few salmonellae, will I certainly get typhoid fever. May be, not, because I may be already resistant to typhoid fever due to previous immunization. Therefore, another factor to be considered in development of human diseases is, besides the organism (agent), the human being himself too. Now, there is yet another factor which needs to be considered also. You would agree that the salmonella cannot just enter my mouth of its own accord! There should be water or food which should be contaminated with the faeces of a patient of typhoid fever. Therefore, the third thing, besides the microbial organism and the human being, which determines the disease, is the “environment”. This is known as the triad of agent, host and human factors. We have deliberated on these details earlier in this chapter.

You and me may not get typhoid fever, while many others around us would get it, because of various reasons like :

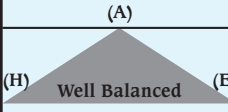

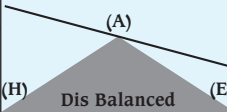

- Being public health trained persons, we know that typhoid bacillus is spread by contaminated food and water, so we will deliberately not consume such food and water about which we are suspicious, while an unaware human being may consume them because of ignorance.
- We won't be forced to consume contaminated food or water because of our better socio-economic status, while a poor person may not have any other alternative other than consuming unhygienic but cheaper food and water.
- Even if we consume such an infected food or water, being healthy and well nourished, possibly having been immunized against typhoid (being from public health services) and hence better immunity, we may not actually develop the disease as compared to a person who is sick, malnourished and not immunized.

We would therefore agree that the mere presence of agent, host and environment is not enough to cause the disease. As long as the agent, host and environment are in a state of equilibrium disease will not be initiated; the process of human disease would be initiated only if there is an appropriate interaction and a loss in equilibrium, between the agent, host and environment. For example, if we become malnourished due to an attack of severe measles or take on to heavy alcoholism, or become poor and hence forced to consume contaminated food or water, or are exposed to a very heavy dose of infection (for example, drinking raw water in a flood like situation), we would become "susceptible" to developing typhoid fever. Just note what we have said - we have become "susceptible" though still no pathological process of disease had started in our body.

The point which needs to be noted is that in any disease, there is a phase between the state of perfect health and the point from where actual pathological processes of the disease start. This phase is called as the phase of 'pre-pathogenesis' (since actual pathological processes have not started still) and also called as the phase of "susceptibility" (since the human being has become susceptible to developing the disease). This stage thus occurs even before the human being is actually involved with the disease process. This phase is important to be understood, since quite commonly, we tend to view health as a state of absence of disease. Factually speaking, then, health is not equivalent to an absence of disease, because in the phase of pre-pathogenesis or susceptibility, there is no disease, but the state of perfect health has also been compromised at the same time. This is also the ethos in the WHO definition of health which states that health is a state of perfect physical, social and mental well being and not merely an absence of disease or infirmity. Thus, people in the stage of susceptibility or the pre-pathogenesis stage are not in a state of health, though they may not be having any disease.

Now, let's see what happens after the disease agent enters the human host, i.e. the course of disease in man. Initially, there is a "silent period" during which the pathological processes keep developing inside the body but outwardly there is no sign or symptom; thus the person is not aware that he has some disease process developing inside the body, nor can any of the routinely used clinical or other diagnostic procedures detect the disease. For instance, the typhoid bacillus would settle down in the cells of RE system and multiply silently, during this phase. The pathogenesis period starts from this point and this phase is known as the "phase of early pathogenesis". While

Fig - 3 : Natural History of Disease & Levels of Prevention

Stage of Positive Health	Stages of Susceptibility (Pre Pathogenesis)	Stages of Pathogenesis			
		Asymptomatic (Early Pathogenesis)	Early, Discernible Disease	Full-Blown (Classical) Disease	Termination
(A)  Agent, Host and Environmental factors are in perfect balance	(A)  Balance between Agent, Host and Environmental Factors is disturbed; conditions have been created for disease process to start; however pathological processes have still not started.	Pathological process has started. However, outwardly, there are no signs or symptoms what so ever. Detection is only possible by specialized pathological / investigative studies.	There are very mild or non-specific signs / symptoms which occur at a very early stage of clinical course; not easy to detect at this stage unless very fine clinical acumen and / or specialized equipment is used.	Full fledged disease in classical form; quite easy to diagnose.	- Complete Recovery - Chronic Disease - Life With Residual Disability - Death
Health Promotion	Specific Protection	Early Diagnosis and Prompt Treatment		Disability limitation	Rehabilitation
Primary Prevention		Secondary Prevention		Tertiary Prevention	
Levels of Prevention					

there are no signs or symptoms of the disease, still this phase is very important for two reasons. Firstly, the person, though undetectable, can still spread the disease; secondly, if we can use certain specialized procedures to detect the disease during this stage, we could treat it at this early stage and hence save from a lot of complications, which could occur if the disease is detected when it has become very advanced.

Now after this phase, the typhoid bacillus produces the typical manifestations of the disease. Initially, we have the stage of early, discernible lesions, which give us some indication that some disease, possibly typhoid fever, had occurred, as fever, headache, mild cough and constipation. Later, the disease presents with full fledged manifestations as remittent fever of step ladder pattern, rash, pea soup stools and splenomegaly. If allowed to progress further, some patients may pass on to complications as intestinal haemorrhage / perforation, toxemia and death, while some may develop long term disabilities as chronic typhoid carrier state. However, during this phase itself, the body also mounts the immunological response and most of the persons get cured by way of body's defence response overcoming the infective process.

Thus, the broad phase of "pathogenesis" has four sub-phases, namely, phase of early pathogenesis (also referred to as phase of asymptomatic disease), phase of early discernible lesions, phase of full blown disease and phase of termination; the last one (termination) has a wide spectrum ranging from full recovery at one end and death at the other and various grades of residual disability / chronicity in between.

These stages in the natural history of disease are not only for infectious diseases as typhoid fever but is true for non communicable diseases like IHD also. In IHD, there is no single "agent" (as typhoid bacillus in enteric fever) but multiple, interacting agents as tobacco smoking, saturated fats and cholesterol in diet, physical inactivity, raised blood pressure and so on. Let's take the example of a young boy who doesn't smoke, is physically active, eats a diet primarily of cereals, pulses and vegetables and has little stresses of life excepting for his studies. From this state of perfect health, suppose he gets a highly paid job, with prolonged working hours. Apparently, he starts driving to his office, starts eating fat-rich junk food available in a nearby restaurant, gets little time for physical exercise and games and starts smoking due to stressful office jobs. At this stage, while the pathological process of atherosclerosis may have still not started inside his body, so that he is still not "diseased", however, he is not in a state of perfect health but rather in the phase of susceptibility. Now, if this situation continues, the process of atherosclerosis will start off in its most initial forms of atheromatous plaque and increasing obliteration of coronaries. At present, this person won't have any outward sign or symptom of IHD but would now be considered in the "phase of pathogenesis" since the pathological processes have, in any case started. More specifically, he would be considered to be in the phase of asymptomatic disease since he does not have any symptoms and cannot be detected by routine clinical and diagnostic procedures but can be detected using some very specialized procedures as stress ECG test. The disease would now progress to the phase of early discernible lesions, in which the person

would start having symptoms of effort intolerance or angina; a good clinician with a good diagnostic level of suspicion would be able to diagnose and treat him. The disease would further progress to one of full blown disease, manifesting as acute myocardial infarction and thereafter would progress on to termination, either as death, or full recovery or else life with residual disability.

Now, what is the importance of understanding these sequences of action in the natural history of a disease? The importance is that it serves as the basis of planning the preventive activities. In fact, we take preventive actions throughout the entire sequence of the natural history of the disease, as shown in Fig. - 3.

Levels of Prevention

In general, there are three major levels of prevention, depending on the phase of the natural history of the disease :

Primary Prevention

These are all measures of prevention that are undertaken during the phase of pre-pathogenesis (phase of susceptibility), before the disease process has had onset. Primary prevention involves two types of sub-steps, as follows :

Health Promotion : These include all steps undertaken to improve the level of general health and well being so that conditions for initiation of disease process are prevented. However, these steps are not specific for any disease or a group of diseases. These actions include improvement in the overall socio-economic status of the population, health education, feeding programmes for mothers and children, promotion of breast feeding, promotion of small family norms, education and motivation for healthy lifestyle and such similar measures.

Specific Protection : These include measures to prevent the initiation of specific diseases or a group of diseases. Examples include immunization to protect against specific diseases, fortification of foods with specific nutrients (as salt with iodine), use of condoms to protect against sexually transmitted diseases (STDs), use of chemoprophylactic drugs to protect against particular diseases (as malaria, meningococcal meningitis, plague, tuberculosis, leptospirosis, etc), use of helmets to protect against head injuries, etc.

The difference between health promotion and specific protection should be clearly understood. Both are a type of "primary preventive" strategy, undertaken during the stage of susceptibility (pre-pathogenesis), with a view to obviate the very initiation of the disease process. However, health promotional approach improves the general health so that a number of diseases are aimed at, from preventive point of view and not a single disease. For example, when we promote breast feeding among children, we are trying to prevent general malnutrition, vitamin A deficiency, providing antibodies against various diseases, preventing diarrhoeal diseases (because artificial feeding carries the risk of infection) and so on. On the other hand when condom is used, it is for a very specific group of diseases i.e. STDs; when measles vaccine is given it is for a specific disease viz. measles.

In addition, there is also an increasing role of "primordial prevention" being recognized in contemporary public health.

Primordial prevention is different from primary prevention. Primary prevention focuses on steps so that the disease process is not initiated, i.e. the stage of pre-pathogenesis is not crossed, though the adverse agent, host and environmental factors may be present. For instance, in the example of the natural history of IHD given above, if we educate and motivate the young man not to start smoking, despite the fact that cigarettes are available, we are practicing primary prevention. On the other hand, primordial prevention endeavours to prevent the very creation of such environment or the establishment of such conditions, that are conducive to the development of the disease. For example, if we create conditions in which cigarettes are not available or even tobacco is not produced, then we are preventing the development of those very conditions which lead to the state of pre-pathogenesis; hence this would be primordial prevention.

Secondary Prevention

These include all actions undertaken at the stage of early pathogenesis (asymptomatic disease) with a view to halt the progress of disease at its earliest, incipient stage, by "early diagnosis and prompt treatment". It is like stamping off a fire when it has just started rather than call the fire brigade after the fire has become voluminous. The person is not aware of any signs or symptoms and the routine clinical methods also may not be able to detect a disease at this stage, since the disease process is in the very preliminary stage. However, by using special procedures we can uncover a disease in such early stages. The classical example of this level of prevention is "screening for disease" as for breast cancer (using mammography) and cervical cancer (using pap smear). Various types of medical examinations as those of school children, infants and young children, of industrial workers and various disease screening camps are all examples of this level of prevention.

Tertiary Prevention

These include all measures undertaken when the disease has become clinically manifest or advanced, with a view to prevent or delay death, reduce or limit the impairments and disabilities, minimize suffering and to promote the subject's adjustment to irremediable conditions. Tertiary prevention has two types of approaches inbuilt into it, viz. disability limitation and rehabilitation.

Disability Limitation : These include all measures to prevent the occurrence of further complications, impairments, disabilities and handicaps or even death. For example :

When we apply plaster cast to a patient who has suffered Colle's fracture, we are actually trying to prevent complications and further disability like mal-union or non-union.

When we give complete rest, morphine, oxygen and streptokinase to a patient of Acute MI, we are actually trying to prevent death or complications like arrhythmias / CHF.

The sequence with which a disease turns into a handicap is as follows :

Disease : This is a pathological process and its manifestations which indicate a departure from the state of perfect health.

Impairment : This is the actual loss or damage of a part of body anatomy or an aberration of the physiological functions

that occurs consequent to a disease.

Disability : This is defined as the inability to carry out certain functions or activities which are otherwise expected for that age / sex, as a result of the impairment.

Handicap : This is the final disadvantage in life which occurs consequent to an impairment or disability, which limits the fulfillment of the role a person is required to play in life.

For example, let us say an agricultural worker gets acute myocardial infarction. This is the disease. Because of this disease, he would have necrosis of a part of the myocardium, inadequate perfusion of the myocardium and inadequacy in the pumping action of the heart with a compromise in the oxygenation of the blood. These are the "impairments" due to the disease. Due to these impairments he will not be able to undertake hard manual labour, which an otherwise healthy male of his age would have undertaken - this is the disability, resultant to the impairment. Finally because of this disability, he will lose his job of an agricultural worker and hence not able to earn adequate livelihood - this is the handicap, consequent to the disability.

Rehabilitation : This is the second component of tertiary prevention. Rehabilitation stands for the combined and coordinated usage of all the available medical, social, educational and vocational measures, for training and retraining the person to the highest level of functional ability.

Rehabilitation emphasizes on the fact that the duty and obligation of a Doctor who cares for a patient does not end simply by curing the patient of his / her symptoms. It is also an obligation to assist the patient in getting rehabilitated so that he / she gets fully adjusted in the family and social milieu and lives a happy and productive life. When you treat a patient of Hansen's disease, it is not simply enough to treat the patient with the recommended antibiotic regime and then forget about the patient. A lot still has to be done. The patient would be having claw hand and would need the hands to be made as near normal as possible by corrective surgery, so that he can work productively as well as undertake the daily activities of life. The patient also needs to be trained in some vocation so that he can make a living. The patient's family and the society has to be educated to accept this patient as a normal human being and not one who has been cursed by the Gods. The patient himself would be emotionally weak and labile and would need to be emotionally supported. These all activities come under the purview of "Rehabilitation" (Re =restore into, habitat = the original home or environment of the person). Accordingly, rehabilitation is undertaken at four dimensions :

Medical rehabilitation : This is done through medical / surgical procedures to restore the anatomy, anatomical functions and physiological functions to as near normal as possible.

Vocational rehabilitation : This includes steps involving training and education so as to enable the person to earn a livelihood.

Social rehabilitation : This involves steps for restoration of the family and social relationships.

Emotional and Psychological rehabilitation : This involves steps to restore the confidence, personal dignity and

confidence.

The Iceberg Phenomena in Human Diseases

Measurement of the level of health and disease is a major issue in public health. One way is to measure the magnitude of sickness that has come to the notice of health care providers. For instance, if we want to estimate the load of hypertension in our community, we may work out the details of cases of hypertension admitted to all the government hospitals and private nursing homes as also seen at the OPDs, dispensaries and by the GPs, during the entire year and develop our estimates. We are quite likely to grossly under-estimate the magnitude of the problem, if we take such a recourse, for we would be missing out a very large number of cases who are present in the population with undetected hypertension and those with mild disease who never reported to a health care provider. This is what is referred to as the “iceberg” phenomena in human diseases - the magnitude of disease that is apparent clinically is a small fraction of the entire load; the major part of the load is not clinically apparent (lies below the clinical horizon) and hence lies hidden in the community. This is in the same way that the part of an iceberg which lies above the surface of water is actually a very small part of the total iceberg which lies submerged beneath the water surface.

In the past, many accidents have happened among ships that could not appreciate this iceberg phenomena and, underestimating the actual bulk of the iceberg, crashed and sank in the sea. Similarly, public health professionals should be careful while making an assessment of the load of diseases and their associated risk factors in the community, remembering that the real load lies hidden in the community and is not clinically apparent. This will help preventing failures which may otherwise occur consequent to inadequate planning due to underestimation, in public health programmes.

Summary

Right from the pre-historic times onwards, man has been trying to find out the causes of disease from “supernatural causes”, “bad air” and the “miasma” theory by Farr. It was in the second half of the 19th century that the germ theory of the human disease was put forth which was the central philosophy of the famous Koch’s postulates, formulated by Robert Koch (now also known as Henle-Koch postulates). Later, thought processes were started to explain the role of other factors in accentuating or attenuating the effect of the “germ” or “agent” of disease which finally culminated into the “Epidemiological triad”. This theory hypothesizes that there are 3 important determinants of the state of health or disease in a human being, namely the agent factors, host factors and the environmental factors. As long as a state of fine balance or equilibrium is maintained between these factors, the person stays in a state of health and the moment this fine balance is disturbed, a departure from the state of health occurs. The “BEINGS” model of disease causation postulates that human disease and its consequences are caused by a complex interplay of nine different factors - Biological factors innate in a human being, Behavioural factors concerned with individual lifestyles, Environmental factors as physical, chemical and biological aspects of environment, Immunological factors, Nutritional factors, Genetic factors,

Social factors, Spiritual factors and Services factors, related to the various aspects of health care services. The Theory of “Web of Causation” was postulated by McMahon and Colleagues to explain the occurrence of non-communicable diseases like IHD, wherein the various factors are like an interacting web of a spider. Each factor has its own relative importance in causing the final departure from the state of health, as well as interacts with others, modifying the effect of each other. For preventing a disease, it is not necessary to take action against all the factors - if we could identify a few “weakest links” in the inter-lacing webs, actions directed to these may be of considerable value in prevention. The “wheel” theory visualizes human disease in the form of a wheel, which has a central hub representing the genetic components and the peripheral portion representing the environmental component that has spokes (3 in this model) representing the social, biological and physical components of the environment.

The theory of “necessary” and “sufficient” cause : A necessary cause is one whose presence is essential for disease causation, but which alone, by itself may or may not be able to finally cause the disease. Disease may or may not occur in its presence but will not occur in its absence. At times, necessary cause may by itself be a sufficient cause for the disease (e.g. infection with HIV is a “necessary” as well “sufficient” cause for AIDS).

Induction period is the time interval that elapses between the point when “sufficient cause” becomes operative to the point when the first pathological changes of disease start in the body. On the other hand latent period is the time period that elapses between the initiation of pathological change till the point when the earliest diagnosis of the disease is possible with the currently available clinical and diagnostic armamentarium. The counterpart in infectious disease epidemiology is the “incubation period” which refers to the time period that elapses between the entry of the infectious agent into the body till the point the earliest manifestation of the disease are evident. The “generation time” on the other hand refers to the time between entry of the infectious agent into the body and the maximum infectivity of the human host.

A large number of other factors present, based on whose optimum permutation and combination, the “sufficient cause” finally emerges, are classified into : Predisposing factors (which create a state of susceptibility, so that the host becomes vulnerable to the agent or to necessary cause, e.g. age, sex, previous illness), Enabling factors (those which assist in the development of or in recovery from the disease; e.g. housing conditions, socio-economic status), Precipitating factors (those which are associated with immediate exposure to the disease agent or onset of disease, e.g. drinking contaminated water, close contact with open case of pulmonary TB), Reinforcing factors (those which aggravate an already existing disease, e.g. malnutrition, repeated, exposures, etc), Risk factors (defined as a condition, quality or attribute, the presence of which increases the chances of an individual to have, develop or be adversely affected by a disease process; a risk factor is thus not necessarily the cause of a disease but does increase the probability that a person exposed to the factor may get the disease; may be modifiable or non-modifiable), Risk Marker (is only a surrogate or a proxy indicator of the risk of the disease,

mostly because of its association with another risk factor) and Risk Groups and Risk Approach (a high risk group can be defined as a group of people or a subsection of the population, who, by virtue of certain characteristics, are likely to have a higher probability of suffering from one or more diseases or from general ill health). The “high risk approach” is defined as a health care management strategy which endeavours to provide special care to those who are at higher risk of being affected by adverse health conditions, due to some identified characteristics, while, at the same time, providing optimum care to all other members of the community.

Natural History of Disease is defined as the “natural course that a disease would take when it has not been affected by any treatment or any other intervention. The broad phase of “pathogenesis” has four sub-phases, namely, phase of early pathogenesis or phase of asymptomatic disease, phase of early discernible lesions, phase of full blown disease and phase of termination; the last one (termination) has a wide spectrum ranging from full recovery at one end and death at the other and various grades of residual disability / chronicity in between.

In general, there are three major levels of prevention, depending on the phase of the natural history of the disease : Primary Prevention (all measures of prevention that are undertaken during the phase of pre-pathogenesis or phase of susceptibility, before the disease process has had onset and involves two types of sub-steps : Health Promotion - which includes all steps undertaken to improve the level of general health and well being so that conditions for initiation of disease process are prevented; Specific Protection - includes measures to prevent the initiation of specific diseases or a group of diseases.), Primordial prevention (which endeavours to prevent the very creation of such environment or the establishment of such conditions, that are conducive to the development of the disease), Secondary Prevention (which includes all actions undertaken at the stage of early pathogenesis or asymptomatic disease with a view to halt the progress of disease at its earliest, incipient stage, by “early diagnosis and prompt treatment”) and Tertiary Prevention (which includes all measures undertaken when the disease has become clinically manifest or advanced, with a view to prevent or delay death, reduce or limit the impairments and disabilities, minimize suffering and to promote the subject’s adjustment to irremediable conditions; it includes disability limitation rehabilitation. The iceberg phenomena in human diseases describes that the magnitude of disease that is apparent clinically is a small fraction of the entire load; the major part of the load is not clinically apparent (lies below the clinical horizon) and hence lies hidden in the community.

Study Exercises

Long Question : Describe the natural history of disease, taking tuberculosis as an example.

Short Notes : (1) Theories of disease causation (2) Phases in the natural history of disease (3) Levels of prevention.

MCQs & Exercises

- Human diseases are due to bad clouds was a part of which theory? : (a) Supernatural causes (b) “Miasma” theory (c) Germ theory (d) Epidemiological triad
- The “BEINGS” model of disease causation postulates that

human disease and its consequences are caused by a complex interplay of how many different factors ? : (a) 3 (b) 6 (c) 9 (d) 10

- The theory of “epidemiological web of causation” was forwarded by : (a) Robert Koch and Louis Pasteur (b) McMahon and Colleagues (c) Henle-Koch (d) John Stuart Mill
- Epidemiological Wheel Theory visualizes human disease in the form of a wheel, which has : (a) a central hub representing the genetic components and the peripheral portion representing the environmental component (b) a central hub representing the environmental component and the peripheral portion representing the genetic components (c) interplay of nine different factors in causation of disease (d) various factors like an interacting web of a spider with each factor having its own relative importance in causation.
- According to the Epidemiological Wheel Theory, in malaria, there is : (a) a large central hub, while out of the environmental factors, all the three components have unequal roles (b) a large central hub, while out of the environmental factors, all the three components have a major and equal role (c) a small central hub, while out of the environmental factors, all the three components have unequal roles (d) a small central hub, while out of the environmental factors, all the three components have a major and equal role
- The time interval that elapses between the point when “sufficient cause” becomes operative to the point when the first pathological changes of disease start in the body is : (a) generation time (b) induction period (c) Latent period (d) lag phase
- A condition, quality or attribute, the presence of which increases the chances of an individual to have, develop or be adversely affected by a disease process is known as : (a) Predisposing factor (b) Risk factor (c) Precipitating factors (d) Risk Marker
- Education and motivation for healthy lifestyle is : (a) Primordial prevention (b) Secondary prevention (c) Health Promotion (d) Specific Protection
- The inability to carry out certain function or activity which is otherwise expected for that age / sex is known as : (a) Disease (b) Impairment (c) Disability (d) Handicap
- Disability Limitation is part of : (a) Primordial prevention (b) Primary prevention (c) Secondary prevention (d) Tertiary Prevention
- Screening for breast cancer using mammography is : (a) Primordial prevention (b) Primary prevention (c) Secondary prevention (d) Tertiary Prevention
- Fortification of foods with specific nutrients as salt with iodine, is an example of : (a) Primordial prevention (b) Primary prevention (c) Secondary prevention (d) Tertiary Prevention
- Primary Preventive measure can be applied at which stage of the natural history of disease : (a) stage of positive health (b) asymptomatic (early pathogenesis) (c) early, discernible disease (d) full - blown (classical) disease
- Use of chemoprophylactic drugs to protect against malaria is : (a) Primordial prevention (b) Primary prevention

- (c) Secondary prevention (d) Tertiary Prevention
- 15) Measures that can be applied at the stage of early, discernible disease include : (a) Primordial and Primary prevention (b) Primary and Secondary prevention (c) Secondary and tertiary prevention (d) Primary, secondary and tertiary prevention

Match the Following :

1. An agricultural worker gets acute myocardial infarction
 2. Necrosis of a part of the myocardium and inadequate perfusion
 3. Not be able to undertake hard manual labour
 4. Lose his job and hence not able to earn adequate livelihood
- a. Disease; b. Disability; c. Impairment; d. Handicap

Fill in the Blanks :

1. _____ is the theory which postulated that human diseases are due to bad clouds.
 2. Koch's postulates, formulated by Robert Koch, later came to be known as _____

3. "BEINGS" model of disease causation postulates that human disease and its consequences are caused by a complex interplay of nine different factors which are _____
 4. According to the Epidemiological Wheel Theory, in phenylketonuria the major role is played by _____ factors
 5. Measures adopted to prevent the initiation of specific diseases or a group of diseases is known as _____ .

Answers :

MCQs : (1) b; (2) c; (3) b; (4) a; (5) d; (6) b; (7) b; (8) c; (9) c; (10) d; (11) c; (12) b; (13) a; (14) b; (15) c.

Match the Following : 1-a; 2-c; 3-b; 4-d.

Fill in the Blanks : 1. Miasma theory; 2. Henle-Koch postulates; 3. Biological factors, Behavioural factors, Environmental factors, Immunological factors, Nutritional factors, Genetic factors, Social factors, Spiritual factors and Services factors. 4. Genetic factors; 5. Specific Protection.

4 Measuring the Level of Health in a Population : Epidemiological Measures (Indicators) of Health and Disease in a Community

RajVir Bhalwar

"----- For the health administrator, nothing could be more valuable than to have, at his command, one or more measuring rods to help him in his task and also in assessing his specific problems relating to the health of the people, in designing his plans to deal with these, in guiding his administration and in evaluating his schemes ----- " (WHO).

In the previous chapter, we discussed the "summary measures" in epidemiology i.e. incidence rate, prevalence, etc. In real health care practice, these measures are actually expressed in terms of indicators which provide a quick idea of the status of health, disease and health related conditions in the community. These measures (also called as "Indicators") can be grouped as:

Health Status Indicators

These include Measures of Mortality and Morbidity.

Indicators of Health Care

These include measures of Health Infrastructure; Human Resources in health; Health Finance indicators; and Indicators of accessibility & utilization of health care services.

Indicators of "Quality of Life"

These include such measures as disability days, bed days, limited activity days, days on which activities of daily living

are compromised and days requiring "aids" for walking or such other routine activities of life.

Demographic Indicators

These include measures of fertility and population distribution.

Socio-economic and Human Development Indicators related to Health

These include measures of literacy, income, accessibility to safe water supply and sanitary excreta disposal facilities, etc.

Other Indirect Indicators related to Health

These are measures as nutritional status, child development, environmental indicators, etc.

Summary Measures of Population Health (SMPH)

These summarise, in a single numerical figure the level of health in a large population of country, as HALE, DALY, PYLL, etc.

Measures of Mortality

Measures of mortality in community health practice could be either Crude indicators or standardized indicators, or else Specific indicators. The commonly used ones are :

Crude Mortality Rate : The Crude Mortality Rate, also known as Crude Death Rate (CDR), gives the number of deaths in a defined community in a year per 1000 population in the middle of year (i.e. on 1st July).

$$CDR = \frac{\text{Total deaths in a defined community OR defined area in a year}}{\text{Mid-Year population (01 July) of that community OR defined area}} \times 1000$$

The CDR is useful for making “quick” comparisons regarding death rates between two population groups and for making a quick estimates of load of mortality in a given population. However comparison of CDRs between two populations may differ from each other because of confounding factors (e.g. the observed differences in the CDRs of 2 populations may be because of the different age-structure of the 2 populations). Therefore, “adjustments” for such factors are made by the procedure of “standardization”, to calculate “Standardized Mortality rates”, by statistical methods of Direct or by Indirect Standardization. The methods of direct and indirect standardization are dealt in detail in another chapter in the section on Biostatistics, Secondly, the CDR does not define as to which particular “subgroups” are most affected or what are the important causes of mortality. For this reason, “specific rates” are computed.

Specific Morality Rates : Specific mortality rates provide more meaningful information as compared to CDR, by identifying the “risk of death” in different subgroups or risk of death due to specific diseases. The commonly used specific mortality rates are :

(a) Age Specific Mortality Rates (ASMR) : This is calculated as the No. of deaths in a particular age group in a defined area over a defined time period per 1000 “mid-point” population of that particular age group in that defined area. For example, the ASMR for school age group children (5 to 14 years) in Delhi, in 2007 will be calculated as

$$\text{ASMR} = \frac{\text{Total deaths among children in the age group 5 to 14 Years in Delhi, during 2007}}{\text{Population of children in the age group 5 to 14 Years in Delhi, as on 01 July, 2007}} \times 1000$$

(b) Sex Specific Mortality Rate (SSMR) : This is calculated as the No. of deaths occurring in a particular sex group in a defined area and defined period of time (usually 1 year) per 1000 Mid-point population (usually mid year population) of that particular sex in that area. For example, the SSMR for women in Delhi, in 2007 will be calculated as

$$\text{SSMR} = \frac{\text{Total deaths among women in Delhi, during 2007}}{\text{Population of women in Delhi, as on 01 July 2007}} \times 1000$$

(c) Cause Specific Mortality Rate (CSMR) : The CSMR is calculated as No. of deaths occurring in a defined area due to a particular disease, in a defined period of time (usually 1 year) for every 1000 Mid point (usually mid year) population in the defined area. The CSMR gives the risk of death due to that disease, in the defined population, over the period of interest. It also gives the relative importance of the disease as a cause of mortality in the community. e.g. the CSMR due to pulmonary tuberculosis for a ten year period of 1st January 1991 to 31st December 2000 in entire India would be calculated as

$$\text{CSMR} = \frac{\text{Total deaths due to Pulmonary Tuberculosis, in India during 01 Jan 1991 to 31 Dec 2000}}{\text{Population of India as on 01 Jan 1996}} \times 1000$$

(d) Cross combination of Age, Sex, Cause etc. : Depending on the requirements, further combinations of age, sex, cause, occupation etc. (as relevant) may be made to further enquire and identify special risk groups. For example, we can make the cause specific (Lung CA) death rate in a specific age group (40 to 60 years) and in a specific sex (males) working in a specific occupation (Asbestos industry) in a city (Pune) during 2007 would be calculated as :

$$\frac{\text{No. of deaths due to Lung CA among male asbestos workers, of the age group 40 - 60 Years in Pune during 2007}}{\text{Population of all 40- 60 Years old male asbestos workers in Pune as on 01 Jul 2007}} \times 1000$$

(e) Case Fatality Rate (CFR) : The CFR is calculated as No. of persons, dying due to a particular disease, during a defined time period, in a defined area per 1000 persons in that area, having that particular disease. For example, the CFR due to rabies in Mumbai during the year 2007 would be calculated as:

$$\frac{\text{Total deaths due to Rabies in Mumbai, during 2007}}{\text{Total cases of Rabies in Mumbai during 2007}} \times 1000$$

The CFR does not give the risk of dying due to the given disease which a person in the defined community has or the importance of the disease as a leading cause of mortality in the community at large (that is given by cause specific mortality rate); it rather gives the “killing power” of the disease; e.g. the CFR for Rabies is very high (100%); for acute MI and Japanese encephalitis it is quite high (30-40%) while it is very low for common cold (almost 0%).

(f) Proportionate Mortality ratio (PMR) : This gives the proportion of total deaths that are due to a given cause, out of the total deaths. It is calculated as Total deaths due to the particular disease in a defined area over the given time divided by the total deaths (due to all causes) in that area during that time and multiplying the result by 100 to get it as a %. Thus, PMR for Acute MI in Lucknow during 2007 will be calculated as:

$$\frac{\text{Total deaths due to acute MI in Lucknow District during 2007}}{\text{Total deaths (due to All Causes) in Lucknow District during 2007}} \times 1000$$

Cautions to be Observed while Interpreting the Various Measures of Mortality

While interpreting the various types of measures of mortality, the epidemiologist should be careful about certain “biases” that may occur. Such biases can occur in two ways :

(a) Errors in the numerator : This can occur because of inaccurate or incomplete reporting of the various causes of death in large population groups; e.g. in a developing country, road accident deaths may be diagnosed, recorded and reported more accurately as compared to deaths due to various neoplasms.

(b) Errors in the denominator : This may occur because of inadequate or incorrect enumeration of either the “population”

or the deaths, depending on which one of the two is in the denominator.

Special Mortality Indices used in Maternal and Child Health Care

In maternal and child health care, certain measures of mortality are commonly used, as follows :

(a) Infant Mortality Rate (IMR) : This is calculated as the No. of deaths among children less than 1 year age in a year for every 1000 live births in the same year in the same area. The IMR is one of the most sensitive indicators of the health and socioeconomic conditions of a community, since it is affected by diseases that directly cause infant deaths (Acute Respiratory Infections, Diarrhoeal diseases etc), by the availability and utilization of health care services and by various social factors like income, family size, customs, beliefs etc.

(b) Maternal Mortality Rate (MMR) : It is calculated as the No. of deaths due to “maternal causes” in a given community, in a year per 1000 live births in the same year in the same area. (Maternal death is defined as death occurring to woman, while pregnant or within 42 days of termination of pregnancy, irrespective of the duration and site of pregnancy, from any cause related to or aggravated by pregnancy, but not from accidental or incidental causes). Similarly, the MMR is another very sensitive indicator of the health status of women in the reproductive age group, as well as of the obstetric services. Truly speaking, the MMR is not really a rate, as it is commonly referred to but rather a ratio, since the numerator is not a part of the denominator.

(c) Neonatal Mortality Rate (NMR) : This is calculated as the deaths in a year, in a defined area, among children upto (and including) 28 days age per 1000 live births in the same year in the same area. (Note that in IMR, MMR and NMR, the denominator is the ‘total live births’ and not the mid point population of that particular group). Thus, the component of Infant mortality rate which occurs after neonatal period is also often referred to as “Post-Neonatal Mortality”.

(d) Perinatal Mortality Rate (PMR) : This is defined as the No. of foetal deaths of > 28 weeks gestation plus infant deaths of < 7 days age in a defined area in one year per 1000 “live births plus foetal deaths” of > 28 weeks gestation (i.e. total live and still births) in the same area and in the same year.

The point to be noted is that as overall socioeconomic conditions and health care systems improve, the IMR may decrease quite fast but the NMR, especially PMR, may not decline so fast. This is because most of the causes of “Post-Neonatal Mortality” (i.e. deaths between 1 month to 12 months age) are amenable to good health care in the form of immunization of children, early diagnosis and treatment of acute respiratory infections / diarrhoeal diseases and nutritional care. However, the causes of NMR (and especially PMR) are less amenable to such improvements in health care delivery, being often related to causes like congenital malformations.

It also stands to reasoning that, since MMR, IMR and other indicators are all closely related, if health care is improving, all of them should show decline. A decline in one without a proportionate decline in the others should initiate a search for a possible “disproportionate” development of health services.

For example, a decline in MMR, without a corresponding decline in IMR may be because of much improvement in obstetric care to the community without simultaneous improvement in childhood immunization or early treatment of acute infections among infants.

Measures of Morbidity

While mortality indicators are, by and large, “incidence measures” (since they are nearly always related to some period of time over which the “follow up” has been done), morbidity measures can be either in the form of incidence or prevalence and are calculated as counterparts of “mortality measures”, as Crude Morbidity Rate, Age or cause specific Morbidity, etc. For example, the “annual incidence”, or else the “prevalence” of HIV infection in a community will be worked out as

$$\text{Incidence} = \frac{\text{Total new cases of HIV occurring in a year in a community, out of those initially sero -Negative Total persons who were 'At Risk' of developing HIV at the start of follow up}}{\text{Total persons who were 'At Risk' of developing HIV at the start of follow up}} \times 1000$$

$$\text{Prevalence} = \frac{\text{Total persons in a community found to be having HIV positivity at the time of the survey}}{\text{Total persons in the community who were examined}} \times 1000$$

Interpreting the Various Indicators of Morbidity and Mortality

While interpreting the various morbidity rates (incidence or prevalence) the epidemiologist should again be cautious of the errors that can occur either in the numerator or else in the denominator, as we have already explained in indicators of mortality.

Errors in Numerator may Occur due to the following Important Reasons

Inadequate reporting of the disease : Inadequate reporting of the disease in a particular area or community due to inadequate diagnostic facilities; inadequate training of physicians in recognizing the disease; low index of diagnostic suspicion about the disease since the disease is uncommon in that region; or due to poor coverage by the health care facilities (due to poor facilities, poor accessibility, adverse behaviour of health care providers, etc), leading to a section of the population not being covered by the health workers or by the reporting hospital. It may also occur because for certain particular diseases, the community may be seeking care from the practitioners of Indigenous systems of medicine and hence the disease may not be completely reported; or else due to possible stigmas related to the disease and hence either the physicians may not report the disease or the persons may not come forward to get themselves tested.

Over-reporting of the disease : Over-reporting of the disease in a particular area or community because of very fine diagnostic facilities or the particular health care facility may be specializing in that disease; due to vague case definitions so that many other diseases may be included (as “viral fever”

may actually include a number of cases of malaria, dengue, etc); or because the disease has been newly discovered or has re-appeared in that area after a long time (as plague) and hence medical personnel are over-enthusiastic about the disease.

Cross-reporting of the disease : Cross-reporting of the disease in a particular area or community; for example, some of the patients with that particular disease may actually report and seek treatment from a health centre of another district and hence will be reflected in the other district while the population base from where they come, will be taken in the numerator of their parent district.

Changes in diagnostic criteria : Changes in diagnostic criteria over time, due to Changes in International Classification of Diseases (ICD) criteria or changes in the diagnostic criteria or case definition of the disease, by expert bodies, over time; or else due to availability of better diagnostic facilities over time, even in the same community or nation.

Similarly, errors in denominator may occur because of :

- Inadequate enumeration of total population, as in countries with inadequate census facilities.
- The enumeration of total population may suddenly improve and hence it may be erroneous to compare the current rates with previous rates.

Once the epidemiologist has undertaken a logical reasoning about the apparent mortality or morbidity rates and has satisfied herself that there are no errors in the numerator or denominator, then only she should proceed to analyse as to why the disease is posing a health problem and how best can we tackle it.

Measures of Fertility

Epidemiologic measures of fertility are extensively used in fields of demography, family planning and health administration. The selected indices are :

Crude Birth Rate : It is calculated as number of live births in an area during one year per 1000 mid year population. The CBR has the advantage of ease of compilation. However, the denominator in CBR is total population; on the other hand, the real contribution to the births in a population comes from the females in the reproductive age group (15 to 44 years age). This deficit of CBR is overcome in General Fertility Rate (GFR).

General Fertility Rate (GFR) : It is defined as Number of live births in a given area during a year per 1000 mid year population of females in the reproductive age groups (15 to 44 years) in that area, during that year.

While GFR is definitely an improvement over CBR, comparisons

between two populations based on GFR may not be accurate because the populations structure of ladies within the category of 15 to 45 years age may be quite different between the two population (for example, one population may have much higher proportion of females aged 15 to 30 years, while the other population may have higher proportion of females aged 30 to 45 years). Secondly, the GFR does not allow for identifying the “high risk” age group of females, as far as conception is concerned, so that family planning activities can be directed towards such high risk groups. This difficulty is overcome by computing the Age Specific Fertility Rates (ASFR).

ASFR : It helps in identifying the age groups of women having the highest reproductive potential, so that family planning measures can be directed towards such groups. It is calculated as Number of live births to women in a specified age group (e.g. 20 to 25 years age group) in a given area and in a given year per 1000 mid year population of females in the same age group (e.g. 20 to 25 years) in that area during that year.

Total Fertility Rate (TFR) : This gives the estimated number of children which a group of 1000 women would bear, if they were to start their reproductive life at a common point of life and were to pass through their entire reproductive span, subject to the current age-specific fertility rates. This measure is calculated by summing up the ASFRs for the different age groups and multiplying such sum by the class - interval on which the age groups have been formed; e.g. if we have made the age groups as 15-19, 20-24 years and so on (thus the class interval being 5 years), the ASFRs would be summed up and multiplied by 5 to get the TFR. The TFR is quite an accurate epidemiological measure of fertility and provides valid answer to the issue “How many children would a woman have, on an average?” (or, in case the ASFR have been calculated as “per 1000”, it will tell us how many children 1000 women are likely to have).

Gross Reproductive Rate (GRR) : This is a measure of the average number of female live births that would occur to a female new born, growing up and passing her entire reproductive age, if the current fertility rate were to apply. The GFR assumes that these women will not die before completing their childbearing age, which is more of a hypothetical assumption and this drawback is overcome through compilation of Net Reproductive Rate (NRR). The GRR is thus equivalent to TFR for female children only.

Net Reproductive Rate (NRR) : The NRR is a measure of the average number of female live births that will occur to a newborn female as she grows up and passes through her

Table - 1 : Calculation of the Human development indices

Index	Measure	Minimum value	Maximum value	Formula
Longevity	Life expectancy at birth (LE)	25 yrs	85 yrs	$L = \frac{LE-25}{60}$
Education	Literacy rate (LR)	0%	100%	$E = \frac{2LR + CGER}{3}$
	Combined gross enrollment ratio (CGER)	0%	100%	
GDP	GDP per capita (PPP)	100 US Dollars	40,000 US Dollars	$E = \frac{\log_{10} GDPpc - 2}{2.60206}$

entire reproductive age group, provided she was subjected to the current rates of fertility as well as mortality. Thus, the NRR is similar to GRR, but, in addition, also caters to the fact that some women will die before completing the child bearing age, while making the calculations. The NRR is a sensitive indicator of population growth. If the NRR is 1.00, it indicates that each generation of mothers is being replaced by an exactly equal number of daughters; in other words, the female population is “maintaining itself”. India, as well as a large number of other developing countries have kept a target of achieving a NRR equal to 1.00, as a part of their family welfare programmes.

Population Growth Rate : This is also known as the natural rate of population increase. It is calculated as the difference between CBR and CDR. For example, if the CBR in a country is 21 per 1000 while the CDR is 9, the population growth rate would be 12 per 1000 or 1.2%.

Dependency Ratio : The dependency ratio is calculated as the ratio between (Population < 20 years age + population > 65 years) divided by the population in the age groups 20 to 64 years. Higher the dependency ratio, lower is the productive work-force in that community or country. Ideally, this ratio should be 1.00 or lesser.

Indicators related to “Health Services”

These are indicators which either measure the “availability” (as, Doctor - Population ratio, Population served by each Health centre, Population - hospital bed ratio); or, “expenditure on health care” (as, percentage of national budget earmarked for health sector, Average finances spent per person on health care); or, “health coverage” (e.g. percentage of children fully immunized, deliveries conducted by trained birth attendants, % of cases of pulmonary TB brought under ATT, % of houses that were adequately sprayed with an insecticide, etc.); or “accessibility” (e.g. Mean distance in Kms required to be traveled in a village to reach the health centre); or, “utilization” (e.g. % of women who availed of cervical cancer screening camp out of those who were eligible); or, finally, the “policy” (e.g. availability of a stated health policy and enunciated targets).

These indicators are discussed in more detail in the section on health management.

Socio-Economic Indicators

As has been explained in the opening chapters of this book, health is the result of a complex interplay between the human beings and their environment, including the various array of socio-economic factors. Hence, in the process of measuring the health of a community, the epidemiologist cannot do without various socio-economic indicators. The major indicators as relevant to health care are :

Life Expectancy : Life expectancy at birth is a commonly used summary measure of the health status of a population. It is defined as the average number of years in a population (or a nation) that an individual is expected to live from birth onwards, if the current mortality rates continue. Another variant is “life expectancy at 1 year age”. Life expectancy at birth, 1 year age or at any other age is calculated through “life tables”, the discussion on which is made in another chapter. Comparisons based on life expectancy may be made between two countries or else may be made for different periods of time for the same country.

Indicators of overall development : The Human Development Index (HDI) is an index combining normalized measures of life expectancy, literacy, educational attainment and GDP per capita for countries, worldwide. It is claimed as a standard means of measuring human development, according to the United Nations Development Program (UNDP). The HDI combines three basic dimensions, viz. Life expectancy at birth, as an index of population health and longevity; secondly, Knowledge and education, as measured by the adult literacy rate (with two-thirds weighting) and the combined primary, secondary and tertiary gross enrollment ratio (with one-third weighting) and, thirdly, the standard of living, as measured by the natural logarithm of Gross Domestic Product (GDP) per capita at Purchasing Power Parity (PPP) in US Dollars. The Human Development Index (HDI) thus represents the average of these

Table - 2 : Road traffic accidents (RTAs)

Age Group (years)	Mid point of the age group	Population	Deaths due to RTA in one year	YPLL (65 minus mid point of age)	Age specific YPLL (Coln 4X Coln 5)
(1)	(2)	(3)	(4)	(5)	(6)
0-4	2.5	18252000	1190	62.5	74375
5-14	10	34146000	2397	55	131835
15-24	20	38252000	14447	45	650115
25-34	30	43315000	10467	35	366345
35-44	40	34305000	5938	25	148450
45-54	50	23276000	3576	15	53640
55-64	60	22019000	3445	5	17225
65-74	70	17668000	3277	Not applicable	Not applicable
75-84	80	9301000	2726	Not applicable	Not applicable
>=85	90	2867000	778	Not applicable	Not applicable
Total		213565000	41460		1441985

three general indices as shown in Table 1.

The HDI is finally calculated as $(L + E + G) / 3$. An index of below 0.5 indicates poor development, while an index of 0.8 and above indicates good development of a country. Reviews in 2007 indicate that India, with an Index of approximately 0.6 is progressing but has still a long way to go. Countries like Norway, Canada and Japan have been often taking the first place.

Percentage of Population Living below Poverty Line : This is another very commonly used index of overall standard of living and economic status of a country. Poverty line actually means inability to buy adequate food calories which is equivalent of 2400 Kcal per day in rural and 2100 Kcal per day in urban areas. It is also taken as equivalent of a family income of less than Rs. 1,500/= per month. In India, about one-fourth (26.1%) of the population is still living below poverty line.

As per the Government of India, poverty line for the urban areas is Rs. 296 per month and for rural areas Rs. 276 per month. As per GOI, this amount will buy food equivalent to 2400 Calories per day. This actually translates to Rs. 3552 and Rs. 3312 per capita per year for urban and rural areas respectively. According to the Planning commission, the poverty line for all India is rural Rs. 356.30 and urban Rs. 538.60 per capita per month. However, these levels are for overall all India guidelines; individual states have different levels. The World Bank's definition of the poverty line, for underdeveloped countries like India, is US\$ 1/day/person or US\$ 365 / year/ Person. As per this definition, more than 75% of all Indians are below the poverty line.

Percentage of population in different socio-economic classes: Various scales of measuring socio-economic status are being used in public health care. The commonly used ones in India are the Prasad's Modified Scale and the Kuppuswamy's scale, which takes into consideration the combined effect of Income, Education and Occupation. Details are given in the section of sociology.

Indicators of educational Levels : The simplest and widely used indicators in public health work are the "Adult Literacy rate" and the "School Enrolment rate".

Indicators of "Empowerment of Women" : Percentage of women employed in industry, or executive jobs and in government jobs and the Adult literacy rate among women/ School enrolment rate among girls are used as surrogate indicators of empowerment of women in a society.

Summary Measures of Population Health (SMPH) : An Emerging Concept in Public Health Practice

Regular assessment of population health is a key component of public health policy development. So far we have seen indicators of morbidity, mortality and health states. These are useful for planning, evaluating, etc. However, if these different indicators are to be used for making comparisons of health status between 200 countries, a vast array of indicators would need to be generated and their interpretation would become extremely challenging. It would become even more unwieldy if a large number of diseases are being compared over time, across population groups, or else before and after some intervention.

Therefore some indicator is needed, which can combine information of mortality as well as non-fatal outcomes, so as to measure the population health level in a single number. Such "summary figures" are called as "Summary Measures of Population Health" (SMPH). SMPH do not replace the more detailed reporting of data on specific aspects of health and disease (discussed so far). They supplement this data with more comprehensive indicators that can be used to monitor trends and make wider comparisons. The important uses of SMPH are :

- To make comparisons of the average health levels in different population subgroups or in the same population over time.
- Assessment of the relative contribution of two different diseases, injuries or risk factors, to overall population health.
- Identifying and quantifying overall health inequalities within a population, thus identifying the "at risk" or vulnerable groups, needing greater services.
- Provide inputs for short-listing of national health priorities for national health planning.

Types of SMPH

Broadly, there are two categories of SMPH

a) Summary Measures of Health "Expectancies" : The common ones are Healthy Life Expectancy (HALE), Active Life Expectancy (ALE), Disability Free Life Expectancy (DFLE) and Quality Adjusted Life Expectancy (QALE).

b) Summary Measures of Health "Gaps" : The commonly used are Years of Potential Life Lost (YPLL) and Disability Adjusted Life Years (DALY).

A detailed description of some of the important SMPH us as follows :

Years of Potential Life Lost (YPLL) : This is defined as the years of potential life lost due to premature death. In contrast to other mortality measures, YPLL emphasizes the processes underlying premature mortality in a population. By this method, deaths occurring at younger ages accrue more years of life lost than deaths at later ages.

An illustration is given in Table-2 below which shows the hypothetical details of deaths due to Road Traffic Accidents (RTAs).

The last 3 age groups have been shown as strike-through, since they have not been used in analysis; as the analysis in YPLL only involves age groups upto 65 years. From Table-2, the YPLL due to road traffic accidents, for this population are 14,41,985 years. To calculate the YPLL rate per 1000 this formula can be used :

$$\text{YPLL Rate (Per 1000)} = \frac{\text{YPLL}}{\text{Population under age of 65 years}} \times 1000$$

Here, it can be calculated as $(1441985 \times 1000) / 213565000 = 6.8$ YPLL per 1000 population below the age of 65 years.

Disability Adjusted Life Year (DALYs) : This is a health gap measure that extends the concept of "Potential Years of Life Lost" (PYLL) due to premature death, It also includes equivalent

“Years of Life Lost due to Disability” (YLD) by virtue of being in states of poor health. The DALY combines, in one measure, the time lived with disability and the time lost due to premature mortality. One DALY can be thought of as one lost year of ‘healthy’ life and the burden of disease as a measurement of the gap between current health status and an ideal situation where everyone lives into old age free of disease and disability. Thus, DALY = YLL + YLD.

Physical Quality of Life Index (PQLI) : This index combines three measures into a single indicator. These are Literacy status, Infant Mortality rate (IMR) and Expectation of life at 1 year of age. Each of the three components is marked on a scale of 0 (absolutely hopeless state) to 100 (absolutely best state). An average of the 3 components, with equal weight to each is calculated, which again would range from 0 to 100. PQLI has been often used in making international comparisons.

Sullivan's Indicator : Sullivan's indicator is a health state measure of a group of persons which is independent of its age structure. It offers a possibility to compare health states of the entire population between two dates in spite of a modification of its age composition (provided that the sizes of the age groups are not too large). The comparability is also increased by the calculation of this indicator separately for males and females.

Some Facts & Figures for India in respect of Important Measures of Health

The current levels and our targets to be achieved in national context, in respect of some important measures of morbidity,

mortality, fertility and health care are given in Table - 3.

Summary

During epidemiological and medical research studies, a large amount of data is collected in respect of various variables, for a large number of subjects who have been studied in the study. To make sensible interpretations from this large collection of data, it has to be reduced to certain summary figures, namely, means, or medians or proportions, which facilitates quick understanding of the magnitude of the problem as well as in making comparisons. Most often, these summary figures are either the incidence or else the prevalence of the condition of interest in the study.

In actual epidemiological practice, there are various types of diseases and other outcomes which are to be studied. Hence, these incidence and prevalence measures are actually worked out in the form of “indicators” which summarise the health status of the population. These indicators of health and disease are of the following categories :

Health Status Indicators include various measures of mortality and morbidity. Mortality indicators include crude death rates, specific death rates and standardized death rates. Important specific death rate indicators are age and sex specific death rates, cause specific death rates, case fatality rate and proportional mortality ratio. Special indicators of mortality pertaining to maternal and child health care are Infant Mortality rate and Maternal Mortality rate. Morbidity indicators are broadly either incidence rates or else prevalences of specific

Table - 3 : Some facts & Figures for India in Respect of Important Measures of Health

Health Indicators in Indian Context	Current (Figures)	Goals
Crude Birth Rate (CBR)	24.1 (SRS, 2004)	21 (NPP- 2010)
Crude Death Rate (CDR)	7.5 (SRS, 2004)	9 (NPP- 2010)
Total Fertility Rate (TFR)	2.7 (NFHS-3, 2006)	2.1 (NPP- 2010)
Net Reproductive Rate (NRR)	1.5 (1990)	1 (NPP- 2010)
Couple Protection Rate (CPR)	56.3 (NFHS-3, 2006)	60 (NPP- 2010)
Infant Mortality Rate (IMR)	57 (NFHS-3, 2006)	<30 (NPP- 2010)
Under five Mortality	74 (UNICEF, 2005)	41 MDG (2015)
Neonatal Mortality Rate	43 (WHO Report, 2005)	----
Maternal Mortality Ratio (MMR)	3.01 (SRS, 2003)	<1 (NPP- 2010)
Institutional Deliveries	40.7% (NFHS-3, 2006)	80% (NPP- 2010)
Delivery by Trained personnel	48.3% (NFHS-3, 2006)	100% (NPP- 2010)
Tuberculosis Mortality (per lakh)	30 (WHO Report, 2006)	----
Children 12-23 months fully immunized	43.5 (NFHS-3, 2006)	100% (NPP- 2010)
Children 12-23 months who have received BCG (%)	78.2 (NFHS-3, 2006)	100% (NPP- 2010)
Children 12-23 months who have received 3 doses of polio vaccine (%)	78.2 (NFHS-3, 2006)	100% (NPP- 2010)
Children 12-23 months who have received 3 doses of DPT vaccine (%)	55.3 (NFHS-3, 2006)	100% (NPP- 2010)
Children 12-23 months who have received measles vaccine (%)	58.8 (NFHS-3, 2006)	100% (NPP- 2010)

(NFHS : National Family Health Survey; NHP : National Health Policy; NPP : National Population Project; SRS : Sample Registration Scheme; MDG : Millennium Development Goals)

diseases. Indicators of health care includes the measures of Health Infrastructure; Human Resources in health; Health Finance indicators; and Indicators of accessibility & utilization of health care services. Indicators of "Quality of Life" include such measures as disability days, bed days, limited activity days, days on which activities of daily living are compromised and days requiring "aids" for walking or such other routine activities of life. Demographic Indicators include measures of fertility and population distribution, as crude birth rate, General fertility rate, Age Specific fertility rate, Total fertility rate, gross reproduction rate and Net reproduction rate. Socio-economic and Human Development indicators related to health include measures of literacy, income, accessibility to safe water supply and sanitary excreta disposal facilities, etc. Other Indirect Indicators related to health are nutritional status, child development, environmental indicators, etc. Summary Measures of Population Health (SMPH) summarise, in a single numerical figure the level of health in a large population of country, as HALE, DALY, PYLL, etc.

Study Exercises

Long Question : Classify the various measures of health of a population in public health work. Discuss the merits and demerits of the various measures of mortality.

Short Notes : (1) Potential errors in interpretation of indicators of morbidity (2) Human development index (3) Maternal Mortality rate (4) Goals and present situation regarding important indicators of fertility and demography in the Indian context (5) SMPH

MCQs & Exercises

1. Calculate the HDI for a hypothetical nation having average expectancy of life at birth as 65 years, Adult literacy rate of 55%, Combined gross enrolment ratio of 60% and with a GDP of 2000 US dollars per capita per year. (\log_{10} 2000 is 3.301).
2. In a community development block area with population of one lac, there were 500 cases of TB and 5 cases of rabies during 2006. During the same year there were a total of 250 deaths, out of which 5 were due to rabies and 50 due to TB. Calculate the CDR. Also calculate, separately for TB and rabies, the cause-specific mortality rate (CSMR), CFR and PMR.
3. In a township with population of 1 lac, the following are the statistics for the year 2007. From the table, calculate the CBR, GFR, ASFRs for the 6 age groups, TFR and GRR (all rates to be calculated per 1000).

Age Group	Mid-year population of females	Births in the year	
		Total Live Births	Total female live births
15-19	5000	400	192
20-24	5000	700	347
25-29	4000	700	331
30-34	4000	500	240
35-39	4000	400	189
40-44	3000	300	151
Total	25000	3000	1450

4. In a state during 2007, approximately 10% of all deaths in age group 0 to 14 years were due to accidents and injuries, while in the age group 15 to 35 years, 20% of all deaths were due to accidents and injuries. How many times is the risk of dying due to accidents and injuries among 15 to 35 years as compared to 0 - 14 years? (a) 2 (b) 0.5 (c) 1 (d) 4 (e) cannot be concluded from the data.
5. If, in the computation of GFR, women who have undergone hysterectomy are not considered, the GFR will : (a) Increase (b) Decrease (c) will not be affected (d) None.
6. The population of District 'X' as on 01 July 2006 was 2 lac. As pr the Dist. TB control programme register, there were 186 active cases of Pulmonary TB on this date, while 12 new cases of active pulm TB occurred between 1st January to 30th June 2006. With the above information, answer the following (a) The incidence rate of active pulm TB for the six month period was (i) 6 per 100,000 (ii) 12 per 100,000 (iii) 0.60 per 1000 (iv) cannot be calculated (b) The prevalence of active pulm TB as on 01 July 2006 was : (i) 372 per lac (ii) 93 per lac (iii) 0.93 per 1000 (iv) None.
7. Lung cancer is a highly fatal disease and patients die in a very short duration after onset of disease. Which of the following statements is correct for this disease : (a) Incidence and mortality rates will be almost similar in a year (b) Mortality rates will be higher than incidence rate (c) Incidence rates will be higher (d) There will be no relation between the two.

Answers : (1) HDI = 0.578 (L = 0.667, E = 0.567, G = 0.50). (2) CDR = 2.5 per 1000; CSMR : TB - 0.5 / 1000, rabies - 0.05 / 1000; CFR : TB - 10%, rabies 100%; PMR : TB - 20%, rabies 2%. (3) CBR = 30; GFR = 120; ASFRs respectively 80, 140, 175, 125, 100, 100; TFR 3600 (or 3.6 per woman); GRR 1740.65 (or, 1.7 per woman). (4) The correct answer is (e). The % of deaths are actually PMRs (proportional mortality ratios) for the two age groups. The PMR gives up the proportion of deaths that are due to a given cause out of the total deaths but does not give us the risk of dying due to that disease. The risk of death due to accidents and injuries in a particular age group would be given by the age and cause specific mortality rate (5) (a) (because the denominator will decrease due to removal of women having hysterectomy, but the numerator will not change since these women do not contribute to child births). (6) (a) : (i); 6 (b) : (ii) and (iii) both are correct; (7) a.

Vijay K. Bhatti

We may define classification of diseases as a system of categories to which morbid entities can be assigned in accordance with certain established criteria. In epidemiological practice, a basic requirement is to identify the disease. The simplest way is to develop “case definitions”. However, there will be a need to standardize the case definitions, do as to bring about uniformity, while making comparisons between two different places or over periods of time, as regards differences in disease frequency. To ensure such standardization, it is necessary that a system of disease classification be worked out so that each and every disease can be allocated a particular “code”, which should be followed by all health care persons / institutions all over the world.

One of the most standard and time tested means to obtain this end is through the International Statistical Classification of Diseases and Related Health Problems, commonly known by the abbreviation ICD (International Classification of Diseases). ICD is a part of the WHO Family of International Classifications (WHO-FIC).

The ICD is used to classify diseases and other health problems recorded on many types of health and vital records including death certificates and health records. In addition to enabling the storage and retrieval of diagnostic information for clinical, epidemiological and quality purposes, these records also provide the basis for the compilation of national mortality and morbidity statistics by WHO Member States. ICD is published by the World Health Organisation. It assigns a unique category and a code upto six digit characters long to classify diseases and a wide variety of signs, symptoms, abnormal findings, complaints, social circumstances and external causes of injury or disease. Every health condition can be assigned to a unique category & given a code, up to six characters long. ICD is revised periodically and is currently in its tenth edition i.e. ICD-10.

Historical Evolution of ICD

François Bossier de Lacroix (1706-1777), better known as Sauvages, is credited with the first attempt to classify diseases systematically. His comprehensive treatise was published under the title *Nosologia methodica*. At the beginning of the 19th century, the classification of disease in most general use was one by William Cullen (1710-1790), of Edinburgh, which was published in 1785 under the title *Synopsis nosologiae methodicae*.

For all practical purposes, however, the statistical study of disease began with the work of John Graunt on the London Bills of Mortality. He attempted to estimate the proportion of liveborn children who died before reaching the age of six years, no records of age at death being available. He took all deaths classed as thrush, convulsions, rickets, teeth and worms, abortives, chryosomes, infants, livergrown and overlaid and added to them half the deaths classed as smallpox, swinepox, measles and worms without convulsions. Despite the crudity of this classification his estimate of a 36 % mortality before the

age of six years appears from later evidence to have been a good one. In 1837, the General Register Office of England and Wales, William Farr (1807-1883) laboured to perfect classifications of disease available at the time and tried to secure better classifications and international uniformity in their use.

The International Statistical Institute, in Vienna in 1891, constituted a committee, chaired by French man Jacques Bertillon (1851-1922), with the preparation of a classification of causes of death. The report of this committee was presented by Bertillon at the meeting of the International Statistical Institute in Chicago in 1893 and adopted by it. In 1898, the American Public Health Association (APHA) recommended that the registrars of Canada, Mexico and the United States also adopt it. The APHA also recommended revising the system every ten years to ensure the system remained current with medical practice advances.

The French Government therefore convoked in Paris, in August 1900, the first International Conference for the Revision of the Bertillon or International List of Causes of Death. Delegates from 26 countries attended this Conference. A detailed classification of causes of death consisting of 179 groups and an abridged classification of 35 groups were adopted on 21 August 1900. The desirability of decennial revisions was recognized and the French Government was requested to call the next meeting in 1910. Similar subsequently revisions occurred every 10 years to reach the current version of ICD 10. The revisions that followed contained minor changes, until the sixth revision of the classification system. With the sixth revision, the classification system expanded to two volumes. The sixth revision included morbidity and mortality conditions and its title was modified to reflect the changes : Manual of International Statistical Classification of Diseases, Injuries and Causes of Death (ICD). Prior to the sixth revision, responsibility for ICD revisions fell to the Mixed Commission, a group composed of representatives from the International Statistical Institute and the Health Organization of the League of Nations. In 1948, the World health Organisation (WHO) assumed responsibility for preparing and publishing the revisions to the ICD every ten years. Only the time lag between ICD 9 (promulgated in 1979) and 10 (promulgated in 1999) was 20 years.

Types of WHO - FIC Classifications

The WHO-FIC is comprised of three types of classifications, the Reference Classifications, the Derived Classifications and the Related Classifications.

1. Reference Classifications : These are the main classifications on basic parameters of health. They are categorized into three heads :

- (a) International Classification of Diseases (ICD)
- (b) International Classification of Functioning, Disability and Health (ICF)
- (c) International Classification of Health Interventions (ICHI)

2. Derived classifications : Derived classifications are based on the reference classifications (i.e. ICD and ICF). Derived classifications are prepared either by adopting the reference classification structure and categories, providing additional detail beyond that provided by the reference classification or they may be prepared through rearrangement or aggregation

of items from one or more reference classifications. Derived classifications in the WHO-FIC are :

- (a) International Classification of Diseases for Oncology, Third Edition (ICD-O-3)
- (b) The ICD-10 Classification of Mental and Behavioural Disorders
- (c) Application of the ICD to Dentistry and Stomatology, Third Edition (ICD-DA)
- (d) Application of the ICD to Neurology (ICD-10-NA)
- (e) ICF Version for Children and Youth (ICF-CY)

3. Related Classifications : Related classifications are those that partially refer to reference classifications, or are associated with the reference classification at specific levels of structure only. Related classifications in the WHO-FIC are :

- (a) International Classification of Primary Care (ICPC)
- (b) International Classification of External Causes of Injury (ICECI)
- (c) The Anatomical, Therapeutic, Chemical (ATC) classification system with Defined Daily Doses (DDD)
- (d) Technical aids for persons with disabilities : Classification and terminology (ISO 9999)

Basic Structure and Principles of Classification of the ICD

The structure of present day ICD has developed out of the one proposed by William Farr. William Farr had proposed that for all practical purposes statistical data on diseases should be grouped in the following way :

- (a) Epidemic diseases
- (b) Constitutional diseases or general diseases
- (c) Local diseases arranged by site
- (d) Developmental diseases
- (e) Injuries

This is the pattern that is seen in ICD-10. The basic ICD is a single coded list of three - character categories, each one of which can be further subdivided into up to ten four character subcategories. In place of the purely previous numeric coding system the tenth revision uses an alphanumeric code with a letter in the first position and a number in the second, third and fourth positions. The fourth character follows a decimal point. Possible code numbers therefore range from A00.0 to Z99.9. The letter 'U' is not used.

Organisation of ICD-10

It consists of three volumes. Volume 1 contains the main classifications; volume two provides the guidance to the use of ICD; and volume three is the alphabetical list to the classification. Most of volume 1 has the main classification consisting of the three character categories and the tabular list of inclusions and four letter sub categories. The "core" classification - list of three character categories in volume 1 is the mandatory level for reporting to the WHO mortality database and for general international comparisons. The tabular list is the one which gives the full details of the four character level and is divided into 21 chapters. Volume 1 also contains the following -

- (a) Morphology of neoplasm
- (b) Special tabulation lists - 4 such lists are present in the Volume 1, list 1 and 2 are on general mortality and lists 3 and 4 are for infant and child mortality (0-4yrs)

- (c) Definitions
- (d) Nomenclature regulations

Chapters

The classification is divided into 21 chapters, the first character of the ICD code is a letter and each letter is associated with a particular chapter except for the letter D and H. Letter D is used in chapter II (Neoplasms) and chapter III (diseases of the blood and blood forming organs and certain disorders involving the immune mechanism). The letter H is used in both chapter VII (diseases of the eye and adnexa) and chapter VIII (diseases of the ear and mastoid process). Four chapters (I, II, XIX and XX) use more than one letter in the first position of their codes.

Not all codes in a chapter are used - some are left blank for future revision and expansion. Chapters I to XVII relate to diseases and other morbid conditions. Chapter XIX deals with injuries, poisoning and certain other consequences of external causes. Chapter XVIII contains symptoms, signs and abnormal clinical and lab findings not classified elsewhere. Chapter XX covers external causes for morbidity and mortality. Chapter XXI covers the factors influencing health status and contact with health services.

Block Categories

Each chapter is divided into homogenous blocks of three character categories. The range of categories is given parentheses after each block title.

Three -Character categories : In each block some of the three character categories are for single conditions while other are for groups of diseases with some common characteristics.

Four - character subcategories : Most of the three character categories are subdivided by means of a fourth numeric character after a decimal point, allowing upto 10 subcategories. Where a three character category is not subdivided it is recommended to use letter "X" at the fourth place so that codes are of standard length for data processing. The four character subcategory is usually used in whatever way is most appropriate, identifying, for example, different sites or varieties if the three category code is for a single disease, or for individual diseases if the three character category is for a group of diseases.

Supplementary subdivisions for use at the fifth or subsequent character level : The fifth and subsequent character levels are usually sub-classifications along a different axis from the fourth character. They are found in Chapter XIII (sub divisions by anatomical site), Chapter XIX (subdivisions to indicate open and closed fractures as well as intra-cranial, intra-thoracic and intra-abdominal injuries with and without open injuries) and chapter XX (subdivisions to indicate the type of activity being undertaken at the time of the event).

The unused "U" codes : The codes U00-U49 are to be used for the provisional assignment of new diseases of uncertain aetiology. Codes U50-U99 may be used in research, e.g. when testing an alternative sub classification for a special project.

International Classification of Functioning, Disability and Health (ICF - 2001) : It belongs to a family of classifications developed by the WHO for applications in various aspects of health care. In WHO's family of international classifications, health conditions are classified mainly in ICD - 10, which

basically provides an etiological framework. On the other hand, ICF aims to provide a unified and standard language and framework for the description of health and health related states. The health states associated with diseases, disorders or other health conditions are classified in ICF. The ICD - 10 and ICF are therefore complementary. ICD - 10 provides a “diagnosis” and this information is enriched by the additional information given by ICF. Together, information on diagnosis and functioning provides a broader and more meaningful picture that describes the health of individuals or populations. ICF - 2001 has moved away from its earlier version, namely the International Classification of Impairments, Disabilities and Handicaps (ICIDH - 1980) to a “components of health” classification. ICF organises the information in 3 components:

- The Body Construct comprises two classifications, one for functions of the body system (physiology and psychology, as vision) and one for body structure (anatomy, as eyes). The chapters of both these classifications are organised as per body systems.
- The Activities and Participation Constructs cover the complete range of domains denoting aspects of functioning from both an individual and societal perspective. These are listed in a single common list, which covers the full range of life areas (as basic learning and watching to more composite ones as social tasks). Each of these two domains are qualified by two basic qualifiers, viz, performance and capacity.
- A list of Environmental factors also forms part of the classification. Environmental factors have an impact on all the three construct and are organised from the individual’s most immediate environment to the general environment.

The ICF codes are only complete by the presence of at least one qualifier which denotes the magnitude of the level of health (e.g. severity of the problem) either in terms of “performance” or “capacity”. Qualifiers are coded as one or two numbers after a decimal point. Use of any code should be accompanied by at least one qualifier. Without qualifiers, codes have no meaning.

Summary

ICD is a commonly used abbreviation for International Statistical Classification of Diseases and Related Health Problems. ICD is published by the World Health Organisation. The ICD is used world-wide for morbidity and mortality statistics, reimbursement systems and automated decision support in medicine. This system is designed to promote international comparability in the collection, processing, classification and presentation of these statistics. William Farr had proposed that for all practical purposes in ICD statistical data on diseases should be grouped into Epidemic diseases, Constitutional diseases or general diseases, Local diseases arranged by site, Developmental diseases and Injuries.

The ICD is a core classification of the WHO Family of International Classifications (WHO-FIC). ICD assigns a unique category and a code to classify diseases and a wide variety of signs, symptoms,

abnormal findings, complaints, social circumstances and external causes of injury or disease. ICD 10 is contained in three volumes. Volume 1 contains the main classifications; volume two provides the guidance to the use of ICD; and volume three is the alphabetical list to the classification. The basic ICD is a single coded list of three -character categories, each one of which can be further subdivided into up to ten four character subcategories. In place of the purely previous numeric coding system the tenth revision uses an alphanumeric code with a letter in the first position and a number in the second, third and fourth positions. The fourth character follows a decimal point. Possible code numbers therefore range from A00.0 to Z99.9. U codes are left unused for use for provisional new diseases and research.

International Classification of Functioning, Disability and Health (ICF - 2001) belongs to a family of classifications developed by the WHO for applications in various aspects of health care. ICF aims to provide a unified and standard language and framework for the description of health and health related states. The health states associated with diseases, disorders or other health conditions are classified in ICF. The ICD - 10 and ICF are therefore complementary.

Study Exercises

Short Notes : (1) Basic structure and principles of classification of the ICD (2) International Classification of Functioning, Disability and Health.

MCQs

- 1) The structure of present day ICD has developed out of the one proposed by (a) John Gruant (b) William Farr (c) Langmuir (d) John Last
- 2) The number of characters in main categories of the basic ICD is (a) Three (b) Four (c) Five (d) Six
- 3) The number of volumes in ICD-10 (a) 2 (b) 3 (c) 4 (d) 5
- 4) In ICD-10, the letter which is not used for coding is (a) i (b) u (c) x (d) o
- 5) In 1948, the World health Organisation (WHO) assumed responsibility for preparing and publishing the revisions to the ICD every (a) 10 years (b) 9 (c) 20 (d) 15
- 6) The time lag between ICD 9 (promulgated in 1979) and 10 (promulgated in 1999) was (a) 10 years (b) 9 (c) 20 (d) 15

Answers : (1) b; (2) a; (3) b; (4) b; (5) a; (6) c

Leo S. Vaz, Sunil Agrawal & RajVir Bhalwar

Universal health care is the provision of health care at all levels and available to all members of the community. The well-off, both in relatively wealthy industrialized countries and in the poorer developing world, may be able to get health care including clinical services from sources they prefer and can pay for in the private sector. The vast majority of people in most countries, however, are dependent in various ways upon health services provided by the state, to which they may contribute comparatively little or, in the case of poor countries, nothing at all.

Health for all

In developed countries the rate of infectious diseases decreased through the 20th century largely due to broad public access to water and sewage systems, sanitation, immunizations and economic prosperity. Public health then began to put more focus on chronic diseases such as cancer and heart disease. However, in developing countries people remain plagued by largely preventable infectious diseases, exacerbated by malnutrition and poverty. More than a billion people lack access to clean drinking water and over 2.4 billion lack access to proper sanitary facilities. There are more people in the world's hospitals today suffering from water-borne diseases than any other ailment. Poor nutrition contributes to 1 out of 2 deaths (53%) associated with infectious diseases among children under the age of five in developing countries. Under-nutrition among pregnant women in developing countries leads to 1 out of 6 infants born with low birth weight. Keeping this in view, the WHO propounded a new theory for providing the basic minimal health facilities to the maximum populace.

WHO Declaration of Alma-Ata

In 1977, the Director General of WHO called for a new strategy, acknowledging that although the health care strategies of the industrialized world—that of big hospitals, drugs and curative medicine—had been exported to developing countries for thirty years, the health of the world had not improved. The International Conference on Primary Health Care was convened in Alma-Ata, Kazakhstan, in 1978 and was attended by virtually all the member nations of the World Health Organization (WHO) and UNICEF. 134 governments ratified the WHO Declaration of Alma-Ata, asserting that :

- (a) Health for all could be achieved by 2000.
- (b) Governments have a responsibility for the health of their people that can be fulfilled only by the provision of adequate health and social measures.
- (c) Primary health care is the key to attaining a level of health that will permit their citizens to lead a socially and economically productive life.

The Alma-Ata Declaration of 1978 emerged as a major

milestone of the twentieth century in the field of public health and it identified Primary Health Care (PHC) as the key to the attainment of the goal of Health for All (HFA). Following are excerpts from the declaration :

- The Conference strongly reaffirmed that health, which is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity, is a fundamental human right and that the attainment of the highest possible level of health is a most important worldwide social goal whose realization requires the action of many other social and economic sectors in addition to the health sector.
- The existing gross inequality in the health status of the people, particularly between developed and developing countries as well as within countries, is politically, socially and economically unacceptable and of common concern to all countries.
- The people have a right and duty to participate individually and collectively in the planning and implementation of their health care.
- An acceptable level of health for all the people of the world by the year 2000 can be attained through a fuller and better use of the world's resources, a considerable part of which is now spent on armaments and military conflicts. A genuine policy of independence, peace, détente and disarmament could and should release additional resources that could well be devoted to peaceful aims and in particular to the acceleration of social and economic development of which primary health care, as an essential part, should be allotted its proper share.
- All this could be achieved by provision of Primary Health Care.

Definition of “Health For All (HFA)”

HFA is defined as “the attainment by all peoples of the world by a particular date (kept at that time as the year 2000), of a level of health that will permit them to lead a socially and economically productive life”. It does not imply that by that date, everybody in the world will have the most state of the art health care but that by that date, everybody in the world will attain a level of health so as to enable him or her to lead a physically, mentally, socially and economically fulfilling life and contribute fully, depending on his / her capabilities, towards the socio-economic development of the community and nation. The Global Strategy for Health for All by the Year 2000 (HFA2000) set the following guiding targets to be achieved by year 2000 :

- Life expectancy at birth above 60 years
- Infant mortality rate below 50 per 1000 live births
- Under-5 mortality rate below 70 per 1000 live births.

Health for All in the 21st Century

In May 1998, the World Health Organisation adopted a resolution in support of the new global Health for All policy. The new policy, Health for All in the 21st Century, succeeds the Health for All by the Year 2000 strategy launched in 1977. In the new policy, the worldwide call for social justice is elaborated in key values, goals, objectives and targets. The 10 global health targets are the most concrete end points to be pursued. They can be divided into three subgroups, viz. health outcome targets (total four targets), targets on determinants

of health (two) and targets on health policies and sustainable health systems (four targets).

Global Health Targets

Health Outcome

1. Health equity : Childhood stunting—By 2005, health equity indices will be used within and between countries as a basis for promoting and monitoring equity in health. Initially, equity will be assessed on the basis of a measure of child growth.

2. Survival : Maternal mortality rates, child mortality rates, life expectancy—By 2020, the targets agreed at world conferences for maternal mortality rates (<100/100,000 live births), under 5 years or child mortality rates (<45/1000 live births) and life expectancy (>70 years) will be met.

3. Reverse global trends of five major pandemics : By 2020, the worldwide burden of disease will be reduced substantially. This will be achieved by implementing sound disease control programmes aimed at reversing the current trends of increasing incidence and disability caused by tuberculosis, HIV/AIDS, malaria, diseases related to tobacco and violence or trauma.

4. Eradicate and eliminate certain diseases : Measles will be eradicated by 2020. Lymphatic filariasis will be eliminated by the year 2020. The transmission of Chagas' disease will be interrupted by 2010. Leprosy will be eliminated by 2010 and trachoma will be eliminated by 2020. In addition, vitamin A and iodine deficiencies will be eliminated before 2020.

Determinants of Health

5. Improve access to water, sanitation, food and shelter : By 2020, all countries, through intersectoral action, will have made major progress in making available safe drinking water, adequate sanitation and food and shelter in sufficient quantity and quality and in managing risks to health from major environmental determinants, including chemical, biological and physical agents.

6. Measures to promote help : By 2020, all countries will have introduced and be actively managing and monitoring, strategies that strengthen health enhancing lifestyles and weaken health damaging ones through a combination of regulatory, economic, educational, organisational and community based programmes.

Health Policies and Sustainable Health Systems

7. Develop, implement and monitor national Health for All policies : By 2005, all member states will have operational mechanisms for developing, implementing and monitoring policies that are consistent with this Health for All policy.

8. Improve access to comprehensive essential health care: By 2010, all people will have access throughout their lives to comprehensive, essential, quality health care, supported by essential public health functions.

9. Implement global and national health information and surveillance systems : By 2010, appropriate global and national health information, surveillance and alert systems will be established.

10. Support research for health : By 2010, research policies and institutional mechanisms will be operational at global,

regional and country levels.

The Member States of WHO have to translate the Regional Health Policy into realistic national policies backed up by appropriate implementation plans. WHO, on its part, will provide support to the Member States based on countries' realities and needs, especially community health problems, the strengthening of health systems and services and the mobilization of countries and the international community for concerted action in the harmonization of national policies with regional and global policies.

Primary Health Care

Primary health care is defined as “essential health care based on practical, scientifically sound and socially acceptable methods and technology, made universally accessible to individuals and families in the community through their full participation and at a cost that the community and country can afford to maintain at every stage of their development in the spirit of self-reliance and self-determination”. It forms an integral part both of the country's health system, of which it is the central function and main focus and of the overall social and economic development of the community. It is the first level of contact of individuals, the family and community with the national health system bringing health care as close as possible to where people live and work and constitutes the first elements of a continuing health care process. Primary Health Care was identified as the key measure through which HFA was envisaged to be achieved.

In India the first National Health Policy in 1983 aimed to achieve the goal of 'Health for All' by 2000 AD, through the provision of comprehensive primary healthcare services. It stressed the creation of an infrastructure for primary healthcare; close co-ordination with health related services and activities (like nutrition, drinking water supply and sanitation); active involvement and participation of voluntary organisations; provision of essential drugs and vaccines; qualitative improvement in health and family planning services; provision of adequate training; and medical research aimed at the common health problems of the people.

The “Graded (3-Tier)” System of Health Care

In the curative domain there are various forms of medical practice. They may be thought of generally as forming a pyramidal structure, with three tiers representing increasing degrees of specialization and technical sophistication but catering to diminishing numbers of patients as they are filtered out of the system at a lower level. Only those patients who require special attention either for diagnosis or treatment should reach the second (advisory) or third (specialized treatment) tiers where the cost per item of service becomes increasingly higher. The first level represents primary health care, or first contact care, at which patients have their initial contact with the health-care system.

Primary health care : It is an integral part of a country's health maintenance system, of which it forms the largest and most important part. It deals with the entire gamut of the community at the grass-root level. Primary health care is a comprehensive team-work between medically qualified

physician as well as a wide range of nursing and paramedical personnel. Quite often, primary health care systems are further subdivided into three levels - the most peripheral level which is in direct contact with the community and is usually managed by one or more members from within the community who are trained and equipped in preventive and Promotive health care as well as in the most basic clinical and emergency care. The next higher level is managed by one or more nursing / paramedical workers, while the highest level within primary health care is managed by a medical person along with his team of nursing and paramedical persons. In our country, these 3 levels correspond to the ASHA / VHG, MPWs at subcentres and the Primary Health centre, respectively.

Secondary health care : The vast majority of patients can be fully dealt with at the primary level. Those who cannot are referred to the second tier for the opinion of a specialist. Secondary health care often requires the technology offered by a local or regional hospital.

Tertiary health care : The third tier of health care, employing super specialist services, is offered by institutions such as teaching hospitals and units devoted to the care of particular groups. The dramatic differences in the cost of treatment at the various levels is a matter of particular importance in developing countries, where the cost of treatment for patients at the primary level is usually only a small fraction of that at the third level.

Characteristics of Primary Health Care

These are :

- (a) Stresses prevention rather than cure.
- (b) Relies on home self-help, community participation and technology that the people find acceptable, appropriate and affordable.
- (c) Combines modern, scientific knowledge and feasible health technology with acceptable, effective traditional healing practices.
- (d) Should be shaped around the life patterns of the population.
- (e) Should both meet the needs of the local community and be an integral part of the national health care system.
- (f) Should be formulated and implemented with involvement of the local population.

Components of Primary Health Care

There are eight essential components :

- (a) Education about common health problems and what can be done to prevent and control them;
- (b) Maternal and child health care, including family planning;
- (c) Promotion of proper nutrition;
- (d) Immunization against major infectious diseases;
- (e) An adequate supply of safe water;
- (f) Basic sanitation;
- (g) Prevention and control of locally endemic diseases;
- (h) Appropriate treatment for common diseases and injuries.

The Four Pillars of Primary Health Care

Primary health care is not simply treating patients or immunizing children and so on. It is an ethos, a concept, which

is built up as a system. For this concept to be successful, it should employ the following four essential principles :

Community Participation : While most of the efforts in providing health care come from the state, the system of primary health care should be based on full participation and involvement of the community. It is akin to placing people's health in people's hands. In our country, the concepts of ASHA, VHG, TBAs are all examples of community participation.

Appropriate Technology : Appropriate technology is one which is scientifically sound, adapted to local needs, acceptable to those who apply it and to those on whom it is applied and which can be maintained by the people, as a part of self reliance and within the resources which can be afforded by the community and the nation. Outstanding examples of appropriate technology are the use of coloured tapes / bangles for measuring mid-upper arm circumference and use of coconut water for oral rehydration.

Inter-Sectoral Coordination : Health care, especially primary health care's preventive and Promotive functions can not be executed in isolation by health sector alone. A large number of other sectors concerned with human development will need to function in close cooperation and tandem. These include health, education, legal, urban / rural development, agriculture, industrial and such other sectors. Even at the grass root level, health care functionaries cannot function in isolation but will need to function with various other functionaries for obtaining best results. An outstanding example of inter-sectoral coordination at the grass root level is that of the Anganwadi, as a part of ICDS programme.

Equitable Distribution : Health services should be available to each and every one in the community and not depend on one's capability to pay for the services. In fact, those who are not in a position to pay are the one's who are in most need of health care. Similarly, disadvantaged groups within the homes / society (as women in a household or persons belonging to Scheduled Castes / Scheduled Tribes in the community) should have equal access and right to provision of health care, for it to be successful.

Millennium Development Goals (MDGs)

The Millennium Development Goals derive out of the eight chapters of the United Nations Millennium Declaration, which were officially established at the Millennium Summit in September 2000, where 189 world leaders adopted the United Nations Millennium Declaration. These are intended for the Member Countries to take efforts in the fight against poverty, illiteracy, hunger, lack of education, gender inequality, infant and maternal mortality, diseases and environmental degradation. The Millennium Declaration adopted 8 development goals, 18 time-bound targets and 48 indicators to be achieved by 2015. Three of the 8 goals, 8 of the 18 targets and 18 of the 48 indicators are related to health. The various health related goals and targets are :

Goal 1. Eradicate extreme poverty and hunger

Target 1 : Reduce by half the proportion of people living on less than a dollar a day

Target 2 : Reduce by half the proportion of people who suffer

from hunger

Goal 2. Achieve universal primary education

Target 3 : Ensure that all boys and girls complete a full course of primary schooling

Goal 3. Promote gender equality and empower women

Target 4 : Eliminate gender disparity in primary and secondary education preferably by 2005 and at all levels by 2015

Goal 4. Reduce child mortality

Target 5 : Reduce by two thirds the mortality rate among children under five

Goal 5. Improve maternal health

Target 6 : Reduce by three quarters the maternal mortality ratio

Goal 6. Combat HIV/AIDS, malaria and other diseases

Target 7 : Halt and begin to reverse the spread of HIV/AIDS

Target 8 : Halt and begin to reverse the incidence of malaria and other major diseases

Goal 7. Ensure environmental sustainability

Target 9 : Integrate the principles of sustainable development into country policies and programmes; reverse loss of environmental resources

Target 10 : Reduce by half the proportion of people without sustainable access to safe drinking water

Target 11 : Achieve significant improvement in lives of at least 100 million slum dwellers, by 2020

Goal 8. Develop a global partnership for development

Target 12 : Develop further an open, rule-based, predictable, non-discriminatory trading and financial system Includes a commitment to good governance, development and poverty reduction - both nationally and internationally

Target 13 : Address the special needs of the least developed countries Includes : tariff and quota free access for least developed countries' exports; enhanced programme of debt relief for HIPC and cancellation of official bilateral debt; and more generous ODA for countries committed to poverty reduction

Target 14 : Address the special needs of landlocked countries and small island developing States

Target 15 : Deal comprehensively with the debt problems of developing countries through national and international measures in order to make debt sustainable in the long term.

Target 16 : In cooperation with developing countries, develop and implement strategies for decent and productive work for youth.

Target 17 : In cooperation with pharmaceutical companies, provide access to affordable essential drugs in developing countries

Target 18 : In cooperation with the private sector, make available the benefits of new technologies, especially information and communications.

Summary

The International Conference on Primary Health Care was convened in Alma-Ata, Kazakhstan, in 1978 and was attended by virtually all the member nations of the World Health Organization (WHO) and UNICEF. 134 governments ratified the WHO Declaration of Alma-Ata, asserting that Health for all could be achieved by 2000, Governments have a responsibility for the health of their people that can be fulfilled only by the provision of adequate health and social measures; and Primary health care is the key to attain a level of health that will permit their citizens to lead a socially and economically productive life. The Alma-Ata Declaration of 1978 emerged as a major milestone of the twentieth century in the field of public health and it identified primary health care (PHC) as the key to the attainment of the goal of Health for All (HFA). HFA is defined as "the attainment by all peoples of the world by a particular date (kept at that time as the year 2000), of a level of health that will permit them to lead a socially and economically productive life". The new policy, Health for All in the 21st Century, succeeds the Health for All by the Year 2000 strategy launched in 1977. In the new policy, the worldwide call for social justice is elaborated in key values, goals, objectives and targets. The 10 global health targets are the most concrete end points to be pursued, which are divided into three subgroups, viz. health outcome targets (total four targets), targets on determinants of health (two) and targets on health policies and sustainable health systems (four targets).

Primary health care is defined as "essential health care based on practical, scientifically sound and socially acceptable methods and technology, made universally accessible to individuals and families in the community through their full participation and at a cost that the community and country can afford to maintain at every stage of their development in the spirit of self-reliance and self-determination". It forms an integral part both of the country's health system, of which it is the central function and main focus and of the overall social and economic development of the community. Primary Health Care was identified as the key measure through which HFA was envisaged to be achieved. Health care System forms a pyramidal structure, with three tiers representing increasing degrees of specialization and technical sophistication. There are eight essential components of PHC a) Health education b) MCH including family planning c) promotion of proper nutrition d) immunization e) an adequate supply of safe water f) basic sanitation g) prevention and control of locally endemic diseases h) appropriate treatment for common diseases and injuries. The four essential principles: Community Participation, Appropriate Technology, Inter-Sectoral Coordination and Equitable Distribution.

The Millennium Development Goals derive out of the eight chapters of the United Nations Millennium Declaration, which were officially established at the Millennium Summit in September 2000, where 189 world leaders adopted the United Nations Millennium Declaration. These are intended for the Member Countries to take efforts in the fight against poverty, illiteracy, hunger, lack of education, gender inequality, infant and maternal mortality, diseases and environmental degradation. The Millennium Declaration adopted 8 development goals, 18 time-bound targets and 48 indicators to be achieved by 2015.

Three of the 8 goals, 8 of the 18 targets and 18 of the 48 indicators are related to health.

Study Exercises

Long Questions : (1) Discuss the characteristics, Components and Principles of Primary Health Care. Describe briefly 3-tier Health care System in India. (2) Enumerate the eight goals in Millennium Declaration. Discuss in detail the Health related goals with respective targets.

Short Notes : (1) Alma-Ata Declaration of 1978 (2) Components of Primary Health Care (3) Principles of Primary Health Care (4) Health related MDG goals.

MCQs :

1. Alma-Ata Declaration was held in (a) 1976 (b)1977 (c) 1978 (d) 1980
2. The Global Strategy for Health for All by the Year 2000 (HFA2000) set the following guiding targets to be achieved by year 2000 except (a) Life expectancy at birth above 60 years (b) Infant mortality rate below 50 per 1000 live births (c) Under-5 mortality rate below 70 per 1000 live births (d) MMR below 301/lakh
3. The Millennium Development Goals which were derive out of the eight chapters of the United Nations Millennium Declaration was held in the year (a)1999 (b)1978 (c)2000 (d) 2001

4. The health related targets in MDGs are (a) 8 (b) 18 (c) 48 (d) 3
5. The health related indicators in MDGs are (a) 8 (b) 18 (c) 48 (d) 3
6. The MDG goal related to reducing the Child mortality is (a) 3rd (b) 4th (c) 5th (d) 6th
7. The MDG goal related to improving the maternal health is (a) 3rd (b) 4th (c) 5th (d) 6th
8. The MDG goal number 7 deals with (a) lack of education (b) gender inequality (c) infant and maternal mortality (d) environmental degradation
9. Target 6 of MDG-5 aims at reducing the maternal mortality ratio by (a) three quarters (b) half (c) one-fourth (d) two thirds.
10. Target 5 of MDG-4 aims at reducing the mortality rate among children under five by (a) three quarters (b) half (c) one-fourth (d) two thirds

Answers : (1) c; (2) d; (3) c; (4) a; (5) b; (6) b; (7) c; (8) d; (9) a; (10) d.

Public Health in Developing Countries and Countries with Transitional Economies - History, Development & Policies

Amitava Datta

Historically, especially in resource poor countries, public health was synonymous with health development efforts undertaken by government agencies. Public health action was seen also as various health interventions aimed at groups of individuals and included efforts to provide community hygiene, sanitation, safe water supply, health education, maternal and child health care and disease control activities. These activities were provided by specially trained workers who were known as public health workers. The spectrum of public health activities covered preventive, promotive, curative and rehabilitative measures. With time the concept of public health evolved to include the involvement of people together with the government in provisioning of health activities. This helped in increasing the acceptance and utilization of the health facilities by the

targeted community. This concept of a wider public role in health development has become more prevalent today when both non-communicable diseases as well as communicable diseases are simultaneously present in the country in significant numbers.

Health of the people has always been one of the prime concerns of democratically elected governments. With more and more states becoming independent from their colonial masters, the clamour for improving the health status of their people had increased in the later parts of the 20th century. Increasing globalization had also increased international concerns on prevailing poor state of health of a large number of the developing countries. It was also realized that health status of people living in the developed countries could not be assured without upliftment of health in the vast numbers of developing countries. The increased cooperation between developed and developing countries in the field of health specially under the aegis of different organs of the United Nations specially World Health Organisation has been the hallmark of public health activities during the later part of the 20th century.

The historical development of public health in the developing countries can be better appreciated if viewed in four parts - first, ancient public health; second, the development of public

health under the colonial structure; third, the efforts made by the countries as soon as they attained independence; fourth, the change in concept of public health from narrow disease control interventions to multi sectoral approaches. Today, developing countries except those ravaged by bitter sectoral war or dispute are moving towards an era of public health development with twin problems - infectious diseases as well as chronic problems. The health system of these countries are functioning with limited local resources but also obtaining resources from the international society to provide the best possible health for their citizens.

Ancient Public Health

Since ancient times, human life has been threatened with diseases of all kinds. The teachings of Lord Buddha as well as the Bible and Koran covered various aspects of personal hygiene and other public health practices. Royal decrees were used to ensure sanitation measures for the common good of the country. Heavy punishments were used to prevent food adulteration or littering of streets. Quarantine or prohibition were major measures used historically to protect against transmission of diseases within a country as well as from one country to another. However, very few records of public health in developing countries exist for the ancient ages till the 18th century.

Colonial Public Health

Massive shifts of native populations were indulged by the ruling powers to work on plantations, construction sites, mines or industries mainly from Asia and Africa. The colonials established their own administrative, legal and medical care systems with varying degrees of autonomy and authority. To protect the health of their own people and the workers, colonial rulers established laws similar to those in their home countries. Specific public health legislation varied with each colonial power of which some have still remained in place today in many countries in Asia, Americas and Africa. The public health measures made a great impact in these countries. Some colonial powers introduced their social and cultural identity, mainly through religious groups and their educational systems. European and American religious missionaries also embarked on expeditions around the world. Many of them established medical care institutions as well as general educational systems. Introduction of the “Western” system of medicine in some of these countries of Asia and Africa was the first exposure and increasing access by the people in these countries to so called “Western medical care”.

The late 18th century saw an increasing momentum in public health education with establishment of undergraduate and post-graduate courses at first in the home countries and then in the colonies. Some of these public health educational and research institutions in India such as the “School of Tropical Medicine and Hygiene” and the “All India Institute of Hygiene and Public Health” both located in Kolkata, were established in British India in the early 1920s. The “Haffkine Institute” in Mumbai, “King’s Institute of Preventive Medicine” in Chennai, “Central Vaccine Research Institute” at Kasauli, “National Institute of Communicable Diseases” (earlier known as Malaria Institute of India), “Indian Research Fund Association” (later known as Indian Council of Medical Research) and the National

Institute of Nutrition were the exemplary research and teaching institutions established at that time. Similar institutions were established in Thailand, Philippines, Malaysia, Singapore, Hong Kong, Indonesia, Sri Lanka (earlier Ceylon), Ghana, Nigeria, South Africa, Mexico, Brazil and so on.

However the actual development of public health and medical care services for the general public remained rudimentary in these former colonial countries and territories. Infectious diseases posed formidable obstacles to attainment of good health in these areas. Developments in science and technology in the early 20th century led to an explosion in applications in public health practices. Improved communications by radio and telephone speeded up communications among people. International concerns lead to the major public health initiative in prevention and control of smallpox through vaccination. Pilot disease control projects under Rockefeller foundation also demonstrated means to control prevailing diseases in some developing countries which could be replicated in other countries as well.

Public Health in Immediate Post-Independence period

With the end of the Second World War, the spirit of solidarity, peace, security and tranquility lead to the creation of inter governmental institutions like United Nations and its specialized agencies like World Health Organisation (WHO). The main functions of WHO are directing and coordinating international health development. Former colonial countries saw Second World War as the beginning of the end of colonial rule. Within a few years many countries achieved independence. After gaining independence, many countries adopted ambitious plans for socio-economic development, including health. The health care facilities were however non-existent. Many countries thus initiated reviews of their national health situations and formulated long term development plans. In India, the Bore Committee was established in 1945 to review the health situation and to recommend improvements in the Indian health system. In Myanmar (earlier Burma), the Sorrento Villa Plan in 1947 and the Pyidawtha Plan in 1950 were drawn up for achieving rapid socio-economic growth, including the expansion of health and education. Similar socio-economic plans were initiated by other developing countries. Most developing countries in the post Second World War period followed the advice and support of WHO and other international agencies to improve their health systems infrastructure based on the western system of hospitals and health centres. Health workers who had only undergone minimal training ran these centres in rural areas. National projects on maternal and child health, school health, etc were established to expand the basic services. Health care services were mainly provided “free” but were few and mainly concentrated in towns and cities. These were mainly those existing during the colonial period. Training of different categories of health auxiliaries, such as health assistants, medical assistants, sanitary workers, community educators, laboratory technicians, etc was initiated by the establishment of paramedical training institutes. These workers were deployed to serve at the various health institutions, especially those established in the rural areas. A number of rural health development and demonstration centres were also

established in many countries. The Kalutara rural health project in Sri Lanka, the pilot project Aung San demonstration rural health unit in Myanmar and the Singur rural health project in India were a few of them. The development of human resources for health especially by creating medical, nursing and other paramedical schools was more intense between the 1950s and 1970s.

Change in Concepts of Public Health

The International Rural Health Conference held at New Delhi, India in 1953 under the aegis of WHO reviewed the concepts of rural health services and use of multi purpose village health workers for delivering comprehensive rural health services. It recommended that rural health centres were the basic units through which comprehensive health care could be provided to the rural areas. Simultaneously under the guidance of WHO and UNICEF, governments were encouraged to focus on provision of maternal and child health services as a means to reduce the unduly high maternal and infant mortality. The initial vertical approach of provision of maternal and child health services had to be soon reviewed as they did not produce the necessary impact. Countries recognized the need to provide comprehensive basic health services while focusing on the problems of mothers and children. The relatively high levels of maternal and child mortality and morbidity compounded with a rapid growth in population adversely affected the social and economic development in the developing countries. Since the early 1960s, most developing countries started adopting population policies in which family planning was the main strategy. In spite of availability of technology the utilization of contraceptive services in these countries continued to be comparatively low, thus hastening the increasing population. The "Green Revolution" of the 1960s had a positive impact in better availability of food and nutrition. The initial focus of the "Green Revolution" was on cereals rather than on pulses and vegetables. Vitamin A deficiency was thus widespread in Asia. Although the proportion of population with inadequate nutrition steadily decreased, however the increasing population ensured that hunger and malnutrition continued to be the most devastating problems in the developing countries.

Promotion of environmental sanitation was also given a high priority along with provision of basic health services. This was based on the experience of the developed countries through the 18th and 19th centuries. Promoting the provision of safe drinking water and adequate sanitation specially in rural areas were key initiatives. However progress was hindered due to insufficient financial resources, inappropriate application of technology and lack of community participation. Large scale migrations in search of work started occurring from the rural areas to urban areas as the agriculture based economy could not support the increasing population. Industrialisation also hastened migration. The sanitary infrastructure already inadequate in the towns and cities became overloaded and slums developed in the peripheries as well as within towns. A WHO survey carried out in 1970 in 91 developing countries showed that only 29% of the total population had access to safe drinking water and only 50% of the urban population had access to safe water. The access to safe sanitation facilities was

even worse. Considerable attention thus started being given to care for these under developed urban clusters which were developing in a completely unplanned manner.

Most governments invested large amounts of funds and human resources in the prevention and control of Malaria. During the early 1950s, WHO demonstrated in various pilot projects that residual spraying of human dwellings with DDT and the effective treatment of Malaria cases, with 4-amino quinolones could interrupt the transmission of malaria effectively and efficiently. Erratic availability of DDT despite efforts of WHO and inadequate planning and supervision of spraying operations led to increasing resistance among malaria vectors. Still there were drastic reductions of malaria as well as collateral benefit in reduction of visceral Leishmaniasis. Leprosy, the oldest and widely prevalent disease in developing countries was the focus of public health action. Availability of dapsone provided a welcome boost to the leprosy control activities which were based on early case detection through mass screening and treatment with dapsone, together with health education. Millions of leprosy cases were detected and provided with long term dapsone therapy. Effective treatment with long lasting penicillin in 1948 changed the control measures against sexually transmitted diseases in Europe. Few pilot projects on venereal disease control were initiated in developing countries in 1950s to identify appropriate community intervention strategies. These included early case detection, effective contact tracing, early treatment, continuous surveillance and health education. Availability of effective treatment conveyed a false sense of public health security which ignored the increasing prevalence of prostitution, promiscuity and homosexuality besides rapid urbanization, industrialization and migration of labourers - thus promoting syphilis and other STDs.

Control on the spread of an acute bacterial disease, cholera, could be achieved in western countries with the provision of adequate sanitation and safe drinking water assisted by quarantine measures. Development of a cholera vaccine in the 1950's, also helped to arrest the further spread of cholera. A new cholera biotype, eltor, appeared in 1965 in Indonesia and invaded all of Asia, creating waves of epidemics. The eltor epidemic took thousands of lives and affected millions of people for more than two decades. It also spread to Africa and Americas and caused major public health crisis. *Vibrio cholerae* 0139, a new bacterial strain has been identified in India and other parts of Asia and has spread slowly to other parts of the world.

However, all was not gloomy in the public health picture in developing countries. Assistance of international agencies like WHO, UNICEF besides philanthropic institutions like Rockefeller foundation promoted global disease control campaigns against major communicable diseases. Demonstration projects were established in different countries to identify appropriate country specific disease prevention and control strategies. Many educational and research institutions were established which provided the much needed pool of trained manpower. Spectacular success was achieved in the field of Yaws control, reduction in morbidity and mortality due to malaria, leprosy, sexually transmitted diseases, cholera and smallpox.

Public Health Successes and Failures

The greatest success achieved by the developing countries in the twentieth century was the prevention and control as well as ultimate eradication of small pox. Although vaccination had been introduced in the developing countries by their colonial masters, however, control could not be achieved due to technical reasons. With the coordinated efforts of WHO, this dreaded disease could be eradicated through a mixed approach of mass vaccination, special searches for cases and providing rewards for reporting of cases.

Efforts by governments had reduced the burden of epidemic and endemic diseases. With the assistance of international organizations, the health care delivery systems were also strengthened. However, in 1975 more than two-thirds of the population of developing countries still did not have reasonable access to permanent form of health care. Health care facilities were mainly in urban areas. Professional and paramedical workers were disinclined to work in rural areas which contributed to the disparity between the different parts of the country. Much of the health planning was done at central level without closer involvement of the people responsible for the implementation. Life expectancy was far lower in Africa and Asia as compared to Europe. Infant mortality was 10-15 times higher than in the developed world. Proportion of GDP spent on health was 1-6 percent in many developing countries as compared to more than 10 percent in the developed world. Traditional systems of medicine like Ayurveda, Siddha, Unani-Tibb, Chinese, Tibetan and others had almost been abandoned by governments during and immediately after the colonial days. These systems again started being promoted in the developing countries.

The 1970s and 1980s were economically and politically unstable decades. Armed conflicts in various parts of the world had serious consequences on world economy. Problems of high morbidity and mortality due to maternal and childhood diseases, infectious diseases and malnutrition were compounded by rapidly increasing population. Too much focus on technological advancements and dominance of biomedical science approach without adequate focus on community led to failure of many mass control programs. Health planners came to believe that in view of political needs and demands of the community, the widening gaps between health needs and available resources require fitting clinical medicine into a social context. The value of health as a fundamental human right and its attainment as an essential social goal were firmly recognized. These debates led to the World Health Assembly adopting the historical resolution on "Health for All by the year 2000". It was expected that governments would use better approaches for preventing and controlling diseases and alleviating illness and disability. The obstacles for attaining the goals for Health for All led to the "Alma Ata declaration" which called for protecting and promoting the health of all the people using the primary health care approach.

Developing countries saw the Alma Ata primary health care conference as an opportunity for restructuring their health systems to reach the goal of Health for All by year 2000. They formulated new health policies and strategies as well as plans

of action to launch and sustain primary health care. With international assistance, these countries attempted to organize and manage comprehensive national health systems within the primary health care framework. Accessibility to primary health care elements rose to more than 80 percent in most countries. However, shortcomings in provision of maternal and child health care as well as safe water and sanitation remained. Use of community health volunteers, after minimal initial training, to support the existing health care workers in provision of many public health interventions like immunization, maternal and child health care, environmental health promotion, etc was successfully implemented by many countries.

The successful implementation of the Expanded program of Immunisation to protect all children against the main vaccine preventable diseases is another major public health success in the developing countries. It is estimated that approximately 2 million children were saved by this program.

Developing countries participated in several disease elimination/eradication programs. The polio eradication program has had mixed success despite use of innovative strategies. The concept of national immunization days for mass immunization has successfully eliminated polio from many countries. However, cases of wild polio continue to occur in some of the countries like India, Afghanistan, Pakistan and Nigeria. Leprosy elimination with use of multi drug therapy has become a possibility even in the previously hyper endemic countries like India. Dracunculosis (Guinea worm disease) which afflicted annually more than 10 million cases in Africa and South Asia before the 1980s has been drastically reduced with many countries claiming eradication including Pakistan(1997) and India(2000). Onchocerciasis (River Blindness), which afflicts people in tropical Africa, Latin America and Arabian Peninsula has also been targeted for control using better case management and an effective drug (Ivermectin). Sustained program with strong international support should lead to global elimination of Onchocerciasis in the near future. There has however been emergence of a disease which threatens to wipe out the gains of the 20th century - HIV / AIDS. In the absence of an effective vaccine, this disease which is mainly transmitted by sexual route is planned to be controlled by political advocacy, mass education (including sex education), behavioural intervention and social mobilization. Other diseases like malaria, viral hepatitis B, yellow fever, plague and tuberculosis have reappeared in increasing numbers leading to considerable morbidity and also mortality. WHO promoted the use of "Directly Observed Treatment Short Course" (DOTS) strategy for effective management of infectious tuberculosis cases. The malaria situation in Asia especially due to chloroquine resistant Plasmodium falciparum is serious. WHO initiated program "Roll Back Malaria" in 1998 in the developing countries with multi-pronged interventions and well coordinated strategies.

Developing countries had adopted prevention and control of diarrhoeal diseases and respiratory infections as part of major health interventions. Training of basic health workers on Integrated Management of Childhood Illnesses (IMCI), using easy to use algorithms for management of these two groups of killer disease is considered very effective. Unfortunately, only one-third of the families know about it and have access to it.

Non-communicable diseases have witnessed a sharp increase due to improved longevity, changes in lifestyle and diets, besides increased use of tobacco and alcohol. Diabetes mellitus, cardio-vascular diseases and cancers are showing a rapid rise for which the developing countries are inadequately prepared. This double burden of disease (tackling existing and re-emerging communicable diseases along with the rising non-communicable diseases) has made it difficult for health planners, policy makers and administrators to decide on equitable allocation of scarce resources. This epidemiological transition may be the biggest challenge for public health at the start of the new century in developing countries. Globalisation has however shrunk the world in terms of relative distances. Local control of outbreaks of diseases has become a global struggle. The increasing opportunities in developing countries and numbers of international travelers pose threat of rapid spread of diseases.

The Road Ahead

It is however a stark fact that more than a quarter of the developing world's people still live in poverty as measured by the human poverty index (a composite measure including life expectancy, basic education and access to public and private resources). Around 2.5 billion people live on less than \$2 a day (40% of the world's population) and 1 billion live on less than \$1 a day. Not only is health a long recognized human right, but improving health is associated with a decrease in poverty by securing better livelihoods. WHO estimates that in 2015 in developing countries, the burden of disease (DALYs) and death rates will be slightly higher for chronic diseases (including smoking-related disorders) than for communicable, maternal and nutritional disorders combined. The prevention of chronic diseases in low and middle income countries is now a priority. Heart disease, diabetes and cancers are increasingly affecting poor people in developing countries. The costs of treating them are high and contribute to household poverty. WHO's stated goal is to work with the developing countries to focus global efforts to build healthy populations and communities. The efforts of national and international communities should aim at promoting healthy living, reducing the double burden of disease and making essential health care accessible to all. To tackle this massive agenda clear targets are required to provide milestones against which progress can be measured. These are based on recent UN Conventions and Resolutions including setting of Millennium Development Goals (MDGs). The four key areas for health gain suggested are Infant and child mortality, Maternal mortality, Reproductive health and control of HIV, Tuberculosis, malaria and other communicable diseases. As is however very clear from the MDGs, improved health will only be possible through inter-sectoral coordination to simultaneously eliminate extreme hunger and poverty, provide education to all, enable empowerment of women, besides protection and better management of the natural and physical environment. The goals, targets and their indicators have been enunciated for action by all countries. MDGs will however only be successful if there is the political will to address international cooperation and involvement of both poorer and richer countries in this gigantic task.

Summary

Historically, in resource poor countries, public health had been synonymous with health development efforts taken by Government agencies. Very few records of public health in developing countries exist for ancient ages. With the start of the 18th century, Colonials (Americans and Europeans) established their own administrative, legal and medical care with varying degree of autonomy. The late 18th century saw an increased momentum in public health education first in home countries then in colonial countries. However, the actual development of public health and medical care services for the general public remained rudimentary in these colonies. Development in science and technology in the early 20th century led to explosion in the application in public health practices. Public health in immediate post independence period evolved with the creation of inter Government institutions like United Nations and its specialized agencies like World Health Organization. Most developing countries in the post Second world war period followed the advice and support of WHO and other international agencies to improve their health systems-National health programmes were started; health care services were provided free; training of health workers initiated and development of human resources for health was focused. The initial vertical approach of provisioning of health services was reviewed to provide comprehensive basic health services. Promotion of environmental sanitation - provision of safe drinking water, adequate sanitation etc was also given high priority. Shift from agriculture based economy to industrial economy posed additional burden of these facilities and simultaneously increasing incidence of communicable and non communicable diseases. Assistance of international agencies promoted global disease control campaigns. Demonstration projects were established in different countries to identify country specific disease prevention and control strategies. Spectacular success was achieved in the field of Yaws control, reduction in morbidity and mortality due to malaria, leprosy, sexually transmitted diseases, cholera and smallpox. The prevention of chronic disease in low and middle income countries is now the priority. Efforts are now directed against promoting healthy living, reducing the double burden of disease, making health care accessible to all - all included in the Millennium Development Goals.

Study Exercises

MCQs & Exercises

- (1) The "School of Tropical Medicine & Hygiene" is located in:
(a) Delhi (b) Mumbai (c) Kolkata (d) Chennai
- (2) The "All India Institute of Hygiene & Public health" is located in : (a) Delhi (b) Mumbai (c) Kolkata (d) Chennai
- (3) The "Haffkine Institute" is located in : (a) Delhi (b) Mumbai (c) Kolkata (d) Chennai
- (4) The "Central Vaccine Research Institute" is located in : (a) Delhi (b) Mumbai (c) Bangalore (d) Kasauli
- (5) The "National Institute of Communicable Diseases" was earlier known as _____
- (6) The "Indian Research Fund Association" was later known as _____
- (7) The International Rural Health Conference in 1953

- was held at : (a) New Delhi (b) Mumbai (c) Kolkata (d) Chennai
- (8) The initial focus of the 'Green Revolution was on : (a) Pulses (b) Cereals (c) Vitamins (d) Minerals
- (9) In 1950s, spraying of DDT for Malaria, had a collateral benefit in reduction of : (a) JE (b) Dengue (c) Kala-Azar (d) Chikungunya
- (10) The oldest & widely prevalent disease in the developing countries was : (a) TB (b) Malaria (c) Kala-azar (d) Leprosy
- (11) A new cholera biotype, Eltor, appeared in 1965 in : (a) India (b) Indonesia (c) Sri Lanka (d) Burma

- (12) The drug used for treatment of Onchocerciasis is : (a) Chloroquine (b) Doxycyclin (c) Ivermectin (d) Artesunate

Answers : (1) c; (2) c; (3) b; (4) d; (5) Malaria Institute of India; (6) ICMR; (7) a; (8) b; (9) c; (10) d; (11) b; (12) c.

Public Health in Developed Countries

Amitava Datta

Public health today is really a reflection of history of the developed world. People today live longer, fewer parents experience death of young children, fewer adults die of communicable diseases like tuberculosis and are less likely to experience periodic famines or epidemics. People are less likely to experience chronic pains or deformities from which only death provides a merciful release. An expectation of health and a pre-occupation with it are the hall marks of modern society. Public health in the modern era, which took roots in the developed world mainly in the 19th century, reflects in the way they collect and evaluate demographic data, keep cities clean and provide the means to the public to ensure their health. There have always been controversies in the aspect of definition of health and the role played by the public which invariably affect their health. Measures to be adopted by the state to preserve or promote the health of their citizens have also been dominated by politics. Even when there arose widely accepted reasons of state intervention and agendas of state responsibility for actions to ensure the health of their citizens, not every state was in a position to act on them. The responsibility of action was often unclear or overlapping.

Evolution of Concepts of Public Health

The combating of infectious diseases has often seemed the core of public health to be provided by the state. The levels and kind of physical and mental well being which should be guaranteed by the state has often been seriously debated. The problems posed in the actual causation of diseases based on personal, social, cultural, political, economic and biological considerations provides adequate reason for differing opinions regarding actions needed to be initiated to prevent or contain these diseases. The increasing concern for equity in ensuring public health based on principles of non-discrimination has

been increasing. Health status of certain groups was considered as a threat to others and therefore actions aimed at such groups were initiated to improve their health with a broader view to ensure the health of the benefactors themselves. The responses to disease in these groups range from calls to advice or aid them to the extremes of planning to imprison, banish or even kill them. The aspects of public health which have become refined are :

- Clear differentiation of aspects considered to be clearly the responsibility of the state or community vis-à-vis those which were clearly the responsibility of the individual.
- Application of concepts of inter-sectoral coordination with greater appreciation of fields other than medicine like engineering, social sciences, economics, religion, etc in their contribution to provision of health and prevention of disease.
- Provision of public health services considered to be above politics with claims of high moral ground by the proponents of public health action.

In the developed countries of the world, public health therefore revolved around three main aspects :

- Response to an epidemic situation
- As a regulatory or 'police'
- As a means to provide improvement or better life

The initial public health actions revealed mainly a reactive mechanism in response to outbreaks of epidemics of communicable diseases in neighbouring countries or within the country itself. Closing of borders or ports, instituting prophylactic measures like fumigation of ships and aircraft are clearly examples of this response mechanism to protect themselves. Like in the evolution of community living, regulation of aspects considered as threats to health of the members became part and parcel of the public health initiatives of countries. Control of food adulteration, prostitution, concern over substance abuse and smoking became the responsibility of public health providers. The political vision to provide improvement in health for all was last to arise in the field of public health. These were made possible by technological

achievements, like better vaccines, better diagnostic facilities, better demographic information and an optimistic view of possibility for progress in human life and not accept aspects like infant mortality as inevitable.

Public health aspects of epidemic response : The public health actions to meet an epidemic stemmed from the realisation that something could be done in these circumstances by the public. In some cases the replacement of supernatural explanation for causation of diseases like in small pox also occurred but not necessarily coincided with start of public action. The containment of plague epidemics in Europe started the public health movement in those regions. The Italians included development of 40 day hold on ships or other traffic coming from potentially infected areas, isolation of victims and numerous means like burning sulfur, burning clothes and bedding and washing surfaces with lime or vinegar. Plague control required officials to oversee quarantine or isolation procedures, staff to disinfect and a structure for gathering health information. Response to yellow fever and malaria consisted of flight and abandonment of cities by those who could afford it. The response to syphilis was variable among different countries. Mainly the state approach shifted from cure to prevention by aiming to regulate prostitutes, who were considered reservoirs of the disease. The efforts to contain epidemic diseases did not reflect any sense of obligation to individuals. At stake were mainly the military, commercial and cultural welfare of the state and individual's welfare was only incidental. The typhoid, typhus, relapsing fever and yellow fever were tackled by public action to improve the living conditions comprehensively to provide the physical and social changes that would produce a sound human being.

Public health aspects of 'police' action

Regulation of communities for common good was practiced by western nations. By the eighteenth century they were broadly being called 'police' action. The police functions included the following :

- Enforcing basic rules of sanitation, building construction and public morality
- Caring for poor and orphans
- Regulation of modes of work and work hours
- Regulation of markets and sale of commodities
- Marriage and midwifery practices
- Travel regulations and restrictions
- Maintaining population statistics
- Regulating medical practice

The business of public 'police' in the 18th and 19th century Europe did affect health in many ways. It also covered much of what would later belong to the domain of public health. Mainly however the concern was with amenity, morality and public order. The concept of medical 'police' arose first in Germany and Austria, to be followed by Scotland, Scandinavia, Italy and Spain. The importance of regulating personal behaviour to improve the health of soldiers and sailors was gaining recognition. Hence the idea emerged of trying the same on the rest of society among some rulers of countries in Europe. In America and England the 'police' concept did not really catch on. Modern public health may be considered to approach the domain of comprehensive 'police'. It recognizes that a wide

range of factors are implicated in health conditions including current concerns like effects of violent entertainment, prevention of gun violence and the conditions of the workplace. Modern liberal democracies today however consider these concepts as deeply problematic and are uncomfortable with infringing on personal liberties of their citizens.

Public health aspects of provision of better life : Public health emerged in the western countries as not something which was only reactive. It took upon itself the goal of reduction of morbidity and mortality. Originating in the 18th century, this aspect of public health had complex causes. Public health developed the ability to compare morbidity and mortality profiles of different population groups. Technological advances started to provide for means for prevention of diseases like vaccines besides diagnostic tests for diseases and carrier status. Armed with these information, public officials like John Simon in England, argued with towns with poor morbidity and mortality statistics to analyse the reasons and take appropriate action. The gathering and analysis of health data has become a central part of modern public health. However, new medical knowledge and technological advances did not necessarily precede the determination to improve the health for all. The sanitary campaigns against urban filth, which were based on a vague, flexible and erroneous concept of pathogenic miasmas, is the best example of the determination to improve the living conditions as a means of provision of better and healthier life. There was also greater resistance to accepting differential morbidity and mortality in disadvantaged population groups and need to initiate appropriate action. It needed two centuries to evolve to the present modern concept which admits no justifiable reason other than climatic and biological factors for differential morbidity and mortality figures among different groups, communities or nations - the concept of health equity.

Phases of Public Health

The available literature clearly brings out the changes which public health has undergone in the developed countries over a period of time, mainly the last two centuries. It would be appropriate to divide these into three phases to under the evolution of the concepts.

Age of liberalism (1790-1880) : The concepts of equity in health started with this age. John Simon pioneered work with English state medicine to change to the concept that the best policies were those that maximized human worth and welfare. The recognition of Human rights was still not transcribed in terms of health. Concern with public health arose accidentally and at different times in different countries of the developed world. Revolutionary France wished to abolish medical licensing and other aspects which were associated with 'police' functioning. These were quickly given up once the state interest was realized. States like Sweden and France weakened with depopulation due to disease focused attention on health and welfare of individuals. Edwin Chadwick developed "the Sanitary Idea" in 1830s. Only USA propagated the idea that individual's health was a private matter. All countries of Europe were strong proponents of need for state enforcement of sanitation policies and practices.

Golden age of public Health (1880-1970) : During this period European nations, America and later Japan, competed for

colonies and international influence. Realisation of weakness of its citizens forced action by powerful states like Britain to provide expanded public health services. Development of diagnostic facilities lead to diagnosis of diseases and containment measures. Persistently high infant mortality even in relatively well sanitized country like England lead to concern for containment of this avoidable loss of life. Concern for health conditions of women and of workers mainly in factories began to attract attention as never before, reflecting commercial and other interests. Public health measures, which could address the concern for reducing the high morbidity and mortality were sought, in spite of they infringing on an individual's life in all aspects like home, work, family relations, recreation, etc. The germ theory of disease matured in France and lead to concern for the human body as a harbour of germs. This was especially so in diseases like typhoid, tuberculosis and syphilis where it was recognized that the human body could harbour the disease in spite of not manifesting disease. Inspection and regulation were the public health strategies suggested as an outcome of the germ theory. The example of 'Typhoid Mary' who was incarcerated for 26 years by the city of New York, is an extreme example of this intervention. The legal limits and cultural sensibilities could be however be worked out over a period of time as a compromise between public health and civil liberties.

The emerging science of heredity was a contemporary of the 'germ theory'. The concept of eugenics as a hope for the improvement of health of people exercised the minds of many involved with public health. The extreme application occurred during Nazi Germany's attempt to exterminate Jews and other 'races' regarded as inferior. Negative eugenics was also practiced through American laws which prevented reproduction by those considered 'unfit'. Proponents of eugenics focused attention on human genome and urged public health to take cognizance of heredity as a basis for disease causation.

Nutritional sciences also developed leading to association of pellagra with over dependence on maize in southern parts of America and role of vitamin D and sunlight in prevention of rickets. Diet like genes, loomed large in the minds of the public as the cause of all troubles and provided a source of hope. Public health included attention to a varied diet which ensured adequate vitamins. People thus learnt to fear three entities-invisible germs of disease, mysterious genes and peculiar set of trace nutrients missing in their diets

Return to liberalism (1970 onwards) : Post second world war, threats posed by most of the known infectious diseases receded with better focus on public health. Pro-active actions of World Health Organisation ensured internationalization of public health and preventive action. The mission statement of WHO, that health was the birthright of all persons, emphasized the liberal attitudes of international community. However, the failure to combat chronic diseases by countries became highlighted in the absence of significant infectious diseases. Deadly effect of good living including smoking and a rich diet was brought sharply into focus. A new set of actions focusing on personal discipline emerged to control lifestyle diseases and accidents. Public health institutions and the people were increasingly at loggerheads over differing perceptions of role

of regulatory agencies in protecting environment and health of people. Even aspects of lifestyle could be attributed to the broader social environment. People smoked tobacco, drank alcohol, used narcotic drugs, ate too much or too little, failed to practice safe sex and spent hours in front of televisions and personal computers. They also beat up their spouses or children, fought with their co-workers and used readily available firearms to shoot themselves or others as they were unable to cope with the stresses of day to day living. Analyses of these events were however not conducive to solutions in view of the existence of serious vested interests. Arising of many widespread cancers and debility associated with ageing populations started focusing attention on the need for public health to also focus on these issues. The newly emerging diseases were not infectious and could be suffered by individuals privately without disturbing the community. However these certainly impacted on the fulfillment of human potential and could therefore justify the demands for action by the governments of these citizens. Efforts to expand state responsibility for health have generally worked when medical professionals have viewed them as personally advantageous. The relationship between expanded public health action and social welfare has however been problematic at other times. Suggestions for regulating human behaviour and lifestyle as a means of prevention of diseases associated with lifestyle have invariably drawn vociferous protests and lobbying actions. The context of tobacco control in several nations is an apt example of this dichotomy. The absurdity of the situation can be assessed when viewing that on the one hand countries and states were subsidizing tobacco production which was leading to addiction in other countries, while blaming their own citizens for smoking and damaging their health over a period of time. The relationship between the public health institutions and the citizens on whose behalf they claim to be working will remain one of the most serious challenges of the modern day public health.

The Way Forward - Need for Continued Public Health Action

The momentous achievements of the 20th century revolutionised health and the consequent demographic transition, leading to new patterns of disease. There has been a major shift in causes of death and disability from infectious diseases to non-communicable diseases. Not only have the major causes of death changed but the average age of death has been steadily rising. There appears to be niggling doubts to the branding of the situation as a complete success story with the persistence of sub-populations of disadvantaged people. Reducing the burden of that inequity is a priority on the public health agenda. Health policy planners will need to deal with the twin problems of emerging and re-emerging infectious diseases compounded with the problems of non-communicable diseases. Mental depression and Injuries - both intentional and unintentional are fast emerging as leading causes of ill health. It is estimated that by 2020 injuries may rival infectious diseases worldwide in morbidity and mortality. Among infectious diseases malaria, HIV/AIDS and tuberculosis are diseases which continue to pose public health problems due to the microbial evolution - the growing resistance of the disease

producing organisms to anti-microbial drugs and other agents. Increase in international travel, trade (particularly food trade) and tourism mean that many of the deadly disease producing organisms can be rapidly transported from one continent to another. No region or country can therefore be considered safe and protected from infectious diseases. There is need to further strengthen the existing global surveillance and cooperation in the field of infectious diseases.

Even the wealthiest countries may not be able to provide entire populations with every intervention that has medical value. Priorities need to be debated, consensus generated and implemented in a manner conducive to universal access to affordable and effective health care. Priority setting varies from country to country. In Sweden, principles enunciated are human dignity irrespective of personal characteristics and social functions, need and solidarity and cost effectiveness. Innovations in health financing will be needed to achieve stated public health goals as costs of health care are beyond the capability of even wealthy countries. However, leaving the disadvantaged populations to fend for themselves even in capitalistic countries will deny the concepts of health equity which these countries propagate. Health research and development must also be prioritized in the scheme of public health actions planned to provide the means for transforming health concerns into actions. The critical gaps in knowledge and need for products have already been substantially identified. It may be necessary to provide incentives to individuals and institutions to focus research activities in the desired field of health research.

One of the ways of planning action for the future is to look to the past and consider what should have been done if only we could have had foresight. What do we wish that reasonable people had done in the past? When we look at the current conditions of rapid population expansion, environmental degradation, low birth weights, drug use, violence and a multitude of medical and social problems, it is tempted to wish that public health people of the past had acted differently. For example, what if public health people had taken a strong stand on tobacco when it first became obvious that this was a health problem? It was identified as a health problem in the 1930s. Even if America had waited until 1964, when the Surgeon General's report outlined strong proof regarding the role of tobacco in disease, 30 years of sustained effort would have put America in a situation quite different from the one it now finds itself. If decision-making had been based on public health evaluation, without the barriers of political decisions, the effects would have been completely different.

Similarly, there has always been suffering in the long run when public health officials took a local view of problems. Repeatedly reminders are required that public health must take a global perspective knowing that all things are interrelated and that health must be seen to involve all areas of life. Based on these experiences, it may be agreed that all future public health activities would be based on simple norms that programs would be planned from a global viewpoint, with the goal of providing what is best for the largest number of people and that programs would be planned with the longest time span possible.

What is the likely impact of a program on persons living hundreds of years in the future? What is the level of impact? These questions must be considered and rationally answered at the planning stage itself. For example, an episode of diarrhoea in an adult, while extremely annoying may have no long-term impact, whereas such an occurrence in a young child may be the pivotal event leading to death; the child's illness thus would assume greater priority. Similarly, vitamin A deficiency may lead to lifetime blindness, whereas the lack of education may lead to lifetime bondage; therefore, both must be viewed as being of concern. It must however be appreciated that some problems have an impact that can never be repaired. Population growth, the destruction of rain forests and depletion of ozone are examples of conditions that must be attended to no matter what the cost. The bottom line is that, while it would be great to see into the future, a rational step can be taken by looking at what was neglected in the past, to our current regret and making sure that these problems are not shared by the future. Population programs, anti-tobacco programs, alcohol control programs, the reduction of global weapons, the reduction of violence, adequate nutrition and primary education for all children, but especially for females, programs to reduce poverty and to control sexually transmitted diseases and other infectious diseases would be paramount.

It is possible to provide a new vision for public health, where truth and equity propel the decisions and common sense frames the priorities. Health would be seen to involve all aspects of the world. Interventions would benefit this generation as well as those to follow. We could be ideal ancestors while making relatively few changes in the way we operate.

Summary

Public health today is a really a reflection of history of the developed world. An expectation of health & a pre-occupation with it are the hallmarks of modern society. Measures to be adopted by the state to preserve or promote the health of their citizens have also been dominated by politics. The combating of infectious diseases has often seemed the core of public health to be provided by the state. The actual causation of diseases based on personal, social, cultural, political, economic & biological considerations provides reason for differing opinions regarding actions to prevent them. There is an increasing concern for equity in ensuring public health. The public health aspects in terms of clear differentiation of areas which are the responsibility of state/community, application of the concept of inter-sectoral co-ordination & provision of public health services have been refined.

In the developed countries, public health revolves around three main aspects viz. response to an epidemic situation, as a regulatory or 'police' & as a means to provide improvement or better life.

The public health actions to meet an epidemic stemmed from the realization that something could be done under these circumstances by the public. The efforts to contain epidemic diseases did not reflect any sense of obligation to individuals. At stake were mainly the military, commercial & cultural welfares of the state & individuals welfare was only incidental. Regulation of communities for common good, practiced by

western nations were broadly called 'police' action. The concept arose first in Germany & Austria. The gathering & analysis of health data has become a central part of modern public health. New medical knowledge & technological advances didn't necessarily precede the determination to improve the health for all.

Public health has undergone changes in the developed countries mainly in the last two centuries. These can be divided into three phases under the evolution of concepts into :

- Age of liberalism (1790 - 1880)
- Golden age of Public health (1880 - 1970)
- Return to liberalism (1970 onwards)

The achievements of the 20th century revolutionized health & the consequent demographic transition, leading to new patterns of disease. Reducing the burden of inequity is a priority on the public health agenda. Health policy planners need to deal with twin problems of emerging & re-emerging infectious diseases compounded with the problems of non-communicable diseases. Even the wealthiest countries may not be able to provide entire populations with every intervention that has medical value. Priorities need to be set & consensus implemented, to ensure universal access to affordable & effective health care. It is possible to provide a new vision for public health, where truth & equity propel the decisions, & common sense frames the priorities. With relatively few changes in the way we operate, we could benefit both the present & future generations.

Study Exercises

MCQs and Exercises

- (1) The public health aspects in terms of clear differentiation of areas which are the responsibility of state/community have not been refined : True/False
- (2) In the developed countries, public health revolves around the aspects of all except : (a) Response to an epidemic (b) Regulatory or 'police' (c) provide improvement or better life (d) None
- (3) The public health actions to meet an epidemic stemmed from the realization that something could be done under these circumstances by the public : True/False
- (4) Regulation of modes of work & work hours, form part of the 'Police' action. True/False
- (5) Maintaining population statistics doesn't form part of the 'Police' action : True/False
- (6) The concept of medical 'Police' arose first in (a) Germany (b) Scotland (c) Scandinavia (d) Italy
- (7) The Golden age of Public health is : (a)1790-1840 (b)1840-1880 (c) 1880-1970 (d) 1970-2000
- (8) By 2020, injuries may rival infectious diseases worldwide in morbidity & mortality : True/False

Answers : (1) False; (2) d; (3) True; (4) True; (5) False; (6) (a); (7) c; (8) True.

State of Health in the World : Disparities and Divides

Sunil Agrawal

Within the various regions and continents of the world, there is persistence of extreme inequality and disparity both in terms of access to care as well as health outcomes. There are large within country differences in the coverage gap between the poorest and wealthiest population quintiles. In India and Phillipines, the wealthiest groups are three times more likely to receive care than the poorest. In terms of absolute difference, Nigeria has the largest inequity in coverage : the difference between maximum and actual coverage is 45 percentage points larger for the poorest than for the best off population quintile. Some countries, including the formerly socialist Azerbaijan and Turkmenistan, have remarkably small differences by

wealth quintile. Inequalities between population groups are particularly high for maternal and neonatal care, which includes antenatal care and the presence of a skilled attendant at delivery. The difference is smallest for the treatment of sick children and family planning. Global deaths and DALYs figures in 2000 are given in Table - 1.

The Americas, Europeans and western pacific region's life-expectancy at birth is about 23 years more than that of Africa region. IMRs in Africa region is about five times that of America, Europe or Western pacific region. MMR in Africa region is more than ten times that of America and western pacific region where it is about 30 times that of European region. The MMR of south East Asia and eastern Mediterranean region is also about five times that of America, European and western pacific region. Infant Mortality rates among regions also reveal wide variations. This high degree of variation of health indices is itself a reflection of the high variance in the availability of health services in different countries of the region.

WHO Region	Deaths All causes, 2000		DALYs from deaths, All causes 2000	
	Thousands	Percent	Thousands	Percent
African Region	10,681	18.9	357,884	24.4
Regions of Americas	5,911	10.5	145,217	9.9
South East Asia Region	14,467	25.6	418,844	28.5
European region	9,703	17.2	151,223	10.3
Eastern Mediterranean Region	4,156	7.3	136,221	9.3
Western Pacific region	11,636	20.6	257,868	17.6
Globally	56,554	100.0	1,467,257	100.0

Demographic Indicators

Population Statistics (2006)

The global population in the year 2006 was 6580 Million with median age of 28 years. The total population of South East Asia and Western Pacific region are highest and more than double than any other region in the world. Global Population figures as on 2006 are given in Table - 2.

WHO Region	Total Population (000s)	Under 15 (%)	Over 60 (%)	Annual growth rate (%) 1996-2006	Popn in urban areas (%)
African Region	773,791	43	5	2.5	38
Regions of Americas	894,943	26	12	1.3	73
South East Asia Region	1721,049	31	8	1.6	32
European region	887,455	18	19	0.2	73
Eastern Mediterranean Region	540,284	35	6	2.0	49
Western Pacific region	1763,399	22	12	0.8	47

Age Distribution : Worldwide under 15 yrs population is 28% and about 10% population is of >60 yrs age group. However, annual growth worldwide has declined from 1.6 to 1.3 with decline in all the regions of WHO.

Infant Mortality Rate (IMR) : The global IMR is 49/1000 live births (Male-51, Female-47). For last two decades there is steady decline in IMR in all the regions of WHO. The major decline was seen in European region where it has declined from 81 to 14 per 1000 live births. It shows wide regional and inter country variation with countries like Afghanistan, Angola, Nigeria, Liberia, Sierra Leone having IMR of >150/1000 live births whereas, countries like Andorra, Cyprus, Czech republic, Denmark, Finland, Iceland, Italy, Japan, Luxembourg, Monaco, Norway, Portugal, San Marino, Singapore, Sweden have very low IMR of <=3/1000 live births. Neonatal mortality (at 28 per 1,000 live births) constitutes nearly 60%-65% of the IMR in various countries. Concerted efforts will be required under Home Based Neonatal Care (HBNC) to reduce the IMR and Neonatal Mortality Rate (NMR) further. Global statistics on IMR is given in Table - 3.

Neonatal Mortality : An estimated 4 million deaths occur during the first 28 days of life, accounting for 38% of all deaths of children under five. Causes include infections (36%), preterm birth (27%) and asphyxia (23%). Intensive care is not required to save most of the babies. Developed countries and some low income countries for e.g. Sri Lanka, have achieved neonatal mortality rates of 15 per 1000 without intensive care, which is less than a third of current neonatal mortality rates in Sub Saharan Africa.

Interventions like breast feeding, extra care of moderately small babies, cleanliness, warmth, community based management of acute respiratory and acute diarrhoeal diseases along with standard maternal and child health package is likely to be highly effective.

Childhood Illnesses and Mortality among Children under Five : Neonatal mortality rates and mortality rates for children under 5 can be reduced by large margins, at an affordable cost, by using interventions proven effective in low income settings. Improvements are likely to come from increasing the coverage of preventive measures, such as breast feeding and from expanding the scope of existing childhood vaccines beyond the traditional six antigens in areas where existing coverage is relatively high and where new antigens address diseases of significant burden, particularly pneumococcal vaccines. Curative interventions include case management of ARIs, malaria and acute diarrhoeal diseases which hold promise for lowering the 6 million preventable deaths each year in this age group. Global statistics on under 5 mortality rate is given in Table - 4.

Maternal Mortality Ratio (MMR) : The target for monitoring progress towards Millennium Development Goal 5 (MDG 5) (improve maternal health) is to reduce the maternal mortality ratio in all countries so that by 2015 it is one quarter of its 1990 level. The latest estimate is that 536000 women died in 2005 as a result of complications of pregnancy and child birth and that 400 mothers died for every 100 000 live births. The maternal mortality ratio was 9 in developed countries, 450 in developing countries and 900 in sub Saharan Africa.

WHO Region	Males			Females			Both Sexes

WHO Region	Males			Females			Both Sexes		
	1990	2000	2006	1990	2000	2006	1990	2000	2006
African Region	49	49	50	52	52	52	51	50	51
Region of the Americas	68	70	72	74	77	78	71	73	75
South East Asia Region	58	61	63	59	63	65	58	62	64
European Region	59	68	70	61	76	78	60	72	74
Eastern Mediterranean Region	67	61	63	74	64	66	70	63	64
Western Pacific Region	42	32	22	50	39	25	46	35	24

This means that 99% of the women who died in pregnancy and childbirth were from developing countries. Slightly more than half of these deaths occurred in sub Saharan Africa and about a third in southern Asia; together these regions accounted for over 85% of maternal deaths worldwide.

Meeting the MDG target for maternal mortality requires a decline in the maternal mortality ratio by around 5.5% each year. No region in the world has achieved this result. Globally the maternal mortality ratio showed a total fall of 5.4% in the 15 years between 1990 and 2005, an average reduction of 0.4% each year. The present MMR is 400 per 1,00,000 live births (2005) (WHS, 2008). Levels of maternal mortality vary greatly across the regions due to variation in access to emergency obstetrical care, prenatal care, anaemia rates among women,

education level of women and other factors. The MMR in regions like Africa, South East Asia and Eastern Mediterranean Region contribute maximum MMR of 900, 450 and 420 per 1,00,000 live births respectively. The maximum MMR is found in Sierra Leone, Afghanistan, Nigeria etc with around 2000 per 1,00,000 live births.

Total fertility rate (TFR), per women at Global level is 2.6, with high rates in Africa region (4.7) and Eastern Mediterranean region (3.5). However, there is constant decline in TFR all over world in last two decades.

Life Expectancy at birth : Average life expectancy in low and middle income countries increased dramatically in the past half century, while cross country health inequalities decreased. In the countries with the best health indicators, life expectancy

increased a substantial two and one half years per decade since 1960 and low and middle income countries on an average, had life expectancy gains of about five years per decade. Average life expectancy at birth 50 years ago was 38 years in sub Saharan Africa, 41 years in Asia, 45 years in the Middle East, 51 years in Latin America and the Caribbean and 60 years in Oceania. Over the following 50 years, average life expectancy at birth improved all over the world, increasing by almost 27 years in Asia, 23 years in the Middle East, 21 years in Latin America, 14 years in Oceania and 11 years in sub Saharan Africa.

Improvement in average income, education levels, generation and diffusion of new knowledge, low cost appropriate technologies etc contributed to these worldwide gains in health.

In SE Asian region both male and female Life Expectancy since 1990 has been steadily increasing, whereas, in eastern Mediterranean region it has actually declined. Increasing life expectancy is leading to increasing number of elderly persons in the population for which specific health facilities will need to be provided. Global statistics of life expectancy at birth is given in Table - 5.

Socioeconomic Indicators

Education

Literacy rate has increased by 10.6% during last decade (1990-2000). The global adult literacy rate is 78.4%. Many countries have Literacy rate above 95% like Bulgaria, Chile, Croatia, Cuba, Greece, Maldives, Mongolia, Ukraine while some countries like Mali, Nigeria, Afghanistan have literacy rate < 30% (Table-6).

WHO Region	Adult Literacy Rate (%) 1990-1999	Adult Literacy Rate (%) 2000-2005
African Region	51.8	59.3
Region of the Americas	-	-
South East Asia Region	52.0	66.8
European Region	-	-
Eastern Mediterranean Region	53.4	64.4
Western Pacific Region	79.1	90.7

Total Expenditure on Health as % of Gross Domestic Product

The various mortality and morbidity indicators are inversely proportional to the total expenditure on health as % of gross domestic product. The regions which have high expenditure show low levels of morbidity and mortality indicators (Table - 7).

WHO Region	Total expenditure on health as % of gross domestic product 2000	Total expenditure on health as % of gross domestic product 2005
African Region	5.8	5.9
Region of the Americas	11.3	12.7
South East Asia Region	3.5	4.0
European Region	8.0	8.6
Eastern Mediterranean Region	4.5	4.9
Western Pacific Region	5.7	5.8

Drinking Water and Sanitation

The percentage of population having access to safe drinking water facility and access to improved sanitation in both urban and rural areas are given in Table - 8.

Globally 86% of the population has access to improved drinking water whereas only 60% of population has access to improved sanitation. However, same has increased marginally in last two decades. Access to improved drinking water has increased from 95% to 96% in urban areas and from 62% to 78% in rural areas, whereas improved sanitation has increased from 76% to 78% in urban areas and from 34% to 44% in rural areas globally.

Health Status Indicators

Communicable Diseases Morbidity

Tuberculosis : Tuberculosis had an estimated 8.8 million new

WHO Region	Access to improved drinking water source (%)			Access to improved sanitation (%)		
	Urban	Rural	Total	Urban	Rural	Total
African Region	82	46	59	46	26	33
Region of the Americas	98	81	94	92	68	87
South East Asia Region	94	84	87	58	27	37
European Region	100	92	97	97	85	92
Eastern Mediterranean Region	93	75	82	85	43	60
Western Pacific Region	98	82	89	79	61	69

cases in 2003, fewer than half of which were reported to public health authorities and WHO. Approximately 3.9 million cases were sputum smear positive. The African region has the highest estimated incidence rate (345 per 1,00,000 population), but the most populous countries of Asia harbor the largest number of cases : Bangladesh, China, India, Indonesia and Pakistan together account for half the new cases arising each year.

Globally, 12 percent of new adult tuberculosis cases were infected with HIV in 2003, but there was marked variation among regions-from an estimated 33 percent in Sub Saharan Africa to 2 percent in East Asia and the Pacific. Approximately 1.7 million people died of TB in 2003, including 229,000 patients who were also infected with HIV.

HIV/AIDS : HIV/AIDS is one of the most urgent threats to global public health. The number of people living with HIV worldwide in 2007 was estimated at 33.2 million. Sub Saharan Africa continues to be the region most affected by HIV/AIDS. In 2007, one in every three people in the world living with HIV lived in sub Saharan Africa, a total of 22.5 million. Although other regions are less severely affected, 4 million people in South and South East Asia and 1.6 million in Eastern Europe and Central Asia were living with HIV/AIDS.

Although the total number of people living with HIV has increased significantly over the years, the proportion infected has not changed since the end of 1990s. In fact, the number of people who become infected every day (6800) is greater than the number who die of the disease (around 6000). Worldwide, 0.8% of the adult population (aged 15-49 years) is estimated to be infected with HIV, with a range of 0.7-0.9%. In sub Saharan Africa, the estimated proportion of the population infected has actually fallen steadily since 2000. Current data indicate that HIV prevalence reached a peak of nearly 6% around 2000 and fell to about 5% in 2007.

Leprosy : At the global level the prevalence rate of less than 1 per 10,000 has been achieved which were known as elimination levels for Leprosy. The number of cases registered for treatment worldwide fell from 5.4 million in 1985 to 460,000 by the end of 2003. Leprosy is reported from all regions of the world, but the burden of disease, which is estimated at 192,000 DALYs is concentrated in few countries. During 2003, 513,798 new cases were detected of which more than 80 percent were in Brazil, India, Madagascar, Mozambique, Nepal and Tanzania. India alone accounted for 75 percent of the new cases.

Communicable Diseases Mortality

The maximum mortality due to HIV/AIDS was in African region, where HIV/AIDS is still one of the highest cause of mortality (203 deaths per lac population) whereas western pacific region had minimum mortality due to HIV/AIDS with 4 deaths per 1,00,000 population. However, deaths worldwide from HIV/AIDS are expected to rise from 2.2 million in 2008 to a maximum of 2.4 million in 2012 before declining to 1.2 million in 2030.

Malaria is endemic in many of the world's poorest countries. Malaria indicator surveys show important within country disparities showing that children living in wealthiest households are better protected by bed nets; they have a lower chance of carrying malaria parasite and when they fall sick they are more likely to be treated with antimalarial medication. Proportional Mortality Ratio among children aged < 5 years (%) is given in Table - 9.

Non Communicable Diseases

Cardiovascular disease (CVD) : At the beginning of the 20th century, CVD was responsible for less than 10 percent of all deaths worldwide, but by 2001 that figure was 30 percent. About 80 percent of the global burden of CVD death occurs in low and middle income countries. Cardiovascular disease is the number one cause of death worldwide. CVD covers wide array of disorders, including diseases of the cardiac muscle and of the vascular system supplying the heart, brain and other vital organs.

Murray and Lopez (1996) predicted that CVD will be the leading cause of death and disability worldwide by 2020 mainly because it will increase in low and middle income countries.

Cancer : Globally, cancer is one of the top ten leading causes of death. It is estimated that 7.4 million people died of cancer in 2004 and, if current trends continue, 83.2 million more would have died by 2015. Among women, breast cancer is the most common cause of cancer mortality, accounting for 16% of cancer deaths in adult women. In developing countries, the top five female cancers in rank order of incidence are breast, cervical, stomach, lung and colorectal cancer and the top five male cancers are lung, stomach, liver, esophageal and colorectal cancer.

Diabetes : In 2003, the worldwide prevalence of diabetes was estimated at 5.1 percent among people aged 20 to 79. The prevalence of diabetes was higher in developed countries than

Table - 9 : Proportional Mortality Ratio among children aged < 5 years (%).

WHO Region	Neonatal causes	HIV/AIDS	Diarrhoea	Measles	Malaria	Pneumonia	Injuries	Others
African Region	26.2	6.8	16.6	4.3	17.5	21.1	1.9	5.6
Region of the Americas	43.7	1.4	10.1	0.1	0.4	11.6	4.9	27.9
South East Asia Region	44.4	0.6	20.1	3.5	1.1	18.1	2.3	9.9
European Region	44.3	0.2	10.2	0.1	0.5	13.1	6.2	25.4
Eastern Mediterranean Region	43.4	0.4	14.6	3.0	2.9	19.0	3.2	13.5
Western Pacific Region	47.0	0.3	12.0	0.8	0.4	13.8	7.3	18.4

in developing countries. In the developing world, the prevalence was highest in Europe and Central Asia and lowest in Sub Saharan Africa. In 2003, 194 million people worldwide aged 20-79 years had diabetes and by 2025 the number is projected to increase to 333 million, a 72 percent increase. During the same period, the number of people with diabetes is projected to double in three of the six developing regions : the Middle East and North Africa, South Asia and Sub Saharan Africa.

The WHO estimates that, in 2001, 959,000 deaths worldwide were caused by diabetes, accounting for 1.6 percent of all deaths and approximately 3 percent of all deaths were caused by non-communicable diseases. Also in 2001, diabetes resulted in 19,996,000 disability adjusted life years (DALYs) worldwide. More than 80 percent of the DALYs resulting from diabetes were in developing countries.

Reproductive & Child Health

Globally 65% births were attended by skilled health personnel (Doctor/Nurse/Other health worker) in 2000-2006 which is marginally more than 61% during 1990-1999. The births attended by skilled health personnel were maximum in Regions of America, European region and western pacific region with >90% whereas African region and South East Asia region had only <50% births attended by skilled health personnel. This contributes immensely to high infant mortality rates and high maternal mortality rates in these regions. Similarly, there are wide variations in the nutritional status of children as given in Table - 10 :

WHO Region	Low birth weight newborns (%) 2000-2002	Children aged <5 years (%) 2000-2006	
		Stunted for age	Underweight for age
African Region	14	43.3	23.0
Region of the Americas	9	13.7	3.9
South East Asia Region	26	42.0	32.8
European Region	8	-	-
Eastern Mediterranean Region	17	25.6	15.5
Western Pacific Region	8	15.3	6.7

Contraceptive use : Percentage of people using contraceptives in world is 63.3% in the year 2000-2006 using any contraceptive methods. There is a great variation in Contraceptive prevalence within the regions of WHO as per the Table -11.

Child immunization coverage : The immunization coverage among 1 year old was around 80% for both DPT and Measles in the year 2006 world wide. There were great regional differences with American region, European region and Western Pacific

region more than 90% whereas African region (73%) and South East Asia region (65%) had low immunization coverage. The immunization coverage of Eastern Mediterranean Region was around 86%. The immunization coverage in all the regions has shown an impressive improvement in last two decades, however, in South East Asia region the coverage has gone down for DPT from 70% in 1990 to 63% in 2006.

WHO Region	Contraceptive Prevalence (%)
African Region	24.4
Region of the Americas	70.0
South East Asia Region	57.2
European Region	-
Eastern Mediterranean Region	43.0
Western Pacific Region	85.5

The immunization coverage is seen less than 50% in countries like Angola, Central African Republic, Nigeria and Somalia. The greatest burden of vaccine preventable diseases is in Sub Saharan Africa, which accounts for 58 percent of Pertussis deaths, 41 percent of Tetanus deaths, 59 percent of Measles deaths and 80 percent of Yellow Fever deaths. East Asia and the Pacific has the greatest burden from hepatitis B with 62 percent of deaths worldwide. South Asia also experienced a high disease burden, particularly from tetanus and measles.

Risk Factors : Tobacco use is the single largest cause of preventable death in the world today. Tobacco kills a third to a half of all those who use it. On average, every user of tobacco loses 15 years of life. Total tobacco attributable deaths from ischemic heart disease, cerebrovascular disease (stroke), chronic obstructive pulmonary disease and other diseases are projected to rise from 5.4 million in 2004 to 8.3 million in 2030, almost 10 percent of all deaths worldwide. More than 80 percent of these deaths will occur in developing countries.

Tobacco use is highly prevalent in many countries. According to estimates for 2005, 22 percent of adults worldwide currently smoke tobacco. Some 36 percent of men smoke compared to 8 percent of women. Over a third of adult men and women in eastern and central Europe currently smoke tobacco. Adult smoking prevalence is also high in South East Asia and northern and western parts of Europe. However, nearly 2/3rd of the worlds smokers live in just 10 countries : Bangladesh, Brazil, China, Germany, India, Indonesia, Japan, the Russian federation, Turkey and the United States, which collectively comprise about 58 percent of the global population (Table-12).

Health System Resources

Globally, the density of physicians per 10,000 population is 13 whereas density for nurse and midwifery is 28 per 10,000 population. The density of dentistry personnel is 3, pharmaceutical personnel is 4, community & traditional health workers is 1, laboratory health workers is 3 and other health

service providers is 18 per 10,000 population (Table-13).

Table - 12 : Alcohol and current tobacco use among adults aged ≥ 15 years

WHO Region	Alcohol consumption adults aged ≥ 15 years (litres/person)	Prevalence of current tobacco use among adults aged ≥ 15 years (%)		
		Male	Female	Both sexes
African Region	4.09	17.3	2.8	10.1
Region of the Americas	6.66	30.1	18.7	24.6
South East Asia Region	0.51	39.1	4.6	21.9
European Region	8.84	44.4	23.2	34.1
Eastern Mediterranean Region	0.19	32.7	4.5	18.4
Western Pacific Region	5.18	55.7	5.0	30.5

Table - 13 : Health workforce and hospital beds (per 10,000 population)

WHO Region	Health Workforce		Hospital Beds
	Physicians density	Nurse density	
African Region	2	11	9
Region of the Americas	19	49	24
South East Asia Region	5	12	-
European Region	32	78	63
Eastern Mediterranean Region	10	15	14
Western Pacific Region	14	20	33

Health Service Coverage

Coverage is defined as the percentage of people receiving a specific intervention among those who need it, is a key health system output and an essential indicator for monitoring health service performance. The coverage gap is an aggregate index of the difference between observed and 'ideal' or universal coverage in four intervention areas : family planning, maternal and neonatal care, immunization and treatment of sick children. Estimates from the most recent surveys showed that the mean overall gap across all 54 countries was 43%, with values for individual countries ranging from more than 70% in Chad and Ethiopia to less than 20% in Peru and Turkmenistan. In 18 of the 54 countries, the gap was 50% or more; it was between 30% and 49% in 29 countries and less than 30% in the remaining 7

countries.

The percentage of births attended by skilled health personnel is highest in European region with 96% whereas, in African and South East Asia region it is less than 50%. Globally 65% of births are attended by skilled health personnel which are 4% more than 1990-1999 figures (Table - 14).

Table - 14 : Global situation of attended births and protection against neonatal tetanus

WHO Region	Births attended by skilled health personnel (%) 2000-2006	Neonates protected at birth (PAB) against neonatal tetanus (%) 2006
African Region	44	74
Region of the Americas	92	83
South East Asia Region	48	86
European Region	96	68
Eastern Mediterranean Region	63	82
Western Pacific Region	92	75

Worldwide, percentage of neonates protected at birth against neonatal tetanus is 81% which has increased by more than 10% in last 15 years. Surprisingly, the percentage of children protected at birth against neonatal tetanus is lowest in European region.

In view of modern pandemic of HIV and Tuberculosis, another indicator of health services coverage is ART coverage and Tuberculosis detection rate and treatment success rate. Worldwide, only 22% of people with advanced HIV infection have access to anti retroviral therapy. This coverage is highest in America with 58% and lowest in eastern Mediterranean region with just 4%.

Table - 15 : ART coverage, TB detection rate and TB treatment success under DOTS

WHO Region	ART Coverage (%) of People with advanced HIV infections (2006)	TB detection rate under DOTS (%) 2006	TB treatment success under DOTS (%) 2005
African Region	21	46	76
Region of the Americas	58	69	78
South East Asia Region	17	67	87
European Region	13	52	70
Eastern Mediterranean Region	4	52	83
Western Pacific Region	23	77	92

The TB detection rate and treatment success under DOTS is about 61 percent and 85 percent respectively in the world. The TB detection rate under DOTS has drastically improved from 11 percent in 1995 to 28 percent in 2000 and now 61 percent in 2006. In spite of DOTS programme implemented more than a decade back the treatment success rate has marginally improved from 79 percent in 1995 to 85 percent in 2005 (Table-15).

Summary

Within the various regions and continents of the world, there is persistence of extreme inequality and disparity both in terms of access to care as well as health outcomes. The global population in the year 2006 was 6580 Million with median age of 28 years. Worldwide under 15 yrs population is 28% and about 10% population is of >60 yrs age group. However, annual growth worldwide has declined from 1.6 to 1.3 with decline in all the regions of WHO. The global IMR is 49/1000 live births (Male-51, Female-47). An estimated 4 million deaths occur during the first 28 days of life, accounting for 38% of all deaths of children under five. Total fertility rate (TFR), per women at Global level is 2.6, with high rates in Africa region (4.7) and Eastern Mediterranean region (3.5). However, there is constant decline in TFR all over world in last two decades. Average life expectancy in low and middle income countries increased dramatically in the past half century, while cross country health inequalities decreased.

Literacy rate has increased by 10.6% during last decade (1990-2000). The global adult literacy rate is 78.4%. The various mortality and morbidity indicators are inversely proportional to the total expenditure on health as % of gross domestic product. In 2005, while the American region spends 12.7%, South-East Asia spends only 4%. Globally 86% of the population has access to improved drinking water whereas only 60% of population has access to improved sanitation. However, same has increased marginally in last two decades.

Tuberculosis had an estimated 8.8 million new cases in 2003, fewer than half of which were reported to public health authorities and WHO. Approximately 3.9 million cases were sputum smear positive. Approximately 1.7 million people died of TB in 2003, including 229,000 patients who were also infected with HIV. The number of people living with HIV worldwide in 2007 was estimated at 33.2 million. Worldwide, 0.8% of the adult population (aged 15-49 years) is estimated to be infected with HIV. HIV prevalence in Sub Saharan countries reached a peak of nearly 6% around 2000 and fell to about 5% in 2007. Deaths worldwide from HIV/AIDS are expected to rise from 2.2 million in 2008 to a maximum of 2.4 million in 2012 before declining to 1.2 million in 2030. At the global level the prevalence rate of Leprosy of less than 1 per 10,000 has been achieved which were known as elimination levels for Leprosy. Malaria is endemic in many of the world's poorest countries.

At the beginning of the 20th century, CVD was responsible for less than 10 percent of all deaths worldwide, but by 2001 that figure was 30 percent. Cardiovascular disease is the number one cause of death worldwide. Globally, cancer is one of the top ten leading causes of death. It is estimated that 7.4 million people died of cancer in 2004 and, if current trends continue, 83.2 million more would have died by 2015. In 2003, the worldwide prevalence of diabetes was estimated at 5.1 percent among people age 20 to 79. Tobacco use is highly prevalent in many countries. According to estimates for 2005, 22 percent of adults worldwide currently smoke tobacco. Some 36 percent of men smoke compared to 8 percent of women. Over a third of adult men and women in eastern and central Europe currently smoke tobacco.

Globally 65% births were attended by skilled health personnel in 2000-2006. Percentage of people using any contraceptives in world is 63.3% in the year 2000-2006. The immunization coverage among 1 year old was around 80% for both DPT and Measles in the year 2006 world wide. The immunization coverage in all the regions has shown an impressive improvement in last two decades, however, in South East Asia region the coverage has gone down for DPT from 70% in 1990 to 63% in 2006. Globally, the density of physicians per 10,000 population is 13 whereas density for nurse and midwifery is 28 per 10,000 population.

Study Exercises

MCQs

1. Currently, the annual growth rate worldwide is (a) 1 (b) 1.3 (c) 1.9 (d) 2.
2. The global IMR is (/1000 live births) (a) 40 (b) 49 (c) 59 (d) 39.
3. Total fertility rate (TFR) per women at Global level is (a) 2.6 (b) 2 (c) 2.9 (d) 3.
4. The global adult literacy rate is (a) 70.2% (b) 78.4% (c) 80.9% (d) 62.9%.
5. Globally, the percentage of population having access to improved sanitation is (a) 60 (b) 80 (c) 86 (d) 72.
6. In 2003, the worldwide prevalence of diabetes was estimated to be (a) 15% (b) 10.1% (c) 5.1% (d) 12%.
7. HIV prevalence worldwide in 2007 is (a) 2% (b) 5% (c) 10% (d) 28%.
8. The immunization coverage among 1 year old for both DPT and Measles in the year 2006 world wide was around (a) 60% (b) 70% (c) 80% (d) 92%.
9. Globally, the density of physicians per 10,000 population is (a) 16 (b) 10 (c) 11 (d) 13.

Answers : (1) b; (2) b; (3) a; (4) b; (5) a; (6) c; (7) b; (8) c; (9) d.

Sunil Agrawal

India has 28 states and 7 Union Territories. There are 593 districts, 5470 sub districts and 5161 towns. There are 638588 villages. India is the second most populous country of the world after China and has changing socio-political-demographic and morbidity patterns that have been drawing global attention in recent years. Despite several growth-orientated policies adopted by the government, the widening economic, regional and gender disparities are posing challenges for the health sector. About 75% of health infrastructure, medical man power and other health resources are concentrated in urban areas where 27% of the population live.

Disparities and Divides

Interstate

Within the country, there is persistence of extreme inequality and disparity both in terms of access to care as well as health outcomes. Kerala's life-expectancy at birth is about 10 years more than that of Madhya Pradesh and Assam. IMRs in Madhya Pradesh and Orissa are more than five times that of Kerala. MMR in Uttar Pradesh is more than four times that of Kerala and more than three times that of Haryana. Crude death rates among states also reveal wide variations. Crude death rates in Orissa and Madhya Pradesh are more than twice the crude death rates in Delhi and Nagaland. This high degree of variation of health indices is itself a reflection of the high variance in the availability of health services in different parts of the country.

Rural/Urban

Public health care system in rural areas in many states and regions leaves a lot to be desired. Extreme inequalities and disparities persist both in terms of access to health care as well as health outcomes (Table-1). This large disparity across India places the burden on the poor, especially women, scheduled castes, scheduled tribes and other tribal / disadvantaged groups. Inequity is also reflected in the availability of public resources between the advanced and less developed states.

Table - 1 : Urban/Rural Health Indicators

	Crude Birth Rate (per 1000)	Crude Death Rate (per 1000)	IMR (per 1000 live births)	Prevalence of Anaemia among Children (6-35 months) (%)	Prevalence of Anaemia among Pregnant Women (%)
Urban	19.1	6.0	40	72.7	54.6
Rural	25.6	8.1	64	81.2	59.0
Total	23.8	7.6	58	79.2	57.9

Source : Ministry of Health & Family Welfare (GOI), 2006 & NFHS 3, IIPS (2005-06).

The current available data regarding health status and health services in the country obtained from a range of reliable sources and surveys. The data can be grouped under the headings of Demographic, Socioeconomic, mortality, morbidity and other Health status indicators.

Demographic Indicators

Demographic indicators will give an overview of country's population size, its composition, territorial distribution, changes therein and the components of changes such as natality, mortality and social mobility. Demographic indicators can be divided into two parts -

- Population statistics : Include indicators that measure the population size, sex ratio, density and dependency ratio.
- Vital statistics : Include indicators such as birth rate, death rate and natural growth rate, life expectancy at birth, mortality and fertility rates.

Population Statistics (Census 2001)

India accounts for a meager 2.4% of the total world surface area, yet it supports and sustains 16.7% of the world population. India's population on 1st March 2001 (census of India) was 10286 lakhs (5322 lakhs males & 4964 lakhs females) which has increased from 8464.2 lakhs estimated during 1991 census (Fig. - 1). However, there is decrease in Decennial Change (%) & Average Annual Exponential Growth Rates compared to corresponding growth rates during previous decades. Projected population for 2016 is 12689.61 lakhs; a 40% of this increase will occur in four states mainly i.e. UP, Bihar, MP and Maharashtra.

Sex Ratio : Sex Ratio is 933 female/1000 male [for last four decades it is around 930 (1971- 930, 1981- 934, 1999- 926, 2001- 933)]. It is lowest in Daman & Diu (710) followed by Chandigarh (770) & highest in Kerala (1058).

Population Density : Population Density is 325/sq.km. Urban Population is 27.8% of total population. Urban migration over last decade resulted in rapid growth of urban slums. It varies from 13/sq.km in Arunachal Pradesh to 903/sq.km in

West Bengal. UTs like Delhi (9340/sq.km) & Chandigarh (7900/sq.km) have highest population density.

Age Distribution : It is 34.2% in 0-14 age group & 7.5% in 60 plus age group. Kerala has got highest percentage of elderly people (11%) whereas Delhi has just 5% of its total population as elderly.

Birth & Death Rates : Overall UP has got highest birth rate (30). States like Goa & HP have lowest birth rate. MP has highest rural birth rate (31.2). Death Rate is highest in Orissa (9.3). It is higher in rural areas as compared to urban areas. Projected crude death rate is 7.2 / 1000 population. There is not going to be much change in death rate in next 20 years. The birth and death rates of India are given in Table - 2.

	1993	2006 (Total)	2006 (Urban)	2006 (Rural)
Birth Rate	28.7	23.5	25.2	25.2
Death Rate	9.3	7.5	6.0	8.1
Growth Rate	19.4	16.0	12.8	17.2

Life Expectancy at birth : Female Life Expectancy in 1997-2001 was 63.6 then it decreased to 63.3 in 1998-2002 & from thereafter it is steadily increasing, whereas Male Life Expectancy is steadily increasing. Projected value for life expectancy for 2021-25 is 69.8 for males & 72.3 for females. Projected overall life expectancy is 69.8. Increasing life expectancy is leading to increasing numbers of elderly persons in the population for which specific health facilities will need to be provided. The life expectancy at birth is given in Table - 3.

	1991-95	2001-05
Males	59.7	62.3
Females	60.9	63.9

Source : Registrar General of India

Vital Statistics

Infant Mortality Rate (IMR) : IMR is 57/1000 live births (Rural-62, Urban-39). For last three years decline in IMR was minimal, whereas it had shown steady decline from 1998 till 2004. It shows wide inter-state variations, with states like Assam, Bihar, Chhattisgarh, MP, Orissa, Rajasthan & UP having high IMR. MP tops the list with 74 whereas minimum IMR of 11 is in Manipur. Neonatal mortality (at 37/1,000 live births) constitutes nearly 60-75% of the IMR in various states. Concerted efforts will be required under Home Based Neonatal Care (HBNC) to reduce the IMR & Neonatal Mortality Rate (NMR) further. The trends of IMR are shown in Fig. - 2.

Maternal Mortality Ratio (MMR) : The present MMR is 301 per 1,00,000 live births (2001-2003) (RGI, 2006). The trends are shown in Fig. - 3. Levels of maternal mortality vary greatly across the regions due to variation in access to emergency obstetrical care, prenatal care, anaemia rates among women, education level of women, and other factors. The MMR in states

like UP, Rajasthan, Orissa, MP, Assam, Bihar are maximum and U.P. has contributed maximum MMR of 539 per 1,00,000 live births.

Total Fertility Rate (TFR) : TFR at national level is 2.9, Rural (3.2) and urban (2.1). Bihar (4.4 & 3.2), MP (4&2.5), Rajasthan (4.0 & 2.7) and UP (4.5 & 3.3) are states with high total fertility rate.

Socioeconomic Indicators

Socioeconomic indicators provides data on education, gender, poverty, housing amenities, employment and other economic indicators which help in understanding the health scenario of a country.

Literacy Rate

Literacy rate has increased by 13.86% during last decade (1991-2001) and it is 64.8% among population aged 7 yrs and above, according to census-2001. Literacy rate among males is 75.3% while among female it is 53.7%. Kerala and Mizoram have highest literacy rates of 90.9% and 88.8% respectively and Bihar and UP are least with 47% and 56% respectively (Fig. - 4).

Mean Age at Marriage

The mean age at effective marriage of females is 20.20 years. The break-up is 19.7 years in rural and 21.7 years in urban areas.

India in the International Scenario

The comparative picture with regard to health indicators such as life expectancy, Total Fertility Rate (TFR), Infant Mortality Rate (IMR), and Maternal Mortality Ratio (MMR) points that countries placed in almost similar situation such as Indonesia, Sri Lanka, and China have performed much better than India. The health indicators among selected countries are given in Table - 4.

Fig. - 4 : Percentage of literates (Major states)

Table - 4 : Health Indicators among Selected Countries

Country	Infant Mortality (per 1000 live births)	Life Expectancy M/F	Maternal Mortality Ratio	Total Fertility Rate
India	58	63.9 / 66.9*	301	2.9
China	32	70.6 / 74.2	56	1.72
Japan	3	78.9 / 86.1	10	1.35
Republic of Korea	3	74.2 / 81.5	20	1.19
Indonesia	36	66.2 / 69.9	230	2.25
Malaysia	9	71.6 / 76.2	41	2.71
Vietnam	27	69.5 / 73.5	130	2.19
Bangladesh	52	63.3 / 65.1	380	3.04
Nepal	58	62.4 / 63.4	740	3.40
Pakistan	73	64.0 / 64.3	500	3.87
Sri Lanka	15	72.2 / 77.5	92	1.89

*Projected (2001-06)

Source : India - RGI, Govt. of India (Latest Figures); Others - State of World Population, 2006.

Economic Indicators

Population Living Below Poverty Line (BPL)

The percentage of the population living below the poverty line decreased from 55% in 1973-74 to 36% in 1993-94. However, still there are 27.5% of population living below poverty line

in India in 2004-05. 28.3% of population in rural & 25.7% in urban areas live below poverty line according to planning commission estimates for the year 2004-2005. In Orissa 46.8% of population in rural area & 44.3% of population in urban area is BPL.

Gross National Product (GNP)

GNP for the year 2006-07 was INR 37,60,285 crore at current price & Rs 28,45,155 crore at constant price.

Employment

Total 26.5 million people are employed in organized sector, out of which 17.6 million in public and 8.8 million in private sector which is only 4.4% of population in age group 15-59. According to census 2001 there are total 40,22,34,724 workers i.e. 39% of total population.

Housing and Amenities

According to 2001 census there are 19,19,63,935 households which gives average of 5.36 persons per households and out of which only 51.79% households are permanent. Total 55.85% of these houses have electricity (Rural 43.58%, Urban 87.58%). There is wide variation between states; Goa, HP, Punjab, Chandigarh, Daman & Diu and Lakshwadweep have electricity in more than 90% of houses whereas states like Bihar and Jharkhand have only 5.13% and 9.99% of houses having electricity in rural areas.

Most of the houses in rural areas have no drainage (14.26%-73.38%) and less than 5% of houses have got closed drainage in rural areas. The availability of sanitary toilet within the house is also a rare commodity with 79.5% of rural Orissa being without toilets. In urban areas the Union Territories like Pondicherry, Delhi, Chandigarh and states like Maharashtra, Goa and Tamil Nadu do not have toilets in 15 to 25% of houses.

Safe Drinking Water Facilities

The percentage of households having safe drinking water facility in India has improved over the last decade. States like Punjab and Haryana have more than 90% population having access to safe drinking water, both in urban as well as rural areas (Table - 5).

Table - 5 : Safe drinking water facilities in India

	1991	2001
Rural	55.5	73.2
Urban	81.4	90.0
Total	62.3	77.9

Health Status Indicators

India is in the midst of an epidemiological and demographic transition with increasing burden of chronic diseases, decline in mortality and fertility rates, and ageing of the population. While communicable diseases as malaria, tuberculosis, HIV-AIDS, diarrhoeal diseases and ARIs are continuing to be major issues, Non-communicable diseases such as cardiovascular diseases, cancer, blindness, mental illness, etc. are also imposing increasing burden on the already over-stretched health care system of the country.

Communicable Diseases

Among the various communicable diseases the following diseases accounted for the maximum number of cases during 2007 (Table - 6)

Disease	No. of cases (2007)
Acute Respiratory Infections (ARI)	2,33,79,578
Acute Diarrhoeal Diseases (ADD)	94,78,813
Malaria	13,63,279
Pulm TB	7,20,395
Enteric Fever	6,94,862
Pneumonia	6,60,392
Gonococcal	1,53,050
Viral Hepatitis	97,827

Tuberculosis remains a public health problem, with India accounting for one-fifth of the world incidence. Every year 1.47 million people in India develop tuberculosis, of which 0.8 million are infectious smear positive cases. The emergence of HIV-TB co-infection and multi drug resistant tuberculosis has increased the severity and magnitude of the problem. Revised National Tuberculosis Control Programme (RNTCP) has achieved nation wide coverage in March 2006. Since the inception of the programme, over 6.3 million patients have been initiated on treatment.

National Vector Borne Disease Control Programme was initiated during 10th Plan with the convergence of on-going programmes on malaria, kala-azar, filariasis, Japanese encephalitis and dengue. Malaria cases in India declined from 3.04 in 1996 to 1.36 million cases in the year 2007. The number of *Plasmodium falciparum* (Pf) cases has also been decreasing. More than 80% of malaria cases and deaths are reported from North Eastern (NE) States, Chhattisgarh, Jharkhand, Madhya Pradesh, Orissa, Andhra Pradesh, Maharashtra, Gujarat, Rajasthan, West Bengal, and Karnataka. Under the Enhanced Malaria Control Project (EMCP), 100% support was provided in 100 districts of 8 states, predominantly inhabited by tribal population. These areas reported a 45% decline in malaria cases.

Dengue fever and Chikungunya are emerging as major threats in urban, peri-urban, and rural areas in many states/UTs. There were 56355 suspected cases out of which 1876 confirmed cases of Chikungunya in 2007 as compared to 13,90,322 suspected and 2001 confirmed cases in 2006.

AIDS is acquiring a female face, that is, gradually the gap between females and males is narrowing as far as number of cases and infections are concerned. The youth are becoming increasingly vulnerable. The prevalence rate of more than 1% amongst pregnant women was reported from four states, that is Andhra Pradesh, Karnataka, Manipur, and Mizoram. During 2007, a total of 1,99,453 cases of AIDS were reported. The risk of TB infection in HIV positive persons increased manifold. The HIV prevalence is stabilizing and States like Tamil Nadu,

Andhra Pradesh, Karnataka, Maharashtra, and Nagaland have started showing declining trends. The lessons learnt have been utilized in formulating NACP-III, which will be implemented in the country during the Eleventh Five Year Plan.

Morbidity trends over last eight years shows not much of change in incidence of ARI, ADD, Malaria, Pulm TB, Pneumonia, Gonococcal and Viral Hepatitis. However, it shows continuous increase in incidence of Enteric Fever for past four years. The number of cases and deaths due to important communicable diseases, during 2007 were as given in Tables - 7, 8 and 9.

Disease	Cases	Deaths
Tetanus	7005	272
Tetanus Neonatal	937	93
Diphtheria	3354	37
Whooping Cough	40729	15
Measles	36900	50

Disease	Cases	Deaths
Malaria	1363279	1066
Kala Azar	44001	189
Japanese Encephalitis	4017	989
Dengue	5395	69

Disease	Cases	Deaths
Cholera	2635	3
Acute Diarrhoeal Disease	9478813	2328
Enteric Fever	694862	393

Other communicable diseases : The goal of leprosy elimination at national level (<1 case/10,000 population) as set by National Health Policy (2002); was achieved in the month of December 2005. Even though the disease came down to a level of elimination, still it is prevalent with moderate endemicity in about 20% of the districts. During 2006-07, a total of 1.39 lakh new leprosy cases were detected with current prevalence rates of 0.72 per 10,000 population. The cases and deaths due to other major communicable diseases, during 2007, were as given in Table - 10.

Disease	Cases	Deaths
Pulmonary Tuberculosis	720395	6037
Leprosy	139252	
AIDS	199453	
Rabies	221	

Mortality : Following communicable disease accounted for maximum no. of deaths, during 2007 : Pulmonary tuberculosis - 6037; ARIs - 4019; Pneumonia - 2865; malaria - 1066; JE - 989; Acute viral hepatitis - 480; Enteric fever - 393; tetanus (other than neonatal) - 272; tetanus (neonatal) - 93; meningococcal meningitis - 252; rabies - 221; kala azar - 189 (Table - 11).

Table - 11 : Case fatality rate as reported during 2007 (except Rabies)

Name of the Disease	Case Fatality Rate (%)
Japanese Encephalitis	24.62
Tetanus Neonatal	9.93
Meningococcal Meningitis	5.64
Tetanus other than Neonatal	3.88
Acute Poliomyelitis	1.68
Dengue	1.28
Diphtheria	1.10
Pulmonary Tuberculosis	0.84

Mortality trends in communicable diseases have remained same for most of the disease except Malaria, where there was increase in number of mortality cases in year 2006 (1704 deaths in 2006 as compared to 969 deaths in 2005). It has shown downwards trends in tetanus (neonatal and other than neonatal) and meningococcal meningitis. Orissa has noted maximum No. of deaths due to Malaria followed by Assam.

Annual cases and death due to Cholera in 1991 were 7088 and 150 respectively which now have reduced to 2635 and 3 respectively during the year 2007.

Non Communicable Diseases

India is experiencing a rapid epidemiological transition, with a large and rising burden of chronic diseases, which were estimated to account for 53% of all deaths and 44% of Disability Adjusted life Years (DALYs) lost in 2005. Non-communicable diseases (NCDs), especially Diabetes Mellitus, cardiovascular diseases (CVD), cancer, stroke and chronic lung diseases have emerged as major public health problems due to an ageing population and environmentally-driven changes in behaviour.

The non communicable diseases take the major disease burden in India after communicable diseases. Morbidity indicators for non communicable diseases include incidence, prevalence, deaths and performance of disease control programme for Blindness, Cancers, Coronary Heart Disease and Diabetes. The number of cases of CHD was estimated to be nearly 3.6 crores for the year 2005, which is expected to reach 6.1 crores in 2015. Cervix and breast cancers account for more than 36% of cancer incidence in the country. Estimated prevalence of blindness in 2004 was 11.2 (10.2 males and 12.2 females) per 1000 population and is expected to remain more or less same during the next two decade. There were 314704 accidental deaths reported in 2006.

Cancer has become an important public health problem in India with an estimated 7 to 9 lakh cases occurring every year. At any point of time, it is estimated that there are nearly 25 lakh

cases in the country. In India, tobacco related cancers account for about half the total cancers among men and 20% among women. About 1 million tobacco related deaths occur each year making tobacco related health issues a major public health concern.

In India, more than 12 million people are blind. Cataract (62.6%) is the main cause of blindness followed by Refractive Error (19.70%). There has been a significant increase in proportion of cataract surgeries during the past decade.

Reproductive & Child Health

Mothers who had at least 3 antenatal care visits for their last births are 52% in the country. Goa, Kerala and TN report more than 90% coverage whereas states like Bihar and UP report coverage of 17.0% and 26.6% respectively for ANC. Mothers who consumed IFA for 90 days or more when they were pregnant with their last child are 23.1% nationally, whereas 76.3% pregnant women received at least two TT injections during pregnancy.

Nearly half (48.2%) births are attended by trained personnel (Doctor/Nurse/LHV/ANM/Other health worker) and two-fifths (40.7%) are institutional births in the country. Kerala has 99.7% births attended by trained personnel and 99.5% are institutional births whereas Bihar has 30.9% & 22% and UP has 29.2% & 22% respectively.

Percentage of people using contraceptives in India is 56.3% using any contraceptive methods and 48.5% of population is using any of the modern contraceptive methods. There is great variation in sterilization operations where females had 37.7% while only 1% male sterilization operations take place. NFHS - 3 data indicates that in 2005 - 06, 56% couples with wives in age group 16 to 49 years were effectively protected by contraceptive use (64% in urban and 53% in rural areas).

Child immunization and Vit. 'A' supplementation : The percentage of children aged 12-23 months who were fully immunized are approximately 43.5%. Goa, Kerala and TN have high coverage while Bihar, UP and northeast states have low coverage. Among children aged upto 3 years, 38.4% are stunted, 19.1% are wasted and 45.9% are underweight.

Summary

In India, about 75% of health infrastructure, medical man power and other health resources are concentrated in urban areas where 27% of the population lives. Within the country, there is persistence of extreme inequality and disparity both in terms of access to care as well as health outcomes. The current available data regarding health status and health services is grouped under the headings of Demographic, Socioeconomic, Mortality, Morbidity and other Health status indicators.

Demographic indicators can be divided into two parts Population statistics and Vital statistics. India accounts for 16.7 % of the world population on 2.4% land. As per census, India's population on 1st March 2001 was 10286 lakhs. Sex Ratio is 933 female/ 1000 male but there is wide interstate variation. Population Density is 325/sq.km. Age Distribution is 34.2% in 0-14 age group & 7.5% in 60 plus age group. Birth rate, death rate and growth rate are 23.5, 7.5 and 16.0 respectively. Life expectancy at birth in 2001-05 was 62.3 for males and

63.9 for females. Vital Statistics : Infant Mortality Rate (IMR) is 57/1000 live births (Rural-62, Urban-39). The present MMR is 301 per 1, 00,000 live births (2001-2003). Total fertility rate (TFR), at national level is 2.9, Rural (3.2) and urban (2.1).

Socioeconomic indicators provides data on education, gender, poverty, housing amenities, employment and other economic indicators which help in understanding the health scenario of a country. Literacy rate has increased by 13.86% during last decade (1991-2001) and it is 64.8% among population aged 7 yrs and above, according to census-2001. Countries having similar socioeconomic status have performed better in health indicators like life expectancy, IMR, MMR etc.

Economic Indicators : There is 27.5% of population living below poverty line in India in 2004-05. 28.3% of population in rural & 25.7% in urban areas live below poverty line. Gross National Product for the year 2006-07 was INR 37,60,285 crore at current price & Rs 28,45,155 crore at constant price. According to census 2001 only 39% of total population is employed. The percentage of households having safe drinking water facility in India is 77.9 % (rural 73.2%, urban 90%).

Health status indicators : Tuberculosis remains a public health problem, with India accounting for one-fifth of the world incidence. Every year 1.47 million people in India develop tuberculosis, of which 0.8 million are infectious smear positive cases. Due to National Vector Borne Disease Control Programme (NVBDCP), initiated during the Tenth Plan malaria cases in India declined from 3.04 in 1996 to 1.36 million cases in the year 2007. However, dengue fever and chikungunya are emerging as major threats in urban, peri-urban, and rural areas in many states /UTs. There is continuous increase in incidence of Enteric Fever for past four years. The prevalence rate of HIV/AIDS of more than 1% amongst pregnant women was reported from four states, that is Andhra Pradesh, Karnataka, Manipur, and Mizoram. The goal of leprosy elimination at national level (<1 case/10,000 population) was achieved in the month of December 2005. The number of cases of CHD was estimated to be nearly 3.6 crores for the year 2005, which is expected to reach 6.1crores in 2015. Cancer has become an important public health problem in India with an estimated 7 to 9 lakh cases occurring every year. Estimated prevalence of blindness in 2004 was 11.2 (10.2 males and 12.2 females) per 1000

population. There were 314704 accidental deaths reported in 2006.

Reproductive & Child Health indicators : Nearly half (48.2%) births are attended by trained personnel (Doctor/Nurse/LHV/ANM/Other health worker) and two-fifths (40.7%) are institutional births in the country. Percentage of people using contraceptives in India is 56.3% using any contraceptive methods and 48.5% of population is using any of the modern contraceptive methods. The percentage of children aged 12-23 months who were fully immunized are approximately 43.5%. Among children aged upto 3 years, 38.4% are stunted, 19.1% are wasted and 45.9% are underweight.

Study Exercises

Long Question : Describe in brief National Health Profile of India in 2007.

Short Notes : (1) Demographic indicators in India (2) Socio-economic indicators in India (3) RCH indicators in India (4) Health status indicators in India.

MCQs

1. Sex ratio of India (2001 census) (a) 933 (b) 901 (c) 949 (d) 923
2. Communicable disease which accounted for the maximum number of deaths during 2007 (a) ARI (b) ADD (c) Malaria (d) Pulmonary TB
3. According to NFHS-3, Prevalence of Anaemia among pregnant women % (a) 58 (b) 69 (c) 47 (d) 52
4. Growth rate of India according to NFHS-3 (a) 16 (b) 18 (c) 21 (d) 14
5. Life expectancy of females (2001 census) (a) 63.9 (b) 61.6 (c) 65.1 (d) 60.8
6. According to NFHS-3, Prevalence of Anaemia among Children (6-35 months) (%) (a) 66 (b) 79 (c) 84 (d) 71
7. Communicable disease which accounted for the maximum number of cases during 2007 (a) ARI (b) ADD (c) Malaria (d) Pulmonary TB

Answers : (1) b; (2) a; (3) a; (4) a; (5) a; (6) a; (7) d.

RajVir Bhalwar

The roots of "Epidemiology" can be traced back to somewhere around 400 BC, when Hippocrates had related the occurrence of human diseases to the environment in his treatise "On Airs, Waters and Places". (1). After a long lull for almost 2000 years John Graunt in 1662 and William Farr in the nineteenth century (2,3), revived the interest and laid the seeds of the modern epidemiological surveillance systems. These efforts were boosted by John Snow's field investigations of cholera epidemic in London in 1850s (4). However, it was only after 1940 that epidemiology really expanded as a modern science, with the initiation of cohort studies at Framingham, the clinical trials of anti - tubercular drugs, the preventive trial of injectable polio vaccine, the community intervention trials of fluoridation of water supplies, and the advent of Case - Control studies on smoking and lung cancer, by Sir Richard Doll and Sir AB Hill (5 - 7). By now, epidemiology has become an all pervasive science and a basic tool for understanding and practice of all specialties of medicine (8). In fact, the understanding of epidemiology involves two things - firstly, the knowledge of the principles of medicine; and, secondly, the knowledge of certain basic "principles" of epidemiology, which we shall endeavor to explain in this chapter.

For instance, if we, as medical person, or for that matter even an undergraduate medical student were asked to write a short essay on a common disease like malaria, the essay would read something like : " Malaria is caused by a parasite called plasmodium. It is transmitted by the bite of female anopheles mosquito. It manifests as an acute febrile illness with chills and rigors. If untreated, many cases recover after a few febrile attacks but, in some, the disease may take a serious course and even some of those who recover may get a relapse. In our country out of every 1000 people, 2 to 3 are likely to get malaria every year. The disease is more common among the children, the poor people, among foreigner tourists, immuno - compromised persons, and among the agriculturists. It is commoner in North - Eastern states of our country, in rural areas and in urban slums but is not seen in highland areas. It is also much more common during and immediately after monsoons. Malaria can be prevented by spraying insecticides on water collections and on the walls of our dwellings. It can be diagnosed by a simple blood test and can be treated effectively by oral chloroquine and primaquin"

If we examine the above essay, we would appreciate that we have systematically covered certain facets, which are summarized in Table - 1. We would have covered up an essay in the same way for any other disease - IHD, HIV, Road Accidents or Neurosis.

The above facets, according to which we consider any disease, put together, are nothing but what we call "EPIDEMIOLOGY". Epidemiology is that branch of medicine which answers the issues related to all human health problems and diseases, the magnitude that they pose, their distribution according to persons, place and time, and the various factors which

determine the causation, risk, prognosis, management and prevention of the diseases.

Table - 1 : Aspects covered in a hypothetical essay on malaria

Facet	Example in our essay
What is the disease (<i>Identification</i>)	Malaria, which presents with fever and chills
How much is the disease, i.e. how frequently does it occur (<i>frequency</i>)	2 to 3 out of every 1000 people in our country
How is the disease distributed according to :	
Person characteristics (who are the persons affected)	Children, poor people
Place characteristics (where)	Rural areas, slums, NOT in highlands
Time characteristics (when)	During & immediately after monsoons
Why and How does it occur? (what are its <i>determinants</i>)	
What is the cause (<i>etiology</i>)	Plasmodium
What are "risk factors" which predispose to this disease	Foreigner, agriculturist
What is its natural history	Many recover, some relapse
What is its prognosis	Untreated cases may turn serious, some die
What can be done about it? (How can it be prevented or mitigated?)	
How can it be diagnosed	Blood test
How can it be treated	Chloroquine, Primaquin
How can it be prevented	Insecticide spray, mosquito nets

Definition

With the above background, we can define epidemiology as "*The study of the frequency, distribution and determinants of diseases and health - related states and events in human populations*" and the application of this knowledge in prevention, control and mitigation of these problems (9 - 12) . (Greek; Epi = upon, Demos = populations, Logos = scientific study). The major purpose of epidemiology is to obtain, interpret and use health information to promote health and reduce disease in a community.

Historical evidence

How Epidemiology helped humanity even before scientific facts were discovered.

Epidemiology believes in promoting health, preventing ill health and mitigating disease and its effects. To achieve this purpose, epidemiology has, on a number of occasions, shown the way to

develop public health and clinical policy, much before the actual biological mechanisms became evident. This also goes on to prove that for implementing measures for health promotion and disease prevention among populations, epidemiological suggestions are enough to initiate action; one need not wait for final scientific proof of cause and effect relationship. Some of the notable instances are :

- In 1768, Edward Jenner, a British physician heard from a dairy maid “I won’t get smallpox because I already had cow pox”. It was just an observation, which Jenner followed up by administering the material from a cow pox lesion from a dairy maid (Sarah Nelmes) to a 8 year boy (James Phepps). After six weeks, he inoculated this boy with a material taken from an actual small pox lesion; the boy did not develop small pox. It would be appreciated that the variola virus and the theory of immunity were discovered many years later.
- In 1747, James Lind, a British Navy Surgeon, based on his observations and subsequent experiment on board the ship “Salisbury” observed that food consisting of lemon juice and fresh oranges could prevent / cure scurvy, a disease which was playing havoc among sailors at that time. 45 years later, the British navy accepted this and introduced lime juice and oranges as a part of naval rations (that is why British sailors were called “limeys”) and virtually eradicated scurvy from their navy. The actual scientific process of the mechanism (involving Vitamin C) was however, discovered almost a century later.
- In mid - nineteenth century, Semmelweis, a surgeon, observed a high occurrence of puerperal fever among post partum cases. He attributed this to some ‘contagion’ which the medical students were possibly carrying on their hands (at that time, medical students used to attend obstetric clinics after attending autopsies). Semmelweis insisted that medical students should wash their hands after attending autopsies and before entering labour room. At that time, the opponents of the contagion theory rubbished him to the extent that he had to leave his practice and died a broken man. After half a century mankind got scientific confirmation that Semmelweis was absolutely correct!
- In the mid nineteenth century, London was being ravaged by an epidemic of cholera which had caused innumerable deaths. John Snow, an anaesthesiologist (famous for administering obstetric anaesthesia to Queen Victoria) undertook very systemic study of cholera cases, between 1848 - 49 and 1853 - 54, visiting each house, noting their source of water supply and deaths due to cholera. At that time, water supply in London was from two companies, namely, Southwark and Vaxhall company and Lambeth Company. Snow was severely criticized, among others, by none other than another famous epidemiologist, William Farr. Farr, as a proponent of the “miasma” theory (that cholera is caused by a cloud which contains disease and which is more dense near the surface of earth, so that the disease will be more common near the surface of earth) had shown that cholera cases actually declined as the altitude of residence from the Thames River increased. However, the evidence produced by Snow was so compelling that finally Farr also had to agree and had to issue an order asking

for households to give information regarding the company they were getting water from. One of the summary tables which Snow prepared was as follows (Table - 2) :

Company supplying water	Population	No. of deaths from Cholera	Cholera death rate per 1000 population
Southwark and Vaxhall	167654	844	5.0
Lambeth	19133	18	0.9

John Snow thus clearly proved (and this had a major public policy implication in Britain at that time) that cholera is caused by polluted water; it is noteworthy that the actual organism was discovered by Robert Koch almost three decades later!

- In mid twentieth century, Doll and Hill, based on observational (case control) studies showed that smoking causes lung cancer. The actual harmful effects of tobacco were worked out much later but these epidemiological studies helped developing a public health policy regarding tobacco prevention well before that.
- In the early twentieth century, Goldberger (observations on pellagra) and Fletcher (observations on Beri Beri) clearly showed that these diseases were caused by maize diet and polished rice respectively. Preventive actions were thus formulated well in time, much before the actual discoveries of Niacin and Thiamin.
- More recently, early epidemiological observations on the transmission of HIV AIDS had put in place, preventive recommendations regarding promiscuity and needle sharing, well before the actual agent (HIV) was identified.

How does Epidemiology Differ from Clinical Practice:

Epidemiology uses the same tools and techniques as clinical medicine, excepting for the following major differences :

- In clinical practice the focus is on an individual, the patient; however, in epidemiology, the focus is on a group of human beings (patients or healthy people) which we refer to as “population” (13).
- In clinical practice there is no effort at “quantifying” by converting the findings into numbers, but epidemiology is essentially a “quantitative” science, in which the findings are analysed after converting them into “frequencies” which are numerical figures that “summarise” our findings.

Uses of Epidemiology

There are a large number of uses of epidemiology (14), which can be broadly classified into 4 headings :

Principal Uses of Epidemiology
<ul style="list-style-type: none"> • In Health Care Management • In Understanding the disease process • In Public Health Practice • In Clinical and preventive practice

Uses in Health Care Management

(a) Making a Community Diagnosis : In clinical settings, the clinician makes a clinical diagnosis before proceeding to manage the case. In health care of large community, the health provider must make a “Community Diagnosis” by epidemiological methods to obtain information on the important health problems and their associated socio - demographic characteristics, quantifying and summarizing them (15, 16) . Once a Community Diagnosis has been made, we can decide as to which programmes would be best for improving the health status of a community; only thereafter relevant health care for the community can be organized. This is in the same way as a clinician decides the best modality of management after she has made a clinical diagnosis.

(b) Planning and Evaluation of Health Services : Any planning process will need accurate information about the socio - demographic profile, the diseases, the health care facilities, communications, etc. Similarly, while evaluating a health programme, we will again need current information about various diseases and compare it with the “baseline” state that existed when we started the programme. This quantified and summarized information is available only through epidemiological steps (17).

(c) Developing Health Policies : Since Epidemiology is indispensable for making assessment of community “diagnosis” and “needs” and the fact that it provides “ evidence based” decisions about the risks for the individuals and communities, due to various exposures, makes it a key discipline for developing Public Health Policies (18). As will be illustrated with examples at the end of this chapter, the unique strength of epidemiology is that it leads to development of preventive and curative policies even well before the actual “cause” or the “modality of occurrence” of that disease has been scientifically proven.

Uses in Understanding the Disease Process

(a) Study of the Natural History of Diseases : What we know today of the natural course of HIV or pulmonary TB or any human disease has been possible due to systematic observations on hundreds and thousands of patients and describing the summarized findings from the observations on these large number of patients, which is only possible by epidemiological methods.

(b) Searching for the Causes and Risk Factors of Diseases: How do we say that smoking is a cause of IHD? Or obesity is a risk factor for diabetes? It is by observing thousands of obese and non - obese people and following them forward to see what percentage in each group develops diabetes (cohort epidemiologic approach) or else by asking hundreds of IHD people compared to hundreds of healthy people about smoking history (case - control epidemiologic approach) (19, 20).

(c) Historic study of rise and fall of diseases : Small pox rose to its peak, killed millions and was finally eradicated; plague almost vanished after killing huge proportions of humanity and then again reappeared. Epidemiological studies of such rise and fall of diseases are essential to understand the various factors which can be effectively utilized in preventing

the occurrence or re - emergence of other diseases.

(d) To Identify Syndromes : The idea of “syndrome” is that two or more different medical phenomena (constellation of signs / symptoms) occur more frequently together than can be accounted for by simply a “chance” association. It is only after obtaining data on hundreds of patients from various countries about signs & symptoms of a related nature, through epidemiological methods, that we are able to put the pieces of information together and identify “syndromes” and their etiological factors. For instance, till 1920s, peptic ulcer was thought to be a single entity. Based on collection of large scale epidemiological data (from death certificates and surgical records) and its analysis according to sex, social class, anatomical site and time - related trends the two entities, viz, duodenal and peptic ulcer were clearly distinguished (22, 23). More recently, obesity, central obesity, raised blood pressure, impaired glucose tolerance and raised triglycerides / low HDL - Cholesterol were all identified individually as CHD risk factors; however, only after studying the data from large number of subjects, across various countries, in a consolidated manner, it was observed that these tend to cluster together more frequently than can be expected simply due to chance, as “Metabolic Syndrome X” (24, 25).

Uses in Public Health practice

(a) Investigations of Epidemics and Other Field Investigations : While epidemiology, today, is involved in practically all aspects of medicine and health care, the fact remains that it originally started as the science dealing with investigations of epidemics (26) and even today, this remains one of the most important duties of the epidemiologists.

(b) Surveillance for Diseases : In addition to investigations of epidemics, disease surveillance was another important function for which epidemiology came into being. Surveillance essentially monitors trends in the occurrence of selected diseases, thereby giving early warning about increase in their occurrence so that early control measures can be instituted. Today, we have huge national & international surveillance systems which all essentially involve epidemiological principles of information generation, consolidation, analysis interpretation and feed - back of results.

(c) Making Projections : Quite often we hear that there will be so many million cases of IHD in our country by 2025 and so on! How are these projections made? They are actually mathematical models developed by epidemiologists after collecting data from large populations for the past many years and then developing the mathematical models to calculate what is likely to occur in future.

(d) Assessing the Programmes for Mass Screening for Diseases : Based on epidemiological principles of “diagnostic test assessment”, the mass screening programmes are planned and subsequently evaluated for their effectiveness in large population groups.

(e) Assisting in formulating medical teaching curricula : Today's medical teaching curriculum are often blamed for not being able to actually target the needs of the community, that the doctors and nurses trained by these medical schools would later serve. In fact, if we utilize the principles of epidemiology,

find out and quantify as to what are the priority health problems in a given state or district, and what are the available resources to tackle these problems, we could plan a very effective medical curriculum which would be very appropriate for teaching the would be doctors, nurses and paramedicals.

Uses in Clinical and Individualized Preventive Practice

(a) As the basic and indispensable science for clinical research : The question that we may, quite intuitively, ask is that we are all very well qualified and experienced; we can conduct research pretty well, with the capability to execute research improving with increasing clinical experience. Why should we have text books or training curriculum in “Medical Research Methodology”. In Fact, medical research methodology is nothing but an extension of the wise clinician's intuitively explorative faculties. However, such an extension of this faculty (of educated thinking, observing, analyzing and reasoning) as well as the understanding of essential principles and methods of epidemiological research does not occur simultaneously and concurrent to the learning and practice of medicine. For instance, history of medicine is replete with examples, wherein results based on unscientifically conducted research (gastric freezing, blood letting, “tape - seton’ and so on) have been applied, only to cause harm to the patients, just because they were based on unscientific research methods. It therefore needs, in addition to our qualifications and experience in medicine and public health, a working knowledge of the essential principles of epidemiology, research methodology and biostatistics, that need to be clearly understood by all medical persons who are interested in research (26 - 35).

(b) Assessing the effectiveness of treatment and preventive modalities : How can we conclude whether a newly formulated herbal antihypertensive drug which has been sponsored by a pharmaceutical agency is better than the standard treatment regime using a ACE - inhibitor? Any treatment modality, be it a drug, surgical intervention, or else any preventive modality (vaccine, immunoglobulin preparation, chemoprophylactic drug, lifestyle change, personal protective measure, etc.) has to be evaluated through the epidemiological approach of “Randomized Controlled Blinded Trial” (RCT or Clinical trial) before it can be taken up in clinical usage.

(c) Assessing Prognosis : Does appearance of flapping tremors indicate bad prognosis in the course of otherwise uncomplicated Viral Hepatitis A (VHA)? This issue can only be answered when we follow up a large group of patients with VHA with flapping tremors and another large group of VHA patients without flapping tremors and see how much mortality occurs in each group. Thus, epidemiological studies on a large sample of patients, using the “cohort” approach are essential for evaluating the role of a prognostic factor in predicting the outcome of a disease.

(d) Assessing the effectiveness of diagnostic procedures : Any new diagnostic procedure, as a new laboratory test or a radiological test or even a clinical algorithm has to be evaluated for its diagnostic accuracy as well as utility, by studying it on a adequately large sample of patients who are all also subjected to the gold - standard test, based on epidemiological principles

of “diagnostic test evaluation studies”.

(e) Guiding Clinical decision : If you see a five year old child with cervical lymphadenopathy and gradual loss of weight, you will, in India, make a diagnosis of “Tubercular Cervical Lymphadenitis”.

However, if you were in a developed country as USA, you would have made the diagnosis of lymphoma! Why is this difference in approach at two different places for the same presentation?

Summary Box : Definition & Uses
Definition : Study of Frequency, Distribution and determinants of diseases and health problems in human populations and it's application in prevention, control and mitigation of health problems.
Uses
1. In Health care management <ul style="list-style-type: none"> ● Making Community Diagnosis ● Planning & Evaluation of Health Services ● Developing Health Policies
2. Understanding Disease Process <ul style="list-style-type: none"> ● Studying natural history of diseases ● Searching for Causes & Risk factors ● Historic studies of rise and fall of diseases ● Identification of Syndromes
3. Uses in Public health practice <ul style="list-style-type: none"> ● Investigations of Epidemics ● Surveillance for Diseases ● Making Projections for Future ● Disease Screening Programmes ● Formulating medical teaching curricula
4. Assisting in Clinical Practice <ul style="list-style-type: none"> ● Assessing Effectiveness of Treatment Modalities ● Assessing Effectiveness of Preventive modalities ● Studying Prognostic factors ● Studying Effectiveness of diagnostic Modalities ● Assisting in Clinical decision making ● Basic and Indispensable science for planning, conducting and analyzing clinical research

It is because epidemiological information about the various diseases tells us as to what are the “common” diseases in a particular country or community. Even in the same country you may approach a disease in different manner at different times. If you have a young man with clinical presentation of pneumonia, you may routinely not ask about his occupation, but if epidemiological information has told you that bird flu case are being reported from that area recently, you would certainly ask about exposure to fowls and other birds. In addition, modern epidemiological methods as “clinical decision trees” are being increasingly used in clinical practice for taking decisions regarding optimum clinical management of individual patients.

Study Exercises

Long Questions : (1) Define Epidemiology. Discuss its uses. (2) Epidemiology is a basic and indispensable science for public

health and community medicine. Discuss this statement, with common examples.

Short Notes : (1) Similarities and dissimilarities between epidemiology and clinical practice. (2) Epidemiological approach in planning and evaluation of health care. (3) Role of epidemiology in major clinical areas - diagnosis, risk evaluation, assessing prognosis, treatment and prevention. (4) How does epidemiology guide clinical decision - making ? (5) Community Diagnosis.

MCQs & Exercises

1. Some situations / concepts in the field of medicine / health care are listed in column 'A'. Match each one of them with the most appropriate use of epidemiology as listed in column 'B' Refer to the table on previous page.

2. The book "Airs, waters and Places" was compiled by : (a) John Graunt (b) William Farr (c) Hippocrates (d) Alexander Fleming
3. Which of the following has been considered, sometimes or the other, as a part of definition of epidemiology : (a) Study of frequency, distribution and determinants of diseases (b) Study of epidemics (c) Study of mass phenomena of diseases (d) All of the above
4. Epidemiology is different from clinical practice as regards all the following aspects, except : (a) Epidemiology focuses on a large number of subjects and not a single person (b) In epidemiology we 'quantify' the findings (c) In epidemiology, we do not use clinical skills (d) In epidemiology the focus is whether the subject being examined has the disease we are interested while in clinical practice our

<i>Match the following (See Exercises - Q. 1 overleaf)</i>			
A		B	
a	Among Indians, increased waist circumference, diabetes and raised blood pressure tend to occur together and greatly increase the risk of Ischaemic heart disease (IHD)	I	Making Community Diagnosis
b	Certain tribal populations in our country have been identified, who suffer from difficulty in geographical accessibility, leading to low education, high infant and maternal mortality and high occurrence of tuberculosis.	II	Planning & evaluation of health services
c	A Doctor who practiced for about 20 years in Bihar (India), moved on a 3 - year contract to Uganda. He saw a case of jaundice and thought of yellow fever as the first possibility	III	Developing health policies
d	The use of Rofecoxib, initially used as an excellent anti - inflammatory drug, was discontinued due to demonstration of adverse cardio - vascular effects	IV	Study of natural history of disease
e	It has been recently observed that people who have elevated levels of homocysteine in their blood have a higher chance of getting IHD	V	Searching for risk factors
f	In India, health workers visit every house in a fortnight and find out about the occurrence of any fever case. This information is regularly reported to the Primary health centre (PHC) and then to the District malaria Officer.	VI	Historic studies of rise & fall of diseases
g	One of the states in India have recommended to start a 3 - year medical degree in which training would be given about the major locally prevalent diseases and their treatment using locally available resources	VII	Identification of syndromes
h	A number of experts, after reviewing the national health scenario, have recommended that we should have a PHC for every 30,000 population rather than having super - specialty hospitals in urban areas	VIII	Investigations of epidemics
I	A combination of exercise - ECG and echocardiography has been found to be quite effective in diagnosing IHD	IX	Surveillance of diseases
j	A number of cases of eosinophilia - myalgia syndrome (EMS) were reported in a district over a short period of time. These cases were found to have used tryptophan, produced by a particular drug company, as a dietary supplement	X	Making projections for future
k	Tuberculosis, which was a major problem in USA and Europe, declined to a very low level at the start of 20th century, even before BCG and anti - tubercular drugs were discovered	XI	Disease screening programs
L	Community programmes using pap smear for cervical cancer are being widely used and found to be quite effective	XII	Formulating medical teaching
m	It is estimated that by the year 2020, the number of hypertensives in India may grow to 200 million.	XIII	Assessing effectiveness of treatment modalities
n	Earlier, the overall approach to family welfare program in our country was based on allotting 'targets' (e.g. vasectomies or tubectomies to be undertaken in a year). Since the year 2000, this type of approach has been discontinued.	XIV	Assessing effectiveness of preventive procedures
o	HIV infected persons who develop multidermatomal or recurrent herpes zoster are likely to die earlier	XV	Study of prognostic factors
p	The asymptomatic stage in HIV infection usually lasts for 8 years; thereafter, death is likely in the next 2 years.	XVI	Effectiveness of diagnostic procedures
q	Use of Insecticide Treated bed nets (ITBN) has been found to be quite helpful in preventing malaria in endemic areas.	XVII	Assisting in clinical decision making

focus is “which is the disease that the patient has”.

5. Community diagnosis means : (a) Quantifying and summarizing the important health problems and their associated socio - demographic characteristics in a community (b) Priority wise listing of the common diseases seen in a community (c) Summarising the standards of living and lifestyle factors in a community (d) None of the above

6. Which of the following function does not fall within the purview of “uses of epidemiology” (a) Deciding whether our community needs one PHC or 4 subcentres (b) Establishing the natural history of HIV infection (c) Training the medical students in conducting delivery (d) Investigating an outbreak of food poisoning

Answers : (1) a-vii; b-i; c-xvii; d-xiii; e-v; f-ix; g-xii; h-ii; I-xvi; j-viii; k-vi; l-xi; m-x; n-iii; o-xv; p-iv; q-xiv; (2) c; (3) d; (4) c; (5) a; (6) c.

The Essential “Building Blocks” of Epidemiology and Research Methodology

RajVir Bhalwar

Since all of us are very well qualified and experienced, we feel that we can conduct research pretty well. Thus there is a question that we may quite intuitively ask. Why should we have text books or training curriculum in “Medical Research Methodology”? In fact, medical research methodology is nothing but an extension of the wise clinician's intuitively explorative faculties. Unfortunately, such an extension of this faculty (of educated thinking, observing, analyzing, reasoning and the understanding of principles and methods of epidemiological research) does not occur concurrently with the learning and practice of medicine. History of medicine is replete with examples, wherein results based on unscientifically conducted research (gastric freezing, blood letting, “tape - seton’ etc.) have been applied, only to cause harm to the patients. A working knowledge of the essential principles of epidemiology, research methodology and biostatistics is therefore essential to conduct research. This chapter deals with these essential principles.

The First Building Block : The Research Question

Funny though it may sound but as per the collective opinion of a number of expert referees of some of the most esteemed international medical journals, in almost half of the research articles that they get for reviewing, the authors did not seem to be clear as to what they wanted to do! Therefore, the first stepping stone in any effective medical research is to develop a proper research question. An appropriate research question, developed after fair amount of academic reading and discussions, is an essential requirement (26). Developing an epidemiological or research question is essentially an academic exercise, consisting of a series of steps. They will be discussed in detail in the next chapter.

The Second Building Block : One Subject or Many ?

Let us look at an example drawn from a report in a reputed journal published in 1969 “..... a 58 year old woman

with moderately severe Parkinson's disease recounted to her family physician that 3 months ago, while taking amantadine hydrochloride 100 mg twice daily to prevent flu (then used as an anti - viral drug), she experienced a remarkable remission in her symptoms of rigidity, tremors and akinesia. These symptoms promptly returned on stopping the drug after six weeks”(27). The effect in the patient was striking. At that time, medical world was in desperate need of an effective drug for Parkinsonism. However, this report based on a single case could not lead to immediate change in clinical practice. Clinicians tried out Amantadine in a limited number of patients of Parkinsonism and observed beneficial effects in many of them. They, thereafter, tried out the drug in a standard clinical trial, randomly dividing a group of patients of Parkinsonism into two, giving Amantadine to one group and the existing standard therapy to the other and noticing the much larger beneficial effects in the Amantadine group. From the initial description in 1969, it took the medical fraternity a couple of years before introducing Amantadine into clinical practice as an anti - Parkinsonism drug.

There is reason for such delays, for no inferences regarding a risk factor or prospective marker, diagnostic agent, therapeutic procedure or preventive agent can be drawn from observations on only one or even a few patients or subjects. It is because, there is a well known natural phenomenon of variability - no two human beings are likely to be the same. Hence what happens in a single patient may be simply due to chance just because of this natural law of variability. It may be just because of chance that the first patient of lung cancer whom you see may not have even touched a cigarette over his lifetime but that does not mean that smoking is not a risk factor for lung cancer. Inferences about the role of smoking in causation of lung cancer were based on history taken from hundreds of patients of lung cancer and comparing them with hundreds of healthy persons (28, 29).

Thus, an important building block in research methodology is the concept that while clinical practice and research utilize exactly similar procedures, in clinical practice, our focus is on a single individual - the patient, but in clinical research, the interest is not on a single but large number of patients or subjects. And it is from here that many of the (apparent) difficulties of research methodology originate, because, in research, you have to study

a “large” number of patients (“subjects”) vis - à - vis only one patient in clinical practice.

Third Building Block : Ultimately, Research is the Relationship between “Variables”

In the process of medical research, we decide the various headings under which we will make measurements on our subjects. For example in a trial of the efficacy of a new lipid lowering drug, we would note down the age, sex, blood pressure, blood glucose, total / LDL / HDL cholesterol, etc. We will note down whether the particular subject was given the standard lipid lowering drug or the new drug. Other relevant observations like the final level of lipids after, say, 6 months will be noted down. In research methodology, these various “headings” are called “Variables” (30). Thus, Age, Sex, name of the drug administered, LDL level, etc., are all “variables”. A variable is thus any quantity or quality of a subject which can be measured and which ‘varies’, i.e. likely to have a different value from one subject to another. Thus, sex is a “variable” since it is a “quality” which is likely to take some different value (either male or female) between two subjects. In fact, when reduced to the lowest terms, all epidemiological and medical research practice is simply the study of relationship between variables.

It becomes very important for the epidemiologist to specify as to what ‘variables’ will be studied and how the values of each of these, for the various subjects, will be recorded. We will make a detailed discussion regarding these aspects in a subsequent chapter.

Fourth Building Block : The “Data” Needs to be Summarised

In the process of medical research, we would collect the information on a large number of variables as are relevant to our research work. However, this large collection of data does not convey any meaning. Hence, we need to summarize our data into “summary figures” which will convey, in one sight, what our data tends to convey. Depending on the way we have measured the various variables, these summary figures would be either “mean”, or “median” or more commonly, a proportion or a rate. In turn, a proportion is generally worked out as “prevalence” while a rate is worked out as “incidence”. We would further clarify these concepts in a subsequent chapter in this section.

Fifth Building Block : Whether to Study One Group or two Groups

Have a look at the following results of a research study : “..... *Some strokes are caused by cerebral infarction in the area of brain distal to an obstructed segment of the internal carotid artery. It should be possible to prevent stroke in people with these lesions by bypassing the diseased segment so that blood can flow to the threatened area normally. Also, it is technically feasible to connect the superficial temporal artery to the internal carotid artery, distal to an obstruction. Because its value seemed self evident on anatomic and physiological grounds, the procedure was applied on a series of patients who were offered surgery, out of which quite a few showed improvement. With this background, as also the documented*

success of another analogous procedure, the CABG, this new surgical procedure of extracranial - intracranial - arterial - bypass became widely used in 1970s & 1980s. (However it may be noted that no control group was studied at that time).....”.

In 1985, the EC/IC bypass study group conducted a randomized controlled trial in which patients with cerebral ischemia and an obstructed internal carotid artery were randomly allocated to surgical or medical treatment. In the surgical group, “*the operation was a technical success - 96% of the anastomoses were patent a year after surgery. However, surgery did not help the patients. Mortality and stroke rates after 6 years were, in fact, slightly higher in the surgically treated patients as compared to medically treated patients; Moreover, deaths had occurred earlier in the surgically treated patients*” (31).

An important building block of epidemiological research methodology is to realize the fact that final conclusion about the risk factors, therapy, prevention or prognosis can be drawn only after comparative research. While results derived from observations made on only one group of subjects may give valuable suggestions for further exploration, however, putting into action, conclusions based on only one group may be fallacious. Studies which describe certain phenomenon or clinical outcomes in only one group are called descriptive studies; they generate strong suggestions or hypothesis but certainly do not give us the final verdict. For getting the final verdict we have to do a comparative study in which a group having the factor of interest is compared with another group which does not have the factor. If the result is better in the group with the factor then only we can conclude that the particular factor really makes a difference. We will further deliberate on these issues in subsequent chapters.

Sixth Building Block : Quantifying the Exposure (Cause) - Outcome (Effect) Relationship

The following is a hypothetical example : In the 1970s an issue in the treatment of pulmonary TB was that the patients who had been issued their medicines for the complete month (Domiciliary, self administered ATT) were not showing the desired cure rate despite the documented efficacy of multidrug regimen. It was felt that some form of directly observed intake of drugs, which ensures compliance, may be more effective. To test this question, 300 patients of Pulmonary Tuberculosis (Pul TB) were divided into 2 groups of 150 each. One group was managed with directly observed regimen while the other with the conventional, self administered regimen. Outcome criteria of cure were based on microbiological, clinical & radiological parameters after six months of treatment. The results were as shown in Table - 1.

It is clear that out of the 150 patients given the exposure, 121, i.e. 80% achieved the outcome (were cured) while 40% of the non exposed group achieved the outcome. These values of 80% and 40% are in technical language called the incidence of outcome in the exposed and the non exposed groups respectively. If we were to ask you whether DOTS was effective, you would immediately say yes. How many times is DOTS more effective than self administered treatment? : Two times. How did you work out this figure? : by dividing 80% by 40%. In epidemiological research practice, this value of “2

times more” is called the RR (Relative risk or Risk ratio) and we work it out by simply dividing the incidence of outcome in the exposed group with the incidence of outcome in the non exposed group.

Table - 1

Exposure (intervention modality)	Achieved outcome (cured)	Did not achieve outcome (not cured)	Total
Given Trial modality (DOTS)	121 (80 %)	29 (20%)	150 (100%)
Not given trial modality but given control modality	59 (40 %)	91 (60%)	150 (100%)
Total	180 (60%)	120 (40%)	300 (100%)

One of the key issues in understanding epidemiology and medical research methodology is to understand and be comfortable with the 2 X 2 table. It is a cross combination of exposure at 2 levels (given or not given) and the outcome also at 2 levels (achieved or not achieved)

These simple issues of describing the exposure - outcome relation and calculating the overall effect through the conventional 2x2 table are actually one of the most important building blocks in epidemiology and research methodology : We would have detailed deliberations on the mechanics of the 2X2 table in a later chapter.

Seventh Building Block : Concept of Population and Samples and External Validity

In the second building block we had agreed that in medical research, to make any valid conclusion, we have to study not one, but many patients or subjects. But then, what do we mean by “many”. How many? Ten ? Thousand ? A million ? Or all the patients with that disease in this universe. One of the major considerations that crops up in epidemiology and research methodology is that we always study a “sample” and not the entire collection of patients in the world having that disease. The moment we do that, two issues become prominent. Firstly, the sample may not be representative of the total population, so that we may not be able to apply our findings from our study, to the total population; this is the problem of “external validity”. Secondly, the sample may be too small and hence our findings may not be precise. We will discuss these issues in a subsequent chapter.

Eighth Building Block : Concept of Random Error or Chance

In the previous building block, we said that there are two major issues which come up when we study samples. First one is the issue of “representativeness” which affects the external validity. Which is the second issue? Now, in epidemiological research, the moment we start studying a sample, besides the issue of external validity due to a non representative sample, there is another major issue that needs to be addressed - that of Sampling error also called Random error Sample to Sample

error or more simply, Chance. This is an error which occurs because, as long as you are studying a sample, your results from the sample will be different from the actual reality that exists in the total population from which you have drawn the sample. This is a natural phenomena which will occur despite your most honest and meticulous efforts. For instance, if you are examining a sack of grain for presence of weevil (insects which infest the grain) and let’s say that, in reality, every 100 grams of grain has 5 weevil in this bag, your one sample fistful of 100 grams may contain 4 or 6 or even 10 weevil; your next fistful may contain 1 or 5 or 11 weevil and not exactly 5 of them. Hence, as long as we are studying a sample and not the total population, which we would be doing any way, some error should always be accepted. But we can actually do two things about this error.

- Firstly, we can minimize this error by using an adequately large sample. Calculation of adequately large sample, using statistical procedures, is dealt later in the section on Biostatistics.
- Secondly, after the research is over, while analyzing the results we apply statistical procedures to calculate the probability by which our result may differ from the real value in the “total population”, because of random error. This is undertaken through various statistical procedures, which we would deliberate in detail in the section on biostatistics.

Ninth Building Block : Confounding : Compare Apples with Apples, Not with Oranges

Well, while minimizing the random error by studying an adequately large and representative sample and calculation of the p - value which gives the probability of the random error is all very important, it is just one of the three major errors, that we have to guard against, in epidemiology and medical research (see Box - 1). In fact, it is more important to effectively neutralize the other two errors. These two errors are, firstly, confounding error and secondly, systematic error also called bias or loss of internal validity or error of measurement.

Box - 1 : In medical research we should understand where all “errors” can occur :

- Since we study a ‘sample’ from a “population”, error of loss of external validity may occur if representative sample is not taken
- Random error (sample to sample error or chance) will occur because we study samples from a population.
- Error will occur if our basic measurement process is wrong.
- If we systematically differentiate while comparing the two groups (Bias or systematic error or loss of internal validity)
- If the groups being compared are dissimilar in various other respects (Confounding error).

Let us take a hypothetical study which evaluated the risk factors of IHD by taking 100 cases of IHD and 100 comparable but perfectly healthy people and obtaining the history of various putative risk factors. One of the factors which the investigators considered was the history of habitual defecation in privies

versus open fields. The findings are displayed in Table - 2.

Exposure (defecation habit)	Outcome		Total
	O+ IHD cases	O - Healthy controls	
E+ (Privy latrines)	70 (70%)	30 (30%)	100
E - (Open fields)	30 (30%)	70 (70%)	100
Total	100	100	200

It would be appreciated that 70% of the IHD patients gave history of defecation in proper latrines, while much less (30 %) of the healthy people gave this history, preferring the traditional “open air” practice. Going to the open fields apparently, seemed to be a great protective factor against IHD while sitting on the commode inside a privy increased the risk by more than two fold! The authors were thrilled about the scientific breakthrough they had made, when a scientist told them that something seemed to have gone wrong! What had actually gone wrong was the occurrence of a very common phenomenon which occurs in research : that of confounding. In this case there was another variable which created all the confusion - it was socioeconomic affluence, for the rich who used their privies and had more IHD not because of their hygienic habit but because of the affluent unhealthy lifestyle. This phenomenon occurred because this study did not follow the basic doctrine of research which says that two group being compared should be similar to each other in all other respects except for the factor being studied.

Never compare apples with oranges. In all correctness the authors should have selected the groups whose subjects should have been similar in all other respects like age, sex, race, family history and socioeconomic status except for that one group had IHD, and other did not. In confounding, an observed association between an exposure (e.g. defecation practice) and an outcome (e.g. IHD) is “explained away” by a “third” variable (e.g. ‘socio - economic status, in our example). This creates a ‘confusion’ or a nuisance (32 - 34). It is imperative for an epidemiologist and a medical researcher to always be on guard against this phenomenon of confounding, a detailed discussion about which will be made in a subsequent chapter.

Tenth Building Block : Precautions against “Bias” (Syn : Systematic Error Measurement Error Misclassification, Lack of Internal Validity)

Some trials undertaken earlier showed that patients with inguinal hernia who undergo laparoscopic repair seem to have less post operative pain and more rapid return to work than open conventional surgery. Is this result really correct or might be that laparoscopic repair may appear better because of certain bias. The following points need consideration :

- Perhaps laparoscopic repair is offered to patients who are in a better health or seen to have better tissue strength because of age or general health
- It may be possible that surgeons and patients are more inclined to think that this procedure should cause less

pain, because it is new.

- As the scar is smaller, the patients report less pain and the surgeons are less likely to ask for pain or record it in the case sheet
- Perhaps patients who get laparoscopic surgery return to work earlier, than those who get open surgery, because the surgeons have so guided them.

If any of the above reasons were true, the favorable result of laparoscopic repair may be related to systematic differences in how the patients are selected for laparoscopic procedure, how they report their symptoms or are asked about them, or how they were told what they can do rather than a true difference in the success rates. A clinical trial conducted after carefully taking care of these possible biases, found that patients given laparoscopic surgery in fact do experience less pain and a more rapid return to work, every thing else being equal (35).

One of the essential requirements in any scientific process is to measure correctly what we actually want to measure. In the above example, we had actually intended to measure “the relief in pain and rapidity of resuming normal day to day work” as brought about by laparoscopic versus conventional procedure. However, at a number of points we systematically departed from the correct state, making measures which were different than what we really intended to. It is a surprising and concerning fact, the central issue of measuring what we really intend to measure is lost in many a study. Any measurement must have the following two characteristics :

- It should have ‘reliability’ (Syn : precision, repeatability, replicability) - in that repeated measurements should give consistent results.
- It should be ‘valid’ (i.e. accurate) - It must measure what is really intended to be measured. Loss of validity (accuracy) occurs if a measurement process tends to produce results that depart systematically from the true value. (Bias) (36). Bias has to be visualized during the planning stage and steps taken to prevent it. It will be discussed in detail in later chapters.

Eleventh Building Block : Selecting the Appropriate “Research Design”

Selection of the correct design is a vital issue in epidemiologic research and depends on a thorough understanding of the research question. For a given research question there is one ‘most suited’ design. The various types of designs, viz., Descriptive, Analytic (Case - Control, Cohort, Cross - sectional), Experimental, and Diagnostic test studies are described in detail in subsequent chapters.

Twelfth Building Block : No Epidemiologic Research is an End by Itself

A well conducted study not only yields invaluable scientific data but also opens up other interesting issues that are worth pursuing further. Epidemiologic research is therefore an ongoing academic process wherein we critically review our work, ask further questions and try to solve them by further epidemiological research studies. The cycle is unending

Summary

Epidemiology is the basic and essential science for the study of human health and disease. As a result, therefore, medical

research methodology is totally dependant on epidemiology an its sister science, biostatistics. This science is dependant on certain essential scientific considerations or “building blocks, as follows :

Any epidemiological or medical research study must start only after a proper question has been formulated after adequate amount of academic reading and discussions. While in clinical practice our focus is on a single individual (the patient), in epidemiology and medical research, our focus is on a large number of subjects or patients. It is only on the basis of information drawn from this large body of subjects that we can make conclusions about the health state of a population and about causes, risk factors, treatment, prognosis and prevention of a disease.

When we consider a large number of subjects for drawing conclusions, there are four types of potential and serious errors that can occur and which need to be prevented in our epidemiological studies :

We will always be studying a “sample” and making inferences about the large population from which the sample has been drawn. Now, the sample may not be representative of the population and hence we may not be able to “generalize” the results of our sample on to the population. This is the error of external validity or lack of generalizability. As a part of the natural phenomena of random error (syn. Chance, sampling error sample to sample error), our results from even a representative sample may not be exactly the same as the truth that is there in the large population. This error is prevented by studying an adequately large sample and by estimating the extent of “chance” through p - value calculated by statistical procedures after the study has been done. Our observed association from the study may be actually un - real, due to a third variable, which is acting indirectly. This is the error of confounding. Our basic measurement process may be wrong or we may be systematically differentiating between the two groups which we are comparing in our study. This is the error of measurement or systematic error or bias. Finally, we must

remember that no epidemiological study is an end in itself; it generates further questions which again need to be addressed by subsequent error - free studies. This is the epidemiological or research cycle.

Study Exercises

Long Question : Discuss, with suitable examples, the essential building blocks of epidemiology & medical research methodology.

MCQs

1. Any epidemiological study should start with a well formulated research question, developed by : (a) Discussions with colleagues and experts (b) Thorough academic reading (c) Our own clinical experiences (d) all of the above (e) none of the above.
2. The situation when an observed association between two variables is explained away by a third variable, due to indirect associations is known as (a) chance (b) Bias (c) Confounding (d) lack of generalizability.
3. While undertaking a study for the load of diabetes in a city, a sample of subjects was taken. All were asked if they saw ants being attracted to the place where they had passed urine; if the answer was yes, they were taken to be diabetics, otherwise not. Which of the following errors is potential in this case : (a) Error of Confounding (b) Error of measurement (c) Random Error (d) None of the above.
4. By random error we mean that : (a) No sample is likely to give us results which are exactly the same as the truth in the total population (b) No two samples drawn from the same population are likely to give us the same results (c) It will not occur if we study the entire population (d) all of the above (e) none of the above.
5. In an epidemiological study to find out whether smoking is related to laryngeal cancer, IHD is (a) Exposure variable (b) Outcome variable (c) Both exposure and outcome variable (d) confounding variable. (e) Secondary outcome variable.

Answers : (1) d; (2) c; (3) b; (4) d; (5) e.

13

Developing the Correct Epidemiological (Research) Question

RajVir Bhalwar

For most of us, asking a epidemiological research question seems to be so simple and “taken for granted” that we often tend to overlook its importance. The results of such casual approach may be disastrous. It is ironical that a large number of workers when asked on the completion of their study, as to

what exactly was their research question are unable to clearly state the same. The entire planning, design, conduct and analysis of any research work, is dependant on the research question itself. A carelessly developed research question, therefore, leads to wastage of and adds another (un)scientific paper to the many that already exist !

Steps in Developing a Research Question

Developing a research question is neither automatic nor haphazard. It involves a series of meticulously steps. The research question is the ultimate objective of the study. It often begins with a general concern which then should be narrowed down to a concrete, researchable issue. For example, consider

the question “Should middle aged adult men undertake more exercise?” This is a good point to begin, but we need to get more focused before we can start any worthwhile research. This involves breaking the question into specific components and concentrating on one or two of them. The components in this example could be :

- How often do people undertake physical exercise? What is the usual intensity and duration?
- Does regular moderate intensity physical exercise for 30 minutes a day reduce the risk of diabetes?
- Will jogging and weight training have the same effect as regards protection from diabetes?
- Will regular jogging carry an increased risk of osteoarthritis, sudden death and musculoskeletal injuries?
- Will postural “Yoga” exercises have the same protective effect on cardio - vascular health, as brisk walking?

The sequence of steps for proper development of a research question could be :

Step 1 - Do not let the research question be forced upon you

: It is important to realize at the very outset one must conform to his interest. Very often a particular research work is forced upon us (peer group pressure, obtaining “funding” from an agency, etc.). It must be realized that if we take up a research work which does not genuinely interest us, we would not plan and design it properly, would conduct it half - heartedly and the end product would be an invalid, unattractive piece of work.

Sometimes initially you are not interested in a particular research area. However, before rejecting it, one may undertake some reading in the area. You may start getting interested in it. (In marriage, what is important is to fall in love, whether you fall in love and get married or else get married and then fall in love !).

Step 2 - Find a general area of interest : After having assured oneself of the ‘genuine interest’, find the “broad or general area”. This is a “broad field” in the particular area of medicine; e.g. “AIDS” or “Urinary Tract Calculi” or “Patellar Fractures”, etc. One should turn to various personal resources for identifying such broad field of interest, as :

- Our own intrinsic interests
- Clinical observations that accrue over the years of professional experience
- Deliberations made at medical conferences and clinical meetings
- Discussions with colleagues
- Questions asked by our students and subordinates

Step 3 - Read “around” the topic : Once a general area of interest has been identified, a “wide” (extensive) study is undertaken in that area. Care needs to be taken at this stage not to make the reading an “in - depth” (i.e. intensive) one. The purpose is achieved by a superficial “browsing” of books and going through abstracts of articles published during past 3 - 5 years. Make a list of relevant journals. Scan through index of these journals. Browse through their abstracts. If the abstract seems interesting, note the reference for getting back to the article later. Avoid reading the complete article at this juncture. Internet can be a useful tool.

Step 4 - Identify an area of “specific” interest : The superficial reading leads us to identify areas with certain gaps in the existing body of knowledge and that one can try to fill up. We thus, identify certain “specific” areas of interest within the “general” area of interest. For example, after a wide reading in the general area “urinary tract calculi”, we may get specifically interested in “risk factors for urinary calculus formation”.

Step 5 - Read into the topic : We must now do an “indepth” (intensive) study into this specific area (in contrast to the wide, extensive study of step - 3). This would involve detailed study of published articles, personal communications with experts who have worked in that particular specific area and computer based searches of medical literature, giving the carefully selected, relevant key words.

By now, the readers would be convinced that developing a research question needs a definite scholarly attitude and plenty of reading.

Step 6 - Formulate a ‘tentative’ research question : A specific item has now been identified, where some work has already been done but still certain gaps exist in its knowledge, which need to be investigated. We can thus write a statement indicating our “tentative guess” which we wish to prove (or disprove) in our proposed research work. This is what we call as our “tentative research question”. For example, after a thorough in - depth reading on “risk factors for urinary tract calculi” we develop an idea that “Will ensuring drinking at least 5 litres of water a day prevent urinary tract calculus formation in tropical areas?”. We would come to this conclusion after consideration of following facts

- Some amount of work has been done in this area
- There are, however, gaps in the body of existing knowledge that need to be filled up. For instance, while there may be some published evidence that adequate drinking water prevents urinary tract calculi in temperate climates, it may not be clear whether the same holds good for tropical climates also. Or else, there may be evidence regarding efficacy in overall population but not in certain specific populations as some particular industrial workers or sports persons or among soldiers.
- This has generated our interest in the issue.
- We must decide if we would be able to undertake this research, given our capabilities and facilities?

Step 7 - Evaluate the tentative research question for its ‘suitability’ : The next step is to answer the issue “Whether it can be done by us?” We should note that the research question that we have developed by now is only a ‘tentative’ one. This tentative research question is to be tested for its ‘suitability’, before we proceed further. In other words we should evaluate it on the following parameters :

(a) Is it “Do - Able?” - Answer the following questions -

- (i) Do we have the required technical support in terms of patients, hospital beds, laboratory support etc.? Will adequate number of patients (or healthy subjects) be available? Do we have the required diagnostic and therapeutic facilities?
- (ii) Do we have enough funds available to finance our research requirements ? Will some research body be ready to finance us?

(iii) Are we professionally qualified to undertake this research work? If not, is professional support of qualified persons (co - guides / co - workers) available?

(iv) Will we be able to muster the required administrative and logistic support in terms of administrative sanctions, manpower, vehicles, equipment etc.?

(b) Is the research question 'pertinent' ?

Does it have relevance to our specialty? For example, "attitudes regarding family planning in a rural community" may be a very good research question, but possibly not if a vascular surgeon working in a tertiary care hospital has to do it, since it neither has much relevance to his specialist fraternity (Vascular Surgeons) nor to his "usual" settings of medical practice.

(c) Is it Ethical ?

(i) Does our proposed research work involve a breach on "confidentiality" of human subjects? Will we be able to keep the information obtained, confidential?

(ii) Does our proposed research expose the subjects to a potentially hazardous agent?

(iii) Does our proposed research has a likelihood of depriving the human subjects of a known or potentially useful agent?

(iv) Will it be possible for us to develop a system of obtaining 'informed consent' from the subjects, if required?

(v) Has the project been discussed in the "ethical committee".

(d) Will our research question pass the "If so, so what" test, after the research has been completed?"

(i) Will the findings of our proposed research work benefit the medical fraternity in general, or our specialist fraternity in particular, in some way?

(ii) Are the recommendations that may finally come out, likely to be "practicable"?

(iii) Is something new likely to come out of the research work, thus, filling the gaps in the existing body of knowledge? Or is it, that we are finally going to draw the already well known conclusion like "cigarette smoking is injurious to health" !

The importance of step 7 (evaluation of a research question for its suitability) needs no emphasis. A research question may be technically very well developed, through meticulously following steps 1 to 6; however, if the various evaluation criteria mentioned in step 8 raise doubts about its suitability, it must be reconsidered.

Step 8 - Make the "tentative research question" as specific as you can : The more specific a research question is, the more fruitful would subsequent research be. We should examine our written statement at this point, to assess whether there is any element of vagueness or some "general" form of statement which can be made more "specific". As an example, in the above cited research work in the specific area of "adequate hydration for prevention of urinary calculi", a specific research question can be : "Can drinking 5 litres of water per day reduce the risk of renal stone formation by 25%, in young, physically active males, in tropical climate, after duly considering the confounding effects of primary renal disease, dietary factors, racial background, occupation, hypercalciuria, hyperoxaluria, and hyperuricosuria ?

Pragmatically, it may not be always possible to develop a fully

specific question. However, efforts should be made to develop as specific a question as possible. A well developed and specific research question will give us the following indications :

(a) The suspected "exposure" or "cause" - e.g. "lack of drinking enough water" (5 litres per day) in the above mentioned research question.

(b) The postulated "effect" or "outcome" - e.g. urinary tract calculi.

(c) The "magnitude of the effort" - e.g. 25% reduction following removal of the risk factor / cause

(d) The possible confounding factors - e.g. primary renal disease, dietary factors etc.

(e) The general settings of the study - e.g. young, physically active males in tropical areas.

A word about Research hypothesis and Null Hypothesis :

The research question, when expressed in a statement form (rather than an interrogative form) becomes the research hypothesis, e.g. the research hypothesis in the above situation would be "Drinking 5 litres of water can reduce the risk of renal stone formation by 25% among young, physically active males, in tropical climate, after duly considering the confounding effects of primary renal disease, dietary factors, racial background, occupation, hypercalciuria, hyperoxaluria, and hyperuricosuria". The research hypothesis is a tentative guess which we wish to test and finally accept or reject in our proposed research work.

At this point let us also elaborate on the term "Null Hypothesis". The null hypothesis is nothing very special; it is simply the research hypothesis stated in a negative manner. For example, the null hypothesis for the above mentioned research hypothesis would be "Drinking of 5 litres water per day *does not have any effect* in reducing the risk of renal stones (by 25% at least) among young, physically active males, in tropical climate, after duly considering the confounding effects of primary renal disease, dietary factors, racial background, occupation, hypercalciuria, hyperoxaluria, and hyperuricosuria".

The finer aspects of the distinction between Null hypothesis and research hypothesis at this juncture, may not be immediately required to be understood. However, it is important to note, at this point, about these two forms of hypotheses, since (as we shall note subsequently in the sections on bio - statistics), that during the statistical analysis of our research data, we proceed to accept or reject the "Null hypothesis" and not the research hypothesis.

Step 9 - Write down the research question and its significance :

Quite often, we do not follow this step, but it will be a really gainful exercise to reduce the research question, once finalized, to writing in a sentence or two (as given in the example on urinary tract calculi in step 7 above). This would provide a permanent reference during the entire conduct of the study; in addition, it would be easier for us to further refine it.

In addition to writing down the research question, we should also write down its 'significance' in brief. The same would come very handy, for writing the "Introduction" of our research paper or thesis. In addition, it is an obligatory requirement of all the funding agencies. The significance of our research question should briefly bring out the following aspects :

- (a) The importance of the particular disease or health condition (on which the research work is proposed) for public health or clinical practice.
- (b) What is already known in this area, based on review of recent literature.
- (c) What are the potential gaps in the existing knowledge that need to be filled up.
- (d) How the findings of the present study are likely to resolve the present uncertainties in the area, and influence / improve clinical or public health practice / policy.
- (e) What are the potential problems in executing the proposed research work, in terms of feasibility, ethical issues and methodological issues and how they are proposed to be overcome.

Summary

A well formulated research question ensures that half the job of research work is well completed. Developing a research question is a very scientific and deliberate process involving comprehensive academic inputs.

Developing a good research question involves the following steps

- Find a 'general' area of interest
- Read 'around' the topic - a wide and extensive study in that area
- Find a 'specific' area of interest
- Read 'into' the topic - an in - depth, intensive reading in the specific area
- Formulate a tentative research question
- Make the research question as 'specific' as possible - specify the exposure, outcome and confounding variables, the settings, the dose response relationship & the expected magnitude of effect
- Test the tentative question for feasibility, relevance, ethical angle, and novelty.
- Write down the final research question and its background significance in a page or two.

Study Exercises

Long Question : Describe the steps in developing a research / epidemiological question

Short Notes : (1) Ethical considerations while developing a research question (2) Null Hypothesis (3) Considerations while making a research question as specific as possible.

MCQs

1. Which of the following steps follows the step "find a general area" of interest, while developing a research question : (a) Read around the subject (b) read into the subject (c) Make the question as specific as possible (d) Find a specific area of interest.
2. The best way of selecting a research topic for your thesis / dissertation is by : (a) Looking at the list of topics which have been taken up for dissertation during past 5 years (b) Extensive academic reading in your areas of clinical or public health interest (c) Going through the details of the research project which your guide is undertaking at present (d) None of the above.
3. Detailed reading of the entire articles published in relevant journals will be undertaken during the stage of (a) making the research question as specific as possible (b) Read into the subject (c) read around the subject (d) All of the above stages.
4. Which of the following does not represent a "specific area of interest" : (a) Does regular, brisk walking have a protective effect against IHD (b) Is laparoscopic repair of inguinal hernia better than conventional open repair (c) What is the problem of marasmus in India (d) Does HRT prevent osteoporotic fractures among post - menopausal women ?
5. Once a research question has been developed, which of the following is NOT a criteria for assessing its suitability : (a) It should be feasible (b) It should be tailored according to budgetary allocation for research (c) It should be ethical (d) There should be something new in the proposed research.
6. For passing the "if so, so what" test, a research work should be able to : (a) recommend practical suggestions for improving public health or patient care practices (b) get published in an international journal (c) Open up further research questions (d) bring out statistically significant results.
7. Specification of which of the following is NOT an essential requirement for making a research question "specific" : (a) cause (exposure) (b) magnitude of effect (c) general settings of the proposed work (d) cost of conducting the research.
8. Which of the following is not required to be included in the background significance of a proposed research work : (a) What is already known in that field (b) How the proposed research work will be conducted (c) how the results are likely to improve the health care practice (d) what are the potential gaps in the existing body of knowledge.

Answers : (1) a; (2) b; (3) b; (4) c; (5) b; (6) a; (7) d; (8) b.

RajVir Bhalwar

Epidemiology and medical research is one field where 'measurement' assumes paramount importance - the entire research depends on how correctly measurements have been planned, executed and recorded.

The First Step in Epidemiologic Practice identifying the Disease and "Case Definition"

As we have seen in the previous chapter, the first step in epidemiology is "identifying" the disease or a health event or state, which is of interest to us. Hence at the very outset, the epidemiologist must clearly give a "case definition" of the disease or health related phenomena that she is going to study. It may appear too simple but is not so in reality. If our interest is to study "tobacco use", how do we define a tobacco user? - Anybody who has even once put tobacco inside the mouth in the lifetime? Or those who smoke at least one cigarette a week? Or who smokes at least one cigarette a day for at least three days in a week? Or moving towards an infectious disease, how do we say that a given child is a case of Dengue fever or not?

Apparently, one has to give some definition. This, in epidemiology, is known as "case definition". Naturally, we should have a case definition which identifies each and every person who has the disease (sensitive) and at the same time, excludes every person who does not have the disease (specific). In practice, getting a definition which is 100% sensitive as well as 100% specific is never possible, for pragmatic reasons. Hence, we draw an optimum trade - off between sensitivity and specificity, and quite often, make case definitions according to two or three levels of certainty, as "suspected", "probable" and "confirmed" (37), e.g. we may define the three levels for dengue as shown in Box - 1.

Box - 1 : Case Definition - Dengue Fever

Suspected : Fever of at least two days duration with myalgia, arthralgia, retro - orbital pain and severe backache, occurring between July to October in an area where at least one confirmed case of dengue had occurred during past 3 years.

Probable : A clinically compatible case with a single convalescent phase serum IgG titre of 1280 or above or positive IgM.

Confirmed : 4 fold rise in dengue antibody titre in paired sera taken at least 10 days apart, or detection of dengue virus.

Now, having defined the various diseases or health related phenomena that we are interested in studying, we would decide

the various headings on which we will make measurements on our subjects. In fact, not only in epidemiology and medical research, but also in medical practice, the process of measurement according to some pre - decided headings is inevitable. Let us say we are dealing with a patient who has come to us with history of fever and joint pains. Mentally, during the entire course of history taking and physical examination, something like the following chart would be drawn, (subconsciously, though) (Table - 1) :

We are often unaware, but such a data - sheet does form in our mind for every patient we see. Finally, we diagnose the patient as "compensated, uncomplicated rheumatic mitral stenosis" and proceed to manage her. The only difference between medical practice and research is that in clinical practice we stop at every patient and treat her; thereafter, a new chart forms up in our mind for the next patient. On the other hand, in epidemiology and medical research, we continue recording, explicitly, on a chart or performa, as shown in Table - 2, the details for a large number of patients as required by the sample size. Thus, epidemiological and medical research methods are nothing but an extension of the principles of medical practice.

In epidemiology, the above chart, duly completed with all details for the required sample of patients / subjects is what is known as 'Data - Set'. Data can thus be defined as "*an organised collection of information, containing the 'values' of the various variables, obtained from a sample of subjects, and which would be subsequently used to derive conclusions through the process of scientific analysis and reasoning*". In any epidemiological study, data would be obtained by the process of making measurements, on various "items" which are of interest to us. In epidemiology, these "items" on which we make measurements are called as "Variables". All data is recorded in respect of variables. The headings given in the Table - 2 (Sex, Fever, Dyspnoea etc.) are all variables. A variable is thus *any quality, characteristic or constituent of a subject which can be measured and which 'varies', i.e. likely to have a different value from one subject to another*. In fact, when reduced to the lowest terms, all medical research is simply the study of relationship between variables. Thus in the above example, when we would finally try to show that Rheumatic Heart Disease (RHD) is more common in females, we are actually studying the relationship between two variables - Sex and RHD.

The next step is to decide, from the statistical point of view as to which "scale" would we be recording each of these variables. Whenever measurements are made, there has to be a "scale" of measurement, for each of these variables (like we measure length and mass on "metric" scale). In epidemiology, depending on the way we record the measurements, the variables can be, broadly, either of the following two types -

(a) **Quantitative variables** : When information is recorded in terms of mathematical figures; e.g. Blood Pressure, Serum lipids, Body Weight, Number of Carious teeth etc. Since such

Table - 1

Sex	Age	H/o fever & joint pains	Palpitations	Dyspnoea	Precordial pain	Fever	Pulse	Enlarged Liver & Spleen	Mid - Diastolic murmur
F	11	Yes	Yes	Yes	Yes	Yes	Irregular	Yes	Present

data is recorded in form of numerals, one can also call it as 'Numerical data'.

(b) Qualitative variables : When information is not recorded in form of numbers but according to certain defined attributes; e.g. Sex - Male/Female; Outcome of treatment - Recovered/ Dead; Blood group - A, B, AB or O; Satisfied with treatment - Yes or No, etc. It is also known as "attributive" scale or a "nominal scale" since it records the attributes or the characteristics by classifying the characteristic (or attribute) into categories to which a given subject belongs or does not belong, or else the property or quality that a subject possesses or does not possess.

It is quite simple to find out whether the data being collected for a particular variable is of qualitative or quantitative variety. Just see the space opposite that particular heading in your data collection form. If you are going to record the answers in mathematical figures, i.e. some sort of "numbers" which may be whole numbers, decimal figures or fractions (e.g. BP, Serum Cholesterol, No of Children) then the data is of quantitative type. On the other hand, if you are going to record the answer in words (e.g. sex - Male/Female; Response to treatment : Recovered/Not recovered, Blood Group - 'A', etc.) then the data is of qualitative type. Each of these two types of data (qualitative and quantitative) have 3 distinct sub - scales of measurement:

Quantitative Variables

These can be further of 3 types

1. Discrete Scale : This type of data has the following characteristics

- They correspond with a count of some sort
- They are recorded as integer numbers
- They cannot take any decimal value
- The numbers have a definite mathematical relationship.

A number of variables are measured on discrete scale; e.g. No. of DMF teeth; No. of abortions; No. of spells of a given disease for individual subjects; No. of doses of a vaccine taken; No. of visits to the hospital and so on.

Let us take an example. We did a study about the number of episodes of haemoptysis among patients attending a chest hospital OPD. A sample of 1000 patients was studied. The 'variables' of interest were 'Number of episodes of haemoptysis'

and "Type of Respiratory disease - Tuberculosis or otherwise". The other variables were fever score (0= no fever, 1 = mild and so on), and Blood group. The "data - set" would look like as shown in Table - 3. In this data set, the variable 'Number of episodes of haemoptysis' is measured on a discrete scale because the measurements are made in the form of meaningful numbers which can take only integer values and never any decimal value (you can not have a patient saying that she had "2.31" episodes of haemoptysis!) and there is a definite mathematical relationship between these numbers, in that 4 episodes of haemoptysis are actually equal to two times of 2 episodes, or equal to 3 episodes plus 1 episode and so on.

2. Numerical, Continuous Scale : Like the numerical 'discrete' scale, in a numerical continuous scale, the observations are recorded as quantities which have mathematical relationship; however the major difference from discrete variable is that the observations can take any value (theoretically at least) along a 'continuum' between 2 integers (and not compulsorily restricted to integers, as in a discrete scale). Take, for example, a variable like systolic BP. While we would generally measure systolic BP as 118, 120, 122 etc., this is only because we have calibrated the instruments accordingly. Theoretically at least, SBP can be recorded as 199, 121 etc.; and can also be measured as 119.5 or 121.7, or even, for that matter, as 119.5397501 or 121.7039267 (provided we had a sphygmo - manometer so precise and the desire to do such a precise recording). Not only BP, but a large number of measurements in health practice are made on this scale - e.g. age, blood sugar, various other biochemical parameters, body weight, height, BMI, stroke volume, CSF pressure and so on.

Often, the continuous and the discrete scales are together referred to as "ratio" scale also.

3. Numerical Ordinal Scale : The ordinal scale is a very interesting one. It uses numerical symbols for recording the data, but these numbers do not have any meaningful mathematical relationship. Let us take the example of the hypothetical example of our data set that we have presented earlier. For recording the variable 'H/o fever', we can record it in terms of categories like No fever, Mild, Moderate and High fever. We can go further and give numerical values to these categories as No fever =0, Mild fever =1, Moderate = 2, High

S. No.	Sex	Age	H/o Fever & joint pains	Palpitation	Dyspnoea	Precordial pain	Fever	Pulse	Enlarged Liver, Spleen
1	STOP AFTER 1st PATIENT IN CLINICAL PRACTICE BUT CONTINUE TILL THE REQUIRED SAMPLE OF PATIENTS IS COMPLETED, IN EPIDEMIOLOGY AND MEDICAL RESEARCH								
2									
.									
.									
51									
.									
.									
100									

= 3. In fact epidemiology and medical research is full of such examples (grades of dyspnoea 0 to 5; grades of murmur 1 to 6; levels of satisfaction; grades of cancer 1 to 4; degree of relief from pain; APGAR Scores, and so on). However, it is here that the catch point lies. The numbers 0, 1, 2 and 3 are not real mathematical numbers - high grade fever is not really equal to 3 times mild grade nor do a patient each of nil, mild and moderate fever added together will give a clinical state equal to high fever! The catch point is important to understand because the statistical tests to be used in such situations (non - parametrics) are very different from the usual parametric tests used for discrete or continuous scales. For the present, it may be noted that it is advisable to work out the median and not the mean when confronted with ordinal numerical data. The non - parametric tests, in fact, compare the medians and not the means.

Qualitative Data

The peculiarity of qualitative data is that the recording of observations is not made in form of numbers as in quantitative data, but in form of words. The major 'scale' for recording the qualitative data is "categorical", also called a "nominal scale" in which two or more categories are made; and depending on whether there are only 2 categories or else more than 2 categories, the scales are called as "nominal, dichotomous" and "nominal, polychotomous" respectively. In addition there is a third category of "polychotomous, ordinal" scale.

(i) Nominal Dichotomous : In nominal dichotomous there are only 2 possible alternative answers to the information being recorded; e.g. Hypertensive - Yes / No; Status - Dead / Alive; Response - Recovered/ Not recovered; Tobacco user - Yes / No; and so on. In other words, the response will be recorded as "either - or" of the 2 alternatives, in words, not numbers. (At this point it should be noted that the response may sometimes be recorded as '0' for No and '1' for Yes especially when a logistic regression analysis is being planned; however, even if the response is recorded as 0 (for No) and 1 (for Yes) (or 0 for male and 1 for female etc.), the scale remains a dichotomous one only. For example, in our hypothetical data set above, "Type of respiratory disease" is recorded as a dichotomous variable, being recorded as either 'TB' or 'non TB'. The presentation of the variable finally will be in the following form, by listing the various possible categories and calculating the percentages

S. No.	Particulars of patient	Fever Score	Type of Respiratory Disease (TB / non TB)	Number of episodes of haemoptysis	Blood group
1.	XYYX	2	non TB	2	A
2.	XXXY	3	TB	4	AB
3.	XYYY	0	non TB	3	B
.
.
1000	XYXY	1	TB	1	O
Total 1000	:		TB = 800 non TB=200	2850	

(Table - 4)

Type of respiratory disease	Numbers & percentage
TB	800 (80%)
Non TB	200 (20%)
Total	1000 (100%)

(ii) Nominal Polychotomous : In a nominal polychotomous scale, there are more than 2 alternative answers or possibilities for the information being recorded; and the information is recorded in words, not in numbers. In addition, the categories in a nominal polychotomous scale do not have any "natural" ordered relationship, in contrast to the ordinal scale where there is a definite ordered relationship. A number of variables in medical research are recorded on nominal polychotomous scale; e.g. Blood groups (A,B, O, AB), race, religion, geographic area of residence, hospital where being treated and so on. In our hypothetical data set, blood group is recorded on a nominal polychotomous scale.

(iii) Ordinal Polychotomous : Sometimes the investigator may not give numerical scores to his ordinal variables but treat them on a polychotomous (ordinal) scale. While doing so, he may not record the fever grade in numbers (0, 1, 2, 3) but in words (nil, mild, moderate, severe). This is also acceptable but the statistical analysis will be slightly different from the usual tests used for nominal polychotomous data. For example, in our hypothetical data set, we may decide not to give scores to fever grade but rather record and present it as shown in Table - 5 :

Fever grade	Patients	
	Tubercular	Non TB
Nil	200 (25%)	50 (25%)
Mild	100 (12.5%)	75 (37.5%)
Moderate	200 (25%)	50 (25%)
High	300 (37.5%)	25 (12.5%)
Total	800	200

The relevant test in such a situation would be 'Chi square test for linear trends in proportions' rather than a 'non parametric' test, which would have been done if we were recording grades of fever in terms of numbers (0, 1, 2 etc.) as explained earlier under the "numerical ordinal" scale.

The difference between a "nominal polychotomous" and an "ordinal polychotomous" scale must be appreciated. In both of these scales, there are more than two possible categories (if there are only two possible categories then it would become a nominal dichotomous scale). However, the essential difference is that in "nominal polychotomous" scale, the various possible categories do not have any natural sense of ordering (e.g. Blood groups A, AB, O, B can be written in any order or Race - Caucasian / Mongoloid / Negroid can be written in any order). On the other hand, in an "ordinal polychotomous" scale, there is a definite natural ordering which stands to common sense reasoning; e.g. Grades of pain will be naturally appreciated in the order of no pain, mild pain, moderate pain and severe pain and no disturbance of such order (as moderate pain/no pain/marked pain/mild pain) would be appreciated. As far as dichotomous scale is concerned, there need not be any distinction between anything like "nominal dichotomous" and "ordinal dichotomous" for the apparent reason that there are only two possible categories.

It becomes very important for the investigator to specify, soon after he / she has formulated the epidemiological question, as to what 'variables' will be studied and what would be the 'scale for recording' each of them. The decision is important because the subsequent analysis of data will depend upon the type of recording scale for different variables. However, whenever in doubt it is wise to remember that a continuous (or discrete) scale contains the maximum amount of information followed by an ordinal scale while the dichotomous scale records the least information (DBP of 96 or 130 will both be recorded as 'hypertensive'). If the data has been recorded on a continuous or discrete scale (of course, if at all it is possible to do so), it can be later collapsed into polychotomous or dichotomous categories but if it has been recorded on a dichotomous scale it can not be expanded subsequently, because the detailed information was never collected.

Summary

At each and every step of epidemiology & medical research, or even clinical practice, we are making measurements. We select certain headings (e.g. age, sex, BP, mid - diastolic murmur, history of joint pains etc.) and record the value of each and every such heading; these are called as "variables", since they are likely to have different values for every next subject. The organised collection of the values of various variables in respect of all the subjects is called "data - set". For recording the 'values' of the different variables, there are definite laid down scales of measurement. The final statistical analytic procedure will depend on the "scale" on which measurements were recorded for various variables. These scales of measurement are :

(a) Quantitative variables : When the various values of the variable are recorded as "quantities", i.e. mathematical numbers. These can be of further 3 subtypes

- (i) Discrete Scale : The values are recorded in real mathematical numbers which can take only integer (but no decimal or fraction) values.
 - (ii) Continuous Scale : The values are recorded in real mathematical numbers which can take any decimal or fraction value.
 - (iii) Ordinal Numerical Scale : The values are recorded in real numbers (i.e. these numbers are not meaningful from mathematical aspect).
- (b) Qualitative (categorical) variables : When the various values of the variable are recorded as "qualities" or characters, i.e. in words. These can also be of further 3 subtypes :
- (i) Dichotomous (Binary) Scale : When there are only two possible categories which are recorded in "either this or that" manner.
 - (ii) Polychotomous Nominal Scale : When there are three or more possible categories and there is no natural or common - sense ordering among these categories.
 - (iii) Polychotomous Ordinal Scale : When there are three or more possible categories and there is a definite natural or common - sense ordering among these categories.

Study Exercises

MCQs & Exercises

1. The association between exposure to television viewing and mental acuity in children was studied and the following information was recorded for each child in the study; Religion (Hindu or any other religion), age (in years), and amount of exposure to TV viewing (rated from 0 for no exposure to 3 for more than three years exposure to TV viewing). Which of the following choices lists these variables in the order of : dichotomous nominal, ordinal, and continuous? (a) Amount of exposure, religion, age (b) Age, religion, amount of exposure (c) Religion, age, amount of exposure (d) Religion, amount of exposure, age (e) None of the above
2. What are the alternative scales of measurement in which the variable "serum cholesterol" can be recorded in an epidemiological research work? Tick the correct combination : (a) Continuous, discrete, dichotomous, polychotomous - nominal; (b) Discrete, polychotomous - ordinal, polychotomous - nominal, dichotomous; (c) Continuous, numerical - ordinal, dichotomous, polychotomous - ordinal ; (d) All of the above
3. Data regarding a qualitative variable can be summarised by the following method : (a) By calculating the arithmetic mean (b) By making categories and calculating percentages in each category (c) Both the above methods (d) None of the above methods
4. APGAR scores of newborns were recorded in an epidemiological study and results were presented to state that the mean APGAR score of newborn was 6.43. Was this correct ?
5. Match the manner in which data was recorded for various variables as shown in column 'A' with the appropriate scale of measurement shown in column 'B'.

'A'		'B'	
S. No.	Method of recording the data	S. No.	Scale of measurement
a	Satisfaction with services provided by health worker. Responses recorded as - 2 (highly dissatisfied), - 1 (somewhat dissatisfied), 0 (neutral), +1 (reasonably satisfied) and +2 (Highly satisfied)	(i)	Dichotomous - Nominal
b	Obstetric history recording the gravida status	(ii)	Numerical - Continuous
c	Clinical efficacy of an anti - cancer drug recorded as either survived or died at end of five years	(iii)	Polychotomous - Ordinal
d	Coronary angiograms recorded as no blockage, mild, moderate and sever blockage of coronaries	(iv)	Numerical - ordinal
e	Coronary angiograms recorded as actual diameter of coronaries	(v)	Discrete - numerical
f	Indoor admission data from a chest diseases centre wherein diagnoses were recorded as lung disease, heart disease, diseases other than those of heart and lungs.	(vi)	Nominal - Polychotomous

Answers : (1) d; (2) c; (3) b; (4) Incorrect (5) a-iv; b-v; c-i; d-iii; e-ii; f-vi.

15 Populations and Samples

RajVir Bhalwar

A major reason for having an insight into the science of epidemiology and research methodology is that we always study a 'sample' and, based on the results obtained from the sample so studied, we draw conclusions about the whole lot of subjects having that particular disease or health related condition, from which the sample was drawn. In fact, the concept of studying 'samples' is not unique to the field of medical research alone - Let us take the examples of a housewife examining a fistful of rice from a sack to get an idea of the quality, or else a mother preparing feed for her baby. After she cooks the feed, she 'tastes' a tablespoonful after stirring the entire mixture well, and one can see the 'nod' of satisfaction on her face, approving the various characteristics of the feed, like adequacy of cooking, taste, salt and sugar content, warmth etc. Now, ideally, for drawing conclusions about these various characteristics of the entire feed, she should have eaten the entire feed, but she does not do that (and should not - she would be a fool if she does that). Rather she draws conclusions only from a tablespoonful (i.e. the sample). The analogous situation in epidemiology is that with the ultimate objective of finding the real state of affairs that exist in large collection of humanity or patients, we draw a 'sample' and depending on the results of the sample, we

draw conclusions about the 'reality' that would be existing in the entire population.

At this point, let us distract slightly and briefly discuss another common activity - the tossing of a coin. This is an experiment in which the 'reality' is already known to us - i.e. half of the coin is 'heads' and half of it is 'tails'. In other words if we toss the coin 10 times, we should get heads and tails on 5 occasions each. More generally, if we toss a coin 'n' number of times, we should get heads as well as tails on "n/2" occasions each. However, if we actually undertake this "tossing game" (you can do it yourself just for the sake of fun, as long as it remains fun) the results we would get would be something like shown in Table - 1.

No. of times coin tossed	Results	
	Heads	Tails
1	1 (100%)	0 (0%)
10	8 (80%)	2 (20%)
100	72 (72%)	28 (28%)
1000	647 (64.7%)	353 (35.3%)
1,00,000	52825 (52.8%)	47175 (47.2%)
Infinite number of times	50%	50%

We can describe the above experiment as follows : “we were trying to estimate a truth that exists in the universe, i.e. how much of the coin is heads and how much is tails, on tossing. Unlike the usual situations wherein the ‘truth’ is not known to us and we try to estimate it with our sample, in this particular situation, luckily, the truth is already known to us - it is 50 % each. However, when we tossed the coin only once, we had widely missed the truth, concluding that the coin would exhibit 100 % heads and 0 % tails. On tossing the coin 10 times, we moved nearer to the truth, the results being 80% heads and 20% tails, but were still quite far away from the reality of 50% each. We kept getting closer and closer to the reality as we increased the number of tosses to 100, 1000 and so on; however, even after tossing it one lakh times, we were still not exactly at the reality of 50% each, though we did get quite close to it (52.8% and 47.2%). For exactly getting on to the reality, i.e. 50% each, we will have to toss the coin infinite number of times, and if ever we could do that, we would be right on the ‘truth’.

Let us see one more situation. Let us say we decided to estimate the truth about the coin with the sample of one lakh tosses and we decided to do five such experiments. The results are as shown in the Table - 2.

Experiment No.	No. of Heads	Truth
1.	47800 (47.8%)	50%
2.	55301 (55.3%)	50%
3.	51980 (51.9%)	50%
4.	48002 (48.0%)	50%
5.	53067 (53.9%)	50%

The next take home message from the above study is - even if we study repeated samples of the same size, drawn in the most representative manner, no two samples are likely to give us the same result, nor the result for any sample likely to be the same as the truth which exists in the large population from which the samples were drawn. Why does this occur ? This occurs because of a very interesting natural phenomenon called “Random Error” or “Sample to Sample error” or more simply “chance”. As long as we are studying a sample, which we would be doing any way, some error should always be accepted.

Let us transpose this simple concept to epidemiology. Let us say, we have developed an important research question, viz, “What is the seropositivity for HIV infection among apparently healthy, young males in our country? This is a real epidemiological research situation, in which we are trying to estimate some “truth” (seropositivity for HIV) that exists in a “large population” (the entire healthy, young males in our country). Unlike the previous example of the tossing game in which the “truth” (50% each of heads and tails) was known to us ‘a priori’, in the present situation, the ‘truth’ is not known to us. Just for the sake of discussion, let us assume that the truth is, say, 1% (seropositivity for HIV infection among healthy young males in the country as decided by a confirmatory test like Western Blot).

Proceeding on the lines of the tossing experiment, if we do our

study on a sample of just 10 men, we may not get any positive, thus our conclusion about seropositivity would be 0%. If we do the study on 100 subjects, we may get 3 positives, thus concluding that seropositivity rate is 3% (again widely away from the reality or truth of 1%). If we increase the sample to 1000 or 10,000 respectively, we may get 15 and 80 positives, thus giving seropositivity rates of 1.5% and 0.8% respectively. Now, what is happening is, that, as we are increasing the sample size, we are definitely getting nearer and nearer to the truth; however, if we want to get a result which is exactly the truth (1%), we will have to study the “whole population” of all the healthy young males in the country.

The conclusion that can be therefore drawn is that as our sample size increases, we are more and more likely to get nearer to the truth or reality that exists in the “total population”, and which we are trying to estimate from our sample; however, we will never be able to confidently say that we have exactly estimated the truth, unless we study the whole population.

The take - home message for the medical researcher is that there is nothing like a “completely adequate” or “foolproof” sample size. We have to accept some “deviation” or “error” from the reality that exists in the “total population” (and which we are trying to estimate from our sample being studied). The only solace is that as we keep increasing the size of the sample, this error or deviation from reality will be lesser and lesser, but this error or deviation will certainly be there, more or less, unless we decide to study the complete “reference population”. We should be ready to accept some deviation that is likely to occur from the truth; even more than that, we should be able to specify the amount of deviation that is acceptable to us. Once this “acceptable deviation” has been specified, we can calculate the “optimum sample size”. For example, in our above mentioned study on seropositivity for HIV infection we may specify that “reality in the reference population is likely to be about 1%, and we are ready to accept a “deviation” of 0.2% on each side of this expected truth of 1% i.e. we accept that our sample is likely to give us a result that may vary from 0.8% to 1.2% (1% + 0.2%) and not exactly at 1%”. Once this has been specified the sample size for such a situation will work out to 9500 subjects. The details of statistical methods for calculating the sample size in different situation are dealt in detail in a subsequent chapter. What is more important at the present stage is that the epidemiologists and medical researchers should understand this concept and should be ready to specify these “parameters” (i.e. the expected truth that is likely to exist in the reference population, and the acceptable deviation from this likely level of truth) to our statistician colleagues if we approach him for calculating the sample size.

The Second Requirement of a ‘sample’ : By now, the foregoing deliberations would have amply clarified the fact that the first requirement of a sample is that it should be of “adequate size”. At this point, if we get back to the opening paragraphs of this chapter, we would notice a peculiar statement - the mother, before taking a ‘sample’ tablespoonful of the feed, stirs the entire feed well, before drawing the tablespoonful. This is because, had she not stirred it well and taken a spoonful from, say, the surface itself, she would not have got the correct estimate of taste, warmth, adequacy of cooking, etc. This idea

is central to another very important aspect while drawing a sample - that the sample should be “representative” of the reference population from which it has been drawn, otherwise the results obtained would be very different from the reality that we are trying to estimate.

Let us get back to the above mentioned research example on seropositivity for HIV infection. Suppose we have worked out the “optimum sample size” of 9500 and are prepared to collect it. Now, if we take these 9500 subjects from either a private blood bank patronised by professional blood donors or from subjects attending a STD treatment clinic, we may get a result which may be as high as 5% seropositivity, thereby grossly over - estimating the “reality” (which is likely to be around 1%, as assumed). In other words, if the subjects in a sample are “non - representative” (i.e. systematically different from the total or reference population), the result that we get will not be representative of the total population. Thus, we will not be able to “generalise” these results by saying that the seropositivity for HIV infection among healthy young males in our country is 5%. This is what we call as the “lack of external validity” which leads to loss of generalizability of results. The methods and techniques of drawing a representative sample are discussed in detail in a subsequent chapter.

However, there is a little piece of consolation. If the study itself has been conducted properly (i.e. proper procedures for drawing and testing blood samples by ELISA / Western Blot have been ensured, and so on) we may still be able to “generalise” our results to another “population” of professional blood donors or patients attending STD Treatment Clinics. Thus, from such a study, while we cannot conclude that the seropositivity among healthy young males in our country is 5%, we can, nevertheless, conclude that the same among professional blood donors or STD patients, is about 5%.

External validity, if lost, leads to loss of generalizability of results to the total population which the investigator has in mind. However, the results can still be generalised to another “population” of which the sample, so drawn, is representative. On the other hand, if the study itself has been undertaken using wrong methods (untrained laboratory workers, haemolysed blood samples, outdated kits, etc.), then it leads to loss of internal validity. If, in a study, internal validity has been compromised or lost (i.e. ‘bias’ has come in) , the study becomes fit for rejection only. Out of the two components of validity, internal and external, while both are important, it is the “internal validity” which has to be maintained at all costs.

Now that we have gone through the two important requirements of a sample, let us discuss some terms which are often used in epidemiological and medical research :

1. Total Population (Syn - “Universe”; “Reference population”; “Source population”) : This is the total collection of all subjects or units of study that the investigator keeps in mind while drawing her sample and on which she proposes to generalise her results. Quite often, the “total population” is very large, difficult to define precisely and more of “conceptual” in nature; e.g. “all healthy young males in the country”; or “all patients with acute Myocardial Infarction”, and so on. In a nut shell, it is the investigator’s study question / objectives and the

clinical and demographic characteristics that define the Total Population.

2. Actual Population (Accessible population or Study population) : Since the total population is usually difficult to precisely define, for actually drawing the study sample, the researcher often specifies a “subset” of the total population from which he proceeds to take the study sample. For example, in the HIV seropositivity study mentioned above, since the total population (i.e. all healthy young males in the country) is difficult to define precisely, the investigator may specify that he will select the sample from 5 Districts located at different places in the country. Similarly, in a study on the association of “Transverse Ear Lobe Crease” with IHD, while the “total population” is “all patients with IHD in the world”, the investigator will define his actual (study) population as “all IHD patients admitted to a particular teaching hospital”, and draw the sample from this actual (study) population. The assumption is that such “study population” is a “representative subset” of the “total population”. If, for some reason or the other, this assumption is not tenable, then the external validity and generalizability would become restricted. For example, if the 5 Districts selected for drawing the sample in HIV seropositivity study are those which have a high occurrence of intravenous drug abuse, we may not be able to generalise the findings to the entire country (though we could still generalise our results on to all districts having a high occurrence of intravenous drug abuse). Deciding whether the Actual (study) population is a representative subset of the total population depends on the experience of the investigator. One should not hesitate in seeking the advice of one’s peer groups and experts if ever in doubt. It is the similarity to the Total Population and the geographic and temporal (time related) characteristics that define the actual or accessible population.

3. Sample (Syn - Study Subjects) : From the actual (study) population, the investigator chooses a “sample” of the required optimum size, using methods which ensure that the sample so selected will be representative of the study population. In case the sample, for some reason, does not remain representative of the study population, the external validity, and hence generalizability, will be once again comprised, as explained above. The procedures for calculating the “optimum sample size” and methods of drawing a “representative sample” are elaborated in subsequent chapters.

4. “External Population” : For understanding the concept of “external population” and how it is different from “target population”, have a look at the following example : Suppose our results from our sample indicate that HIV seropositivity among our country is 1%. After some deliberations regarding whether our sample was representative of the actual (study) population and whether the actual (study) population was in turn, a reasonably representative subset of the target population, we could reasonably assume that the overall seropositivity in the entire country would also be about 1%. Can we, based on these results, derive some conclusion about our neighbouring countries also? Deriving such conclusions actually would go beyond simple methodological issues and would involve judgements about other findings, conceptualisation of the disease process, related biological processes and comparative

features of the “Target Population” (in this example, “the Indian people”) in relation to such “External Populations” (in this case the “Pakistani or Sri Lankan people”). However, this exercise (of applying the results from one Target population of a given research to another “External Population”) is very common in clinical research. Why go far - almost all the clinical research pertaining to preventives, diagnostics and treatment modalities, undertaken on USA population is also applied for practice in our Indian population, without any further research. External validity, thus, has to be assessed at three different levels.

The first external validity consideration (depicted by “1” in Fig. - 1) is the generalisation from the sample intended to be studied, to the actual (study or accessible) population. The issues of selecting a probability sample come into play at this level. The second consideration (denoted by “2”) comes when we are generalising from the accessible population to the target (syn : universe; reference) population. This goes beyond the issues of sampling methods and involves the understanding of the socio - demographic and temporal characteristics and similarities / dissimilarities between the accessible and the target population. Finally, the third consideration in external validity (denoted by “3”) comes when we further try to generalise our study results from the sample to some “external population”. As said earlier, deriving such conclusions actually would go beyond simple methodological issues and would involve judgements about other findings, conceptualisation of the disease process, related biological processes and comparative features of the “Target Population” in relation to such “External Populations”.

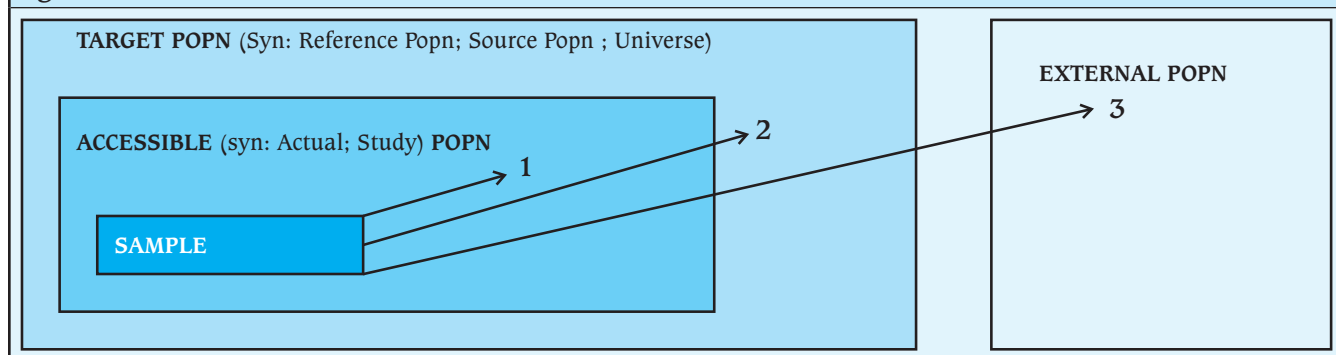

It is very important to think and decide on the issues related to the definitions of “populations” in one’s epidemiological study, right from the planning stage, and write them explicitly in the protocol. The following is the suggested sequence :

- (a) First of all, specify (preferably, write down) the target population (universe) on the basis of your research question and taking into consideration the various clinical and demographic characteristics that are relevant to your research issue. The basic guiding criteria at this stage is that the target population so specified by you should be well suited to your research question. For instance, let us say your overall research issue is to study the prevalence and risk factors for “Hepatitis - B” carrier state in middle aged male paramedical persons in our state. So, we can

define our target population as “all male personnel who are working as paramedical persons in our state and who are aged >35 years”.

- (b) As the next step, one should then specify the accessible population on the basis of temporal and geographical characteristics. The overall guiding criteria, now at this stage, is the overall representativeness of this accessible population, vis - à - vis the target population and the ease of study. Thus, in our above example, we may define our “accessible or actual or study population as all male paramedical persons aged above 35 years working in government and private hospitals in our city, during the period of July 2005 to July 2008”.
- (c) Next, one should design an approach to select a sample that will be representative of the accessible population. This is done by selecting an appropriate method of “sampling” as discussed in one of the later chapters. In our example, we may specify, at this stage, that we will select the sample from a list of all paramedical persons who are registered for work or on active payroll of government and private hospitals in our city, using the method of “Multistage sampling”.
- (d) Now, specify the “inclusion criteria”, looking at the target population. The guiding principle at this stage is to clearly think and specify as to what all characteristics of the target population need to be specifically included, to answer the issue adequately. For example, we may specify the inclusion criteria as all male paramedical persons, serving in either government or private hospitals in our city, who are aged above 35 years, and are apparently asymptomatic.
- (e) Now, apply the “exclusion criteria”. Be very sparing while formulating the exclusion criteria. Apply them for excluding those subjects who may be having a very high probability of being lost to follow up, or the particular treatment being tried may be contraindicated in these subjects, or some of their characteristics may directly interfere with the study results. In our continuing example, we may say that subjects who are already under treatment with interferon or are having any STD, will be excluded.
- (f) Finally, think of some possible “External Populations” to which you may contemplate generalising your results. In our continuing example, can these results about hepatitis - B among middle aged male paramedical persons of our state be also applied to the female paramedical persons? Or to paramedical workers of another state or country?

Fig. - 1

Clearly, this issue would need a lot of considered discussion with the experts.

Summary

An extremely important consideration in epidemiology and medical research is that we nearly always keep a large population in mind, in our research question, but we actually undertake the study only on a “sample” and not on the total population. The total population (also known as the target population or universe) is that large collection of humanity which the investigator has in mind in the research question and on whom the results of the study are intended to be applied. Since this large total population is often very large and difficult to delineate, the epidemiologist specifies a subset of this total population, which is easily accessible and from which the sample is actually drawn. This is known as the “actual” (also called as accessible or study) population.

When we study a sample, two issues which come up are firstly, if the sample is not representative of the large population, we may not be able to apply the results from our study on to the total population; this situation is known as lack of generalizability or loss of external validity. For overcoming this problem, we should ensure that we draw a representative sample for our study, using one of the “probability sampling techniques”.

The second issue which comes up is that the results obtained from a sample are always likely to be different from the reality which exists in the large population, from which we have drawn the sample. This would happen no matter how accurate we have been in actually undertaking the various measurements and despite our having drawn the most representative sample. Similarly, the results from consecutive samples, drawn from the large population, in the most representative manner, are likely to be different from each other as well as likely to be different from the reality that actually exists in the large total population. This is a natural phenomena which is known as “chance” or sampling error or random error. Smaller the sample size that we have studied, more will be the likelihood of this error; conversely, as we increase the sample size, the probability of random error decreases to the point that if we study the entire population, there will be no random error. There are two steps that need to be taken for this error. Firstly, we should study a sample, which besides being representative, should also be of “adequately large” size, as determined by various methods as sample size calculations. Secondly, we should, at the end of our research work, estimate the probability of random error having produced results which could be different from the reality that is present in the total population. This is done by using various statistical procedures and calculating the “p” value.

Study Exercises

Short Notes : (1) External validity (2) Random Error (3) Reference population versus external population.

MCQs and Exercises

1. An epidemiological study was undertaken to find out use of condoms among truck drivers, by carrying out a personal, confidential interview of all truck drivers who ate at a road - side restaurant just outside Mumbai on the Mumbai - Pune Highway. Which of the following best

describes the reference population in this study : (a) All people who drive on highways (b) All Truck Drivers in India who use condoms (c) All truck drivers who eat on road - side restaurants (d) all of the above (e) none of the above.

- In the above study, the workers found that condom usage among truck drivers who visited CSWs was 25%. They concluded that the condom usage among visitors of CSWs is likely to be 25%. Which population were the workers applying their results on.
- If we study the entire source (reference) population, which of the following errors will not occur : (a) Random error (b) Measurement error (c) Error of External validity (d) none of the errors will occur.
- After we have completed an epidemiological study and are calculating the p - value based on statistical tests, we are : (a) trying to minimize the random error (b) trying to see whether our study population was representative of reference population (c) trying to estimate the probability by which our results are likely to be different from the truth, because of random error (d) Trying to find out the extent of measurement error in our study.
- Which of the following set correctly names all the synonyms of “chance” : (a) Sampling error, Sample to sample error, sampling variations, sample to sample variations, Random Error. (b) Sampling error, Measurement error, sampling variations, sample to sample variations, Random Error (c) Sampling error, Error of external validity, sampling variations, sample to sample variations, Random Error. (d) Sampling error, Measurement error, sampling variations, sample to sample variations, Error of external validity.
- Which of the following set correctly lists out all the synonyms of “Reference Population” (a) Target population, Source population, Universe. (b) Target population, Study population, Universe. (c) Target population, Source population, External population. (d) All the above (e) None of the above
- An epidemiological study was carried out in Delhi City (DC) to see whether obesity is associated with hypertension in young adults. The investigators decided that it was not feasible to take a sample from all the young adults in DC. It was felt by the investigators that commercial fitness centres may provide a good source of young adults in DC. A random sample of young adults was studied from several fitness centres, randomly selected from a detailed list of fitness centres in DC and the body weight and blood pressure of the selected subjects was measured. Answer the following questions : (a) What is the target (source) population for this study ? (b) What is the actual (study) population in this study ? (c) Does the sample represent the study population ? (d) Does the study population represent the source population ?
- In the above example in Q. No. 7, suppose the researchers thought that it was important to obtain a sample from all young adults in DC and not simply from those who attend fitness centres. They used the census figures available with corporation office in DC to get a list of all young adults. A random sample was then taken from several randomly selected wards in the city and their body weight and

blood pressure levels are measured. Answer the following questions : (a) What is the target (source) population for this study ? (b) What is the actual (study) population in this study ? (c) Does the sample represent the study population ? (d) Does the study population represent the source population ? (e) can you visualize one situation in which the sample may not remain representative?

9. After the above study was completed, the investigators found an association between obesity and hypertension. They recommended obesity control measures for the entire country. Explain as to what type of population was being considered in this instance.

Answers : (1) e; (2) The workers were trying to generalize their results to an “external population”, which most probably can be defined as “visitors of CSWs”. This is quite different from the reference population defined above; (3) a; (4) c; (5) a;

(6) a; (7) (a) All young adults in DC. (b) All young adults who attend fitness centres in DC (c) Yes, since the sample studied was randomly selected from the study population at two stages - at the first stage some of the fitness centres were randomly selected from all the centres in DC and at second stage, young adults were randomly selected from all those who actually attended these selected centres. (d) No, since young adults who attend fitness centres are not representative of all adults in DC, being very different as regards their health related attitudes and obesity levels. (8) (a) All young adults in DC. (b) All young adults in DC (c) Yes (d) Yes (e) If all those selected for the study do not participate in the study, the sample may not remain representative. (9) External population, because the study was actually restricted to young adults of DC. Extrapolating the results to the entire India goes beyond the considerations pertaining to the methodological aspects of the study.

16

Measures of Disease Frequency / Health Outcomes

RajVir Bhalwar

In one of the earlier chapters, we had discussed the fundamental principles of data management. To revise it quickly, with an example, a data - set of a hypothetical research work on the research question whether “Waist : Hip Ratio is related with IHD” is presented in Table - 1

This data - set has a lot of scientific information but does not convey much to the reader (or for that matter even to the

investigator who has undertaken this research). The investigator should therefore, reduce these ‘values’ to certain ‘summary’ figures. Depending on the type of ‘scale’, the summary figures can be of the following types :

- (a) For numerical continuous or discrete variables, the investigator would calculate the arithmetic ‘mean’; e.g. for waist - hip ratio, we may calculate the overall mean as 0.90.
- (b) For variables, measured on ordinal scale, work out the ‘median’, e.g. we may calculate the ‘median’ value of dyspnoea grade as ‘2’ among IHD cases and ‘1’ among healthy people.

Some variables are measured on “categorical” (dichotomous or

Table - 1

Sr. No.	Subject's Name	Dyspnoea grade	Waist (cms)	Hip (cms)	Body Mass Index	Tobacco Smoking	SBP	DBP	Physical Exercise	IHD
1.	XXXV	3	90	100	27.5	Yes	146	92	None	Yes
2.	ACDB	1	84	96	23.2	No	132	78	Regular	No
3.	XBTC	0	76	84	21.2	Yes	128	82	Irregular	Yes

polychotomous) scale. These tell us if a health related outcome of interest has occurred or not.

While “outcome” forms the ultimate end point of research, the starting point is what we call as “exposure” or “cause”, the desire being to see whether a particular “exposure” leads to a certain “outcome”. Thus, smoking, ACE - inhibitor drug, and meningococcal vaccine are the “exposures” for the respective “outcomes”, viz., Lung cancer, control of hypertensive state and prevention of meningococcal disease, respectively.

It would also be appreciated that like the outcome, in most of the usual research situations, the exposure is also generally measured on a dichotomous scale (e.g. smoker / non smoker ; ACE - inhibitor drug given / not given ; Vaccine given / not given). Such dichotomous data is conveniently represented through a “2 x 2 table” (discussed in detail in another chapter) (Table - 2)

		Outcome (O)	
		Present (O +)	Absent (O -)
Exposure (E)	Present (E +)	a	b
	Absent (E -)	c	d

Can't we Compare Numbers ?

The first trap which we should always be aware of is that, comparing numbers is unscientific. One may “count” the patients of leprosy (all forms) in District “A” as 1000 and in District “B” as 100, thereby inferring that Leprosy is 10 times more common in District “A”. This difference, in reality, may be simply because the population of District “A” is 10 million while that of “B” is only 1 million. In fact, there are 1000/10,00,000 = 0.01% Leprosy patients in District A, and the same percentage, i.e. (100) / 10,00,000 = 0.01% in District B.

As another example, let us examine the following hypothetical study : A study collected the total number of cases of oral cancer which occurred in a defined district, in one year. All the cases were asked about the history of tobacco chewing. A total of 300 cases were thus studied, and the replies were as given in Table - 3.

	Tobacco - Users	Non - Users	Total
Cases of Oral CA	100	200	300

The comparison based solely on numbers would give a fallacious impression that oral cancer is 2 times more common among those who do not use tobacco (200 cases) as compared to those who do so (100 cases). However, when we relate the above numbers to a “denominator” i.e. the total population in the same province which were tobacco users or non - users, we got the correct picture as in Table - 4.

The correct picture which emerges is that Oral CA is 10 times more common among tobacco users (rate : 1000 per million), as compared to the non - users (rate : 100 per million).

Thus, whenever we are measuring variables on a categorical scale (i.e. qualitative data), like dichotomous or polychotomous scales, we must convert the numbers, counted in each category, into some form of “frequency” by putting the numbers so counted into a “numerator” and relating this numerator to a denominator (e.g. total population in the example).

	Tobacco Users	Non Users	Total
Cases of Oral CA	100	200	300
Total Population	1,00,000	20,00,000	21,00,000
Rate of Oral CA per million Population	1000	100	142.9

The Choice of Denominator

Let us do a simple study on primary hypothyroidism in our teaching hospital. Out of the 100 patients of primary hypothyroidism, 10 were males and 90 were females. The various types of “frequency” measures which we can use can be explained as follows :

(a) **Ratio** : In the above example, for relating the females to males, we will use the following equation :

$$\text{Ratio of females to males} = \frac{\text{No. of females}}{\text{No. of males}} = \frac{90}{10} = 9 : 1$$

Thus, “ratio” is a measure of frequency in which the numerator is not included in the denominator. In the above example, the numerator (no. of females) is not included in the denominator (no. of males). The ratio also gives us the idea of another very important measure - the “odds”. Here, given that primary hypothyroidism has occurred, the “odds” of being a female in such a disease are 9 times as compared to being a male.

(b) **Proportion** : A proportion also has a numerator and a denominator; however, in contrast to ratio, the numerator is included in the denominator in a proportion. For example, in the above study,

$$\text{Proportion of females} = \frac{\text{No. of females patients}}{\text{Total No. of patients}} = \frac{90}{100} = 0.9$$

Here, the numerator (no. of female patients) is included in the denominator (total no. of patients).

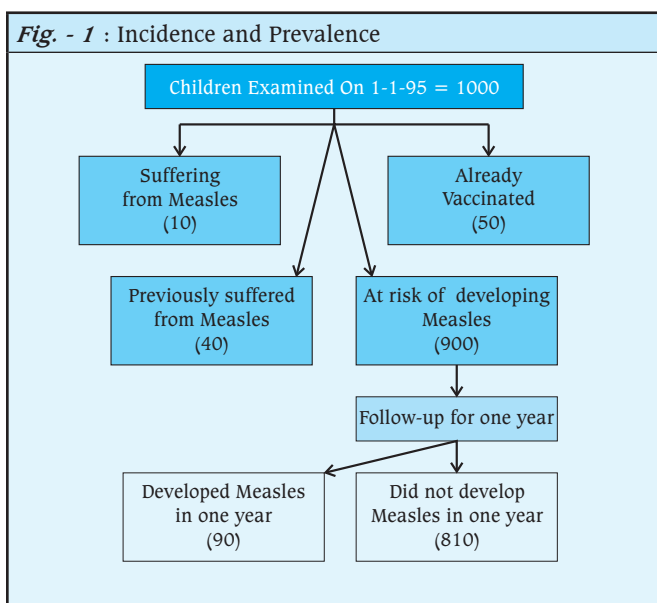

The “proportion” gives the idea of a important measure in research methodology - the “probability”. In the above example we would draw a conclusion that the probability (or “chance”) that a patient of primary hypothyroidism would be female, is 0.9 (or 90%). (Multiplying a proportion by 100 would give us the percentage).

(c) **Rate** : The “rate” is basically a proportion, but with an added relationship with time. Let us say, we assembled 100 healthy ladies in their thirties, without any evidence of hypothyroidism. We now followed them for 10 years and found that over the 10 years period, 10 out of these 100 ladies developed primary hypothyroidism. Thus, the “proportion” of ladies who developed hypothyroidism is 10/100 = 0.1 (or 10%). However by relating

it to the time factor we would say that the “rate of development” (or occurrence) of primary hypothyroidism among ladies, is 10% over 10 years or 1% per year.

The Two Basic Measures of Frequency in Epidemiology

Following an elaboration on the types of “frequency” measures, we are now in a position to discuss the two most basic (but, at the same time, the most important) measures of disease frequency used in epidemiology and medical research. Let us start with another hypothetical example. We took a sample of 1000 children aged 1 to 2 years from a rural community. We found that 10 of them were already suffering from measles. In addition to these, another 40 had already suffered from measles earlier, while yet another 50 had received measles vaccine. Thus, these (10+40+50) = 100 children, were no longer “at risk” of getting measles; the remaining 900 were “at risk” of the same. We now followed up these 900 children for a period of 1 year and found that over this one year period, 90 developed measles (see Fig. - 1 below).

The ‘frequency’ of children who were having measles at the time of the first medical examination (on 1.1.95), was 10/100 or 0.01, or 1%. This is what we call “prevalence”, a very common measure.

Prevalence : Thus, prevalence is the proportion of persons “having” (i.e. found to be present with) the disease (or any other health related condition of interest), out of the total subjects who were examined. Thus,

$$\text{Prevalence} = \frac{\text{No of Subjects who are having (present with) the disease at that point of time}}{\text{Total no of subjects studied}}$$

Incidence : On the other hand, out of the 900 children who were initially at risk of developing measles, 90 developed the same over a period of 1 year. Thus, the “rate” at which susceptible children would develop measles is 90/900, i.e. 0.1 or 10% over a one year period. This is the second important

measure of disease frequency - the “incidence”.

Incidence is thus defined as the rate at which new cases of the disease of interest will occur out of those who were initially “at risk” of developing it, over a given period of time.

The specification of time is very important for incidence - an incidence of 10% over a 3 year period will have very different implication compared to an incidence of 10% over a 1 year period. For example, suppose you come across a journal article which says “Men aged 50 years have a 2% risk of dying from IHD”. This statement actually leads us nowhere. Is this 2% risk of dying due to IHD over the next one day or one month? Even 1 year may be an overestimate unless these men have some other major risk factor for IHD, as a previous attack of Myocardial Infarction. On the other hand this would be considered as too small a risk if it is over next 40 years. Therefore specification of time is extremely important in incidence. Thus,

$$\text{Incidence} = \frac{\text{No of new cases of the disease occurring during a period of time.}}{\text{No of people who were "at risk" of developing the disease, at the start of follow up}}$$

An epidemiologist must clearly appreciate the difference between incidence and prevalence. The differences are clarified in Table - 5.

The Relationship between incidence and Prevalence : If the disease takes a prolonged duration in its natural course (e.g. leprosy), the prevalence will be high despite a low incidence because more and more of the cases will keep on getting added on to the “pool” of disease. On the other hand, if the disease has a short duration (e.g. common cold, most of the acute infectious diseases, etc.), the prevalence will be low despite a high incidence. In fact, the relationship between prevalence, incidence and duration of a disease is so characteristic, that if the conditions are stable, i.e. there has been no change in the natural history of disease due to, say better treatment or better diagnostic facilities and there was no change in the population “at risk” (unlike migration during natural disasters) and the prevalence has been low (i.e. <5%), then,

$$\text{Prevalence} = \text{Incidence} \times \text{Duration} (P = I \times D).$$

Incidence actually measures the “RISK” of developing a disease : For example, if we examine 100 patients of viral hepatitis in our medical wards and find that one of them is having clinical evidence of hepatic failure, the prevalence of hepatic failure out of all cases of viral hepatitis is 1/100 or 1%. It is the probability of any patient of viral hepatitis having hepatic failure at any given point of time is one in a hundred (1%). However, it does not mean that only 1% of all patients with viral hepatitis will develop hepatic failure, since some of them might have already died before we did our prevalence study. On the other hand, let us say, we followed up 100 cases admitted, with viral hepatitis, from the day of their admission for a period of one month, and 5 of these 100 patients developed hepatic failure over the observation period of one month. The incidence of hepatic failure among cases of viral hepatitis is therefore 5/100 = 5% over a 1 month period. We would thus conclude that a patient who is admitted to our medical wards with a diagnosis of viral hepatitis has an overall 5% risk of

Table - 5 : Difference between Incidence and Prevalence		
Point of Difference	Incidence	Prevalence
Numerator	New case of the disease of interest occurring over the defined time	Cases found to be present at the time of study
Denominator	All persons who were “at risk” of developing the disease at the start of follow up	All persons who were examined at the time of study
Relation to time	There is always a specified time period of follow up	No relation to time period of follow up; Cases detected with disease are taken to be at that point of time.
Rate or proportion	It is truly a rate since it relates to a time period of follow up	Is not truly a rate but only a proportion since there is no relation to time
Number of times a subject is examined	Each subject is examined at least twice - once initially to exclude the presence of the disease, so that only those who are “at risk” of developing the disease are followed up and later, at least one more examination of all these subjects being followed up, to see whether they have developed the disease or not. In our above example on measles, each of the 1000 subjects in our study were examined on two occasions - initially, to exclude the 100 subjects who were not at risk of developing measles and, subsequently, at least one more examination of the 900 children being followed up, to find out whether measles occurred during this period or not.	Subjects are examined only once. For instance, in the above example on measles, when we worked out the prevalence as on 1 - 1 - 95, we examined all the 1000 children once, and during this single examination, all those who were found to be having measles (i.e. 10) were included in prevalence (while the process of examining 1000 children would have certainly taken a few weeks or even months, the fact remains that each child was examined only once while we were working out “prevalence”).
Evidence of temporal relationship	Incidence gives a proof of temporal relationship since we start observations at a point of time when the disease had not occurred (only the exposure to suspected risk factor had occurred), and follow up till a later point of time when the disease occurs; thus we are sure that the suspected risk factor actually preceded the disease	Prevalence does not give a proof of temporal relation since both the disease and the suspected risk factor are found to be present at the same point of time. It thus gives an indication of association between the two but we are not sure that the risk factor actually preceded the disease
“Occurrence” (how things came to be) versus “State”(how things are).	By following up the persons from the point of exposure to final occurrence of the disease, incidence tells us as to how the disease occurred, like a video recording. It is therefore very valuable when studying the natural history of a disease, its causes, risk factors, prognostic factors, and therapeutic / preventive modalities.	Prevalence, like a “snap shot photo” shows only the “state”, i.e. how things are? For this reason, it is not very scientific when drawing conclusions regarding natural history of a disease, its causes, risk factors, prognostic factors, and therapeutic / preventive modalities.
Time, money and logistic efforts	Involves high cost and efforts since a large number of subjects have to be examined, assessed on at least two occasions and followed up for a period of time, which, in many diseases could be long.	Results are obtained quickly since only one assessment is done in prevalence study and no follow up is done. For this reason prevalence studies are cheaper, less difficult and quicker.

developing acute hepatic failure over a period of 1 month. Thus it is the incidence (and not prevalence) which gives us the idea of the “risk” of developing a disease (see Box - 1)

The Two Types of Incidence Measures

Having made a detailed discussion on incidence and prevalence, let us now deliberate upon the two types of measures of incidence used in epidemiology and medical research. These are Cumulative Incidence and Incidence Density.

Cumulative Incidence (CI) : Let us take a situation in which the disease is such that the period of follow up required is

short, say, 3 to 5 years (e.g. risk factors / natural history / prognostic factors / therapeutic and preventive trials in case of most of the infectious diseases, obstetric outcomes, pediatric settings, etc.). Secondly, we should be having reasons to believe that the subjects in the sample being studied are fairly ‘stable’. i.e. in general, they will not be leaving the study group during the follow up period and new subjects from outside will not keep on entering the study sample. If these two assumptions can be made then the incidence rate can be measured as “Cumulative Incidence” (CI). The definition of CI is exactly the same as we had used to define “incidence” earlier in this

chapter. i.e.

$$CI = \frac{\text{No. of people who develop the outcome of interest over the specified time period of follow up}}{\text{Total no of people who were "at risk" of developing the outcome at the start of follow up}}$$

The CI gives the “risk” of developing the disease over the specified period of time. In our example on the study of measles, the CI was $90/900 = 0.1$, or 10%. This means that a child aged 1 to 2 years, (who is at risk of developing measles) has 10% “risk” or “chance” of developing measles over the next 1 year. Since CI measures the risk, it is also often called as “Risk Rate” or simply as “risk” or “Incidence” in epidemiologic and research terminology.

Incidence Density (ID) : Recent advances, following increasing interest in chronic diseases, have been responsible for forwarding the concept of ID. Let us take a disease which takes long time to develop (as CHD, effects of drugs in therapy of cancers etc.) and secondly it is not possible to follow up each and every person till the end point of the predicted period of follow up. Thus a number of subjects will go out of the study group (due to migration, development of the outcome of interest, death, etc.) before the specified period of follow up is completed. Similarly, new subjects will keep on entering the study group as the study progresses. A hypothetical situation that will result is presented in Fig. - 2.

We started the above study to find out the incidence of cervical cancer. Naturally, we started with ladies who were “at risk” of developing the disease. We planned to have a 10 years follow up, from 1.1.80 till 1.1.90. When we started our study we had 5 subjects (subject nos. 1 to 5). In addition, 5 more subjects (subject nos. 6 to 10) entered our study at different points of time.

Subject no. 1 and 2 were followed up till the end (i.e. till 1.1.90), for 10 years each and none of them developed cervical

cancer. Subject no. 3 was followed up for 5 years, when finally on 1.1.85 she was found to have developed cervical cancer. The fourth subject was followed up for 7 years, till 1.1.87, after which she migrated to some other country (i.e. lost to follow up). The fifth subject could be followed up for only one year since on 1.1.81 she died of some other disease (say, vehicle accident). Subjects no. 6 and 7 were enrolled in our study on 1.1.81. The former was followed up for 7 years till 1.1.88; thereafter she emigrated to some other place. The latter was followed up till 1.1.90, i.e. for 9 years and did not develop cervical cancer. The eighth subject entered the study on 1.1.83 and did not develop cervical CA till 1.1.90, i.e. after 7 years of follow up. The ninth and tenth subjects were enrolled in our study on 1.1.84; the former was followed up for 4 years, when on 1.1.88 she was detected to be having cervical cancer, while the latter completed 6 years of follow up till 1.1.90 without developing cervical cancer.

Now, the total time of follow up given by our subjects was $(10+10+5+ \dots +4+6) = 66$ years (or better called as 66 person years). Out of these 66 “person - years” of follow up, 2 new cases of cervical cancer occurred among our subjects, who were initially “at risk” of developing cervical cancer. The Incidence Density of Cervical Cancer from our study is thus,

$ID = 2/66 \text{ Person years} = 0.03 \text{ per person year}$ (or multiplying by 100, it becomes 3 per 100 PY). (The figure is also written as 0.03 per PY^{-1} or as 3 PY^{-100}).

This means that in that particular age group of ladies, there will be 3 cases of cervical cancer if 100 person - years of follow up is done.

ID thus gives the idea of an “instantaneous change” in the rate of a disease at a given point of time, corresponding to the statement “the speed of my car is 60 kilometers per hour” gives an idea of the instantaneous change at which our vehicle is moving. Thus, if we find that the ID of cervical cancer in another country is 6 per 100 person years, it indicates that at any given point of time, cervical cancer is occurring at a much

Fig. - 2

Subject No	Follow up details for CA Cervix											Total time of Observation	
1	>-----O											10 Years	
2	>-----O											10 Years	
3	>-----X												5 Years
4	>-----?												7 Years
5	>-----A												1 Year
6		>-----?											7 Years
7		>-----O										9 Years	
8			>-----O									7 Years	
9					>-----X							4 Years	
10					>-----O							6 Years	
Year	1980	81	82	83	84	85	86	87	88	89	1990	66 Years	

Legend : > = Follow up starts; O = Follow up ends, subject remains without cervical CA; A = Subject died due to some other disease; ? = Subject was lost to follow up; X = Subject developed CA cervix

faster speed (i.e. twice the speed or rate) as compared to our study population. Thus ID gives the “forces of morbidity” (or mortality) due to a disease at given point of time. ID is also often called as “person - time in epidemiologic practice”. Very frequently, ID is referred to as “Incidence Rate” and sometimes as “Hazard”, since it also gives an idea of the hazard that a subject has of developing an outcome at a given point of time, which we found the ID to be 3 per 100 person years.

Of course, a problem with ID is that the same person - time may be obtained differently. In our above example of cervical dysplasia, such 100 person years could be achieved if 10 ladies are followed up for 10 years each or if 4 ladies are followed up for 25 years each or even if 100 subjects are followed for 1 year only. If a disease has long latent period, as IHD or cancers, the last situation (i.e. following 100 persons for 1 year) may reveal a very low incidence rate because hardly any case would occur in 1 year follow up. The researcher should therefore be careful in deciding what would be the optimum time of follow up required for the particular disease / outcome being studied.

The following example will further help clarifying the difference between CI and ID. Suppose we follow up 2 groups of asymptomatic HIV positive subjects, each group having 50 subjects. All subjects were having CD4 cell count of between 300 and 400 when follow up started. The follow up continued for 3 years. One group was given ART while the other group was given placebo. Different subjects gave us different time periods of observation in both the groups. The hypothetical results are shown in Table - 6.

Characteristic	ART group	Placebo group
Total subjects	50	50
Total person years of observation	113	61
Total who died of AIDS in 3 years	50	50
CI (Risk of death)	100%	100%
ID (Hazard of death)	44.25 per 100 person years	81.97 per 100 person years

The above hypothetical results indicate the difference between CI and ID. The CI, which is 100% in both the groups indicates that the “risk” that a patient of either of the two groups will die in next 3 years is 100%, whether given ART or not. However the ID is much higher in the untreated group (81.97 per 100 PY), compared to the ART treated group (44.25 per 100 PY). This indicates that patients of such type who are not given ART will die at a much “faster speed or rate” compared to those who are given ART, though at the end of 3 years all would be dead, anyway. The medical researcher should therefore be clear in her mind as to what the objective of her research is? If the overall interest is the overall risk or probability of developing a disease, death or outcome of interest at the end of the follow up period, then CI is the correct measure. On the other hand if the interest is to know as to how quickly the outcome is going to occur, then ID would be the appropriate measure.

Which incidence measure to use - CI or ID : In most of the “usual” settings of epidemiology and clinical research, we can reasonably assume that our study subjects form a “fixed, stable population”, i.e. there will be only minimal movements in the form of new entries and exits during the intervening period of follow up. Secondly, in most of the usual medical and health settings, (risk factors for infectious diseases / non communicable diseases which do not take more than 3 to 5 years to develop / pediatric and obstetric studies / drug trials / trials of operative procedures etc.), the period of follow up is not very long, rarely beyond 3 to 5 years. In all such settings, CI is the preferred measure of incidence.

On the other hand, if our epidemiological research work is going to have a prolonged period of follow up because the outcome of interest has a long “latent” or “induction” period, (e.g. IHD, Neoplasms, Stroke, Emphysema etc.) and there is likelihood, as given in the above example, that subjects will keep leaving the study group or keep entering during the intervening period of follow up, then ID is definitely the better measure of incidence.

The Two Types of Prevalence Measures

Like the incidence measures, prevalence measures are also of two types - point prevalence and period prevalence.

Point Prevalence : The word ‘prevalence’, as we described earlier, when used in an unqualified manner, refers to “point prevalence”. Thus, the number of cases of the disease refer to a single point of time, though, of course, the actual study on such prevalence may take a long time, may be months or even years. The essential feature is that while the actual process of assessment for presence or absence of the disease in the sample may take many months, the study subjects are examined only once, and the study is deemed to have taken place at a particular point of time. Most of the comparisons in medical research are made using “point prevalence”.

Period Prevalence : Period prevalence is actually more of academic importance. It essentially involves calculation of both, the point prevalence at the time of starting the study, as well as the incidence over the subsequent period of follow up. A combination of the initial point prevalence and the subsequent incidence gives us the period prevalence. Since period prevalence is a mixture of two entirely different frequency measures, viz., incidence and prevalence, it is not recommended for scientific research work.

Let us illustrate this with an example. With an interest in Leprosy, we did a point prevalence study on 1.1.94 on a sample of 100 subjects and found that there were 10 patients of leprosy present at that point of time (though the actual conduct of this survey may have taken 1 month, say, from 1 - 1 - 94 to 31 - 1 - 94, but this would be basically taken as a point prevalence as on 1 - 1 - 94). Now, having identified the 10 prevalent cases on 1 - 1 - 94, we followed up the remaining 90 cases (who were at risk of developing leprosy) for a 1 year period, till 31 - 12 - 94. During this 1 year period, 9 new cases of leprosy occurred out of the 90 at risk, while 3 cases out of the 10 cases found on 1 - 1 - 94 died during this period. The findings are summarized below :

(a) Total Sample = 100; (b) Cases found present on 1.1.94 = 10; (c) Persons "at risk" on 1 - 1 - 94 = (a - b) = 90; (d) New cases of leprosy developing between 1.1.94 and 31.12.94, out of (c) above = 9; (e) Old cases of leprosy, out of (b) above who died during the period = 3; (f) Cases of leprosy present on 31 - 12 - 94 = (10 - 3 + 9) = 16.

Thus,

- (a) Point prevalence as on 1 - 1 - 94 = $10/100 = 10\%$
 (b) Cumulative Incidence for 1 year period of 1 - 12 - 94 to 31 - 12 - 94 = $9/90 = 10\%$ per year
 (c) Period prevalence = (Initial Point prevalence + Incidence)

$$= \frac{\text{(Cases existing at start + new Cases occurring during follow up)}}{\text{Total population at start of study}} = \frac{(10+9)}{100} = 19\%$$

- (d) Point prevalence as on 31 - 12 - 94

$$= \frac{\text{No. of patients present on 31-12-94}}{\text{Total population present on 31-12-94}} = \frac{(10+9-3)}{(100-3)} = 16/97 = 15.9\%$$

(e) In this example, 3 cases died of leprosy. However, if we could assume that the disease is 'stable' i.e. there are no deaths occurring due to the disease and there is no likelihood of a change in the natural history of the disease in future (e.g. due to possible introduction of an effective therapy), then the prevalence after 5 years, i.e. on 31 - 12 - 1999 can be calculated as follows :

$$\begin{aligned} \text{Prevalence} &= (\text{Incidence} \times \text{Duration}) + \text{Initial Prevalence} \\ \text{Now, Point prevalence as on 31 - 12 - 94} &= 15.9\% \text{ (say, } 16\%) \\ \text{Incidence} &= 10\% \text{ per year} \\ \text{Duration} &= 5 \text{ years} \end{aligned}$$

Thus, prevalence on 31 - 12 - 99 = (Initial Point Prevalence) + (Incidence x Duration) = 16 + (10 x 5) = 66%

(Readers may note that incidence and duration should be measured in the same units of time, e.g. in this case, both are measured in years).

Comparative Uses of Incidence and Prevalence

Both incidence and prevalence measures have their own utilities, as follows :

Prevalence : It is desirable to work out prevalence measures under the following situations :

1. When assessing the "load" of a disease or risk factor in a community or in a health care facility.
2. For planning the health and hospital services.
3. Prevalence helps us in deciding the correct clinical approach, based on the "commonness" as shown by prevalence. For instance, while dealing with a case of "lymphadenopathy", the clinical approach would be towards "tuberculosis" in a developing country, but "lymphoma" in a developed country.
4. Prevalence of a disease helps us in correct application of a diagnostic test. As we shall see later, in the chapter on diagnostic test evaluation studies, the yield of cases in screening of disease is much better when applied in a population which has higher prevalence of the target disease.

5. Prevalence measures help the clinician become aware of new diseases in a population, and the particular age / sex / occupational groups that are involved by those diseases, as HIV, SARS, Legionellosis, Avian Influenza, etc.
6. Prevalence does give an initial idea of some association between an exposure (cause) and an effect (outcome), though incidence is the ideal measures for studying such associations. This is especially useful since prevalence measures, as compared to incidence measures, can be worked out quickly and at little cost. Hence, prevalence measures are good for development of hypothesis regarding a possible exposure - outcome relationship and also for initial exploration of a hypothesis through cross - sectional analytic studies.
7. Prevalence measures are not very useful for final testing of hypothesis regarding a risk factor or the effectiveness of a treatment or preventive modality. They are also not very suitable for evaluation of the natural history of a disease or evaluation of a prognostic factor.

Incidence : As compared to a prevalence measure, the epidemiologist should use incidence measure in the following situations :

1. When studying the natural history of a disease (e.g. natural history of the course of HIV infection) or the course of a natural phenomena (e.g. growth and development of children).
2. When evaluating a prognostic factor.
3. When assessing the role of a risk factor in a disease, especially after initial prevalence studies have given an indication of an association.
4. When evaluating the effectiveness of a treatment modality.
5. When evaluating the effectiveness of a preventive modality.
6. When evaluating the effectiveness of a screening programme.

Summary

In epidemiology and medical research, a large amount of data is collected, in respect of the various variables for a large number of subjects who have been studied in the epidemiologic or research work. This large collection of information, known as the "data set" has a lot of information in it but conveys no meaning to the medical fraternity, unless the information is reduced to certain "summary figures" for drawing conclusions from the data.

When talking of the summary figures, the first pitfall which every epidemiologist and researcher should guard against is that comparisons or conclusions should never be made based solely on numbers, since this may be quite fallacious. Scientifically speaking, the numbers counted in epidemiology should be reduced to some frequency measure, by putting these numbers so counted as the numerator and relating this numerator to a denominator. The final summary figure would firstly depend on the scale on which the outcome variable has been measured. If the outcome was measured on a discrete or continuous variable, the summary figure would be a "Mean"; it would be a "Median" if the outcome variable of interest was

measured on a numerical - ordinal scale, while it would be a “frequency” measure (like a percentage or a fraction) if the outcome was measured on a qualitative scale.

Now, depending on the choice of the denominator the frequency measures could be of 3 types, viz., “ratio”, in which the numerator is not included in the denominator; “Proportion” in which the numerator is included in the denominator; and, “rate” in which besides the numerator being a part of denominator there is also a specification of time over which the numerator (i.e. the disease or the outcome of interest) has occurred.

The two major types of frequency measures used in epidemiology and medical research are “Incidence” and “Prevalence”. Incidence is defined as the new cases of a disease (or any other specified outcome of interest) which occur over the specified period of follow - up, out of those who were initially at risk of developing the outcome. On the other hand, prevalence is defined as the total number of subjects who are found to be present with (i.e. having) the disease, out of the total examined at that point of time. Incidence gives us the “risk” that a person has of developing the disease over the defined period of follow - up; prevalence tells us the probability that a person would be found to be having the disease at that point of time. Incidence is truly a rate while prevalence is not a rate but rather a proportion.

Incidence has the advantage that it gives us an estimate of the ‘risk’, is ideal for evaluation of natural history of a disease, its risk factors, prognostics factors, preventive modalities and therapeutic regimens, and tells us as to “how” the disease develops over time. However, it takes long time to measure, is costly and logistically difficult. On the other hand prevalence gives us quick and cheap results and is quiet good for obtaining data for planning the health and hospital services and for generation of hypothesis as well as “quick - initial testing” of hypothesis regarding risk factors, prognostic factors, treatment and preventive modalities. However, prevalence data is quite often biased due to the type of people who survive with the disease, whether they are in the remission stage and does not prove that the cause actually preceded the effect; hence prevalence is not the ideal measure for inferences regarding the role of a risk factor, prognostic factor, treatment modality or a preventive regimen, for which only incidence can give the final and accurate answer.

Incidence measures can be further of two types, viz., the Cumulative Incidence (CI), also known as “risk”, or “risk rate” and is measured as has been described for incidence above. The other incidence measure is the “Incidence Density” (also called as hazards or incidence rate or force of mortality or morbidity) in which the denominator is the “person - time” instead of “number of persons at risk” which is the denominator in CI. Similarly, prevalence measures can also be of two types, viz., point prevalence, which is same as we have defined prevalence as above and secondly, period prevalence (which is not much used), which is the initial point prevalence plus the incidence over a defined period of time.

Study Exercises

MCQs and Exercises

Problem-1 : A researcher followed up a group of pregnant ladies from the date of registration in the ante - natal clinic, till delivery. She measured the haemoglobin level as well as also the height. Ladies were divided into low maternal height (145 cms or less) and normal height (> 145 cms). The birth weight of the new born was also measured and divided as normal weight (2500 gms and above) or low birth weight (< 2500 gms). In addition, the APGAR score of the newborn and the fact whether the mother had Antepartum haemorrhage (APH) or not was also recorded. Which summary measures should she use to finally describe her findings as regards the undermentioned variables (you can select your answer out of the following options - Mean, Median, Prevalence, Cumulative Incidence). (a) Maternal Haemoglobin (b) Mothers with low maternal height (c) APGAR Score (d) Whether APH occurred (e) Children delivered with low birth weight.

Problems - 2 to 5 : The figure below depicts the occurrence of Tuberculosis (TB) (Pulmonary and Extra - pulmonary) in a population of 100 subjects with HIV infection treated at a research hospital over a four - year period. During the observation period, the population remains stable (i.e. no members die, move away, or refuse to be examined at the beginning of every year).

2. What is the prevalence of TB in January 2000? : (a) 5 / 100 (b) 8 / 100 (c) 5 / 95 (d) 8 / 95 (e) 5 / 92
3. What is the prevalence of TB in January 2002? : (a) 5 / 100 (b) 9 / 100 (c) 5 / 95 (d) 5 / 80 (e) 9 / 80
4. What is the three - year CI of TB for the period January 2000 to January 2003? : (a) 20 / 100 (b) 15 / 100 (c) 20 / 95 (d) 15 / 95 (e) None of the above
5. What is the CI of TB for the year 2002? : (a) 5 / 100 (b) 5 / 85 (c) 5 / 95 (d) 10 / 85 (e) None of the above

(Incidentally, if you are asked “what was the period prevalence for the period January 2000 to January 2002?” Now period

prevalence = (prevalence at start + new (incident) cases during the period) divided by total population at start. The prevalent cases at start (Jan 2000) were 5. 5 new cases each occurred in period Jan 2000 to Jan 2001 and in period Jan 2001 to Jan 2002. thus, period prevalence = $15 / 100 = 15\%$.

Problem - 6 : Calculate the incidence (specifically as Cumulative Incidence or else Incidence Density) in following situations :

- (a) In a study of IHD, 100 subjects not having any evidence of IHD at the start of follow up, were followed up. The study started on 01 January 1997. The subjects entered the study at different points of time and were followed up till they developed IHD, or died of some other cause, or were lost to follow up or the date of 01 January 2007 was reached, on which day the study ended. Out of these 100 subjects, a total of 10 cases of IHD occurred from 500 person - years of follow up.
- (b) In an outbreak of measles in a primary school, 50 of the children developed measles over the next 20 days. It was also found out that out of these 200 children, 60 had already suffered from measles earlier while another 65 had already been immunised against measles much earlier.

Problems 7 - 10 : Trishul estate is a tea plantation community with a population of 99,000. Its residents can be divided into three age ranges : 25 - 44, 45 - 64, and 65 and older - each comprising one third of the population. In 2007, 100 cases of hepatitis E occurred in Trishul Estate and were traced to the consumption of water contaminated with sewage due to cross - connections between water pipe lines and sewer trunks. Of these 100 cases, 20 between the ages of 25 and 44, 10 between the ages of 45 and 64, and five over the age of 64 ultimately proved fatal. Prior to 2007, Trishul had never reported a case of hepatitis E.

7. What is the year 2000 disease specific mortality rate for hepatitis E in Trishul? : (a) 350 per 10000 residents (b) 1.01 per 10000 (c) 3.54 per 10000 (d) 1.06 per 10000 (e) Cannot be determined from the data
8. What was the incidence of hepatitis E in 2007 (assuming that no cases of the disease occurred in Trishul prior to 2007)? : (a) 0.00101 (b) 0.00035 (c) 0.35 (d) 0.04 (e) Cannot be determined from the data
9. What is the age - specific mortality rate for residents (per 10,000) over 64 years of age? : (a) 3.03 (b) 4.55 (c) 6.06 (d) 3.54 (e) 1.52
10. What is the case - fatality rate (per 10,000 residents) for hepatitis E? : (a) 3.03 (b) 3.54 (c) 350 (d) 1.01 (e) Cannot be determined from the data

Problem - 11 : If 20 guests arrive every day in a hotel and each guest stays for 5 days, how many guests will be there on the tenth day.

Problem - 12 : A prevalence survey conducted from 1st January to 31st December 2007 in a large metropolis of 2 million population, identified 1000 cases of schizophrenia. Earlier data

shows that the incidence rate of schizophrenia in this city is 5 per lac per year. You can assume that cases of schizophrenia have a fairly long life and the population of the city is fairly fixed with little inward or outward migration.

(a) what percentage of the 1000 cases detected in 2007 would have been newly diagnosed in 2007? (b) what would be the possible duration of schizophrenia?

Answers : (1) (a) Mean Hb% (b) Prevalence of mothers with low maternal height (c) Median APGAR score (d) Cumulative Incidence of APH during pregnancy (e) Prevalence of low birth weight at delivery (2) a; (3) a; (4) d; (5) b; (6) (a) Incidence Density = 10 per 500 PY or 20 per 1000 PY or 0.02 per PY or 0.02 PY - 1 (b) Cumulative Incidence = No. developed the disease over the period of follow up / No. at risk at start of follow up = $(50) / \{ 200 - (60+65) \} = 50 / 75 = 66.7\%$; (7) c; (8) a; (9) e; (10) c;

The clarifications for solution 7 to 10 : Because Trishul estate did not report a case of hepatitis E prior to 2007, all 99,000 residents were at risk for dying from the disorder at the beginning of the follow - up period. During 2007, 35 deaths from hepatitis E occurred. The 2007 hepatitis - E specific mortality rate is therefore $35 / 99,000 = 0.000354$, or 3.54 deaths per 10,000 residents. The population at risk for contracting hepatitis E at the beginning of 2007 (assuming no prior cases) was 99,000. During the one year observation period, 100 individuals contracted hepatitis E. The cumulative incidence (CI) of hepatitis A in 1990 was therefore $100 / 99,000 = 0.00101$ (i.e. 10.1 cases per 10,000 residents). An age specific mortality rate refers to the death rate within a specified age group. Five deaths from hepatitis E occurred in 2007 among the 33,000 residents over the age of 64. The age specific mortality rate for this group is therefore $5 / 33,000 = 0.000152$, or 1.52 per 10,000 residents. The case fatality rate is the proportion of cases that ultimately result in death. Thirty - five deaths occurred among the 100 cases of hepatitis E in 2007. Thus, the case fatality rate is $35 / 100 = 0.35$ or 35% or 350 deaths for every 1000 cases of hepatitis A.

(11) The problem pertains to the relationship between incidence and prevalence in a stable state, which is given by the term $P = I \times D$. In this problem, the incidence is 20 per day and the duration is 5 days. We need to work out the prevalence. This would be $20 \times 5 = 100$. Note that on days 1, 2, 3, and 4, this equation will not hold since the number of guests on these days will be 20, 40, 60 and 80 respectively. (12) (a) Since the incidence is 5 per lac, therefore, out of the population of 2 million in the city, 100 new cases would have been newly occurred in one year (2007), which is 10% of the 100 cases detected by the prevalence survey. (b) Duration = Prevalence / Incidence. The prevalence was 1000 per 2 million or 50 per lac. Incidence was 5 per lac per year. Hence average duration of schizophrenia is 10 years.

RajVir Bhalwar

As said earlier, “data” means an organised collection of individual measurements for each subject, in respect of every variable of interest. Once this data has been collected, collated and “summarised” it is called “Information”. Thus, information is a “factual presentation” i.e. a “Summary of facts” from the data and as they exist without any added element of interpretation of facts. Once this information is viewed and evaluated against the backdrop of a given “socio - demographic” setting by experts in their respective fields, it becomes transformed into what is called as “Intelligence”. Finally, intelligence is viewed against various socio - economic and political considerations and depending upon the priorities allocated by the society and government, a “policy” is finally developed. Obtaining data, in epidemiologic practice, may take either of the two modalities. Firstly, the investigator may decide on the epidemiologic or research question, select an adequately large and representative sample, and collect the data by making measurements on each subject, herself. This situation, when the data is collected by the investigator primarily for the purpose of the epidemiologic study is called “primary data”. In most of the medical research work, primary data is generally collected, specifically suited for the research question. Sometimes, in public health work, the epidemiologist resorts to collection of primary data, by means of surveys, to make a community diagnosis and for planning the health care services, especially if no data is available from any other source.

However, often the epidemiologist, especially in public health care, cannot be so idealistic but rather has to be more realistic. She may have to depend on various “other” sources of information as information on a wide variety of subjects is needed (Box - 1).

Getting information on all these aspects, by resorting to primary data collection, may be an impossible task. Moreover, it would be a tremendous waste of money and resources. In such situation, the epidemiologist utilizes the data which has been collected for some other purpose, and is already available at other places. Such method is called “secondary data” analysis. In the present chapter, we would have an overview of the various common sources of obtaining such secondary data for community health care. Such sources of information can be those as shown in Fig. - 1 (39).

The “individual data” and “aggregate data” are two different entities. Let us say, we collected information from hospital records (case sheets and autopsy reports) from patients of oral cancer, regarding their tobacco chewing habits and show that 80% of the oral cancer cases gave history of oral tobacco use. This data, though secondary data, is apparently coming from individual persons and is an example of individual data. On the other hand we may collect information about oral cancer cases from cancer registry in a state and tobacco sale from the excise department and show that districts which have high sale of tobacco also have higher incidence of oral cancer.

This data is not from individuals but is rather an aggregate of data, and is referred to as aggregate data. Aggregate data is frequently used while undertaking ecological (correlational) type of epidemiological studies which is discussed in detail in another chapter.

Box - 1

Minimum Information required by a Public Health Specialist in most Settings

General Information : Location, Governmental and Societal patterns, geographical and topographical features, roads & other communications, languages, physical and climatic characteristics of the block / district.

Socio - demographic profile : Population size, age & sex constitution, distribution of population in different areas of the district, fertility indicators, growth rate, education, occupations and economic strata.

Morbidity and Mortality : Incidence or prevalence of mortality, morbidity and diseases with epidemic potential; demographic indices as infant mortality and maternal mortality rates.

Health Related indicators : water supply, disposal of excreta, housing patterns, food availability.

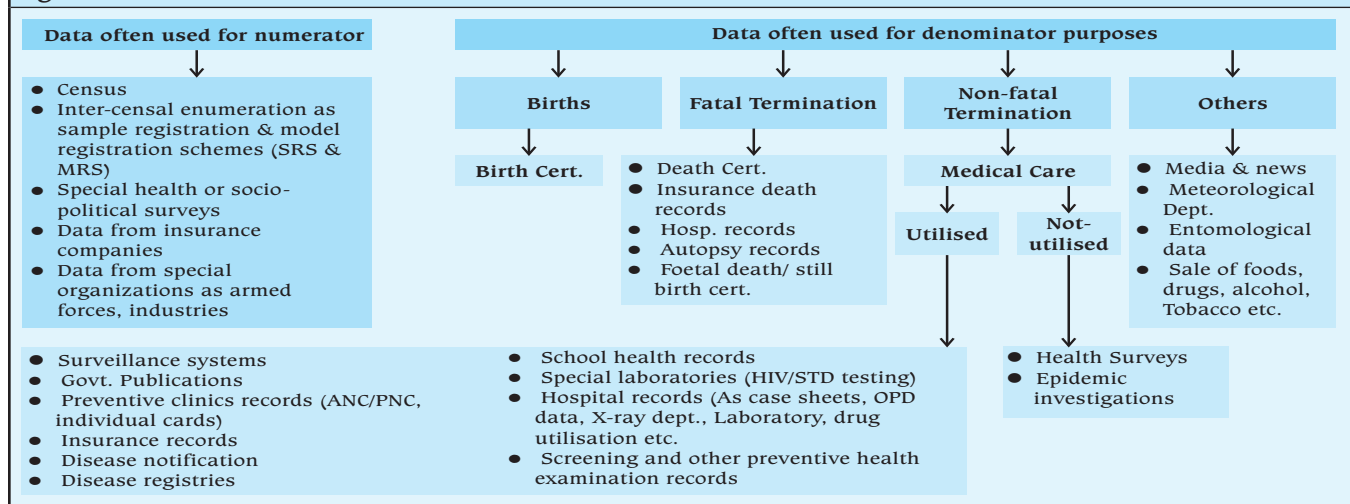

Health Services : Strength and location / distribution of various categories of health care personnel, governmental and non - governmental; availability, location and adequacy of health care supplies, equipment and other logistics.

Preventive / Promotive Health programmes : Availability, locations and adequacy of major programmes as immunization, HIV - AIDS / TB / ARI / Diarrhoeal diseases / malaria control programmes.

Census

Census means “to enumerate”. It consists of a sequence of activities concerned with collection, collation and factual presentation of data pertaining to social, demographic and health related factors, in respect of a nation (or large population group), undertaken periodically, and having some sort of statutory back - up for it to be undertaken. A census, in essence, gives the information, regarding the size and composition of a population, the forces that determine such size and composition, and the trends anticipated in future. The periodicity of census is generally kept as once in ten years, and it is generally undertaken during the first quarter of the first year of the decade. The amount of data collected may vary, from as little as population size and age / sex structure on one end to a large number of social, economic, demographic and health related variables on the other end; however, a fairly developed census mechanism would usually provide information regarding total population, density according to per square kilometers of land area, decadal growth rate, literacy rate, economic conditions, occupational characteristics, and selected indicators of mortality like overall death rate and infant mortality rate. A legal authority constituted by the government is generally made responsible for the collection, collation and publication of census data. There are two general

Fig. - 1 : Sources of information

methods of collection of data in a census :

(a) de - facto method : Persons are enumerated according to their location at the time of enumeration. This method is used in developing countries like India.

(b) de - jure method : This method is used in developed countries like U.S.A. The persons are assigned according to their “usual” place of residence and not according to their location at the time of census, as practiced in de - facto method. This method provides a better indication of permanent population and related socio - demographic factors of an area, though it is more expensive and needs much better level of training of census - data collectors.

Indian Census

In India, the activity of census started in 1881 and is carried out once in ten years, during the first quarter of the first year of the decade (i.e. 1981, 1991, 2001, and so on). The census is an official task under the authority of the Census Commissioner of Govt of India, with adequate legal backing provided by the census Act - 1948. Census 2001 was carried out in two phases - the house numbering and the house listing operations followed by population enumeration. If we talk of the last census, the house listing operation was conducted in during April to September 2000. In addition to collecting data on characteristics of the house, information on availability on certain amenities and assets were also collected during this phase. The population enumeration was undertaken between 9th and 28th Feb 2001 with a revisional round from 1st to 5th March. The “census moment”, i.e. the referral time at which the snapshot of the population is taken was 00.00 hours of 1st Mar. 01. For the first time during census 2001, permanent location code numbers were assigned to ensure comparability of the data at the village & other administrative levels. Special features of Census 2001 included additional collection of data on drinking water (within premises/outside premises), source of lighting, availability of toilet facility within the house and type, number of married couples living in the household having independent room for sleeping, disposal of waste water, availability of separate bathroom and kitchen etc. For the first

time during this census, the signature/thumb impression of the respondent was taken. The salient findings are shown in Box - 2.

Box - 2	
Population	
Total population	1,027 million
Total increase in population since last census	180.6 million
Annual growth rate	2.1% (it was 2.5% for last 30 - 40 yrs)
Children in the age group 0 - 6	15.42 % (17.94 % in 1991)
Population Density	324 persons per sq km (267 in 1991)
	Highest density : 9,294 persons per sq km (Delhi)
Sex ratio	933 females per 1000 males (927 in 1991)
Overall Literacy	65.4 % (52.2 %in 1991)
Male literacy rate	75.8 % (64.1 %in 1991)
Female literacy rate	54.2 % (39.3 %in 1991)

Sample Surveys

In sample surveys, instead of covering the whole population as is done in census, only a sample, which is representative of the population, is studied and inferences about the population strength and composition are made. Sample surveys are quite relevant in underdeveloped countries where full fledged census is not possible; they are also useful in countries where census mechanism is present because they give interim information without waiting for the census which is generally done after 10 years. Sample surveys are retrospective in nature, in which the trained data collectors ask the selected households about events (usually births and deaths and other selected events) for a defined period of recall, usually kept as 1 year form the date of interview. The important forms of sample surveys in India

are the Sample Registration System (SRS) and the National Sample Survey (NSS).

SRS : The SRS is undertaken under the authority of the Registrar General of India. At present there are more than 3,700 sample units, each consisting of a set of villages and urban blocks. Each rural sampling unit has a complete village (subject to maximum population of 1500) while each urban sampling unit is equivalent to an urban census enumeration block with population of 750 to 1,000. As of now, the SRS has more than 6670 sampling units, including 4435 in rural and 2235 in urban areas, covering a sample population of almost 6 million population.

SRS is based on a system of double recording method. The first part of record collection is done by a part time enumerator (usually the local school teachers) in his or her area. In the second part, once in six months, an official from the SRS department, who is a full time enumerator independently collects data on these aspects form all the households in the sample villages and urban blocks. Each independent full time enumerator is incharge of about 6 sample units. The two sources of information are cross checked and the data which does not match or only partially matches is then actually verified in the field. Before the entire process of survey is launched, an initial baseline collection of data is undertaken which includes listing and numbering of houses and basic socio - demographic information as name, age, sex and marital status.

The reports of findings are published as annual report and half - yearly bulletins, which provides the age and sex structure of the population, fertility indicators and age and sex specific death rates.

NSS : The NSS functions under the National Sample Survey Organisation (NSSO), Govt of India. The NSSO undertakes surveys, usually on an annual basis, and provides useful information on one particular aspect of social, demographic or health issue in a particular survey; for example, the survey during 1995 - 96 provided information on medical care and ageing, and during 1998 on hygiene and sanitation, besides other useful information.

The Rapid Household Survey (RHS) and the Facilities Survey (FS), under the Reproductive & Child Health (RCH) Programme : These two surveys are being conducted as an ongoing component of the RCH program. The RHS is undertaken in all districts of our country, from women in the age group 15 to 44 years, from about 1000 selected households in both urban and rural areas of each district, with a view to obtain information on the coverage of ante - natal and immunization services, method of deliveries, contraceptive use and intentions to use contraceptives, utilization and satisfaction from health services and knowledge about RTIs and HIV / AIDS. The sample households and eligible couples for the survey are selected as a multistage random sample, selecting districts in the first stage, villages / urban blocks in the second and the households in the third stage. The FS is carried out to assess the availability of trained personnel and manpower, and the utilization of these facilities at PHC, CHC, First Referral Unit (FRU) and District Hospital level. In states with population more than 20 million, the FS in one district every month, while for states with population between 5 and 20 million it is carried out in one

subdivision of a district every month. For UTs it is carried out in one block of a district every month.

Vital Statistics

Vital statistics means the ongoing recording of all vital events' such as births, deaths, marriages etc. Registration of Births and Deaths is a legal requirement in our country.

(a) Death Certificate : It is one of the most important source of information about the distribution of a number of diseases. The death certificate as recommended by the WHO is depicted in the example in Box - 3. The standard death certificate has two parts. Part - I requires the cause of death to be filled up. Cause of death is defined as "morbid condition or disease process leading directly or indirectly to death". It does not mean the mode of dying as "heart failure" "asphyxia" "Hepato - renal failure" "circulatory collapse" etc. In part - I, there are usually three lines. Here, the particular cause which started the final chain of events should be entered in the bottom most line, and this is taken to be the cause of death; on the other hand, the condition in the chain of events which finally directly led to death is shown in the top most line.

Box - 3 : Death Certificate
PART I
Disease Or Condition Leading To Death
(a) Pulmonary Embolism
Due to or as consequence of
(b) Pelvic Vein Thrombosis
Due to or as consequences of
(c) Septic Abortion
PART II
Other significant conditions contributing to death but not related to the disease causing it.
Non Insulin Dependent Diabetes Mellitus

In the example given above, the patient had septic abortion which is entered in the bottom line of part - I and will be taken as the cause of death during compilations. This led to pelvic vein thrombosis which finally led to pulmonary embolism directly leading to death (note that cardio - respiratory failure is not entered as the final cause since it is the "mode of dying"). In this part II, NIDDM is entered as a significant condition contributing to death but not related to the disease causing it (i.e. septic abortion). In addition to entering the cause of death correctly, the international classification of Diseases (ICD) number of the particular cause should be entered. The problem with death certificates, regarding cause of death, is the inaccurate/incomplete filling of certificates as also inadequate reporting to the relevant statistical authority. This aspect must be especially considered if comparisons regarding cause of death are being made between two countries or areas.

While utilizing death certificates as a source of data, the epidemiologist should keep a guard against certain biases that may occur, as follows

- Diseases that are rapidly fatal, or have high "Case fatality ratio", or the ones which can be diagnosed with relative

ease (as oral cancer, pulmonary tuberculosis, etc.) are most likely to be accurately recorded in the death certificate, while diseases like chronic bronchitis may not be so well recorded.

- Diseases which have a long time between onset and death (as chronic leukaemia) may not be entered and another more acute cause as pneumonia may be entered instead.
- Diseases that are apparent (as melanoma skin) are more likely to be entered as compared to carcinoma of pancreas.
- Diseases which carry stigma (as AIDS, suicide) are less likely to be entered as a cause of death.
- Very often, the physician who has actually been caring for the patient and knows the totality of her medical background, may be different from the one who actually prepares or signs the death certificate (often, in a hospital, the death certificate is prepared by the duty nurse and signed by the casualty medical officer).
- Diagnostic fads may occur in a state or a country, e.g. chronic bronchitis could be more popular in one country and emphysema in the other.
- Availability of diagnostic procedures or introduction of a new diagnostic procedure may make a difference all of a sudden, as regards the causes of death.
- The elderly often die of multiple pathologies but generally only one cause of death is entered.

(b) Birth Certificates : These are useful for epidemiologic research as well as health services management; they provide a denominator data for calculating various important rates IMR, MMR, etc. Ideally, a birth certificate should contain information about date, place of birth, details of parents, domiciliary/institutional birth, sex of newborn birth attendant's details, type of delivery and complications if any, age of mother and birth order of the child.

(c) Other vital events : These include registration of marriages and divorces; reporting of still births; and reporting of foetal deaths.

Health Surveys

Health surveys are an important source of reliable health information. Such surveys may be directed towards a particular disease (e.g. sample survey for TB); or general health surveys directed towards specific population groups like a cluster of villages/ a tribal area/school children; or surveys concerned with planning and evaluation of health services in the form of survey committees appointed by the Government or private agencies to evaluate health programmes or assess general health situations and needs; or surveys directed towards determinants of health, like dietary surveys or air/water pollution surveys. Surveys provide valuable information for planning/evaluation of health services/programmes; for identifying community needs; for providing information about available health manpower and other resources; for suggesting "hypothesis" regarding individual or community risk factors; and for providing statistics for public health/educational programmes. A paradigm situation can be quoted regarding the "National Health Survey" of USA.

In India, the National Family Health Survey (NFHS) is an important step for generating epidemiologic information. The

NFHS - 3 has provided information on population, health & nutrition in India as a whole and each of its 29 states. The main objectives of NFHS are

- to collect data at the national and state level on demographic rates pertaining to fertility, IMR, PMR, and reproductive health patterns
- to measure prevalence of contraceptive practices
- to collect and analyze data on HIV/ AIDS related behaviour
- to collect and analyze data on health of slum populations.

The survey is based on a sample of households which is representative at the national and state levels. Total of 10.9 million households including 19.8 million men and women were interviewed using the method of multistage sampling, the sample being selected in two stages. Three types of questionnaire were administered in NFHS : The village questionnaire to collect information about basic health care and education facility; the household questionnaire to collect general data about household and women's questionnaire for eligible women from household sample. The findings of NFHS - 3 revealed that knowledge of HIV/ AIDS among men and women was found to be 80% and 57% respectively. In general, knowledge found to be much better in urban setup rather than rural areas. Some findings regarding key indicators are shown in Table-1.

S. No.	Indicators	Fig-ures
1.	Total Fertility Rate	2.7
2.	Institutional Deliveries (%) last 3 yrs	41
3.	Contraceptive Use (%) (Currently married woman (15 - 49 yrs)	56
4.	Childhood Immunization & Vitamin A supplementation (12 - 23 months fully immunized children)	43.5
5.	Children under 3 yrs who are underweight (%)	45.9

Disease Notification and Registration

At the international level, cholera, plague and yellow fever are notifiable to the WHO under International Health Regulations. In addition, Malaria, Rabies, Salmonellosis, Influenza, Polio, Epidemic (louse borne) Typhus and Relapsing Fever are subject to international surveillance. Similarly, under the National Integrated Disease Surveillance Programme (NIDSP), a number of diseases have been made notifiable in our country. The general problems with notifications and registrations of diseases is the inadequacy in respect of complete coverage and the delay in initiating the notification report. However, it may be mentioned that even though under-reporting is common, still one can always monitor the trends and take action to prevent/control impending epidemics, using such information.

Disease Registries

A disease registry keeps a record of salient features of the cases suffering from a particular disease in a defined population or geographical area. It also helps in monitoring trends of a disease. Population based as well as hospital based cancer

registries have been established quite methodically in many countries over the world, including India (40). In India, registration of cancers is being undertaken under the overall auspices of the ICMR, as a part of the national Cancer Control programme and publishes valuable data on the occurrence of cancers in our country.

Information from Special Populations

Some groups have well maintained and extensive health data (e.g. uniformed services, factories, mines, occupational groups, Insurance policy holders, persons covered by various health insurance programmes etc.). However, one must remember that these groups have special characteristics and it may be difficult to apply the findings regarding health status and its determinants on the general population.

Records of Hospitals and Health Services

In developing countries with inadequate notifications of morbidity and mortality, hospital records are important tool for the epidemiologist as well as the health administrator. Even in countries with a well developed system of notification, hospital records are often used for epidemiological assessments and clinical research. In addition to hospitals, records from other health services (national health programme offices, Community/Primary Health centers) also provide valuable data. There may be a large number of sources of epidemiological data within the hospital/health centres and the investigator would need to decide the relevant sources depending on the objectives. However, the important inpatient sources are : Hospital admissions and discharges book and discharge slips, case sheets for indoor patients, Reports and returns raised by the hospital as an administrative requirement, Laboratory investigation registers, especially microbiology department, Registers and log books of radiology department, "Health cards" issued by hospitals/health centres to patients, as Ante Natal / Post Natal cards, under fives card and so on, OPD records and emergency department records, Records of specialized clinics as diabetes clinic, Birth and death certificates, Immunization and other preventive health care activities records, Data on drug inventory, and, Autopsy reports.

Advantages and Disadvantages : Data from hospitals / health centers has its own advantages as well as disadvantages which have been reviewed in detail by Masi (41). The advantages are that hospital data can be utilized very appropriately (in fact, it may be the only available data at times) in the following epidemiological situations

- For establishing "sentinel surveillance". The classical example is sentinel surveillance of Acute Flaccid Paralysis (AFP) and other vaccine preventable diseases
- To study the risk factors/etiology/treatment of rare diseases, since these are very likely to be admitted to the hospital, but very difficult to search in the community.
- To establish "Registries". The classical example is Cancer Registries, registration of Stroke, IHD, Congenital malformations, and so on.
- During the initial stages of establishing a "surveillance" system to monitor the "trend" of a disease and to give early warning of an epidemic
- For studies into the epidemiology of hospital acquired

infections.

- For studies into the planning and evaluation of hospital/ health centers services as well as for planning of "satellite" hospitals and outreach centers/ super specialty centers.
- For studies on "adverse drug reactions" and "drug resistance patterns".
- For epidemiological studies of "delayed effects of medical treatment".
- For epidemiological studies on Diagnosis, Prognosis and Therapy
 - Performance of diagnostic tests
 - Trial of new drugs/treatment modalities
 - Studies on prognosis of a disease
- For studies of natural history of a disease since patients admitted to the hospital generally represent the serious form of the spectrum and thus help in completing the entire picture of natural history of disease
- When a case control study is being planned, especially if the disease is rare or effects of multiple exposures are being studied.
- For undertaking "Retrospective Prospective Studies" starting from hospital records. (See chapter on cohort studies for further details).

There are, of course a number of disadvantages in hospital/ health centers data and the epidemiologists should be careful about these. The major disadvantages are :

- The patients in a hospital are generally not completely representative of the general population for several reasons like
 - a. Accessibility - The hosp may not be accessible to all because of distance, communication problems or ability to meet the hospital cost.
 - b. Utilisation - The catchment area population may not be equally utilizing the health services of hospital because of attitude towards health services or behaviour of hospital staff.
- Hospital patients represent the survivors and not those who have died due to the disease, and those who died may be systematically different from those who have survived.
- The patients admitted to hospital represent only 'severe' part of the spectrum. If a disease has a wide spectrum (as low backache) then the mild and asymptomatic cases may not be found in the hospital.
- Data which is recorded in forms and case sheets may not contain the information which is actually required by the epidemiologist.
- In case sheets there is hardly any 'structuring' of format of recording the details. Thus, the epidemiologist may have to sift through large volumes of information to get the few pieces of information actually required by her.
- Problems of disclosure of identity of the patients may come up. Moreover, the hospitals generally give permission to utilize/scrutinize their record only after great difficulty.
- Going through the records, particularly hand written case sheets, may be a very tedious job. However, if the hospital records are automated, it may be helpful.
- The diagnostic capabilities of different physicians within the hospital may be different and hence biases due to over/

under - diagnosis.

How best can we utilise hospital/ health centre data for epidemiological purpose : As we have seen, hospital/health centre data plays an important role in epidemiological practice; however it has its own advantages and disadvantages. Hence, whenever we wish to utilize hosp/health center data for epidemiological purposes, we must work out as to how best we can utilize this so that it remains 'adequate' and 'accurate' (i.e. has internal validity) as well as 'generalisable' (has external validity). At the outset, we should analyze for 'appropriateness'. Such appropriateness may be

- **Appropriateness in the hospital**
 - (a) Within the hospital, use multiple sources of information, as, besides, case sheets also see records of x - rays and laboratory reports.
 - (b) Try to get an approximate idea about the population base that hospital is serving so that the disease frequency can be calculated. Try to relate this with local census data.
 - (c) Take a group of hospitals at different levels (primary/secondary/tertiary) in an area rather than only one hospital.
- **Appropriateness of the disease**
 - (a) Prefer data for diseases which are commonly treated in hospital (e.g. cancers, acute MI, etc.)
 - (b) Prefer data on diseases which are clearly defined diagnostically (e.g. fracture of tibia on x - ray) rather than vague ones (e.g. chronic fatigue syndrome)
 - (c) Prefer data which has been obtained in the hospital as a part of sentinel surveillance of diseases, for disease registry, for hospital acquired infections and drug reaction.

Epidemiological Surveillance Data

Ongoing surveillance systems are generally built up in the various national health programmes. Such data can be used for calculating the incidence of the particular disease by relating it to population size being served by the surveillance system. Similarly, 'sentinel surveillance' data from selected hospitals can be utilised for various epidemiological purposes. Detailed discussion on epidemiological surveillance has been made in another chapter in this section. In India, vast amount of information is available from Integrated Disease Surveillance Programme (IDSP) from NICD, Delhi and the State / district headquarters.

Health Related Publications

A number of publications are available which are rich sources of health related information at all levels : state, national and international levels. The Ministry of health & Family Welfare, publishes an annual report "health information - India" which gives details of various causes of morbidity, mortality and health services in the country. Similarly, the ICMR, the Director General of Armed Forces Medical Services, DGHS Govt. of India, and the State Health Directorates publish their respective annual reports. On the International level, The WHO, the UNICEF and the CDC Atlanta bring out various publications as MMWR, Weekly Epidemiological Reports, Report on the state of health of world's children, and so on which can be gainfully utilized.

Other Sources of Information

Depending on the information needs, the epidemiologist may need data from the meteorological / environmental departments; from governmental offices regarding availability of medical/paramedical manpower and available training facilities; or data of controlled drugs and their utilization may have to be obtained from the relevant Drug Controller's office.

Summary

In most of the real life situations of epidemiology as applied to public health, the epidemiologist may not be able to collect the data for the purpose of his epidemiological requirements, as is often done in most of the clinical research settings. Rather, the epidemiologist has to obtain information from sources which have already collected the data, albeit with some other objective. Such data, which has not been collected for the purpose of one's epidemiological study, but has rather been collected with some other purpose, is called "Secondary Data". The advantage of such secondary data is that since it is already available, it minimizes the cost and also ensures quick decision. However, the disadvantage is that since the data has not been collected for the purpose of present epidemiological study, it may not have information on many aspects, may be incomplete and may lack adequate coverage. The common sources of secondary data in our country are :

Census, Sample Registration Scheme, Model Registration Scheme, Death Certificates, Registration of Marriages, Records available from various Govt hospitals and Primary / Community Health centres, School Health Records, Industrial Health Records, Records of Armed forces Medical Services, Data from various National Health Programmes, Cancer Registry Programme, Reports of Notifiable diseases, Integrated disease Surveillance Programme - from NICD and state / district headquarters, Reports from Public Health laboratories of States, Reports from Laboratories of special institutions as NICD, NIV, NIN, etc., National Sample Survey Reports, National Family Health Survey Reports (NFHS), Records of special clinics and surveillance centres as STD clinics, VCTC / ICTC, Ante - natal clinics, etc., Special survey reports as National Tuberculosis Survey, etc., Health Information - India and other Publications by various Governmental and Private offices, Reports of Epidemic Investigations, News broadcasts, news magazines and newspapers.

Study Exercises

MCQs & Exercises

1. Miss 'ABCD', a 15 years old girl child, daughter of Mr. 'XYZ' resident of 24 - B Indra Colony, Pune was a case of rheumatic mitral stenosis with mitral regurgitation. The child developed fever and was admitted to the district hospital. On examination, she was found to have fever, irregular pulse, tender splenomegaly, BMI of 16.5 and splinter hemorrhage in the nails. After 3 days she developed edema feet, engorged neck veins and ascitis. The child died on 13 Aug 05. The attending physician filled up the cause of death as 'cardio respiratory failure'. Comment on the cause of death and fill up a draft death certificate.
2. The national tuberculosis survey was undertaken with the objectives of finding out the magnitude of problem

of tuberculosis in the country and the high risk groups. Trained investigators collected data from randomly selected households. This was an example of : (a) primary data collection (b) secondary data analysis (c) aggregate data analysis (none of the above)

3. What is the best routinely available source of data for the following : (a) Cancer morbidity in India (b) Accidents in Dhanbad coal mines (c) Incidents of malaria in a district in a year (d) Possible impending outbreak of meningococcal meningitis (e) 5 leading causes of death in a state (f) Decline in female : male ratio
4. Encircle all the possible advantages that death certificates have, in our country, as a source of epidemiological information : (a) There is a uniform national law for enforcing filling of death certificates (b) The cause of death is usually confirmed by autopsy (c) The ICD system of cause of death has remained constant over last 50 years (d) Nearly all deaths are recorded (e) The personal physician of the deceased has to complete the death certificates based on his own knowledge of past illnesses of the deceased.
5. How will you go about organizing the following information: (a) Incidence rates of breast cancers in Mumbai (b) Incidence rate of acute appendicitis among residents of Pune during 2007 (c) The prevalence rate of osteoarthritis among women in Delhi (d) Changes in blood pressure level as age advances, among army officers (e) Deaths due to Road Traffic Accidents in Lucknow during 2004
6. Which of the following statements are true for YPLL (more than one statement can be true) : (a) It is a probability statement (b) It is a measure of premature mortality (c) It is used to determine the major causes of death in a population (d) It can be used to compare premature

mortality in different segments of the population.

7. Which of the following statements are true for certificate of registration of death (more than one statement can be true): (a) It is the basis for making policy decisions regarding allocation of finances to various health programmes (b) It is issued by the treating physician (c) It is legal requirement in our country (d) It is a basis of important vital statistics.
8. The referral date for Indian census 2001 was (a) 1st April 2001 (b) 1st Feb 2001 (c) 1st March 2001 (d) 1st Apr 2000.
9. The sex ratio is described as (a) Females for every 1000 males (b) males for 1000 females (c) fraction of females divided by males (d) fraction of males divided by females
10. The greatest advantage of hospital data is : (a) Incidence rates can be calculated (b) Diagnosis recorded is quite accurate (c) Clinical research can be undertaken (d) all patients of fatal diseases will definitely be admitted.

Answers : (1) The entry was wrong since cardio - respiratory failure indicates a mode of dying and not a cause of death. The death certificate should have been filled as : Congestive Heart failure, due to or as a consequence of Sub Acute bacterial Endocarditis, due to or as a consequence of Rheumatic Mitral valve Disease; (2) a; (3) (a) Annual report of National Cancer Registry Program (ICMR) (b) details of Claims submitted under Workmen's compensation Act (c) records of District malaria Officer (d) Annual Health Report issued by the State health directorate (e) Census. (4) a, d; (5) (a) Numerator data from cancer registry program office at Mumbai and denominator data from census bureau (b) numerator data from all government and private hospitals in Pune and denominator data from local census office (c) sample survey of middle aged / elderly women in Delhi (d) Individual Health record cards of the Army Officers (e) From the office of Police Chief of Lucknow district. (6) b and d are correct. (7) c and d are correct. (8) c; (9) a; (10) b.

18 Measures of Association & Effect

RajVir Bhalwar

In the previous few chapters we have seen that the epidemiologist or researcher specifies the “variables” which are of interest to her in the research question, specifies the “scales of measurement” of these variables, collects the “data” on the variables as per the scale of measurements and finally, the data is reduced to summary figures as mean, proportions or rates (incidence, prevalence). The conclusions which the researcher would derive would be in the form of the following statements, shown as hypothetical example :

- The average serum homocysteine among patients of IHD

was found to be 14 mcg/dl. Thus, patients with IHD have a high serum homocysteine; hyperhomocysteinaemia, therefore, MAY be important in the etiology of IHD.

Our results, in the form of summary statements, given above, thereby “describe” the phenomena of interest (raised homocysteine in IHD, etc.). In addition, they help us to develop certain guesses or hypothesis about “cause and effect” relationship, e.g. “serum homocysteine, if raised MAY have a role in the etiology of IHD”.

However, mark the word “MAY”. While we do get an indication that possibly a cause and effect relationship may be existing, i.e. we are able to develop a hypothesis, however, it is no proof of the cause and effect relationship. So what if the mean serum homocysteine in IHD patients is 14 mcg / dl ? For all you know, it may be 15 mcg / dl among healthy people of the same age

group! In that case, nobody would agree to an etiologic role of serum homocysteine in IHD.

Thus, it is logical that once we have summarized our data in the form of summary expressions like “mean”, “prevalence” or “incidence”, we are able to “describe” the phenomena of interest and also develop certain “hypothesis” regarding possible “cause and effect” relationship. However, the final proof of such hypothesis will involve a “COMPARISON”, wherein we would have to prove that the phenomena observed (e.g. homocysteine among IHD patients be 14 mcg/dl) is really “outstanding”. In that while the levels are high in IHD cases, it is low in normal population. In other words, our summary measures of disease frequency (incidence or prevalence) help us develop a hypothesis; to finally accept or reject such hypothesis, we have to proceed with “comparative measurements”. Once we compare the disease frequency (incidence or prevalence) among two such groups, we get another “summary expression” which tells us the extent of “association” or “effect” or “risk”; this is the topic of deliberations in the present chapter.

The Preliminary Method of Making “Comparisons” : Looking for Significant Difference

The measurements in respect of various variables can be made, in general, on either of Numerical - Continuous, Numerical - Discrete, Numerical - Ordinal, or else on Categorical scales (Qualitative) (of which the Dichotomous scale is the most common). Depending on the type of scale that has been used, the comparisons between two groups can be made as follows :

(a) When the variables have been measured on a numerical continuous or numerical discrete scale : Take an example of an epidemiological question for studying whether breast CA is related to the number of living children (a numerical discrete variable) born to the lady. In such a study, we could take two groups of ladies, one having breast CA and the second group not having the same (to serve as “comparison” group). We would then take the history of number of live births from all the subjects and work out the average number of children in both groups. Using the procedure explained later in the chapter on testing the difference between means, in the section on statistics, we would compare the two groups by a ‘t’ test to see whether the average number of children in breast CA group is “significantly different” from the healthy group.

To answer the research question regarding role of serum homocysteine (a numerical - continuous variable) in the etiology of IHD, we would take a group of IHD patients, measure their serum homocysteine. Similarly measure serum homocysteine of a group of well matched healthy subjects (who do not have IHD). Carry out a ‘t’ test to see whether the average serum homocysteine level in IHD patients is “significantly different” from that of healthy subjects.

(b) When the variables have been measured on a Categorical (Qualitative), i.e. Dichotomous or Polychotomous scale : Let us take up an example of whether Streptococcal sore Throat (SRT) is a precursor of Acute Rheumatic Fever (ARF). We would pick up, say 100 children who have suffered from SRT and another 100 who have not; we would then follow up the 2 groups for a reasonable period to see how many in each group develop ARF. Let us say 20 children in the sore throat group

and 10 in the other develop ARF. We would now convert these numbers into a measure of disease frequency (i.e. 20% and 10% respectively) and compare the two groups to see whether this difference in the two proportions is “significant” or not, using a Chi - square test or a test for the difference between proportions, as explained in the chapter for testing the difference between proportions.

Limitations of Tests for Difference between Means, Medians or Proportions

The problem with the ‘t’ test, Mann Whitney U test or Chi - square test for seeing the difference between means, medians and proportions is that they only test a hypothesis (i.e. the research hypothesis which says that there is a difference versus the null hypothesis which says that there is no difference). This is explained in detail in the section on statistics. However, such hypothesis testing procedures based on critical level of p - value (usually 0.05) do not tell us anything, about the “magnitude of association or effect”. We will clarify this with an example. Let us say, in the sore throat - ARF study quoted above, we found 20% of the children with sore throat and 10% of the children in the other group developed ARF. Apparently, the incidence of ARF was two times higher among children who had suffered from sore throat (20% compared to 10%). A Chi - square test would tell us that the incidence of ARF is “significantly” more among sore throat group as compared to the other group

Assume the incidence to be 40% and 10%, and not 20% and 10% as mentioned earlier. In this situation the incidence of ARF is “4 times more” among the sore throat group (instead of only 2 times more which was found earlier). However, a Chi - square test would even now only tell us that the incidence of ARF is significantly higher in sore throat group, a result which it (Chi - square test) had given us in the earlier situation also. Thus, significance testing for difference between means, medians or proportions using ‘t’, non - parametric or Chi - square tests, only test a hypothesis which says that one of the two means/ medians / proportions is significantly higher (or lower) than the other. However, these tests do not tell us the “magnitude”. For answering these two extremely important questions, we have the measures of “Effect”.

Measures of Effect

The 2x2 table is formed when the “exposure” (i.e. cause) variable and “outcome” (effect) variable take a dichotomy of either absent or present. On the axis of exposure, we have two categories : exposure present (E +) and exposure absent (E-). On axis of outcome, we have, outcome present (O +) and outcome absent (O -). The typical 2 x 2 table is shown in Table - 1 :

To answer whether smoking is a risk factor for IHD, assume that a study was started with 5000 healthy adults and IHD was excluded at the start by means of relevant diagnostic work - up. These 5000 subjects were interrogated about smoking habits (exposure); it was found that there were 1500 smokers (E +) and 3500 non smokers (E-). These two groups (E+ and E -) were then followed up for 10 years to see whether IHD (the outcome) developed (O +) or not (O -). It was found that out of 1500 smokers (E +), 150 developed IHD (E + O +) while 1350 did not (E + O -). On the other hand, out of the 3500 non

smokers (E -), 175 developed IHD (E - O +) while 3325 did not (E - O -). The typical 2 x 2 table can be constructed as shown in Table - 2 :

Exposure (or cause)	Outcome (or Effect)		Total
	Present (O +)	Absent (O -)	
Present (E+)	a	b	a + b
	(E + O +)	(E + O -)	(all E +)
Absent (E -)	c	d	c + d
	(E - O +)	(E - O -)	(all E -)
Total	a + c	b + d	a + b + c + d
	(all O +)	(all O -)	(grand total = n)

Smoking (Exposure)	IHD (Outcome)		Total
	Developed (O +)	Did not Develop (O -)	
Present (E+)	150 (10%)	1350 (90%)	1500 (100%)
	a	b	a + b
Absent (E -)	175 (5%)	3325 (95%)	3500 (100%)
	c	d	c + d
Total	325	4675	5000
	a + c	b + d	a + b + c + d

The heart of the 2 x 2 table has 4 “cells”, represented by ‘a’, ‘b’, ‘c’ and ‘d’ as follows :

a = Subjects who have both the exposure as well as the outcome, i.e. E + O+ (e.g. all those smokers who develop IHD, i.e. 150 in above example).

b = Subjects who have only the exposure but not the outcome, i.e. E+ O - (e.g. all those smokers who do not develop IHD, i.e. 1350 in above example).

c = Subjects who do not have the exposure but develop the outcome, i.e. E - O+ (e.g. all those non smokers who developed IHD, i.e. 175 in the above example).

d = Subjects who do not have the exposure and also do not develop the outcome, i.e. E - O - (e.g. all those non smokers who develop the outcome. i.e. 3325 in the above example).

a+b = Total number of subjects who have the exposure, irrespective of whether they develop the outcome or not, i.e. E+ (e.g. all smokers, whether they developed IHD or not, i.e., 1500).

c+d = Total number of subjects who do not have the exposure, irrespective of whether they develop the outcome or not, i.e. E - (e.g. all non smokers, whether they developed IHD or not, i.e. 3500).

a+c = Total number of subjects who developed the outcome, irrespective of whether they had the exposure or not, i.e. O+

(e.g. all those who did develop IHD, whether they used to smoke or not, i.e. 325).

b+d = Total number of subjects who did not develop the outcome, irrespective of whether they had the exposure or not, i.e. O - (e.g. all those who did not develop IHD, whether they used to smoke or not, i.e. 4675).

a+b+c+d = The grand total of all subjects studied (or simply “n”) (e.g. 5000 in the present example).

Note : Often in epidemiological and research parlance, the terms “exposure”, “predictor”, “independent” and “cause” variable are used interchangeably; similarly, the terms “outcome”, “effect” and “dependent” variable stand for the same meaning.

Relative Risk

The above 2 x 2 table tells us that the incidence of IHD (over a 10 year period) was 10% among smokers (150 out of 1500) while it was 5% among non smokers (175 out of 3500). This can also be taken as the risk of developing IHD.

When asked if smoking is a risk factor for IHD, your answer, almost instantly, would be “yes, it is two times more among smokers”. You are correct. This conclusion of “two times” more is arrived at by simply dividing 10% by 5%. “Incidence of the outcome (IHD) among those with the exposure (smokers)”, (i.e. 10%) is divided by the “incidence of the outcome (IHD) among those without the exposure (non - smokers) (i.e. 5%). This equation is the Relative Risk (RR) or the “Risk Ratio”. Thus,

$$RR = \frac{\text{Incidence of outcome among those having the Exposure (I}_E)}{\text{Incidence of outcome among those not having the Exposure (I}_O \text{ or I}_{NE})}$$

More precisely, if we are measuring Cumulative Incidence (CI), then we would write CI_E and CI_O ; while if we are measuring Incidence Density (ID), then we would write ID_E and ID_O . In certain texts on Epidemiology, “Risk Ratio” is taken to indicate the ratio of CI_E and CI_O while “Incidence Rate Ratio” or “Hazards Ratio” is taken to mean the ratio of ID_E and ID_O .

The Relative Risk (RR) gives an idea of the number of times that the Incidence is likely to be more among those who have the exposure compared to those who do not have the exposure. An increasing value of RR indicates increasing quantum of risk. If the RR is very high (say, 5 or more), we are convinced that, particular exposure carries a very high risk of the outcome to develop. In other words, higher the RR, there is a higher likelihood of an association between the exposure and the outcome. The RR indicates, in addition to the magnitude, the “strength of association” between an exposure and the outcome variable.

What happens if the RR is equal to one or less than one ? : Let us change the findings of our study on smoking - IHD association a little, and assume that the findings were as per Table - 3.

Here the incidence of IHD among smokers as well as non smokers is 10% each (RR = 10% / 10% = 1). Thus the incidence (i.e. Risk) of developing IHD among both, smokers and the non smokers is the same.

Smoking	IHD		Total
	Developed	Did not Develop	
Present (100%)	150 (10%)	1350 (90%)	1500 (100%)
	a	b	a + b
Absent (100%)	350 (10%)	3150 (90%)	3500 (100%)
	c	d	c + d
Total	a + c	b + d	a + b + c + d
	500	4500	5000

Consider yet another situation that could occur (Table - 4)

Smoking	IHD		Total
	Developed	Did not Develop	
Present (100%)	150 (10%)	1350 (90%)	1500 (100%)
Absent (100%)	700 (20%)	2800 (80%)	3500(100%)
Total	850	4150	5000

Here the RR would be $10\% / 20\% = 0.5$. The data would indicate that if one smokes, the risk of getting IHD is 10%; on the other hand if one does not smoke, the risk is 20%. Smoking thus reduces the risk of getting IHD by half. If RR is less than 1, it indicates declining risk, i.e. a protective effect. With the above finding of RR as 0.5, we would say that smoking protects against IHD by 50%. (i.e. reduces the risk of IHD by half). Moreover, farther the RR is from one (towards zero), more is the strength of this protective association.

The interesting part of this scale of RR is that with a null value of 1, while the increased risk ranges on a very wide gradient of more than one to infinity (if incidence in exposed group is 100% and in unexposed it is 0%, the RR will be $100\% / 0\% = \text{infinite}$); however, on the protective side it can range only in a narrow range from zero to one (in the most protective situation, the incidence among exposed group can be 0% while in the non - exposed group may be 100%; thus, RR in this extreme situation would be $0\% / 100\% = 0$).

How to Estimate the “Risk” When We are Doing Our Research “The Other Way Round” : The Odds Ratio

The examples we just discussed were the ideal settings of research in which we start from a point when the outcome (e.g. IHD) has not occurred and we follow up the subjects forward (a group with the exposure and not having the outcome when we start, i.e. at risk of developing the outcome and another group not having the exposure and also not having the outcome).

Scientifically ideal though it may be, such “forward proceeding” research has its own drawbacks too, as we shall discuss in detail in a later chapter on architecture of epidemiological

designs. In short, it needs a very long time of follow up (may be 10 years or even more) which may be logistically difficult. Such research also needs a large number of subjects to be followed (usually in thousands) for that long a time, thus making such research very costly and tedious.

For these reasons, a good alternative is to do this research the “other way round”, i.e. instead of starting from a point when the outcome has not occurred and then proceeding into the future, we could pick up some subjects in whom the outcome has already occurred and a comparison group in which the outcome has not occurred, and compare these two groups regarding the history of exposure. For example, we can take 50 persons diagnosed with IHD and 50 without IHD, obtain the history of smoking during past 10 years from them and set the data into the following 2x2 table (Table - 5).

History of Smoking (Exposure)	IHD (Outcome)		Total
	Present	Absent	
Present	25 (50%)	17 (34%)	42
	a	b	a + b
Absent	25 (50%)	33 (66%)	58
	c	d	c + d
Total	50 (100%)	50 (100%)	100
	a + c	b + d	a + b + c + d

The above setting is the classical “case control study” which, we shall discuss in another chapter. Apparently, this 2 x 2 table may appear to be similar to those presented earlier. However, there are many fundamental differences. The most important difference is that in the present setting we are not following up, in a FORWARD manner, the 2 groups of subjects (smokers and non - smokers developing or not developing IHD); but since the outcome (IHD) had already occurred, we are picking up “samples” of cases and healthy persons (50 each) and going BACKWARD from outcome to exposure. Thus we cannot calculate the “incidence” of IHD in smokers and non - smokers as $a/(a+b)$ and $c/(c+d)$ respectively. Since incidence cannot be calculated, the RR too cannot be calculated.

Another parameter, the Odds Ratio (OR) can be calculated from a case control study. The OR is a valid estimator of the RR as it gives as a reasonably accurate idea of the RR. However, for the “valid estimator” concept to hold good, there are two assumptions which should be met with :

- The outcome, i.e. the disease of interest (e.g. IHD in this case) should be a ‘rare disease’, i.e. the incidence of the outcome should be $<5\%$ in the total population. Luckily, most of the human diseases are uncommon ones, with this parameter of $<5\%$.
- The “controls” i.e. the comparison group (the 50 healthy persons) should be “representative” of the same total population that gave rise to the “cases”.

The odds ratio in a case control study is calculated by the

equation :

$$OR = \frac{(E+O+) \times (E-O-)}{(E+O-) \times (E-O+)} = \frac{(a \times d)}{(b \times c)} \quad (\text{also called "cross product ratio"})$$

(where a, b, c and d are the 4 cells described earlier in this chapter, in the form of E+O+, etc.). In our present example, the odds ratio

$$= \frac{(25 \times 33)}{(17 \times 25)} = 1.94$$

And since the OR is a valid estimator of RR, we would conclude that the risk of IHD due to smoking is 1.94 times as compared to non - smoking.

The odds ratio in a case control study basically measures the "exposure odds ratio". To clarify the aspect, let us once again draw the 2 x 2 table (Table - 6).

Total Exposure	Outcome (Diseases)		Total
	Present	Absent	
Present	a	b	a + b
Absent	c	d	c + d
Total	a + c	b + d	a+b + c+d

The "odds" of a case being "exposed" = Ratio of "exposed" cases to "non - exposed" cases = a/c and similarly, the odds of a control being exposed = b/d. Thus, the "Ratio" of the "odds of exposure among cases" to "odds of exposure among controls"

$$= \frac{a / c}{b / d} = \frac{(a \times d)}{(b \times c)} = OR$$

Technically speaking therefore, the odds ratio from a case control study means that the "odds" of cases being exposed are "so many times higher" compared to the "odds of controls being exposed". In our above example, the correct interpretation of OR = 1.94 is that a case of IHD is 1.94 times more likely to be having the exposure (i.e. history of smoking) as compared to a person not having IHD. However, if the 2 assumptions, enumerated above are met, the OR approximates the RR and so we conclude that the risk of IHD is 1.94 times more if one smokes.

Interpreting Increase or Decrease in RR or OR in Terms of Multiples or Percentage Change

There are various ways, in which the RR or OR may be interpreted. An RR or OR of 1.5 means "one and a half times increase in risk" (of getting the outcome when exposure is present as compared to when exposure is not present). It also means the risk is increased by 50% among those with the exposure as compared to those without the exposure. An RR or OR of 0.33 means that the risk is only one - third among those who have the exposure as compared to those who do not have the exposure; it also means that the risk among the exposed is only 33% as compared to those not having the exposure; it also means that there is a 66% decline in risk when exposure is

present; it can also be interpreted as that there is a two - third reduction in the risk, if exposure is present. In general, if we have to calculate the percent increase (or decrease) in risk for a given value of RR (or OR), the general equation is :

"Percentage increase or decrease in risk among the exposed group = $\{(RR \text{ or } OR) \approx 1\} \times 100$ " (where the symbol \approx means "difference, ignoring the minus or plus sign"). Thus if OR is 1.85, the percentage increase in risk will be $(1.85 \approx 1) \times 100 = 85\%$; if RR is 0.4 the % decrease in risk will be $(0.40 \approx 1) \times 100 = 60\%$. Similarly if RR is 8, it would also be stated as an increase in risk by 700%.

The Measures of Differences in Risk

The measures of "effect", i.e. "risk ratios" that we have discussed till now were RR and OR in a case control study. They are extremely important measures of the "strength of association" between an exposure and its suspected outcome. The further the RR (or OR) is from the value of one, the more confident we become about a "cause and effect" relationship, be it regarding risk factors for a disease, or prognostic makers, or evaluation of efficacy of drugs, vaccine or any other therapeutic/ preventive procedure. For example, if the RR (or OR) of lung cancer due to smoking (as compared to non - smokers) is 5, we are quite confident of the role of smoking as an important risk factor in lung cancer.

But the measures of "risk ratio" (RR or OR) do not tell us anything about one aspect - "how much more" (though they answer the issue "how many times"). If the cost of a brand new music system is five times more than a second hand one, you may start considering buying a second hand one only; however, if we tell you that the cost of the brand new system is Rs. 2500 and that of second hand one is Rs. 500, you may rethink in terms of buying the brand new one itself because while the cost of buying the brand new system is five times more but the absolute difference is Rs. 2000 only. On the other hand, if a brand new car costs Rs. 5 lakhs, while a second hand model costs Rs. 2.5 lakh, the cost of a brand new model is only 2 times of the second hand one, but one may still think of buying the second hand model, because the absolute difference is, in this situation, Rs. 2.5 lakh. Let us look at this situation from a clinical point of view, by browsing at the hypothetical data shown in Table - 7 :

		Incidence per lakh population per year	
		Lung CA	IHD
a)	Among Smokers	10	250
b)	Among Non - Smokers	1	125
	RR for smokers (a / b)	10	2
	Absolute difference (a - b)	9 per lakh	125 per lakh

Apparently, with a relative risk of 10, there is little doubt that smoking is a very important "cause" of Lung CA. However, if we examine the above data from a slightly different perspective, we will find that if smokers were to stop smoking, it will result

in a decrease of 9 cases of Lung CA per lakh population, but the same action will result in a decrease of as much as 125 cases of IHD per lakh population. Thus, while smoking may not be a very strong causal factor for IHD (as much as it is for lung CA), the amount of difference that it is going to make on public health will be tremendous for IHD but meager for Lung cancer.

Measures of Risk difference (impact) in a forward study

In a hypothetical data set of typical “forward - moving” study, we studied a sample of 60,000 male subjects, aged 40 - 49 years, who were initially free of IHD. Further, out of these 60,000 subjects, 20,000 were smokers and 40,000 were non - smokers. We followed up all these subjects for a period of 10 years, looking for the development of IHD. The results are presented in Table - 8.

	Developed IHD	Did not develop IHD	Total
Smokers	400	19600	20,000
Non Smokers	400	39600	40,000
Total	800	59200	60,000

From Table - 8, Incidence of IHD among those “exposed” to smoking and “not exposed” can be calculated as :

$$I_e = 400 / 20,000 = 0.02 \text{ (or 2\%)}$$

$$I_o = 400 / 40,000 = 0.01 \text{ (or 1\%)}$$

$$RR = I_e / I_o = 2\% / 1\% = 2$$

(a) Measure of Absolute Effect : The difference in two incidence rates therefore gives us the “absolute effect” and is measured in terms of “Attributable Risk” (AR). Truly and very technically speaking, the absolute effect should be more appropriately called as Absolute Risk Difference (ARD) or simply as Risk Difference (RD); this RD can be either “Absolute Risk Reduction” (ARR) or else an “Absolute Risk Increase” (ARI), depending upon whether the risk (incidence) is increasing or decreasing in one group, as compared to the other. The AR or RD is defined as the difference between the incidence among exposed group (I_e) and the incidence among unexposed group (I_o). Thus, $AR = I_e - I_o$. In our example, $AR = 0.02 - 0.01$ (or 1%). We would describe this finding as “there is likely to be one ‘additional’ case of IHD among every 100 smokers as compared to 100 non smokers”.

(b) Measures of Attributable Fractions (Impact) : These are of the following categories : Attributable fraction for exposed; and, population attributable risk. We deliberate on these in the succeeding paragraphs.

i) Attributable Fraction for Exposed (AF_e) (Syn, Etiologic Fraction (EF), Etiologic Fraction for Exposed (EF_e), Attributable Risk Percent (AR%) : This is calculated as :

$$AF_e = \frac{(I_e - I_o)}{I_e} \times 100$$

Now, dividing both the numerator as well as the denominator by I_o , we get

$$AF_e = \left[\frac{\frac{I_e}{I_o} - \frac{I_o}{I_o}}{\frac{I_e}{I_o}} \right] \times 100$$

Now, since $(I_e/I_o) = RR$

$$AF_e = \frac{(RR - 1)}{RR} \times 100$$

In our example above, RR was 2, thus,

$$AF_e = \frac{(2 - 1)}{2} \times 100 = 50\%$$

The AF_e tells us as to what percentage of the load of outcome among the exposed is because of the exposure; in other words, it tells us that if all the exposed people were to give up their exposure, then it would result in so much percentage reduction in the outcome among the exposed group. To simplify this statement, in our example, this means that 50% of the IHD load AMONG SMOKERS is due to smoking. If smoking is given up by SMOKERS, a 50% reduction in IHD AMONG SMOKERS will be obtained.

The limitation of AR% is that it tells us the quantum of reduction in the disease that would be achieved in the “exposed” group if “exposure” was given up by them. However, it does not tell us about the reduction that will occur in the “total population”. It would be noted that, as health administrators, we would be also interested in the possible reduction in IHD that would occur in the total population (consisting of a mixture of smokers and non - smokers) if this total population stops smoking, and not only in the reduction in IHD that would occur among smokers if they stop smoking (which is the AR%). This difficulty is overcome by calculating the PAF or else PAR%, which we shall now discuss.

ii) Population Attributable Risk Percentage (PAR %) (Syn. Etiologic Fraction in Total Population (EFTP))

The PAR % is given by the equation

$$PAR \% = \frac{P_e \times (RR - 1)}{1 + [P_e \times (RR - 1)]} \times 100$$

In our example on smoking - IHD association; $P_e = 0.33$ as calculated above; $RR = 2$

$$PAR \% = \frac{0.33 \times (2 - 1)}{1 + [0.33 \times (2 - 1)]} \times 100 = 24.8\% \text{ (25\% approx.)}$$

The PAR % can also be worked out using another equation, namely,

$$PAR \% = \frac{PAF}{I_t} \times 100$$

Where, PAF = Population Attributable Fraction as described above, and I_t = Incidence of the disease in the total reference population. In our example, the representative sample of 60,000 subjects showed that 800 cases of IHD developed over a 10 year period. Thus, $I_t = 800 / 60,000 = 0.0133$ over a 10

year period.

$$\text{Thus, PAR \%} = \frac{0.0033}{0.0133} \times 100 = 24.8\% \text{ (25\% approx.)}$$

Another equation for calculating PAR% is $\text{PAR\%} = \{(I_t - I_o) / (I_t)\} \times 100$, where, I_t = incidence in the total population and I_o is the incidence in the non - exposed group. In our example, $I_t = 800 / 60,000 = 0.0133$ (or 1.33%) and I_o was $400 / 40000$, i.e. 0.01. Thus, $\text{PAR\%} = \{(0.0133 - 0.01) / (0.0133)\} \times 100 = 24.8\%$ (25% approx.). This means that if cigarette smoking is one of the causes of IHD, then about 25% of all IHD in the total reference population can be prevented if smoking is completely stopped by the entire reference population.

iii) Population Attributable Fraction (PAF) : For details of this particular measure of risk difference and its calculations, readers are suggested to consult one of the books quoted in further suggested readings, at the end of this chapter.

(c) Preventive Fractions : The term Preventive Fraction (PF) is used as a replacement of Attributable Fraction for exposed (AR %), when the exposure is protective, i.e. reduces the risk of outcome. For example, if “physical exercise is the “exposure” and IHD is the “outcome”, then the incidence of outcome (IHD) in the exposed group (doing physical exercise) will be lesser than the incidence in non - exposed group (not doing physical exercise). In such a case, the RR will be less than one (protective RR). Now if we calculate the AR % in this case using the equation

$$\text{AR\%} = \frac{I_e - I_o}{I_e} \times 100$$

Then the AR % will come out in negative sign (since I_e will be lesser than I_o) and will cause difficulty in interpretation. One way of sorting out this problem is to put the “risk increasing” factor as the “exposure”, e.g. in this case we can take “Lack of Physical exercise” as the exposure, in which case the RR will be more than one and this difficulty will be sorted out. However, often for reasons of clinical interpretation we may feel that this may not explain our findings well. For example, we may feel that it is better to put the things as “If physical activity is promoted, it will lead to a decrease in IHD by 50%” rather than putting it like “If *lack of physical activity* is removed, it will lead to a reduction in IHD by 50%”. In such cases, Preventive Fraction (PF) is calculated as

$$\text{PF} = \frac{I_o - I_e}{I_o} \times 100$$

The use of PF becomes most apparent in trials of vaccines where it is also called as “Efficacy of Vaccine” (EV) and is measured as :

$$\text{PF(EV)} = \frac{\left[\begin{array}{l} \text{Incidence in Unvaccinated (I}_o\text{)} \\ - \text{Incidence in Vaccinated (I}_e\text{)} \end{array} \right]}{\text{Incidence in Unvaccinated (I}_o\text{)}} \times 100$$

As a hypothetical example, in a study on the association between physical activity and IHD, presence of regular physical exercise was defined as the exposure variable (E+), while those not undertaking regular exercise were taken as (E-). It

was found that the incidence of IHD among those who were physically active (E+) was 4% (0.04 as a fraction out of one), over 10 years of follow up, while the incidence among inactive (E -) was 10% (i.e. 0.1). The PF in this example is $\{(0.1 - 0.04) / (0.1)\} \times 100$, i.e. 60%. The interpretation is that there will be a reduction of IHD by 60% among those who are physically inactive if they become physically active.

Calculation of Measures of Differences from a “Case Control” Study

As we would recall that in a case control study, we cannot calculate the incidence and hence we cannot calculate the RR. What we can do is that we can calculate the Odds Ratio (OR) which is a valid approximation of (i.e. almost as good as) the RR, and thus, it gives us an approximate idea of the “risk” due to the exposure of interest. Since the measures of “risk difference” that we have discussed above involve calculation of RR, a direct calculation of these measures of difference in a case control study is difficult. However, certain methods have been devised by which we can calculate the measures of difference from a case control study also, basically by using the concept that OR from a case control study is approximately equal to the RR.

Let us consider another hypothetical example of a case control study which was undertaken to study the risk of Thrombo - Embolism (TE) due to Oral Contraceptive (OC) use. 100 ladies suffering from TE were taken from a hospital (cases) and another 200 healthy ladies of same age who had not suffered from TE were also taken up for comparison (controls). History of intake of OC was obtained from all the 300 subjects. The hypothetical data is as per Table - 9 :

History of OC Intake	TE Cases	Controls	Total
Present	42	38	80
Absent	58	162	220
Total	100	200	300

Now, in the above data set,

$$\text{OR} = \frac{(a \times d)}{(b \times c)} = \frac{(42 \times 162)}{(38 \times 58)} = 3.09$$

Since OR is approximately equal to RR, we can conclude that the risk of getting TE is more than 3 times higher among OC users as compared to non - users. Now, the measures of difference can be calculated as follows :

(a) Attributable Fraction for Exposed (AF_e) (Syn - EF; EFe; AR %) : We would remember that earlier we had calculated the AR% as :

$$\text{AR\%} = \frac{(RR - 1)}{RR} \times 100$$

and since OR is approximately = RR, therefore,

$$\text{AR\%} = \frac{(OR - 1)}{OR} \times 100 = \frac{(3.09 - 1)}{3.09} \times 100 = 67.64\%$$

This means that 67.6% (i.e. more than two thirds) of

Thromboembolism among OC users is because of OC use; if OC users give up its use, then there will be a 67.6% reduction in TE among them (of course, the remaining 32.4% TE will still remain because of causative factors other than OC use).

(b) PAR % from a case control study : In a forward type of research, calculation of PAR % involves two parameters - the 'RR' and 'Pe'. Since OR is approximately equal to RR, we can do this substitution. As far as 'Pe' (i.e. proportion of total population likely to have the exposure) is concerned, we would fall back on our assumption that in a case control study, for OR to be a valid estimator of RR, the controls should be representative of the total population. Thus, the "proportion of controls having the exposure" can be used as a good approximation to the proportion of total population having the exposure; thus,

$$Pe = \frac{\text{Number of Controls having the exposure}}{\text{Total number of controls}} = \frac{b}{(b + d)}$$

It may be contested at this point that the total population will have both cases and controls. Apparently, the level of exposure among the cases will be likely to be much higher than the exposure among controls. Therefore, in the total population (having a mixture of both cases and controls), the proportion of exposure is likely to be higher than the proportion among controls alone, and if this be true, then we cannot estimate "Pe" as " $(b / (b+d))$ ".

To counter this argument, we will use the first assumption that we have made in a case control study - that the disease being studied should be rare. Hence, the total number of cases in the total population will form a very small fraction of the total population, the large majority of the total population will be made of the controls. Thus the higher rate of exposure among cases will not make any practical difference and therefore the proportion of controls having exposure can be used as a valid approximation to the proportion of total population having exposure. Now, since,

$$PAR \% = \frac{Pe \times (RR - 1)}{1 + [Pe \times (RR - 1)]} \times 100$$

now, substituting RR by OR

$$PAR \% = \frac{Pe \times (OR - 1)}{1 + [Pe \times (OR - 1)]} \times 100$$

Where $Pe = b / (b + d)$ of the 2 x 2 table of the case control study.

In our example, $b = 38$, $d = 162$, $b+d = 200$

Therefore, $Pe = 38 / 200 = 0.19$ and $OR = 3.09$, and hence

$$PAR \% = \frac{0.19 \times (3.09 - 1)}{1 + [0.19 \times (3.09 - 1)]} \times 100 = 28\%$$

This means that 28% of all TE in the total (reference) population can be prevented if OC use is stopped by the reference population.

Can we work out the AR and PAF from a case control study?: Based on the data of case control study alone, we cannot work out the AR. We can only work out the AR% and PAR%, as described earlier. However, if we have an idea regarding

incidence of the disease, from some other source (or else, if the case - control study is a nested case control design), then we can work out the AR. Readers are suggested to consult one of the advanced textbooks cited in the list of further suggested readings, for details of calculations.

The interesting and paradoxical feature of attributable risk in public health policy - "Preventive Paradox" : A peculiar situation while studying and formulating the public health policy may come up in situations in which the RR for a given disease or a particular level of a given disease process may be much lower but the Attributable Risk or AR% may be much larger. Take for example the fact that increasing levels of diastolic BP (90 to 104 mm Hg, 105 to 114 mm Hg and 115 mm Hg or above may carry consistently and markedly larger RRs for increasing the risk of mortality due to stroke, CHD and heart failure. However, what also is a fact is that a substantially large proportion of hypertensives is actually in the 90 to 104 mm Hg category, lesser in 105 - 114 mm Hg and very few in ≥ 115 mm Hg category. Thus the greatest % of excess deaths in the population due to hypertension (in fact, almost 60%) is attributed to mild levels of hypertension of diastolic 90 to 104 mm Hg category. Paradoxically, then, physicians could save more number of lives with effective treatment of lower rather than higher levels of hypertension. This fact, so counter - intuitive to clinical thinking, has been termed as the *preventive paradox*. The explanation of the above phenomenon is that even with a large relative risk, the AR or AR% may be small if the disease is rare or else the risk factor is uncommon, and vice versa.

Measures of Benefit - Numbers Needed to Treat (NNT)

This measure is being increasingly used to describe the practical utility of a treatment. It indicates the number of patients who will need to be treated with the treatment modality under study, to get one additional case of cure, as compared to the standard modality of treatment which was used as a control procedure. It is calculated as the inverse of AR.

$$NNT = \frac{1}{AR} = \frac{1}{I_e - I_o}$$

For example, in a trial of a new oral antidiabetic, 60 of the 75 patients were rendered normoglycaemic while 50 of the 75 in the control group getting standard oral hypoglycaemics could be controlled. Thus, $I_e = 60 / 75 = 0.80$ and $I_o = 50 / 75 = 0.67$. Thus $NNT = 1 / 0.13 =$ approximately 8. Thus, we will need to treat 8 cases with the new drug to get one additional case of cure, as compared to the existing oral hypoglycaemics.

Summary

Once data has been collected in an epidemiological study, the same has to be reduced into summary figures, usually incidence or prevalence, which give us an idea of the entire data in one look. These summary figures help us in developing certain hypotheses regarding the possible role of a variable as a treatment / preventive modality or regarding its possible role as a risk factor. However, while we can develop hypotheses on the basis of such summary figures, it is no final proof; for finally accepting these hypotheses, one needs to make comparisons.

This is done by comparing the summary figures (incidences or prevalences) in two groups, one group having the factor and the other not having the same. Thus, we get another summary figure, which gives us the magnitude of the effect. The larger this magnitude, the more we are convinced about the role of that factor as a therapeutic, preventive, prognostic or risk factor. Such summary figures which compare two frequency measures are called as measures of effect or impact.

Measures of effect can be broadly of two types - Ratio measures and Difference measures. Ratio measures answer the question "How many times is the difference?" On the other hand, difference measures answer the question "How much is the absolute difference?". In a classical "forward-looking" study, we calculate the incidence of the "outcome" in the two groups the exposed and the non - exposed group. The ratio between the incidence in the exposed (Ie) and the non - exposed (Io) is called as the relative risk (RR). Since incidence also gives us an idea of "Risk", RR is also called as Risk Ratio. RR gives us an idea of the strength of association. Farther the value of RR from "one", stronger is the relationship between exposure and outcome likely to be. Values of RR higher than one indicate increasing risk of outcome due to the exposure; values lower than one indicate decreasing risk (protective effect). Value of exact one indicates no effect, this way or that way, and hence the value of one is called as "null" value of RR.

In a case control study, we cannot calculate the incidence and hence we cannot calculate the RR. However, given the assumption that the outcome being studied is "rare" and the controls have been derived from the same source population which gave rise to cases, we can calculate the Odds Ratio (OR) as the cross - product ratio $(a \times d) / (b \times c)$ and this OR is a valid estimator of RR. While measures of risk ratio (RR or OR) are important for assessing the association between two variables, the overall clinical or public health impact of an exposure is measured by measures of Risk Difference (RD); The commonest and the simplest of these is "Attributable Risk" (AR). It is calculated as the absolute difference between Ie and Io and tells us the number of additional cases with the outcome among those having the exposure as compared to those not having the exposure. Another common measure of RD is the AR%, also called as etiological fraction in the exposed; it tells us as to what percentage of the load of outcome among the exposed is because of the exposure; in other words, it tells us that if all the exposed people were to give up their exposure, then it would result in so much percentage reduction in the outcome among the exposed group. In addition, there is a measure which tells us the total contribution which the exposure variable makes for the outcome in the total population - this is called population attributable risk or etiologic fraction in total population. In a case control study, there are different methods of calculating the measures of impact, as have been described in the text.

Study Exercises

MCQs & Exercises

- The following table shows the annual incidence of Thrombo-Embolism (TE) for every lakh women using and not using Oral Contraceptives (OCs) according to age groups 30 to 39 years and 40 to 49 years. Calculate the RR and AR in each

age group.

History of OC use	Incidence of Thromboembolism (TE) per lakh	
	Age Group (Years)	
	30 to 39	40 to 49
Users	5.3 per lakh	29.15 per lakh
Non - Users	1.8 per lakh	9.9 per lakh

- In one of the studies, smokers and non - smokers, not having lung cancer, were followed up for 15 years and observed for the development of lung cancer. The data is set out in the following table. Calculate the various measure of risk ratio and risk difference.

Cigarette Smoking	Developed Lung CA	Did Not Develop Lung CA	Total
Smokers	70	6930	7000
Non Smokers	3	2997	3000
Total	73	9927	10000

- From the health department of the country, the following data is available for the incidence of Lung cancer and IHD among smokers and non - smokers. Calculate various measures of effect and make your clinico - epidemiological interpretations

Smoking habit	Incidence per lakh population	
	Lung cancer	IHD
Smokers	10.1	242
Non Smokers	1.48	119
Total Population	2.13	207

- The overall incidence of IHD in a state is 191 per lakh population. Among smokers and non smokers, the incidence is 242 and 119 per lakh respectively, while among obese and non - obese people it is 172 and 113 per lakh respectively. In the state, 20% of the people are smokers and 54% are obese. Calculate the various measures of effect and give your main interpretations.
- In what all different ways would you interpret (a) RR of 3.25 (b) OR of 0.11.
- Say true or false : RR or 4.0 indicates 3 times more risk as compared to an RR of 2.0.
- A journal review article regarding air pollution - related lung disease says that the disease has increased by 900% in the last half century. What level of RR does it correspond to?
- A disease has been consistently increasing in a country. What will be the level of RR that will correspond to (a) 20% increase in risk (b) 900% increase in risk ?
- Which of the following procedure will give us an idea about the strength of association between an exposure and an outcome variable : (a) 't' test (b) chi - square test (c) both

the above (d) none of them

Answers : (1) RR of TE due to OC use in age group 30 to 39 years is $5.3 / 1.8 = 2.9$; in age gp 40 to 49, the RR is the same $(29.15 / 9.9) = 2.9$. The AR for these two groups is $5.3 - 1.8 = 3.5$ per lakh while for the higher age group it is $29.15 - 9.9 =$ approximately 20 per lakh. (2) $I_e = 70 / 7000 = 0.01$ or 10 per 1000; $I_o = 3 / 3000 = 0.001$ or 1 per 1000; $I_t = 73 / 10,000 = 0.0073$ or 7.3 per 1000; $P_e = 7,000 / 10,000 = 0.70$ or 70%; $RR = 0.01 / 0.001 = 10$; $AR = 0.01 - 0.001 = 0.009$ or 9 per 1000; $AR\% = \{(0.01 - 0.001) / (0.01)\} \times 100 = 90\%$; $PAR\% = \{(0.0073 - 0.001) / (0.0073)\} \times 100 = 86\%$; $PAF = 0.09 \times 0.7 = 0.063$ or 63 additional cases per 1000 ; (3) RR (due to smoking) = 6.8 for Lung CA and 2.03 for IHD; $AR = 8.62$ per lakh and 123 per lakh respectively for Lung CA and IHD; $AR\% = 85.3\%$ and 50.7% respectively; $PAR\% = 30.5\%$ and 42.5% respectively;

For PAF (use the equation "PAF (as fraction) = {It x PAR (as %)} / 100, in this case, since P_e is not known from the data); thus PAF for Lung CA = $(0.0000213 \times 30.5) / 100 = 0.000065$ or 6.5 cases of lung cancer per million population; for IHD the PAF = $(0.00207 \times 42.5) / 100 = 0.00088$, or 880 cases of IHD per million population.

The interpretation from clinical and epidemiological point of view is that while smoking is a very strong risk factor for Lung Ca (there remains little doubt as the association seems to be very strong with a RR of almost 7), it is a moderately strong risk factor for IHD. However, on the large population basis in the country, the good effects of giving up smoking will be mainly seen in reduction of IHD rather than Lung Ca; if smoking was stopped in the country, there would be, for every million population in the country, 880 lesser cases of IHD and 6 to 7 lesser cases of Lung cancer. Thus, the incidence of the disease in the total population greatly determines the load of

disease that will be prevented due to removal of a risk factor.

(4) For IHD : $RR = 2.03$; $AR = 0.00123$ (123 per lakh); $AR\% = 51\%$ approx; $PAR\% = 17\%$ approx; $PAF = 0.00035$ (35 per lakh). For Obesity, $RR = 1.5$ approx; $AR = 0.00059$ (59 per lakh); $AR\% = 33\%$ approx; $PAR\% = 22\%$ approx; $PAF = 0.00042$ (42 per lakh).

The interpretation is that while smoking has higher RR as well as higher AR and AR% for IHD, when it comes to PAR% and PAF, it is higher for obesity. Thus, on a population basis, control of obesity in the total population may bring about more reduction in IHD than smoking control. This paradoxical situation has occurred because the P_e for obesity is much higher than P_e of smoking. Thus, if a risk factor is more commonly distributed in the population, the overall reduction in the disease caused by it will be much more than a risk factor which is less commonly distributed in the population, even though the risk that this factor carries for causing the disease may not be so high.

(5) (a) 3.25 times increase in risk, or risk is increased by three and a quarter times, or 187% increase in risk (b) risk is only one - ninth in the exposed group; or risk decreases by 89% in exposed group; or risk decreases by eight - ninth in exposed group.

(6) It is True. RR of 4 indicates 300% increased risk while RR of 2 indicates 100% increased risk. Thus the increased risk is $300\% / 100\%$ i.e. 3 times.

(7) RR of 8.0. Since % increase in risk = $(RR \approx 1) \times 100$, and since % increase in risk = 900%, thus, $900 = (RR \approx 1) \times 100$; or $RR - 1 = 9$; thus $RR = 8$ times.

(8) (a) $RR = 1.2$ (b) $RR = 10.0$; (9) d.

Errors of Measurement, Confounding and Bias

RajVir Bhalwar

The very basis of any scientific activity, be it medical research, clinical practice or any other discipline is to make measurements. At every step in our medical practice - whether asking the history of a symptom, looking for a sign or reviewing the investigations, we are in fact making 'measurements'. When we ask our patient regarding history of smoking, we have made a 'measurement', treating the variable 'smoking' on a dichotomous scale of measurement (smoker / non - smoker). Of course, most of the times we are not conscious of the fact that we are making 'measurements'. We usually tend to refer to the process of making measurement when the

process is explicit, e.g. measuring the enlargement of liver in mid - clavicular line, in centimeters. Moreover, we tend to refer to instruments as only the 'physical instruments' (as sphygmo - manometer, ECG machine, reagents and so on). However, in the process of medical research any implement we use to make a 'measurement' is referred to as an instrument. Thus, the questionnaire used to record the history of certain exposures like tobacco use and knowledge regarding a disease, is also an 'instrument'.

What all Variables should be Measured

Before proceeding to make any measurements, we must decide as to what all variables we would be measuring, and the 'scales' on which we would measure them (continuous, ordinal, dichotomous etc.). This will, in turn, depend on our research question. In general we should list out the following categories of variables related to our research objectives :

(a) The exposure variable (s)

- (b) The outcome variable (s)
- (c) The potential confounding variables and probable effect modifiers.

For example, in a study proceeding with the research objective of studying the association between alcohol use and oral cancer, the variables of study would be :

Exposure variable : Alcohol use

Outcome variable : Oral cancer

Potential Confounding variables and possible effect modifying variables : Age, Sex, tobacco use, oral hygiene, dental malformations and genetic background. (A detailed discussion on confounding variables is being made in this chapter).

Where all can a Measurement Process go Wrong

Measurements of the variables listed in the above 3 categories (exposure, outcome and confounders) should ensure “correctness” of measures. Broadly, there are three reasons due to which our measurement process may become incorrect, as follows :

- The basic technique of measurement may be incorrect, due to defective instruments, wrong techniques, inadequately trained data collectors, etc. This is the situation of “measurement error”.
- While selecting the two groups or else while making measurements on the two groups of subjects, which are to be compared, we start treating the two groups in a differential manner. This is known as systematic error or Bias.
- The observed association which we have shown between the exposure and the outcome variables, is actually due to a third, indirectly acting variable and not really due to an association between the exposure and outcome variables. This is the situation of confounding error.

Any one or more of the above erroneous situations, if present, will lead to “lack of internal validity” of the epidemiological or research work.

Basic Measurement Technique

The basic measurement process should have two essential requirements. i.e. it should be “valid” and “reliable”, as follows:

(a) **The measurement process should be valid**, i.e. the measurements which we are making and recording should correctly measure what we really intend to measure. For example, if we desire to measure ‘anaemia’, then visual examination of nails and palpebral conjunctiva may not be very ‘valid’ process, while measurement of Hb% would definitely be. This aspect is called as ‘validity’; any systematic departure, in the process of making measurements, wherein we start measuring something different from what we actually intend to measure, leads to a loss of validity, i.e. measurement error. Validity (syn : accuracy) of a measurement has two major components, viz.

Sensitivity : That is, any person who has the disease being looked for should be identified as positive by our measurement process.

Specificity : This means that all those who are not having that disease should be called as “negative” by the measurement process.

(b) **Secondly, the measurement process should have “Reliability”** (Syn : Precision, consistency, replicability, repeatability) : This is the ability of a measurement process to give consistent results when repeated applications are made. Reliability would be compromised in the following situations :

Due to observer : This can occur due to “between observer variations” (2 different data collectors can produce different results from a medical interview or even BP measurement) or may be due to “within observer variations” (same interviewer can get different values of BP on 2 different occasions using the same sphygmomanometer and patient).

Due to subjects : Again this may be to “within the subject variations” (circadian - rhythm, mood fluctuations) or “between the subjects variations” (biological variations - no two human beings are alike).

Due to instruments and techniques : Different BP instruments or different techniques (recumbent or sitting position) will produce different BP values.

The degree of reliability is judged using statistical procedures of correlation coefficient for continuous variables (e.g. 2 BP readings); or Kappa coefficient for categorical variables. Details of calculation of kappa coefficient are given in the chapter on “studies on diagnostic test evaluation and screening for disease”.

How to Ensure Correctness of Basic Measurement

A checklist of major steps which will greatly help in reducing measurement errors is as follows :

- Clearly write down the research question in adequate detail. Identify the “variables” in the study, in respect of which the measurements are going to be made. This should be written down as “Exposure”, “Outcome” and “Confounding” variables.
- Now, write down clear details of what measurements should ideally be made for each of these variables. This is done by going through the published evidence and consultation with experts. For example, if one of the outcome variables is IHD, the ideal (gold standard) measurement would be either coronary angiography, or a combination of echocardiography and exercise ECG.
- Now, write down how you are actually proposing to measure this variable in your study and whether it is scientifically acceptable. How near does it come to the gold standard? Most of the times the measurement process actually being used may not be (rather cannot be) the gold standard itself. For instance, in a field / community based research on IHD, it may not be at all possible to do coronary angiography on such healthy, free living subjects. In such case, one may decide to use a combination of symptoms with resting ECG as evidence of coronary insufficiency.
- Next, discuss with the experts whether the methods of measurements you are planning for each of the variables is scientifically sound / accepted by eminent organisations/ has already been used by some eminent workers earlier ? For example, a combination of symptoms and resting ECG, using the laid down Minnesota code criteria, is often used for healthy, population - based subjects for evidence of IHD in epidemiological research work which is accepted

by WHO and used in earlier large scale community - based epidemiological studies.

- Now, write down a detailed “protocol” on how exactly the measurement is going to be made, e.g. how the ECG will be recorded, who will record it, and how it will be read.
- Next, write down how “quality control” will be ensured. For example, one may specify that a random sample of the positively and negatively read ECGs will be reviewed by a cardiologist for independent evaluation and quality control.
- Now, see the equipment, reagents etc., which will be used for measuring this variable. Are they accurate? Standardise them, initially and periodically in between the study, against some standard machine. Remember that questionnaires are also instruments. Develop them properly. As far as possible, use the questionnaires and other scales which have already been used and standardised (e.g. Jones criteria; quality of life questionnaire; MPQ etc.).
- Standardise the method (technique) of making any measurement. Preferably use a standardised technique as recommended by a standard professional body (e.g. WHO, American Heart Assn etc.) or a standard text book. Write down the detailed technique in an “operations manual”.
- Train all the interviewers/ data collectors centrally, test them and certify them. If you are yourself the sole data collector get trained and certified by an expert.
- If possible, take repeated measures (e.g. 3 readings of BP).
- Try to make “unobtrusive” measures so that subjects are unaware; e.g. alcohol consumption may be recorded by going through wine bills rather than only asking the subjects.

Confounding

Let us take a hypothetical study which was done to see whether consumption of alcohol is a risk factor for oral CA. 100 cases of oral CA and 100 healthy subjects were asked regarding the history of alcohol consumption during past 15 years. The results are presented in the 2 X 2 table below (Table - 1) :

History of Alcohol	Oral Cancer		Total
	Present	Absent	
Present	80	20	100
Absent	20	80	100
Total	100	100	200

Since the above is a case - control type of study, we can calculate the odds ratio as $(a \times d / b \times c)$ i.e. $(80 \times 80) / (20 \times 20) = 16$

Thus we would conclude that the risk of getting oral cancer is 16 times higher if a person drinks alcohol. Someone would object to our findings, saying that this observed association is false, due to the “hidden” effect of tobacco use. This is because people who drink alcohol are also often the ones who also use tobacco; and tobacco use is itself a direct cause of oral cancer, whether one drinks or not.

It would also be evident that this occurred because the variable

“tobacco use” was directly related to both, the exposure variable (people who drink alcohol are also usually the ones who use tobacco) and was also directly related to the outcome variable (people who use tobacco are at higher risk of getting oral cancer, irrespective of whether they drink or not). Thus, a confounding variable is defined as one which explains away the observed association between an exposure and an outcome variable. A confounder variable should have the following properties :

- Be associated with the exposure of interest.
- Be (independent of the exposure), related to the outcome of the interest.
- It should not be in the direct chain or link between the exposure and outcome; its associations with exposure and outcome are indirect and independent.
- It exerts its effect because it is differentially distributed in the two groups (see later).

Medical literature is replete with examples when a particular factor has been proved to be a risk factor for a disease simply because the effect of third variable (the confounder) was not thought of, thereby making the entire research work invalid.

So, what do we do now? Apparently with the above observation, the only way left for us is to make two “strata” or groups - the group which uses tobacco and another which doesn’t use tobacco. Now, by simple reasoning, if the risk of cancer due to alcohol remains high in both the strata, i.e. the risk of cancer due to alcohol is high whether a person uses tobacco or not, we would conclude that the risk is not due to tobacco but due to alcohol itself. On the other hand, if the risk is not evident in the 2nd stratum, then we would conclude that there was a “confounding” due to tobacco; alcohol, by itself does not carry any risk. Let us see what happens when we dissect our hypothetical data into two strata (Tables - 2 and 3) :

History of Alcohol	Oral Cancer		Total
	Present	Absent	
Present	60	15	75
Absent	20	5	25
Total	80	20	100

Stratum OR = $(60 \times 5 / 15 \times 20) = 1$

History of Alcohol	Oral Cancer		Total
	Present	Absent	
Present	5	20	25
Absent	15	60	75
Total	20	80	100

Stratum OR = $(5 \times 60 / 20 \times 15) = 1$

Surprisingly, we notice that after making adjustment for the use of tobacco as above, the odds ratios in both the strata fall down to 1 each, i.e. there is no risk of cancer due to alcohol, after adjusting for the effect of tobacco. The earlier observed association between alcohol and oral cancer (OR=16) was only because of a confounding effect of tobacco. When we made adjustment for this confounding effect of tobacco, we found that alcohol, by itself, has no risk. Had we not done this adjustment for confounding, we would have drawn a wrong conclusion that alcohol causes oral cancer. The phenomenon of “differential distribution” also becomes more apparent from the above 2 strata tables. We would appreciate that a very large number of cancer patients who consume alcohol are tobacco users (60 out of 80 i.e. 75%) while very few patients who consume alcohol are non - users of tobacco (5 out of 20, i.e. 25%).

How do we overcome the problem of Confounding : There are various methods by which we can overcome this issue, either while we are planning our research or else during the stage of analysis. However, what remains extremely important is that all the PCFs must be identified and, if the adjustments are going to be in the stage of analysis, the data on them must be recorded. Now, since all the PCF must be identified before the actual study, one must work meticulously on this issue from the very time he / she is working on the issue of developing the research question itself. In fact, while reading and discussing as regards the research question, one must very specifically start identifying what are the exposure and outcome variables of interest and what all PCF can confound this relationship between exposure and outcome because of their independent and indirect relationship with both the exposure as well as the outcome variable.

Methods for Controlling for Confounding

Once the confounding variable(s) have been identified, action must be taken to prevent or adjust for them. Such actions can be taken either during the conduct of a study - at the stage of planning and, secondly, during the stage of analysis.

Control during Planning (Designing) Stage

This can be achieved by any one or more of the following methods :

(a) Randomisation : If a group of subjects is divided into two, using “random allocation” (syn. Randomization) (described in the section on Biostatistics and in the chapter on experimental designs), the 2 groups will be similar to each other in all respects. The beauty, therefore, is that the 2 groups will be “similar” to each other not only in respect of all “known PCF” (age, sex, blood groups and so on) but also in respect of those factors which may be “confounders” but we are not aware of them (e.g. HLA type and, may be, the average number of hair on the head!). Thus the 2 groups will be absolutely similar to each other with the only difference being that one group gets the trial modality while the other will get the control modality. Any difference in the outcome between the two groups can be safely assumed to be due to the intervention being studied. The singular drawback of randomisation is that it can be done only in an experimental design (e.g. drug trial, vaccine trial etc.); however, it is not applicable to most of the “cause

- effect” research that we do in clinical practice (you can not “randomise” people into 2 groups, telling one group to “smoke” and the other “not to smoke”).

(b) Restriction : We can so plan our study that the subjects having the particular confounding variable(s) are not taken up at all; e.g. in a study of the possible association between physical inactivity and IHD, young age (< 35 years) and female sex may be the PCF. In this case, we may restrict our study to “only males more than 35 years of age”. The difficulty with restriction is that one tends to exclude out a lot of potential subjects, thus increasing the cost and effort of study; Secondly, the effect of the variables on which restriction has been done can not be studied - e.g. in this example, the role of female sex and younger age can not be studied.

(c) Matching : We said earlier, that a confounding variable exerts its nuisance effect due to “unequal distribution” in the two groups. It stands to simple reasoning, therefore, that if the groups could be made “equal” in respect of the confounder, the nuisance effect can be nullified. This is the basic principle behind the very commonly used procedure in epidemiological research - “Matching”. Let us say we are doing the above - mentioned study on alcohol and oral CA. Once we identify tobacco use as a confounder, what we can do is that for every case of oral CA, we would take a healthy person as control who has the same tobacco use as that of the case, i.e. if the case is a tobacco user, we take the control who is also a tobacco user and vice versa. The final result will be that we will have equal number of tobacco user cases and controls as well as equal number of non - user cases and controls in our study and any relation between alcohol and oral CA will now be due to alcohol, without any confounding due to tobacco.

This method in which we match “one for one” (i.e. for every subject or case, we take a control who is similar to that case in respect of the confounding variable), is called as “Pair Matching”. The second method of matching is to do a “group matching” or “frequency matching”. Suppose we want to match on 3 variables (tobacco use, age and sex) . Let us say, out of 100 cases we have 25 of them as “40 - 50 years old female tobacco users”. We will then select out an equal number of controls who fit into this criteria, i.e. 25 healthy females who are 40 - 50 years old and tobacco users as controls.

In general, it is advisable for the researcher engaged in usual clinical/health research not to lay too much stress on matching. “Frequency matching” can be done for the ‘universal confounders’, i.e. age and sex and additionally for any particular confounder which can be easily matched. As regards other PCF, which have not been matched, data regarding them must be collected and later adjustment for their confounding effect should be made during analysis (45 - 47).

Adjustment During Analysis

If matching has not been done for a PCF (but the data has been collected), adjustment for its confounding effect can be done during analysis by following methods :

Stratified analysis : The logic of stratified analysis has been presented earlier when we described that we would make 2 strata, one with the confounder (tobacco users) and one without the confounder (non - users). If the risk in individual stratum is

the same as overall risk, then there is no confounding. On the other hand, if the odds ratios in the strata are very different from the overall OR (e.g. in our very first example of alcohol - oral CA study where the overall OR was 16 but the stratum OR after adjusting for tobacco was 1 each), we would conclude that there is confounding. In stratified analysis, we use certain specialized statistical procedures (Mantel - Haenszel adjustment technique) and calculate the adjusted estimates, which give us the estimate of risk due to the exposure variable, after adjusting for the effect of the confounding variable.

Confounding

Definition : A confounding variable is one which throws into confusion, an observed association between an exposure and an outcome variable, since :

- It is related with the exposure variable.
- Independent of its association with the exposure variable, is also associated with the outcome variable.
- It does not lie in the chain of sequence between the exposure and outcome variable.
- It is “differentially” distributed in the two groups.

How do we control for confounding : The most important step is to be aware of the phenomena of confounding and to identify all Potential Confounding Variables (PCV) right at the time when the research question is being developed. Once all PCV have been identified, action may be taken to control them either in planning stage or during analysis, by following methods :

- During planning : By
 - Randomization (random allocation)
 - Restriction
 - Matching
- During analysis : by either “Stratified Analysis” or by “Regression Analysis”.

Multiple regression analysis in the control of confounding:

While stratified analysis is very effective in control of confounding during analysis, however, if there are a large number of confounding factors, then a large number of strata will have to be made and the individual figures in the individual strata will become very small, often zero. This is the limitation of stratified analysis. In such cases one has to resort to regression analysis (48). Further explanation about the 3 common types of regression analysis is presented in the section on Biostatistics.

Bias (Syn : Systematic Error Measurement Error Misclassification, Lack of Internal Validity)

Let us take an example of a simple clinical trial in which we gave a new drug, 'A' to a group of patients with headache while the standard existing drug 'B' was given to another group. After analysing the data we finally concluded that drug 'A' was better in relieving headache than drug 'B'.

Such conclusion might have been correct, but may also have occurred because we might have selected subjects who were

mentally robust in gp 'A', or weaklings in gp 'B'; or else, the severity of headache in gp 'A' as such was lesser than gp 'B'; or perhaps the subjects, knowing that we (their treating physicians) were studying the good effects of drug 'A' were too willing to please us, without our knowledge; or maybe, the nursing officer, knowing our hypothesis, ensured a high level of drug intake (compliance) in gp 'A'; it may also be possible that gp 'A' was assessed in detail by a highly experienced professor while the task of assessing gp 'B' was left to inexperienced interns; or perhaps our questions regarding relief from headache were ambiguous - we were actually asking them “how are you feeling?” Finally, it may have occurred that a much larger number of subjects in gp 'B' who actually finally got relief, also got them discharged before our assessment and so were not available for the final evaluation (selective loss to follow up). Thus, at a number of points, we systematically departed from the correct state, making measures which were different than what we really intended to.

Loss of validity (accuracy) will occur if there is any process, which while making the measurements, will tend to produce results that depart systematically from the true value. This state is also called 'measurement error'. The first place this can occur is when the basic process of measurement is wrong, as discussed in detail in the earlier part of this chapter.

Secondly, whenever we are testing hypothesis regarding associations or differences, we would apparently be comparing two “groups”. Remember that validity will be compromised and bias (systematic error) will occur if at any point, while either selecting the subjects or else while making measurements on them, we tend to systematically depart (consciously or as happens most of the times, unconsciously), thereby treating the two groups being compared in a different manner (49). Thus, bias can occur at two points. Firstly, it may occur if the two (or more) groups of patients or subjects that we intend to compare, are selected in a differential manner. This is called “Sampling” or “Selection” bias. Secondly, it can occur if while recording the information (i.e. making measurements), we tend to treat these two groups differentially. This is known as the “Information” or “Measurement” bias.

“Systematic error” or “Bias” leads to Loss of Internal Validity. This will occur when we are actually measuring something other than what we actually wanted to measure, as follows:

- Basic measurement technique is wrong
- Variations between observers or subjects
- Systematically differentiating between the two groups being compared at the point of
 - Selection (Selection Bias)
 - Making measurements (Measurement or Information Bias)

Selection Bias

Selection bias is a systematic error resulting from the way the subjects are either selected in a study or else are selectively lost to follow up. In a case control study, the major source of selection bias is the manner cases or controls or both are selected and the extent to which the presence (or absence) of

exposure may influence such selection. On the other hand, in cohort and experimental studies, the major source of selection bias is non-response / withdrawal from the study / losses to follow-up. In a cross-sectional study (as also in a case control study), the primary source of selection bias is “selective survival”, because only those who are alive can be included in such studies. The following are the ways in which selection bias can occur :

(a) Self selection bias / Volunteers induced bias : In general, as far as possible, avoid volunteers in any research study since they may be systematically very different from the usual population (50, 51).

(b) Berkson's bias (hospital selective admission) (52 - 54) : This can be a problem in case-control studies. It occurs because patients with two concurrent diseases or health problems are more likely to be admitted to a hospital than those with a single condition. For example, people who have both peptic ulcers and also smoke are more likely to be admitted to the hospital than people who have either of them. A case control study trying to evaluate the relationship between smoking and peptic ulcers may therefore find a much stronger association between the two than would really exist in the general community.

(c) Incidence - prevalence bias (Syn - Survivorship bias, Neyman's bias) : This is a major issue in case-control and cross-sectional studies (55, 56). For example, a case control study to evaluate the protective effect of physical exercise on MI was undertaken by taking cases of MI and healthy controls and asking them about the history of regular physical exercise. Surprisingly, a large no. of both the cases and controls give a history of regular physical exercise; the study concluded that regular physical exercise does not protect against MI. The conclusion was, in reality, a biased one. We know that 25% to 33% of the cases of acute MI die within the first 3 hours. Only those who live get admitted to the hospital and are available as cases. Now, regular physical exercise may be an important factor in helping the person to overcome the acute myocardial episode. Thus, out of the cases of MI, those who did not undertake regular exercise died, while the ones who did exercise were the ones who lived to give such a history.

(d) Healthy worker effect : A comparison between health status of military and civilian population may show a better health status of the soldiers; one of the important reasons may be because of the initial medical examination during which the ‘unfit’ persons are excluded and only ‘healthy workers’ are included in the army. The basic dictum of selection and comparisons in research should be to “compare likes with likes” (57).

(e) Exposure related bias : This is a special type of Berkson's bias. If the hospital admission probability is different among those who have and those who do not have the suspected cause, such a selection bias can occur. This is specially liable to occur in case control studies. As an example, such an exposure related selection bias was viewed with concern in a case-control study that found an association between use of dietary supplementation with L-tryptophan and “Eosinophilia - Myalgia Syndrome” (EMS). The main criticism was that the initial press publicity about a suspected association may have

resulted in a preferential diagnosis among known users of L-tryptophan as compared to non-users. Thus the estimate of risk (OR) obtained from such studies may have overestimated the true effect of risk.

(f) Bias due to loss to follow-up : This is a special problem in cohort and experimental studies. If subjects drop out / are withdrawn / die before assessment of outcome / Do not respond later on / cross over to the other treatment modality in between the follow up phase, then it is also possible that those who were lost to follow up could have been systematically different from those who continued.

(g) Bias due to selection of inappropriate control group : This is another major issue in case control studies. The basic dictum that should be followed in a case-control study is that the controls should be derived from the same source population from which cases have come and that the controls should also be equally at risk (i.e. have equal opportunity of being “exposed” to the suspected risk factor) as the cases. Take the example of a case-control study which desired to assess the risk associated with non-use of condoms (exposure) with the development of STD (outcome). In a hurry, the investigator selected cases from a STD clinic and also controls from the same STD clinic who were found to be free of STD after evaluation, at this clinic. However, many of these controls may not have developed STD probably because they had sex partner who did not himself / herself had STD, and hence these subjects had no chance of exposure (to STD) whether they used condom or not. Hence the right choice of control group in this research would have been to take people who were known sex partners of persons known to be having STD but were themselves found clear of STD, while cases should have been those who had known STD persons as sex partners and were detected to be having STD.

Information (Measurement) Bias

Information bias is a systematic error that arises because of incorrect information while making measurements on one or more variables in the study. As said earlier, it may occur, firstly, when the basic measurement process is incorrect (Wrong instrument, wrong technique, wrong definitions, and so on). Secondly, it would occur even when the basic process of making the measurement is correct but the measurements are made in a systematically “differential fashion” between the two (or more) groups being compared. This will result in “misclassification” of either the disease (outcome) or “exposure” status, or even both of them. Information bias is likely to occur in the following ways :

(a) Recall bias : This is a major problem in case-control as also in cross-sectional studies. The fact that a person has become diseased, he or she is more likely to recall the possible exposure; e.g. in a study of X-ray exposure during pregnancy and subsequent leukaemia in children, mothers of leukaemic children are likely to recall more and thus give more history of X-ray exposures (58).

(b) Detection bias : This is more of a problem in prospective studies. Those who are exposed to the factor of interest may also be more liable to be subjected to diagnosis and hence detection of the disease of interest; e.g. in a follow up study on the question whether smoking is the cause of emphysema,

we would take a group of smokers and another group of non-smokers (both groups free of emphysema at the start of follow-up) and would follow them for a defined period of time to see for development of emphysema. Now, smokers are more likely to report sick because of various other problems (cough, IHD, dyspnoea etc.), and hence more likely to be diagnosed as emphysema, once they report to a medical facility.

(c) Observer's (Interviewer's) bias : If the interviewer is aware as to which group is having the particular exposure (in a follow up study) or the disease (in a case control study) then he/she would be more inclined (subconsciously) to interrogate/examine that particular group more exhaustively, to prove the research question.

Types of Bias	
Selection Bias	Measurement Bias
Self selection (volunteers) Bias	Recall Bias
Berksons' Bias	Detection Bias
Survivorship (Neyman's) Bias	Observer's Bias
Healthy worker effect	
Exposure - related Bias	
Loss to follow - up Bias	
Inappropriate control gp.	

Prevention of Bias : Checklist

The following check list will help in preventing bias in most of the "usual" settings of epidemiology and clinical research.

- As far as possible, ensure blinding - definitely in an experimental design; even in a case control study or cohort study, the observer can be "blinded".
- If possible, do not tell your research hypothesis to the subjects (helps preventing recall bias). In addition, if possible, try and take information about exposure from other sources, in addition to the subjects.
- In a follow-up study (cohort study or clinical trial), take a well defined population to avoid loss to follow up; develop methods to retrieve those subjects who are getting lost to follow up.
- Select two or more than 2 "groups" of controls in a case control study (e.g. one from hospital and another healthy group); try and take different categories of diagnoses if selecting hospital controls.
- In cohort or experimental studies (follow-up studies) specify clearly the future dates of examination and examine all subjects of both groups at the pre-decided dates using "similar" methods of history taking, physical examination and investigations, and make arrangements that losses to follow up are minimized.
- In a case control study, use the correct time frame for recording exposure (e.g. for a study between pneumonia and cold exposure, the time frame should be 6 days and not 6 months).
- See, in a case control study, specifically for
 - That the controls come from the same "source" population from where cases have come; and that cases

and controls have the same "selection factors" for getting admitted to that particular hospital.

- Is there any possibility of "survivorship" bias ?
- Is the disease such that the initial symptoms may have led to a change in exposure? (e.g. initial dyspeptic symptoms of gastric CA may cause the patient to give up tobacco).
- Did the controls have a reasonable chance of being exposed to the factor of interest? (hysterectomised women in any case do not have a 'chance' of exposure to OC, so do not keep them in controls in an Oral Contraceptives - Thromboembolism study).
- In any type of study, see the "entire spectrum" of the outcome or disease - e.g. in IHD, also see in addition to MI, angina, sudden death and asymptomatic ECG changes.
- In an experimental design (clinical trial), ensure Random allocation, Blinding and Placebo control.

Summary

The indispensable issue in any epidemiological or medical research study is that we should measure what we really intend to measure; in other words, any error of measurement has to be avoided.

Broadly, errors of measurement can occur at one or more of three situations - the basic measurement process is wrong (error or basic measurement); or else, systematic error or bias in which we have systematically differentiated between the two groups being compared, either while selecting them (selection bias) or else while making measurements on them (measurement bias); and, thirdly, the observed association between the exposure and the outcome variable is explained away by a third, indirectly related variable (confounding error).

Any measurement process that we select should have validity (should measure what we actually intend to measure) and reliability (repeated applications of the measurement process should give consistent results). The key to preventing basic error of measurement is to ensure "standardization" by selecting the correct instruments and techniques, having proper pilot testing, frequent quality control procedures and adequately training all data collectors in the measurement process.

The second type of error occurs due to confounding. This happens when the observed association between an exposure and an outcome variable is explained away by a third variable, called as the confounder variable. A confounder variable is one which is related to the exposure variable, is also related to the outcome variable (independent of its relation with the exposure variable), does not lie in the direct link of chain between the exposure and the outcome variable, and is "differentially" distributed in the two groups. What is extremely important is that all the potential confounder variables should be identified by thorough academic reading and discussion with experts. Once identified, confounder variables can be controlled during planning stage of a study (by either of restriction, randomization or matching, which could be individualized pair matching or group / frequency matching). Confounders can also be controlled during analysis of data by either stratified analysis using Mantel - Haenszel technique or by linear regression analysis.

The third type of error is systematic error or Bias. In most of the situations in epidemiology and medical research, we would be comparing two or more groups. This could be comparisons between a group having the exposure and the other not having the exposure, as regards the frequency of out come in the two groups; or else, it could be comparison of a group of subjects having the outcome with another group not having the outcome, as regards the frequency of exposure in these two groups of subjects. Whenever we tend to systematically differentiate between these two groups, while selecting the subjects in these two groups or else while making measurements in these two groups, bias will occur, which will be either selection (or sampling bias) or else measurement (or information) bias respectively. The various types of selection biases are : Self selection bias, Berkson's bias, Incidence - prevalence bias (Syn: Survivorship bias, Neyman's bias) , Healthy worker effect Bias, Exposure - related bias, Bias due to loss to follow - up and Bias due to selection of inappropriate control group. The various types of information bias are : Recall bias, Detection bias and Observer's (Interviewer's) bias. The important aspect of bias is that all possible sources of bias should be visualized during the planning stage of the epidemiological study and steps taken to prevent them, since unlike confounding, it is very difficult to control or adjust for it during analysis stage, once the study has been completed.

Study Exercises

MCQs & Exercises

1. An investigator developed the research question as to what percentage of IHD patients take aspirin prophylaxis. She defined her reference (target) population as "all patients in the country having IHD", and the phenomena of interest to be studied was the percentage of IHD patients taking aspirin for prophylaxis. She defined the actual study population as all patients of IHD seen at her clinic during last calendar year and obtained the information about aspirin use by mailed questionnaire. Out of the 287 patients of IHD seen at her clinic last year, 270 were sent the questionnaire (addresses of remaining 17 were not recorded in her clinic records, being emergency cases which were referred to ICU after first aid). After repeated requests, 118 questionnaires were received back. Out of these 118, total of 19 (16.1%) reported use of aspirin. Examine, where all errors can occur in this study.
2. Kappa coefficient is a procedure which can be used to (a) assess the validity of answers given by a group of patients (b) assess the agreement, beyond chance, as regards responses to two different sources (c) assess the correlation between blood pressure readings taken on the same patient by two different nurses (d) all of the above.
3. The ability of a measurement process to diagnose correctly as positive those who really have the disease is called as (a) sensitivity (b) specificity (c) precision (d) reliability.
4. Which of the following is not an essential characteristic of a confounding variable : (a) It should lie in the direct chain of causation between exposure and the outcome variable (b) It should be related to the exposure variable (c) It should be related to the outcome variable, independent of it's relationship with the exposure variable (d) it should

be differentially distributed.

5. Which of the following is not a method of control of confounding : (a) Restriction (b) Matching (c) Stratified analysis (d) Ensuring use of accurate instruments.
6. Another name for randomization is : (a) random sampling (b) random allocation (c) random error (d) random variable.
7. During a rifle firing practice, a soldier fired the shots Which are depicted in Fig. - 1. The point of the Arrow indicates the centre of target on which the soldier was actually aiming, while the four crosses "x" indicate the points on the target that he actually fired. In this example, there was (a) neither accuracy nor precision (b) both accuracy and precision (c) precision but poor accuracy (d) accuracy but poor precision.
8. To identify patients having jaundice, a medical officer examines the bulbar conjunctiva for yellowness, a procedure for which she has been well trained during graduation. This method of detecting jaundice : (a) lacks validity (b) lacks reliability (c) lacks both validity as well as reliability (d) has both, adequate validity as well as reliability.
9. In the above example given in Q.8, the method of assessing jaundice will be (a) Quite sensitive (b) quite specific (c) neither sensitive nor specific (d) both sensitive as well as specific.
10. Which of the following is not a method of control of confounding during planning stage : (a) stratified analysis (b) restriction (c) pair matching (d) frequency matching.
11. An epidemiologist wanted to study whether blood group 'O' is protective against peptic ulcer disease as compared to the other three blood group types. Here, the outcome variable is : (a) blood groups (b) peptic ulcer disease (c) both the above (d) none of them.

Answers : (1) (a) The patients at her clinic may not be a representative subset of all patients of IHD in the country (which was the defined reference population). This is problem of external validity (generalisability). (b) The 270 patients who were sent the mailed questionnaires and finally out of them the 118 who actually returned the questionnaire may be systematically very different from those who received the questionnaire, as regards their aspirin use - this is a problem of internal validity of the type of selection bias. (c) Responses on mailed questionnaire by the 118 subjects who returned the questionnaire may have been inaccurate, depending on how well the questionnaire was designed and how well the subjects understood the questions - this is again the problem of internal validity, of the type of information (measurement) bias. (d) The estimate of 16.1% is subject to random error or chance - the reality in the real population may be different and also repeated samples from the same clinic's patients may show different estimates. This needs to be minimized by studying an adequately large sample size and calculating the 95% Confidence Interval around the estimated percentage, by statistical procedures. (2) b; (3) a; (4) a; (5) d; (6) b; (7) c (8) a; (9) b (10) a; (11) b.

RajVir Bhalwar

Developing Questionnaires

In a large number of health - related measurements (pain, fear, satisfaction, attitudes, practices, beliefs, etc.), there is no clear cut physical standard. The usual approach in such settings is to construct a questionnaire, consisting of a group of questions designed to measure these specific phenomena.

Selecting the Items to be Included in Questionnaire

The first thing to do is to undertake an extensive reading in the subject to find out whether any questionnaire is already existing which can cater to one's requirement in "toto", or after slight modifications. If so, it is advisable to use such an existing questionnaire since it has already been validated by the earlier workers. However, one must remember that if the general nature of population of the earlier work was different from one's own study, or else if major changes have to be made in the existing questionnaire, then the same must be pre - tested and validated on the population in which the study would be conducted. If no questionnaire is already existing then one would need to develop a questionnaire of his own. In such cases, the following steps should be undertaken.

General Steps in Developing a Questionnaire

- i) Make a detailed list of the following variables of your study, based on your extensive reading undertaken while developing the research question :
 - Exposure variable (s).
 - Outcome variable (s).
 - Potentially Confounding Factors (PCFs).
- ii) Recapitulate your own theoretical and practical knowledge, thinking extensively on what all can be included.
- iii) Consult at least 3 different experts in the field of proposed research for their opinion regarding various items to be included.
- iv) To start with, collect as many items / questions as possible (though many may appear instantly irrelevant). Subsequently, keep "pruning" away the irrelevant items so that the final questionnaire, after pre - testing would have only a few, relevant items.
- v) For each of the exposure, outcome and confounding variables, make out questions which must cover the following 5 aspects :
 - When did that particular variable start.
 - When did it end (if applicable).
 - The dose during each episode of exposure.
 - The frequency of exposure.
 - The duration during each period of exposure.

(For example, if asking about the details of tobacco smoking, draft out questions which refer to the exact age when the person first took on to smoking, when did he stop, when did he again start, what is the present status, how many cigarettes or other forms as pipe / beedis on an average in a day are / were

consumed during each spell of smoking, how frequently, i.e. whether daily, alternate day and so on).

- vi) Now write a draft questionnaire, which apparently will be quite long. Revise it yourself and show it to 3 different experts to remove a large number of items which are not relevant for your research; thus, a more consolidated questionnaire will be available.
- vii) Pre-test this consolidated questionnaire on your population of interest using a small "convenience" sample (friends, colleagues, etc.). Further revision would now occur. Now pretest this further revised version on a random sample of 25 - 50 subjects from the study population and make the final revision.
- viii) Do the pre - coding of the final revised version. Get it printed in a neat, legible and presentable format.

"Structured" or an "Unstructured" Questionnaire

In the former, the interviewer asks the same questions in the same way and in the same order from all subjects; in other words there is a pre - designed schedule on which questions are already written down in sequence. On the other hand, in "unstructured" questionnaire, there is lot of flexibility and the questions asked from the study subjects may vary at the discretion of the interviewer (e.g. interviews taken by a journalist; psychiatric history taking). By and large, it is always desirable to have a structured questionnaire since it ensures standardisation and reduces variations.

"Closed Ended" or "Open Ended" Questions

(a) Closed ended questions : All the possible answers are listed in front of the question and the respondent has to simply indicate the answer he feels correct, by a tick or encircling the number besides that answer, e.g.

"AIDS" is caused by :

1. A small germ. 2. Chemical pollution of water. 3. Bad air.
4. Dirty under - garments.

Closed ended questions are always desirable, since they have the obvious advantage of standardized answers. While constructing closed ended questions, the investigator should mention all possible answers - this will be possible by extensive reading of the subject and a proper pre-testing of the questionnaire. It will also be advisable to have a final category of answer as "any other? (specify) _____" for few of those respondents, who do not find a suitable answer from the list provided. The answers should be simple so that the respondents understand them. In fact, a good method of making closed ended questions is to start with open ended questions, do a pre-testing, and based on the various answers obtained on pre-testing, finally convert them into closed ended questions.

Two more aspects which should be kept in mind while developing closed ended questions are :

- If there are more than one possible correct answers, indicate the same in the question, by asking the subject to tick more than one answer if he/she feels so.
- If there is a possibility that some subjects may not be sure of any alternative answer, put, in addition to "any other (specify)", another category as "Don't know / Not sure".

(b) Open ended questions : In open ended questions, a blank space is provided after the question and the respondent's reply is recorded verbatim, without any structured choices as happens in closed ended questions, e.g. "What is the cause of AIDS?" _____ .

The problems with open ended questions are that they lack standardization, the responses would be very variable and thus the subsequent analysis of data and interpretation of results would be very difficult. As a general recommendation, in a usual medical research work, one should keep closed ended questions (with a last open ended category of "any other (specify)", if required). However, open ended questions may be preferable in some of those settings in which simple facts are being elicited and in which there would be a large number of different responses; e.g. "which Textbook of Medicine do you follow?" Even in such situations, one can intelligently, after a proper forethought and pre-testing, convert it to a closed ended question as : "Which Textbook of Medicine do you "usually" follow : Harrison / Davidson / Oxford / API / Any Other (specify) _____".

Recording the Responses

If the outcome is to be recorded on a "continuous" scale, try to record the answer on a Visual Analog Scale (VAS), to get the maximum possible information. E.g. for a question on pain, we can draw a line of 100 mm, with '0' indicating 'no pain' and 100 indicating 'pain of the most extreme type' and ask the patient to put his finger at the point he feels optimally describes his severity of pain.

If the response is to be recorded on a "nominal" scale (i.e. as "categories"), the optimum is to keep 5 to 6 categories. Also try and change the order of response in successive questions; e.g. if Q.1 is recording the response from "high" to "low" try to record the response on Q.2 as "low" to "high". "Likert's" type of scales, in which the responses are framed on an "Agree - Disagree" continuum can often be used in such situations. E.g. for a question "Is the OPD giving satisfactory service?", the responses could be

Strongly agree	Agree	No opinion	Disagree	Strongly disagree
----------------	-------	------------	----------	-------------------

Precautions to be Observed while Making the Questions

Avoid ambiguity : Avoid statements or questions which are likely to be interpreted differently. E.g. instead of the question "Have you been recently away from home?", it will be more apt to ask " Have you been away from home since 01.01.2007?".

Avoid "double - barrelled" questions : e.g. "Do you have precordial pain and dyspnoea while walking?". Now, what if the subject has any one of them? In such cases make two

different questions.

Avoid technical jargon : The question "Are you hypertensive" may be interpreted by a layman as "too much mentally tense".

Avoid "value - laden" words or hypothetical questions : e.g. In the question "Would you like to move to a better hospital?" would evoke various judgement responses because of words "like" and "better" which are hypothetical. In such cases, increase the number of questions and be more specific, e.g. :

- Do you want to move out from this hospital? Yes/No.
- If Yes, to which hospital? _____
- Why do you want to move to that hospital? Better administration/ better doctors/ better investigations / less expensive/ any other (specify)

Avoid questions that are not self explanatory : e.g. the answers to question "What type of home do you have?" may bring out different answers like "happy", "concrete", "well ventilated", "small" and so on. In such cases, specify the question in details or give closed / semi closed answers in front of the question.

Do not ask about events which most people will not remember : e.g. "How many times per week did you drink milk when you were between 6 and 10 years old?" may be quite difficult to answer. In such cases, if you must ask about such a long past, try to verify/ supplement this information from other sources (records, parents, friends, siblings, spouse etc.).

Alternate questions : Alternate questions which are likely to bring out 'yes' answers with those likely to bring out 'no' answers.

Dummy, Check questions : Keep some "Dummy, check questions" in the questionnaire. These questions may not be related to the study but may enable us to cross check the validity of information. E.g. in a study on sexual practices, details of alcohol and tobacco use may not be directly relevant to study objectives; however, answers to such questions may be cross checked with records, friends, family members, etc. and would give an overall idea of the validity of information being provided by the subject.

Interviews in Epidemiological Research

Types of Interview

There are three types of interviewing formats :

(a) Structured interview : Where everything is set out in advance. In addition to a closed - ended questionnaire, even the places where probing is to be done, the words in which the probing is to be done, the introductory statements - everything is written down and followed in "letter and spirit" by the interviewer, without any deviation.

(b) Semi-structured : This interview is done using a closed - ended questionnaire with general, broad directives written down; however at certain, unforeseen situations, the interviewer is allowed to make use of his experience and tact in, say, making probes, giving introduction or providing explanations. Semi structured interview is the most commonly used. It has the advantage of structured interview in reducing errors, and at the same time, it carries the advantage of unstructured interview in establishing rapport between subjects and interviewers which

is also quite important for ensuring accuracy.

(c) Unstructured : This consists of only an open ended questionnaire with everything else left to the discretion of the interviewer, e.g. a journalist's interview.

Actions before Starting an Interview

There are certain steps which should be taken before an interview, as they go a long way in ensuring the success of the interview :

- (a) As an interviewer, develop a personality which shows that you have a sincerity of purpose, straight - forwardness, politeness, proper attire and a clear, non - shaky voice.
- (b) Practice the confidence to deal with awkward replies like "what is the catch in this question", "why don't you take somebody else for your research", etc.
- (c) Take necessary administrative sanctions for conducting interviews from relevant authorities like Principal of School, Government Officers, Superintendent of the hospital etc.
- (d) Secure a proper appointment from the subject. Try and take a time when the respondent is likely to have the least commitments; e.g. school games time for children, weekend holidays for office going personnel, midday for house wives etc.
- (e) Try and find a place for the interview that is comfortable, has optimum privacy and there are no barriers to communication.
- (f) Do not forget to carry your identity card / introductory letter issued to you from your department.

Starting the Interview

Once the interviewer and interviewee have moved to the selected site of the interview, a few minutes must be spent in developing rapport. Introduce yourself briefly and thank the subject for accepting to be interviewed. This should be followed by a brief and general description of the purpose of the research, and an assurance that the identity of the subject will be kept confidential. It is worthwhile telling the subject that the interest of research is not at all in the personal identity of the subject but rather in collecting some information which would be analysed 'in toto' and not according to "individuals". In fact, if possible, the interviewer can go one step forward by specifically saying that we do not want to note the name (or any other personal identifier, as official "number" of industrial workers); this would further enhance the faith of the subject in "assured confidentiality" and he/she would give more accurate replies, especially for sensitive issues. A few minutes spent on these various aspects before actually starting the interview would go a long way in ensuring its success.

Asking Questions

When asking the questions, give consideration to the following points :

- (a) Read the questions exactly as they are worded in the questionnaire.
- (b) Read each question aloud and at a slow speed; in fact, slower than we normally read.
- (c) If a question is not been understood by the subject, read entire question again (and not a part thereof)
- (d) Read the questions with correct intonation and emphasis.

(e) If the subject needs to be 'probed', use the following methods of probing :

- i) Repeat the question after an appropriate introduction like "I am not sure that I got your answer right. So, let me repeat the question - - - - -" .
- ii) Give an 'expectant pause' to indicate to the subject that you are waiting for more information.
- iii) Put some 'neutral' questions in the following ways;
 - What do you mean by - - - - - ?
 - In what way?
 - Could you explain that a little?
 - Can you tell me what you have in mind?
 - Anything else?
- iv) Try and give assurance, e.g. by saying, to a subject who seems to be stuck up, "there are no right or wrong answers in these questions. Just give whatever answer you think is the right one".
- v) Give feedbacks like "Yes, yes"; "that's exactly how we wanted the information". Also, if needed, give negative feedbacks as "I think you have answered that a bit too quickly", to an incomplete answer.

Recording the Responses

Take care to follow the under mentioned guidelines while recording the answers given by the respondents :

- (a) Do not "infer" a response from an incomplete reply. Probe on to get a complete response.
- (b) Let the respondent answer; you do not answer for the respondent.
- (c) Record all the responses during the interview itself; do not leave things to memory.
- (d) Preferably, repeat aloud the subject's response as you are writing - this may prompt him to give more information.
- (e) Record the answers verbatim as said by the respondents (and not what the interviewer has apparently "inferred").
- (f) Write clearly "refused to answer", besides any question that the respondent refuses to answer.
- (g) Immediately after the interview is over, but before leaving the place, check the questionnaire for the following :
 - All questions have been answered.
 - If missing data is discovered, the question should be immediately asked from the respondent.
 - Important 'probes' (if used) are noted in a pencil, below the questions.
 - All unclear responses are clarified by a parenthetic note.
 - Abbreviations have been explained.

Supervision of Interviewers

During the first 2 days, the interviewer should be accompanied by the principal worker(s) who act as observer only, without interfering in the process of interview. In addition, during the first month of the study, all filled up questionnaires should be personally 'edited' by the principal worker(s). Subsequently, throughout the study period, the main worker should :

- Re - interview about 10% of the subjects independently, as

a quality control procedure.

- Constantly analyse data in respect of few selected variables for seeing variations between interviewers; e.g. one interviewer may be reporting too many subjects as undertaking physical exercise, compared to others.
- Provide immediate feedback and corrective advise.

Training of Interviewers

The principal worker should undertake the responsibility of training, pre - testing and supervision of interviewers. The training should be done centrally. The following topics should be covered.

- General introduction to surveys and sampling methods.
- Questionnaires and their types; details of questionnaire being used in the “present study”.
- Operating procedures manual of the present study.
- The role of interviewer, seeking the interview, initial contact, rapport building, confidentiality, ethical issues, dealing with difficult respondents.
- Asking individual questions and recording replies in the present questionnaire; how to deal with complex questions; how to ‘probe’.
- Transferring information from questionnaires to manual or computer “data sheets”.

The methods for training should consist of permutation and combination of Lectures, Discussions, reading the operations manual, “query solving” sessions, Demonstration of interviews in progress, Mock interview exercises, Real interview exercises, and Final assessment and certification.

Summary

Most studies depend on questionnaires for data collection. Questionnaires may be structured or unstructured, closed - ended or open - ended. Structured questionnaires are designed in such a way that the identical questions in fixed sequence are put to each study subject. Unstructured questionnaires do not follow any fixed sequence of questions, allowing for flexibility according to the discretion of the interviewer. In closed - ended questionnaires, the respondents have to choose from fixed options whereas in open - ended questionnaire, the participant can answer in his own words. Unstructured and open - ended questionnaires are difficult to standardize and analyze. Structured and closed - ended questionnaires are preferred in quantitative research. Questionnaires should be developed after thorough academic reading into the subject and discussions with the experts in that field. If any questionnaire which has been used for the particular type of study is already

available, the same should be used, as far as possible. If a new questionnaire is being developed, it should be developed scientifically, as per guidelines given in detail in this chapter. All questionnaires need to be pre - tested and validated in a pilot study and suitably modified if indicated.

Interviews may be structured, semi - structured or unstructured depending on the type of questionnaires used in the study. The investigator should ensure that prior permission and consent are obtained from all concerned before starting the interview. The interview should be carried out in quiet surroundings allowing for privacy and in an atmosphere of confidentiality. Training and supervision of interviewers are an important activity during the conduct of the study.

Study Exercises

(Study Exercises and chapter Summary contributed by A Banerjee)

Long Question : Discuss the process of development of a questionnaire in epidemiological research.

Short Notes : (1) Visual analogue scale (2) Actions to be taken when starting an interview (3) pretesting a questionnaire

MCQs & Exercises

- How much visible saturated fat such as ghee and butter do you consume daily? : “ _____ ”.
Discuss the inadequacies in the above question. How will you elicit the desired information?
- Which of the following is NOT a feature of structured questionnaires? (a) Fixed sequence of questions (b) Less flexibility in conduct of the interview (c) Easily standardized (d) Lead to wide inter - observer variation of the information elicited.
- Pre - testing and validation of the questionnaire is done : (a) During the pilot study (b) Can be done concurrently as the main study is in progress (c) Is done midway during the study (d) Can be done during the analysis stage.
- Likert Scale is a type of : (a) Categorical scale (b) Ordinal scale (c) Dichotomous scale (d) None of the above
- Visual Analog Scale is used for : (a) Testing of visual acuity (b) Measurement of abstract variables such as pain (c) Computer recognition of data (d) None of the above.

Answers : (1) The major flaws in the question are that it is double barreled, open ended, and uses technical jargon like, ‘saturated fat.’ To elicit the information on consumption of visible saturated fat, the investigator should first list all the common sources, and design closed-ended question for each source. (2) d; (3) a; (4) b; (5) b.

RajVir Bhalwar

The various aspects covered till now deal with the basic, fundamental principles, a knowledge of which is essential for any type of epidemiologic and medical research. However, once the correct epidemiological question has been asked and due consideration has been given to the various basic principles dealt with earlier, the worker has to select out the particular type of epidemiological “design”, most suitable for the question (59). As described earlier, any epidemiologist would be, very broadly, undertaking one of the following 2 types of exercises:

- (a) He/She may be simply ‘describing’ a phenomena of interest, expressing it in terms of a measure of health or disease (as mean, median or incidence or prevalence). In such instances, we do not have a ‘preformed hypothesis’ regarding cause and effect relationship (i.e. this particular ‘exposure’ leads to that possible ‘outcome’). It is only after a ‘descriptive study’ has been completed that the researcher, based on the results of the study, develops one or more hypothesis regarding causal association. Such studies are called “Descriptive Studies”.
- (b) The second general situation is that the investigator may be proceeding with a “preformed hypothesis” regarding a cause - effect relationship (i.e. this ‘particular exposure’ leads to that particular ‘outcome’). In other words, the investigator proceeds to investigate his hypothesis of cause - effect relationship between a possible exposure and postulated outcome. These studies are called ‘Analytical Studies’.

Descriptive Studies

As stated earlier, on a number of occasions the epidemiologist does not have any preformed hypothesis regarding a cause - effect relationship. His object is, rather, to describe certain clinical or health related phenomena and, at the end of study, to develop some sort of hypothesis regarding a possible cause - effect relationship, which can be further subjected to evaluation by analytical studies. A descriptive study gives a strong suggestion that a causal association may be present but doesn't prove it. For example, the incidence of acute glomerulonephritis among children developing sore throat may be found as 10%. This gives a strong indication that sore throat may be causally related to glomerulonephritis; however for proving such an association, one has to do an analytic study by comparing the incidence of acute glomerulonephritis in two groups - a group which had suffered from sore throat and another that did not. Thus, a descriptive study does generate hypotheses; however to prove them, analytical studies are required.

As is evident from the nomenclature, a descriptive study “describes” our findings of the epidemiologic study. Such descriptions are given according to three types of epidemiological variables, namely, distribution of the disease according to time (when does the disease occur), place (where all) and persons (who all are affected).

In contrast to descriptive studies, in analytical studies, the investigator proceeds with a ‘preformed hypothesis’ regarding a “causal exposure”. A large number of epidemiological and health research questions are answered by undertaking analytical studies. The various settings in which the epidemiologist proceeds to establish a relationship between exposure and an outcome may address issues related to treatment, preventive or diagnostic modalities, or regarding the role of a risk factor or prognostic marker (Box - 1).

Box - 1

Issues in which “Comparative” (Analytical) studies are required

Risk factor : e.g. “Is tobacco smoking a risk factor for IHD (as compared to when people do not smoke)?”

Prognostic marker : e.g. Is appearance of melena in viral hepatitis associated with increased mortality”? (as compared to when melena doesn't appear).

Treatment modality : e.g. can “Dopexitine be effective in treating premature ejaculation” (as compared to when only placebo is given) ?

Preventive modality : e.g. “ Can use of condom be effective in preventing STDs among promiscuous persons” (as compared to when condom is not used) ?

Diagnostic modality : “Can a combination of cold intolerance and unexplained weight gain diagnose hypothyroidism” (compared to the gold standard of T3, T4 and TSH) ?

The key word in analytical studies is “COMPARISON”. The basic prototype of such comparative research is the 2 X 2 table which we have already explained at length, earlier in the chapter on measures of effect and which gives us the notations E+, E-, O+ and O- (see Table - 1).

Table - 1

Exposure (E)	Outcome (O)		Total
	Present (O+)	Absent (O-)	
Present (E+)	E+O+ (a)	E+O- (b)	All E+ (a+b)
Absent (E-)	E-O+ (c)	E-O- (d)	All E- (c+d)
Total	All O+ (a+c)	All O- (b+d)	a+b+c+d

Now, “Comparison” of the two groups in any analytical study can be made by either of the two methods :

- (a) Either we take a group with the exposure (E+) and another without it (E-); follow them up for a reasonable period of time and observe how many in each group have developed the outcome (O+); e.g. we can collect two groups of subjects, all free of colonic CA, one group eating low fibre diet (E+) and another eating high fibre diet (E-); follow up both these groups for 15 - 20 years and see how many in each group develop colonic CA. The comparison would then be made between “those who develop the outcome out of total exposed” (i.e. a / (a+b)) and “those who develop the outcome out of the total not exposed”, (i.e. c / (c+d)). This can be demonstrated as

$$\text{Criteria for comparison} = \frac{a/(a+b)}{c/(c+d)} = I_e / I_o = RR$$

In case this resulting figure from this comparison is “much more than normally expected” (the “normally expected” being defined by statistical tests) we would conclude that the exposure is definitely associated with (or carries a high risk of) the outcome.

(b) The second way of doing the comparative analysis could be to collect a group of subjects who have already developed the outcome (O+) and another group of subjects who do not have the outcome, and then interrogate all the subjects regarding history of exposure (E+ or E -) e.g. we may take a group of patients already suffering from colonic CA (O+) and another not suffering (O -) and take the history of low dietary fibre intake during last 15 - 20 years from all of them. In this contingency, the comparison would be made between “those with the outcome having the exposure” (i.e. a / (a+c)) and those without the outcome but having the exposure (i.e. b / (b+d)). The comparison thus would be :

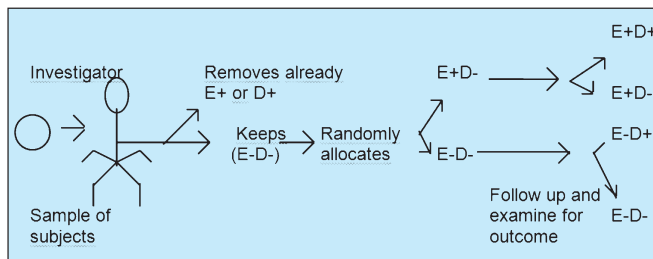

$$\{a / (a+c)\} / \{b / (b+d)\}$$

If the result is much more than ‘normally expected’, we would conclude that the association exists; i.e. the exposure carries a risk of the outcome.

The Individual Types of Analytical Designs

(I) The ideal setting - Experimental Design : The most scientifically reasonable setting would be, apparently, when the researcher collects a group of subjects in whom neither the exposure nor the outcome has occurred; i.e. all subjects are initially “E - O - ”. Now the researcher “randomly allocates” these subjects into two groups, so that both these groups are exactly similar to each other in all respects. Now, one of the groups is deliberately given the exposure (i.e. made to become E+O - from E - O -) and the other group is not given the exposure (i.e. continues to be E - O -). The investigator now follows up both these groups over a reasonable period of time to see how many in each group become O+ and makes the comparison as

$$\frac{(E+O+) / (a+b)}{(E-O+) / (c+d)}$$

This type of research design is called the ‘Experimental’ or “Intervention” design. This is scientifically the strongest design, because :

- Since it is the investigator who decides (on a random basis) and allocates the exposure, the possibility that “subjects might have taken up the exposure due to natural selection factors which may also be related to the outcome”, is ruled out.
- Since the outcome has been excluded from both the groups to start with, (the investigator takes only E - O - to start

the study) and then both the groups are followed up over a period of time for the development of outcome (O+ or O -), one is definite that exposure preceded the outcome; i.e. the absolute requirement of “temporality” for a “cause - effect” relationship is fulfilled.

- Since the exposure status (E+ or E -) has been recorded by the investigator himself at the start of the study, there is no possibility of recall ‘bias’ which could happen if the investigator was asking the history of “exposure” from the subjects who have already developed the outcome (O+ or O -).

This type of research, while scientifically the most sound, suffers from the problem that while studying “risk factors”, “markers” and “prognostic factors” it is impossible for the investigator to randomise the subjects into two groups - one getting the exposure and the other not. E.g. in a study of the association between cigarette smoking (exposure) and Lung CA (outcome), it is impossible for the investigator to “randomly allocate” the subjects into 2 groups, one group being told to smoke and other being told not to do so”. However, for any study directed to answer the questions about “treatment (therapy)” or “preventive procedure”, the experimental design must be used since the subjects can be randomised into 2 groups, provided it is ethically correct do so.

(II) The next situation - “Cohort Study” : In case it is not possible to “randomly allocate” the subjects into two groups, what we can do is that we can select out two groups at the start of the study, one having the exposure (E+) and other not having the exposure (E -). Now, those subjects, in both the groups, who already have the outcome (O+) at this point of starting the study are excluded, so that we have two groups, one having the exposure but no disease (E+O -) and the other neither having the exposure nor the disease (E - O -). The groups are followed up for the required period of time and comparisons made between (E+O+) / (a+b) and (E - O+) / (c+d) as for an experimental study.

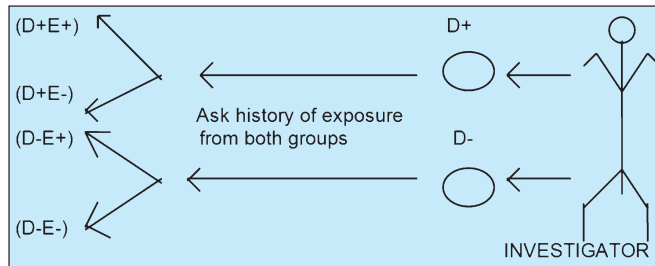

The advantages of this design, called ‘Cohort Design’ are the last two mentioned for experimental design, i.e. temporal association is ensured and recall bias is minimised. The main scientific drawback of this study is that it lacks the effect of “equal distribution due to random allocation” and hence the problem of “natural selection factors” related to both exposure and outcome may be forwarded. Hence, as far as effects of therapeutic regimes or preventive measures are to be seen, the experimental design is to be taken up, since random allocation can be undertaken. However, for study of “risk factors”, “markers” and “prognostic factors”, the cohort study remains the choice.

This design has disadvantages too. Firstly, if the period of follow up is very long, the medical fraternity has to wait for many years before the final conclusions can be drawn. Secondly, if the outcome is rare, the investigator needs to follow up a very large number of subjects to get a reasonably adequate number of subjects who develop the outcome. Thirdly, a large number of subjects may be lost to follow up/die/ drop out during the period of follow up leading to “loss to follow up bias”. Fourthly, such study needs quite a bit of logistical effort in terms of men, material and money.

(III) The third situation - Case control study : The problem of “cohort study” can be sorted out by using the method we mentioned in making the second type of comparison between the two groups. What we can do is that we can start by selecting a group of subjects who have already developed the outcome (O+) and another who have not developed the outcome (O-) and ask the history of exposure (E+ or E -) from all the subjects. The comparison is then made as :

$$\frac{(O+E+) / (O+)}{(O-E+) / (O-)}$$

The above situation is a very special type of study, the “case - control” design. Intuitively, this study design appears very appealing. However, it suffers from a large number of problems:

- The fact that the investigator has not recorded the exposure (E+ or E -) himself but is dependent on the history given by the subjects leads to possibility of “recall bias”.
- Since the investigator has not started from the exposure and followed up subjects till the outcome (as happens in an experimental or cohort study), one is not sure whether exposure really preceded the outcome i.e. “temporality” is not guaranteed.
- What the investigator starts with in such a design are the subjects who are present with a given outcome, i.e. living with the outcome of interest but not those who have already died of, or have been cured of, the outcome. The possibility of “survivorship bias” is, therefore, high.
- The problem of confounding also remains high as in cohort study.
- As explained in detail in the chapter on Measures of Association and Effect, we cannot calculate the incidence of the disease either in the exposed or else in the non - exposed groups and hence we cannot calculate the RR. What we can calculate is the Odds Ratio (OR), which is a reasonable estimator of RR.

The case control design has its own advantages, however. It is very good for a rare disease (in contrast to a cohort design)

because a large number of cases of a rare disease can be picked up from a hospital. It does not need any (prolonged) follow up effort. It is cheap and logistically simple. It becomes the method of choice when we are doing an initial evaluation of a hypothesis (fishing expedition) for “risk factors” and “markers”. It becomes particularly good method if the exposure is not likely to change over time and can be objectively ascertained (e.g. blood group, race, religion, sex, seropositivity for certain infections etc.).

(IV) The fourth setting - Cross - sectional analytic design:

In a case control design, the researcher starts by collecting a group of subjects who have the outcome (O+). This he does in a hospital. But if a disease is mild, or has a marked ‘gradient’ of mild, moderate and severe cases, a large number of cases will not be admitted in the hospital and hence will not appear in the case control study. In fact the mild (not admitted) cases may be systematically different from the serious hospitalised cases as regards the exposure itself.

In such settings, therefore, instead of doing a case control design, the researcher takes a “sample” of subjects from the ‘total population’. At this point he is not aware whether the subjects are having the disease or not. Now, the investigator examines each and every subject for the presence / absence of outcome (O+ or O -) and exposure (E+ or E -) at the same point of time and hence gets the four groups, E+O+, E+O-, E - O+ and E - O - at a given point of time. This is what we call the “Cross - Sectional Analytic Design”. In addition to those diseases that have a wide spectrum of symptoms, the design is also quite useful when the investigator wants to see for correlations between variables which need to be studied among healthy people and not necessarily hospitalized patients; e.g. if we want to see whether waist circumference correlates well with blood pressure, we will have to do such a study and not a case control one. The problems of proving temporal relationship, survivorship and recall bias are major drawbacks of cross sectional analytical studies as they are for a case - control study.

The essential difference between a case control study and cross-sectional study is the point of start - it is a known “case” in a case control study while it is a “subject” (who may be a case or control) in a cross - sectional study. Thus, in a case control study, the investigator starts by picking up people who have the disease (cases) and those who do not have the disease (controls) and thereafter makes an assessment of the presence or absence of the exposure, usually by taking the history or on the basis of some type of records. On the other hand in a cross - sectional study, the investigator starts with a subject (not knowing whether this subject is a case or a control) and assesses the presence of both exposure as well as the outcome in the subject at the same point of time.

The essential difference between the four types of analytical studies (experimental, cohort, case control and cross - sectional) is explained in the following paragraphs, using an example. Let us say, we are interested to determine whether physical activity is protective against IHD (or conversely, is lack of physical exercise a risk factor for IHD). We can take the following 4 approaches depending on how we wish to approach the issue; in any of these approaches we would be completing

the four cells of 'a', 'b', 'c', and 'd' (E+O+, E+O-, E-O+, E-O-), as follows :

Experimental Design : We may take a group of healthy persons who are free of IHD at present. We would randomly allocate these persons into two groups and tell one group to start exercising while the other group is told not to exercise. We now follow up these two groups for the next about ten years and see as to how many subjects develop IHD in each group, calculate the incidence of IHD in the two groups and make comparisons of the two incidences to get the RR.

Cohort design : We take a group of subjects, do an initial assessment and exclude all those who already have IHD. Now we find out from each subject as regards the physical activity details and thus get two groups - a group who are exercising and another who are not. We now follow up both the groups for another about 10 years and compare the incidence of IHD in the two groups, as above.

Case - Control Design : We take a group of patients who have already got IHD and another group of similar persons who do not have IHD. We now take the history of physical exercise carried out by both these groups during the past 10 years and calculate the Odds Ratio (OR).

Cross - Sectional Analytic Study : We take a sample of subjects from the general population. Put each subject to the diagnostic tests and find whether he / she has IHD and, at the same time, we ask for the details of physical exercise undertaken during past 10 years. We would get 4 groups of the 2X2 table (subjects not undertaking exercise and having IHD (E+O+), not undertaking exercise and not having IHD (E+O-), undertaking exercise and having IHD (E-O+), and undertaking exercise and not having IHD (E-O-)). With these 4 groups we will calculate the OR.

(V) The last setting - The Diagnostic test study : The analytical approach for the evaluation of a diagnostic test (which may be a Pathological / Radiological/ Microbiological procedure or even a "set of signs / symptoms") in diagnosing a given outcome (or disease) is slightly different. Firstly, in such a study the investigator must enunciate a "gold standard", against which his diagnostic tool which is to be evaluated, will be validated. Secondly, each and every subject must be subjected to both the procedures (the gold standard as well as the test under study), thereby getting 4 category of subjects. Let us say, we are evaluating the efficacy of pap smear in diagnosing CA Cx, the gold standard being biopsy. We will then have the following setting, as shown in Table - 2 and Box - 2.

Result of Pap Smear	Biopsy (Gold standard) results		Total
	CA Cx present	CA Cx absent	
Positive	a	b	a + b
Negative	c	d	c + d
Total	a+c	b+d	a+b+c+d

The investigator now does not work out the statistical tests

for associations (as Chi - square) and risk (as RR or OR), but something different - he works out the validity (or accuracy) of the test under consideration by calculating the sensitivity, specificity, positive and negative predictive values and likelihood ratios, the details of which we shall discuss in the chapter on screening for disease and chapter on diagnostic test evaluation studies.

Box - 2

a = Subjects who are having the disease (+ve by gold standard) and also identified +ve by the test under consideration (True Positive or TP); b = do not have the disease but called +ve by the test (False Positive or FP); c = have the disease but called -ve by the test (False Negative or FN); d = do not have the disease and -ve by the test (True Negative or TN) ; (a + b) =Total number found +ve by test (i.e. TP + FP); (c + d) =Total number found -ve by test (i.e. FN + TN); (a + c) =Total number actually having the disease, by gold standard (i.e. TP + FN); (b + d) =Total number not having the disease by gold standard (i.e. FP + TN)

How do we Decide as to which Epidemiological Design we should use?

It is of importance that the correct "Research Design" be selected by the researcher. The following guidelines, are shown in a flow chart in Fig. - 1, to assist you in selecting the design most appropriate to your epidemiological research question.

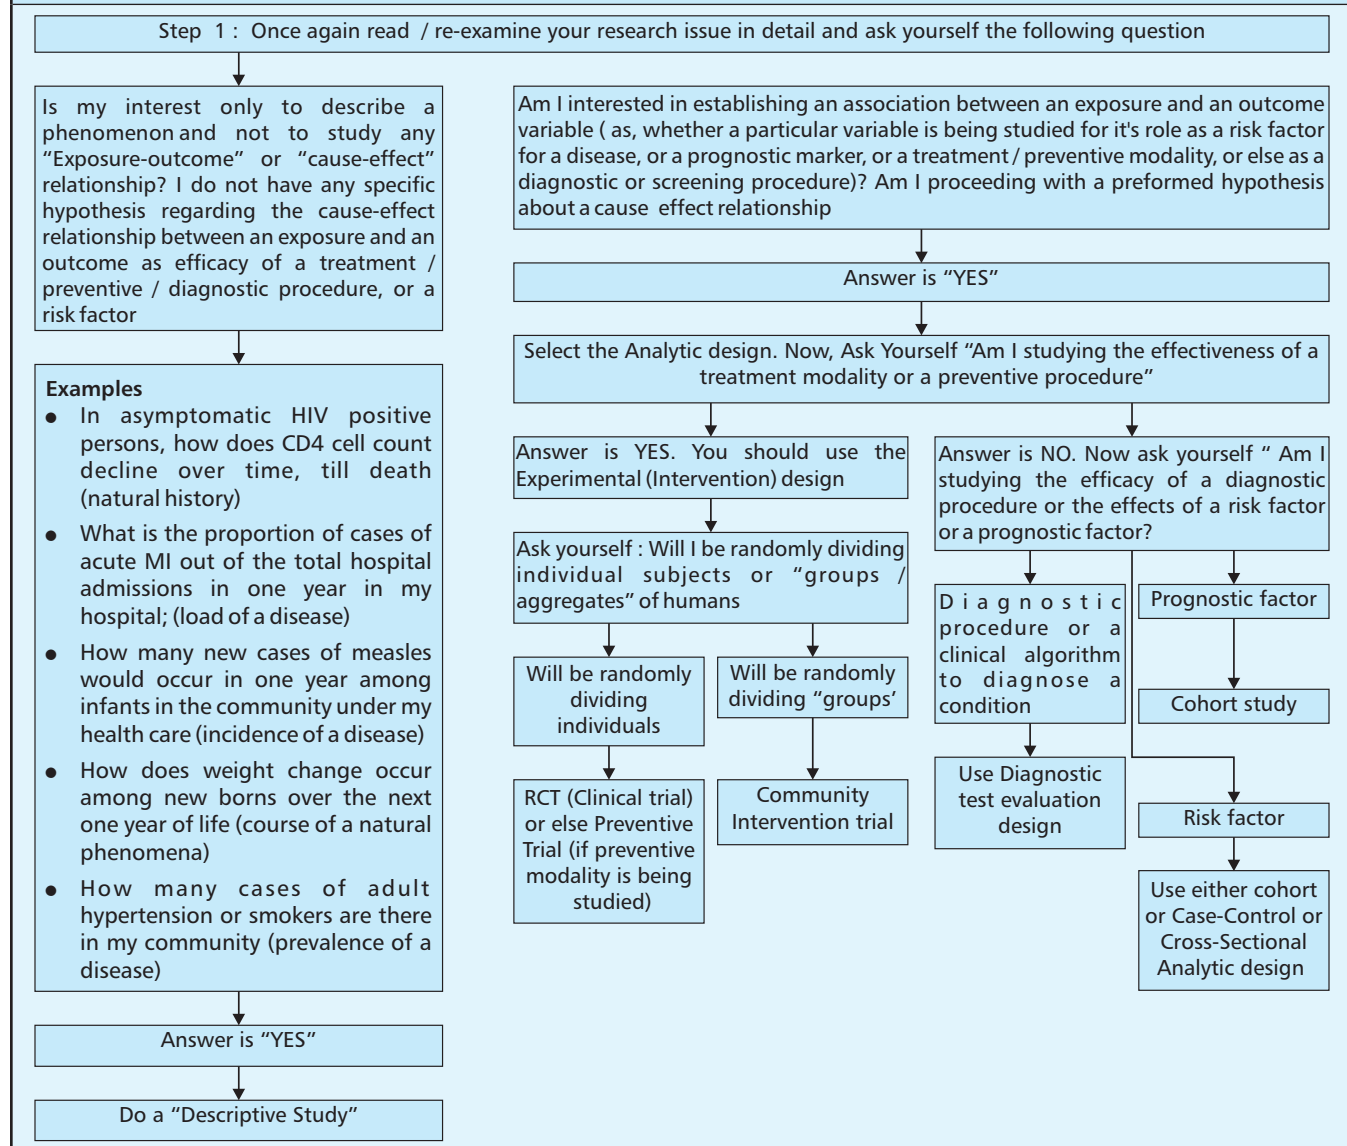

Deciding how Strong is the Evidence ?

Very often, in public health and epidemiologic / research situations, a decision has to be taken whether the evidence which has been put forward by a particular epidemiologic research is compelling or not, and whether it needs to be considered for developing the public health policy? In such situations, there are three aspects which need to be considered for assisting in taking a decision :

- What is the magnitude of association as indicated by relative risk? An RR of 1.01 till 1.50 (or 0.99 till 0.90) indicates a mild strength of association; between 1.51 till 3.0 (or 0.89 till 0.75) indicates a moderate strength; 3.01 till 4.99 (or 0.75 till 0.50) indicates a strong association, while an RR of > 5.0 (or < 0.5) indicates a very strong association.
- What is the strength of the study design used? As per the hierarchy of the strength of epidemiological designs, as shown in Box - 3, evidence coming from a Randomized Controlled Trial (RCT) is the strongest, while that coming from an ecological study or descriptive study is the weakest.

Based on the above evaluation, the evidence may be classified as "definite" (RR or OR is > 3 or < 0.5, evidence has come from a experimental design or meta - analysis and similar results shown by most of the studies in different settings); probable (RR or OR 2.0 to 2.99 or 0.5 to 0.75, evidence from cohort or many cross - sectional studies, more than half of the studies show such results); possible (evidence from case - control studies, RR 1.2 to 2.0 or 0.76 to 0.90, few studies show such results); or suspect (evidence from correlational or descriptive

Fig. - 1 : Deciding which Epidemiological design to use

studies, RR or OR between 1.0 to 1.2 or 0.91 to 0.99, only few studies show similar results).

Classification chart of Epidemiological designs is shown in Fig. - 2.

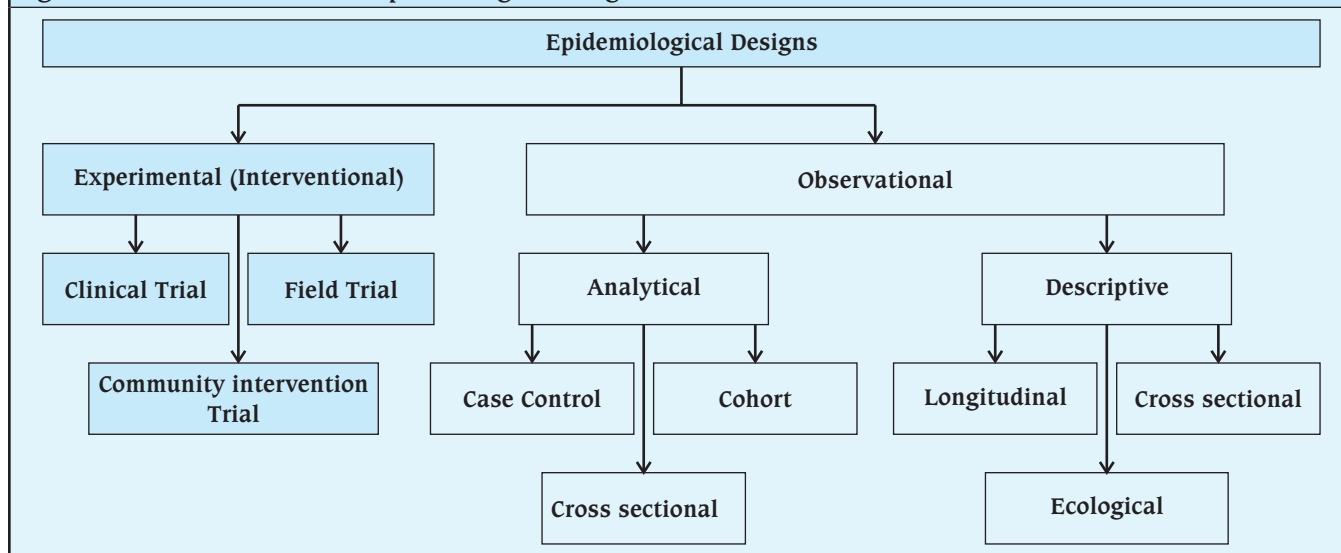

Box - 3 : Strength of Evidence Based on Type of Epidemiological Designs

Strongest	<ul style="list-style-type: none"> - Randomized Controlled Trials - Community Intervention Design - Quasi Experimental design - Meta-analysis - Cohort Design - Cross-sectional design - Case-Control design - Ecological & other descriptive designs
Weakest	

Summary

Epidemiological studies are broadly of two types, Observational and Experimental (Interventional). Observational studies are of further two broad categories, viz., descriptive and analytical. Experimental studies, in which the subjects are randomly assigned to exposed and unexposed groups, provide the best evidence of causal association, as they control for both known and unknown confounders. Ethical considerations, however, restrict the conduct of experimental studies in many situations. Experimental studies are therefore utilized when studying the efficacy of a treatment or a preventive modality, in which situations, they become an essential scientific requirement. Of the observational studies, Descriptive studies describe the occurrence of a disease or a health related event in terms of time,

Fig. - 2 : Classification Chart of Epidemiological Designs

place and person. However, they can only generate hypotheses; not test them. For testing hypotheses, analytical studies are undertaken. Among analytical studies, Cohort studies are forward - looking studies in which two groups of subjects, one with the exposure and one without the exposure are followed over a period of time, after which the outcome in the two groups are compared. The strength of association is calculated by the RR. Advantage of cohort studies are : no ambiguity about temporal relation, absence of recall and survivorship bias. They are also suitable for rare exposures. Major disadvantages are the high cost, resources needed and loss to follow up. They are also not suitable for rare outcomes. Case control studies are backward looking studies which assemble a group of cases (persons with the disease) and controls (persons without the disease) and presence or absence of exposure (which has occurred in the past) is ascertained from history given by the respondents. The advantage of case control study is the low cost and availability of study results in quick time. The disadvantages are recall bias, and survivorship bias. Moreover, the incidence of disease and exposure cannot be calculated directly and instead of RR, an estimate of RR is calculated, i.e. the OR. In cross sectional studies, a cross - section (sample) from the target population is studied. Measurement on exposure and outcome are carried out at the same point of time. Drawbacks are the inability to ascertain temporal relationship and survivorship bias. In studies of diagnostic tests, the performance of a diagnostic test is compared with a 'gold standard' or confirmatory test. The quality of the new test is evaluated by measures of validity (accuracy). These are : Sensitivity, Specificity, Positive and Negative Predictive Values (PPV and NPV).

Study Exercises

MCQs and Exercises

Study Exercises & summary contributed by Amitava Banerjee

- (1) Identify the study designs from each of the following narratives :
 - (a) Cases of viral hepatitis are monitored by the District

Health Officer in his district. Each case of viral hepatitis is indicated by a dot on the map of the district. He also records the seasonal variations annually by monitoring the number of cases each month. He classifies the cases according to age, gender, occupation, source of water supply and other personal attributes.

- (b) Two groups of teenagers were identified, one who were given education on safe driving by their parents or school teachers and the second who did not receive such education. The outcome measure which was compared was the rate of involvement in both fatal and non - fatal traffic accidents in the two groups over the next 10 years.
 - (c) To test the hypotheses that children of separated parents are more likely to become drug addicts, cases of drug addiction were identified from a de - addiction centre. They were compared with people without drug addiction, who were matched for age, sex, literacy and socioeconomic status with cases of drug addiction. The history of separation of parents was obtained from both cases and controls and cross checked from records.
 - (d) Using two masked pieces of paper, one labelled study group and the other control group, each participant in a study is offered to pick up one chit and replace it after he is allotted the group according to the chit he picked up. After this method of going either into study and control group, the participants in the study group are given Deltamethrin (an insecticide) impregnated mosquito nets, to use during night time, while the control group is given ordinary mosquito nets. The outcome measured is incidence of malaria in the two groups.
 - (e) A survey among under - five children is carried out in five selected villages to find out malnutrition among them and the factors associated with various grades of malnutrition.
2. Descriptive studies perform all the following functions Except : (a) Test hypothesis (b) Describe disease occurrence by time (c) Describe the place distribution of health related

- event (d) Generate hypothesis.
- Which of the following is not a unique feature of experimental study : (a) The study is prospective (b) The study can be both prospective and retrospective (c) There is random allocation of subjects to the study and control groups (d) The investigator introduces an intervention.
 - It is sometimes difficult to establish temporal association in the following study design : (a) Experimental study

- (b) Cohort study (c) Cross - sectional study (d) All of the above.
- Loss to follow up or attrition is a problem with : (a) Case control study (b) Cross - sectional study (c) Cohort study (d) All of above.

Answers : (1) (a) Descriptive, (b) Cohort, (c) Case control (d) Experimental (e) Cross sectional; (2) a; (3) b; (4) c; (5) c

RajVir Bhalwar

Except in the limited situations of describing a phenomena of interest, most of the times the epidemiological and clinical research is directed towards finding out the “causal” association; e.g. “Is smoking a cause of IHD ?” or “is giving vaccine or a drug a cause of reduced sickness?” In epidemiologic research this is called as study of “cause - effect” relationship; it is also equivalently called as “exposure - outcome” relationship. E.g. “not giving the vaccine” is the exposure (or cause) “and getting the disease” is the outcome (or effect). These aspects have been discussed in detail, in an earlier chapter.

At the outset let us clarify that modern medicine takes into consideration the multi factorial causation of disease. Thus, while M tuberculosis is necessary for the causation of TB, TB may not necessarily occur even in the presence of M tuberculosis; various other factors like race, genetic factors, immunity, etc. may also have a role. Similarly, smoking may be an important cause of IHD; however various other factors like obesity, physical inactivity, dietary patterns, hypertension, genetic background, age, sex may also have a role. In other words epidemiological and medical research today is interested in finding out “a cause of a disease” rather than “the cause of a disease”, giving due consideration to the fact that there may be various other factors also which may act independently, or cause ‘confounding’ or lead to an effect modification, as described in the last chapter.

A “cause and effect” (or exposure and outcome) relationship can be defined as one in which a change in the frequency or quality of one leads to a detectable change in the other; e.g. if smoking is a cause of Buerger’s disease, increase or decrease in smoking should lead to a corresponding change in the disease occurrence.

The Process of Establishing a “Cause and Effect” (or “Exposure and Outcome” Relationship)

Establishing a cause and effect relationship, i.e. this particular ‘exposure’ is the cause of that particular ‘outcome’, needs a research on the lines of ‘hypothesis testing’, i.e. it is not simply

a descriptive study but rather an analytical study. Once the investigator proceeds with a “cause and effect” hypothesis and conducts a study, the final establishment of an “exposure - outcome” relationship consists of a sequence of steps as follows :

Step 1 : Has the study been done using correct methods ? Has the investigator ‘measured’ what he or she really wanted to ‘measure’ ? Has the validity and reliability been preserved in the study and there is no bias ? In other words, we ensure that the results of the study are accurate and not “spurious”.

Step 2(a) : Do the statistical results indicate that the ‘exposure’ and ‘outcome’ are “associated”? In this step, the investigator ensures, through statistical tests of significance and 95% Confidence Interval, that the differences / associations observed in his sample are not simply due to matter of “chance” or in other words, variations that could occur when different samples from the same whole population are drawn (chance; random variations; sampling variations). For usual settings of clinical research, if the ‘p’ value after the test of significance is less than 5% (0.05) or the 95% CI of the difference between means / proportions does not include zero, we conclude that the exposure and outcome are statistically related. The details of these calculations have been elaborated in relevant chapters in the section on biostatistics.

Step 2(b) : If the statistical results show that the statistical relationship is not significant, we must still give consideration to the possibility that a real association might have been missed out due to low power of the study, i.e. a high Beta (type II) error consequent to a small sample size. Hence, before finally denouncing the association as “not statistically related”, the investigator must back - calculate the “power” of the study (of having detected a difference or association if it really existed); in case it is found that the power was inadequate (say less than 80% for the usual research settings), the investigator should suggest additional studies using large sample (or else, a ‘meta - analysis’ type of study), rather than straightaway dismissing the ‘exposure - outcome’ association as non - causal. Details of power calculation are discussed in an exclusive chapter, later on.

Step 3 : If the tests of step 2 show that the relationship is “statistically significant” the investigator should now evaluate as to whether this relationship is due to ‘indirect relationship’

with a third variable; in other words, the investigator should undertake analytic procedures for control of confounding (stratified analysis or regression analysis) and work out the “adjusted estimates” i.e. the independent relationship that is still present between exposure and outcome variables after making “adjustments” for the various PCF, as described in the last chapter.

Step 4 : Once it has been demonstrated in step 3 that the exposure - outcome relationship is not due to confounding (i.e. holds good even after adjusting for confounding variables), the investigator should now test this postulated “causal” relationship on the following criteria of “causal association” :

(a) Temporality : The absolute requirement for any postulated cause and effect relationship to hold good is to demonstrate that the suspected cause (exposure) preceded the effect (outcome). E.g. for smoking to be a cause of IHD, smoking should start before the occurrence of IHD.

(b) Strength of Association : The “strength of causal association” is shown by Relative Risk (RR) or Odds Ratio (OR); farther the RR or OR is from the value of “1”, more is our confidence regarding the causal association. In general, if (after ensuring validity, controlling for confounding and ensuring statistical association) the RR or OR is 3 or above or 0.8 and lesser, our belief in cause - effect relationship becomes strong; if it is 5 or more (or 0.5 and lesser), little doubt then remains regarding such an association. However, one must remember that a low RR or OR (say 1 to 3 or else between 0.99 to 0.8) does not exclude a causal relationship. The only thing is that in such cases it becomes difficult to exclude alternative explanations.

(c) Consistency : Whether a number of different studies conducted by different investigators at various times in different geographical areas on different populations have indicated similar “cause and effect” association as regards our exposure and outcome variables. E.g. smoking - lung CA association has been consistently demonstrated in various countries, religions and sex, etc.

(d) Biological gradient : Usually, increasing dose of exposure should be associated with increasing occurrence of outcome; e.g. with increasing consumption of tobacco, the occurrence of IHD rises. This is also called “dose - response relationship”. However, the investigator should remember that not all causal associations would demonstrate this phenomenon; e.g. the association between DES consumption by mothers and vaginal CA in daughters many years later does not exhibit this ‘gradient’ phenomenon, possibly due to a phenomenon called “sufficient dose for maximum effect”.

(e) Biological plausibility : Does the cause - effect association forwarded by us “stand to reasoning” i.e. commensurate with the already known and accepted facts. However, here too the researcher must note that biological plausibility is a relative phenomena based on present day knowledge of the state of affairs; what we think nonsensical today may be accepted as correct tomorrow, e.g. in the mid 19th century when a clinician recommended hand washing by medical students and teachers before attending obstetric units, his recommendations were dismissed by medical fraternity as “doesn’t stand to reasoning”! The rest is history.

(f) Experimental evidence : An evidence, in the laboratory or in human subjects, based on deliberate introduction of the cause (exposure), thereby demonstrating that the outcome (effect) occurs in the group which has been subjected to the exposure and not in the other group, further strengthens our faith in the cause and effect relationship. Here again it should be noted that such experimentation on human subjects may be often impossible; (e.g. we cannot deliberately tell a group of human beings to smoke and the other group not to smoke and watch them for the development of lung CA). However, even in such cases, basic laboratory proof (e.g. microscopic demonstration of histological changes in the respiratory tract of animals subjected to tobacco smoke or in tobacco using humans) may further strengthen our belief in a “causal” association.

(g) Other criteria : Like ‘analogy’ (e.g. if one drug can cause congenital malformations, others can also do so); ‘Specificity’ (i.e. one cause, one effect) and ‘coherence’ (findings should not conflict with the known natural history of the disease) have also been forwarded to finally test a causal association. However, in general, criteria mentioned in step 4(a) to (c) are most important; (d) to (f) may lend additional support to the causal reasoning while those mentioned in (g) may also be considered.

Summary

Most research aims at studying aetiological or cause - effect relationships in which change in the cause produces change in the effect. Diseases may have a single cause or (more commonly), have many causes (multifactorial). To establish cause - effect relationship one should choose the appropriate study design. During conduct of the study, measurement errors and bias should be eliminated or minimized. The role of chance should be ascertained by appropriate statistical tests. Control or adjustment for confounders should be done during planning or analysis stage. In the next step one needs to ascertain whether the association observed is statistically significant or not. Finally, once it has been ascertained that the study has been undertaken using the correct epidemiological design and using the correct, valid method of measurements, the associations observed are statistically significant and are not due to indirect relationships (confounding), then additional criteria for causation (as enunciated by Sir A B Hill) should be applied. These are : temporality, strength of association, consistency, dose - response relationship, biological plausibility, analogy, and experimental evidence.

Study Exercises

(Study questions and chapter summary contributed by Amitav Banerjee)

Long Question : Define “causal association”. Describe the sequence of steps while establishing a cause and effect relationship.

Short Notes : (1) Hill’s criteria for causal association (2) Indirect association (3) Insignificant association

MCQs

1. Cause effect relationship can be tested by the following study designs *Except* : (a) Ecological study (b) Case - control study (c) Cohort study (d) Randomized Controlled

- Trial.
- Most likely reason for failure to establish a cause effect relationship with small sample sizes is : (a) Alpha error or Type I error (b) Beta error or Type II error (c) Measurement errors (d) Observer errors.
 - The strength of association in a cause effect relationship is indicated by : (a) 'p' value (b) The magnitude of the RR or OR (c) Consistency of association (d) All of the above
 - If RR or OR is 1, it indicates that : (a) There is no cause effect relationship (b) There is Alpha Error (c) There is type 1 error (d) None of the above.

- The fact that most people infected with *Mycobacterium tuberculosis* do not suffer from Tuberculosis indicate that : (a) *Mycobacterium tuberculosis* is not a necessary cause for tuberculosis (b) *Mycobacterium tuberculosis* is a necessary but not sufficient cause for Tuberculosis (c) *Mycobacterium tuberculosis* may be of atypical form (d) None of above.

Answers : (1) a; (2) b; (3) b; (4) a; (5) b.

Descriptive Studies (Including Ecological Studies) & Epidemiological Distribution According to Person, Place & Time

Rajvir Bhalwar

Definition

A descriptive study can be defined as one in which only one group, i.e. subjects having the outcome (disease or any other health related phenomena of interest) are studied, without any comparison group, for describing the outcome or health - related phenomena according to its frequency or such other summary figures (as mean), and its distribution according to selected variables related to person, place and time. Finally, it forwards tentative guesses (hypothesis) about the possible causal role of certain factors in the outcome of the interest, but does not confirm such causal role because of the absence of a comparison group.

Characteristics of a Descriptive Study

The characteristics of a descriptive study can be described as follows :

- They do not proceed to test a "pre - formed hypothesis" regarding an association between a particular exposure and an outcome.
- The study is done only on one group of subjects; there is no comparison group.
- The main objective of a descriptive study is to "describe" the "mean value" of a health related condition, or a "proportion" (i.e. incidence or prevalence of a disease or health - related condition) or the natural history of disease or a health - related phenomena; and, in addition, the study also intends to describe the "distribution" of such means, proportions or natural progress of health - related phenomena, according to variables related to "person" (e.g. age, sex, blood groups etc.), "Place" (e.g. residential area)

and "time" (e.g. seasons).

- Having described the means / proportions / progression of health related phenomena and the "distribution" of these health problems according to various characteristics of person, place and time, a descriptive study culminates by making suggestions / hypotheses about certain "cause and effect" relationships which can be further tested by analytical studies.

Essential Differences between a Descriptive and an Analytical Study

It is important, at this juncture, to understand the difference between a descriptive and an analytical study. The difference is, at times, so fine that it leads to confusion. The essential differences are given in Table - 1.

Table - 1 : Difference between Descriptive and Analytical Study

Descriptive	Analytical
Only one group is studied	At least 2 groups are studied for making comparisons.
At the start of the study, there is no explicit hypothesis regarding cause - effect relationship	At the start of the study there is a definite hypothesis regarding an exposure possibly causing an outcome
The study ends with development of possible hypotheses regarding cause and effect relationship but does not confirm or reject such hypothesis.	At the end of the study, it confirms or rejects the hypothesis with which it started.

Types of Descriptive Studies

(a) Case Reports and Case Series

This type of study is based on reports of a single, or else a series of cases of specific treated or untreated condition without any specific comparison (control) group. In addition to describing

the signs, symptoms or patho - physiological parameters in the series of patients, we may also work out “proportions” (e.g. percentage of cases that belong to a particular age group, sex, ethnic group etc.). However, we must remember that these proportions do not indicate risk since the denominator is still the number of cases and not the population at risk, e.g. in a case series of STD, we may find that 80 out of 100 cases (80 %) belong to a particular community. This should not be interpreted as that the risk for that particular community of getting STD is very high, since this may have happened because the particular community may as such be forming 80 % of the total population. This aspect must be kept in mind since it has been a common source of confusion and misinterpretation in medical literature.

(b) Cross Sectional Descriptive Studies

Such descriptive studies are done on a sample of the total population and may be community based or hospital based. They are mainly directed to work out the :

- i) “Prevalence” of a factor of interest, e.g. prevalence of leprosy among general population, i.e. community based, or prevalence of nosocomial *Pseudomonas* infection in renal units, i.e. hospital based.
- ii) “Mean” of a factor of interest (e.g. Hb% level in ladies in the community; or serum protein levels among patients admitted with open pulmonary TB).
- iii) Description of a “Pattern” (e.g. pattern of antibiotic prescription in an Acute Medical Ward; or knowledge, attitudes and practices regarding contraceptives in a community).
- iv) As a surrogate for longitudinal descriptive studies : say, for weight charting of children from birth till 5 years age, on a monthly basis, ideally, we should collect a group of (say 1000) children born recently, and follow them up for next 5 years, recording their weight every month. This is the ideal, but often a difficult way (longitudinal descriptive study). To overcome the problems of follow up, what we can do is that we can take a “cross sectional” sample of say, 100 children each of ages 1, 2, 3 and so on, till 60 months and weigh them; the average weights could be used for making a growth chart as would have been done by a longitudinal study. Excellent and easy though it may look, the method has a flaw. The children whom we take up in such a study at different age groups are the ones who have survived to this age. It is quite possible that malnourished (under weight) children might have been dying progressively more, and not reaching the next month of age. If this were true, a chart based on cross sectional study would show higher mean values as compared to a (more correct) chart based on longitudinal descriptive study.

(c) Longitudinal Descriptive Studies

In contrast to a cross sectional descriptive study, a longitudinal descriptive study follows up a single group of subjects over a defined period of time. These studies are more scientific than cross sectional ones but at the same time more costly and time consuming. These studies are undertaken with the following general objectives :

- i) To see the *incidence* of a disease (e.g. the incidence of poliomyelitis among children in the community or the

incidence of acute glomerulonephritis among children admitted in hospital, with acute sore throat).

- ii) To describe the ‘*natural history of a disease*’ (e.g. the clinical progression of cases of AIDS in hospital; or the clinical progression of cases of viral hepatitis in a community).
- iii) To describe a health related *natural phenomena* (e.g. the examples of weight charting of children given earlier).
- iv) To study the ‘*trend of a disease*’ (e.g. to see whether the incidence of TB is rising or falling in a community).
- v) To study the ‘*trend of a health - related phenomena*’ (e.g. to see whether the blood pressure of children from well - to - do families rises progressively; or whether the level of knowledge regarding prevention of AIDS is rising, falling or remaining stationary).

The basic difference between a cross sectional and a longitudinal descriptive study can be appreciated by the essential difference that in a cross sectional study the researcher examines every subject only once; while in a longitudinal study each subject is examined *at least* twice. For this reason, a cross - sectional study gives us the “prevalence” while a longitudinal study gives us the “incidence”.

Epidemiological Descriptions according to Person, Place and Time

Having identified the disease, or the health related outcome that is of interest to the epidemiologist, and having collected data using valid and reliable methods, the epidemiologist takes the next step, i.e. of “describing” his findings about the disease, in terms of its “distribution” according to relevant variables of person, place and time, and the relevant combinations of person, place and time related variables. Such detailed description regarding distribution of the disease helps the epidemiologist in developing “hypothesis”, i.e. tentative guess - works regarding the various possible causes of the disease or its prevention / mitigation (i.e. why does the disease occur and what can be done for it). The important variables related to person, place and time, which the epidemiologist commonly studies, are described in succeeding paragraphs.

Person Related Variables

People may be characterized according to an infinite number of variables. However, in practice, the number must be limited according to specific purposes of the study and resources available. The more commonly studied person related variables are :

1. **Age** : Age is a person related variable that is almost universally studied. One should always see the distribution of the disease that one has studied, according to “age - specific” rates, both for morbidity and mortality. In general, death rates tend to be highest during the infant & preschool age and extreme old age, while they tend to be lowest during 5 - 24 years group. Diseases like Road accidents and AIDS have a mortality peak in young / early middle age, while non - communicable (chronic) diseases show a rising trend during middle age. “Bimodality”, i.e. two peaks in the age distribution of morbidity or death due to a particular disease (as occurs in Hodgkin's disease) must always arouse interest - it indicates that the total subjects in the study do not form a homogenous material and the entity under examination needs to be divided into at least two distinct

subgroups with different experiences.

2. Sex : In general, while death rates are higher for males, the morbidity rates are higher for females. This differential is present irrespective of age, occupation, rural - urban differences, etc. Also, some diseases as those of gall bladder and thyroid are more common in females while CHD and lung cancer is less common. The sex related differences may be due to hormonal or other biological differences or due to differences in attitude towards life.

3. Ethnic Group : Ethnic group is defined as a group of persons who have a greater degree of homogeneity than the population at large in respect of biologic inheritance and present day customs. Various categories of variables, that are studied under the broad heading of 'ethnic group' are :

- Race - e.g. Mongoloid, Caucasian & Negroid.
- Nativity - e.g. European, Indian, Chinese etc.
- Religion
- Local reproductive and social units - These are groups which have maintained strictness regarding marriage within the group, e.g. certain religious communities. As an example, Jews have higher prevalence of the gene for Tay - Sachs disease as compared to non - Jews.

In addition to genetic differences between ethnic groups that may account for the disease differences, such differences may also be due to differences between these groups and the population at large as regards customs, diet, life style, socio economic factors etc.

4. Social Class : Social status or socio economic status is one of the most commonly studied person - related variable. Social status may be an independent risk factor for the disease or it may be indirectly associated with the disease in question, e.g. due to association with the type of housing. In India, two commonly used scales are the Prasad's scale based on per capita per month income and Kuppaswamy scale which takes an ordinal combination of education, occupation and income. The details are given in the section on Social & Behavioural Sciences.

5. Occupation : Association of disease with occupation is often studied, particularly in context of diseases that are likely to be related to occupation. The stress of occupation and exposure to various physical, chemical and biological disease agents therein, may be associated with high occurrence of such diseases. On the other hand, entry into occupation is itself likely to be related to particular physical (e.g. soldiers) and mental (e.g. Doctors) capabilities and this aspect must be considered since it can be an important source of selection bias in epidemiologic studies. In case of studies on children, it is also usual to study the occupation, education and income of the father and mother.

6. Education : Education leads to an improved level of knowledge and hence is likely to be associated with reduced risk of disease. This is the traditional "Knowledge Attitudes and Practices" (KAP) model, though it may not hold true in all conditions. In epidemiologic studies it is usual to study the distribution of disease according to level of formal education as illiterate, just literate (upto 5th standard), upto matriculation,

upto college, graduate, and post - graduate or Doctoral level.

7. Marital Status : In general, mortality rates are lowest among married, followed by single, widowed, and divorced, in that order, irrespective of sex. In addition, concordance of disease among spouses points towards strong environmental influences as infections, diet, customs and reduces the chances of genetic or immunological mechanisms in being operative in such diseases.

8. Family Variables : Depending on the scope of the epidemiological investigations at hand, various family variables as family size, birth order, maternal age, parental deprivation during childhood, familial aggregation of disease, and so on, are studied.

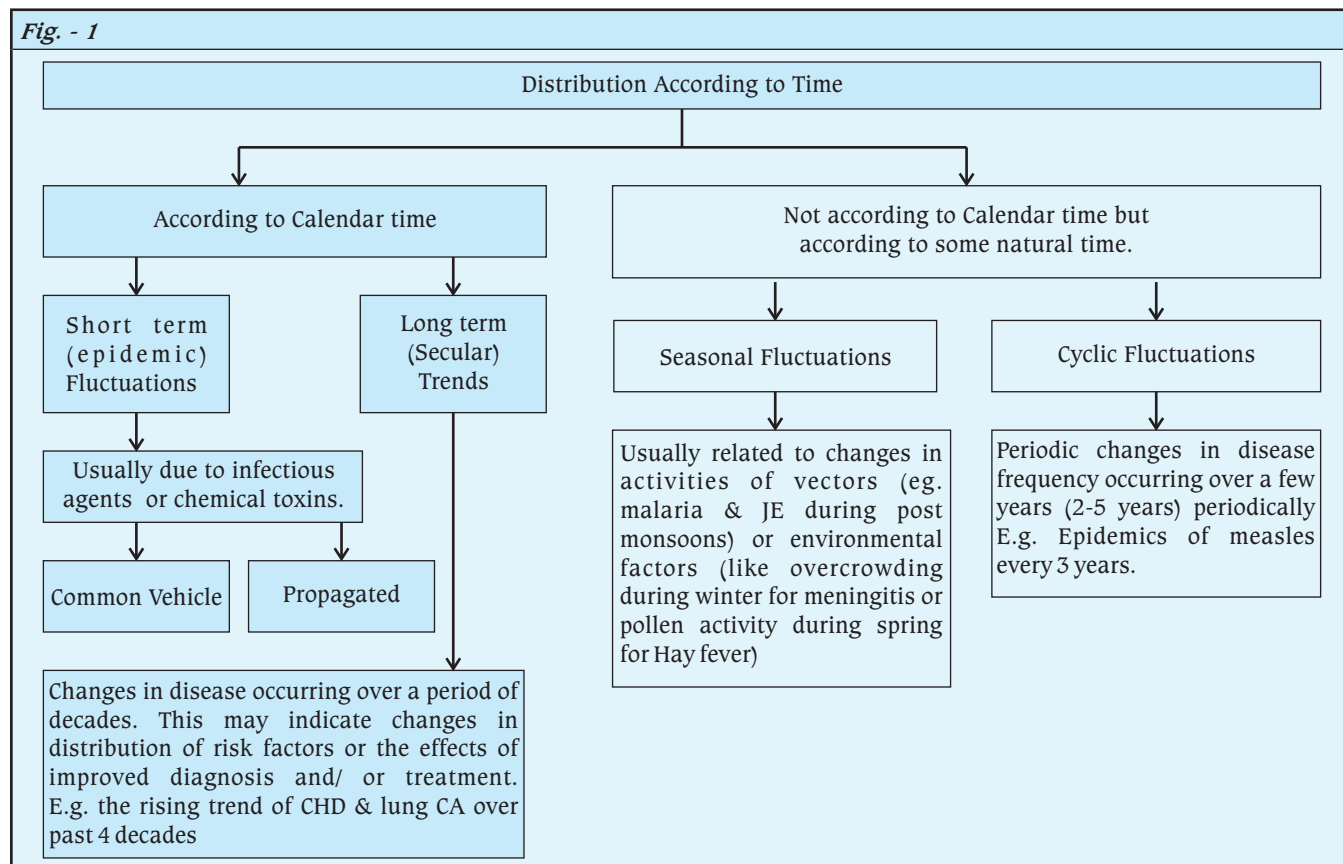

9. Twin Studies : These are very powerful methods for evaluating the genetic background of a disease. They work on the premise that monozygotic twins (being formed from the division of a single fertilized ovum) carry identical genes, while dizygotic twins are simply like two different siblings from genetic point of view. Thus, concordance of a disease in monozygotic twins as compared to dizygotic, is a strong indication of genetic background. On the other hand, discordance as regards a disease among monozygotic twins points towards environmental etiology. Developed countries have established "twin registries" for large scale epidemiological studies in this field.

10. Other Variables : The variables described above are the ones which are quite commonly used in epidemiological studies. However, as said earlier, there can be thousands of possible "person - related" variables in the form of various Socio - Demographic, Physiological, Biochemical, Immunological characteristics. An epidemiologist will have to choose the relevant ones, depending on her epidemiological question.

Interpretation of Person - Related Descriptive Epidemiology: While assessing the results from person related variables and forming hypothesis based on these descriptions of a disease, one must consider whether any of the following points could give an alternative explanation :

- (a) Differences in availability of health services (the rich may go to private doctors for treatment of STDs so that their disease is not reported and hence it may seem that STD is lesser among the rich); differences in utilization of health services (girl child may not be taken to the health care facility and hence a disease may appear to be lesser among girls); differences in precision of diagnosis (STDs are more difficult to diagnose among women than men); or differences in reporting the disease (Females may report STDs less often than males).
- (b) Differences which may be due to indirectly associated variables, i.e. confounders; e.g. difference in CHD between whites and blacks may not be because of racial factors but rather because of differences in socioeconomic status of the 2 racial groups.
- (c) Once the above 2 possible causes of apparent differences have been excluded, one should explore the possible environmental, biological and genetic factors as an explanation for the observed person - related distribution.

Fig. - 1

Distribution According to Time

Descriptions of changes in disease pattern occurring over time are important in developing hypotheses regarding its etiology and prevention. Distribution in time may be of the following types, as shown in Fig. - 1.

1. Common Vehicle Epidemics : A common vehicle epidemic occurs due to presence of infectious or a chemical noxious agent in a common vehicle which serves as the channel of transmission, e.g. food, drink, air, pooled blood etc. Depending on the duration of persistence of the agent in the vehicle and the frequency of contact of the vehicle with the susceptible population, these may be of 3 types (refer to Fig. - 2 for graphical presentations) :

(A) Common Source (Vehicle), Single (Point) Exposure: The infective material remains present in the vehicle for a brief period of time; during this period all those who come in contact with the vehicle become exposed to the infection. This is classically seen in outbreaks of food poisoning and such outbreaks of cholera that are due to brief contact of an incubatory carrier with food or water. An epidemic curve, plotted with the frequency of the disease along the vertical (Y) axis and measure of time (dates, hours, weeks etc.) along the horizontal (X) axis shows certain characteristic features :

- (i) All cases occur within one known incubation period of the disease.
- (ii) The epidemic curve has a sharp onset and an equally abrupt decline.

(iii) The peak of the epidemic is sharp and coincides with the median incubation period of the disease.

(B) Common Source, Continued exposure : Such an epidemic would occur when an infectious agent persists in the common vehicle for some amount of time. The final decline of the epidemic occurs either because the cause of contamination is removed or else because of the fact that all possible "susceptibles" have become infected. Such curves are seen in contamination of surface / ground or piped water supplies with human excreta, as in infectious hepatitis or cholera, or food borne typhoid fever outbreaks due to carriers or contaminated tinned foods. The epidemic curve rises slowly, and also falls gradually; the peak is not sharp but rather plateau - like and the duration of epidemic is stretched out, depending on the duration that contamination had persisted in the vehicle.

(C) Common Source, interrupted exposure : In such epidemic, there is a common source, but the source introduces the infection into the vehicle only interruptedly. For example, out of the 4 nurses looking after a urological ward, 1 maybe carrier of *Pseudomonas aeruginosa*. Now, as and when this particular sister is on duty, she would introduce the infection through the catheters that she may be passing into the patients. Such a curve will show an increase in frequency but the curve will be almost flat with occasional irregular waves coinciding with the periodic introductions of infection.

2. Propagated Source : In such an epidemic, the source itself propagates, i.e. multiplies. For example, in a group of school

Secular Trends of Incidence of Lung Cancer in a developed country

children, the first (index) case of diphtheria may pass on droplet infection to 3 others; these 3 may then pass on to 9 others and thus the source multiplies. The fall of the epidemic occurs due to development of enough herd immunity so that no more susceptibles can be effectively infected. The epidemic curve rises slowly, in waves, reaches a flat plateau and then declines slowly. Such curves are seen in droplet infections like Diphtheria, Mumps, Measles; in vector borne diseases like Malaria, JE and Dengue epidemics, Influenza and in STD and HIV epidemics.

Seasonal fluctuations : Diseases like Malaria and JE are commoner during immediate post monsoon season due to increased breeding of vectors; airborne / droplet infections are commoner in winters when people tend to congregate and overcrowd. Similarly, asthma shows highest incidence during spring and autumn suggesting specific environmental factors in its causation. In fact, till the early years of 20th century, European as well as American typhus were both believed to be epidemic, due to lice transmission; however, Maxcy, while studying the seasonal pattern of these two groups of typhus fever demonstrated that while the European (louse borne, epidemic) typhus was higher in the first half of the year, the American form was higher during the second half of the year. This difference in seasonal pattern, coupled with the subsequent person and place related factors finally pointed out the fact that American typhus was clearly distinct from the European form and was possibly associated with rodents; today we know it as Rat flea borne (murine, endemic) typhus.

Seasonal fluctuations are usually demonstrated by line diagrams. They may help differentiating two similar - appearing illnesses like JE and meningococcal meningitis - the former having a peak during post monsoon and the latter manifesting a peak during peak winters.

Cyclical Changes : These are periodic peaks in disease frequencies occurring every 3 - 5 years. The common example is of measles in which epidemics tend to occur in cycles of 2 - 3 years, possibly due to accumulation of enough susceptibles.

Secular trends : These are time trends occurring over a period of decades. Secular trends during this century have been noticed for cancers of various sites - a declining trend in death rate due to cancers of stomach and uterus and a rising trend for cancers of lung and pancreas, while there is no change in breast cancer mortality rate.

Interpreting the distribution according to time : Changes in trends of morbidity or mortality of a disease may be real or artifactual and hence, while evaluating secular trends, one must consider whether such an observed trend could be artifactual due to any one of the following reasons :

(a) Errors in numerator :

- (i) Change in recognition of a disease, e.g. better diagnostic facilities.
- (ii) Change in rules for classification of cancers or death or procedures in ICD which is brought out decadal by WHO.
- (iii) Changes in accuracy of reporting the age at death.

(b) Errors in denominator due to errors in enumeration of population

Once the above alternative explanations have been considered, the epidemiologist should consider the following possibilities for a real change in time trends :

- (i) Changes in age distribution of a population.
- (ii) Changes in survivorship (e.g. better treatment available).
- (iii) Changes in actual incidence of disease resulting from changes in environmental or genetic factors. This final evaluation may bring out very important epidemiologic findings; e.g. an increasing trend during 1959 - 67 in asthma mortality, after excluding all the other possibilities, pointed towards some environmental factors. Further investigations showed that this had occurred due to increased availability (due to over - the - counter sale) of pressurized aerosol bronchodilators, especially which contained isoprenaline, which had led to a large number of sudden deaths.

Distribution According to Place

Place is the third determinant of the distribution of disease. Many diseases have typical spatial relationships; goiter is common in foothill regions, Anthrax and brucellosis in rural areas and CHD is commoner in affluent countries. Thus, differences in the distribution of a disease according to place may be made according to political boundaries (e.g. international comparison, regional comparison within countries) or according to natural boundaries (e.g. rural - urban differences, altitude, or local distribution of disease) as follows :

1. International Comparisons : Japan has very low CHD mortality rates but high rates for cerebro - vascular accidents, Hypertension and gastric CA; UK has high lung CA rates while USA has high CHD rates. When making such international comparisons in respect of a disease, one must initially assess whether these observed differences are artifactual due to errors in numerator or errors in denominator (as already explained under "TIME"). Thus, National, Regional or International differences in the availability of medical services, diagnostic practices of physicians, quality of available diagnostics, differences in disease classification procedures, completeness of reporting of death & disease and completeness of census may all introduce artifactual differences.

Once these considerations indicate that the differences are not artifactual, but real, i.e. either due to the play of environmental factors or else genetic factors, a good method of dissecting this out are "*Migrant Studies*". Let us say a group of people 'M', have immigrated from the original country 'X' to a new country 'Y'; Now, these immigrants will carry with them their genetic background of the original country to the new country; however they would be exposed to a set of environmental conditions (lifestyle, housing, water supply, nutrients) which would be different in the new country as compared to the original country. Let us say, the mortality (or morbidity) rates due to a given disease of interest 'A' are as follows :

Rates in original country = 'X'; Rates in new country = 'Y'; Rates among the migrants = 'M'.

Now, if the international differences in a disease are due to environmental factors, then 'M' would approximate 'Y' but 'M'

would tend to be different than 'X'. On the other hand, if the disease is determined by genetic factors, 'X' and 'M' will be equal, and 'X' and 'M' will be different from 'Y'.

International immigrant studies have been done in respect of CHD, CVD and CA esophagus, while within the country immigrant studies have been done in USA on multiple sclerosis.

2. Regional Variations within countries : e.g. goiter is a place related disease in India with high frequencies in the foot hill areas. Such regional differences help in developing hypothesis about role of possible environmental agents (as Iodine content of water and soil), in the etiology of the disease.

3. Rural - Urban differences : Rural - Urban differences again would point out towards possible environmental factors; e.g. IHD, STDs, Hypertension etc. are more common in the urban areas while oro - faecal infections are more common in rural areas. While making interpretations, one must evaluate the role of possible confounders like housing, education, economic status etc., in causing such differences.

4. Local distributions : Most often, the epidemiologists have to study local distributions, i.e. the differences in disease occurrence according to place within small, defined localities. For examining such differences, the epidemiologist makes a "spot map" which is a detailed layout map of that area or locality, showing the accommodation, water sources and supply lines, nightsoil disposal systems, vector breeding areas, eating establishments and various other environmental factors of relevance. On the same map, the epidemiologist plots the cases of the disease according to their frequency, looking for the places where there is a high frequency of cases and then trying to relate them with the possible environmental factors. Proper use of 'spot map' is almost mandatory while investigating most of the epidemic outbreaks; in fact, spot maps have provided important clues in finding out disease etiology, e.g. John Snow's investigation on cholera in London and Maxcy's investigation on Typhus (endemic) in USA.

The finding that a disease is related to a given place may finally be due to one of the two reasons :

1. The inhabitants of that place, by virtue of their genetic factors (e.g. sickle cell trait prevalence in African regions leading to differences in malarial prevalence) or because of their socio-environmental factors (e.g. Kuru due to cannibalistic ritual feeding in new guinea), are different from those at other places.

OR

2. Some etiologic factors, characteristic in the place are present. If this is the reason, then :
 - (i) High rates of disease will be observed in all ethnic groups in that area.
 - (ii) High rates are not observed in persons of similar ethnic groups living in other areas.
 - (iii) Healthy persons entering that area become ill with a frequency similar to the indigenous inhabitants.
 - (iv) Inhabitants who have left that area do not show high rates.
 - (v) Some evidence of the disease may also be found in animals in the same area.

Methods of Displaying and Analysing Place Related Disease: the common methods used in epidemiology are :

1. **Spot Mapping** : The details of making a spot map have already been explained above. It is the simplest, yet a very productive method of displaying the place - related distribution of a disease and must be practiced well by all persons proceeding to study public health and epidemiology.

2. **Map - on - map** : In this technique we combine two maps to bring disease frequencies, plotted as coloured dots, into visual approximation with other variables like roads, rivers, indices of poverty etc. This technique may also be used for studying "movement" of a disease in both time and place.

Steps in Designing a Descriptive Study

The following is a sequential plan of steps for undertaking a descriptive study :

1. Write down your research question and its background significance (e.g. "to study prevalence of seropositivity of HIV among voluntary blood donors at a blood bank") and the design to be used (e.g. cross - sectional or longitudinal descriptive study or case - series).
2. What are the variables you want to study?
 - (a) Main variables : Name one or two variables which are of most interest to you, e.g. HIV seropositivity; any other STD.
 - (b) Other variables of secondary interest : These are the variables which you would like to study in addition to the main interest variables. Try to limit these to not more than 3 to 5 (e.g. other chronic diseases).
 - (c) What are the variables related to person, place and time according to which you will describe the "distribution" of the "main" and "secondary interest" variables, e.g. :
 - i) Person related : as age groups (less than 20, 20 - 30, 30 - 40, more than 40); sex; socio - economic status; history of needle sharing; marital status; frequency of visits to CSWs; use of condoms; knowledge about HIV and STD etc.
 - ii) Time related : as month - wise detection of cases out of total tested.
 - iii) Place related : as rural - urban differences of cases.
3. Specify the 'scales' of measurements in respect of the each of the main variables & secondary variables and those person / place / time variables on which "distribution" is to be described; i.e. whether on continuous / discrete / ordinal / dichotomous / polychotomous scales.
4. Define the 'total' and 'actual' (study) population, as per detailed discussion undertaken in the chapter on population and samples (e.g. in our above example, total population can be defined as voluntary blood donors in the country while actual (study) population may be voluntary blood donors in large hospitals in a particular district).
5. Calculate the sample size and specify the sampling procedure : Sample size is calculated by specifying the 'p', (or mean and SD), in respect of the main study variables and the acceptable deviation (d). (Refer to chapters on sample size and sampling methods). If there are more than 1 main study variable, calculate the sample size in respect

of all the main variables and study the largest calculated sample size.

6. Explicitly state any specific 'inclusion' or exclusion criteria: for example, you may make an exclusion criteria that "female blood donors will be excluded".
7. Give a detailed thought to your methods of 'measurement' and how you will obviate bias/ensure validity and reliability : Refer to chapter on measurements and validity for details. Preferably, write down entire methodology in a small "operations manual".
8. Pilot study : Do a pilot study on about 10% of the total sample size for pretesting your instruments, questionnaire and techniques (including interview methodology) and refine your methodology. Meet the relevant administrative authorities and seek their permission / clearance to do the study.
9. Conduct the data collection : Explain your study to the subjects; assure confidentiality; take informed consent. Keep supervising your data collectors and undertake various quality control steps.
10. Organize data management : Transfer the data recorded on the individual performae to master charts and if computer is available, from master chart to a standard computer package. Do not wait for the study to be completed before transferring the data to master chart and computer. Do this as a continuing process, say once a week. Meticulously check the performae / master charts for any missing data and get back to the subjects to get the information that is missing.
11. Analyse the data : Analysis of data in a descriptive study should be very clear, simple and appropriate. The following steps are generally undertaken :
 - (a) Calculate the "summary statistic" to describe the condition" - Depending on the scale on which the "target condition" is being measured, the "summary statistic" would be :
 - i) If the target condition is measured on categorical scale : The summary statistic would be a proportion, (percentage, if multiplied by 100). This proportion would be "prevalence" in case of a cross sectional descriptive study and "incidence" in case of longitudinal descriptive study.
 - ii) If target condition is being measured on numerical - continuous or numerical - discrete scale : For example, we may be trying to describe the serum LDL among patients of IHD (continuous variable) or number of children among households (discrete). In such exigencies, we will calculate the "mean" and Standard Deviation (SD). In addition, data on continuous and discrete variables can also be "categorized" into groups, by making frequency distribution tables.
 - iii) If target condition is measured on numerical - ordinal scale : E.g. we may be describing the APGAR score of children born in our hospital. The summary statistic in such cases will be the Median and Range.
 - (b) Calculate the 95% confidence intervals : The details of calculation of 95% CI have been explained in the section on biostatistics and this should be calculated to give an

estimate of the range in which the "reality" in the total, reference population is likely to lie.

- (c) Describe the data according to the selected variables related to person, place and time : This is a very important step as it is crucial for drawing conclusions and developing hypotheses. The key word is to make sensible "subgroups" of selected person, place and time related variables and calculate "subgroup specific summary statistic" for these selected variables.
- (d) Describe the data according to graphical methods like Bar diagram, histogram, time - curve, spot map etc. Intelligent use of the various methods, as described in the section on biostatistics, must be made to describe the distribution of the target condition, according to selected variables related to person, place and time.
12. Draw conclusion : See the statistical findings against the light of your clinical/health experience and draw conclusion and recommendations. Write down only the conclusions and recommendations that you have actually studied and not the ones that are simply based on your imaginations / assumptions. Finally, suggest one or more hypotheses that emerge out of your findings of the descriptive study.

Ecological Studies (Syn. Correlational Studies)

One of the very well quoted studies on women's health (60) obtained data from 20 developed countries from western Europe, USA, Australia, New Zealand and Eastern Asian regions. National data was obtained on per capita consumption of fats in diet as well as incidence of female breast cancer in these countries. The results very clearly showed that as the per capita consumption of fat in a country increased, the incidence of breast cancer also increased. This finding could compel us to finally agree that dietary fat is a risk factor for breast cancer. Should we finally accept this result and start making a policy on lowering the fat consumption to prevent breast cancer? Or is there some lacuna?

There is a lacuna - with this data, we do not know whether the individual subjects who developed breast cancer in these countries actually had high fat intake or not, because the data is an aggregate (group) data for the entire country. Thus, while the country as a whole may be having high incidence of breast cancer as well as high per capita consumption of dietary fats, it is also quite possible that those who actually develop breast cancer may be eating less amount of fat, while those who did not develop breast cancer were the ones who were eating more fats. All that we know is the mean value of fat consumption for each country as well as the incidence of breast cancer for each country; no consideration is given, as would have been expected in an ideal epidemiologic design, to obtain the presence or absence of breast cancer and the level of fat consumption of each individual. This fallacy, that we may be ascribing, to members of a group, a risk factor that they do not actually possess as an individual, is called "*ecological fallacy*" or "*ecological bias*", which is quite common in these studies. Ecological fallacy can be defined as the state when an association which has been seen among variables, on an aggregate level may not necessarily represent an association at

the individual level.

This problem actually occurs in an ecological study because we only have data for groups but we do not have exposure and outcome data for each individual in that group. This issue would become clearer with the following example : Let's say we wanted to undertake the fat consumption - breast cancer study as a typical epidemiological study, which could be either case - control, cohort or cross - sectional type. Let's choose cross - sectional type. We would have taken a sample of say, 10 lakh women, asked each and every woman about her dietary fat consumption history and also examined her to ascertain whether she has breast cancer or not. Thus, we would have got data on each and every cell (recapitulate the cells a, b, c, and d of the 2 X 2 table in chapter - 9), as per Table - 2. However, in an ecological study as presented above, we only have data on the total having exposure (i.e. a+b) and the total diseased (i.e. a + c) (Table - 3).

Table - 2 : Cross - sectional study

Exposure (Fat in diet)	Outcome (Breast cancer)		Total
	Present	Absent	
Present	(a) Y	(b) Y	a+b Y
Absent	(c) Y	(d) Y	c+d Y
Total	a+c Y	b+d Y	a+b+c+d Y

Table - 3 : Ecological study

Exposure (Fat in diet)	Outcome (Breast cancer)		Total
	Present	Absent	
Present	(a) N	(b) N	a+b Y
Absent	(c) N	(d) N	c+d N
Total	a+c Y	b+d N	a+b+c+d N

Index : Y = Data will be available in the study; N = Data will not be available

For the reason that the data is not complete, as explained above, ecological studies are also known as "incomplete designs". At this juncture, one may ask as to why don't the investigators obtain data from individual subjects as regards the individual level of fat consumption as well as ascertain from each of them whether they have breast cancer or not. The reason is simple - the investigators obtained data from the cancer registries of these countries as regards breast cancer incidence, and from the central marketing organizations of these countries as regards sale of edible fats. Both these type of data are easy to obtain and takes little logistic effort, especially when data has to be obtained over 20 different countries. Obtaining data from individuals for these two variables would have been an almost impossible task.

The question which arises, then, is whether ecological studies are of value, given the problem of "ecological fallacy"? The answer is, Yes, they are valuable. If there are suggestions from ecological studies about a cause - effect relationship, our hypothesis becomes more strong and we could then further

explore this issue by specifically designed studies, either case - control type or of the cohort type. Ecological studies are therefore valuable for opening up avenues of research and for further strengthening a possible cause - effect relationship which has been earlier developed by other descriptive studies, so that these hypothesis can be further explored by specific hypothesis testing studies. However, alone and by themselves, ecological studies do not give final proof of cause - effect relationship. In fact, some epidemiologists do not consider ecological studies as a part of the basic epidemiological designs but place them in a separate category of "incomplete designs", for reason enumerated above.

Ecological studies can be of two types, viz., cross - sectional and longitudinal. In a cross sectional ecological study, the association between variables is seen at a given point of time, as the example of breast cancer - dietary fat study given above. Longitudinal ecological studies, on the other hand, are usually a part of ongoing surveillance systems. For example, in USA, ongoing surveillance data on the incidence of malaria has been correlated with the return of large numbers of soldiers from abroad and it was shown that the upsurges in incidence during 1950s, 1960s and 1980s coincided with return of soldiers from Korea, Vietnam and increased immigration into USA, respectively.

Summary

Descriptive studies address only one group of subjects having the outcome of interest. There is no comparison group. Such studies do not have any pre - formed hypothesis. They may, however, generate a hypothesis at the end of the study, after studying the person, place and time distribution of the outcome of interest.

Different types of descriptive studies in increasing order of complexity are : case reports, case series, cross - sectional and longitudinal studies. Case reports and case series describe the signs and symptoms or other unique features such as a lab investigation, X - ray features, etc. in a single or a group of patients, treated or untreated. Since there is no information of the population at risk (denominator), nor a comparison group, neither can risk be calculated nor can a hypothesis be tested. Cross - sectional descriptive studies estimate prevalence only, as measurements are made only at one point in time, whereas longitudinal studies can record incidence, as well as study the natural history of disease or trends in health related phenomenon over time.

Person related factors are age, sex, ethnicity, socioeconomic status, marital status, family history, lifestyles, etc. Time distribution may show short term changes as in acute communicable diseases or long term changes (secular trends) as observed in most non communicable diseases. Time trends may be also seasonal (as observed in most vector borne diseases), or cyclical (e.g. measles outbreaks every 2 - 5 years before the era of vaccination). Place distribution may be international comparisons which may offer clue to etiology, or regional variations within countries. Diseases may also show rural - urban difference. Spot map can depict the place distribution of disease occurrence in defined localities.

In ecological studies the unit of measurement is undertaken

at the population level rather than at the individual level. This can lead to ecological fallacy or bias since the association seen at the aggregate level may not necessarily represent an association at the individual level.

Study Exercises

Study questions and chapter summary contributed by Amitav Banerjee

Long Questions : What are the merits and demerits of descriptive studies as compared to analytical studies. Enumerate the major person, place and time related variables which are usually presented in a descriptive study.

Short Notes : (1) Ecological fallacy (2) Epidemic curves (3) Secular trends (4) Twin studies (5) Migrant studies

MCQs & Exercises

- The following is the hypothetical data obtained year-wise, as regards the seroprevalence of HIV (per 1000) among truck drivers, obtained from the national serosurveillance system and also the number of states that had launched a condom promotion program for truck drivers

Year	Seropositivity	Number of States
1997	1.93	5
1998	1.87	7
1999	1.81	8
2000	1.82	8
2001	1.50	10
2002	1.47	12
2003	1.29	15
2004	1.10	18
2005	1.01	22

- What conclusions can you draw from the above data?
- What can be the fallacy in the above conclusion?
- What type of study design is the above study?
- Is the above design a descriptive or an analytical design?
- Besides the fallacy you have named in (b) above, what other bias could have happened?

- During a year, all consecutive full time normal births were studied in a teaching medical college hospital. Each infant's birth weight was measured, and at the same time, the mother's attendance at antenatal visits was ascertained from the records. The antenatal visits was classified into more frequent (i.e. > 3) and less frequent (3 or < 3). Analysis of data showed that

the mean birth weight of infants born to mothers who attended > 3 antenatal clinics was more than the mean birth weight of infants born to mothers who attended 3 or < 3 antenatal clinics. This difference was statistically significant.

- What type of study is this and why?
- What 'person - related' variables which are potential confounders should be adjusted for before we put forward the hypothesis that number of antenatal visits is related to birth weight?
- What other factors may affect birth weight?

- The following is age distribution of cases during an outbreak of viral hepatitis E in a hostel

Age group (Years)	Number of cases (%)
17 - 20	195 (73.58)
21 - 25	40 (15.09)
26 - 30	11 (4.15)
Above 30	19 (7.16)
Total	265 (100)

The above table shows that 195 or 73.58% of the cases were in the age group 17 - 20 years. Do we conclude from this data that Viral Hepatitis E is more common in this age group? Explain your answer with reasons.

Answers : (1) (a) A hypothesis can be considered that implementation of condom promotion program for truck drivers may be effective in reducing the HIV infection among them. (b) Ecological fallacy, since the data is reflective of "groups" or aggregates and not from individual truck drivers. (c) Ecological (Correlational) study design. (d) Neither descriptive nor analytic; it is classified as a separate category as "Incomplete Designs". (e) Effect of other factors cannot be studied; for example the reduction in seropositivity among truck drivers could have been due to an intensive health education programme so that the visits to CSWs came down rather than due to increasing use of condoms.

(2) (a) The study is cross - sectional because the cause i.e. number of antenatal visits and the outcome i.e. birth weight are measured at the same time. (b) Potential confounders such as socioeconomic status should be adjusted for since mothers with better socioeconomic status are more likely to have more number of antenatal visits as well as higher birth weight of their infants because of associated factors such as better nutrition during pregnancy. (c) Other variables such as tobacco use, maternal disease, etc. may also affect birth weight.

(3) No we cannot conclude that the disease is more common in this age group as we do not have the denominators or population at risk in each age group.

RajVir Bhalwar

We have already deliberated on the situations in which a medical researcher should select the case control design to answer her research question. The case control design is one of the finest and easiest methods of analytical research available to the doctor who has an easy access to patients of a particular disease admitted to the hospitals. At the same time, case control studies may be considered as the “Acid Test” for the capabilities of an epidemiologist and seasoned researcher because of the high potential for ‘bias’ that they have.

Definition : A case control study is defined as an epidemiological approach in which the researcher starts by picking up ‘cases’ who have already developed a particular disease or ‘outcome’ of interest, and a comparison group (controls) of subjects who, except for the fact that they have not developed the particular disease, are otherwise similar to the cases. Having assembled the two groups, the investigator finds out the presence (or the history) of the particular ‘exposure’ which she thinks is a risk factor and compares the two groups (cases and controls) as regards the presence (or history) of exposure.

The case control study has a special value in epidemiology and medical research because of the special advantages that it offers. However, the method carries certain distinct disadvantages and the researcher choosing this design must remain careful to take preventive action against them (see Box - 1).

Box - 1 : Case - Control Studies

Advantages

- Inexpensive, requires only a few subjects gives quick results
- Well suited for diseases which have a long latent period (e.g. cancers, AIDS, MI, CVA etc.)
- Well suited for an outcome which is ‘rare’
- Well suited for conditions in which medical care is usually sought
- Helps in examining multiple etiologic factors - once we have the cases of the disease, we can take history of all the factors that we feel may be risk factors
- Reasonably good for diseases that have a “relatively rapid onset” and are usually hospitalised (e.g. most of the acute infections; injuries etc.)

Disadvantages

- Not a good method for studying rare ‘exposures’
- Does not give any idea of ‘incidence’ or ‘prevalence’; it only gives us a measure of Odds Ratio (OR)
- Particularly prone to various forms of selection and information biases, particularly survivorship Bias, Recall Bias and observer’s bias.
- ‘Temporal Relationship’ is usually only a matter of conjecture but not a proof

Designing and Conducting a Case Control Study

Step 1 - Specify the total population and actual (study) population : Specification of actual (study) population at this stage becomes especially important as it will give us an idea of the “population” from which cases have come and thus we would be able to ensure that our controls should also represent the same population, (an essential requirement of a case control study).

Step 2 - Specify the major study variables and their ‘scales’ of measurement:

- *Outcome variable :* In case control study this will be the particular disease or outcome of interest. Most of the times this will be measured on a ‘dichotomous’ scale (i.e. disease present = cases, and disease absent = controls).
- *Exposure variable(s) :* This is the suspected ‘cause’ that the investigator is studying for the association with the disease under study.
- Specify the scales of measurement of the exposure variable - usually it is dichotomous (exposure present or absent).
- *Potential Confounding Factors (PCF) :* List out all the PCF by thorough reading of the literature and discussion with experts. Specify the ‘scales’ of measurement.

Step 3 - Calculate the sample size : The details have been discussed in the section on Biostatistics.

Step 4 - Specify the selection criteria of cases as per following headings :

- *Diagnostic criteria :* Enunciate clear cut diagnostic criteria for the disease of interest. As far as possible use criteria given by expert bodies. If there is doubt, make categories like “definite”, “probable” and “possible” and analyse them separately.
- *State the inclusion or exclusion criteria :* One of the central issues in a case control study is that cases should have had a reasonable possibility of the disease being induced by the suspected exposure; and that the controls should have had a “reasonable chance” of being exposed to the exposure. This leads to the fact that any case or control who does not meet these criteria should be excluded from the study. E.g. in a study of recent OC use (exposure) and TE (outcome) we would like to exclude “TE cases occurring postpartum/ during pregnancy / post operatively/ post menopausal ladies / ladies on other contraceptives / hysterectomised ladies”. One thing the worker must ensure is that the exclusion / inclusion criteria should be clearly defined and must equally apply to cases as well as controls.
- *Source of cases :* The usual source of the cases is “hospital”. However, for diseases for which a large number of subjects may not be admitted (low backache; anal fissure etc.), the researcher must tap the OPDs, General practitioners or even think of population based cases by searching them in the population.
- *Incident or prevalent cases :* Specify whether you would like to consider only the newly occurring (incident) cases or all those who are already present including the old cases (prevalent). It is always advisable to take the incident cases since the prevalent cases might have changed their exposure status due to medical advice etc.

- *Method of sampling* : The most common method of sampling is either to take a systematic random sample of cases as they keep reporting; alternatively, if all the cases have already collected and a detailed list is available, a simple random sample may be drawn.

Step 5 - Specify the selection procedure of controls : One of the most important issues in a case control study is the selection of controls. The following specifications are to be made :

- *Source of Controls* : Whether Hospital based or else Population based controls : Patients admitted to the same hospital for diseases other than the one under study can be used as controls. They are easy to obtain, cooperative, and more likely to remember the exposure. The disadvantage is that they do not represent the healthy population and being ill, may be different from the healthy persons in number of ways. While selecting hospital controls, the best is to take a diagnostic assortment, i.e. patients from various diagnostic categories. On the other hand, healthy controls from the population would give a very good comparison provided it is logistically possible to study them and provided that they represent the same source population that gave rise to cases. The difficulties are that they are expensive and may refuse to participate.
- *Exclusion / Inclusion criteria* : The same criteria as for cases should equally apply.
- *Number of controls per case* : In general, 1 control per case is studied. The number of controls per case may be increased to upto 4 or 5 per case with slight increase in statistical precision but the cost of the study will increase tremendously. In any case the number of controls should never be less than the cases.
- *Number of control groups* : Usually, one “control group” is studied. However, if feasible, the worker may study 2 different control groups (e.g. one from population and another group from hospital); the procedure will improve the validity of the results.
- *Matching* : The details of ‘matching’ have already been explained in the chapter on control of confounding. In general, in a case control study it is recommended that one must carefully list out all the PCF; match for the universal confounders, i.e. age (in broad categories of 5 or 10 years of age groups) and sex, using frequency (group) matching. Record the data on all other PCF and adjust for confounding during analysis.

Step 6 - Specify the procedures of measurement and specially take care to ensure validity and reliability : The biggest disadvantage of a case control study is its particular susceptibility to various forms of selection and information biases. The detailed methods of prevention of bias and ensuring validity and reliability have been presented in chapter on confounding and bias. A summary is given in box - 2. In addition, quite often the investigator would be using a questionnaire in a case control study. The guidelines for preparation of questionnaires have been given in an earlier chapter.

Step 7 - Do a pilot study : Pre-testing on 5 - 10 cases and controls would be adequate in most situations to refine the methodology. If major changes are made following the results

of pilot study, then do not include the pilot study cases and controls in the analysis.

Step 8 - Conduct the study : Ensure valid collection of data, as described under the details of making measurements.

Step 9 - Analysis of data : Calculate the Odds Ratio (OR) and its 95% Confidence Interval (95% CI). Undertake hypothesis testing as described in the chapter on Biostatistics. Usually it will be a chi - square for 2X2 table or at times, a chi - square for linear trends in proportions. At times there may be requirement of a ‘t’ test instead of chi - square test, depending on the way the variables have been measured. Control of confounding will require stratified analysis using Mantel - Haenszel technique or a multiple logistic regression. The details are described in the section on Biostatistics. If the data is from a “Pair matched” study, use McNemar’s procedure for calculating chi square and odds ratio (OR) and 95% CI of OR. Consult a research methodologist for assistance.

Summary

Planning, Design, Conduct & Analysis of a Case - Control Study

- Review your research question and confirm that case - control study is the right design (you should be studying a risk factor and not any prevention / treatment / diagnostic/ prognostic factor.
- Specify the outcome, exposure and confounding variables.
- Specify the “reference” and “actual” populations.
- Specify the inclusion and exclusion criteria; apply them equally to cases and controls.
- Specify the selection modality for cases :
 - Diagnostic criteria for cases / case - definitions.
 - Source (hospital, OPD, or population based).
 - Sample size for cases
 - Procedure for sampling the cases
 - Incident (new) or prevalent (old & new) cases.
- Specify the selection procedure for controls :
 - Source of controls (healthy population based or hospital based)
 - No. of controls
 - No. of control groups
 - Method of sampling the controls
 - Matching, if considered.
- Specify the methods of measurement of various variables.
- Set up checks for obviating “biases” :
 - Ensure that controls are derived from same source population from which cases have come.
 - Ensure that controls have same chances of getting the exposure as cases had.
 - See if there is any problem of survivorship.
 - Avoid recall bias
 - If possible, blind the observers to case / control status.
 - If possible, use multiple sources of information and make “unobtrusive” measurements
- Do a pilot study on 5 to 10 cases and controls.

Box - 2 : Biases in a case - control study (See chapter on Bias for details of examples quoted herewith)
Selection Biases
Berksonian Bias : The probability of admission to hospital or detection of the outcome (disease) may be more among the cases simply because of the exposure. See example on unduly high chances of detection of cervical cancer (outcome) among OC users (exposure).
Selection of inappropriate Cases or Controls : Cases or controls who do not have adequate chance of exposure. For example, in a study of OC use (exposure) and thrombophlebitis (outcome), cases or controls who have undergone hysterectomy or using some other contraceptive, will not have adequate chances of exposure.
Self selection Bias : Patients who are admitted to a particular hospital and hence taken as cases may be systematically very different from most of the patients with the disease but who are not admitted to that hospital, as regards the exposure status.
Survivorship Bias : Case control study generally takes the patients who are living. Cases who have died are generally not taken and these may be systematically very different from living case as regards the exposure status (see example on Physical exercise and Acute MI).
Incidence Prevalence Bias : Cases who have been prevalent for long may have changed their exposure status due to medical advise or symptoms of disease (see examples on IBD and dietary fibre and hypertension and physical exercise).
Selection of wrong control group : Controls who are not from the same source population from where the cases have come; selection of close friends of cases - since they would in general have the same behavioural factors as cases (birds of a feather flock together !); or example of condom use and STDs given in the chapter on validity.
Information (measurement) Biases
Recall bias : Cases who are suffering from a disease are likely to recall much more as regards their exposure (example on congenital malformation and exposure to X - rays).
Observer bias : If observer is aware of the case - control status, she may subconsciously tend to ask much more from cases.
Confounding Bias
This is an important issue in case - control study (see chapter on confounding).
Bias due to lack of evidence on temporality

- Conduct the study.
- Statistical analysis
- Calculate Odds Ratio (OR) as $(a \times d) / (b \times c)$ and not the Relative Risk (RR)
- Calculate 95% CI of OR
- Do a Chi - square test for hypothesis testing, or a 't' test, depending on scale of measurement.
 - For control of confounding, undertake stratified analysis using "Mantel - Haenszel" method.
 - For many confounders, undertake multiple logistic regression analysis.
- Make interpretations : specifically see if "temporal relation" can be shown; is there any possibility of bias remaining; have all potential confounders been identified and controlled.

Study Exercises

Study questions contributed by Amitav Banerjee

Long Question : Enumerate the advantages and disadvantages of case control studies. Discuss, in detail, the various biases that can occur in a case control study and the methods of preventing them.

Short Notes : (1) Measurement of outcome in a case control study (2) Compare and contrast Case control study with Cohort study.

MCQs & Exercises

1. Case control studies are : (a) Forward looking studies (b) Backward looking (c) Can be both backward looking and forward looking (d) Same as cross - sectional studies
2. All of the following are true about case - control studies Except : (a) Both exposure and outcome has occurred before start of the study (b) Study progresses backwards from outcome to exposure (c) Uses control group for testing hypotheses (d) Loss to follow up (attrition) is the main disadvantage.
3. Berkson's bias refers to : (a) Interviewer's bias (b) Recall bias (c) Bias due to different rates of admission to hospitals for those who have more than one disease (d) None of the above.
4. Odds ratio is a measure of : (a) Confounding (b) Strength of association (c) Attributable risk (d) Burden of disease
5. Which of the following is the most problematic in conduct of case control studies : (a) Time (b) Cost (c) Attrition (d) Selection of appropriate controls
6. All are true about case - control studies Except : (a) Risk factors can be identified (b) It measures incidence (c) Used for rare diseases (d) Takes less time
7. In planning a case control study to test the hypothesis whether a person with a family history of breast cancer has higher risk of developing breast cancer : (a) How will you select the cases? (b) How will you select the controls? Can

you take controls from the same family? (c) How will you measure family history of breast cancer? What can be the bias in this method? (d) How will you measure the strength of association and what statistical test of significance can you apply? (e) How will you deal with confounders?

Answers : (1) b; (2) d; (3) c; (4) b; (5) d; (6) b; (7) (a) Cases can be selected from malignant disease hospital or a cancer registry. (b) Controls should be selected from the general population in the catchment area of that hospital or cancer registry. They should be matched for potential confounders such as age, age at first pregnancy, lactation, etc. Family control could not be selected in this case as this will lead to 'overmatching' i.e. predictor variable of interest (family history) will also be matched masking the association, if any. (c) Family history of breast cancer can be elicited from interview of cases and

controls. There may be information bias in form of "recall bias" if cases recollect positive history more vividly than the controls. Another form of information bias can be observer bias, in case the observer elicits the history more persuasively from the cases than from the controls. To some extent, these biases can be minimized by masking the status of cases and controls from the observer and the study question from the respondents. (d) Strength of association should be measured by odds ratio with 95% confidence intervals after tabulation of the data in the 2x2 table. Chi square test can also be performed. (e) Confounders can be dealt with by matching during the planning stage. During analysis, they can be adjusted for by stratified analysis (Mantel - Haenszel) or by multiple logistic regression.

25 Cross - Sectional Analytic Studies

RajVir Bhalwar

The case control study is a very practical and quick method of ascertaining the association between (and indirectly estimating the risk due to) a suspected exposure (cause) and an outcome (effect), when both the cause and effect have already occurred and one has to go back retrospectively, tracing the history of exposure among the cases and controls. However, under the following situations, the case control design may not suit the needs of the investigator :

- If cases of the disease are not likely to be admitted, since the disease is perceived to be a "routine" illness; e.g. influenza, sore throat, scabies, dental caries, pediculosis, pyoderma and so on.
- If the disease has a "wide clinical spectrum" so that a large number of cases who are from the milder part of the spectrum may not come to the hospital, e.g. low backache, anal fissure etc.
- When the objective is not to study the cause of a disease but rather the cause of a health related phenomena and hence the subjects have to be obtained from the general population and not from the admitted patients from a hospital; e.g. Is the "health awareness regarding use of contraceptives" (exposure) more among the users of contraceptive (cases) as compared to non users (controls); or "Is tobacco smoking by adult males (cases) related to the history of their father being smoking (exposure)".
- When the objective is to see the "correlation" between two continuously distributed variables either in the hospital settings (e.g. In a group of diabetics, is serum cholesterol related to blood sugar?) or in the settings of healthy

community subjects (e.g. in the general population of adult males, is waist : hip ratio correlated with HDL : LDL ratio).

In all the above settings, the investigator cannot proceed starting with cases and controls. Instead, he has to take a 'sample' of subjects from the study population and then search for the presence or absence of the disease (e.g. anal fissure, sore throat etc.) or the attribute (presence or absence of adequate knowledge regarding contraceptives) or make readings about the two continuously distributed phenomena (e.g. collect data on serum cholesterol & blood sugar, or waist : hip and LDL : HDL) from each and every subject.

The above instances, when the investigator draws a 'sample' out of the study population of interest, and examines all the subjects to detect those having the disease / outcome and those not having this outcome of interest; and also, at the same time finds out whether or not they have the presence of the suspected cause (exposure) (or give a History of such an exposure in the past), is called the "Cross sectional analytic study". It is so named since it is like cutting a "cross section" of a sample of the study population and ascertaining the presence/ absence of both the exposure and the outcome at a single, given point of time.

This form of study differs from the case control study in that in a case control study the investigator starts with a group of subjects already diagnosed to be having the disease (or health outcome) of interest and picks up a comparison group (of usually equal number) of controls (presumed to be coming from the "same source population that gave rise to cases") and compares the two groups regarding the presence (or history) of the suspected exposure. On the other hand in a cross sectional analytic study, the investigator starts with a "sample" of subjects and then finds out who in this sample have the disease (or the health related outcome) of interest and who do not have

it, as well as finds out, at the same time, whether or not they have the exposure (or give a history of exposure).

The Cross-Sectional Study Design has Certain Additional Distinct Advantages over a Case-Control Study :

- (a) Since the subjects having the disease (or the health related outcome) of interest, i.e. the cases, as well as those not having it, i.e. the controls, are derived from the same 'sample', one is definite that the controls represent the same source population that gave rise to cases (a requirement which is mandatory for the validity of case - control studies but, however, many a times the investigator is never really sure that this assumption holds good or not).
- (b) While in a case control study one does not get any idea of either the incidence or the prevalence, in a cross - sectional analytic study, one straightaway gets the prevalence of the disease or outcome of interest, e.g. in the preceding example, the prevalence of scabies is $100/1000 = 10\%$ in the population; one also gets an idea of the prevalence of the exposure of interest, e.g. the prevalence of "wrong apprehensions" about Tubectomy / vasectomy is $770/1000 = 77\%$ in the population.
- (c) Having worked out the 'prevalence', one is really sure whether the disease or outcome of interest is really a 'rare' one or not (an assumption central to the validity of the odds ratio (OR) from a case control study being a valid estimator of risk; however once again the investigator is often not sure in a case control study whether this is really so or not).
- (d) The investigator can study "correlations" between two "continuously distributed phenomena" (e.g. Blood sugar and serum cholesterol; waist; Hip ratio and LDL : HDL ratio) - an objective which cannot be fulfilled in a case control study.
- (e) The cross - sectional analytic study at many times can be used as the starting point of a cohort study (which can not be achieved in a case control study). For example, having identified the 'acceptors' and 'non acceptors' of vasectomy/tubectomy, the investigator can now follow up these 2 groups (taking acceptors as 'exposed' and non acceptors as 'non exposed' groups from now), and compare the rate of certain given medical complications (e.g. low backache, neurosis etc.) in the 2 groups.

The Advantages of a Cross-Sectional Analytic Study over Case-Control Study come at the Cost of Certain Disadvantages :

- (a) The investigator has to take a much larger sample; e.g. for studying the association between Lung CA and smoking, the investigator may need to examine about 1 million healthy subjects to get 100 cases; on the other hand for the same objective to be fulfilled by a case control study, the investigator needs to collect 100 cases from a cancer hospital and another 100 controls - just 200 subjects would suffice.
- (b) In addition to the large number of subjects, the logistic support needed for diagnostic work up would be tremendous - imagine a large number of specialist Doctors and their diagnostic back up equipment moving around in

the community, examining one million persons !

When to Use the Cross-Sectional Analytic Study ?

Keeping in view the advantages and disadvantages of the cross sectional analytic design versus case control method, it is recommended that when the investigator is faced, as her research objective with any of the four situations (a) to (d) mentioned on the first page of this chapter, she should consider using the cross - sectional analytic approach.

If there is a 'Cross-Sectional Analytic', then there should be a 'Longitudinal Analytic' Design also !

Yes, the 'Cohort study' and the 'experimental studies' are what we can call "longitudinal analytical studies", studying the exposure - outcome relationship by starting from the exposure (or cause), following up the subjects (i.e. moving longitudinally) and finally assessing the development of outcome of interest.

Steps in conducting a Cross-Sectional Analytical Study

Step 1 : State your research question, research hypothesis, objectives, and background significance of the research question.

Step 2 : Define the "Total (whole, reference) population" on which the study results will be applicable; and the "actual (study) population from which the sample will be drawn. The "actual (study) population" may be hospitalized patients or general community. Ensure that the actual population is a "representative subset" of the total population.

Step 3 - Specify your study variables and the 'scales' of measurements :

(a) **Outcome variable :** This may be dichotomous (e.g. low backache present or absent) or polychotomous ordinal (normal, mild backache, moderate, severe) or continuous (Blood pressure, Serum cholesterol etc.) or discrete (e.g. number of DMF teeth) or ordinal (satisfaction scores regarding health services, minus 2 as very dissatisfied, minus1 as slightly dissatisfied, 0 as neutral, +1 as slightly satisfied, +2 as highly satisfied).

(b) **Exposure variable :** Once again, the exposure variable may be measured on any of the scales mentioned under outcome variable. One has to intelligently decide this, based on the research question and objectives, as to what she really wants to study.

(c) **PCF :** Make a detailed list of all the variables that can confound the exposure - outcome relationship and specify the scales of their measurement - usually the scale would be dichotomous (e.g. smoking present / absent) or polychotomous (cigarette smoking categories) : non smoker / mild smoker (0 - 10 per day) / moderate (10 - 20) / Heavy (>20). If the purpose of research is to see the correlation between two continuous variables (e.g. between waist : hip ratio and LDL : HDL ratio), one may decide to measure certain confounders either on a continuous scale (e.g. Body Mass Index, Alcohol intake etc.), or on a discrete scale (e.g. no. of days on which physical exercise is done in a week).

Step 4 - Calculate the sample size : For example, we may be doing a cross sectional research with the objective of seeing the association between veg or non veg diet (exposure) and presence

or absence of anal fissure (outcome), the outcome being measured on a dichotomous scale. The general equation for calculating the number of cases required to be studied will be (see chapter on sample size calculation and case control studies for use of this equation).

$$\frac{(z_{1-\alpha/2} + z_{1-\beta})^2 \times 2 \times p \times q}{(P_1 - P_0)^2}$$

Now if the number of cases calculated by the above equation comes out to be 100; and say, the expected prevalence of the disease is 10%, i.e. 0.1, then the total sample size required for the cross sectional study

$$= \frac{\text{No. of cases required}}{\text{Prevalence}} = \frac{100}{0.1} = 1000$$

Thus, we will need a sample of 1000 subjects to do this study, in which we will get about 100 cases and 900 controls.

Step 5 - Describe the sampling method : Having determined the sample size, the investigator has to specify the method to choose a random, representative sample. In a hospital based cross - sectional analytic study the advisable method is to draw a systematic random sample or a consecutive sample. In a community based study with large population of subjects, it is usually advisable to go in for a multistage sampling, selecting randomly, administrative or geographical units in the first and second stages and finally drawing a systematic random sample of subjects from the selected units (See chapter on sampling methods).

Step 6 - Ensure validity and reliability, prevent bias : Thorough consideration must be given to these aspects before starting the data collection. In general, the checklist which has been given in the chapter on case - control studies for prevention of bias applies equally well for cross sectional studies and should be checked meticulously.

Step 7 - Data Collection : Collect the data on a predesigned form. Ensure that before you start the data collection, you have undertaken a pilot study on a sample of 10% of the total required sample (5% in case of large sample studies) for validating and standardizing all your instruments, questionnaire and techniques. During the data collection of the actual study, frequently examine your performae for any missing data and get back to the subjects if there is any missing data, at the earliest. If data collection is being done by different data collectors, cross check at least 20% of the filled performae independently for ensuring quality control of data and reducing observer variations. Enter data into Master chart or computer periodically and at an early date.

Step 8 - Analysis of data : The various procedures of analysis are the same as explained in the previous chapter on case - control studies, viz., calculation of OR and statistical hypothesis testing by chi - square test (or a 't' test if either the exposure or the outcome variable has been recorded on a numerical scale). In case both the exposure as well as the outcome variable have been recorded on numerical scale, then correlation coefficient is calculated. Control of confounding is undertaken by Mantel - Haenszel stratified analysis, or else by regression analysis if

there are a large number of confounding variables.

Summary

The case control study is a practical and quick method of ascertaining the association between a suspected exposure (cause) and an outcome (effect), when both have already occurred. However, it may not suit the requirement of investigator under certain conditions like if cases of the disease are not likely to be admitted, if the disease has a "wide clinical spectrum", when the objective is not to study the cause of a disease but rather a health related phenomena and hence the subjects have to be obtained from the general population and not from the admitted patients from a hospital or if the objective is to see the "correlation" between two continuously distributed variables either in the hospital settings or in the settings of healthy community subjects. In such settings the investigator cannot proceed starting with cases and controls. Instead, he has to take a 'sample' of subjects from the study population. This kind of study is known as "cross sectional analytic study". It is so named since it is like cutting a "cross section" of a sample of the study population and ascertaining the presence or absence of both the exposure as well as the outcome at a single, given point of time.

The cross - sectional study has certain distinct advantages over a case - control study in that one is definite that the controls represent the same source population that gave rise to cases; also, it gives an idea about the prevalence of the disease of interest and hence we can find out whether the disease is rare or not, both of which are essential assumptions for the Odds Ratio. It can also be taken as the starting point of cohort study. Disadvantages are larger sample size and huge logistic support required.

In a cross sectional analytic study, each subject is examined only once and the assessment regarding the presence or absence of exposure as well as regards the disease in each subject is made at this single point of time. This design gives us the 'prevalence' and, as a measure of risk, the 'Prevalence Odds Ratio' (POR). It remains prone to the problem of recall bias, survivorship bias and the difficulty in proving temporal relationship.

For conducting cross sectional analytic study enlist outcome variable, exposure variable and potential confounding factor and their scale of measurement in actual study population. Sample taken should be of adequate size and representative of actual population. Data should be collected on above mentioned variable and analyzed by relevant statistical test. The measure of risk calculated from the cross sectional analytic study is the Odds ratio which is calculated as the cross - product ratio, as for a case control study.

Study Exercises

Long Question : Describe the steps in planning, conduct and analysis of a cross - sectional analytic study to answer the question "Drinking hard water is likely to be protective against systemic hypertension".

Short Notes : (1) Biases in cross sectional analytic studies
(2) Cross sectional versus longitudinal analytic studies
(3) Sample size calculation in a cross sectional analytic study.

MCQs & Exercises

1. What does cross sectional study give as a measure of risk?
(a) Prevalence odds ratio, (b) Risk odds ratio (c) Exposure odds ratio (d) None of the above
2. When we want to study the “correlation” between two continuously distributed variables either in the hospital settings or in the settings of healthy community subjects, the design used is (a) Cohort study (b) Case control study (c) Cross sectional analytic study (d) None of the above
3. The disadvantages of cross sectional study vis a vis case control study are (a) Huge logistics (b) Large sample size (c) Both (d) None of the above
4. Cross sectional study gives (a) Incidence of the disease (b) Infectivity of the disease (c) Prevalence of the disease (d) None of the above
5. All these bias are present in cross sectional study except
(a) Recall bias (b) Hospital related bias (c) Survivorship bias (d) Measurement bias

True or false

6. In longitudinal analytic study each subject is examined only once.
7. In Cross sectional analytic study each subject is examined more than once.
8. Cross sectional analytic study gives incidence of the disease.
9. In cross sectional analytic study exposure and outcome are measured in subjects simultaneously.

Answers : (1) a; (2) c; (3) c; (4) c; (5) b;(6) F; (7) F; (8) F; (9) T

Cohort Studies

RajVir Bhalwar

As discussed earlier, a major disadvantage of case control study is that it is prone to various types of selection and information biases. Some of the major problems of case control study are overcome by cohort study, though by paying a higher cost and tremendous increase in logistic effort.

A ‘cohort’ means a group of people sharing a common exposure. In this study, the investigator starts by picking up two comparable groups, one having the exposure (e.g. tobacco users) and the other not having the exposure (e.g. non users of tobacco). She then excludes the presence of the outcome of interest (e.g. lung CA) in both the groups at the start of the study, and then follows up both the groups for a reasonable amount of time, observing for the outcome of interest in both the groups and finally makes comparison as regards incidence of the outcome in the two groups. The cohort study has certain major advantages in medical research.

When to Select a Cohort Design

The cohort design should therefore be undertaken if the answer to the following question is “Yes” :

- Is the disease a reasonably common one?
- Is the follow up period required “reasonably short”, so that you can conveniently complete the study within the time frame?
- Has some amount of evidence regarding the association between exposure and outcome been provided by case control studies?
- Are the subjects in your two groups (exposed and not exposed) reasonably likely to continue in the study?

- Are you sure you are studying risk factors / markers/ prognostic factors and not therapeutic/ preventive/ diagnostic procedures?

Steps in Designing, Conducting and Analysing a Cohort Design

Step 1 : Specify the research question, objectives and background significance.

Step 2 : Specify the variables of interest and their scales of measurement

- *Exposure variable* - Usually in a cohort study the exposure variable is measured on a ‘dichotomous scale’ (i.e. exposed or not exposed), or at times on a ‘polychotomous ordinal scale’ (not exposed, slightly exposed, moderately exposed, intensely exposed etc.).
- *Outcome variable* - The outcome variable would be the disease or other health related outcome which the investigator hypothesizes to occur as a result of the exposure. The outcome may be dichotomous (e.g. developed/did not develop lung CA) or polychotomous ordinal (remained normotensive/ developed mild hypertension / developed moderate hypertension / developed severe hypertension) or quantitative (e.g. serum cholesterol levels, no. of DMF teeth, score of respiratory disability 0,1,2,3 due to occupational exposure).
- *PCF* : Make an intensive search of the literature and contact the experts to find out all the variables that could be potential confounders of the exposure - outcome relationship. And record the data regarding confounders during the study.

Step 3 - Specify the exclusion criteria : e.g. we may like to restrict the study to males with a view to control confounding due to sex, or exclude such subjects who are likely to be lost to follow up or subjects with a disease which may interfere with

the occurrence of outcome of our interest.

Step 4 - Calculate the sample size : The details have been discussed in the section on Biostatistics and “use of Statistical software”. The researcher would need to specify the magnitude of acceptable type - 1 and 2 errors, the expected proportion of non - exposed cohort who are likely to develop the outcome (Po) and the magnitude of risk (RR) that the study desires to detect in a significant manner.

Step 5 - Select the study cohort : The study cohort is the one which has the ‘exposure’. This may be either *Special Exposure Groups* (e.g. radiologists for studies on effect of radiation; ANC cases having PIH for studying the outcome of pregnancy, etc.); or else it could be *Cohort defined on basis of geographical or administrative boundaries* (e.g. people living in a given state or district like Framingham heart study). The special advantage of such cohort is that the same group will give an exposed as well as unexposed (comparison) cohort; e.g. for the study on association of smoking during pregnancy (exposure) and low birth weight (outcome), all patients enrolled at an ANC may be followed up. This group will give, within itself, an exposed cohort (smokers) and an unexposed cohort (non - smokers). Thirdly, we may select a study cohort from *Groups offering special resources* (e.g. all registered doctors can be followed up for development of IHD after recording their physical activity levels. They will give special advantage of an accurate reporting as well as ease of follow up).

Step 6 - Select the comparison cohort : This is very important. It can be done by either selecting an “inbuilt comparison group” as in example given in step 5 above. This is, in fact, the best method of obtaining a comparison group in general, in the usual settings of clinical research. Secondly, we may make comparisons with general population rates, often done in study of diseases due to occupational exposures. Finally, if required, we may assemble a special comparison cohort - e.g. in a study of the association between exposure to petroleum fumes and subsequent bone marrow damage, workers handling the filling equipment at petrol pumps may be taken as exposed cohort while workers sitting in the offices or ancillary workers in the same petrol pumps may be taken as the specially assembled comparison cohort.

Step 7 - Specify the sampling procedure : The usual method of sampling in both the exposed and unexposed cohort groups is by simple random or by systematic random sampling method. Select about 20% extra subjects, because some will be removed on initial medical examination as already having the outcome and some will be lost to follow up.

Step 8 - Exclude the disease or outcome of interest in both the exposed and unexposed cohort groups at the outset : Do an initial medical examination to exclude out all those subjects, in both the cohort groups, who already have the disease (or outcome) of interest.

Step 9 - Obtain data on exposure level : This is an extremely important issue. We obtain this data by various methods, including *Direct interview of cohort members* (e.g. details of smoking, alcohol, sexual activities, personal habits, dietary information, physical exercise, personality type etc.); secondly, by *medical examinations or diagnostic procedures* by examining

both (exposed as well as non - exposed) groups similarly; thirdly, by measures of environment - (e.g. levels of pollutants in home environment, drinking water pollution levels etc.); and fourthly by going through existing “records” (e.g. for recording the levels of exposure to irradiation, use of drugs, etc. medical records can be used. Initial medical examination card at the time of entry to school or service can provide valuable details of an exposure).

Step 10 - Obtain Data on all PCF : Using methods as described in step 9 above, record detailed data on all the potential confounding factors.

Step 11 - Consider matching : Usually, in a cohort study, matching is not important; Data should be collected for all PCF and adjustment for confounding may be made during analysis. However, if considered feasible, the exposed and non exposed cohort groups may be “frequency matched” in respect of important confounders like - age, sex or other important PCF.

Step 12 - Follow up and ascertainment of ‘outcome’ of interest : Follow up should be meticulously undertaken for the period already decided. Due attention should be paid while making measurements for detecting the outcome of interest. The general measures for ensuring validity and reliability have already been detailed in chapter no. 1. In addition, special attention should be paid to the following types of measurement biases that can crop up in the cohort studies :

- *Measurement (Ascertainment) bias* : This would occur because of ‘differential ascertainment’ of the outcome between the two groups. For obviating this, inform all subjects of both groups well in advance of the dates and timings of medical examination and ensure that both the groups are examined by observers who have similar type of training and using similar type of instruments and techniques.
- *Observer bias* : This occurs because the investigator is aware about the fact as to which subject is ‘exposed’ and who is not exposed. For obviating this, if possible, ‘blind’ the observer to the exposure status, the details of exposure being known only to another co - worker who is, himself, not making any observation regarding ascertainment of outcome.
- *Cross over bias* : This may happen because those having the exposure (e.g. smokers) may cross over to the non exposed group (i.e. become non smokers) and vice versa. Periodic evaluation of both the groups as regards level of exposure, making record entries and subsequent adjustments in the data analysis can help overcoming this problem.
- *‘Loss to follow up’ bias* : Some subjects in any case are likely to be lost to follow up / drop out. However, at times it may become a substantial problem. It is generally accepted that if more than 30% of the study subjects are lost to follow up, then the results of the study are to be viewed skeptically. The following step help in overcoming this type of bias :
 - Take detailed addresses of the subjects as also of their friends and relatives; contact them and make best of efforts to trace those who have been lost to follow up.
 - If the subjects have migrated, try to get information about them through a mailed questionnaire. If they

have died, try and obtain information from medical records and death certificates.

- Do an analysis in respect of certain demographic variables (e.g. age, sex, education, general health status etc.) to see whether those who have been lost to follow up are similar or else quite different from those who have remained in the study.

Step 13 - Analysis : In a cohort study we would calculate the relative risk (RR) as (incidence among exposed divided by incidence among non - exposed), the 95% confidence interval of RR, and hypothesis testing, using a chi - square test or a 't' test or such other relevant procedure as described in the section on Biostatistics.

Certain Special Types of Cohort Studies

Retrospective cohort studies : The investigator identifies a group of individuals based on their characteristics in the past and reconstructs their subsequent disease experiences upto some defined time in the more recent past; e.g. in a study, all military persons who were exposed to "agent orange" many years back during wartime were identified on the basis of records, along with another similar group of soldiers who were not exposed to this agent. Both these groups so identified on the basis of records were then traced forward till the more recent past for various organ / system diseases. This type of study thus differs from the usual prospective cohort study (as described above) in which the cohort is identified on the basis of current characteristics and then followed forward in time.

Nested cohort (Syn - Nested case control) study : Combines the advantages of a cohort and a case control study. The investigator identifies a cohort and follows it up for the required period of time, after recording details of exposure in the subjects. As the cases of disease keep occurring, the investigator keeps picking up these cases along with equal number of controls from the same cohort and compares them for the exposure history. As an example, we may be working on a hypothesis that high serum lithium levels are a cause of subsequent mental illness. The problem is that undertaking serum lithium analysis may be a very costly affair; however, blood samples can be preserved for 15 - 20 years. So, we can take a cohort of say 1000 persons who are free of mental disease, collect their blood sample, cold preserve them and watch for 15 - 20 years. Over this period if 20 cases of mental disease occur, we can take out their blood samples along with 20 randomly selected samples of those who have not developed mental illness (controls who are "nested" in the cohort), analyse these 40 samples for serum lithium and make comparisons between the two groups (who developed mental illness and did not develop it) as regards lithium levels. The tremendous advantages that have occurred are that firstly, instead of doing 1000 serum lithium tests (as we would have done in a normal cohort study) we have done only 40 samples. Secondly, we can calculate the incidence of the disease which would not have been possible in a usual case control study. Thirdly, the problem of recall bias and that the controls may be from a different source population than cases (which occur in a case control study) have been prevented.

Advantages & Disadvantages of Cohort Design are shown in Box - 1. Comparison of case control and Cohort Design is given in Box - 2 at the end of this chapter.

Box - 1 : Advantages & Disadvantages of Cohort Design

Advantages of a Cohort Study

- Scientifically a much "stronger" design as compared to case - control or cross - sectional study.
- Temporal association is more convincingly demonstrated since investigator actually starts from exposure, before outcome has occurred and follows up till outcome.
- No recall bias since exposure is objectively assessed by investigator at start of the study.
- Can study many outcomes of a given exposure of interest.
- Provides a direct estimate of "incidence" of outcome in exposed and non - exposed groups and hence the "RR".
- Results are not biased due to "survivorship".
- Good for studying "rare" exposures.
- Any change in exposure status during the course of study can be recorded.

Disadvantages of Cohort Design

- Quite expensive; needs large number of subjects.
- Results may take very long time to be available.
- Ascertainment bias due to "differential" assessment of exposed and non - exposed groups can lead to bias.
- "Loss to follow up" is a major potential for bias.
- Some subjects may "cross - over" i.e. exposed may leave the exposure and vice versa, during the study.
- Inefficient for study of a rare outcome.

Summary

A Cohort study is defined as an analytical, observational investigation in which the epidemiologist starts by identifying a group of subjects who have the exposure of interest but have still not developed the outcome (the exposed cohort) and a comparable group of similar subjects who also have not developed the outcome and do not have the exposure (the comparison cohort). Having identified these two groups, the investigator follows up these two groups forward in time, to observe the incidence of the outcome in the two groups and calculates the Risk ratio of developing the outcome due to the exposure.

A cohort study starts with clear statement of the research question and statement of the exposure, outcome and confounding variables. The exclusion criteria are enunciated and the total population and actual (study) populations are defined. Sample size is calculated by specifying the type - 1 and 2 errors, the expected proportion of the non - exposed cohort who are likely to develop the outcome and the magnitude of risk (RR) desired to be detected in a significant manner.

Next, the "exposed" cohort is assembled either by sampling the general population which contains both, the exposed as well as non - exposed cohorts. Alternatively, the exposed cohort can be identified on the basis of specially exposed groups or on basis of groups which offer special resources. The non - exposed cohort is selected usually as a part of inbuilt cohort when general population has been used to obtain the exposed cohort; alternatively, a special comparison cohort can be assimilated or else, comparison of incidence rates in exposed cohort can be made with incidence rates in general population.

Having assembled the two cohorts, data on baseline exposure level, as well as also data on all the potential confounders is recorded. Any subject who already has the outcome or else is not at risk of developing the outcome due to any other reason is excluded from the study at this point.

The two cohorts are now followed up for the defined period of time, examining both the groups using methods which are similar and valid. All efforts are made to prevent loss to follow up and any cross over. The occurrence of outcome in both the cohorts is recorded and data is analysed for calculation of Risk (Incidence) in the two cohorts, the RR and additionally, for control of confounding.

In addition to the above - mentioned classical 'prospective cohort study design', other special type of cohort designs include the "retrospective cohort study" in which the study is initiated after the outcome has most probably occurred but the researcher starts by identifying the exposed and non - exposed groups and then moves forward to find the incidence of outcome in the two groups. Another design is the nested case - control study in which the cases are nested in a cohort; as the study proceeds, the cases occurring in the cohort as also controls from the same cohort are picked up and compared.

Study Exercises

Long Question : Give an outline of the steps you would undertake in planning, designing and analysis of a cohort study for answering the issue whether smoking by the mother

during pregnancy is associated with prematurity / low birth weight among newborns.

Short Notes : (1) Advantages and disadvantages of a cohort study (2) Biases in a cohort study (3) Compare and contrast case control study with cohort study.

MCQs & Exercises

1. Measure of risk in cohort study is : (a) Relative risk (b)Prevalence odds ratio (c) Exposure odd ratio (d) None of the above
2. Cohort study can be used to study all of the following, except : (a) Risk markers (b) Risk factors (c) Prognostic factors (d) Preventive factors
3. Direction of reasoning in cohort study is (a) Prospective (b) Retrospective (c) None (d) Ambidirectional
4. Temporal association of disease is best established by : (a) Case control study (b) Cross sectional study (c) Cohort study (d)None of the above
5. Which of the following is correct for a cohort study : (a) We take two groups which neither have exposure nor outcome and follow them for defined period of time (b) Take two groups in which one group have the exposure and other does not, and both groups do not have the outcome and follow both for defined period of time (c) Single group is studied for the presence of exposure and outcome at given point of time (d) Take a group which has exposure but not the disease and follow it for defined period of time.

Answers : (1) a; (2) d; (3) a; (4) c; (5) b.

Box - 2 : Comparison of Case - Control and Cohort Designs			
	Heading	Case Control Study	Cohort Study
1.	Type of design	Observational, analytical	Observational, analytical
2.	Temporality	Retrospective (backward in time)	Prospective (Forward in time)
3.	Direction of reasoning	From outcome to exposure	From exposure to outcome
4.	Occurrence of outcome when study is started	Outcome must have already occurred	Outcome would have usually not occurred (however, in a retrospective cohort study, the outcome may have occurred when study is started)
5.	Calculation of risk estimates	Neither incidence nor prevalence can be calculated. Only the Odds Ratio (OR) can be calculated which under certain assumptions is a valid estimator of RR	Calculates the incidences (risk) in the exposed and non - exposed cohorts and the Risk Ratio (RR)
6.	Temporal association	Never proven; only a matter of conjecture	Proven
7.	Recall, Survivorship bias, incidence - prevalence, hospital related and Berksonian biases	Potential problem	Not an issue
8.	Loss to follow - up and cross - over Biases	Not an issue	Potential problem
9.	Ascertainment Bias	Potential problem	Potential problem
10.	Confounding Bias	Potential problem	Potential problem
11.	Time taken	Results available quickly	Takes longer time
12.	Number of subjects	Small sample size required	Requires large sample
13.	Logistic efforts	Cheap, requires little logistics	Expensive, requires lot of effort

RajVir Bhalwar

The ideal design to practice in medical research settings is the experimental design; in fact it is a model (paradigm) scenario in epidemiology. In this approach, the epidemiologist (investigator) draws a random, representative sample from the study population. He then excludes out, from this random sample, all those who already have the outcome of interest, thus retaining only those who do not have the outcome of interest at the time of starting the study. In addition, quite naturally, none of these selected persons would have the exposure of interest at this point of time. Now, having assembled such a group, the investigator “randomizes” (i.e. randomly allocates) this group into two, such that every subject has similar chance of coming in either of the two groups. He now gives the “exposure” of interest to one group (O - E+) and a ‘placebo’ only to the other group (O - E -) and follows them up for a relevant period of time, at the end of which he compares the two groups as regards the development of the outcome of interest.

The noteworthy aspect in the experimental design is, thus, that it is the investigator who intervenes actively, deciding (of course, in a random fashion) as to who will get the exposure and who will not. It is this aspect which differentiates the experimental design from the other type of prospective study (the cohort study) in which the subjects have themselves taken up the exposure by their own choice (e.g. smokers and non smokers), the exposure not being dictated by the investigator. This issue may sound trivial, but has far - reaching consequences in the validity of research - e.g. lung cancer may be higher among smokers as compared to non - smokers because persons may take on to smoking because of certain genetic factors, and by virtue of these genetic factors, they may be more prone to lung cancer; thus, the cause of lung cancer may not be smoking but those peculiar genetic factors. On the other hand, if the investigator would have “randomly” divided a group of human beings, (initially non smokers and not having lung cancer) into two groups and asked one group to smoke and the other not to, then these two groups would have been exactly similar to each other in all aspects, including genetic factors, being dissimilar to each other only in respect of the exposure so allocated (i.e. smoking), and any difference in the two groups as regards subsequent lung cancer occurrence would have been due to the exposure (smoking). Apparently, such a design using a harmful exposure like smoking is only a theoretical possibility but, nonetheless, explains the scientific importance of “intervention” in epidemiology and research methodology.

To further explain the conduct of an experimental (intervention) design, let us say, we want to study whether it is worthwhile to give Isoniazid chemoprophylaxis to children who are close contacts of open cases of pulmonary TB. For undertaking an experimental study, we would take a random sample of, say, 100 children, out of the study population of, say 1000 children who are close contacts of open cases of pulmonary TB. We would now examine all these 100 children and would exclude,

from our study, all those children who already have our “outcome” of interest, i.e. “Tuberculosis” at this point. Let us say we had to exclude 10 children out of these 100 since they already had TB, thus leaving 90 non tubercular children in our study. Now, we would ‘randomly’ divide these 90 children (say by drawing lottery chits or tossing a coin) into 2 groups and give the ‘exposure’ i.e. Isoniazid tablets to one group (say group ‘A’), while the other group will only get a placebo (i.e. a tablet containing calcium, having shape, size, taste, colour and dosage exactly the same as for Isoniazid). The two groups A & B, of 45 children each, would then be ‘followed’ up for a “clinically meaningful” period of time, say 5 years, and we shall examine all the children (in both groups) periodically during these 5 years for the development of Tuberculosis. Let us say, 3 out of the 45 children in the Isoniazid group developed TB during the 5 years follow up period while 9 children of the 45 given placebo developed TB. Thus, the incidence of TB among ‘exposed’ group (i.e. getting Isoniazid) is $3/45 = 6.67\%$ and among the non exposed (i.e. not getting Isoniazid) is $9/45 = 20\%$; thus, the “relative risk” of developing TB when getting Isoniazid is

$$\frac{\text{Incidence in exposed}}{\text{Incidence in non exposed}} = \frac{6.67}{20} = \frac{1}{3}$$

Thus, we would conclude that the chances of developing TB if Isoniazid chemoprophylaxis is given (to children who are close contacts of open pulmonary TB cases) is only third as compared to when Isoniazid is not given; in other words, Isoniazid chemoprophylaxis reduces the chances of getting TB by two thirds or 66.7%.

The above example of a hypothetical experimental design would let us easily understand the advantages and disadvantages that are inherent in this design :

Advantages

- Scientifically ideal method.
- Removes a large number of biases related to selection and measurement.
- Controls for confounding through randomization; thus the two groups are exactly similar to each other excepting for the exposure of interest. Thereby, it fulfills the basic dictum of research, which says “all other things being equal, it is the exposure of interest that has made the difference in the “outcome”.
- Ensures temporal relationship between exposure and outcome.
- Builds up “faith” in the findings of the study.

Disadvantages

- In many situations, especially those which concern study of “risk factors” or “prognostic factors”, one can not “randomly” allocate human beings into two groups; e.g. in our earlier example on smoking and lung cancer, we can not randomly divide human beings into two groups and ensure that one group smokes while the other does not.
- The second major disadvantage, even when “random allocation” is possible, is the ethical issue; at times it may not be ethical to randomly divide, thus exposing the ‘exposed’ group to a potentially harmful treatment or procedure; or to deprive the ‘non exposed’ group of a

potentially useful measures.

When to Use an Experimental Design

Apparently, one has to carefully examine the advantages and disadvantages that are inherent in an experimental design and decide whether it is correct to use an experimental design for answering his research question. In general, one should ask himself the following two questions; if the answer to both of them is 'Yes', one can go ahead with an experimental design :

Q. No. 1

- (a) Are you studying the efficacy of a therapeutic procedure (Drug, Surgical procedure etc.); OR
- (b) Are you studying the efficacy of a preventive procedure (Vaccine, Sera, Chemoprophylaxis, personal protective measure, exercise programme etc.); OR
- (c) Are you studying the efficacy of a health care system or procedure (e.g. domiciliary v/s. institutional care).

Now, if the answer to any one of the above questions Q. No 1 (a) to (c) is 'Yes', go to question no. 2. However, if the answer is 'No', explore the possibility of using an observational design (cohort; case control etc.).

Q. No. 2

Can you "randomly divide the subjects into two groups, one getting the intervention and other not to get it? : Is it "feasible"? Is it "ethical"?

If the answer to the above (2 (a) and (b)) is "Yes", go ahead with an experimental study. However, if the answer to any one or both of 2 (a) or (b) is "No", consider the possibility of a "quasi experimental" design. If quasi experimental design is also not possible, consider an observational study (case control or cohort) or still better, review and revise your research question - there may be some flaw in your research question.

Types of Experimental Studies

The experimental typology may be adapted to different research settings :

(a) Clinical (Therapeutic) Trial : This is the classical setting of an intervention (experimental) design. Examples are drug trials, trials of surgical procedures or other medical therapeutic procedures concerned with individual patient care. The "unit of study" in a clinical trial are "patients" suffering with a given disease, the therapy of which is to be studied.

(b) Field Trial : As compared to the clinical trial, in a field trial, the unit of study are healthy individuals, usually in the community. The trial is usually undertaken in respect of a preventive procedure as a vaccine, sera, chemoprophylaxis, personal protective measures, etc. For example, the trial of injectable polio vaccine is possibly the largest human experiment ever conducted. Over a million children, apparently healthy, living in the community, were randomly divided and offered either the vaccine or the placebo; the trial finally provided strong evidence of the efficacy of injectable polio vaccine.

(c) Risk Factor Trial : Risk factor trial, is in ethos, same as preventive trial. However, the difference is that the intervention in a preventive trial is an actual medical procedure (as vaccine) which is given (or not given) to individual subjects. On the other hand, in risk factor trial, the intervention is not an actual physical administration but rather an abstract phenomena, e.g.

asking a group of subjects (randomly selected, of course) to start "regular physical exercise". Here, regular physical exercise is the "intervention" of interest which is not physically administered (like a vaccine or drug) but is rather a "conceptual" procedure.

(d) Community Intervention Trial : In a field trial (e.g. trial with a vaccine) we would randomly allocate the subjects, e.g. we will allocate the individual children to the vaccine or the placebo group. However, in a trial which seeks to study whether providing fluoridated water supply is effective in reducing the occurrence of dental caries, it would be practically impossible to randomize individual children to receive or not to receive the intervention (fluoridated water supply). In such a setting, we would randomize at the level of "communities" or "clusters of humans", thus allocating, randomly, a few villages to get the fluoridated water supply and few others to get ordinary supply. However, the unit of assessment still remains the individual subject; e.g. in this example, we would examine each and every child of all the villages (being supplied or not being supplied with fluoridated water) for DMF teeth. This is an example of community intervention trial, where "random allocation" is done at the level of "communities" or "groups" of subjects, though the assessment of outcome is done at individual subject's level. Such trials are of special interest for public health administrators for evaluating the effectiveness of environmental procedures, health educational measures, etc. The understanding of this type of experimental study becomes important since the "unit of random allocation" (i.e. the communities) is different from the "unit of assessment of outcome" (i.e. individual subjects). It is quite possible that the two groups (of communities) formed after random allocation may be quite different from each other in as far as characteristics of subjects are concerned e.g. the children in the group of villages going to receive fluoridated water may be otherwise well nourished, or may be having better oral hygienic practices. A "baseline" comparison between the two communities as regards relevant characteristics of subjects should therefore be done in such studies to show that the two groups are similar to each other (e.g. in the above study, we would compare the children of the two "community groups" regarding their age and sex structure, oral hygienic practices, educational and economic status of parents and habits of eating starchy/sugary foods to show that there is no significant difference between the two communities as regards these characteristics of children; if there is, then data for all the relevant factors should be recorded and later adjusted in analysis (see chapter on confounding).

(e) Health Services Evaluation Trial : Community intervention trials may often be used to answer research questions pertaining to the efficacy or effectiveness of health services or health policies; e.g. "whether to provide 10 Doctors or 100 Multipurpose health workers within the same budget" or "whether to provide free oral rehydration salt packets or else to provide health education to mothers" etc. Basically, the architecture is the same as that of community intervention trials, with an added element of health economic analysis (see chapter on studies on health economic analysis).

(f) Cessation Experiment : A contemporary of "risk factor trial", the only difference being that while in a risk factor trial, a preventive 'concept' is introduced as an intervention

(e.g. physical exercise package), in a cessation experiment, a harmful factor is “removed” from the intervention group (e.g. a group of smokers, free of IHD, may be randomly divided into two groups, and one group may be asked to give up smoking, while the other group continues to smoke; the two groups are then followed up for development of IHD).

The difference between a clinical trial, field trial and community trial should be noted. In a clinical trial as well as in the field trial, the unit of randomization as well as the unit of study (persons on whom measurements are made) are individuals; however, in a clinical trial these individuals are patients suffering from the target disease and usually obtained from the indoor or outdoor of a health care setting, while in a field trial, these are apparently healthy individuals, selected from the community. In a community trial, the unit of study are healthy persons living in the community but the unit of randomization are “communities” or clusters of free living healthy human beings as villages.

The Quasi - Experimental Designs

Ideally, an experimental design should have the three essential elements of “Randomization”; Controls (usually placebo - control); and Blinding. This is what is called the “Randomized, Controlled, and Blinded Trial” (RCT). This is the most scientific way of conducting an experimental study and which we shall discuss subsequently.

However, often such ideal conduct on the basis of RCT may not be possible; one has to be pragmatic and take a practical approach. Say, at times, one may not be able to “randomly” allocate subjects into two groups. At times the “placebo” part of control may be impossible (e.g. surgical v/s medical management of IHD). Such circumstances, when an “intervention” has been given to one group of subjects and not given to another group, but the procedure of “random allocation” or “placebo” control has not been enforced for various reasons of practicability or ethics, are called as “Quasi - experimental” studies. Quasi - experimental studies may be of following types :

(1) Non randomized “concurrent” trial : The subjects keep entering the study and are divided into the two groups, not by random allocation by the investigator but by various other circumstances, e.g. patients of IHD may automatically get divided (depending on their clinical condition, ability to pay etc.) into a group who would continue on medical management and another who would go up for surgical treatment. The two groups can then be compared for studying the efficacy of medical versus surgical treatment for IHD. Another setting could be to take patients of IHD from a cardiology clinic (medical treatment) and post - op cases of CABG attending a chest surgery unit (surgical treatment) and follow them up.

(2) Before and after trial using “historical controls” : The results of a new medical procedure can be compared with the results that used to come up before the procedure was available. e.g. the results of selective vagotomy may be compared with the earlier results when truncal (and not selective) vagotomy was used. Such studies are also quite common in public health administration, e.g. the death rate due to car accidents after introduction of compulsory seat belt legislation was compared, in Australia, with the death rates before such legislation.

The Disadvantages of Quasi - Experimental Design

- High potential that the intervention and control group used for comparison are not similar to each other. One crude method to improve the faith in the findings of a quasi - experimental study is to make a “base line” comparison between the two groups as regards certain important variables like age, sex, education, income, clinical condition etc.; if the two groups are not equal at baseline, efforts to adjust for such confounding variables should be made during analysis.
- “Selection” factors may be operating; e.g. patients who are taken into surgical treatment group for IHD may be in a much better state of cardiovascular function as compared to medical treatment group.
- Improvement noticed in a ‘before and after trial’ may simply be because other patient management techniques may also have improved recently; or else because the data collected earlier was incomplete or erroneous.

It is therefore imperative that whenever a researcher proposes a “Quasi - experimental” study, she should carefully view the above facets to see whether any bias may come up in her study and take actions to obviate such bias; or at least collect the data on all factors so that adjustment during analysis can be done.

Planning, Designing and Analysis of Randomized Controlled Trial (Clinical Trial)

In medical research practice, a clinical trial or RCT represents the strongest design, the ultimate in medical research. The history of clinical trials is not very old. In fact the first scientific clinical trial was done just 250 years ago under the name “Ceterius Paribus”, on board the British Naval Ship “Salisbury” when James Lind had tried out various treatment modalities and shown that a ration of fresh lime juice and oranges was curative for scurvy (61).

Phases of a Clinical Trial

Actually, what we commonly refer to as clinical trial is just one phase of the entire gamut of clinical trials. In fact, clinical trials have four phases which are sequentially studied on human beings, viz. Phase I to IV (37 - 42). Before phase I is undertaken, the new drug or treatment modality should have passed through the animal and laboratory testings and should have shown to have pharmacological effect, safe and free of malignancies and teratogenic effects. Only thereafter can a drug enter the phase I of clinical trials.

- *Phase I* studies are basically “‘clinico - pharmacological studies” which are undertaken on a small number of patients (20 to 80) (sometimes on healthy volunteers) and refers to dose finding studies, to find out as to how large a dose can be given before an unacceptable toxicity is experienced by patients (Maximally Tolerated Dose or MTD) as well as looking for various toxic and pharmacological effects of the drug.
- *Phase - II* are clinical investigations of a larger number (100 to 200) of patients with the target disease, looking for pharmacokinetic and pharmacodynamic effects of the drug on these patients, looking for the efficacy, biological activity and relative safety of the drug in these patients

and to estimate the rate of adverse events at that MTD.

- *Phase - III* is the actual, classical stage of clinical trial which is also known as the Randomised Controlled trial (RCT). Following phase III, the drug is marketed and simultaneously phase IV also starts.
- *Phase - IV* is also called as “Post Marketing Surveillance”. Data on the effect of the drug or procedure is collected from various agencies. Side effects which did not appear in phase - III, are detected in this phase and the drug may be withdrawn or its usage modified. Classical examples are Thalidomide, Isoprenaline containing bronchodilators, and DES.

Steps in Planning, Designing and Conduct of a Clinical trial

The steps in conduct of an experimental study including clinical trials are outlined in the succeeding paragraphs. In addition, readers are advised to go through the published reports on some of the large scale clinical trials (77 - 86).

Step 1 - Deciding - Is clinical trial really required? Should it be done? Can it be done? : Undertaking a clinical trial is not an easy affair. It costs considerable amount of specialized manpower, finances, equipment and dedicated efforts. It is therefore advisable that before one starts thinking of a clinical trial one should carefully assess whether it is really necessary to undertake a clinical trial. Firstly, a detailed review of literature should be undertaken to see whether the question has already been answered by some other workers and whether the findings can be adopted by us for our patients. Meta - analysis of published and even unpublished papers are also advisable because that may answer the issue without actually undertaking the clinical trial (68).

Look into the Ethical Aspects of the Clinical Trial : Ask yourself whether the trial is ethical (69 - 75)? The details of ethics in epidemiology and medical research are given subsequently in an exclusive chapter and readers are advised to go through the same.

Step 2 - Clearly state the research question and the variables of study : The research question should be developed after lot of reading and deliberations with experts. At times, the researcher may have more than one research question. In such cases one should clearly define out the *primary question* - this is one in which the investigators are most interested. The main statistical issues including the sample size calculation would revolve around the primary question. The *secondary questions* are subsidiary to the primary question; or else, sometimes, the data collected for the primary question may also be used for answering the secondary question. Having clearly defined the research question, the investigator should clearly list out as to what all “variables” will be studied to answer the research question. Broadly, there are four categories of variables that need to be enunciated :

The exposure variable : This means the “intervention” under study. The complete details including the dosage, method of administration etc. should be clearly defined.

Co - Interventions : Often co - interventions may be studied in addition to the primary intervention. Co - interventions should be as clearly defined as primary exposure variable.

The outcome variable : The outcome variable is the end point that is of utmost importance to the investigator. Care should be taken to clearly define one “primary outcome” or the “major endpoint” variable which is of most interest to the researcher and around which the analysis and sample size calculations would revolve. In addition, “secondary outcome” or the “other endpoint” variables can be defined.

The confounder variables : Ideally (at least theoretically), there should be no need to measure the confounder variables in a clinical trial, once randomization has been done, since randomization is itself a very powerful tool for controlling confounding. However, in small size trials, randomization may not have that much effect. Secondly it may also be worthwhile to do a baseline comparison between the intervention and the control group in respect of important confounding variables to show that randomization has been effective. It is therefore advisable, rather necessary, to collect data on major confounding variables i.e. those which are directly related to both the exposure and the outcome variables.

Step 3 - Enumerate the inclusion and exclusion criteria: Clearly define the characteristics of patients who would be eligible for entry into the trial, by specifying the “inclusion criteria” - based on demographic and clinical characteristics, to specify the patients or subjects who will be eligible to be included in the study. The more important aspect is the “exclusion criteria” - those who will not be eligible to be included in the study. More the exclusion criteria, more precise will be the findings and lesser will be the requirement of sample size. However, more the exclusion criteria, more difficult will be for you to find the particular type of subjects, and the generalizability of your study will be restricted.

Step 4 - Defining the populations : In the first sub - step we would define the reference population, also called the “universe” or the “target population”. This is the very large collection of patients or subjects to whom the results of the study would be generalized. For instance, if we wanted to do a clinical trial on whether Tamoxifen prevents recurrence of breast cancer, as an ICMR research project, we could define our reference population as “Wives of serving / retired central government personnel dependant on CGHS health care system, aged 40 to 70 yrs having at least one breast intact, not having history of venous thromboembolism, not taking oestrogen, mentally alert and who agree to participate”. The reference population is very large, scattered and difficult to delimit, and hence we cannot directly draw a representative sample from it. For this reason we often specify a well defined subset of the reference population from where we actually draw the sample of subjects. For instance, in our example we may define the actual study population as all the women of the type defined in the reference population “who are staying in Delhi”. It is from this actual study population that we finally draw our required sample. Specifying the actual study population is more of a matter of administrative convenience but we must be convinced that the actual study population is a reasonably representative subset of the reference population.

Step 5 - Sample Size Calculation : Sample size, is a major issue in clinical trials. Too small a sample would produce insignificant results and would be a waste of efforts. With a

small sample the chances are very high that the result would be statistically insignificant. Hence an adequately large sample is important. At the same time we must remember that every subject in a clinical trial costs tremendous amount of money, so even one additional subject may mean poor financial management. The details of calculation of sample size are dealt with in the section on biostatistics.

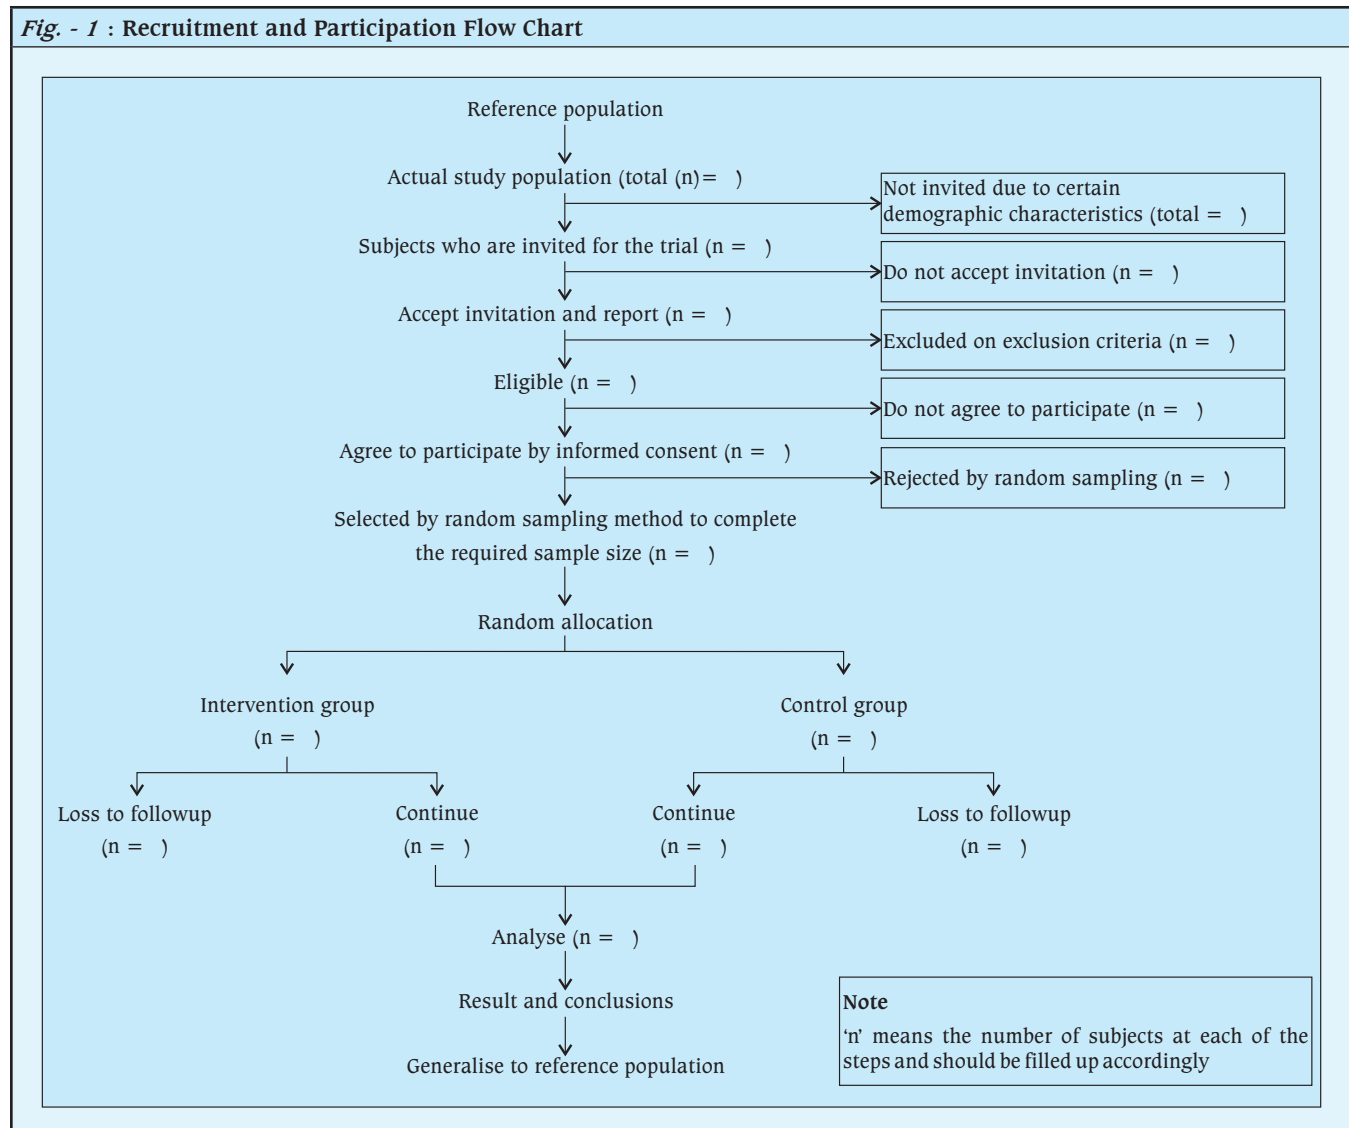

Step 6 - Detailed Descriptions of Measurement Protocols : The most important facet of clinical trials is to ensure that the measurement process is accurate. So, at the stage, develop the detailed protocols of clinical procedures, laboratory investigative procedures, as well as the details of questionnaire and interview protocols. For each and every variable (intervention, co - intervention, confounders and major and minor outcome variables), write down very clearly and explicitly, as regards Who will make the measurement ? When will it be made ? What equipment / instrument will be used ? What technique will be used ? How the equipment, techniques and personnel

be standardized and validated ?

Step 7 - Enrolling the Participants : Once the minimum sample size has been calculated the next step is to enroll a representative sample of the patients from the actual study population. In fact, during the planning and conduct of a clinical trial as well as during writing your research paper, it is important to present the “ Recruitment and Participation Flow Chart” giving the numbers ('n') at each step, as per format in Fig. - 1.

Step 8 - Randomisation : The basic dictum of any research is that the groups being compared should be absolutely similar to each other except for the factor which is being studied. In methodological terms, it means that all confounder variables must be controlled. There are various methods of control of confounding. When it comes to clinical trials the method is randomization or random allocation. So essential is randomization that the other name of this design is “RCT - Randomized Control Trial”. The procedure is quite simple. Random number tables available in any book on statistics or

Fig. - 1 : Recruitment and Participation Flow Chart

computer statistical packages are used to generate random numbers. Accordingly the subjects are allocated to either, receiving treatment A (the intervention under trial) or else treatment B (the control modality). The power of randomization is such that, the two groups so formed consequent to randomization, are absolutely similar to each other. However, there is a note of caution. Randomization works well to create 2 similar groups only when the sample is adequately large. In a small sample, the effect diminishes and may become erratic.

Step 9 - Introduce the Intervention and Placebo Control Modalities : Having created the two groups by random allocation, the investigator now needs to intervene with the trial modality in one group, and the control or the baseline modality in the other group. Certain aspects to be ensured at this stage are :

- Ensure ways and means to bring about compliance in both the groups. Give adequate amount of medicines to all the subjects in both the groups and instruct them clearly on the dose, mode of administration, frequency of intake, etc.
- Develop procedures for checking compliance as, for example, checking the count of balance pills, testing the urine/ other excretions for metabolites and so on.
- Brief both the groups clearly about co - interventions in the trial, if there are any.
- Ensure a placebo control, so that the control group who are not getting the trial intervention cannot make out that they are not getting it. Ensure that they get the placebo drug in the same shape, colour, size and taste and is also administered using similar procedures.

Step 10 - Ensure Blinding : What if the subjects know they are getting a new drug? They may start feeling better just because of this knowledge! They may report improvement just to please their Doctor! And those not getting the new treatment may not feel relieved thinking that they have been deprived of some new, good treatment. And may be, just because of this awareness, some of them may quietly start taking the new regimen or some other co - intervention. More bias may be introduced if the investigator is aware of the status of the subjects. The investigator may differentially probe or investigate more in one group or less in the other group.

To overcome these biases in the standard clinical trial, Blinding is used as an essential requirement. In single blinding, the subject is not aware of his status but the investigator is aware. The ideal standard of course is double blinding, in which neither the investigator nor the subject is aware as to which group a particular subject belongs to. Only the codes are given and these codes are handled by the data manager. The gold - standard in contemporary times for clinical trials is double blinding. Double blinding may sound difficult but can be implemented even in testing situations.

In surgical trials, double blinding may become difficult at times. In such situations, we may ensure that the surgeons who evaluate the outcome, should be independent of the research group and preferably different from the surgeon who operated. The operating surgeon may, however, keep monitoring the patients for purpose of management, not for research. We may also make the outcome criteria as objective as possible.

Step 11 - Follow Up and Assessment : The last but one step in the conduct of clinical trial is to follow up the subjects till the end point, or the period of trial, whichever is earlier and to make ascertainment. The key issue in follow up is to avoid losses to follow up, which may otherwise seriously bias the study results as seen in the following example : “A trial of nasal calcitonin spray to reduce the risk of osteoporotic fractures reported that the treatment reduced the risk of fractures by 36%”. However, critical evaluation revealed that 60% of those who were originally randomized were lost to follow up and it was not known whether fractures had occurred among those who were lost to follow up. Because the overall number of fractures was small, even a few fractures among participants who were lost to follow up could have altered the results of the trial. This uncertainty diminished the credibility of the findings. It is therefore imperative that actions be taken right from the planning stage to retrieve those getting lost to follow up. The following general steps are worthwhile :

- At the very start, inform the participants of the scope of trial, and the time and place where they should report for follow up.
- Exclude, in the beginning itself, those who have a very low probability of continuing.
- Note down the detailed telephone numbers and addresses of the participants, their close friends, relatives and employers and their permanent home addresses to retrieve them.
- Treat them properly when they come for follow up; don't make them wait too long.
- Every time they come for follow up, talk to them about their condition and also about the progress of the trial to keep their interest alive.
- Even if some participants violate the study protocol or discontinue the trial intervention, they should still be followed up so that their outcomes could be used in “Intention to treat Analysis”

Finally during the follow up stage, keep the “Stoppage Rules” open. In brief there can be two reasons for prematurely stopping a trial :

- Evidence comes up in between against the intervention modality.
- Evidence of clearly high mortality or complication in the intervention group comes up.

Step 12 - Statistical Analysis : Statistical analysis is indeed a very important aspect of any research design, clinical trials included. Let us start with an example of a clinical trial which has been published in one of the recent issues of Lancet (86). The DREAM Project was a clinical trial to evaluate whether Rosiglitazone, a Thiazolidinedione drug said to improve insulin sensitivity can prevent diabetes type 2 among subjects who were having IGT or Impaired Fasting Glucose (IFG). 5,629 subjects with IFG were randomly allocated to either receive Rosiglitazone 8 mg per day (2,635 subjects) or a placebo (2,634 subjects) for a follow up period of 3 years. The primary clinical end point was development of diabetes. Those who did not develop diabetes were taken to have achieved the outcome. The final data is summarized in Table - 1.

Exposure	Outcome		Total
	O+ (Did not develop Diabetes)	O - (Developed Diabetes)	
E+ (Given RG)	2329 (89%)	306 (11%)	2635 (100%)
E - (Given Placebo)	1948 (74%)	686 (26%)	2634 (100%)
Total	4277 (81%)	992 (19%)	5269 (100%)

The data shows that as much as 88.4 % of the exposed group, i.e. given Rosiglitazone, remained free as compared to much lesser 73.45 among the placebo group.

An important decision to be taken at this point is whether we want to undertake an “*Intention to Treat Analysis*” or else a “*Per - protocol*” analysis. In the former, which is being often undertaken these days, the outcome is analyzed among subjects according to the group into which they were originally randomized (“analyse as you randomize”). Thus, even if participants assigned to the original intervention group may have discontinued or even crossed over or some of the placebo control group may have finally ended up taking the intervention modality, the analysis will be as per the subjects’ original randomization plan. On the other hand, the per - protocol analysis will include only those participants in both groups who undertook at least 80% of the assigned study medication, completed a certain percentage of their expected follow - up visits, and had no other protocol violation.

The first thing in undertaking statistical analysis of a clinical trial is to present the participant’s recruitment and flow chart, giving the actual data at each step, as explained in one of the earlier steps. The next step is to give a table showing baseline comparison between the interventional group and the placebo group as we have described earlier in the step of randomization. The next step is now to clearly visualize what are your primary exposure and outcome variables and what is meant by exposure present or exposure absent and by outcome achieved or outcome not achieved. Now, make a 2X2 table and place your data in the 2X2 table exactly as per the specifications for cells a, b, c and d that we have already discussed. Same is shown in Table - 2.

Exposure (intervention)	Achieved Outcome (Did not become Diabetic)/ (O+)	Not achieved Outcome (became Diabetic)/ (O -)	Total
Given RG (E+)	2329(89%) a	306(11%) b	2635(100%)
Given Placebo (E -)	1948(74%) c	686(26%) d	2634 (100%)
Total	4277(81%)	992(19%)	5269(100%)

In the DREAM clinical trial, out of 2,365 who were exposed to RG, 2,329 achieved the defined outcome while in the non exposed (Placebo) group 1,948 out of 2,634 achieved the outcome. Please do take care to indicate both the numbers and percentages in the cells. Now, having placed the data in the 2x2 table, calculate the incidence of outcome in the exposed and non exposed group as : $I_E = a/a+b = 2339/2635 = 89\%$ and $I_{NE} = c/c+d = 1948/2634 = 74\%$. And, as the next step, calculate the risk ratio (RR) i.e. the “effect” of the intervention as : $RR(\text{Effect}) = I_E/I_{NE} = 89/74 = 1.20$. This calculation of the effect size is a simple but extremely important parameter which you must calculate. In our example, it means that patients of IFG who got Rosiglitazone will be 1.2 times more likely to remain free of diabetes as compared to those on placebo, over 3 years.

In the next step, calculate the 95% CI of RR. In the DREAM trial example, the RR was 1.20 and its 95% CI was 1.16 to 1.23. The interpretation is like this : “Our sample results show that the effect of Rosiglitazone is to bring about 1.2 times more improvement”. We do not know what the real effect would be in the 2 large populations but we are 95% confident that the real effect in the two large population would be an improvement between 1.16 times to 1.23 times improvement as compared to placebo.

And, in the basic presentation, finally calculate the numbers needed to treat as : $NNT = 1/(I_E - I_{NE})$ (where I_E and I_{NE} are measured as proportions out of 1) (87). In our example, it works out as : $100/(0.89 - 0.74) = 1 / 0.15 = 7$. It means that we will need to treat 7 patients with Rosiglitazone to get one additional case of cure (prevented diabetes) as compared to placebo.

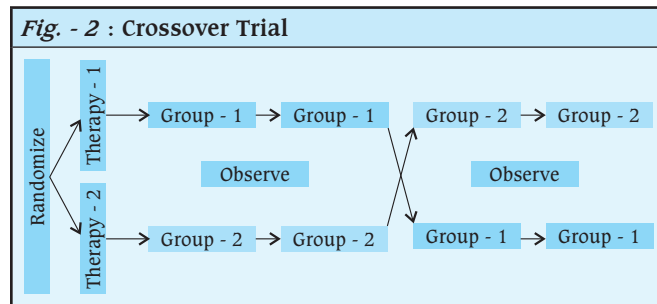

Having presented the basic statistics, the next step in statistical analysis is to undertake probability testing procedures. The details have been discussed at length in the section on biostatistics.

Certain Variants in the Design of Clinical Trials

The details mentioned in the foregoing paragraphs of this chapter pertain to the classical randomised, concurrent placebo controlled, blinded trial. However, at times two of the variants in the methodology can be meaningfully utilized, as follows :

Crossover Trial : Let us assume that we are trying out the efficacy of new antihypertensive drug as compared to one of the standard ACE inhibitor drug. Let us say we decided to study 50 subjects in each group. We took 100 subjects of hypertension, randomised them into two groups of 50 each and gave the trial drug to group ‘A’ and Ramipril to group ‘B’. After treating the two groups for the decided period of 3 months, we measured the BP levels. We now stopped the drugs in both the groups for 1 month, so that the effect of the drugs is “washed off” and the patients returned to the baseline. Now, we gave Ramipril to group ‘A’ and the trial drug to group ‘B’ and followed up for another 3 months. This is an example of the “cross - over” design. Thus in a cross - over design, subjects are initially randomly allocated into therapy ‘A’ or therapy ‘B’ and after being observed for a certain period of time, and giving a period of “wash - out” to remove the existing effects of therapy, the subjects are switched over to the other therapy (i.e. cross over) and are thereafter again followed up for another relevant

period of time. The flowchart for the Cross Over Trial is shown in Fig. - 2.

Cross-over designs have certain advantages. Firstly, each subject serves as his or her own control, thus holding constant the variations between individuals as regards many characteristics that could potentially confound the comparison between two groups. Secondly, for the same reason, the requirement of sample size would be considerably reduced. It improves on the ethical considerations since all subjects are exposed to both therapies, thus nobody is denied of the potential advantages of a particular therapy.

At the same time, cross-over designs have certain disadvantages. Firstly, there is, most of the times, a requirement of giving a period of wash out to remove the residual effects of each therapy, before cross over can be effected. This prolongs the duration of the trial, especially if the period of wash out required is long. Second, it may be at times very difficult to ensure blinding or placebo control, for example if one of the therapy is oral medication while the other modality is parenterally administered. Thirdly, the order in which therapies are given may elicit psychological response; e.g. patients may react differently to the first therapy given in a study, as a result of enthusiasm that often happens at the start of the study, and which decreases over time. Finally, if either of the therapy cures the disease in toto (as an antibiotic for infectious disease) then, naturally, no cross over can be done.

The classical, 'planned cross over design' as described above, should be differentiated from the "unplanned cross-overs" as sometimes may happen in classical RCT. For example, in a trial to assess the efficacy of surgical versus medical treatment in IHD, some patients initially randomly allocated to surgical or medical options, may start having second thoughts and may decide to finally take the other form of therapy to which they were originally not allocated; or some patients initially allocated to medical group may deteriorate and may then be given surgery. Such crossovers may lead to serious objections as regards the validity of the trial.

Factorial Design : Let us take the example of the physicians health study, in which it was envisaged to study the efficacy of aspirin for primary prevention of cardiovascular disease and beta-carotene for primary prevention of cancer. In this trial, each physician was randomly allocated to receive one of the four treatments, viz., both aspirin (A) and beta-carotene (B), only aspirin (A), only beta-carotene (B) and neither of the two (0). The resulting design can be set out in the 2X2 table (Table - 3).

Treatment 'A'	Treatment 'B'	
	Given	Not Given
Given	(Both A & B) (1)	Only A (2)
Not Given	Only B (3)	Neither A nor B (4)

The above is an example of the "factorial design" in which the two or more modalities are tested as per factors (both given, either one given, none given). This design is done when the anticipated outcomes for the two regimens are different and their modes of action are also different, one can economically use the same study population for testing both the regimens. We would evaluate the effects of treatment 'A' by comparing the results in cells (1+2) to the results in cells (3+4). Similarly, the results for treatment 'B' can be evaluated by comparing the results in cells (1+3) to the results of cells (2+4).

In case it becomes necessary to terminate the study on the effects of one of the regime (say, 'A'), this design permits continuing the study to determine the effects of treatment 'B'. For example, in the physicians health study quoted above, the aspirin part of the study was terminated earlier, because evidence of protective effect of aspirin on acute MI had already come in by then. The randomised beta carotene versus no beta carotene trial continued till the originally scheduled time line of 12 years and final results did not show any protective effect on cancers.

Summary

In an experimental design, the epidemiologist excludes at the outset, all those who either have the outcome of interest or exposure of interest, from his study sample. He then "randomizes" (i.e. randomly allocates) this group into two, such that every subject has similar chance of coming in either of the two groups. By random allocation or randomization, the two groups formed will be absolutely similar to each other. So essential is randomization that the other name of this design is "RCT - Randomized Control Trial". He now gives the "exposure" of interest to one group (trial or intervention group (O - E+) and a 'placebo' only to the other group (control group) (O - E -) and follows them up for a relevant period of time, at the end of which he compares the two groups as regards the development of the outcome of interest, by comparing the incidence of outcome in the exposed with that in the non-exposed group. Thus, in the experimental design it is the investigator who intervenes actively, deciding, in a random fashion, as to who will get the exposure and who will not. The experimental design is the method of choice when studying the efficacy of a therapeutic or else a preventive procedure.

Experimental studies can be of various types like Clinical (Therapeutic) Trial, Preventive Trial, Risk factor Trial, Community intervention Trial, Health Services Evaluation Trial and the Cessation Experiment. Randomized Controlled Trial (RCT; Clinical trial) is the classical setting of an intervention design, in which random allocation is done at the level of individual subjects. In community intervention trials, randomization is done at the level of "communities" or "clusters of humans",

rather than individuals, though the unit of assessment still remains the individual subjects.

Ideally, an experimental design should have the three essential elements of “Randomization”; Controls (usually placebo - control); and Blinding. This is what is called the “Randomized, Controlled, and Blinded Trial” (RCT). Such ideal conduct on the basis of RCT may not be always possible. Such circumstances, when an “intervention” has been given to one group of subjects and not given to another group, but the procedure of “random allocation” or “placebo” control has not been enforced for various reasons of practicability or ethics, are called as “Quasi - experimental” studies. Quasi - experimental studies can be in the form of Non randomized “concurrent” trials or else, Before and after trial using “historical” controls.

There are four phases in clinical trials, viz. Phase I to IV. Before phase I is undertaken, the new drug or treatment modality should have proved its effect and safety in the animal and laboratory. Phase I is dose finding studies undertaken on a small number of patients or healthy volunteer. Phase - II can be called as pharmacokinetic and pharmacodynamic studies, undertaken on a small number of patients with the target disorder. Phase - III is the actual, classical stage of clinical trial which is also known as the Randomised Controlled Trial (RCT). Following phase III, the drug is marketed and simultaneously phase IV also starts. Phase IV is also called as “Post Marketing Surveillance”.

Before starting a clinical trial, it is important to decide whether clinical trial is really required, by undertaking detailed review of literature, and by the procedure of Meta analysis of published and even unpublished papers. Once it has been decided to go ahead with a clinical trial, at the first step, decide whether it is feasible or not and one should also look into the ethical issue. Second step is to clearly state the research question and variables of study. At times, the researcher may have more than one research question, in which case one should clearly define the primary question and secondary questions. Having clearly defined the research question, the investigator should clearly list out as to what all “variables” will be studied to answer the research question. Broadly, there are four categories of variables that need to be enunciated : Exposure variable, Outcome variable, Co - interventions and Confounding variables. Care should be taken to clearly define one “primary outcome” or the “major endpoint” variable which is of most interest to the researcher. In addition, “secondary outcome” or the “other endpoint” variables can be defined. Baseline data about common confounding variable like age, sex should be collected and compared in the two groups, to show that randomization has been effective. Next, clearly enumerate the inclusion and exclusion criteria based on the characteristics of patients who would be eligible for entry into the trial - based on demographic and clinical characteristics. Now we define our actual study population and the reference or total population. Sample size is a major issue in clinical trials. Before calculating sample size we must not only specify the type 1 error, type 2 error and power of the study, but also, the expected proportion of the outcome in the Non - exposed (control) group (P_0) and amount of effect due to intervention modality you would consider clinically significant. In the next

step, develop the detailed protocols of clinical procedures, laboratory investigative procedures, as well as the details of questionnaire and interview protocols.

Next step is enrolling the participants in the study. First of all make the list of all eligible participants based on inclusion and exclusion criteria. Now these eligible participants will be informed of the details of the study and asked to participate under informed consent. Those who agree to participate, are randomly allocated into two groups - one group which will be given intervention and other group which will not receive any intervention.

Having created the two groups, the investigator now intervenes with the trial modality in one group, and the control or the baseline modality in the other group. One must ensure ways and means to bring about compliance and develop procedures for checking compliance in both the groups. It should be ensured that the control group subjects get the placebo drug in the same shape, colour, size and taste and is administered using similar procedures. The next, extremely important step is to ensure blinding. In single blinding, the subject is not aware of his status (whether he belongs to the intervention or the placebo control group) but the investigator is aware. Double blinding is taken as gold standard, in which neither the subject nor the investigator is aware of the status of individual. Double blinding removes both respondent’s bias and observer’s bias.

The next step is to follow up the subjects till the end point, or the period of trial, whichever is earlier and to make ascertainment. The key issue in follow up is to avoid losses to follow up, which may otherwise seriously bias the study results. Steps should be taken in planning steps itself to prevent the losses to follow up, by informing the participants of the scope of trial, time and place for follow up; excluding in beginning itself those who have a very low probability of continuing; noting down the detailed telephone numbers and addresses of the participants, their close friends, relatives and employers and their permanent home addresses to retrieve them. Note that even if some participants violate the study protocol or discontinue the trial intervention, they should still be followed up so that their outcomes could be used in “Intention to treat Analysis”. Do ensure in follow up that subjects, irrespective of their trial status, are treated equally in every aspect of examination. And, finally during the follow up stage, keep the “Stoppage Rules” open. Reasons for premature stoppage of trial can be firstly, if evidence comes up in between against the intervention modality; secondly, evidence of clearly high mortality or complication in the intervention group comes up and thirdly, if Statistical, Methodological or Sample size assumptions are proved wrong.

Last step consists of statistical analysis. The first thing in undertaking statistical analysis of a clinical trial is to present the participant’s recruitment and flow chart, giving the actual data at each step, followed by a table showing baseline comparison between the interventional group and the placebo group. The next step is to make a 2X2 table and calculating the incidence in exposed (I_E) and incidence among non - exposed (I_{NE}) and calculating the relative risk. Also calculate NNT (number needed to treat) as : $NNT = 1 / (I_E - I_{NE})$. Having presented the basic statistics, the next step in statistical analysis is to undertake probability testing procedures which will depend on

scales of measurements of exposure and outcome variables.

Study Exercises

Long Question : Discuss the stepwise planning, design, conduct and analysis of a trial to assess the efficacy of “Deltamethrin Insecticide Treated Bed Nets” in reducing the incidence of malaria, in a Primary health Centre (PHC) area with a population of 30,000 spread over 30 villages, located in high malaria transmission area especially during June to October.

Short Notes : (1) Phases of a clinical trial (2) Quasi - experimental design (3) Randomisation (4) Blinding (5) Potential Biases in a clinical trial (6) Numbers needed to treat (7) Intention to treat analysis (8) Cross - over design.

MCQs

- In which of the following study, randomization is done? (a) Case control study (b) Cohort Study (c) Experimental study (d) Cross sectional study
- Which is the ideal (most scientific) setting for epidemiological study? (a) Case control study (b) Cohort Study (c) Experimental study (d) Cross sectional study
- Experimental study can be used in following setting except (a) Study of risk factors (b) Preventive trial (c) Therapeutic trial (d) Health system evaluation trial
- Phase IV of clinical trial is (a) Post marketing surveillance (b) Clinical trial (c) Animal studies (d) None of the above
- Cessation experiment is a type of (a) Cohort study (b) Experimental study (c) Case control study (d) Cross sectional study
- In single blinding, _____ is unaware of the status of the subject? (a) Analyzer (b) Observer (c) Subject (d) All of the above
- While conducting experimental study, arrange the following steps in sequential manner 1) Randomization 2) Blinding 3) Statistical analysis 4) Enumerate the inclusion and exclusion criteria (a) 4, 1, 2, 3 b) 4, 2, 1, 3 (c) 2, 1, 3, 4 (d) 2, 1, 4, 3
- What is the tool for control of confounder in experimental design? (a) Blinding (b) Statistical analysis (c) Randomization (d) None of the above

Answers : (1) c; (2) c; (3) a; (4) a; (5) b; (6) c; (7) a; (8) c.

RajVir Bhalwar

In every area of clinical and public health practice, “diagnosis” becomes the central issue. The process of making diagnosis involves the use of certain tests, laboratory procedures or a constellation of signs and symptoms. The common settings of use of diagnostic tests can be, pathological, radiological, clinical or public health (e.g. mammography for mass screening for breast CA). Apparently, whenever we use any “diagnostic test” (including clinical signs), at the very outset we have to accept the fact that we will never get 100% accurate results. Some deviation on either side (i.e. the test is positive but disease is really absent or the test is negative but the disease is really present), is always likely to occur. The basic aim of any study on the evaluation of diagnostic test is, therefore, to assess and quantify the extent to which we may go wrong.

Essential Requirements of a Diagnostic Test Study

In any diagnostic test assessment, with the above mentioned broad aim in mind, there would be, three essential things required :

- The diagnostic test, which is to be evaluated.
- A ‘gold standard’ criteria of diagnosis. This ‘gold standard’ is that diagnostic criteria, as per current knowledge, can be assumed to be 100 percent accurate in diagnosis. For

example, while evaluating “Resting ECG” as a diagnostic test for Ischaemic Heart Disease, we may keep coronary angiography as the gold standard.

- A group of subjects, *each of whom should be subjected to both the tests* - the test under evaluation and the gold standard test.

Parameters on which a Diagnostic Test is evaluated

Any diagnostic test should be evaluated in terms of these parameters :

- Reliability** : (Syn : Precision, Reproducibility, Repeatability). This denotes the ability of the test to give consistent results when repeated applications are made.
- Validity** : (Syn : Accuracy). This is the ability of the test to correctly diagnose the condition which it is meant to diagnose; in other words, it is the extent to which it correctly identifies those who do have the disease as well as excludes those who really do not have it, against the gold standard.
- Economicity** : (Syn : Efficiency). This is the extent to which the expenditures on the test in clinical and public health practice commensurate with the results. We would describe each of these 3 aspects in the succeeding paragraphs.

Reliability

The ability of any diagnostic test to give consistent results on repeated applications is reliability. It would be affected by variations which can occur due to observers, subjects, instruments or techniques, as per details already discussed in the chapter on validity and confounding. The methods for

improving reliability have also been mentioned in the same chapter and the readers are advised to go through the same. As discussed earlier in the chapter on confounding, reliability can be statistically assessed by estimating the degree of agreement between two measurements.

Consider a study on pulmonary TB, with AFB positivity on sputum smear as the method of measurement. We use laboratory technicians to examine the sputum slides after training them by microbiologist. For assessing the inter - observer reliability, (between the microbiologist and Lab technician), we took 320 stained slides and each slide was examined by both of them. The results are given in Table - 1.

Technician's Diagnosis	Microbiologist's Diagnosis		
	Positive	Negative	Total
Positive	21 (a)	(b) 11	(p1) 32
Negative	37 (c)	(d) 251	(q1) 288
Total	58 (p2)	(q2) 262	(n) 320

Now, the observed agreement (O)

$$= \frac{\text{Where both agree at Yes} + \text{where both agree at No}}{\text{Total Subjects}}$$

$$= \frac{a + d}{n} = \frac{21 + 251}{320} = 0.85$$

And, agreement which was, in any case expected due to 'chance' (E)

$$= \frac{(p1 \times p2) + (q1 \times q2)}{(n \times n)}$$

$$= \frac{(32 \times 58) + (288 \times 262)}{320 \times 320} = 0.754$$

Now, Kappa Coefficient (K)

$$= \frac{O - E}{1 - E} = \frac{0.85 - 0.754}{1 - 0.754} = 0.388 \text{ (or } 38.8 \%)$$

The value of Kappa coefficient (K) will be between 0 and 1 (in our example it is 0.388). If it is 0, it means that the two measurements agree simply because of chance, while if it is 1 it means that the two measurements agree perfectly, irrespective of chance. In the above example, we would conclude that the observed agreement between the 2 observers of assessing AFB positivity is 38.8% of the way between a coincidental agreement purely by chance and a 'perfect agreement'. Nearer the Kappa coefficient is to 1 (or 100%), better the agreement between two observers, or methods of measurement, is likely to be. *Usually, values of kappa of upto 25% indicate mild agreement, 26 to 50% moderately strong agreement, 51 to 75% strong agreement and more than 75% indicate very strong or excellent agreement.*

Validity

Let us consider the following 2x2 table (Table - 2) :

Result of Diagnostic Test under Evaluation	Result of Gold Standard Test		Total
	Positive	Negative	
Positive	True positives (TP) (a)	False Positives (FP) (b)	a+b=Total +ve by test
Negative	False Negatives (FN) (c)	True Negatives (TN) (d)	c+d=Total -ve by test
Total	Total +ve by gold standard a+c	Total -ve by gold standard b+d	a+b+c+d = n = Total subjects studied
	Total Truly Diseased	Total Truly Not - diseased	

Let us say we studied a total of 'n' subjects; each subject was given both the diagnostic test, as well as the gold standard test for final diagnosis. The notations in the above table can be explained as follows :

- Cell 'a' represents those subjects who were diagnosed as diseased by the gold standard as well as called positive by the test being evaluated. They are thus the "True Positives" (TP).
- 'b' are those subjects who were called positive by our test but were not really diseased, as revealed by gold standard. They are thus the "False Positives" (FP).
- 'c' are those subjects who were actually diseased (as diagnosed by gold standard) but our test could not identify them and called them negative. These are the "False Negatives" (FN).
- 'd' are those subjects who were not diseased (called negative by gold standard) and the test also correctly called them negative. These are the "True Negatives" (TN).
- (a+b) are the total number of subjects who were called positive by the test, whether they had the disease or not; thus it is sum of TP and FP.
- (c+d) are the total number of subjects who were called negative by the test, whether they had the disease or not; thus it is the sum of FN and TN.
- (a+c) are the total subjects who were really diseased (gold standard diagnosis) irrespective of whether they were identified as positive by our test or not; thus it is the sum of TP and FN.
- (b+d) are the total number of subjects who were in reality not diseased, as diagnosed by gold standard, irrespective of whether our test called them negative or positive; thus it is the sum of FP and TN.

Let us assume we were evaluating the performance of ELISA as a diagnostic test for HIV infection and the gold standard that we used was PCR. We took 1,00,000 subjects and subjected each and every one of them to both, the ELISA as well as the PCR tests. The hypothetical results are presented in the 2x2 table (Table - 3) :

ELISA	Gold Standard Test (PCR)		Total
	Positive	Negative	
+ve	TP (a) 990	FP (b) 9900	a+b = Total +ve by test 10890
-ve	FN (c) 10	TN (d) 89100	c+d = Total -ve by test 89110
Total	a+c 1000 (actually +ve for HIV)	b+d 99000 (actually -ve for HIV)	a+b+c+d = n 1,00,000

Measures of Validity

(a) Sensitivity : This is defined as the ability of the test to call positive those who really have the disease. Thus, sensitivity

$$= \frac{\text{Positive by test}}{\text{Total diseased}} = \frac{(TP)}{(TP + FN)} \text{ or } \frac{a}{a + c}$$

It is also called "Positivity in Disease" (PID)

In our above example, sensitivity of ELISA = 990/1000 = 0.99, or 99%.

(b) Specificity : This is the ability of the test to call negative those who do not have the disease; thus it is also called as "Negativity in Health" (NIH). Thus, specificity

$$= \frac{\text{Negative by test}}{\text{Actually not diseased}} = \frac{(TN)}{(FP + TN)} \text{ or } \frac{d}{b + d}$$

In our example, specificity = 89100/99000 = 0.9 = 90%

The problems with sensitivity and specificity : Sensitivity and specificity of any diagnostic tests are the basic parameters of validity. They are 'fixed' parameters, i.e. the sensitivity and specificity of any test will not change in different type of settings. However, as doctors, our interest is truly not in sensitivity or specificity, e.g. in the above example, our interest will not be that the ability of the test (ELISA) is 99% in calling positive those who will have the disease. Our interest is to know if one of our patients has tested positive on ELISA, what are his chances of really having HIV infection? Or if he has tested negative, what are the chances that he really does not have the infection? These questions clearly can not be answered by sensitivity and specificity but by a different set of parameters - the predictive values.

(a) Positive Predictive Value (PPV, PV+, post test probability): This is the probability that if a person has tested positive on a test he will really have the disease. Thus, PPV

$$= \frac{\text{Total true +Ve}}{\text{Total +Ve on test}} = \frac{(TP)}{(TP + FP)} \text{ or } \frac{a}{a + b}$$

In our above example, PPV = 990/10890 = 9.1%

Thus, if our patient (of course, one coming from this particular type of population - we will explain this aspect shortly) has tested positive on ELISA there are only 9% chances that he will really be having the HIV infection !

(b) Negative Predictive Value (NPV, PV-) : This is the probability that a person who has tested negative really does not have the disease. Thus, negative predictive value

$$= \frac{\text{True Negatives}}{\text{Total Negatives on test}} = \frac{(TN)}{(FN + TN)} \text{ or } \frac{d}{c + d}$$

In our above example, NPV = 89100/89110 = 99.9%

The difficulties with the predictive values : The difficulty with the positive and negative predictive values is that while the sensitivity and specificity of a test are constant, the predictive values are largely dependent on the prevalence of the disease in the population in which the diagnostic test is being applied. Let us consider the following example :

The sensitivity and specificity of ELISA in diagnosing HIV infection is 99% and 90% respectively, as worked out earlier. Now, let us say, we applied the test in a population with very low prevalence of the disease (HIV positivity), e.g. healthy blood donors (in which the prevalence is known to be about 1%). Let us assume that we took 1 lakh healthy blood donors in this study.

Now, since prevalence of disease = 1%.

Therefore, total who will be truly positive = (1/100) X 1,00,000 = 1,000.

And total truly negative = 1,00,000 - 1,000 = 99,000.

Since, sensitivity of ELISA is 99%, it will correctly identify (99 / 100) x 1000 = 990 of those 1000 who have the infection; thus, 1000 - 990 = 10 will be called negative.

Again, since specificity is 90%, it will correctly call, as negative, 90% of 99000 who do not have the disease, i.e. 89100. Hence 99000 - 89100 = 9900 will be called positive by ELISA though they do not have the infection. We can now complete the 2x2 table as shown in Table - 4.

ELISA	Healthy blood donors		Total
	Having HIV Infection	Not Having HIV Infection	
+ ve	990	9900	10890
- ve	10	89100	89110
Total	1000	99000	100000
Now, PPV = 990 / 10890 = 0.091, or 9.1%			
NPV = 89100 / 89110 = 0.9999, or 99.99%			

Thus, if the prevalence of the disease in the target population is low, the PPV will be low. So, if a healthy blood donor tests positive on first ELISA, the probability that he really has HIV infection is only 9% (This may sound interesting but is a fact. Leading text books of medicine authentically say that, of the healthy blood donors who test positive on first ELISA screen test, only about 13% will finally be confirmed to have the infection. The reason for this is explained above).

Now, let us say - we apply the same ELISA in another population with a very high prevalence of HIV infection; say, commercial sex workers (CSWs) in whom the prevalence is known to be about

50%. Assume that we subjected 1,00,000 CSWs to ELISA test. Now, since the prevalence is 50%, a total of 50,000 CSWs would be having HIV infection out of the 1,00,000 being studied. With a sensitivity and specificity of 99% and 90%, ELISA will give us 49,500 True Positives (99% of 50,000 diseased) and 45,000 True Negatives (90% of 50,000 not infected). The 2x2 table can now be constructed as shown in Table - 5.

ELISA	Commercial Sex Workers		Total
	Having HIV Infection	Not Having HIV Infection	
+ ve	49500	5000	54500
- ve	500	45000	45500
Total	50000	50000	100000

Now, $PPV = 49500 / 54500 = 0.91$, or 91%
 And, $NPV = 45000 / 45500 = 0.989$, or 98.9%

Thus, if the prevalence is high, the PPV is very high. In other words, if a CSW tests positive on first ELISA, the probability that she really has HIV infection is very high - more than 90%.

Clinical implications of prevalence and PPV : The above description of how a test, with a given sensitivity and specificity (which are constant parameters) can give very different positive predictive values depending upon the prevalence of the disease in the target population, has important clinical and public health implications :

(a) Most of the diagnostics tests, after their development, are validated in tertiary care settings, where the prevalence of the disease condition, as such, is very high and hence the PPV in such settings will be high. However, the same test (with the same sensitivity and specificity) will have a hopelessly poor PPV, if applied in the primary health care settings where the prevalence of the disease is low. Let us take a common example:

If we validate Resting ECG as a diagnostic test for diagnosing IHD in a cardiology center, on males more than 35 years age, the prevalence of IHD in this "population" (i.e. males more than 35years age attending a cardiology center) is likely to be substantial (say, at least 15% to 20%). Now let us say, validation studies in these settings indicate that the sensitivity and specificity of Resting ECG in diagnosing IHD is 95% and 80% respectively. Impressed with this sensitivity and specificity, we start applying resting ECG as a screening test for IHD in healthy young males of more than 35 years age, say, sportsmen. Now the prevalence of IHD in this target population is very low, say 1 in 1,000. Let us say we put 1,00,000 healthy sportsmen aged > 35 years to this screening test. Now, since the prevalence is 1 in 1,000, 100 out of the 1,00,000 will actually have IHD and 99,900 will not have IHD. With a sensitivity of 95%, 95 of these 100 will called "True positive" by Resting ECG; and with a specificity of 85%, 84,915 of the 99,900 non diseased will be correctly called non diseased (TN) by Resting ECG; Hence 99,900 - 84,915, i.e. 14,985 will be False positives. The resulting 2x2 table is shown as Table - 6.

Resting ECG Result	TRUTH		
	Have IHD	Do not have IHD	Total
Positive	95	14985	15080
Negative	5	84915	84920
Total	100	99900	100000

$PPV = 95/15080 = 0.0063$ or 0.63%

In other words, a young healthy sportsman aged >35 years who turns positive on resting ECG has even less than 1% chances of really having IHD. The implications can be serious. The 15,080 which are called positive by Resting ECG, will have to be subjected to confirmatory test, leading to excessive expenditure, which could have been diverted to some other fruitful activity and finally not even 1% of these will turn out to be having IHD. Secondly, the adverse psychological impact ("labeling effect") on the 14,985 who really do not have IHD but are called positive by Resting ECG can be tremendous. The clinician, epidemiologist as well as health administrator must keep themselves aware of such phenomena.

(b) Most of the diagnostic tests and equipment which are marketed describe the sensitivity and specificity (which are likely to be quite high), to impress the clinician and health administrators. However, these do not describe the settings in which the validation studies have been carried out. We should therefore, specifically ask them (the manufacturers or promoters) about the "settings" in which such validation studies are done by them and see if our settings of proposed application of the test are the same as the ones in which the test was validated.

(c) We can improve the PPV by bringing the subjects from a population of low prevalence to one of a high prevalence by certain artificial measures. Let us work on an example to see how this can be done. In our example on ELISA done on healthy blood donors, after the first test the 2x2 table (Table - 4) showed that in all, 10,890 persons out of a total 1,00,000 had tested positive.

Now, after doing this first ELISA, let us pick up all the 10,890 who tested positive (these would include 990 who truly have HIV infection and 9,900 who do not have HIV infection but have tested positive, i.e. FP & TP). Now, let us subject these 10,890 to second ELISA test. The results of this second ELISA (again with sensitivity and specificity of 99% and 90% respectively) would be somewhat like Table - 7.

Second ELISA	Healthy blood donors who tested positive with ELISA on first test		Total
	Having HIV Infection	Not Having HIV Infection	
+ ve	980	990	1970
- ve	10	8910	8920
Total	990	9900	10890

Since there were 990 who actually had HIV infection and the sensitivity of ELISA is 99%, 980 of these 990 will be called correctly positive (TP). Again, with a specificity of 90%, 8910 of the 9900 non infected will be called negative while (9900 - 8910). i.e. 990 of the non infected will be called positive (FP). Thus, the PPV would now be $990 / (990 + 980) = 0.498$. i.e. 49.8%. Thus, after the first test the PPV was only 9%; after second test it is almost 50%.

How could this happen ? This occurred because during the first test the prevalence was 1,000/1,00,000, i.e. 1% which was very low. However, during the second test, the prevalence was 990 / 10,890, i.e. 9% (you may like to calculate for yourself what the PPV would be if we pick up all those 1,970 who have tested positive on second ELISA and give them a third ELISA test ? Well, it will be 91% this time - quite high. Thus if a healthy blood donor tests repeatedly positive (3 or more times) on ELISA, you would be more than 90% sure that he does suffer from HIV infection. Even in our everyday clinical practice, we do this exercise, though often unknowingly. If a young athlete walks to our office and complains of 'chest pain' we do not straightaway order for an ECG, because he represents a "population" (of young athletes having chest pain) in which the prevalence of IHD would be very low and hence the PPV of ECG in such a population would be poor. What we do is that we ask him two more question "Does it occur on exertion?" "Does it radiate to left arm? If his answers are yes, we now order for an ECG; because now he represents another "population" (of young athletes with chest pain occurring on exertion and radiating to the left arm) in which the prevalence of IHD is high and hence the PPV of ECG would be high.

When to use a highly sensitive test : A test which has very high sensitivity (though at the cost of low specificity) will identify, as positive, almost all of those who have the disease (i.e. high TP rate) through in the bargain it will also identify a large number of those who do not have the disease (high FP). In other words, the number of false negatives will be low; it means that, if a person comes negative on a highly sensitive test, then we are almost sure that he does not have the disease (if test result is positive, however, then we are not very sure that the person really has the disease because 'FP' will be very high).

It follows, therefore, that a highly sensitive test is of value, clinically, when it is "negative", and in this situation, it helps in "ruling out" the disease; e.g. ELISA is a highly sensitive test for HIV infection (sensitivity 99%); thus, if a person is negative on ELISA, we are pretty sure that he does not have HIV infection, i.e. we rule out the diagnosis. This is also called as "Negativity in Health". However, if ELISA is positive, we are not so sure that the person really has HIV infection and hence we put him to a confirmatory test like Western Blot (or repeated ELISA tests using different systems). It also follows, therefore, that a highly sensitive test would be ideal as an initial screening test.

When to use a highly specific test : On the same reasoning used for a highly sensitive test, a highly specific test will have a large number of True Negatives and a very small (almost minimal) False Positives; however, the price one will pay will be a large number of False Negatives coming in. Because the

False Positives are almost nil in a highly specific test, if such a test is positive we are very sure that the person does have the disease; however, if the test is negative, it will not have much value since it will give a large number of false negative results. Thus, a highly specific test is of value when it is positive; and a positive result from a highly specific test "rules in" the diagnosis (Positivity in Disease). An example is Western Blot Test for HIV infection which is a highly specific test (specificity 99% or more). Once Western Blot is positive we are sure that the individual does have HIV infection. It also follows, therefore, that a highly specific test is best used as a "confirmatory test".

This discussion on highly sensitive or highly specific tests is because a test which is highly sensitive is likely to lose on specificity and vice versa. You possibly cannot have a test which is both highly specific as well as highly sensitive (because, if it is so, it will itself become the 'gold standard').

The Likelihood Ratios : From the foregoing narration it would be clear that the interest of the clinician or the public health specialist is, truly speaking, in the PPV and not the sensitivity or specificity. However, as we have seen, PPV depends on the prevalence of the target condition in the population, which is more often a matter of guesswork. To overcome these problems, the concept of likelihood ratios has been developed.

Likelihood Ratio (Positive) (LR +, LRP) : This is calculated by the following equation :

$$LR+ = \frac{\text{Sensitivity}}{(1 - \text{Specificity})}$$

For example, if the sensitivity of ELISA is 99% (i.e. 0.99 and specificity is 90% (i.e. 0.90), then

$$LR+ = \frac{0.99}{(1-0.90)} = \frac{0.99}{0.1} = 9.9$$

The interpretation is "A positive result on ELISA for HIV is 9.9 times (say, roughly 10 times) more likely to occur in a subject with HIV infection as compared to a subject who does not have HIV infection".

Negative Likelihood Ratio (LR-, LRN) : This is calculated by the equation :

$$LR- = \frac{(1 - \text{Sensitivity})}{\text{Specificity}}$$

In our above example on ELISA,

$$LR- = \frac{(1 - 0.99)}{0.90} = \frac{0.01}{0.9} = 0.011 = 1.1\%$$

The interpretation is that a negative result is only one hundredth times likely to occur in a person who really has HIV infection as compared to a person who does not have HIV infection. Apparently, for ELISA as diagnostic test for HIV infection, the LR minus is quite high (of the magnitude of 100 times) as compared to LR+ (of the magnitude of 10 times). Thus, it is the negative result of ELISA which is more important (a negative result would "rule out" the diagnosis), but not so much importance could be given to a positive result (a positive result of ELISA does not rule in the diagnosis; we have to

further confirm).

The Other Scenario : When the Diagnostic Test Makes Measurements on a “Continuous Scale”

The discussion till now was in settings when the results of diagnostic test are recorded in either of the two categories - “Positive” and “Negative” (i.e. a categorical, “dichotomous” scale). Let us take the following hypothetical example.

We undertook : a study to evaluate Alanine Aminotransferase (ALT) as a screening test for chronic parenchymal liver disease. 500 patients attending a gastroenterology center with symptoms of liver disease were subjected to both, an assay of serum ALT levels as well as a diagnostic liver biopsy which was taken as the gold standard in this case. The results are presented in Table - 8.

Now, the instant question which would come up in any such situation is “what should be the optimum cut - off point for serum ALT by which we have the best probability of diagnosing Chronic Liver disease; i.e. what is that cut - off point at which we could correctly identify, as many as possible of those who have the disease (i.e. high sensitivity) and, at the same time, correctly leave out maximum number of those who do not have the disease (i.e. high specificity)”.

Serum ALT Levels	Chronic parenchymal liver disease (As diagnosed by Liver Biopsy)		Total	Situation
	Present	Absent		
Units / Litre				
≤ 20	0	120	120	
21 - 40	20	150	170	(1)
41 - 60	40	15	55	(2)
61 - 80	40	12	52	(3)
81 - 100	40	3	43	(4)
> 100	60	0	60	(5)
Total	200	300	500	

Now let us see what happens if we place the cut - off point at 20 U/Litre (situation no. 1), and specify that we will diagnose any body who has ALT levels >20 U/L as having chronic liver disease. If this be the situation then we will diagnose all the 200 real patients as having liver disease; but at the same time we would also diagnose 180 non diseased persons (150 + 15 + 12 + 3 + 0) as having Chr. Liver disease. The 2x2 table would appear as Table - 9.

Diagnosed Using ALT Level of >20	Chr. Parenchymal liver disease by Gold Standard	
	Present	Absent
Present	200	180
Absent	0	120
Total	200	300

And, in such situation, the sensitivity would be $200/200 = 100\%$, but the specificity would be $120/300$, i.e. 40% only.

Now, let us say we decide to place the cut - off point at >100, specifying that if we find anybody with ALT level >100 U/L, we would diagnose chronic liver disease, otherwise not. The 2x2 table in such case would be like Table - 10.

Diagnosis based on ALT >100	Gold Standard Diagnosis	
	Present	Absent
Present	60	0
Absent	140	300
Total	200	300

In this instance, sensitivity = $60/200 = 30\%$ (0.3)

And, specificity = $300/300 = 100\%$ (1.0)

In fact we can work out the sensitivity and specificity for each level of cut - off point and put the same as shown in Table - 11.

Cut off level	Sensitivity	Specificity	1 - Specificity*
> 100	0.30	1.00	0
> 80	0.50	0.99	0.01
> 60	0.70	0.95	0.05
> 40	0.90	0.90	0.10
> 20	1.00	0.40	0.60

* We shall discuss the significance of the column (“1 - specificity”) a little later.

The straight conclusion which the above table gives us is that nowhere we would find a cut - off point where both sensitivity and specificity are 100%. If we lower our cut - off point (i.e. make the diagnostic criteria less strict), there will be an improvement in sensitivity from (0% at >100 to 100% at >20 units), but this will be obtained at a corresponding decline in specificity (from 100% at >100 units to 40% at >20); and contrarily as we keep raising the cut - off point (i.e. make the diagnostic criteria more strict) our specificity will keep increasing but at a corresponding decline in sensitivity.

The next question which comes to us, now, is what should be the “optimum cut - off point, i.e. how do we decide the cut off point which gives us the best combination of specificity and sensitivity. For doing this, we undertake the exercise of constructing the “Receiver - Operating - Characteristics curve” (ROC curve). Interested readers may refer to the list given in further suggested readings, for details of ROC curve analysis.

Steps in Planning a Study on Diagnostic Test Evaluation

The following steps can be used as a checklist when planning a study on diagnostic test evaluation :

(a) Clearly define your research question and its background significance

- How your new diagnostic test, being evaluated, will help in better public health care / improved patient management.
- How is it going to be better than the existing tests (in terms of cost, ease of administration, technical ease, higher accuracy or better precision).

(b) *Specify the Variables* : Clearly specify the definition of the disease being diagnosed (as HIV), the variables being studied (as ALT, positivity to ELISA etc.) and the “scales” on which these variables are going to be measured (whether dichotomous or continuous etc.).

(c) *Give a clear description of the following “settings” of your study* :

- The type of hospital where you are going to do the study (e.g. specialized centre; secondary level care hospital etc.).
 - The demographic profile of the subjects (age, sex, race, education, economic status etc.).
 - The “referral filter” that your subjects have passed through before coming to your hospital; e.g. Whether they have come directly or passed through a referral filter of primary health centre, district hospital etc.
 - The “spectrum of disease” that you are including - whether only the severe forms or all the forms, i.e. mild, moderate and severe.
- (d) *As far as possible, include the complete spectrum of disease in your study* - the mild, moderate and severe forms : the typical as well as atypical forms; and also those disorders which are likely to be confused with the target disease.
- (e) *Give a clear description of the “Gold standard” of diagnosis in your study, the reason as to why you are adopting it as a gold standard, and a clear description of the technique of undertaking the Gold standard test.*
- (f) *Give a clear and detailed description of the technique of doing the diagnostic test under study so that your colleagues who read your research paper can also undertake it on their patients.*
- (g) *Clearly mention the Replicability (reliability) of your diagnostic test in terms of variations that may occur due to Observers (inter and intra observer), Subjects (inter and intra subject) and instruments and techniques.*
- (h) *Give a clear description of methods to improve precision, i.e. to reduce variability when applying this test, in terms of Standardization of instruments, Standardization of techniques, Training and certification of observers (workers) and Quality control procedures.*
- (j) *Calculate the sample size* - The sample size in a diagnostic test study is done in two stages :

- 1) *First, specify the expected “sensitivity” of the test* - just a rough estimate as you have seen earlier during sample size calculations; and specify the “acceptable deviation” from this sensitivity on either side of the expected sensitivity. Then,

$$a = \frac{\text{Sens} \times (1 - \text{Sens})}{(\text{Deviation})^2}$$

Let us say, we are validating ELISA test for HIV infection. Our rough estimate is that the sensitivity would be 95% (i.e. 0.95) and we accept a deviation of 3% on either side

(i.e. acceptable range of sensitivity to be detected by the present study sample = 92% to 98%); thus $d = 3\%$ (i.e. 0.03).

$$a = \frac{0.95 \times (1 - 0.95)}{(0.03)^2} = 53$$

- 2) *Now, the actual sample size ‘N’ is calculated by the formula*

$$N = \frac{a}{\text{Prevalence}}$$

Let us say the expected prevalence of HIV infection in the population we are doing our study (say, professional blood donors) is 5% (i.e. 0.05)

Thus,

$$N = \frac{53}{0.05} = 1060$$

Thus, we should take a sample of 1060 subjects from the given population of professional blood donors. (note that if sensitivity is used as a fraction out of 1, then prevalence should also be in fraction form). In our example, we have therefore, taken both, the sensitivity (0.95) as well as prevalence (0.05) in fraction form.

k) And the last, but the most important point during the conduct of a diagnostic test study (which is often forgotten) is “*Put each and every subject of your study to BOTH, the diagnostic test under study as well as the Gold Standard test*”. If this is not done (e.g. only those who come positive on diagnostic test are put to Gold Standard test), it does not remain a diagnostic test study at all.

Summary

For evaluating a diagnostic test, which could be a new pathological or radiological procedure, or even a clinical algorithm, we assess its ability to correctly diagnose a disease as compared to some ‘gold standard’ which would have diagnosed the disease in an absolutely perfect manner. Thus, any diagnostic test should be evaluated in terms of three types of parameters. These are Reliability, validity and Economicity. Reliability : (Syn : Precision, Reproducibility, Repeatability) is the ability of the test to give consistent results when repeated applications are made. Reliability is affected by variations which can occur due to observers, variations due to subjects and variations due to instruments and techniques (Different physical instruments, reagents etc. may give different results). Reliability can be minimized by standardization of definitions of the disease being diagnosed, using standard techniques of measurement, using standardized instruments, training of workers, continued supervision, establishing a quality control system, and by using good quality instruments and reagents.

Validity is the ability of the test to correctly diagnose what it actually intended to diagnose, as compared to the gold standard test. This has two broad components, viz., the ability of the test to correctly call positive those who really have the disease; this is known as sensitivity and is calculated by the number of actually diseased persons called correctly positive by the

test under study (true positives) divided by the sum of true positives and false negatives (people who actually have the disease as per gold standard but our test calls them negative). The second parameter is ‘specificity’ which is the ability of the test to correctly call negative those who do not have the disease and is calculated by dividing the true negatives by the sum of true negatives and false positives (persons who actually do not have the disease according to gold standard but our test has called them positive).

In addition to sensitivity and specificity, equally important are the ‘predictive values’ of a test, which are also of two types. The positive predictive value gives the probability that a person who has a positive result from our test will actually have the disease and is calculated by dividing the true positives by the sum of true positives and false positives. The negative predictive value gives the probability that a person with a negative result from our test really does not have the disease and is calculated by dividing the true negatives by the sum of true negatives and false negatives. A particular issue with the predictive values to be noted is that they are quite dependant on the prevalence of the disease being studied; if the prevalence of the disease is high, the positive predictive value will be high and vice versa. This problem may be overcome by calculation of ‘likelihood ratios’ (positive and negative).

When the diagnostic test is recorded on continuous scale, there is no cut - off which will give 100% specificity and 100% sensitivity. If cut off is lowered, the test will have higher sensitivity value & low specificity; if the cut - off level is raised, it will result in high specificity and low sensitivity. To get the optimum cut off, which gives us the best combination of specificity and sensitivity, we construct the ‘Receiver - Operating - Characteristics curve’ (ROC curve), by plotting the values of sensitivities against the corresponding values of (1 - specificity) at the various cut - off levels.

Before planning diagnostic test evaluation clearly define research question and its background significance and specify the variables. Then give a clear description of your settings in term of type of hospital, demographic profile of the subjects, referral filter and spectrum of diseases. As far as possible take the complete spectrum of disease. Give a description of gold standard test and the technique of undertaking it. Similarly give clear and detailed description of the technique of undertaking the diagnostic test being evaluated. Give considerations to the Replicability (reliability) of your diagnostic test in terms of variations that may occur due to Observers (inter and intra observer), Subjects (inter and intra subject), Instruments and techniques. Give a clear description of methods to improve precision, i.e. to reduce variability when applying this test, in terms of Standardization of instruments, Standardization of techniques, training and certification of workers and Quality control procedures. Finally, ensure that each and every subject of your study is subjected to both, the diagnostic test under study as well as the Gold Standard test. Analyse the results by calculating the sensitivity, specificity, predictive values and likelihood ratios.

Study Exercises

Long Question : Most often, young children are at high risk of death or complications if they develop lower respiratory tract infections, usually with *Streptococcus pneumoniae*. Early institution of oral antibiotics by the paramedical health workers, at domiciliary level may be life saving. The gold standard accepted method of diagnosing this infection, is a combination of chest X - ray and sputum culture. A health policy maker wants to find out the extent to which a combination of fever and tachypnoea (respiratory rate > 40 per mt) can diagnose the condition; if the validity is high, a paramedical worker can be trained to start early antibiotics in the home settings. Forward your plan of undertaking this study.

Short Notes : (1) Validity of a diagnostic test (2) ROC curve analysis (3) Reliability of a diagnostic test (4) Kappa coefficient.

MCQs & Exercises

- The ability of the test to call positive those who really have the disease is known as : (a) sensitivity (b) validity (c) specificity (d) none of the above
- The ability of the test to call negative those who do not have the disease is known as (a) sensitivity (b) validity (c) specificity (d) none of the above
- Essential requirements of diagnostics test are (a) diagnostic test (b) subjects (c) gold standard test (d) all of the above
- Parameters on which a diagnostic test is evaluated are all except (a) reliability (b) efficiency (c) validity (d) strength of association
- What is plotted along the Y - axis in ROC curve (a) sensitivity (b) prevalence (c) specificity (d) predictive values
- In diagnostic evaluation test, (a) only those subjects who are positive on diagnostic test are subjected to gold standard test (b) All subjects are subjected to both the test ; (c) only those subjects who are negative on gold standard test are subjected to diagnostic test. ; (d) None of the above.
- Prevalence will affect the _____ of a test (a) Sensitivity (b) Predictive values (c) Specificity (d) Validity
- Pap smear examination is often used as a screening test for cervical cancer. In developing countries, where resources are scanty, a public health manager wants to find out as to how well ‘Visual inspection (VI)’ can be used as a screening test, when histopathology is taken as the gold standard. For finding this, the investigator took subjects from clinics catering to the rich, affluent socio - economic class. 5000 women who were established to be having cervical dysplasia on biopsy and 10,000 age and parity matched women who were not having cervical cancer were subjected to VI, which was positive in 3600 of the dysplasia subjects and in 1600 of the non - dysplasia group. Answer the following : (a) What is the sensitivity of VI (b) What is the specificity (c) What is the PPV (d) If VI is applied to CSWs, what will happen to these three parameters?
- Two radiologists were asked to independently read 100 USG of bladder area and classify them as normal or abnormal.

Their results are as follows. Answer the questions (a) to (d) below based on this information :

Radiologist - 1	Radiologist - 2		Total
	Abnormal	Normal	
Abnormal	40	20	60
Normal	10	30	40
Total	50	50	100

(a) What was the simple, overall percent agreement between the two radiologists (b) If the USGs which both read as normal are removed, then what was the overall percentage agreement between the two (c) What is the value of Kappa Coefficient

(d) This value of Kappa represents what grade of agreement.

Answers : (1) a; (2) c; (3) d; (4) d; (5) a; (6) b; (7) b; (8) (a) 72% (b) 84% (c) 69.2% (d) sensitivity and specificity will remain the same but PPV is likely to go up, since CSWs are likely to have much higher prevalence of cervical CA as compared to women from high economic status, in which the test was initially assessed. (9) (a) 70% (b) 57% (c) 0.40 or 40% (d) Moderately strong agreement.

29

Epidemiologic and Public Health Basis of Screening for Diseases

Rajvir Bhalwar

One of the priority duties, not only of a public health physician but for all medical personnel is to ensure an early diagnosis and treatment, through “screening for diseases”.

Definition : Screening has been defined by the commission on chronic illnesses (88, 89) as “*the presumptive identification of unrecognized defect or disease by the application of tests, examinations or procedures which can be applied rapidly, to sort out apparently well persons who probably have a disease, from those who probably do not*”. A screening test is not intended to be diagnostic. Persons with positive or suspicious findings must be referred to the physicians for diagnosis and necessary treatment.

The various objectives for which screening is undertaken are shown in Box - 1.

Box - 1 : Objectives of Screening

Screening in community health care is undertaken with the following broad objectives

- To ensure early detection of a disease among individuals, so that prompt treatment may be instituted; e.g. screening for cervical cancer, breast cancer, hypertension etc. This is also called “Prescriptive Screening”.
- To protect the community from disease that the person being screened has, also called “Prospective Screening”; e.g. screening the blood units for HIV.
- For entry into certain forms of occupations (armed services, industries, etc.) with a view to “weed out” those who are unfit or whose existing health status may be adversely affected by occupational conditions.

Requirements of Tests used for Screening

A Screening test should be :

Valid : It should be “accurate”, i.e. should measure correctly what it intends to. It should have high sensitivity, specificity, and positive & negative predictive values.

Reliable (Precise) : It should give consistent results when repeated applications are made.

Yield : It should give enough number of cases to commensurate with the expenditure and inputs involved. Yield will depend on Sensitivity of the test, Prevalence of the disease (If screening is applied to a high risk group, the yield will be better) and availability of medical care (if medical care has not been available to the community being screened, a large number of people with the disease will be diagnosed).

Practical : The test should be easily administered by even persons with ordinary training, should be innocuous, acceptable and should give fairly quick results.

Efficient : The amount of inputs (in terms of expenses and time) should result in reasonable amount of outputs in terms of improved health & satisfaction.

We have already had a detailed discussion on the various aspects of validity (sensitivity, specificity, etc.) and reliability in an earlier chapter on diagnostic test evaluation studies and the readers are suggested to recapitulate the contents of that chapter. Ideally a test should be both highly specific as well as highly sensitive, so as to get the maximum numbers of True Positives (TP) and True negatives (TN). However, in practice this is not possible and some trade off, depending on the disease under consideration is required. If a disease has serious implications if not treated early and has adequate treatment available, then our aim would be to not leave out any “false negative”, even at the expense of getting many false positives; in such instance we would go up for highly sensitive test.

For a screening test in which the result is measured on a continuous scale, the decision regarding cut off point would

need consideration by experienced clinicians and public health administrators. For example, if tonometry is being used as a screening test for glaucoma, the results (18, 18.5, 22, 26.8 mm etc.) would be measured on a continuous scale. Now, possibly most of the eyes with intra ocular pressure upto 22 may be, in fact, non - glaucomatous while most of the eyes with intra ocular pressure more then 26 mm will be, in fact, really glaucomatous. The main problem will be the eyes having ocular pressure between 22 and 26 mm Hg, i.e. the area of overlap between glaucomatous and non glaucomatous eyes. If we keep the cut - off point low, say at 22 mm Hg, we will correctly identify nearly all the glaucomatous eyes (high TP) but will also identify a number of normal eyes as glaucomatous (large numbers of False Positives (FP)). On the other hand, if we keep the cut off at 26 mm Hg, we would correctly identify nearly all the normal eyes (high TN) but would miss out a large number of glaucomatous eyes who have mild rise of pressure (large numbers of False Negatives (FN). In the former instance, when we have a low cut off point (i.e. less stringent criteria) we have, thus, higher sensitivity but lower specificity. On the other hand, in the latter instance, when we have a higher cut - off point (i.e. more strict criteria) we get a higher specificity at the cost of a lower sensitivity. In practice, the public health decision regarding the level of cut off is done based on the potential for treatment following early detection, the actual availability of treatment and the "labeling effect of having a disease", if any. In such cases, advanced statistical techniques in the form of "Receiver Operator Characteristics (ROC) curve analysis" are available to scientifically work out the optimum cut off point, which gives the best trade off between specificity and false - Positives (i.e. 1 - Specificity), as has been already described in the previous chapter.

As we have also explained at length in that same chapter, sensitivity and specificity of any diagnostic test are fixed, i.e. they will not change. However, our interest in screening is not only the sensitivity or specificity but rather the predictive values; i.e. if an individual has tested positive on a screening test, what are the chances that he really does have the disease. This is called the Positive Predictive Value (PPV or PV+). Unfortunately, predictive values are highly dependent on the prevalence of that disease in the population being screened. The same test with the same levels of sensitivity and specificity will give a very high PPV if the prevalence of disease is high but a very low PPV if prevalence is low. The optimum prevalence to get a very high PPV as well as NPV is between 30 - 60%. Thus, the health administrator should aim at getting the population to be screened in such a way that prevalence of the condition for which screening is being undertaken, is between 30% to 60% (90).

Serial (Sequential) and Parallel (Simultaneous) Screening Tests

Two screening tests can be applied in serial (sequentially) one after the other, by taking people who test positive on the first test for the second test. In fact the same test (e.g. ELISA for HIV) can also be done two times in serial. This procedure will greatly increase the specificity and positive predictive value, but lead to decline in net sensitivity. Similarly two tests can be applied in parallel (simultaneously) and the person can be considered

as +ve if any one or both of the tests are +ve which leads to an increase in net sensitivity but a decline in net specificity.

Considerations before Launching a Screening Programme (After Wilson & Jugner) (91)

Screening in public health settings should only be launched after carefully considering various aspects, as summarized in Box - 2. Detection of cancer of uterine cervix using "pap test" is a procedure which meets all these 10 criteria. The test is based on the assumptions that, firstly, a high proportion of cancer cervix detected in situ would progress to invasive cancer over time; secondly, most cancers remain in situ long enough for screening at reasonable intervals to detect a high proportion of cancer cases; and, thirdly, carcinoma in situ is highly curable.

Other diseases which are amenable to screening include breast cancer, Hypertension, Anaemia during pregnancy, Diabetes Mellitus, growth screening in children, CHD screening in high risk groups, phenylketonuria among new born etc.

Box - 2 : Considerations for a screening programme (source: 91)

- The condition should be an important health problem.
- There should be an acceptable and effective treatment.
- Facilities for confirming the diagnosis and for treatment should be available.
- There should be recognizable latent / early symptomatic stage.
- There should be a suitable screening test or examination available.
- The test should be acceptable.
- The natural history of the condition, including development from latent to apparent disease, should be adequately understood.
- There should be an agreed policy regarding whom to treat as patients.
- The cost of case finding (including final diagnosis and treatment) should be economically balanced vis - a - vis the expenditure on medical care as a whole.
- Case finding should be a continuing process and not "once and for all" project.

Evaluation of Screening Programmes

Contemporary medical evidence strongly recommends that the effectiveness and impact of screening programmes must be evaluated by Randomised Controlled Trials (RCTs) by comparing the outcome measures between the screened and unscreened groups.

Biases in Screening Programmes (92 - 95)

Lead time bias : Lead time is defined as the interval between the point a condition is detected through screening and the time it would normally have been detected due to appearance and reporting of signs and symptoms. If early detection has no effect on the course of disease then it will be like giving the patient a few more years of sickness and apprehension rather than health! (e.g. HIV detection).

In such cases, it is possible that screening, through earlier detection, will advance the time of diagnosis without delaying

time of death, thereby increasing the “diagnosis - to - death - time” and tend to show “increased survival” among the screened group as compared to the group not given screening test, though in reality there would be no increase in survival.

Length bias : It has been observed that cases detected through periodic, early detection programs, tend to have longer preclinical stages than those missed out by screening but self detected between examinations. This preclinical stage is defined as the interval between the time a screening test is capable of detecting disease and the time the patient seeks care as a result of experiencing symptom detected patients. Thus, the length bias tends to spuriously show a better survival among screen detected cases.

Self selection bias : If the groups which are offered (and the other which is not offered the screening) are not constituted by random allocation but rather on the basis of self selection (volunteers), it is possible that such volunteers may be more health conscious, educated and more likely to give up associated risk factors; hence survival in such a screened group is likely to be better, not due to screening but because of associated factors.

Public Health Officer's Check List while Planning a Screening Programme

In the past, many screening programmes have been launched simply due to over enthusiasm, without any consideration to the epidemiological facets of proper health planning. The result has been often quite adverse, creating unnecessary public aversion towards screening programmes (due to lack of proper diagnostic test or treatment), and wastage of resources. It is therefore necessary that the Public Health Officer in charge of Community health care should check the following list sequentially, while launching a screening programme.

Do a “situational analysis” : Undertake a quick collection of information, by going through existing records of health institutions and other governmental/non governmental agencies, or else, collect information by a quick survey, in respect of the community to be screened about the :

- Demographic profile;
- Attitudes towards utilization of existing health services;
- Knowledge & practices about disease(s) proposed to be screened;
- Prevalence of important diseases with special reference to the diseases proposed to be screened;
- Expected load of population likely to come up for screening, in respect of the community to be screened.
- *Resource analysis* : Available medical and paramedical personnel, buildings, vehicles, equipment (for screening and final diagnosis), etc. What additional resources in terms of men, money and material will be required to smoothly undertake the screening test (and the final diagnostic test for those who are positive on screening)? Are adequate treatment facilities available?
- Reports on previous screening programmes which were undertaken in the same community earlier and the “weak areas” noticed.

Decide whether it is worthwhile and feasible to screen for the disease(s) in question : These considerations are

very important before launching a screening programme. The important questions that you must ask yourself at this stage are :

- Is the disease proposed to be screened an important health problem?
- What are the high risk groups for the disease?
- What is the prevalence in these groups?
- Is a screening test available and can be administered to the subjects at a place near their home (say within 5 kilometers)?
- Will the screening test be acceptable to the clientele?
- Have the “diagnostic characteristics” (sensitivity, specificity etc.) of the screening test been worked out authentically?
- Is a confirmatory test available? Will you be able to administer it to all those who are positive on screening test?
- If the confirmatory test is to be given in a specialised centre, will that centre entertain your referred subjects? Will the subjects be able to afford the travel and stay at the place of final diagnostic test?
- Are you sure that there is a proper, proved modality of treatment for the disease you are going to screen?
- Will those finally diagnosed be able to “afford” this treatment? Or will you be able to provide treatment out of governmental funds?
- Are you sure that the disease you are screening for does not carry an over - riding “labeling” effect?

Identify the high risk groups : As we know, the prevalence will be high in high risk groups and hence the PPV and yield will be high; e.g. for screening for cervical cancer, “women > 35 years from lower socioeconomic status” may be identified as the high risk groups.

Collect your logistics together : Remember, not to start a screening programme, in anticipation of the resources - you may cut a sorry figure and cause adverse publicity. First get all your required personnel, equipment, reagents, and other logistics ready.

“Standardize” your personnel, instruments and techniques: The only method of ensuring a high repeatability of screening test is to centrally train your observers/ technicians, pretest and certify them, standardize your equipment and reagents, and establish quality control procedures.

Ensure community participation : Remember, a good epidemiologist never takes her community for granted. Your finest screening camp may not draw even a few subjects, simply because community participation had not been ensured. Contact the community leaders, peer groups and other members of the community who may matter, right in the planning stage itself. Explain to them the importance of the disease to be screened, and the usefulness of screening and early treatment. Emphasise on them that *you need their active participation*. Take their opinion as regards how they would like to get the camp organized.

Give proper publicity : Make sure that at least 2 to 3 rounds of wide publicity have been undertaken, with an additional round of publicity for the high risk groups. The last round should ideally be undertaken 2 to 3 days before the start of screening camp. Ensure that those living in the remote, cut - off areas

are covered well with your publicity - they are usually the ones who will benefit most by your screening programmes but are generally missed out by publicity campaigns.

Conduct the screening programme : Do not leave things to chance. Be there yourself at the site, or at least ensure that one of your senior subordinates is there to address the “unforeseen” problems.

Evaluate the screening programme : Set up your “criteria of evaluation well in advance. Write down your evaluation report at an early date while things are still fresh in the mind - this will serve as a good reference document for subsequent screening programmes.

Summary

Screening is defined as “the presumptive identification of unrecognized defect or disease by the application of tests, examinations or procedures which can be applied rapidly, to sort out apparently well persons who probably have a disease, from those who probably do not”. Persons with positive or suspicious findings must be referred to the physicians for confirmation of diagnosis and necessary treatment”. A screening test should be valid (should measure correctly what it intends to), reliable (should give consistent results when repeated applications are made), and should give good yield. Yield will depend on Sensitivity of the test, Prevalence of the disease and availability of medical care. Besides, a screening test should be practical and efficient. The screening test being used should be as highly specific and sensitive as possible. Besides sensitivity and specificity, predictive values are also important (positive predictive values and negative predictive values). The optimum prevalence to get a very high PPV as well as NPV is between 30 - 60%. Two screening tests when applied in series one after the other increase the positive predictive value. Similarly two tests can be applied in parallel and the person can be considered as +ve if any one of the test is +ve (increase in sensitivity) or he may be considered +ve if both the tests are +ve (increase in specificity). Various factors are taken into consideration before launching a screening program, viz., the disease should be an important health problem, facilities for confirming the diagnosis and for effective and acceptable treatment should be available, there should be a suitable and acceptable screening test, the natural history of the disease should be well understood and there should be a recognizable latent / early symptomatic stage in disease history. The effectiveness and impact of screening programmes must be evaluated by Randomised Controlled Trials (RCTs) by comparing the outcome measures between the screened and unscreened groups. The common biases that may occur in screening programmes are lead time bias, length bias and self selection bias. Lead time is defined as the interval between the point a condition is detected through screening and the time it would normally have been detected due to appearance and reporting of signs and symptoms. If early detection has no effect on the course of disease then it will be like giving the patient a few more years of sickness and apprehension rather than health! Length bias refers to the observation that cases detected through periodic, early detection programs, tend to have longer preclinical stages than those missed out by screening but self detected between

examinations. Thus, the length bias tends to spuriously show a better survival among screen detected cases. If the groups which are offered (and the other which is not offered the screening) are not constituted by random allocation but rather on the basis of self selection (volunteers), it is possible that such volunteers may be more health conscious, educated and more likely to give up associated risk factors; hence survival in such a screened group is likely to be better, not due to screening but because of associated factors (self selection bias).

While launching a screening programme, at the outset, one must undertake a situational analysis of the community in which the screening programme is proposed to be launched, by collecting information about demographic profile, prevalence of important diseases with special reference to the diseases proposed to be screened, and the expected load of population likely to come up for screening. This should be followed by a resource analysis. Next step is to identify the high risk groups, as the prevalence and hence the PPV and yield will be high in these groups. Collect logistics together, get all your required personnel, equipment, reagents, and other logistics ready. Next step is to Standardize” personnel, instruments and techniques and training of observer to ensure high repeatability of screening. Ensure community participation by making contact with the community leaders, peer groups and other members of the community who may matter, right in the planning stage itself and explaining to them the importance of the disease to be screened, and the usefulness of screening and early treatment. Emphasise on them that you need their active participation. Give proper publicity to the programme; ensure that those living in the remote, cut - off areas are covered well with your publicity. Make sure that you have catered for providing the final confirmatory test to those who are found positive on screening test and that facilities for treatment have been catered for those who will be found finally positive. Next step is conducting the program itself and lastly evaluate the programme.

Study Exercises

Long Question : Give a draft plan for planning, conducting and evaluating a cervical cancer screening programme in a CHC area covering a rural population of approximately 1 lac.

Short Notes : (1) Biases in screening (2) Requirements of a screening test (3) Criteria for undertaking screening for diseases in a population

MCQs and Exercises

1. A cervical cancer screening programme was conducted in a rural area using pap smear procedure, in the year 2000. Out of the women who participated, Mrs 'A' was diagnosed to be having cervical cancer; however she could not be offered surgery because no gynaecologist was available. She died of cervical cancer in 2005. Out of the women who did not participate, Mrs 'B' developed symptoms of cervical cancer and was diagnosed in 2002. She also died in 2005. This occurrence represents : (a) Successful increase in years lived by Mrs 'A' (b) Length time bias (c) Lead time bias (d) self selection bias.
2. In a screening program for colonic cancer, the test used is stool test for occult blood among middle aged persons.

The camp was undertaken in a semiurban area with an estimated prevalence of colonic cancer of 1% in this age group. If the test has a sensitivity of 70% and specificity of 80%, what would be the PPV?

3. In the above question, if the test was negative, no other test was done. However, if the test was positive, one more test was given and persons who tested positive on the second test also were sent for confirmatory colonoscopy. If this procedure was applied, what would have happened :
(a) Net sensitivity and net specificity are both increased (b) Net sensitivity is decreased but net specificity is increased (c) Net sensitivity remains the same and net specificity is increased (d) Net sensitivity is increased and net specificity is decreased
4. If a screening test is used in series twice, which parameter will increase? : (a) Sensitivity (b) Positive predictive value (c) Specificity (d) None of the above
5. What is the denominator in calculating the sensitivity of a test? : (a) True positive (b) True negative (c) False positive (d) False negative
6. What is the denominator for calculating the specificity of a test? : (a) True positive (b) True negative (c) False positive (d) False negative
7. For ruling in of the disease which test is preferred? (a) Highly sensitive test (b) Low specific test (c) Highly specific test (d) None of the above
8. For ruling out of the disease which test is preferred? (a) Highly sensitive test (b) Low sensitive test (c) Highly specific test (d) None of the above
9. Which of the following is a fixed parameter of screening test? (a) Sensitivity (b) Negative predictive value (c) Positive predictive value (d) None of the above
10. Predictive value of screening test depends on (a) Prevalence (b) Sensitivity (c) Health worker (d) None of the above
11. The optimum prevalence to get a very high PPV is (a) 30 - 60% (b) 5 - 30% (c) 60 - 90% (d) none of the above
12. The following consideration is NOT required to be taken while doing a screening programme (a) The disease should be a public health problem (b) The disease should be vaccine preventable (c) There should be an acceptable and effective treatment (d) Facilities for confirming the diagnosis and for treatment should be available.

Answers : (1) c; (2) 3.5% approx; (3) b; (4) b; (5) a; (6) b; (7) c; (8) a; (9) a (10) a; (11) a; (12) b

At times, information of the required nature may not be available to the public health specialist from the various sources of secondary data that have been discussed in detail in an earlier chapter. In such instances, the public health specialist would need to collect primary data by studying all or a sample of the community members, to generate information about the health status and related aspects, in the population under her health care, by means of a survey. However, as said earlier, surveys require money, material and manpower as well as time to conduct and analyse them before an answer can be given to the public health question. Hence, surveys should, in general, be undertaken only when we are convinced that the requisite information is not available from any other source of data.

Of course, surveys have certain distinct advantages over secondary data. Firstly, the data so generated is primary data, obtained to comprehensively answer the issue at hand and will therefore contain information about all the variables, which may not be the case with secondary data. Secondly, the data is likely to be more accurate in case it is a primary data, since various quality control measures are undertaken as part of survey methodology.

What do we mean by “Survey”? : A survey can be defined as an epidemiological investigation undertaken to examine certain selected features of a community, with a view to work out the frequency (either incidence or prevalence), of one or more diseases or health related phenomena, and often their distribution according to selected person, place and time related variables, by obtaining information from a sample drawn from the population of interest.

In public health, surveys may be undertaken in two broad settings. Firstly, the local public health specialist or health manager at district or Community Health Centre (CHC) level may need a survey to answer some issues related to planning her health care for the community, for example an immunization coverage survey. More often, however, surveys are undertaken by the CHC or district health team as a part of larger survey ordered by the Central or State Govt. (e.g. national tuberculosis survey or NFHS, etc.). Common reasons for undertaking epidemiological surveys in public health are :

- Provide general socio - demographic and basic health data for planning and organizing the health services or to make a community diagnosis.
- To estimate the frequency (incidence or prevalence) of important diseases, as HIV, malaria, tuberculosis, diarrhoeal disease, etc. and the important socio - demographic factors according to which these diseases are distributed.
- To assess the availability and locations of health care facilities (infrastructure, manpower, equipment) in relation to the distribution of the community.

- To assess local beliefs, behaviour patterns, customs and awareness about health / risk factors as well as attitudes towards health services.
- To evaluate the effectiveness of a health program, as immunization program.

Types of Epidemiological Surveys in Public Health Practice

There are three main methodological types of surveys :

(a) Cross sectional Surveys : All subjects are examined only once for the variables of interest, and the results refer to a given point of time (though, as clarified earlier in the chapter on incidence and prevalence, the actual survey may take a lot of time depending on the number of subjects and the number of variables being studied). A cross sectional survey would therefore give “prevalence” of the condition being studied. These surveys have the advantages that they give quick results and are less resource intensive. Most of the public health issues related to planning and evaluation of health services can be answered by cross - sectional surveys. The disadvantage is that they do not measure incidence, and may not accurately answer issues related to cause and effect relationship. They are also not appropriate if the disease being examined is either a rare disease or else it lasts for a very short duration because in such exigencies, most cases of the disease may not be noticed by a cross - sectional survey.

(b) Longitudinal surveys : The essential feature which differentiates longitudinal survey with a cross sectional one is that each subject is examined at least twice, to see the “change” that has occurred as regards the phenomena of interest over a period of time. These surveys measure the “incidence” and give a better insight into “cause and effect relationship”. The major disadvantage is the requirement of considerable resources as well the time required to follow up, before we can answer an issue.

(c) Hybrid surveys : These can often be used to obtain the advantages of both the cross - sectional as well as longitudinal surveys. A very good example is “repeated cross - sectional surveys” which can give an approximate idea of the incidence. For example, if a cross sectional survey in the year 1990 indicates that the prevalence of cervical cancer among women of reproductive age group is 1%, while another cross - sectional survey in the same population, in 2000, indicates the prevalence in the same population to be 2%, it may give a rough idea that the incidence of cervical cancer is $(2 - 1) = 1\%$ over 10 years; however, it should be remembered that this gives only an approximate idea of incidence but is actually not the incidence.

Whether to do a “Hospital based” or else a “Community based” survey?

For most of the health care providers, hospital is a very important point of contact with the community and hence, the desire to use the data available in the hospitals, to work out the health status and needs of the community. The population which, in general, utilizes the services of a hospital is called as its “catchment” population. It should be noted that hospital data has its own strengths and drawbacks. Detailed discussion on these aspects has been undertaken in an earlier chapter on

sources of health information and you are advised to refer to the same. In short, the advantages are that hospital data, either from OPD or indoor admitted patients, is quite economical to be obtained, the data is easily available, can be obtained and compiled quickly, and has diagnostic accuracy. On the other hand, the following are the inherent disadvantages :

- Often, all people who are having a given disease may not be admitted to a particular hospital or even to any of the hospitals in that area.
- It is often quite difficult to work out frequency measures (incidence or prevalence) from hospital data unless one is quite sure that all persons from the catchment area (and none other than the catchment area) fully utilize the hospital for the particular disease(s) which are being studied.

On the other hand, in a community based survey, a representative sample of the entire population is examined and hence the above disadvantages are taken care of. This advantage however, comes at much higher cost, more logistic effort, extra time and, possibly, not - so - accurate diagnosis of the disease. In general, if we are doing an *initial assessment* of community resources or undertaking an *initial planning* for health care and if logistics are available, a community based survey would be definitely preferable. However, if the requirements are of a periodic nature, quick results are required, the hospital adequately draws nearly all the population from the catchment area and adequate resources for undertaking full - fledged community based survey are not available, we may prefer utilizing the hospital data.

Steps in Organising and Conducting an Epidemiological Survey

Step 1 - Clearly define the question that is to be answered :

At the outset, one needs to be very clear about the issue that we are to examine. As said, conducting a community based survey in a valid manner is not an easy task and hence one should be very clear as regards the question for which we are thinking to carry out a survey.

Step 2 - Decide - is it required to do a survey? : A survey takes time and plenty of logistic efforts. Therefore, after having clearly spelt out the issue to be answered, we should examine whether answer to this issue has already been given by some other survey, or can be obtained by some other secondary data source. Thorough reading, discussion with experts and examining all available records / sources of data may be worthwhile at this stage.

Step 3 - Ensure involvement and participation of the community and the administrative machinery and obtain the required sanctions :

This must be the first step. Even the most scientifically planned survey would be a failure, if the community has not been contacted and educated in detail well before the survey and their co - operation has not been solicited. In particular, communicate with the local peers, leaders, and those who are in a position to guide community opinion. Explain to them the need for the survey, how it is going to be beneficial to them and how it is going to be conducted. Solicit, not only their support but also their advice as to how best to actually execute the survey. Similarly, contact the local

government officials and the influential non - governmental bodies for the requisite administrative sanctions and support.

Step 4 - Get an idea of the socio - demographic and geographical distribution of the community and the local seasons of the area in which the survey is proposed:

Undertake a preliminary appraisal of the area and the population proposed to be surveyed. Obtain information about the age and sex profile, major occupations, education, income, roads and communications, attitudes and beliefs, from the local governmental and non - governmental organizations. Find out as to where are the major residential and work areas and how are they approached. You will realize that this knowledge would make a considerable difference for planning your field work and for organizing your logistics. Some of this information would be available in the local government offices but in addition, spend time in walking / driving around the area and meeting local people formally as well as informally. Study the local climatic and seasonal patterns and work out the best times of the year to undertake the survey.

Step 5 - Assess the resources : Based on the broad research question, the type of resources can be technical personnel, administrative personnel, diagnostic and other clinical equipment and expendables, transport, computers, tents, accommodation, finances, etc. Assess availability of these resources.

Step 6 - Define the survey objectives : It will be the research question, which, if clearly stated, will give us an idea of the population to be studied and the various variables to be studied. The entire planning of the survey will depend on this decision. An example could be “What is the prevalence of anaemia among the community served by my CHC”? This clearly stated research question gives an idea that the reference population for this survey would be all community members of all ages and sexes in the CHC area and that the major variable of study will be haemoglobin estimation.

Step 7 - Define the variables of study : In a survey, having specified the research question and objectives of the survey, we would list out all the variables on which measurements would be made. Specify the variable which is of maximum interest. This is known as “primary outcome variable” or “major endpoint”. The primary outcome variable is important since issues like sample size calculation and subsequent analysis hinges around this primary variable. One should be sure to study all the variables in the proposed survey. But each additional variable costs money and effort for its measurement; at the same time if we do not include any particular variable and realize later on that we actually required that data, nothing can be done at that later stage. Hence, survey objectives must be discussed with experts before finalizing.

Step 8 - Write down the process of measurement for each of the variables : Measurement of any variable should have two characteristics validity and reliability. It is also pertinent to define the “case”.

Write down, for each variable, the measurement technique which is “ideal” (i.e. gold standard). Thereafter, write down what is the process that is do - able and satisfactory enough. Measurement modalities must also be worked out.

Step 9 - Develop the survey questionnaire and the interview technique :

Remember that “questionnaires” which are greatly used in surveys are also a type of instrument and recording of data, using this questionnaire, also requires a scientific technique by itself. Even issues like measurement of “age”, though seemingly trivial, may become pretty difficult; for instance in an illiterate population, subjects may not be able to tell their date of birth but rather relate it to some natural calamity that had occurred in the past. Hence, give utmost attention to developing the questionnaires and on the interview techniques, as has been discussed in detail in earlier chapters.

Step 10 - Describe the reference and actual (study) populations :

As discussed in detail in an earlier chapter, reference population (also called as universe or target population) is the large collection of humanity to which the findings of the survey will be generalized. On the other hand, actual study population is that subset of the reference population from where the actual study sample is drawn. For example, while doing a survey on prevalence of anaemia, the reference population could be defined as “all the people living in rural areas of the state”, while the actual study population could be hypothetically defined as “all people living in the Community Development Block No.45”. It is important to explicitly write down the reference and the study populations for the survey.

Step 11 - Calculate the sample size :

Studying an adequate sample size is important to ensure precision, by reducing the random error and to undertake optimum statistical analysis. The details of sample size calculation are discussed in the relevant chapter in the section on biostatistics. What is important is that the epidemiologist should be prepared to give certain specifications to the statistician, namely the approximate expected value of the major outcome variable (as the percentage of people likely to be having anaemia or the approximate expected mean haemoglobin level, in the reference population), the deviation from this expected value that the investigator is ready to accept in this particular survey, and the level of confidence (usually kept at 95% level of confidence). It is always worthwhile to include about 10% to 20% additional subjects over and above the calculated sample size, to cater for unforeseen refusals.

Step 12 - Select the method of sampling :

The sample should be so selected that every person in the study population should have an equal chance of being selected (random sampling technique). The details of probability sample selection are given in the chapter on “sampling methods” in the section on biostatistics. We should decide as to what would be the “sampling unit”, i.e. whether the selection would be of individual persons or of households etc. A list of all these sampling units in the actual study population should be made - this is known as the “sampling frame”. Divide the number of units in the sampling frame by the sample size actually required to be studied, to get the “sampling ratio”. Select out the units to be actually studied from the sampling frame, using one of the probability methods described in the chapter on sampling methods. In most of the community based surveys, particularly when the disease being studied is not a rare one and prevalence (not incidence) is being studied, the methods of “multi - stage random sampling” or

else, the 'cluster sampling' (usually 30 clusters, 7 units in a cluster) is reasonably good enough.

Step 13 - Organise the Logistics and become Administratively Viable : Men, money and material are important for surveys. Write down the fine details of your requirements of :

- Technical personnel, as data collectors, interviewers, entomological workers, laboratory assistants, nurses, general duty doctors, and specialist doctors. Do not forget to include female attendants if you are likely to interview or examine female subjects during the survey.
- Administrative personnel as clerks, computer operators, drivers, cooks and messing staff, ancillary workers, etc.
- Technical Material (as equipments, reagents, diagnostic items, survey forms and questionnaires, computer items). A useful method is to make a check list of items required for each and every technical procedure and then make an overall checklist of various items and equipment that will be required for the survey.
- Logistic material (as vehicles, petrol, tentages, stationery).
- Finances (money for purchasing technical and logistic material, salaries, incidentals, etc.).

Develop a written document specifying the job description of each category of workers, and to make a chart showing the hierarchy of command of the various personnel showing who will be responsible to whom and for what jobs.

Step 14 - Organise technically for the survey : Get your instruments, equipment, disposables and reagents and print your questionnaires. Standardise your equipment against standard equipment. Train your field workers centrally, test them for reliability and certify them. Finally, if possible, develop a detailed "operations manual" which spells out in detail as regards each aspect of how sample will be drawn, how various measurements will be made, how quality control procedures will be established etc.

Step 15 - Examine the ethical issues and cater to them in your proposed survey : In community based surveys, which by definition do not involve intervention and trial of a treatment/preventive procedure, the ethical issues may become less rigorous as compared to a clinical or preventive trial, but nonetheless, should be well examined. As far as possible, the possible ethical concerns should also be discussed with the local community and clearance from the local / institutional ethical committee should be taken if applicable.

In community based epidemiological surveys, the major concerns from ethical point of view pertain to : Firstly, protection of confidentiality as regards the information which has been given by the individual subjects and Secondly, obtaining informed consent from individual subjects for participating in the survey, after they have been informed in detail about the survey.

Thirdly, an important issue is the moral (if not truly legal) need of providing some health care along with the survey. A good old dictum is "no survey without service". For instance while doing a survey for anaemia, it would be quite desirable that Iron and Folic Acid tablets (and possibly anti - helminthics) be given to those who have been found to be having anaemia or

ancylostomiasis; at least some sort of referral to a health care facility may be organised for those who have been found to be having the disease being surveyed.

Fourthly, if medical records of patients are being used as source of data, one must examine the ethical as well legal issues, obtain proper sanctions from the competent authority for using the records and ensure protection of confidentiality of information.

Step 16 - Make an "Action - Plan" showing the time line for various activities : Make a chart and note down your various activities which you will undertake sequentially, in the first column. Thereafter, indicate with horizontal bars or lines, the point of start and completion of each activity. This will greatly help you in your execution of the survey. An example is shown in Table - 1.

Step 17 - Do a Pilot testing : The importance of pilot testing needs no emphasis. It is an essential part of any survey, wherein all methods and techniques, including interview technique, clinical measurements, laboratory and other diagnostic procedures are conducted on a small sample of subjects. The sample of subjects is usually a convenience sample of the strength of about 5% (if final sample size required is >200) to 10% (if final sample size to be studied is upto 200). Each and every procedure is watched for its replicability and validity and the findings are noted. If any defects are noted, the same should be rectified by way of re - training of workers or required improvements in the equipment. If major flaws are noticed, it may be worthwhile to carry out a second round of pilot testing, after proper rectifications. If major changes are made in the methodology following the pilot study, then the subjects studied in pilot testing should not be kept in the final analysis of data.

Step 18 - Inform the Community About the Survey : Success of a survey is quite dependant on how well all members of the community to be surveyed have been informed about the scope, time and place of the survey. Utilize all local resources as community meetings, prayer meetings, local radio broadcasts, school teachers, postman, and even person to person communications, for achieving this end.

Step 19 - Organize and execute the fieldwork : Actual fieldwork in a survey may be by home (or work place) visit method, wherein subjects selected by the sampling procedures are visited at their residence or workplace / school. The second is the "survey centre" method in which a centrally located building as community centre or school is utilized and all the selected subjects come to this place.

When using the household (or workplace) visit method, be judicious in calculating the number of households that can be interviewed by a worker. For an interview and clinical examination which may take about 45 minutes for one household, an interviewer can collect data on maximum 6 to 7 households in a day. Male investigators must be accompanied by female attendants or a local female social worker if female subjects are to be interviewed. Invasive / traumatic procedures (as blood sample collection) should be kept towards the end.

If using the survey centre approach, a "line of flow" should be made. 5 to 7 "stations" should be made. For instance, station

1 could be utilized for recording the general information about the subject, station 2 for oral questionnaire, station - 3 for anthropometry and other clinical measurements, station - 4 for non invasive diagnostic procedures as ultrasound or ECG, station - 5 for invasive procedures as drawing blood sample, station - 6 for dispensing required medications if any, and station - 7 for final checking of the completeness of the form and for providing basic health education. The sequence of headings in the form should conform to the sequence of various work stations as per line of flow. Readers are advised to refer to standard WHO guidelines for organizing the field work and survey centres while doing a survey, as mentioned in “further suggested readings” at the end of this section.

Step 20 - Undertake Quality Control Procedures While the Survey is on : Keep regularly visiting the community and supervising the field workers. Undertake an independent cross check by collecting information of 1 in 10 to 1 in 20 forms filled up by the field workers and see if there are discrepancies. Similarly, develop and undertake quality control procedures for the laboratory and other diagnostic procedures. The dictum is “when field work is on, be there yourself to see that everything is being done correctly”.

Step 21 - Analyse the data : As the field work and data collection is going on, it would be prudent to enter the data into the computer software (preferably a database package). It would be further desirable to also keep a hard copy in the form of a “master chart” of the data. Simultaneous computer / manual entry into the database or manual chart will help identify the missing data points or the ones which are apparently erroneous and one could get back to the original subject before it is too late.

Analysis of data in a survey should be very simple and meaningful. Remember that the main users of analysed results would be the non - medical administrator and the community themselves, hence the analysis should be kept very simple, interesting, and meaningful, while at the same time not omitting any detail. The simplest and best is to make 2 X 2 tables, bar charts, line diagrams and spot maps. Do not make large tables, definitely avoid any table larger than 4 X 4 since it becomes very confusing and uninteresting for a layman. Give proper headings and legends to the tables and figures and always indicate the percentages in the tables.

In general, the following parameters are analysed in a survey and findings are presented accordingly :

- A map of the area, showing major landmarks, streets, residential and work areas and the area under survey.
- Socio - demographic profile showing numbers & percentages, in respect of major variables as age structure, sex, occupation, education, place of residence, place of work.
- The variable of principal interest according to total numbers and percentage and its 95% Confidence limits (CL), (or mean and SD if it was a qualitative variable).
- Other variables depicted as numbers and percentages and their 95% CL or mean & SD.
- Distribution of the major interest variable and other variables according to important socio - demographic variables as age, sex, place of residence and other variables studied, clearly showing the percentages in each table.
- Maps showing the percentage of the major variable according to various places, and line diagram showing the same at different points of time.

Step 22 - Writing the survey report : While the epidemiologist would have put her entire heart and soul into the planning, organizing, conduct and analysis of the survey, it is the report which is actually read by all and hence great care should be exercised while writing the report. The general guidelines have been given in a separate chapter dealing with how to write a research paper and the same should be consulted. One should also remember that there are 4 different categories of people who will be interested in your report, and the language, contents and illustrations contained in the report should commensurate with the target audience. These 4 categories of people are :

- The standard medical journals where the report may be sent as a research article and the medical fraternity who would be reading that article.
- The local health care providers.
- The local administrators and political leaders.
- The general members of the community.

Summary

A survey can be defined as an epidemiological investigation undertaken to examine certain selected features of a community, with a view to work out the frequency (either

Data collection	[Bar chart showing activity from Week 2 of October to Week 4 of November]															
Data analysis	[Bar chart showing activity in Week 1 of December]															
Final report writing	[Bar chart showing activity in Week 4 of December]															

incidence or prevalence), of one or more diseases or health related phenomena, and often their distribution according to selected person, place and time related variables, by obtaining information from a sample drawn from the population of interest. Surveys are generally undertaken only when we are convinced that the requisite information is not available from any other source of data. In public health, surveys may be undertaken in two broad settings either to get answers related to health - planning activity at local level or as part of larger survey ordered by the Central or State Govt.

There are three main methodological types of surveys; cross - sectional surveys, wherein all subjects are examined only once for the variables of interest, and the results refer to a given point of time - these surveys give an estimate of prevalence; longitudinal surveys, wherein each subject is examined at least twice - these surveys give an estimate of incidence; and hybrid surveys - that can be used to obtain the advantages of both the cross - sectional as well as longitudinal surveys - these surveys give an approximate estimate of incidence.

The decision on whether to utilize hospital based data or else to go in for a full - fledged community based survey must be taken after the following considerations : In general, if we are doing an initial assessment of community resources or undertaking an initial planning for health care and if logistics are available, a community based survey would be definitely preferable. However, if the requirements are of a periodic nature, quick results are required, the hospital adequately draws nearly all the population from the catchment area and adequate resources for undertaking full - fledged community based survey are not available, we may prefer utilizing the hospital data.

The first step in a survey would be to ensure involvement and participation of the community and the administrative machinery and obtain the required sanctions - this would necessitate involvement of local peer leaders, government officials and NGOs. Subsequently, it would be prudent to get an idea of the socio - demographic and geographical distribution of the community and the local seasons of the area in which the survey is proposed. The next step would be to define the question that is to be answered, in clear, lucid and unambiguous terms. Subsequently, a decision on whether it is at all required to do a survey, has to be made, based on discussion with experts and scrutiny of available data.

Subsequent to this, we would proceed on to assess the resources and decide whether it is feasible to do the survey, keeping in mind the balance between what the survey aims at on one hand & the resources at our disposal on the other. The next step would be to define the survey objectives clearly and unambiguously. Thereafter, we proceed to define the variables of study, in which due emphasis needs to be laid on definition and selection of the "primary outcome variable", which would be crucial to the survey outcome. Also the other associated variables of interest need to be mentioned at this stage. Subsequently, the process of measurement for each of the variables is to be written down. Developing the survey questionnaire and the interview technique would be the next step - it would be prudent to select a scientifically sound and validated procedure which should be tailor - made for the specific study in question. Thereafter, we move on to describe the reference population i.e. the population

on which the results of the study are going to be generalized; and actual (study) population i.e. that subset of the reference population from where the actual study sample is drawn. After this is accomplished, calculation of sample size would form the next step. In this step, the important points to remember would be to scientifically calculate the sample size, and to include about 10% to 20% additional subjects over and above the calculated sample size, to cater for unforeseen exigencies and refusals.

Selecting the method of sampling would require specifications of sampling unit, sampling frame & sampling ratio need to be made. The next step thereon would be to organize the logistics and become administratively viable. An issue which needs to be specially dealt with at this stage is to develop a written document specifying the job description of each and every category of workers, and to make a chart showing the hierarchy of command and control of the various personnel. Subsequently, we need to organize technically for the survey, which would include standardization of equipment, training of field workers and if possible, development of an Operational manual. Thereafter, we need to proceed to examine the ethical issues and cater to them in the proposed survey - the most critical ones would include confidentiality, informed consent, proper sanction from relevant authority and provision of some health care along with the survey.

An "Action - Plan" showing the time line for various activities needs to be formulated subsequently. The next step would be to do a Pilot testing, having a convenience sample of the strength of about 5% to 10% of the total estimated sample size. Thereafter, informing the Community about the Survey would be imperative - which could be achieved by making optimal use of local resources. Organizing and executing the fieldwork would form the next major step. This can be performed by either of the following two modalities (or a combination of both), namely, the home (or work place) visit method or the survey centre method.

Even while the survey is under way, it would be wise to undertake Quality Control Procedures, which includes independent cross - checking of questionnaires etc. Analysis of data would be the penultimate step, wherein simple and meaningful inferences need to be drawn. The final step in this entire process would be writing the survey report in a manner which is well understood by the target audience.

Study Exercises

Long Question : It is proposed to establish an obstetric unit at a Community Health Centre (CHC) which will serve as a First Referral Unit (FRU) for a population of one lakh, which is already being served by a total of 4 PHCs. Describe the conduct of an epidemiological survey which will be undertaken to generate information for the planning and design of this FRU.

Short Notes : (1) Longitudinal versus cross - sectional survey (2) Advantages and disadvantages of hospital based versus community based surveys (3) Line of flow in a survey centre

MCQs and Exercises

1. Among the following, which type of survey provides an exact estimate of Incidence (a) Hospital - based survey

- (b) Hybrid Survey (c) Cross - sectional survey (d) Longitudinal survey.
2. If we are doing an initial assessment of community resources or undertaking an initial planning for health care and if logistics are available, a hospital - based survey would be definitely preferable. Yes/ No
 3. Arrange the following steps in Organization and conduct of an epidemiological survey, in the sequential & ideal order : (a) Analyse the data (b) Clearly define the question that is to be answered (c) Define the variables of study (d) Make an "Action - Plan" showing the time line for various activities (e) Calculate the sample size.
 4. What type of survey is a Hybrid Survey (a) Repeated cross - sectional survey (b) Hospital - based survey (c) Community - based survey (d) Longitudinal surveys
 5. In estimation of number of subjects for doing a pilot survey, if the final sample size to be studied is upto 200, the sample of subjects is usually a convenience sample of the strength of the following % of the total sample (a) 10% (b) 20% (c) 30% (d) 40%
 6. A list of all the sampling units (persons or households) in the actual study population is known as the (a) cluster sample (b) sampling ratio (c) sampling rate (d) sampling frame
 7. A minimum sample size of 30 persons is almost always good enough for epidemiological studies. Yes/ No
 8. The large collection of humanity to which the findings of the survey will be generalized is called (a) Study population (b) Sample population (c) Universe (d) Common population
 9. It would always be worthwhile to include how many additional subjects over and above the calculated sample size, to cater for unforeseen exigencies and refusals (a) 5 - 10% (b) 10 - 20% (c) 20 - 25% (d) 30 - 40%
 10. All of the following are important ethical issues that need to be addressed in a proposed survey, except (a) Provision of cash benefit (b) Provision of health care benefit (c) Confidentiality (d) Informed consent
 11. An "Action - Plan" is being prepared in the conduct of an epidemiological survey, showing the time line for various activities. Arrange the steps in the ideal and sequential order, from the ones given below : (a) Decision on survey objectives (b) Pilot testing (c) Data analysis (d) Preparing of questionnaires (e) Training of workers
 12. While organizing & executing the field work in conduct of an epidemiological survey, in which method is a "line of flow" (i.e. creation of different stations for different activities) needed to be made : (a) Home visit method (b) Work place method (c) Survey centre method (d) Multi - centric method.
 13. "As part of Quality control during conduct of an epidemiological survey, generally what proportion of forms filled by field workers is independently cross - checked to see for any discrepancies? (a) 1 in 2 to 1 in 5 forms (b) 1 in 5 to 1 in 10 forms (c) 1 in 10 to 1 in 20 forms (d) 1 in 20 to 1 in 25 forms
 14. The primary target audience towards whom the findings of a survey are to be commensurate with, and towards whom the report language is to be directed at, would include all of the following groups of people, except : (a) local administrators (b) local political leaders (c) local health care providers (d) urban elite
 15. Survey and Surveillance are essentially one and the same. Yes/ No
- Answers :** (1) d; (2) No; (3) b - c - e - d - a; (4) a; (5) a; (6) d; (7) No; (8) c; (9) b; (10) a; (11) a - d - e - b - c; (12) c; (13) c; (14) d; (15) No.

Epidemiological Surveillance is a major function of Public Health. The genesis of modern surveillance can be traced back to 1662, when John Gaunt was the first to quantitatively study the patterns of human disease and its possible causes. However, it was only after almost 200 years, when William Farr, in 1838, while working in the office of Registrar General, UK, created a modern surveillance system; he is aptly called the founder of "Epidemiological Surveillance" (105). Twentieth century saw a rapid growth in the scientific concepts and data collection / analytic procedures. By now, public health surveillance activities have widely proliferated, encompassing

a large gamut of communicable as well as non - communicable diseases and many countries also have regularly collected and reported data on important diseases covered by their respective national health programmes. In India, a comprehensive "Integrated Disease Surveillance Programme" (IDSP) has been launched since 2005.

Definition : (Suggested by Alexander Langmuir and adopted by WHO in 1968) : "Surveillance, when applied to a disease, means the *continued watchfulness* over the distribution, and trends of the incidence, through the systematic collection, consolidation and evaluation of morbidity, mortality and other health relevant data, as well as regular dissemination of interpretations to all who have contributed and to all those who are in a position to take action". In a nutshell, surveillance means "information for action". In addition, surveillance is *distinguished by methods having practicability, uniformity and rapidity, rather than by*

complete accuracy (106 - 110).

Surveillance Vs Monitoring : The term 'Surveillance' and 'Monitoring' are often used interchangeably but they are, in fact, distinct. Monitoring refers to ongoing measurements of health services or a health programme with a view to 'evaluate' the particular programme / service or intervention, with constant adjustment of performance in relation to the results. In addition, surveillance concerns general populations while monitoring applies to specific target groups (e.g. vaccinated infants).

The Objectives of Public Health Surveillance

The specific objectives with which surveillance systems are established, are one or more of the following (111) :

To study the trends of disease : Changes in the frequency over short term or long term periods help in identifying as to whether significant rising or falling trends are present and to predict the future course of the disease.

Early warning of epidemics : Constant analysis of surveillance data of a disease would identify any upward trend, at a very early stage. This is, in fact, the commonest reason for which surveillance systems are established.

To provide quantitative estimates of magnitude of health problem : By providing data on incidence and prevalence and further descriptions of incidence/ prevalence according to various socio - demographic characteristics, surveillance helps in identifying the priority (i.e. high risk) groups.

To study the natural history of disease : Surveillance of AIDS during the last decade has added significantly to our knowledge regarding the natural history of HIV infection and AIDS.

Demonstrating the spread of a disease in time and place: Description of surveillance data using time and space combinations can demonstrate the spread of a disease and identify the possible vehicles and routes of spread.

To develop epidemiologic research questions : Sensible interpretations of surveillance data can open up interesting research questions; e.g. increase in the sales of pentamidine noted by CDC Atlanta, in 1981, led to generation of research questions and finally "AIDS" was recognised.

To test epidemiologic hypothesis : Sometimes surveillance data can be used to test hypothesis; e.g. in 1973, a particular insecticide was suspected of being related to birth defects. However surveillance data for 1970 - 73 showed decrease in total birth defects even though there was five fold increase in insecticide sales during the same period, thus acquitting the particular insecticide.

Evaluation of control and preventive measures : Surveillance data on poliomyelitis during 1950's in USA showed a dramatic decline in disease incidence, thereby confirming the efficacy of polio vaccination campaign.

Monitoring of change in infectious agent : Development of antibiotic resistant gonococci have been identified with the help of surveillance data.

Detecting changes in health practices : Surveillance of delivery practices has shown that caesarian deliveries increased

from 5% to 25% in developed countries.

Criteria for Identifying High Priority Areas for Establishing Surveillance Activities

Surveillance activities are costly and hence should not be launched inadvertently. Careful consideration should be made beforehand as to whether the particular disease is a high priority area from public health point of view. This includes review of the data on *Frequency of the disease* (in terms of incidence of mortality, and incidence/prevalence of morbidity, due to the disease); *Severity* (in terms of case fatality ratio, proportionate mortality ratio, hospitalization rates due to the disease and disability rates); *Economic impact* (in terms of direct costs that accrue due to medical treatment for the disease and indirect costs due to reduction in productivity); Preventability ; and, *Public interest* (community attitudes towards the disease and political will).

Organization and Structure of a Surveillance System

The essential components of a surveillance system are :

- An overall organization : Consisting of personnel, finances, logistics and administrative back up.
- The originators of data : This would include the sources of data, data collectors and data collecting mechanisms.
- The transmission of data to the surveillance centre, with specification of the mode of transmission and frequency of such transmission.
- Data management and analysis : This includes manual / computerized data files, and statistical analysis procedures.
- The sensible interpretation or results : Including their consolidation and preparation of reports.
- A system of feed back of results : To the originators of data and to those who are in a position to enforce preventive steps.
- A system to periodically evaluate the surveillance system itself.

Steps in Establishing a Surveillance System

Step 1 - Is it justifiable to Establish a Surveillance System:

It must be analysed whether it is really required to initiate a surveillance system by confirming if the disease is of public health importance (see criteria above) and whether prevention/ control measures are available. It needs to be appreciated that every country, state or district will have some system of its own of collecting routine health information and reporting it from the peripheral health care facilities (as PHC) to the central level (as District or state headquarters). Such information is generally collected at the peripheral health care facilities and is recorded in various ways. Unfortunately, often this information recorded at the periphery may be inaccurate or incomplete; moreover, the information may keep lying at the central headquarters and analysed only after many months, without any feedback information to either the originators of the data, thus reducing the efficacy of this data for surveillance.

More often the need is to improve an existing source of data collection and ensure its prompt analysis and feedback rather than to start up a completely new surveillance system. It should also be noted that emphasis should be on collection of

minimum amount of inescapable data, in a very simple manner, particularly at the primary care level. Secondly, controlling the quality of collected data is of vital significance and requires frequent checks and quality control measures. One way of ensuring this is by developing the forms in a way that they are directly useful to the health workers at the primary level also, thus helping the health workers at PHC, CHC and district level to plan and evaluate their own programmes.

Step 2 - Spell out the objectives of surveillance system : The following issues should be addressed :

- Clearly specify the disease (s) proposed to be brought under surveillance.
- *Specify* : Who needs what information, for what purpose? (e.g. whether a rapid case count for epidemic warning is required by the District Health Officer or detailed information to identify temporal trends is required by the state ministry?)
- *The target population* : e.g. whether it is “mothers and children” or “blood donors” or “all population living in the hilly areas of the state”.
- *The health problem* : e.g. whether only Acute MI or entire spectrum of IHD is to be put to surveillance ?
- *Nature of control programmes* : e.g. if it is a rare disease or a disease moving towards eradication, a fine surveillance will be needed; on the other hand if it is a common disease, a crude surveillance would suffice.

Step 3 - Specify the organization and structure of the surveillance : At the planning stage, clear specifications should be made as to “who will do what, how, and will be responsible to whom”.

Step 4 - Clearly define the disease(s) being considered for surveillance : Case definitions should be meticulously worked out after detailed consultation with experts. They should be adequately inclusive (i.e. sensitive) as well as adequately exclusive (i.e. specific). All those involved in the collection of data should be well trained in the use of these case definitions/ diagnostic methods. Case definitions/ diagnostic procedures should be simple enough so as to be understood and used by all those on which the system depends for reporting. It would be desirable to report the cases under three different diagnostic categories, viz., confirmed / probable / suspect, with clear definitions for each category stipulated. Some sample case definitions as per these three levels are given in the chapter on investigations of an epidemic.

Step 5 - Specify the Details of Collection of Information : Collection of data is the most costly and difficult component of a surveillance system. The quality of a surveillance system is as good as the quality of the data collected. The epidemiologist will therefore have to make the following specifications :

(a) Select the proper sources of data : Various sources of secondary data are available (109) as described in an earlier chapter on sources of information in epidemiology. It would require an intelligent thought by the surveillance officer as to what all sources would be optimum. These include Registration of deaths and death certificates; Reports on various sickness / diseases; Field investigations of epidemics; Public health laboratory reports; Clinical Laboratory reports; Individual case

investigations from hospitals / health centres; Consolidated Hospital statistics; Reports of Health surveys; Studies on Insect vectors and animal populations; Utilisation of drugs and other biological products; Socio - demographic and environmental data about the population; Panels of cooperating physicians who agree to report specific diseases; Data on absenteeism from workplace / schools; and newspapers and news broadcasts.

(b) Specify the method of data collection : Available methods can be :

Passive surveillance : In passive surveillance, the data recipient has to wait for the data providers to report, (e.g. various district headquarters wait for malaria forms to be raised by hospitals / PHCs). Passive surveillance is the most common method of data collection. All the passive surveillance agencies that are required to report should be sensitized and trained. The frequency of reporting should be clearly laid down and a system of issuing prompt reminders established.

Active Surveillance : In certain circumstances, data must be obtained by searching for cases (e.g. health workers go into the community, search for cases of fever and take their blood slide for malarial parasite), and also by periodically contacting those who may know of cases, as GPs, etc. For rare disease, or disease on way to eradication, or during outbreaks, active surveillance is necessary, so that cases which could have been otherwise missed, are promptly identified. Since it is expensive, active surveillance is usually limited to specific diseases, and for specific situation as enumerated above.

Sentinel Surveillance : Data is obtained from selected hospitals who agree to report all cases of the disease.

Special Surveillance teams : Sometimes, special surveillance teams may be formed for carrying out surveys or epidemic investigations and to undertake clinical examinations and laboratory, entomological and environmental assessments.

(c) The forms that will be used : The forms should be *simple* and *as brief as possible*. The question should be clear cut, preferably with closed - ended answer categories and pre - coded for computer data entry. A suggested sample form which can be used for sending information from PHC or CHC level to the next higher level can be as shown in Box - 1.

(d) What time/place of diagnosis will be entered : One has to specify as to what time/place of the three i.e. the actual diagnosis, origin of infection or else first appearance of symptoms is to be recorded. Strict and standardized criteria must be ensured and they should not fluctuate from case to case. It is preferable to ask for time / place when the case actually got the infection and the time / place when first symptoms appeared.

(e) What will be the frequency of reporting? : For a disease like cholera and food poisoning it would be daily (or at the most weekly) report; for malaria, a weekly report would be optimum; for HIV infection a monthly report would be reasonable while for cancer, a quarterly or even half yearly report would be required.

(f) Decide the method of transmission of reports : The simplest is a letter. For diseases that may cause public alarm (plague, JE etc.), reports by telegram/ telephone may be stipulated. The data originators should give due consideration

to possible postal delays that may occur, especially in developing countries or in rural areas and originate the report in time. E-mail can be a good alternative if computer network exists. The central surveillance node should keep a centralized cross-checking mechanism and issue a reminder if timely report is not received from a particular reporting unit.

(g) Central Collection of Data : At the central level all the data received from the peripheral reporting units, should be entered without any delay into a central register. Even if an electronic data registry is available at the central level, it would be still advisable to have a “hard” (register) method of storing the data. The individual forms should also be meticulously filed. The headings in this central register could be as shown in Box - 2.

Step 7 - The Organization and procedures of data Analysis:

The ideal is to have a computerized system, with back-up hard copies on central register. Computerized data should be maintained on a “Database” programme (as ACCESS or Foxpro) or else on a worksheet as EXCEL. For Statistical analysis, the software “EPI - 2002” developed by WHO and CDC Atlanta is quite good. Details are given in a subsequent section. It is better to maintain 2 sets of data bases - one provisional and another final. The statistical analysis will include :

Simple display of data : Data can be displayed through histograms/ bar diagrams/ line diagrams describing the data according to various characteristics of person, place and time. For depiction of “time trends”, line diagrams and histograms are the best. (refer to section on Biostatistics for details).

Descriptive statistics : Give the “Summary statistics” (Incidence rates / prevalence / proportions / Mean / Median) along with the measures of dispersion (SD) and the 95% confidence intervals. This should be done in respect of the important and relevant variables related to person (age, sex, occupation etc.), place (differences in geographical distributions, distributions according to place of contracting the infection, etc.) and distribution according to time. The tables should be small (ideally a 2 x 2 or maximum 2 x 4 table) and should be accompanied by descriptive notes. An example of tabular display of data for age and sex (person related variables), place of residence and time of onset can be shown as in Tables - 1, 2 and 3.

Table - 1 : Distribution of cases according to age & sex

Disease :		Reporting period :			
Sex	Age Group (Years)				
	0 - 4	5 - 14	15 - 44	≥45	Total
Males					
Females					
Total					

Table - 2 : Distribution of cases according to place of residence

Disease :		Reporting period :		
Number of cases according to Villages				
Village - 1	Village - 2	Village - 3	Village - 4	Total

(Note : The above information can be still better displayed in form of a spot map)

Table - 3 : Distribution of cases according to weekly time periods

Disease :		Reporting period :		
Number of cases according to weeks				
Week - 1	Week - 2	Week - 3	Week - 4	Total

(Note : The above information can be better displayed in form of a line diagram)

Inferential statistics : Analytic procedures usually are based on comparing the current incidence against the “Upper and Lower Control Limits” (UCL & LCL).

{A quick method of calculating the UCL and LCL is $UCL \text{ or } LCL = R + 1.023 X A$; (Where R = Average of Incidence rate per 1000 population for the corresponding period for the past 3 years and A is the average of “ranges” for the past 3 years. The resulting UCL and LCL will encompass 99%

Box - 1 : Suggested form for weekly or monthly reporting from PHC or CHC to next higher health care level

Period covered by the report : From (Date) : _____ To (Date) : _____							
Name and address of health facility :

Date				Signature :			

confidence interval}).

Analysing Time (temporal) trends : The comparisons are made between the rates during present period with the rates during the corresponding periods of the last 3 to 5 years; or between the rates or No. of cases reported during current week (or month) with the immediately preceding 4 weeks (or 4 months). For long term secular trends and cyclical trends, the most simple and suitable method is to present a line graph or histogram, indicating the occurrence of disease according to calendar years. More rigorous procedures as “test for linear trends for categorical data” and “time - series analysis” are available, which can be referred from advanced texts (see list at end of this chapter).

Place (Spatial) data : This analysis is important to identify the ‘places’ where significant number of cases are occurring; it may also reveal localized outbreaks. It is always desirable to plot the ‘spot maps’ according to ‘place of contracting the infection’ as well as according to the place of reporting.

Step 8 - Making Scientific interpretations out of the results:

It is not really in the analysis of the data but rather in making sensible interpretations that the skill of epidemiologist lies. Consider whether the apparent, statistically significant, increases or decreases in the disease incidence at a given place and time represent true changes. Fallacious increase or decrease may be due to changes affecting the numerator as improvement in diagnostic procedures, duplicate reporting, or enhanced reporting; or else may be due to changes affecting the denominator as increase in population size. Secondly, one must carefully consider the biases that could have occurred in detecting and reporting at various levels. The cases reported MAY NOT be always truly representative of the total target population under surveillance. A verification must be done by studying the characteristics of the population and comparing with the characteristics of cases reported.

Step 9 - Ensure proper feedback to all concerned : It is extremely important to provide regular (usually monthly) feedback reports to all those who are in a position to take action on the surveillance data (as, secretaries and directors of health department as well as other department concerned with human development, district collector panchayat office, etc.) and not to forget, all those who have provided the data (MO ic of various PHCs and CHCs, pathologists and other specialist

in the hospital, etc.). This will go a long way in keeping their interest alive.

Step 10 - Periodically evaluate / review the surveillance system :

See whether the case definitions need a change? Are there some problems in the timely and accurate reporting and how can it be improved? Periodic evaluation is important to identify defects and reorient the methodology. At the functional level a surveillance system should be periodically evaluated for at least two issues - its completeness and accuracy. Let us illustrate this with an example of a hypothetical surveillance system we have launched in our CHC area covering a population of 1 lac. There are 102 villages each with 200 houses and the average family members in each house is 4.9 persons per household. The total households were thus 20,400. Suppose our surveillance system reported 136 cases of Dengue, which were reported based on visits by the health worker to each household, using the criteria “did any person in your household suffer from fever with severe retro - orbital headache and severe myalgia / backache which lasted for 2 to 5 days, anytime during previous 1 month”.

To evaluate the completeness of the surveillance system, we did a sample survey. The sample consisted of 30 randomly selected villages. In each of the selected villages, a house was randomly selected and this and the next 6 houses were visited. This gave a random sample of 210 houses in the 30 selected villages, giving an estimated population of $4.9 \times 210 = 1029$ persons. Well trained workers visited these households and using the same case definition as used by the surveillance workers, they found that 7 persons gave the history of Dengue fever (DF) in past one month; thus the incidence rate was 7 per 1029 or roughly, 7 per 1000 population.

Now the estimated incidence of DF for all the households for the one month period would be

$$\frac{(\text{No. of cases of DF detected by surveillance} \times \text{Total households in CHC})}{\text{No. of households in the sample studied}}$$

$$= \frac{(7 \times 20400)}{210} = 680$$

Now, our surveillance system had actually reported only 100 cases from the entire CHC area during the same period during

Box - 2 : Suggested headings for the central register for recording details of individual diseases									
Register Page No.:				Name of the Disease with ICD code :					
Reporting period : From :				To :					
Sl No	Name	Address	Age	Sex	Reporting PHC / CHC	Date of onset	Level of Certainty	Died or survived	Remarks
Entries made by (Name & Date) :						Checked and verified by (Name & Date) :			

the same month. Hence our completeness of reporting is $(136 \times 100) / 680 = 20\%$ only. Thus only one in 5 cases of DF are being actually reported by our surveillance system. We should therefore enquire as to why this under-reporting is occurring, starting from the grass-root levels of reporting and examining all the steps in the surveillance system, to rectify this under-reporting.

Check - List for Assessing an Established Surveillance System

At times the Public health Specialist may be asked to assess and comment upon an already existing surveillance system in her own CHC or district, or as an independent evaluator for a system functioning in another district or CHC. A suggested checklist for carrying out such assessment is as follows :

1. What are the broad goals & objectives with which the surveillance system has been established? Is it fulfilling those objectives?
2. Is it adequately staffed for meeting the stated objectives? Are personnel adequately trained?
3. What are the diseases which are under surveillance? What are the diagnostic criteria and case - definitions for these diseases? Are the case definitions adequately sensitive & specific? If strict diagnostic criteria are being used, are facilities for diagnosing available?
4. What are the sources of information for reporting the diseases? Who are the persons who are reporting and how frequently? Are they proficient in asking and recording the case definitions? Are the forms adequately feasible to use by the peripheral workers?
5. Has the information been reported from the periphery well within time? How much is the delay for information before it reaches the central surveillance office from the day of occurrence of the case?
6. How much is the under - or over - reporting?
7. Are central registers, manual files and automated files well maintained in the central office? Is a well trained surveillance officer and staff available at the central office?
8. What is the time lag between receipt of reports and generation of analysed feedback reports, by the central surveillance office? What are the reasons for delay, if any?
9. Are the feedback reports generated in simple and presentable form? Are they forwarded to all concerned, including local and regional health and administrative offices as well as to the originators of data?
10. Has the surveillance information been actually used in planning or evaluation of health programmes at district or CHC level?
11. Is the surveillance system periodically evaluated for its completeness, accuracy, process and adequacy? What remedial measures have been taken on recommendations?

Summary

Surveillance is defined as the continued watchfulness over the distribution, and trends of the incidence, through the systematic collection, consolidation and evaluation of morbidity, mortality and other health relevant data, as well as regular dissemination

of interpretations to all who have contributed and to all those who are in a position to take action. It has to be differentiated from Monitoring, which refers to ongoing measurements of health services or a health programme with a view to 'evaluate' the particular programme/service or intervention, with constant adjustment of performance in relation to the results.

The objectives of Public Health Surveillance are manifold and include : to study the trends of disease, for providing early warning of epidemics, to provide quantitative estimates of magnitude of health problems, to study the natural history of disease, for demonstrating the spread of a disease in time and place, to develop epidemiologic research questions, to test epidemiologic hypothesis, in evaluation of control and preventive measures, monitoring of changes in infectious agents and to detect changes in health practices. If properly implemented and utilized, these will also become the uses of a surveillance system.

In the process of identifying high priority areas for establishing surveillance activities, careful consideration should be made beforehand as to whether the particular disease is a high priority area from public health point of view. The essential components of a surveillance system are : An overall organization, the originators of information, transmission, management, analysis of data and sensible interpretation of results; A system of feed back of results and actions to periodically evaluate the surveillance system itself, are also important.

The first step in establishing a Surveillance System is to consider and evaluate whether it is justifiable to establish a surveillance system. This can be accomplished by asking whether the disease is of public health importance and whether prevention / control measures are available; emphasis should be on collection of minimum amount of inescapable data, in a very simple manner, particularly at the primary care level. The next step would be to spell out the objectives of surveillance system clearly, taking care to address issues such as target population, health problem etc. Thereafter, specifying the organization and structure of the surveillance becomes imperative. Subsequently, we would clearly define the disease(s) being considered for surveillance - emphasise on simple, scientifically sound case definitions. The next step would be to specify the details of collection of information ; with regard to selecting the proper sources of data, specifying the method of data collection (whether Passive Surveillance, Active Surveillance or Sentinel Surveillance); also, specifications have to be made as to the forms that will be used (should be simple & brief), time/place of diagnosis to be entered, and the frequency of reporting. The method of transmission of reports also needs to be decided upon.

The succeeding step would be organization and procedures of data analysis. Under its purview, simple display of data would be essential, in which descriptive statistics (e.g. Distribution of cases according to age, sex etc.) would be worked out, followed by Inferential statistics, wherein the current incidence would be compared against the "Upper and Lower Control Limits" (UCL & LCL). Time (temporal) trends and spatial (place) trends need to be also analysed at this juncture.

Making Scientific interpretations out of the results would be the next step - sensible interpretations of available data are

essential. Proper feedback to all concerned - especially to those who are in a position to take appropriate action - is to be ensured. The final step that needs to be put in place would be to Periodically evaluate / review the surveillance system, by various survey methods. An ideal Check - list for assessing an established surveillance system would include, among other things, the broad goals & objectives, diseases which are under surveillance, under - or over - reporting and so on.

Study Exercises

Long Question : You are working as the MO i/c of a CHC, covering a population of one lac, in an area endemic for malaria and where malaria control program is being undertaken. Discuss the steps that you will undertake to launch a surveillance system for malaria in your area of jurisdiction.

Short Notes : (1) Early warning of epidemics (2) Uses of surveillance (3) Sentinel surveillance (4) Active versus passive surveillance (5) Control limits

MCQs & Exercises

- All of the following diseases are included in the WHO programme for research in tropical diseases, except (a) Tuberculosis (b) Leishmaniasis (c) Schistosomiasis (d) Trypanosomiasis
- Surveillance concerns specific target groups while monitoring applies to general populations. Yes/ No
- Arrange the following steps in developing a surveillance system, in the sequential order : (a) Specify clear - cut case definitions (b) Do a pilot run (c) Define the sources of information (d) Clearly define the target population
- All of the following are the uses of surveillance except (a) To develop epidemiologic research questions (b) To develop registries (c) To test epidemiologic hypothesis (d) To study the natural history of disease
- Frequency of reporting (for purposes of surveillance) for diseases like cholera and food poisoning would be (a) Biweekly (b) On alternate days (c) Daily (d) Weekly
- The comparisons made between the disease rates during present period with the rates during the corresponding

periods of the last 3 to 5 years to derive which type of trends (a) Spatial trends (b) Temporal trends (c) Personal trends (d) Disease trends

- Spot maps come in handy while analyzing what aspect of data? (a) Spatial (b) Temporal (c) Secular (d) Cyclical
- For what two issues should a surveillance system be periodically evaluated at the functional level (a) Incidence and prevalence (b) Relevance and repeatability (c) Completeness and accuracy (d) Sensitivity and specificity
- Health workers going into the community in search of cases is an example of (a) Sentinel surveillance (b) Passive surveillance (c) Mass surveillance (d) Active surveillance
- A crude surveillance would suffice if the disease in question is a common one. Yes/ No
- Prior to setting up a surveillance system, careful consideration needs to be given to all the following aspects of the disease/ health event in question, except (a) Economic impact (b) Public interest (c) Academic interest (d) Preventability
- During data analysis (Inferential statistics), analytic procedures usually are based on comparing the current incidence against the (a) Mean & Standard deviation (b) Upper and Lower Control Limits (c) Standard Error of mean and proportion (d) Co - efficient of variation.
- For long term secular trends and cyclical trends, the most simple and suitable method is to present a (a) Stem and leaf plot (b) Bar diagram (c) Box and whisker plot (d) Line graph.
- Inclusiveness, while developing case definitions for purposes of surveillance, would mean that the definition should be adequately (a) Sensitive (b) Specific (c) Have high positive predictive value (d) None of the above
- Who is called the founder of Epidemiological Surveillance (a) Ramazzini (b) John Graunt (c) William Farr (d) John Snow

Answers : (1) a; (2) No; (3) d - a - c - b; (4) b; (5) a; (6) b; (7) a; (8) c; (9) d; (10) Yes; (11) c; (12) b; (13) d; (14) a; (15) c.

Investigations of an epidemic is one of the most important duties of not only the epidemiologists but for all health care providers concerned with public health. Investigating an epidemic involves a series of steps, as narrated in the succeeding paragraphs. These steps are not necessary to be undertaken in the same sequence. In fact, often, at any given point of time

during the course of an investigation, it is quite possible that a number of steps may be addressed simultaneously (112 - 114). In this chapter, we will explain the various steps in detail, along with a hypothetical example of an epidemic, based on a real life episode (See Box - 1).

Step 1 - Verification of the diagnosis : The earliest report regarding an outbreak is often obtained from a non medical or paramedical person. Often the initial report is not in the form of particular diagnosis but rather in the form of a "syndromic" constellation of symptoms and signs (e.g. outbreak of diarrhoea and vomiting, or fever and skin rash).

Box - 1 : Hypothetical Example

Dr. 'X', was appointed as Medical officer of Health (MOH) in a large township. In the evening of 10th May, the medical officer of a large working women's hostel rang up to inform him that 2 cases of diarrhoea and vomiting with mild dehydration had occurred and she was referring them for admission to the district hospital. The Working Women's Hostel (WWH) was meant to provide accommodation and messing to almost one thousand working, single ladies, working in various companies and business establishments located at various places in the city. There were four "messes" with dining halls (named 'A', 'B', 'C', and 'D' mess) to provide for meals, besides a canteen run by a contractor to provide snacks. These women used to leave early morning in municipal buses or by their own two - wheelers for their respective offices, after breakfast and used to carry packed lunch. They used to come back in late evening from their respective offices and have their dinner in the hostel, before going to bed. At times, at irregular occasions, some of these women would also eat their lunch or dinner outside in local restaurants. Another about 300 personnel who were employees of the hostel, were staying with families in family quarters located in close vicinity of the hostel and shared the same general piped water supply and sewerage system (from municipal sources). These family members of these employees also used to go to the work or schools, located at various places in the city, while the women members of these worked as employees in the hostel. There was a small market nearby with all daily requirements available.

It is therefore essential to verify the diagnosis of the condition that one is dealing with in epidemic form. This also helps in developing the epidemiological case sheet and planning the laboratory, environmental and entomological procedures for investigations, as we shall see later on. At this point, talk in detail with the patients (cases), about their signs / symptoms, about their movements, about the possible exposures and what they think could have caused their present illness, and whether they know of similar cases in their neighbourhood, workplace or among friends. Recording as much details at this point of time may be of great value later when hypotheses are being developed. Verification of the diagnosis is usually made on clinical, laboratory and epidemiological parameters. Most important are the clinical parameters. In real life situations, it may not be necessary to confirm 100% cases by lab parameters; a 20% to 30% random sample, if confirmed by lab tests to be having similar disease should be adequate. At this point it is also very wise to describe the distribution of various signs / symptoms according to frequency distributions, which greatly helps in suggesting the diagnosis and also in developing the case definitions (See Box - 2) .

Guidelines for syndromic diagnosis for common epidemic prone diseases are given in Box - 3.

Step 2 - Confirm the existence of an epidemic : An epidemic is defined as "occurrence of a disease in a frequency which is clearly in excess of the normal expectations". Thus, having verified the diagnosis, one must work out the incidence rate, by dividing the total cases by the population at risk.

Box - 2 : Continuing with the Hypothetical Example

To start with, a "syndromic" diagnosis of "gastroenteritis, without fever & with moderate dehydration" was made. The possibilities which were kept within this tentative diagnosis were food poisoning (due to either of *S aureus*, non - typhoid *salmonella*, *C perfringens*, *B cereus*); cholera; ET EC gastroenteritis; and, algid malaria. The patients were contacted by the MOH at the hospital in the night itself and a quick clinical history and examination was done, and cases were discussed with the Physician and Pathologist. Both the patients were young unmarried women working in the same office and dining in the same ('B') mess. They had 1 - 2 bouts of vomiting in the afternoon, followed by 4 - 6 watery loose motions and felt "weak". There was no fever or tenesmus or blood / mucous in the stools. Except for moderate dehydration, physical examination was non - contributory. The MOH requested the pathologist for undertaking a GBP, PBS for MP, and stool examination for microscopy, hanging drop and culture for enteropathogenic organisms.

This rate is compared with the rate occurring in the same population, during the corresponding period of the past three years. Often, the decision as to whether the present rate is clearly in excess of the normal expectations (based on past three years' rates) is taken on the basis of informed and experienced judgment, though various statistical procedures for calculation of "control limits" are available to further assist in such decision (see previous Chapter on "surveillance" in this section for details). Quite often, in such situations, it is difficult to calculate rates in such an emergency and hence numbers may be compared. Usually, comparison is done of the present rates (or number of cases) with those of corresponding time period of preceding three years. For finding out as to what is the "normal" expectation during the period being compared with, we use the existing data based on records of hospital admission and discharge data and if these are not available, find out from various physicians in the community whether they have been observing more number of cases with the given set of symptoms recently; or lastly, undertake a survey of the community to get an idea of the baseline (historical) data. Ultimately pragmatic considerations are also important as to whether to investigate or not. There could also be situations when a single case of a disease may be enough to call for investigations, e.g. a suspected case of plague, or in many of the day to day situations, even a single case of cholera (See Box - 4).

Step 3 - Develop an Initial (Rough) "Line - listing" of cases :

A line list is like a nominal roll of the cases which have already been reported to the various health care establishments (like dispensaries, general practitioners or admitted to the hospitals) till now. Line listing of the cases is a major help in initial definition of the disease / syndrome that has occurred in epidemic form, in delineating the population at risk, and in preliminary definition of the transmission dynamics of the epidemic according to place and time. A line list is a serial, chronological listing of all the known cases till now, as per the headings shown in Table - 1.

Box - 3 : General guidelines for “syndromic approach” to “common epidemic prone” diseases

Quite often, reporting of epidemic is often in the form of a “syndrome”. Moreover, laboratory diagnostic results may take time to be available and till then the epidemiologist has to proceed with some tentative diagnosis, to give some direction to his investigations. The following list is intended to provide a general reference for the epidemiologist in the field, till definitive results are available.

Syndrome of Fever without Rash

- Usual manifestations : Sudden or insidious onset with fever of continuous, biphasic or recurrent type; frequently headache, myalgias, arthralgias; sometimes GIT manifestations, polyadenopathy or hepato - splenomegaly;
- NO specific localizing sign.
- Common Diseases : Vivax Malaria; Enteric fever; Leptospirosis; Uncomplicated Dengue fever (without haemorrhages or shock; Chikungunya (without haemorrhages); Brucellosis.

Syndrome of Fever with Rash

- Usual manifestations : Onset with fever and systemic symptoms; macular, papular, vesicular or pustular eruptions, either generalized or localized to certain parts of skin or mucous membranes; eruptions are NOT haemorrhagic.
- Common Diseases : Chickenpox; Measles; Rubella; Typhus group of fevers (scrub, louse borne, murine and tick borne typhus); Meningococcal bacteraemia.

Syndrome of Haemorrhagic Fever

- Usual Manifestations : Onset with fever and systemic symptoms; often a second phase of fever after 3 to 5 days with cutaneous haemorrhages (petechiae, ecchymosis or puncture oozing); sometimes internal bleeding (haemetemesis, malena, haematuria, vaginal bleeding); sometimes jaundice with or without terminal shock syndrome.
- Common Diseases : Dengue Haemorrhagic Fever or DSS; Kyasanur Forest Disease; Lassa Fever; Chikungunya (very few patients would have haemorrhagic phenomena.

Fever & Respiratory Manifestations

- Usual manifestations : Onset with fever and often fatiguability; sometimes systemic manifestations; cough; dyspnoea; chest pain; persistent or blood stained sputum.
- Common Diseases :
 - URTI : Pertussis; Influenza; Acute bacterial or viral pharyngitis.
 - LRTI : Streptococcal pneumonia; Pneumonic plague; Influenza, SARS, Avian influenza; Pulmonary anthrax (keep possibility of bio - terrorism).

Syndrome of “Afebrile” Illness

- Afebrile neurological disease : Convulsions, shock or GB syndrome (search for common vaccination history); botulinum food poisoning; Organophosphate Insecticide poisoning (food borne or after spray); mushroom poisoning.
- Afebrile GIT illness : Cholera (epidemic ‘O’ Gp); Food poisoning due to *S aureus*, *C perfringens*, *B cereus* or *V parahaemolyticus*; giardiasis (common - vehicle - food - borne).
- Afebrile Conjunctivitis : bacterial or adenoviral.
- Afebrile rash : Swimming pool associated dermatitis.
- Afebrile genito - urinary syndrome : Gonorrhoea, Chancroid, HSV

Syndrome of Fever & Neurological Manifestations

- Usual manifestations : Onset with fever and systemic manifestations; signs of meningitis or encephalitis or paralysis of central or peripheral type.
- Common Diseases :
 - Mainly paralysis : Paralytic poliomyelitis.
 - Mainly meningitis : Meningococcal meningitis
 - Mainly encephalitis : Japanese encephalitis

Syndrome of Fever & Lymphadenopathy

- Usual Manifestations : Onset with fever and systemic symptoms; Lymphadenopathy (generalized or localized; suppurative or non - suppurative)
- Common Diseases : Bubonic plague; kala azar; hyperendemic filariasis.

Fever with G.I.T. Manifestations

- Usual manifestations : Fever; nausea / vomiting; diarrhoea with or without blood or mucous; abdominal cramps; systemic manifestations usually mild or absent; sometimes neurological manifestations or rash may follow.
- Common Diseases : Non - typhoid *Salmonella* food poisoning; *Shigella* dysentery; Enteroinvasive / Enteropathogenic *E coli* diarrhoea; Rotaviral enteritis especially in children; Giardiasis; Amoebiasis; *Yersinia* or *Campylobacter* food poisoning.

Syndrome of Fever with Jaundice

- Usual manifestations : Initial phase with only fever and systemic symptoms; sometimes there may be no such initial phase; jaundice; sometimes haemorrhages.
- Common diseases : Viral Hepatitis ‘A’, and ‘E’; Viral hepatitis ‘B’ (due to common parenteral experience); sometimes Leptospirosis.

Step 4 - Define the population at risk : By knowing the general population from where the cases have been coming, as evident from the initial line listing and subsequently from the details of cases as recorded on the epidemiological case sheet (see below), one can define, in a demarcating manner, the source population. For example, the population at risk may be defined as “Markandeya Housing society”, or “people living in Gulwadi slum” or “all people working in the main office of Infotech Pvt Ltd”, etc. The more clearly such source population is defined, better the results of investigation would be (Box- 5).

Box - 4 : Continuing with the Hypothetical Example

With 2 cases out of 1000 women staying in the hostel, the rough incidence was worked out as 2 per 1000. Daily epidemiological surveillance system available with the district hospital indicated that maximum of one case of gastro - enteritis with dehydration could be expected in a day during that part of the year, in that general area of the township in which the hostel was located. Moreover, since “cholera” was also one of the possibilities, it was decided to tentatively consider the situation as one of “epidemic”. The Chief Medical Officer of the district and the manager of the hostel were informed and asked for their permission to investigate and their administrative & technical help was sought.

Box - 5 : Continuing with the Hypothetical Example

Urgent telephonic calls were made to the various government dispensaries and private hospitals in the city whether similar cases of gastroenteritis were seen by them on that day. The Duty Medical Officer of the district hospital was asked whether any other case (other than the two in question) with similar symptoms were also admitted to the hospital that day. Since there were no other cases, these two were taken as the initial cases and their details were noted on a line list as per format already discussed above. Since both these cases were from a single place, “people living in that particular hostel” were defined as the “population at risk”.

Step 5 - Develop valid case definition : Often the search for additional cases would involve a number of medical officers / paramedical personnel. It is therefore important that the investigator develops case definitions which are adequately sensitive (i.e. include all those who are having the target disease, though this may entail including many who do not really have the disease) as well as adequately specific (include all those who do not have the target disease, though many mild or equivocal cases of the disease may also be missed out). Apparently, the case definitions should be developed in a way that there is adequate trade - off between both sensitivity and specificity. Development of proper, standardised case definitions is important to ensure uniformity during the investigations. For practical purposes, it is better to have cases in three categories, viz., definite, probable and suspect. Initially during the investigations, while formulating the hypotheses, it may be desirable to have more sensitive definitions, and later, as the hypotheses are being refined / tested, the definitions may

be made more specific by removing the “suspect” category (See Box - 6).

Box - 6 : Continuing with the Hypothetical Example

The case definitions were developed as : *Suspect case* (for use by the paramedical nursing / health assistants) : any person with at least one vomiting and 2 episodes of watery loose motions in a day; *Probable case* (for use by GPs and Dispensary Medical Offrs) : suspect case criteria plus no fever, no tenesmus, and no blood in stools; *Confirmed case* (for use by MOH for investigating the epidemic) : probable case criteria plus laboratory demonstration of ETEC / *V cholerae* / *Salmonella sp* / *Shigella sp* / *Giardia* / *Entamoeba* from stools.

Step 6 - Develop the epidemiological case sheet : The epidemiological case sheet is an extension of the clinical case sheet on which, for each and every subject, the personal and clinical details are filled up. In addition, the details of all factors which are relevant to the mode of transmission for a period which is equal to the *range* of incubation period of the disease, going back from the date / time of onset of symptoms, are also recorded. For example, in an outbreak of cholera, the epidemiological case sheet would include the personal particulars, clinical features, laboratory investigation results, and details of all meals, casual meals, snacks, sources of water supply, drinks, soft - drink etc., consumed by the person between 1 day to 5 days prior to the onset of symptoms. Thus, if the patient had onset of first symptoms of cholera on 10 Aug, we will record all these relevant factors for the period of 06 to 09 Aug. In addition, it will also include details of his movements in time and place during one day to five days prior to the onset of symptoms i.e. the range of incubation period of cholera (See Box - 7).

Box - 7 : Continuing with the Hypothetical Example

Dr ‘X’, as the MOH, had been undertaking regular visits to the various areas in the township, including the women’s hostel, to assess various aspects of hygiene & sanitation, during the past one year, since she had joined. She could identify that the disease being investigated would have come from either drinking water being provided through water coolers placed in each of the mess and each building; or from food which was prepared in the various messes; or from some snacks / Lassi consumed at the local canteen; or from water consumed from coolers or some snacks consumed at workplace; or from one of the two sugar - cane - juice stalls or a sweet - meat shop in the nearby market; or a party which was held in the hostel on 8th May. These various possible factors which could have led to the transmission were specifically kept in the epidemiological case sheet. By now, the hospital laboratory had intimated that organisms with darting motility were seen on hanging drop exam from the two patients; hence the diagnosis was finalized as “cholera” and it was decided to record the history of exposure to these various transmission factors as enumerated above, for a period of 1 to 5 days, retrospectively from the date of onset of symptoms.

Table - 1 : Line listing

Sr No	Name	Age	Sex	Residential address	Work - place address	Date / time of onset of symptoms	Main symptoms/ signs			Name / address of medical facility with date of admission or reporting
							1	2	3	

Step 7 - Organise the laboratory (including Entomological and public health lab) work : A very important step in epidemic investigations is laboratory work. This would include collection, storage and dispatch of body samples (blood, CSF, stool, throat swabs, rectal swabs etc.), environmental samples (water, food items), entomological samples (as mosquito adults and larvae etc.), and animal samples. It would be extremely desirable to consider what all items would be required for such laboratory procedures keeping in view the possible disease which is being investigated. Close liaison with the local hospital laboratory and with the pathologist / microbiologist needs no emphasis (See Box - 8).

Box - 8 : Continuing with the Hypothetical Example

Dr 'X' had kept her small laboratory in the MOH office, in a state of constant readiness to deal with any such public health emergency. However, she once again had detailed discussions with the hospital pathologist as regards various samples to be taken and their method of dispatch to the lab. She quickly organised a portable container having gloves, rectal swabs, rectal catheters, sterile Winchester bottles, specimen vials having Cary - Blair transport medium, sterile vials, centrifuge, and personal protective equipment. She decided to collect and dispatch stool samples / rectal swabs, food samples, water samples and serum for immunology.

Step 8 - Contact administrative and engineering authorities and establish rapport : It is extremely important to explain the objectives and requirements to the local leaders and administrative authorities of the affected community, establish close rapport with them and allay their apprehensions. This way, a lot of information can be obtained without any resistance. Similarly, it is also desirable to establish close rapport with the public health engineering authorities since a substantial part of investigations is likely to be directed towards public health engineering systems like water supply, excreta disposal etc. The layout maps of water supply and sewerage system should be obtained from the engineering and administrative authorities (See Box - 9).

Step 9 - Collection of Information : Having undertaken the preliminary steps, the investigator proceeds to collect information, recording the details on the epidemiological case sheet for each subject. Information is collected in respect of all possible modes of transmission which are relevant to the disease being investigated, and going back for a period which is equal to the "range" (difference between maximum and minimum) incubation period of the disease, going back from the time of onset of first symptom. For example, in an epidemic of hepatitis A, we would ask for details of sources of regular meals, casual meals, water, milk, sweets, snacks, and

Box - 9 : Continuing with the Hypothetical Example

Dr 'X' had kept "spot maps" showing hygiene and sanitation of various areas under her health cover, and constantly updated them after her regular visits to locations. She had also liaised with Public Works Dept (PWD) authorities and kept updated maps of water supply and sewage disposal systems. However, she once again contacted the PWD authorities and asked for their assistance in conducting the investigations. She also sought the sanction of the District magistrate and the CMO, to undertake the investigations. Thereafter she contacted the manager of the affected hotel, took him into confidence and discussed the details as to how the investigations would be undertaken. Finally, she had discussions with lower level PWD functionaries, with the junior functionaries of the affected hostel (canteen owner, cook house in-charge, etc.) and with the paramedical members of her investigative team.

so on, from the date of onset of symptoms and going back for a period of two to 6 weeks. The information is collected from the following sources :

(a) **From the cases** : The persons who have already reported to the health care facility by now (as indicated in the line list) or who report subsequent to the initiation of investigations are the straightway available source of information.

(b) **Search for additional cases and make the final "line - list"** : The cases who have reported to the health care facility may not represent the entirety of epidemic. Many cases may be lying hidden in the community, being mild cases, or those who may have reported to some other agency for treatment. It is therefore mandatory to search for additional cases so that the complete picture of the epidemic may be obtained. Using the standardised case definition, an extensive search is made using door to door survey in the entire population defined to be at risk. In case of very large populations, a random sample (usually a systematic sample) can be taken. The population must be informed well in advance about the search, through mass - media, announcement systems, fixing hand - bills describing the symptoms and requesting the people to report the disease. Apparently, assistance of administrative authorities would go a long way in this process. In addition, other health sources like other hospitals and General Practitioners (GPs) in the area may also be contacted to find out additional cases. In addition to clinical and epidemiological information, laboratory specimen, as applicable, should also be obtained in the field, from suspected cases. Fill up the epidemiological case sheet for cases detected during the search.

A final line list is made. It would include a list of all cases, including those detected on search for additional cases, in a chronological order as they occurred, showing their personal

particulars, date of onset, place of stay, place of work and all exposure histories that are relevant to the disease (e.g. sources of meals and water in case of an epidemic of oro - faecal disease). A review of the line listing of cases will give important clues as regards the various possible sources of exposure - these would be those exposures which are commonly shared by the cases, as seen in the line listing (See Box - 10).

(c) Environmental information: Besides clinico-epidemiological information from cases, a detailed environmental assessment is made of the area, depending on the disease one is investigating. Thus, while investigating an epidemic of cholera, one would make a detailed assessment of water supply system, nightsoil disposal system, cook houses and other eating/drinking establishments in the area where the defined population is staying. Similarly, in a suspected epidemic of dengue, one would make a detailed environmental assessment of vector breeding areas. In addition, various environmental samples (e.g. water, food, etc.) and entomological samples (e.g. larval and adult mosquitoes) would also be collected as required (See Box - 11).

Box - 10 : Continuing with the Hypothetical Example

By now a total of 7 cases had been admitted with same presentation. All were from the same hostel and all showed growth of *V cholerae* Biotype 01, serotype Ogawa from stool samples. The line list was accordingly revised. All cases were interviewed personally by Dr 'X' and detailed information about various transmission factors was recorded on the epidemiological case sheet for the retrospective period of 1 to 5 days from date of onset. Cases were also asked in detail about any other factor which could have led to the transmission and which might not have been included in the epidemiological case sheet. In this regards, 5 of the cases said that they had also been often going to a kiosk selling "fruit - chaat" (mainly water melons) which had come up in the local market recently; accordingly, this was also included in the epidemiological case sheet.

All the local newspapers as well as the local radio and television were asked to announce the "suspect case definition" and inform any person member having such symptoms to come to the MO i/c of local govt. dispensary. The MOs i/c were asked to refer any person or family fitting into "probable case definition" to the district hospital for admission and also inform the MOH. The Health Assistants & Lab Assistants of MOH went "door to door" in the affected area, including their family quarters and asked if any person had suffered with symptoms fitting into "probable" case definition; if yes, their details were recorded on the epidemiological case - sheet and stool samples were taken and dispatched to the hospital lab.

(d) Information from those who did not suffer from the disease: This is a very important step which is often overlooked. While search for additional cases is going on, one must record the information regarding possible exposures (e.g. movements, sources of meals, casual meals, snacks, water, drinks etc.) not only from those who suffered from the disease symptoms, but also from those who were a part of the population at risk but did not suffer (i.e. the controls). This information from controls

is of vital importance in the later part of investigations, when hypothesis regarding various suspected exposures are to be analysed by comparing cases and controls.

Step 10 - Describe the epidemic : Once the information has been obtained, an epidemiological description of the epidemic is prepared. This description is vital for developing hypotheses regarding various possible sources of exposures that could

Box - 11 : Continuing with the Hypothetical Example

A team of the MOH and PWD staff conducted a detailed physical, on - ground check of water distribution and chlorination system and sewage pipe lines was rapidly undertaken. Water and food samples were taken from all messes, water coolers, eating joints in the market and water taps in work - places. These samples were dispatched to hospital lab. Water supply pumps in the affected unit were run for continuous 3 hours by PWD, while the ground was being observed. At one place, there was apparent moistness on the ground overlying a major water pipeline. The affected ground was dug open and it was noticed that there was a break in the water pipe line at that spot; this water pipe line was running approx. 5 feet above a sewage pipe which was also slightly damaged. These were immediately repaired. However, this particular water pipe was a main trunk, which was supplying water to the entire affected unit as well as the adjoining family quarters and not to any single mess.

No other case could be confirmed despite extensive search for cases. Hence information was recorded on the epidemiological case sheet from the seven cases. In addition, 50 healthy people (who did not even fit in the definition of even suspect or probable case), from the same affected military unit were selected from the list of personnel supplied by the unit authorities, by systematic random sampling and all information about various transmission factors as recorded from cases was also recorded from these "controls".

have caused this outbreak. The description of epidemic would include :

(a) Developing the overall attack rates : Using the cases (reported to health care facility plus found during additional search) as the numerator and the population defined to be at the risk as the denominator.

(b) Describing the clinico - epidemiological profile : This would include a percentage wise distribution of major clinical signs and symptoms among the cases, a description of the mild/moderate/severe forms, and fatalities.

(c) Describe the cases according to distribution of person related variables : This step involves development of proportional distribution of cases according to relevant, person related variables like age, sex occupation, source of water supply etc. The detailed line list described in the preceding paragraph is used to describe the cases according to all possible exposures. For example, in an epidemic of cholera, description of cases according to person related variables will include their distribution according to age groups, sex, occupation, place of regular meals, sources of drinking water, sources of casual meals / snacks, etc. (See Box - 12).

Box - 12 : Continuing with the Hypothetical Example					
The following was the description of the 7 cases, according to history of major transmission factors as were recorded in epidemiological case sheet					
Living in hostel dormitories	7 (100%)	Age < 35 yrs	6 (85%)	Took sugar cane juice from kiosk No. 1	5 (72%)
Living with family	0	Female sex	7 (100%)	Took fruit chaat from market	6 (85%)
Eating in 'A' mess	0	Took water from workplace No. 1	4 (58%)	Ate during party on 8th May	6 (85%)
Eating in 'B' mess	6 (85%)	Took water from workplace No. 2	2 (28%)	Had snacks / Lassi from local canteen	5 (72%)
Eating in 'C' mess	0	Took water from workplace No. 3	1 (14%)	Ate sweet - meat from a particular shop in market	2 (28%)
Eating in 'D' mess	1 (15%)	Age > 35 years	6 (85%)	Ate snacks at workplace	2 (28%)

(d) Describe the epidemic according to time : An epidemic is described according to time by plotting an epidemic curve. This curve is developed by plotting the attack rate along the vertical (Y) axis and unit of time along the horizontal (X) axis. The unit of time would depend on the disease; in food poisoning epidemic it would be in hours, in days for cholera and in weeks for Hepatitis A or E outbreaks. Often, it may not be possible to compute the attack rates according to time; in such instances, the epidemic curve may be prepared by plotting the actual number of cases along the vertical axis, instead of attack rates. The shape of the epidemic curve give us important leads as regards the cause. For details of the shapes of various epidemic curves and their interpretation, refer to the chapter on descriptive epidemiology.

(e) Describe the epidemic according to place : Description of the epidemic according to place is given by making the spot map of the area on which the frequency of the disease is plotted as coloured dots. Often, instead of plotting the frequency, only the actual number of cases are plotted and this may be simple and effective method too. Sometimes, different spot maps may have to be developed, e.g. separate spot maps for place of residence, place of work etc., depending on the possible places where exposure to disease could have occurred. For example, in a suspected epidemic of scrub typhus, we may have to prepare separate spot maps for cases, according to places of residence, place of work, places visited while camping as a part of holidaying - all for a period equal to the range of incubation period of the disease, going back from the day of onset of signs / symptoms. Spot map also gives important insight in to the possible causes of the diseases. One would be inclined to develop possible hypothesis regarding the cause of the outbreak, considering those places where the local concentration of cases in high (See Box - 13).

(f) Describe the environmental conditions just before and during the outbreak : A clear description of the findings of environmental and entomological assessment is given. For example, details of damaged water supply lines, cross - connections with sewer lines, unhygienic conditions in cook house, vector breeding and densities are described and efforts made to correlate these finding with description of epidemic according to line listing and distribution according to person,

place and time, thus developing various hypotheses regarding possible causes of the outbreak. It is often worthwhile to superimpose these environmental findings on the spot map for a quick visual evaluation.

Box - 13 : Continuing with the Hypothetical Example
2 cases had onset on 10th May, 3 on 11th and 1 each on 12 and 13th May. There was no case thereafter. The 7 cases were plotted according to the date of onset of their symptoms. The resultant curve showed a sharp rise, a sharp peak and an abrupt fall, indicating a "common vehicle, single exposure (point source)" transmission. It indicated that all these cases had probably got infected at a common source which existed only for a brief period of time, as can occur when a particular meal or drink gets contaminated, or a water storage cistern gets contaminated for a small time till the water is used, or when an infected food handler who is an "incubatory carrier" contaminates a food or drink for a brief period of time, before himself coming down with symptoms.
3 different spot maps were made - according to workplace, place of staying and place of routine eating and drinking, and cases were plotted as coloured dots on these maps. A clear - cut "clustering" was seen in all the three maps - in mess No. 'B', at workplace No. 1 and in Living dormitories No. 4 and 5. Further assessment indicated that large majority of these cases were staying in dormitory No. 4 or 5, as well as eating in Mess 'B' and working in workplace No. 1.

Step 11 - Developing various alternative hypotheses regarding the cause of outbreak : Once the epidemic has been described according to its clinico - epidemiological profile, line - list, and distribution according to person, place and time, various hypotheses are developed regarding possible cause(s) of the outbreak. The basis of developing these hypothesis is to start with the descriptions of cases according to various person, place and time related variables and see as to what are the possible exposures which are very common among cases. If the investigations have been done rightly till now, a large number of hypotheses will be developed (See Box - 14).

Box - 14 : Continuing with the Hypothetical Example

The factors which were very commonly found in a large proportion of cases were female sex, staying without family, age < 35 years, eating meals in mess 'B' or drinking water from its water cooler, drinking water from water cooler of work - place No.1, staying in barrack No. 4 or 5, having lassi or snacks from local canteen, eating in the party on 8th May, consumption of sugarcane juice from kiosk No. 1, and eating fruit - chaat from the market. These were kept as possibilities which could have transmitted the organism (hypotheses). On the other hand, eating snacks at work - place, eating sweetmeats from a particular shop, eating / drinking in messes Nos. 'A', 'C', or 'D' or drinking water from workplaces No. 2 and 3, were very uncommon among cases and hence not kept as "hypotheses" requiring further exploration.

Step 12 - Testing the hypotheses - Comparisons using analytical epidemiology : This step is the backbone of epidemic investigations. A comparison is made between the cases, and those who did not suffer, though being a part of same source population (controls), in respect of each and every possible hypotheses developed in the previous step. The Odds Ratios for each of these exposures are calculated and their statistical significance is seen by a chi square test. Thus, out of the various hypothesized exposures, one would find out one particular exposure in which the cases and controls differ significantly and this is, then, the likely source of the outbreak (See Box - 15).

Step 13 - Further search for environmental and other possibly causative factors : Further exhaustive search is now made, based on the indications given by the preceding step, to explore in detail as to what could have been the reason for transmission of the organism (See Box - 16).

Step 14 - Final Laboratory proof of cause and effect relationship : This is a difficult proposition, but if done, can give the final proof of the cause and effect relationship. For example, if the same organism that is isolated from the food handler, who has also been incriminated by analytical epidemiology (case control step above), is also isolated from the cases, then the link is finally proved.

However, it is not necessary that this step must always be completed, though best efforts should be made. In most of the real life situations, description of epidemic and test of hypotheses based on analytical epidemiological are enough proof of the cause (See Box - 17).

Box - 16 : Continuing with the Hypothetical Example

Once the results of hypothesis testing step focused the suspicion on 'B' mess, the conditions in 'B' mess that existed at the time of the outbreak were further evaluated. Extensive study of hygiene and sanitation of cook house and dining halls, drinking water storage and handling, health state of food handlers and cooking / food serving practices were evaluated. It was noticed that the tap of the water cooler was not functioning and hence drinking water was drawn manually by mess waiters, by immersing a "jug" into the cooler. Water samples were dispatched for bacteriological exam. There were total of 9 food handlers in 'B' mess, including 2 cooks, 2 cleaners and 5 waiters. 1 of the waiters (named herewith as waiter No. 'Q') had not reported for duty because of "upset stomach" from 10th may to 13th May. Clinical exam of all these food handlers was undertaken and rectal swabs of all 9 were dispatched to the laboratory

Box - 17 : Continuing With the Hypothetical Example

Water samples from water cooler showed very high coliform count of 180 per 100 ml but no *E. coli*. Rectal swab of the food handler 'Q' grew *V. cholerae* O1 Ogawa, i.e. the same biotype and serotype as was isolated from the 7 cases.

Control and Prevention

Steps for immediate control measures and long term prevention should not wait for the final proof of the cause of epidemic but should start immediately and continue concurrently as the investigations proceed. The following broad categories of steps are to be undertaken :

(a) Measures directed towards the source of infection : These would include detection and treatment of cases and carriers, isolation if required, notification, and control of zoonotic reservoir if applicable.

(b) Actions directed towards channels of transmission : These would include measures like protection of water supply and food hygiene, vector control, proper disposal of night soil and solid waste, various disinfection procedures, etc., depending on the disease.

(c) Protection of susceptible population : This includes steps like immunization, immunoprophylaxis, chemoprophylaxis, personal protective measures etc.

Box - 15 : Continuing with the Hypothetical Example

comparison of the 7 cases and 50 controls as regards the 6 different hypothesized factors indicated following

Hypothesized factor	Cases	Controls	Statistical results	Hypothesized factor	Cases	Controls	Statistical Results
Eating in 'B' mess	6 (85%)	11 (22%)	p < 0.001	Fruit Chaat	6 (85%)	39 (78%)	p > 0.05
Water from workplace no. 1	4 (58%)	32 (64%)	p > 0.05	Eating in party	6 (85%)	44 (88%)	p > 0.05
Sugar cane juice	5 (72%)	38 (76%)	p > 0.05	Lassi / snacks from canteen	5 (72%)	35 (70%)	p > 0.05

(Large majority of cases compared to statistically much smaller % of controls were eating / drinking in 'B' mess. For other factors, there was no difference)

(d) **Developing a long term early warning system** : A proper epidemiological and public health surveillance system should be developed and launched, so as to give ongoing data regarding the frequency of disease and changes in various environmental risk factors, with a view to give early warning of impending outbreaks (See Box - 18). Details of surveillance are discussed in an earlier chapter.

Box - 18 : Continuing With the Hypothetical Example

Super - chlorination of water supplies to bring the level of free residual chlorine at consumer end point at 1 ppm was ensured from the very first day the epidemic was reported and was periodically checked by sanitary staff. As investigations proceeded, the damaged water pipe lines and sewage lines were promptly repaired. The food handler 'Q' was removed from duty for 5 days and treated with oral tetracyclines at the district hospital; all other food handlers, though not found infective were given a presumptive dose of oral Doxycycline. The damaged tap of the water cooler in 'B' mess was repaired and the top lid was closed and locked. Local medical officer of the hostel was provided guidance to launch a daily surveillance system for diarrhoeal diseases and their reporting to the MOH. The in - charges of cook - houses were trained to undertake regular, daily medical surveillance of all food handlers.

Investigating an Outbreak of Food Poisoning

Investigations of an outbreak of food poisoning takes the same general approach as any other epidemic, as has been outlined earlier. However, there are certain differences in approach, vis a vis the details often described in other textbooks. In the usual situations, as in the case of individual families, where generally all people live and eat as a family group and not in the form of community feeding, the "common" meal (as a banquet, religious get - together, picnic etc.) can be easily identified and the details of food histories of that meal can be obtained. On the other hand, in some other settings as a hostel, the fact that all the inmates live and eat all meals together, every meal is a common meal, and hence identification of the common meal which caused the episode of food poisoning may not be as simple a common - sense conclusion. For instance, if 25 inmates out of 100 staying in a hostel, eating from a common cook house, are admitted with symptoms of gastro - enteritis between 9 a.m. and 3 p.m. on 10 May, which meal do we investigate - whether breakfast of 10 May, or dinner of 9th May or lunch of 9th May? Secondly, the idea of investigations is not simply to incriminate a given food stuff. The goal is to trace back the entire history of that food item to find out why contamination occurred so that the episode does not repeat. We shall deliberate on the steps to be undertaken for investigating an outbreak of food poisoning, illustrating it with a hypothetical example based on a real life episode (See Box - 1a).

Step 1 - Confirm whether it is an outbreak? : An outbreak of food poisoning has three characteristics - Firstly, the symptomatology should be usually referable to gastrointestinal tract (and sometimes systemic in case of mushroom or organophosphate etiology or neurological in botulinum

etiology). Secondly, *a large number of cases should occur in a small period of time*. Thirdly, the cases should have some history of sharing at least one common meal. If these three criteria are fulfilled, we would say that it is an outbreak of food poisoning.

Step 2 - Verifying the Diagnosis & Deciding Which Meal to Investigate? : In a food poisoning episode one has to decide as to which meal is to be investigated and this is done by making a "tentative" verification of diagnosis mainly on clinical grounds. While microbiological diagnosis is always desirable, for all practical purposes it is extremely difficult to establish lab diagnosis quickly because the procedures are highly specialized, available only at specialized centres and

Box - 1a : Hypothetical Example

On 8th March, Dr 'X', the Medical Officer of Health (MOH) got the information that yesterday, i.e. 7th March, an episode of gastroenteritis had occurred in the same working women's hostel, in which she had earlier investigated an epidemic of cholera. Out of 1000 working women in this hostel, 87 were eating in 'B' mess and out of these, 36 developed symptoms and have been detained for observation and treatment at the dispensary at the hostel. Since the incident was concerning, the CMO of the district directed Dr 'X' to move to the affected site and investigate. She left immediately and reached the location at 2 p.m. on 8th Mar. Preliminary investigations revealed that out of the 36 patients, all the cases (100%) had 6 to 8 watery loose motions, 100% had abdominal cramps, 3% had nausea / vomiting, none had fever or blood / mucous in stools. No case had dehydration or any complications. The first 3 cases had onset of symptoms at 7 a.m. on 7th March, 7 between 7 and 8 am, and similarly, 9, 5, 4,3,2,2 and 1 had onset between 8 and 9 am and similar hourly periods; the last case had onset at 3 pm. The peak of the epidemic was reached at 9 a.m. by which time, 19 cases had onset. No food sample of any meal had been kept since the entire episode was not visualized and the hostel had no such procedure of preserving the food samples.

The epidemic curve plotted with the above data showed a classical "common vehicle point exposure" curve typical of food poisoning. As evident from clinical profile, the entire epidemic was clearly due to either *C. perfringens* or *B. cereus* type - 2. Going by the median and range of incubation periods of these organisms, the suspicion converged to some meal which was eaten at about 9 p.m on 6th March.

take time; more important, the food samples are themselves usually not available due to ignorance or deliberation on the part of food handlers. For example, lab confirmation of *C. perfringens* food poisoning requires demonstration of 10⁷ spores per gram of faeces from patients or food handlers and *S. aureus* or mushroom poisoning requires toxin assays available only at few centres in our country.

The mainstay is therefore to see the "clinico - epidemiological" profile of the outbreak by quickly analyzing the frequency of symptoms in the present outbreak and comparing this profile with what is expected during outbreaks caused by common etiological causes of food poisoning, as shown in Table - 2.

Etiologic agent	Median incubation (range)	Nausea / Vomiting	Loose motions	Abdominal Cramps	Fever	Blood / Mucous in stools	Neuro-muscular symptoms
<i>Staph aureus</i> & <i>B cereus</i> - 1	2 hr (1 - 6)	+++	+	+	-	-	-
<i>C perfringens</i> & <i>B cereus</i> - 2	13 (10 - 18)	+	+++	+++	-	-	-
<i>Salmonella spp</i>	18 (16 - 24)	++	+++	++	+++	-	-
<i>Shigella spp</i>	24 (12 - 96)	+++	+++	+++	+++	+++	-
Insecticides / mushroom	Few mts.	++	+	-	-	-	+++
<i>C botulinum</i>	24 (18 - 36)	+	-	-	-	-	+++

(Legend :- +++ = occurs in 80 to 100% patients; ++ = 40 to 60%; + = 20 to 30%; - = 0 to 5% patients show this manifestation)

The first thing is to work out the % of various signs / symptoms in the present outbreak (besides taking all available samples as food samples, water samples, stool samples of cases and food handlers). Ascertain as to, with which etiologic symptomatology (as shown in Table - 2) does the present outbreak match and make a tentative diagnosis of the cause of the present outbreak.

Draw an epidemic curve, plotting the number of cases along the vertical axis and the time according to hourly period (i.e. 9 a.m., 10 a.m. etc.). The peak of epidemic curve must be noted. Also note the first case and the last case. Go back in time, from the peak of the curve, by the known median incubation period of the suspected etiologic agent (as shown in Table - 2) as also the minimum and maximum incubation periods from the first and last case respectively. The meal which was consumed where all these three time periods converge gives the meal which was most probably contaminated and needs to be further investigated (See Box 1a).

Step 3 - Getting the Food Histories about the Suspected Meal : Once the meal which was most probably associated with the epidemic has been identified, a list of *each and every dish* (including even chapattis, rice and water / drinks) which was served during that meal is made. Now, *each and every person* who attended that meal is interviewed and asked about the *history of consumption of each and every food item* that was served during that meal. The information is recorded as per the following work - sheet, which, in fact, is nothing but the line - list, as shown in Table - 3 (Also see Box 2a).

Step 4 - Consolidating the food histories and sickness histories : The details recorded on the above line list are now consolidated into a summary - table as shown in Table - 4.

Now, the food item which shows the maximum Attributable Risk is the food item which most probably was involved in the transmission of the epidemic (See Box - 3a).

[Sometimes all persons who ate the suspected meal may not be available for interrogation. In such instances, the “cases” and a “random sample” of those who ate the meal but did not become ill (controls) are interrogated about the food histories.

This is the case - control approach, wherein we would calculate the Odds ratio (OR) and not the Attributable risk. The food item showing highest OR would be taken as the suspect item].

Box - 2a : Continuing with the Hypothetical Example

Dr 'X' made a list of each and every item which was served during the dinner on 6th March. These items were Mutton Curry, *Matar - Paneer, Moong Daal, Chapati and Rice*. She then interviewed each and every of the 87 ladies who had eaten that dinner in their 'B' mess dining hall and asked them whether they developed any symptom. If they had developed symptoms, details of each symptoms were enquired. Details were also taken about each and every of these 5 food items - whether eaten or not eaten, irrespective of whether the lady developed sickness or not.

Step 5 - Undertake an extensive assessment of the sanitary history and food hygiene of each constituent of the suspected food item : The objective of investigations is to find out why a particular food item got contaminated so that recurrences are prevented in future. Therefore, once a particular dish has been identified as per details given in previous step, all its constituents (including condiments and water) should be noted and detailed history of every constituent should be taken :

- From where they were procured;
- What were the hygienic conditions at the point of procurement;
- How they were stored in the cook house;
- Sanitary conditions at the time of cooking;
- What temperature did the initial cooking achieve;
- Whether the cooked food was eaten hot and freshly cooked or else stored;
- If stored, at what temperature and under what hygienic conditions was it stored;
- If stored, was it adequately re-heated before consumption. (Refer Box - 4a.)

Serial No.	Name & Personal particulars	Whether developed illness (Yes or No)	If ill, Presence of symptoms (Yes / No)				History of eating various food items served during the suspected meal				
			Nausea / Vomitting	Watery Diarrhoea	Abdominal Cramps	Fever	Matar Paneer	Mutton Curry	Kheer	Item No. 4	Item No. 5
1.	ABCD	No	-	-	-	-	Yes	No	Yes	Yes	Yes
87.	XXYZ	Yes	No	Yes	Yes	No	No	Yes	No	Yes	No

Food Item	Those who ate the item				Those who did not eat the item				Relative Risk	Attributable Risk
	Became Sick	Did not Become sick	Total	Incidence among those who ate the item (I_E)	Became Sick	Did not Become sick	Total	Incidence among those who did not eat the item (I_{NE})		
(a)	(b)	(c)	(d)	(e) (b ÷ d)	(f)	(g)	(h)	(i) (f ÷ g)	(j) (e ÷ i)	(k) (e - i)
Item - 1	31	9	40	78%	5	42	47	22%	3.6	66%
Item - 2										
Item - 3										

Food Item	Those who ate the item				Those who did not eat the item				Relative Risk	Attributable Risk
	Became Sick	Did not Become sick	Total	Incidence among those who ate the item (I_E)	Became Sick	Did not Become sick	Total	Incidence among those who did not eat the item (I_{NE})		
(a)	(b)	(c)	(d)	(e) (b ÷ d)	(f)	(g)	(h)	(i) (f ÷ g)	(j) (e ÷ i)	(k) (e - i)
Mutton Curry	31	9	40	78%	5	42	47	22%	3.6	66%
Mutter Paneer	30	31	61	49%	6	20	26	23%	1.19	7%
Dal Moong	27	24	51	53%	9	27	36	25%	2.1	28%
Chappati	32	43	75	42.7%	4	8	12	33.3%	1.27	14.4%
Rice	34	46	80	42.5%	2	5	7	28.6%	1.5	13.1%

Box - 4a : Continuing With the Hypothetical Example

Once mutton curry was identified as the possibly contaminated dish, the suspicion became strong regarding *C perfringens* etiology, since *B cereus* is more likely to be conveyed through rice dish while *C perfringens* is more likely through a meat dish. Dr 'X' quickly made out a detailed list of all items used in making the mutton curry, including condiments, vegetables and water. She thereafter took a detailed sanitary history of each and every item, starting from the point of procurement till the final cooking and subsequent storage / serving of the cooked dish. She also verified the details by personally observing the hygienic conditions on ground.

She noticed some peculiar and interesting findings. The cook house and dining hall were properly constructed, with adequate sanitary standards. The various dry raw edibles as wheat, rice, pulse, condiments, etc. were bought by the catering in-charge from the nearby market, while the vegetables, fruits and meat was supplied by a local contractor on a contract basis. The contractor used to get mutton from a local butchery. On visiting the butchery it was found that the conditions were grossly unhygienic. The floor was cracked and there was no arrangement for washing the floor nor there were arrangements of hygienic disposal of excreta of slaughtered animals. There was no system of starving the animals prior to slaughtering. Animal excreta (which is a rich source of *C perfringens* spores) was seen lying all over the floor of the butchery and the raw meat was apparently getting mixed up with the excreta.

On 6th March, the contractor reached the hostel cook house, with mutton and other fresh items by around 1 p.m. In the 'A', 'C' and 'D' messes, the raw mutton was stored on ice till 6 p.m. and cooking started at about 6 p.m. and was completed by 7 p.m. However, in 'B' mess, since there were lesser cooks, cooking of mutton curry started at about 3 p.m. and was completed by about 4 p.m. Thereafter, this cooked mutton curry was stored in the large utensil, which was kept on a table, since there was no arrangements of a fridge. This dish was therefore kept at an environmental temperature of about 30°C for almost 4 hours, till 8 pm, giving optimum time and temperature for the heat - shocked *C perfringens* spores in the mutton to germinate and produce large amount of toxin. At 8 pm, the mutton dish was "warmed" (to about 40°C) (and not reheated thoroughly which could have inactivated the preformed perfringens toxin) and served for dinner starting at about 8.15 pm till 10 pm.

Step 6 - Make focused recommendations based on the findings of investigations : Make specific and "do - able" recommendations, based on the actual findings and develop a system of keeping a check that these recommendations are being adhered to (See Box - 5a).

Summary

Investigation of an epidemic is one of the most important duties of the health care provider, as well as the epidemiologist. It involves a series of steps. These steps are not necessary to be undertaken in the same sequence, some of them may even be undertaken simultaneously.

The first and foremost step would be verification of the diagnosis of the condition that one is dealing with in epidemic form. For this purpose, it may be adequate to confirm by lab tests, a 20% to 30% random sample to be having similar disease. The next step is to confirm the existence of an epidemic. This is done by comparing the current incidence rate with the rate occurring in the same population, during the corresponding period of the past three years. After this step, an Initial (Rough) "Line - listing" of cases is developed - i.e. a nominal roll of the cases which have already been reported to the various health care establishments.

The next step would be to define the population at risk - the source population. Developing valid case definitions would be the subsequent step. The case definitions should be a fine balance between sensitivity and specificity. Subsequently, an Epidemiological case sheet is to be developed - it is an extension of the clinical case sheet on which, for each and every subject, the personal and clinical details are filled up as well as details of all possible exposures that could have led to this infection, recorded for a range of time equal to the maximum and minimum incubation period, going retrospectively from the date of onset of the disease.

After this is accomplished, it would be advisable to organize the laboratory (including Entomological and public health lab) work, which would include collection, storage and dispatch of body samples, entomological samples, environmental samples

Box - 5a : Continuing with the Hypothetical Example

Based on her findings, Dr 'X' made the following do - able recommendations :

- Meat should not be taken from the particular butchery, since it was difficult to have adequate sanitary control on it.
- An alternative butchery to be identified for supply of meat and should be properly inspected for sanitary conditions by a public health officer.
- After receipt from the contractor raw meat should be stored in a deep freeze.
- Meat dish should be the last one to be cooked for dinner. Cooking of meat dish should start after 6 p.m. so that it is completely ready by about 7 p.m.
- All meals should be served freshly cooked and hot.
- No cooked food item should be stored, unless operationally essential.
- If cooked item is to be stored, the storage should be in a deep freeze or on ice, in ice box and storage should not be more than 4 hours.
- Cooked food item, if stored (even on ice), should be thoroughly reheated to > 60°C before serving.
- In - charge of the catering arrangements of the hostel to check implementation of these recommendations.

and animal samples. The next step would be to contact administrative and engineering authorities and establish rapport. Thereafter, collection of information from the cases and through environmental information should be carried out. Also, additional cases need to be searched for and thereafter, the final "line - list" is made. Information for those who did not suffer from the disease also needs to be included.

The next step would be to describe the epidemic - by developing the overall attack rates, describing the clinico - epidemiological profile, describing the cases according to distribution of person, time and place related variables. Description of the environmental conditions just before and during the outbreak would be appropriate at this juncture of investigating an epidemic.

Various alternative hypotheses regarding the cause of outbreak have to be developed thereafter. Using analytical epidemiology, each of these hypothesis is tested and compared. Thus, out of the various hypothesized exposures, one would find out one particular exposure in which the cases and controls differ significantly and this is, then, the likely source of the outbreak. Final Laboratory proof of cause and effect relationship is not mandatory, but can be performed if facilities are available and will further strengthen the results.

Steps for immediate control measures and long term prevention should not wait for the final proof of the cause of epidemic but should start immediately and continue concurrently as the investigations proceed. These measures are generally directed towards the source of infection, towards channels of transmission, protection of susceptible population and for developing a long term early warning system.

As an example, investigations of an outbreak of food poisoning can be taken and the general steps outlined above may be instituted appropriately. A point in case here would be to deduce the probable meal to be incriminated, by making necessary calculations using time - points along the epidemic curve and knowledge of incubation period of specific agents causing food poisoning. Also to keep in mind would be to get clear food histories and sickness histories.

Study Exercises

Long Questions :

1. You are the medical Officer in charge of a PHC. You have received a message on 10th August 2008 from your Health Assistant of one of the subcentres that there have been unusually large number of patients of jaundice have been reporting at the subcentre during the past one week. Describe as to how will you proceed to investigate this occurrence.
2. You are the Medical Officer in charge of a PHC. From 1 a.m. onwards on 17th June 2008, a number of patients have started coming to the PHC from a local village with complaints of nausea, vomiting, abdominal cramps and occasional watery loose motion. There is no fever or blood in stools. All these patients belong to a "Barat" (marriage party) which came in the evening of 17 June along with the bridegroom, for solemnizing a marriage. Describe as to how you will proceed to investigate this occurrence.

Short Notes : (1) Epidemiological case sheet (2) Line listing (3) Describing an epidemic (4) Hypothesis testing in an epidemic.

MCQs & Exercises

1. The very first step in investigation of an epidemic is (a) Confirmation of existence of an epidemic (b) Verification of diagnosis (c) Develop epidemiological case sheet (d) Formulation of hypothesis.
2. A nominal roll of the cases which have already been reported to the various health care establishments (like dispensaries, general practitioners or admitted to the hospitals) till the present moment would form (a) Line list (b) Epidemiological list (c) Case summary (d) Secondary data.
3. Arrange the following steps in investigation of an epidemic, in the sequential & ideal order (a) Develop the epidemiological case sheet (b) Testing the hypotheses (c) Confirm the existence of an epidemic (d) Develop an Initial (Rough) "Line - listing" of cases (e) Develop valid case definition.
4. For purposes of terming a health - related event as an epidemic, the incidence rate computed is compared with the rate occurring in the same population, during the corresponding period of the past (a) 01 year (b) 03 years (c) 10 years (d) No specific time frame is laid down.
5. As a general rule, to avoid the danger of food poisoning, cooked food item, if stored (even on ice), should be thoroughly reheated to what temperature before serving (a) 60°C (b) 80°C (c) 100°C (d) 120°C.
6. Match the following; While plotting the epidemic curve of a common - source, single exposure epidemic (say, an outbreak of food poisoning), which time period needs to be deducted/ subtracted (i.e. column B) from the given time points along the curve (in column A) so as to draw an inference regarding the most probable meal to be incriminated and its timing

Column A	Column B
A) Peak of epidemic	I) Minimum Incubation period
B) Occurrence of First case	II) Maximum Incubation Period
C) Occurrence of last case	III) Median Incubation Period

7. All of the following categories are to be defined in developing valid case definitions of diseases, except (a) Suspect (b) Fatal (c) Probable (d) Confirmed.
8. While developing an epidemiological case sheet in investigation of an epidemic, it would be prudent to go back by what time period from the onset of the first symptom, so as to get an idea of the agent to be incriminated (a) Maximum Incubation period (b) Minimum incubation period (c) Latent period (d) Range of Incubation period.
9. While investigating an epidemic, the document which is made after including the cases that were earlier missed out, i.e. after inclusion of additional cases,, is known as (a) Final line list (b) Optimal line list (c) Active line list (d) Passive line list.
10. In case of large populations, while looking out for additional cases to complete the line list when investigating an epidemic, which type of sample should be ideally taken

- (a) Cluster sample (b) Multi - stage sample (c) Systematic random sample (d) Stratified random sample.
11. An epidemic is described in all of the following ways/ parameters, except (a) According to time characteristics (b) According to space characteristics (c) According to person characteristics (d) According to place characteristics.
 12. Which measure is to be used while making comparisons using analytical techniques, between those who suffered, and those who did not suffer, though being a part of same source population, for testing the hypothesis in investigation of an epidemic (a) Odds ratio (b) Relative risk (c) Attributable risk percent (d) Population Attributable risk.
 13. Which test of significance is to be used while making comparisons using analytical techniques, between those who suffered, and those who did not suffer, though being a part of same source population, for testing the hypothesis in investigation of an epidemic (a) Paired 't' test (b) Unpaired 't' test (c) 'Z' test (d) Chi - square test.
 14. All of the following are measures directed towards control and prevention of the source of infection, in an epidemic, once identified, except (a) Vector control measures (b) Notification (c) Isolation if required (d) Detection and treatment of cases and carriers.
 15. All of the following are measures directed towards protection of susceptible population, in an epidemic, once identified, except (a) Immunization (b) Chemo - prophylaxis (c) Personal protective measures (d) Quarantine.
- Answers :** (1) b; (2) a; (3) c - d - e - a - b; (4) b; (5) a; (6) A - III, B - I, C - II; (7) b; (8) d; (9) a; (10) c; (11) b; (12) a; (13) d; (14)a; (15) d.

33

Writing the Research Findings

RajVir Bhalwar

While the researcher would have put her entire heart and soul into the planning, organizing, conduct and analysis of the research work, it is the report (often called as the "paper" in research parlance), which is actually read by all and hence great care should be exercised while writing the same. The discussion in the present chapter is intended to serve as general guidelines for writing a research paper or dissertation. The researcher is advised to also obtain a copy of specific guidelines from the journal to which he or she intends sending the article (or the academic council or research body in case of a thesis or project report) and adhere to the finer details provided in such instructions. All leading medical journals publish guidelines for authors, as specific for their journal, in all their issues, or at least once a year, and the same should be checked.

The General Sequence of Presentation in an Original Research Paper or Thesis is usually as follows :

1. Title
2. Abstract (Summary in case of thesis)
3. Key words
4. Introduction
5. Aim and objectives
6. Review of literature
7. Material and Method
8. Findings (Results)
9. Discussion
10. Conclusion
11. Recommendations
12. References
13. Annexures
14. Other Enclosures.

All or most of these headings should be sequentially covered up, whether you are preparing an original research article or a thesis, keeping one major difference in mind, that in a thesis or project report, the various aspects are dealt with in great detail while in a research article, these are condensed. As a general guideline, try and restrict your research paper to 10 to

12 double spaced A - 4 sized typed pages and your dissertation/ project report within 125 to 150 pages.

Title : A large majority of the readers of medical journals generally browse through the list of contents and tend to select the article whose title attracts attention. The take home message is that you must select the words in the title in such a way that it attracts attention. Do not keep the title either too long or too short. A good method is to write down a few titles, revise and modify them a number of times till you get the one which appears to be the best. The optimum number of words in a title should be between 10 and 15. The title should be, in fact, a very short, "telegraphic summary" of your objectives. In addition, the title may also give a very brief indication of the place and general settings of the study and the type of study design; e.g. "A Randomized Controlled Clinical Trial (i.e. the "design") of the effectiveness of acetazolamide in preventing Acute Mountain Sickness (i.e. the *research question*) among young healthy tourists inducted to high altitude in Northern Himalayas" (i.e. the *general settings*).

Abstract : In a research paper, the title is followed by the Abstract. In case of a dissertation or project report, there is an additional page giving the Index (list of contents) interspersed between title page and the "Summary". In a dissertation/ project report you would write a Summary which occupies approximately 5% to 7% of the total pages that are present in the report. The abstract is a short, crisp summary of your entire research paper. Usually, it should be limited to 200 to 300 words (about one typed page in double spacing). Most of the standard journals want the Abstract section to be further subdivided into four sub - headings - Background significance, Material and Method, Results and Conclusion. The abstract should start with a sentence or two on the background of

the research question, including its importance, followed by your actual research question (i.e. objectives) summarised in a sentence or two. Thereafter the salient features of methodology are summarised in about three or four sentences, so as to give an idea of the general settings, the reference population, the sample size, sampling method, type of design, the methods used in making measurements / obtaining information from the subjects and the intervention procedure if any. This is followed by the salient findings (giving the measures of effect like OR and p value in brackets) and finally the main conclusions drawn from the study. In case of summary of a thesis or project report, the above aspects are explained in slightly greater detail, paragraph wise, in about seven to ten typed pages. Avoid including aspects pertaining to "Review of literature" or "Discussion" in the abstract or summary.

Key words : After the Abstract, indicate four or five key words that will help "indexing" your article in Index Medicus or on the internet / computer based databases.

Introduction : Keep it brief, but, at the same time, as clear as possible. The optimum space for introduction is about half page in your typed manuscript; in a thesis/project report the optimum space is 3 to 4 pages. The Introduction should bring out, systematically, the definition of the disease/health problem that you have studied, its "magnitude" in terms of morbidity, mortality and suffering, a brief note on what is already known in this area and finally the facets where gaps exist in the present body of knowledge and which have prompted you to take up the present research work.

Aim and Objectives : In a research article, aim and objectives are usually covered in the last one or two sentences of introduction, without giving any separate heading. In a thesis/project report, a separate heading must be given and the aim and objectives should be spelt out in detail.

Material & Methods : This section is the "backbone" of your entire study. Write your methodology with great care and accuracy. It would be worthwhile devoting upto one complete page to material and methods in a research paper, and up to 12 to 15 pages in your thesis/project report to this aspect. Coverage of all the headings described in material and method section of the next chapter (on research proposal) must be ensured, in detail when writing a thesis and in a summarised form when writing a research paper. (Go through the next chapter for details).

Review of Literature : A review of literature is not required in a research paper. On the other hand it is a must for thesis/project report, wherein it should be a detailed review of recent literature (generally covering the past 5 years). In a dissertation/ project report the review of literature may generally occupy 30 to 40 pages. The order of proceeding with the review of literature usually takes the following sequence :

- (a) Definition(s) of the condition(s) of interest in the present research.
- (b) Historical review of the condition of interest.
- (c) Magnitude of the problem due to the condition of interest, in terms of mortality, morbidity and suffering.
- (d) Major risk factors for the condition.
- (e) Other (minor or possible) risk factors for the condition.
- (f) Review of diagnostic/therapeutic strategies (in case of a

study addressing issues of "therapy" or "diagnosis") Or Review of preventive strategies (in case of study addressing issue of "prevention" or "risk").

Findings (Results) and Discussion : In general, findings and discussion should be in two separate headings. The findings should be "grouped" into broad headings, commensurate with the study objectives. Graphical presentations should be made using appropriate types of figures (diagrams) or tables. Each figure should be appropriately referred to in the text. Each table should have a table number, usually in Arabic numerals, which should be clearly referred to at the appropriate place in the text. The table number should be followed by a clear but concise heading, and the actual findings. It is always a good practice to indicate the percentages along with the numbers. Do not forget to indicate 100% besides or below the number out of which you have calculated the percentage. Also make sure that the totals of the columns as well as the rows have been presented. Following the table, the abbreviated statistical findings as "t = 3. 21, df = 28, p < 0. 05 (significant)" must be given. An example is given as Table - 1.

Smoking History	Cases	Controls	Total
	No. (%)	No. (%)	
Present	67 (76. 1%)	54 (42. 5%)	121
Absent	21 (23. 9%)	73 (57. 5%)	94
Total	88 (100%)	127 (100%)	215
X ² = 23. 9, df = 1, p < 0. 001 (very highly significant)			
(OR = 4. 3; 95% CI of OR = 2. 4 to 7. 7)			

Following the table, describe your own findings in two or three sentences. Do not leave it on your examiner or the reader to make interpretations from the tables. Having given an overview of your findings, discuss them by first bringing out such studies which have given similar findings. Next, give a brief account of studies which have obtained findings that are dissimilar from your findings, and "reason out" the possible causes as to why your findings could be different from theirs. Finally, in a sentence or two, summarise the overall findings and how your findings would affect the clinical or preventive policy.

Conclusions and Recommendations : A point which needs to be emphasised is that the conclusion should be drawn from the premises of your study and not from possible factors which you have not studied. Similarly, while making your recommendations, make sure that they are based on facts which you have studied and not simply a repetition of standard recommendations given in some text book or by some other author. Moreover, the recommendations should be "do - able" (practicable).

Annexures and Enclosures : In general, the annexures that are attached in a thesis/project report are the same as have been explained subsequently in the chapter on writing a research proposal. In addition, if necessary and possible, in a thesis/project report, interesting ECG tracings, Skiagrams etc. may be attached as separate enclosures. Annexures and

enclosures should be properly referred to at appropriate places in the text.

References : The references should be serially numbered in Arabic numerals, in a chronological order, as they appear in the text. Do make sure that a particular reference number should appear in the text for the first time, only after the immediately preceding reference number has appeared in the text at least once. For example, reference number 9 should appear in the text only after reference number 8 has appeared in the text at least once. The style of writing the reference should conform to the one used in *Index Medicus*, which is as per the Vancouver system. For example, for writing a reference of an article published in a journal, the format is as follows : “*Reference No. Name of author(s). Title of article. Name of journal & Year; Volume : Pages from - to*”. (A hypothetical example is as follows - “18. Singh BB, Kumaran R. Epidemiological study of murine typhus in a rural area. *Indian Jr Biology* 1968; 37 : 368 - 73” .). If there are up to 6 authors, then give the names of all; if more than six, give the names of first three, followed by “et al”.

Summary

Great care should be exercised while writing the Report or “paper” as it is actually read by all. A copy of specific guidelines from the journal to which researcher intends sending the article must be obtained and one must adhere to the finer details provided in such instructions. These are generally published once a year. In a thesis or project report, the various aspects are dealt with in great detail while in a research article, these are condensed. Restrict research paper to 10 to 12 double spaced A - 4 sized typed pages and dissertation/project report within 125 to 150 pages. The general sequence of presentation in an original research paper or thesis is usually the Title followed by Abstract (Summary in case of thesis), Key words, Introduction, Aim and objectives, Review of literature, Material and Method, Findings (Results), Discussion, Conclusion, Recommendations, References and finally Annexures and other Enclosures.

The words in the title must attract attention; the optimum number of words in a title should be between 10 and 15. A suitable title can be written by writing few possible titles and modifying them till a suitable title is arrived at. It should bring out the research question, design and the setting of the study. The abstract is a short, crisp summary of your entire research paper, limited to 200 to 300 words. Abstract section may be further subdivided into four sub - headings - Background significance, Material and Method, Results and Conclusion. Do not include aspects pertaining to “Review of Literature” or “Discussion” in the abstract or summary. Four or five key words must be given to facilitate the indexing. Introduction is a brief note on what is already known, what are the gaps in the existing body of knowledge and why this present work was taken up. It should combine brevity and clarity. Methodology must be written with great care and accuracy. A detailed review of recent literature must generally cover the past 5 years. In a dissertation / project report the review of literature may generally occupy 30 to 40 pages. It consists of Definition(s) of the condition(s) of interest in the present research, Historical review of the condition of interest, Magnitude of the problem due to the condition of interest, in terms of mortality, morbidity

and suffering, Major risk factors for the condition, Other (minor or possible) risk factors for the condition, Review of diagnostic/therapeutic strategies (in case of a study addressing issues of “therapy” or “diagnosis”) Or Review of preventive strategies (in case of study addressing issue of “prevention” or “risk”).

The findings should be “grouped” into broad headings, commensurate with the study objectives. It should use graphs, charts and tables to lucidly present the findings. They should be properly referred to in the text. Conclusion should be drawn only from the premises of study. Recommendations made should be fact based and “do - able” i.e. practical and feasible. Interesting and relevant documents should be placed at annexure. References, annexures and enclosures should be serially numbered and properly referred to in the paper.

Study Exercises

MCQs

1. As a general guideline, research paper should be restricted to _____? (a) 10 to 12 double spaced A - 4 sized typed pages (b) 5 to 6 double spaced A - 4 sized typed pages (c) 18 to 20 double spaced A - 4 sized typed pages (d) 1 to 2 double spaced A - 4 sized typed pages.
2. As a general guideline, dissertation/project report should be restricted to _____? (a) 60 to 70 pages (b) 100 to 110 pages (c) 150 to 170 pages (d) 125 to 150 pages.
3. What is the optimum number of words in a title? (a) Between 15 and 20 (b) Between 20 and 25 (c) Between 10 and 15 (d) Between 25 and 30.
4. In a dissertation/project report, Summary which occupies approximately _____ of the total pages that are present in the report ; (a) 5% to 7% (b) 7% to 10 % (c) 1% to 2% (d) 11% to 13% .
5. The abstract is a short, crisp summary of your entire research paper of _____ words. (a) 100 to 150 words (b) 150 to 170 words (c) 300 to 350 words (d) 200 to 300 words.
6. Background significance, Material and Method, Results and Conclusion all are four sub - headings of which part of research paper? : (a) Abstract (b) Summary (c) Introduction (d) Review of literature.
7. What is the recommended number of keywords for indexing of an article in *Index Medicus* or on the internet / computer based databases? : (a) Eight to ten (b) Twelve to fifteen (c) Nine to twelve (d) Four to five.
8. Which section of research paper is also called “Backbone” of the study? (a) Background significance (b) Material and Method (c) Results and Conclusion (d) Summary.
9. In a research paper _____ is not required, while it is a must for thesis/project report? (a) A review of literature (b) Summary (c) Abstract (d) References.
10. In a table showing the results, it is a good practice to indicate the _____ along with the numbers. (a) Decimal (b) Fractions (c) Percentages (d) Rates.
11. The style of writing the reference should conform to the one used in *Index Medicus*, which is as per the _____ system. (a) Verdana (b) New York (c) British (d) Vancouver

Answers : (1) a; (2) d; (3) c; (4) a; (5) d; (6) a; (7) d; (8) b; (9) a; (10) c; (11) d.

RajVir Bhalwar

This chapter lays down the general guidelines for writing a research proposal. Apparently, researchers should also abide by the format which are specifically laid down by the respective funding agencies as ICMR, or by the concerned University.

Introduction : This the first group heading. In a nutshell, the introduction should give a good overview of two aspects - firstly, the *background importance* about the area of study and secondly the *relevance* of the proposed work. The introduction should generally be limited to within 400 to 600 words (2 to 3 double spaced A - 4 size typed pages). The introduction should have specific paragraphs which should logically and sequentially bring out the following aspects :

- Definition of the problem in which the research is going to be undertaken.
- Magnitude of the problem in terms of morbidity, mortality, disability, suffering and socioeconomic consequences.
- A brief statement of what is already known about the condition, depending on the review of literature.
- A statement on what is not known, or areas where gaps in knowledge still exist and which need to be filled.
- What is the research question to be answered in this proposed study. This will include a paragraph giving general statement, enunciating the broad issue of the study.
- A final paragraph should be written on how the study findings will contribute to the existing knowledge, and help in improving the health care or clinical practice.

Aim and objectives : The AIM is a general statement about the research question. The OBJECTIVES are very specific issues through which the aim is going to be achieved. Be very careful while writing down your objectives, since any funding agency will examine them very closely. Secondly, you are also expected to fulfill these objectives at the end of your research and hence, do not keep such objectives which you are doubtful that you will be able to complete them at all.

Review of Literature : Brief review of literature of 3 to 4 double spaced typed pages should be given. The review should generally be of the “recent literature” (i.e. past 5 years or so). The review should bring out the definition of the condition of interest, the magnitude of the problem, a review of what is already known about the topic of research and finally a review of the gaps which exist in the present body of knowledge as far as it pertains to the proposed research.

Material and Method : This is the “heart” of the research protocol. Great care should be exercised while writing this part. In general, the following aspects should be clarified in adequate detail, point wise.

General settings and time line : Define the general settings, i.e. whether the study will be done in a hospital or in general community, the type of hospital (primary / Secondary / Tertiary level or OPD), or the community (Urban, Slums, Rural) etc., and the time - line.

Study design : Specify the exact study design (e.g. “cross - sectional analytical study”). In a few lines, describe as to why this particular study design is being used as compared to the other available study designs.

Reference and Study (Actual) population : Define the reference (total) population on which the study results will be generalised. Next, define the actual (study) population from which the study sample will be drawn. Add a line to justify that the actual (study) population is a reasonably representative subset of the total (reference) population.

Sample size : Clearly specify the statistical procedure that you have followed for calculating the sample size. Do consult a epidemiologist or statistician since this heading is quite thoroughly scrutinized by various research bodies.

Sampling method : Describe as to what will be the sampling ratio, how the “sampling frame” will be developed and by which particular sampling method (simple random, systematic random, multistage, cluster, stratified random, etc.) will the sample be drawn from the actual (study) population.

Exclusion criteria : If you are having “exclusion criteria”, then be very specific in defining them; e.g. “all cases who have undergone hysterectomy will not be included in this study”.

Specify the variables : Specify the variables of interest under the headings of Exposure variable(s) of main interest, Other exposure variables, Outcome variables (Primary outcome variable and secondary ones, if applicable) and the Potential Confounding Variables.

Instruments : Give a clear description of all instruments that will be used to collect the data. This should include the physical instruments (e.g. sphygmomanometer), or laboratory instruments (e.g. stereoscopic microscope) or special instruments (e.g. portable 12 lead ECG machine) and the Questionnaire (remember, Questionnaire is also an instrument).

Techniques : Give a clear description of the technique of using the instruments and making the measurements. In addition, give a description of who will collect the data (e.g. by the principal worker, trained interviewers, trained laboratory technicians etc.). Finally, make a mention as to how training in data collection will be imparted and how testing and certification of the data collectors will be done.

Details of randomization, blinding and Intervention : If the study involves any intervention (e.g. drug, vaccine, program, therapeutic procedure, etc.), then give a very clear and detailed description of the process of Random allocation, the details of blinding (single / double) and the “intervention” which is going to be studied (who will do what to whom, how and how frequently). Even minor points like dose, formulation and frequency of administration of the drug or details of operative procedure must be mentioned. Similarly, details of “Placebo” in case of a clinical trial should be mentioned.

Follow up procedures : In a cohort study as well as a experimental design, mention the details as to how the follow up of the two groups will be done, including details as who will be ascertaining the final and interim outcomes, when and where. In addition, give a clear description of modalities of “retrieving” those who are getting lost to follow up.

Description of gold standard test in diagnostic test study : In a study proposing to evaluate the performance of a diagnostic test, including clinical algorithms, a detailed description of the “gold standard” against which the current test under study will be evaluated, should be given.

Pilot study : In case a pilot study would be done to refine the material and methods, then give a clear description of how many subjects will be required for the pilot study, how will they be sampled, and whether the pilot study subjects are likely to be included in the main study or not, going a brief justification for the same.

Issues of analysis : A general description must be given in the protocol as to what statistical procedures will be used for the basic analysis or for advanced issues like control of confounding. In case the help and guidance of a research methodologist or biostatistician will be taken for handling issues of advanced analysis, then the same should be mentioned. In addition, if data management by computerisation is planned, then a brief description of computer packages should be given. In clinical trials, details of stoppage rules and “intention to treat analysis” if applicable, should be clearly brought out.

Ethical issues : Most research bodies now need the proposal to be cleared by the Institutional Ethical Committee and this should be ensured and, for animal experiments, separate clearance by Institutional Animal Experiments Ethical committee.

Financial Details : This paragraph is mandatory for any study which seeks “funding” from any Governmental or Non Governmental organisation. A detailed description of financial requirements, according to instruments, reagents, drugs, salaries, office contingencies etc. should be made, phase - wise or financial year wise. Work out the financial requirements meticulously, catering to the inflation rates. Contact the various dealers and make an on - ground estimate of prices as well as availability of the equipment, reagents etc. Remember, do not simply go by guess works or estimates made by some other workers or in the past; such an action has been a cause of major embarrassment for many workers.

References : This is the last section. The details of writing the references have already been presented in earlier chapter on writing a research paper.

Annexures : Annexures may be attached to clarify in greater detail, the following

- A particular aspect which has not been clarified adequately in the “Material and Method” section because the same would have become unnecessary voluminous.
- Detailed description of terms and phrases.
- Detailed techniques of making clinical measurements and protocols.
- Minute details of the intervention measure to be used in the proposed study.
- The questionnaire or schedule for recording the data.
- Clearance certificate from ethical committee.
- Minute details of expenses or equipment, instruments etc.

Summary

Introduction to a research proposal should give a good overview of the background importance about the area of study and the

relevance of the proposed work. It should be limited to 400 to 600 words. It should elaborate upon definition, magnitude of the problem, what is already known and not known about the condition, and the research question to be answered in the proposed study. A final paragraph should be written on how the study findings will contribute to the existing knowledge, and help in improving the health care or clinical practice.

Aim and objective of the research proposal must be lucid and achievable so as to stand scrutiny of journal or funding organization. Material and Method should cover General Settings and Time Line of the study, Study design, Reference and Study (Actual) population, Sample size, Sampling method, Exclusion criteria, Variables of study, Instruments, Details of randomization, blinding and intervention, Follow up procedures (if applicable), Description of gold standard test in diagnostic test study, Pilot study and issues of analysis (statistical procedures, computer based data management etc.).

Ethical clearance of the research proposal from institutional Ethical Committee must be taken. For animal experiments, separate clearance by Institutional Animal Experiments Ethical committee is required. A study requiring funding must clearly spell out realistic financial requirements catering to inflation. Details of planned expenditure should be given phase wise or financial year wise and must cater for inflation to avoid hardships at later date.

Last section consists of references. Serially numbered references may be given. For additional details, annexures may be attached containing detailed description of terms and phrases, details of techniques of making clinical measurements, protocols, the questionnaire or schedule for recording the data and clearance certificate from ethical committee. A particular aspect which has not been clarified adequately in the “Material and Method” section because the same would have become unnecessary voluminous may be elaborated in an Annexure.

Study Exercises

Long Question : You are desirous of undertaking a research work in a community development block area among married women aged 19 to 45 years on the usage, acceptance and factors associated with the acceptance and discontinuation of IUD and oral contraceptive usage. You want to approach the ICMR for funding and support to this research project. Give an outline of the proposal that you will write with this background.

MCQs & Exercises

1. The introduction of a research proposal should generally be limited to (a) Within 100 to 200 words (b) Within 300 to 500 words (c) Within 300 to 400 words (d) Within 400 to 600 words.
2. The following is a general statement about the research question : (a) Aim (b) Indicator (c) Target (d) Objective.
3. What are those are very specific issues through which the aim is going to be achieved : (a) Targets (b) Goals (c) Purpose (d) Objectives.
4. Read the following statement : “A researcher should be very careful while writing down objectives, because (A) Any funding agency will examine them very closely (B) He is expected to fulfill these objectives at the end of research and hence must not keep such objectives which

he is doubtful that he will be able to complete them at all". Now, based on above statement, choose the correct option among following : (a) Both A & B are true (b) A is true, B is false (c) B is true, A is false (d) Both A and B are false.

5. What is the "heart" of the research protocol? : (a) Aim and objectives (b) Review of literature (c) Statistical procedures applied (d) Material and Method.
6. Questionnaire is an instrument - True or False?
7. Details of "Placebo" in case of a clinical trial should be mentioned - True or False?
8. Choose the incorrect match : (a) Financial requirements : The inflation rates; (b) Review of literature : Past five years or so; (c) Study design : Gold standard test; (d) Issues of

analysis : Computer packages.

9. A particular aspect which has not been clarified adequately in the "Material and Method" section because the same would have become unnecessary voluminous may be elaborated in : (a) Annexure (b) Analysis (c) References (d) Review of Literature.
10. Clearance certificate from ethical committee may be attached in which of the following sections : (a) Materials and method (b) References (c) Annexure (d) Review of literature.

Answers : (1) d; (2) a; (3) d; (4) a; (5) d; (6) True; (7) True; (8) c; (9) a; (10) c.

35

Critical Appraisal of a Published Article

RajVir Bhalwar

The issue of critical appraisal of a published article in a journal is of much importance to every Public health specialist as well as for the clinician. As Post - Graduate students in the respective specialities, we have periodic "journal clubs" during which research articles are critically evaluated. As practising Doctors, we need to advance our knowledge constantly, by reading the various articles. Similarly, as public health functionaries and senior level health care administrators, we have to keep abreast regarding the contemporary practices in health care administration, therapies, equipment, diagnostics and the financial implications. From the research methodologist's perspective, reading a journal needs a series of well planned sequential steps. The following is a check list proforma :

Step 1 : Deciding whether I should Read this Article

- (a) Look at the title : Is it interesting ?; Likely to be useful in your practice? Yes/No.
- (b) Look at the Abstract : Will the conclusions (if valid), likely to be useful to you, in your area of clinical practice or research areas ? Yes / No.
- (c) Quickly browse through the 'Materials and Methods' section. See if the 'settings' are similar to your own settings of practice (may be dissimilar because of different facilities, different technological availability, grossly different demographic profile of patients, or the level of medical care in which the study was done) - Yes/No

If answers to 1 (a), (b) & (c) are Yes for two or more question, go ahead and start reading the article. Keep giving your comments on a separate paper, as per the general check - list presented in the subsequent paragraphs :

Step 2 : Assess the Research Question of the Authors

- (a) Is there a well defined, clear cut and specific research question?
- (b) Was it feasible for the authors to study this question, given their technical expertise, available facilities, etc.
- (c) Does the research question has some element of novelty (is likely to add to existing knowledge rather than reconfirming the already well established facts).

Step 3 : Assess the Issues of Internal / External Validity, Bias and Methodology in the Study

- (a) Have the authors made a mention (explicit or at least, implicitly) of the -
 - (i) Total (Whole; Reference) Population ?
 - (ii) Actual (study) Population ?
- (b) Is the actual (study) population from which sample was drawn likely to be a "representative subset" of the total population (If no, then external validity / generalisability will be restricted)
- (c) Have the authors :
 - (i) Calculated the sample size ?
 - (ii) Whether they have specified the parameters like Type - I (alpha), Type - II (Beta) errors, OR or RR to be detected, expected Po, or Mean and SD, and acceptable deviation (as applicable to the study design), while calculating the sample size?
 - (iii) Are the above parameters, if specified, likely to be correct / realistic.
- (d) Have the authors :
 - (i) Described the method of sampling ?
 - (ii) Is the method of sampling based on some random (probability) method ?
- (e) Have the authors explicitly mentioned :
 - (i) The exposure variable(s) (only for an analytic design).
 - (ii) The outcome variable(s) (for all types of designs).

- (f) Have the authors clearly identified all the potential confounding factors (PCFs)?
- (g) Have they adequately covered for all PCFs by taking action during designing (Randomisation/ Restriction/ Matching) or during analysis (Standardisation / Stratified analysis/ Mathematical modelling) ?
- (h) What are those PCFs which have either not been considered at all, or else not controlled during design/ analysis ?
- (j) Have the authors clearly described the following items used by them in this study :
 - (i) Physical instruments and reagents ?
 - (ii) Questionnaire ?
 - (iii) Any other scales (e.g. psychological assessment scale).
 - (iv) Definitions of terms and diagnostic criteria for various diseases ?
 - (v) Techniques of using the instruments, questionnaires, scales, etc. ?
 - (vi) Are the techniques of measurement, the definitions of terms and diagnostic criteria used by the authors based on some accepted standards? Have they quoted the references?
- (k) Have the authors mentioned as to how they have standardized / validated :
 - (i) Physical instruments ?
 - (ii) Questionnaires ?
 - (iii) Any other “scales” used by them ?
 - (iv) Quality control procedures during the conduct of study?
- (l) Could any of the following biases have occurred in the study ?

Bias	Yes/ No/NA	If yes, briefly comment as to how
Selection bias		
Referral		
Self selection		
Berkson's		
Survivorship		
Healthy worker		
Exposure related		
Information Bias		
Recall / reporting		
Detection		
Observers'		
Cross over		
Contamination		
Co - intervention		
Loss to follow up		
Note : NA stands for “Not Applicable”		

Step 4 - Analysis

- (a) Has the data been presented in a simple, intelligible

- form?
- (b) Are the statistical tests “correct” for the type of variables being analysed?
- (c) Have the authors worked out the measures of ‘effect’ (i.e. RR or OR) (as applicable to the research question) ?
- (d) Have the authors worked out the 95% CI of the various estimates?
- (e) Have the authors correctly controlled for confounders, in analysis, and worked out the independent, adjusted estimates (e.g. by stratified analysis or by regression analysis).
- (f) Have the authors assessed effect modification?

Step 5 - Conclusions

- (a) If the findings are ‘statistically significant’, are they also of clinical/ public health significance/relevance?
- (b) If the findings are ‘statistically non significant’ is it possible that a real effect may have been missed due to “low study power” as consequence of low sample size (Have the authors back calculated the study power; alternatively calculate it yourself)?
- (c) Are the conclusions drawn by the authors based on the actual findings of the study?
- (d) Do you think the study results can be gainfully utilized in your own clinical / preventive / public health practice?

Step 6 - Additional Actions for Specific Situations

Check the following special points depending on the type of study objective.

(a) For a study assessing the efficacy of a therapeutic or preventive procedure :

- Was allocation to the intervention and control groups done by ‘Randomisation’ ?
- Were the 2 groups similar on baseline comparison ?
- Were all the clinical/health relevant outcomes (good as well as bad) considered ?
- Has the therapeutic / preventive procedure studied, been described in adequate detail?
- What was the level of control? : Placebo control/Non placebo control/ Uncontrolled.
- What was the level of blinding? : Triple / Double/ Single blinding / Unblinded.
- Was the trial ethical?
- Were all the subjects who entered the study accounted for in the final analysis?
- What was the proportion of “lost to follow up” ?

(b) For a study assessing the role of a risk factor / causal factors

- What was the strength of the design itself, as per following hierarchy? :

Very strong	Moderately strong	Minimal strength	Weak
Experimental	Cohort	Cross sectional analytic, Case control	Ecological

- What is the strength of association (as seen by RR or OR)?

- Is the association significant (as seen by test of significance and 95% CI of RR) ?
- Is the temporal relationship (cause or exposure definitely preceded the effect or outcome) definitely demonstrated ?
- Does the association stand to reasoning ?
- Is there a dose response relationship ?

(c) For a study dealing with clinical course and prognostic factors

- Was an 'inception cohort' assembled ?
(subjects should be identified at an early and uniform point (inception) in the course of their disease, such as when they develop unambiguous symptoms or receive their first definitive therapy)

- Was the "referral filter" of the subjects to the health care facility, where the study was done, adequately described?
- Was clinical status of all patients who entered the study accounted for in, the end?
- Were the prognostic outcomes clearly defined ?
- Was the outcome assessment done by physicians who were 'blinded' to the other features of patients ?

(d) For a study on evaluation of a diagnostic test

- Was a proper 'Gold Standard' of diagnosis described and used?
- Was the test or clinical rule being studied clearly described?
- Were ALL subjects subjected to BOTH, the test under study as well as the gold standard test?
- Was the evaluation of test results done by observers who were 'blinded' to the results of Gold Standard test?
- Did the subject sample contain an appropriate 'spectrum' of the target disease? (mild, moderate, severe, atypical, other closely related diagnoses).
- Were the "settings" of study adequately described?
- Was the "referral filter" through which subjects passed before reaching the settings of present study adequately defined?
- Was the reproducibility of test (the range of variations due to observers, subjects, instruments and techniques) adequately studied and defined?
- Were the techniques of carrying out the test under study adequately described?
- Was the "utility" of the test determined? (i.e. whether the authors went beyond the issues of validity and reliability to describe the consequences of the test - whether it really contributed to better patient management or favourably changed the disease outcome for which the test is designed).

Summary

The issue of critical appraisal of a published article in a journal is of immense importance to every Public health specialist and health administrator to keep abreast regarding the contemporary practices in health care administration, therapies, equipment, diagnostics and the financial implications. It is equally useful for the clinicians who need to advance their knowledge constantly by reading various articles.

Reading a journal needs a series of well planned sequential steps beginning with decision whether one should read this

article at all. It is judged by the title, abstract, materials and methods. Next step is to assess the research question - whether it is clear cut, feasible and novel. Readers should also assess the issues of Internal / external validity, bias and methodology in the study. It should be seen if description is made of Reference Population and Actual (study) Population. Make a note whether issues pertaining to sample size, specifying of Type - I and Type - II error and exposure and outcome variables have been made. Note whether potential confounding factors have been identified and controlled for. Standardization and validation of various instruments including questionnaire, and the possibility of various forms of selection and measurement etc. should also be looked into.

Next step is to check the analysis of the research paper. Examine the mode of data presentation, statistical tests applied, measures of 'effect' and control of confounders. Finally, see if results are statistically significant and if not, is it due to effects of low power study consequent to a small sample. Also confirm the utility of the findings in clinical or public health practice.

Additional points should be seen in specific situations; for example, in a study assessing the efficacy of a therapeutic or preventive procedure, specifically check for randomisation, baseline comparison, outcome measures and placebo control. Examine if double or single blinding was done or it was an unblinded trial. Reader must check issues of ethics and loss to follow up which may have lead to vitiation of study results. For a study assessing the role of a risk factor / causal factors one should examine strength of the study design, strength and significance of association, temporal relationship, logical reasoning and dose response relationship. In a study dealing with clinical course and prognostic factors, one must check for inception cohort, referral filter, and prognostic outcomes.

For a study on evaluation of a diagnostic test, readers should examine the Gold Standard of diagnosis and whether all subjects were subjected to both tests. Check if study population had appropriate 'spectrum' of the target disease in form of mild, moderate, severe, atypical, and other closely related diagnoses. Also check the "settings" of study, referral filter, and reproducibility of the test under study. An important component is "utility" of the test i.e. whether it really contributed to better patient management or favourably changed the disease outcome for which the test is designed.

Study Exercises

MCQs

1. Read the following two statements : (i) For a practicing Doctor critical appraisal of a journal article is useful. (ii) It advances his knowledge constantly. Based on above, choose the correct option : (a) Both (i) and (ii) are true (b) Both (i) and (ii) are false (c) (i) is true and (ii) is false (d) (i) is false and (ii) is true.
2. For a study assessing the role of an exposure in leading to an outcome, what is the correct hierarchy as per strength of the design : (a) Experimental > Cohort > Cross sectional analytic and Case control > Ecological (b) Ecological > Experimental > Cohort > Cross sectional analytic and Case control (c) Experimental > Cross sectional analytic and Case control > Cohort > Ecological (d) Cohort > Experimental >

- Cross sectional analytic and Case control > Ecological.
3. Which of the following should be examined to decide whether one should further read a particular article in detail : (a) Title (b) Abstract (c) Material and Method (d) All of above.
 4. What are available methods for a researcher to control for PCFs by taking action during design stage? : (a) Randomisation (b) Restriction (c) Matching (d) All of above.
 5. What are available methods for a researcher to control for PCFs during analysis? : (a) Standardisation (b) Stratified analysis (c) Mathematical modeling (d) All of above.
 6. Referral, Self selection, Berkson's, Survivorship, Healthy worker, Exposure related are all which type of Bias : (a) Selection bias (b) Information bias (c) Both of above (d) None of above.
 7. The strength of association is seen by : (a) RR (b) OR (c) Both of above (d) None of above.
 8. To see whether a diagnostic test really contributed to better patient management or favourably changed the disease outcome for which the test is designed, which of the following parameter is used : (a) Validity (b) Reliability (c) utility (d) None of above.
 9. Test of significance and 95% CI of RR are used to determine : (a) Statistical significance (b) Strength of association (c) Temporal relationship (d) Dose response relationship.
 10. Stratified analysis or regression analysis is used to work out : (a) RR (b) OR (c) Controlling for confounding during analysis (d) None of above.
 11. Randomisation is an important step for : (a) A study assessing the role of a risk factor / causal factors (b) A study dealing with clinical course and prognostic factors (c) A study on evaluation of a diagnostic test (d) A study assessing the efficacy of a therapeutic or preventive procedure.

Answers : (1) a; (2) a; (3) d; (4) d; (5) d; (6) a; (7) c; (8) c; (9) a; (10) c; (11) d.

RajVir Bhalwar

The issues of ethics in medical practice are being increasingly talked about, not simply in medical circles but even in legal, societal and similar “outside - the - medical - fraternity” echelons. Most of these issues naturally pertain to clinical practice, ranging from negligence to frank malpractice. While considerations for ethics in the individualised clinical practice are well understood, the question that arises is whether epidemiology and medical research should also be subject to ethical regulations? If yes, why?

First of all, let us define “Ethics”. It has been defined as “a set of principles of right conduct”. In the medical sense, it has also been defined as “the principles and norms of proper professional conduct concerning the rights and duties of health care professionals themselves and their conduct toward patients and fellow practitioners, including the actions taken in the care of patients and family members”.

Though the ethical practice of health dates back to ancient times, however, the concept of “bioethics” took birth due to the experiences of the Second World War and the atrocities conducted in the name of medical research by Nazis among inmates of concentration camps. As a result, a code of conduct for human research was established. In 1964, the World Medical Association Declaration of Helsinki took this process a step further and underscored certain basic principles for the conduct of human biomedical research (115). More recently, in our country, the ICMR has published detailed guidelines regarding ethics in biomedical research (116). The crux of the

Helsinki declaration is presented at the end of this chapter as an appendix.

Is Epidemiology and Medical Research different from Clinical Practice as far as Ethical Reasons are concerned ?

The answer is yes, it is different and it is so because of two reasons. Firstly, clinical practice is applied on a single individual, the patient, who directly bears the consequences of unethical practice of his or her physician, while epidemiology and medical research is undertaken on a large group of humans and any unethical practice would therefore affect these large numbers. Secondly, the results of epidemiological and medical research studies nearly always have policy implications which may be, at times, very far reaching and are applied on the entire community or nation (for example, when John Snow removed the handle of the broad street pump and showed that cholera is transmitted by contaminated water, it had deep policy implications). Compromise in ethics in any sequence of epidemiological or medical research study will therefore lead to a policy which may be unsound, even unethical!

What are the Basic Principles of Ethics in Epidemiology and Medical Research

The basic principles of ethics in epidemiology and medical research are, in fact, common - sense statements, as follows :

Principle No. 1 : No human being should be exposed to any form of intervention which is likely to be hazardous to human health, safety or well being, just because epidemiological or research principles dictate so. This principle becomes quite relevant in intervention (experimental) type of epidemiological studies. To satisfy this principle, no treatment or preventive procedure should be tried out in human research until its pharmacokinetics and pharmacodynamics have been adequately

studied and it has been clearly shown to be safe & free of toxicity, carcinogenicity, mutagenicity and teratogenicity, in animal studies. Only after these considerations have been met, should the human trials start as phase - 1 trials.

Principle No. 2 : No human being should be denied a treatment or such other intervention which is known to be effective for that particular disease, just because epidemiological or research principles dictate so. Once again, this principle is mainly concerned with experimental studies, since in the process of randomization, two groups will be formed, one of which will be offered the new intervention while the other will be offered the standard (existing) modality of treatment / prevention. Now, if the standard treatment is itself known to be very effective against the disease, then, naturally, the intervention group will be denied this modality. For example, we may be trying out a new antibiotic for treatment for streptococcal pneumonia against the standard treatment with penicillin. Now, penicillin is known to be an excellent treatment modality for this condition and the intervention group (which will get the new antibiotic) will naturally be denied this modality. This aspect should be an important consideration for Institutional Ethical Committees (IEC).

Principle No. 3 : Confidentiality of participants and of the information given by them should be protected. This is a very important issue for all types of epidemiological studies (observational as well as interventional) and becomes, at times, quite difficult to ensure. For instance, there could be occasions when the epidemiologist may be required by law to divulge the information. At times this divulgence may itself be an ethical requirement, if not legal. For example, if during a study on the blood donation practices of HIV infected persons, some of the HIV positive subjects, who have been found positive within the past few days, tell the investigator that they have donated blood, within the past 4 weeks ! Should the investigator go back to the respective blood banks and inform them to incinerate the blood units of these persons, though he has initially promised them confidentiality? However, notwithstanding these tricky issues, which would need to be decided by a consensus, the confidentiality of persons and the information given by them should be protected, as far as possible. The following steps may be utilized :

- Informed consent should be taken from all subjects and they should be clearly informed that their confidentiality would be protected and of the situations when the epidemiologist may need to divulge their personal identification or the information they have provided. Only after an informed consent has been taken after such briefing of the subjects, should the investigator proceed with collecting the data.
- If information is being obtained from medical or administrative records, the requirements of confidentiality as stipulated by the officer in charge of these records, should be followed.
- All data should be kept under lock and key under the personal custody of the investigator.
- Only “code numbers” should be mentioned on the data forms and no other personal identifier should be mentioned. The key for linking these code numbers with the original individual names should be kept separately

under a lock and key, under personal custody of the principal investigator.

- “Individual Identifying Information” should be destroyed at the end of the epidemiological / research study, unless there is specific justification for retaining this information; if so, this should be additionally permitted by the IEC.
- All results should be published only in the aggregate or group form, so that individual subjects are never identified in the final report.
- In general, individual identifying information should not be entered on computer files and individual identifiers should not be included in routine tabulations generated from computerized data.
- The importance of maintaining confidentiality should be regularly impressed upon the research staff.

Principle No. 4 : Any human being should participate in an epidemiological or medical research study only after he / she has been clearly informed of the scope of the research, and having been so informed, the subjects should consent to participate, of their own free will, without any force, coercion or undue motivation (this is the principle of ‘informed consent’). Informed consent includes the following facets :

- The subjects should be clearly informed of the scope of the trial, the major advantages as well as adverse effects of all the modalities (both the intervention as well as control modality).
- They should be clearly told that they would get either of the new intervention modality or the control modality, purely decided by luck (as by drawing a lottery) and that getting the trial or control modality will not be based on their or the investigator’s desire.
- No coercion, force, or undue motivation is undertaken for getting the subjects to agree to participate.
- That the subjects are in a fit state to decide for themselves whether they wish to participate or not.
- Having so informed, as above, the subjects agree to participate, of their own free will and accord.
- It is always desirable to have a written informed consent. It should be obtained from the participant or his / her legally authorized representative.

Principle No. 5 : No incentives or pressure should be there to force or lure the subjects into the study.

Principle No. 6 : In case of any harm resulting due to the research, on the health of a subject, there should be adequate treatment and compensation. The investigators should make available facilities for management of any side effect / complication that may occur in any subject as a result of participation in the trial; for permanent damages / disabilities, suitable compensation as decided by existent laws should be available.

Principle No. 7 : The people who are doing the research should be adequately qualified / competent to undertake the same and the research should be executed using sound research methods. This aspect should also be considered by the IEC and Institutional Review Boards (IRBs) since a research which lacks scientific rigour or does not conform to the laid down principles of research methodology, is as unethical as one which does not follow the other principles of ethics.

Principle No. 8 : (The principle of justice). This says that the benefits and burdens of research and epidemiology should be distributed fairly. To elaborate, this means that people living in poverty (as large populations of developing countries), those who have poor access to health care or who lack adequate capacity to make informed choice, may all seem very attractive to conduct research but as a principle, such populations should not be targeted if other populations could also be suitable participants.

Principle No 9 : The participants should be informed of the information which has resulted from the research, about themselves, as well as provided guidance regarding the future course of action they should undertake. For example, during the conduct of a survey, subjects who have found to be hypertensive, should be informed about the same and guided as regards lifestyle changes as well as further diagnosis and management if required.

Principle No. 10 : Research on animals should be undertaken only when it is absolutely essential and the animals should be treated/sacrificed in humane manner. It is advisable that any research involving animals should be deliberated upon & cleared by “Institutional ethical committee on animal research”.

Institutional Ethical Committee (IEC)

Every institution where health research is taking place should have an IEC, which should review and clear research proposals before they are actually launched. The details of IEC are given in the ICMR document (116) and readers are advised to go through the same. In general, the constitution may be as follows :

- The chairperson should be an eminent person with a well documented record in health research, and should be from outside the institution to give independence of judgement to the committee.
- The secretary should be from within the institution and should be a person with well documented track record in academics and health research.
- Eminent academicians and researchers from various specialities; it is suggested that at least the professor or advisor in one of the basic medical sciences, and from the departments of surgery, medicine, pathology, community medicine and pharmacology be members.
- One member from legal field.
- One independent member representative from the community, with track record in community work.
- Officer in charge of animal house.
- Any other member(s) depending on the type of research may be co-opted for particular meetings.

The IEC should develop detailed Standard Operative Procedures (SOPs) which should be circulated to all members. All research proposals should be scrutinized by the IEC, after giving adequate notice to all members. The copy of proposals to be considered should be sent to all members well in advance for study. The minimum quorum should be clearly defined. The IEC should meet regularly, at least once in a quarter and records of all meetings, duly signed by all members should be meticulously maintained.

Conflicts of Interest

Conflict of interest occurs when researchers may have conflicting

interests that may impair their objectivity or make them biased towards or against a research work. Conflicts of interest occurs due to two main reasons :

Financial conflicts of interest : Studies of drugs or material / equipment for diagnostics / therapeutics are commonly funded by pharmaceutical industry / firms. If the investigator has some interest in the firm, they may reap large financial rewards if the treatment under study is shown to be beneficial.

Conflicts of interest because the investigator is also the care provider : An investigator may be also the health care provider of the eligible research participant. For this reason the patient may consent even if unwilling, or may give biased information.

Methods to Resolve Conflicts of Interest

- The research proposal should be carefully scrutinized by the IEC and it should be obligatory on the researchers to declare any conflict, especially the possible sources of funding / sponsorship or incentives from any pharmaceutical firm.
- Ensuring rigorous randomization, blinding and placebo control during the trial.
- An independent “data safety monitoring board” whose members have no conflicts of interest regularly review the interim data and terminate the study if the data provide convincing evidence of benefit or harm.
- If the research is directly or indirectly funded by a pharmaceutical firm, the contract should give the investigators the control over the primary data, its statistical analysis and the freedom to publish the findings whether or not the investigational drug or equipment is found to be effective or ineffective.
- The investigators should disclose all possible conflicts of interest in their published article / report.

Appendix : The Helsinki Declaration - Recommendations guiding doctors in clinical research

(Adopted by the 18th World Medical Assembly, Helsinki, Finland, June 1964)

I. Basic Principles

1. Clinical research must conform to the moral and scientific principles that justify medical research and should be based on laboratory and animal experiments or other scientifically established facts.
2. Clinical research should be conducted only by scientifically qualified persons and under the supervision of a qualified medical man.
3. Clinical research cannot legitimately be carried out unless the importance of the objective is in proportion to the inherent risk to the subject.
4. Every clinical research project should be preceded by careful assessment of inherent risks in comparison to foreseeable benefits to the subject or to others.
5. Special caution should be exercised by the doctor in performing clinical research in which the personality of the subject is liable to be altered by drugs or experimental procedure.

II. Clinical Research Combined With Professional Care

1. In the treatment of the sick person, the doctor must be free to use a new therapeutic measure, if in his judgment it offers hope of saving life, reestablishing health, or alleviating suffering. If at all possible, consistent with patient psychology, the doctor should obtain the patient's freely given consent, after the patient has been given a full explanation. In case of legal incapacity, consent should also be procured from the legal guardian; in case of physical incapacity the permission of the legal guardian replaces that of the patient.
2. The doctor can combine clinical research with professional care, the objective being the acquisition of new medical knowledge, only to the extent that clinical research is justified by its therapeutic value for the patient.

III. Non - Therapeutic Clinical Research

1. In the purely scientific application of clinical research carried out on a human being, it is the duty of the doctor to remain the protector of the life and health of that person on whom clinical research is being carried out.
2. The nature, the purpose and the risk of clinical research must be explained to the subject by the doctor.
- 3a. Clinical research on a human being cannot be undertaken without his free consent after he has been informed; if he is legally incompetent, the consent of the legal guardian should be procured.
- 3b. The subject of clinical research should be in such a mental, physical and legal state as to be able to exercise fully his power of choice.
- 3c. Consent should, as a rule, be obtained in writing. However, the responsibility for clinical research always remains with the research worker; it never falls on the subject even after consent is obtained.
- 4a. The investigator must respect the right of each individual to safeguard his personal integrity, especially if the subject is in a dependent relationship to the investigator.
- 4b. At any time during the course of clinical research the subject or his guardian should be free to withdraw permission for research to be continued.

The investigator or the investigating team should discontinue the research if in his or their judgment, it may, if continued, be harmful to the individual.

Summary

"Ethics" has been defined as "a set of principles of right conduct". In the medical sense, it has also been defined as "the principles and norms of proper professional conduct concerning the rights and duties of health care professionals themselves and their conduct towards patients and fellow practitioners, including the actions taken in the care of patients and family members". Unlike clinical practice, epidemiology and medical research is undertaken on a large group of humans and any unethical practice would therefore affect these large numbers and also the results of epidemiological and medical research studies nearly always have policy implications.

The basic principles of ethics in epidemiology and medical research are :

- No human being should be exposed to any form of intervention which is likely to be hazardous to human health and no treatment or preventive procedure should be tried out in human research until its pharmacokinetics and pharmacodynamics have been adequately studied and it has been clearly shown to be safe & free of toxicity, carcinogenicity, mutagenicity and teratogenicity, in animal studies.
- No human being should be denied a treatment or such other intervention which is known to be effective for that particular disease, just because epidemiological or research principles dictate so.
- Confidentiality of participants and of the information given by them should be protected.
- Any human being should participate in an epidemiological or medical research study only after informed consent.
- No incentives or pressure should be there to force or lure the subjects into the study.
- In case of any harm resulting due to the research, on the health of a subject, there should be adequate treatment and compensation.
- The people who are doing the research should be adequately qualified / competent.
- The principle of justice says that the benefits and burdens of research and epidemiology should be distributed fairly.
- The participants should be informed of the information which has resulted from the research, about them, as well as provided guidance regarding the future course of action they should undertake.
- Research on animals should be undertaken only when it is absolutely essential and the animals should be treated/ sacrificed in a humane manner.

Every institution where health research is taking place should have an Institutional ethical committee (IEC), which should review and clear research proposals before they are actually launched. Conflicts of interest occur due to financial reasons and when the investigator is also the care provider. Few important methods to resolve these conflicts are scrutinizing research proposal carefully by the IEC, ensuring rigorous randomization, blinding & placebo control; by disclosing all possible conflicts in their published article/report & other methods.

Study Exercises

Short Notes : (1) Basic principles of ethics in epidemiology and medical research (2) Institutional ethical committee

MCQs :

1. Which is false about Institutional ethical committee (a) The chairperson should be an eminent person with a well documented record in health research (b) The chairperson should be from within the institution (c) The secretary should be from within the institution (d) It reviews and clears research proposals before they are actually launched.
2. Method to resolve the conflicts of interest in a medical research is (a) Scrutinizing research proposal carefully by the IEC (b) Ensuring rigorous randomization, blinding and placebo control (c) By disclosing all possible conflicts in their published article (d) All the above.

Answers : (1) b; (2) d.

Vijay K. Bhatti

Research in the field of bio-medicine has produced many significant achievements in the last century leading to a radical change in the experience of health and illness, however many problems of today cannot be solved or understood by biomedicine alone. This is primarily because of the fact that many of the health problems are fundamentally problems of interpretation and meaning; and a complex interplay of social factors. The following questions raise doubts about the adequacy of only quantitative research as a research method to answer various research questions in the field of health :

- “Why is it that people continue to smoke when the evidence about harmful effects of smoking is all around them and known to those who smoke?”
- “Why do people often not take the medicine prescribed for them?”
- “Why do many people not wear seat belts and helmets in spite of knowing that wearing them will save them if an accident occurs?”
- “What difference has the involvement of doctors in health management made to the management of health services?”
- “Why is that though we know clearly the biomedical understanding of how HIV/AIDS is transmitted, the problem continues to be.”

These are questions not easily answered by the quantitative research designs used commonly under the umbrella of hard - core epidemiology and research methodology. They are however the type of questions best answered by qualitative research methods instead, an area of research which has gained momentum and importance in recent years.

Quantitative research is concerned with counting and measuring things, producing estimates of averages and differences between groups (e.g. blood pressure of patients treated with two different drugs) whereas Qualitative research has its roots in social science and is more concerned with understanding why people behave as they do : their knowledge, attitudes, beliefs, fears, etc. Qualitative research allows the subjects being studied to give much ‘richer’ answers to questions put to them by the researcher, and may give valuable insights which might have been missed by any other method. It not only provides valuable information to certain research questions in its own right but it is used to complement quantitative research methods. If the area of interest has not been previously investigated, then qualitative research may be a vital forerunner to conducting any quantitative research; for example, it’s impossible to carry out a meaningful structured questionnaire survey on patient satisfaction with a service, if the important issues from the patients perspective, surrounding the provision of that service, are not known. At the other extreme qualitative research also helps one to understand the findings of quantitative research; for example, it is very easy to discover that some patients fail to keep appointments at outpatients clinics, but uncovering the reasons for this can be more difficult and conventional surveys

may miss some of the important factors.

Qualitative research is often done to answer the question *why* rather than *what*. Quantitative research on the other hand involves techniques to quantify distribution and association of certain variables in a study population, mostly to provide proof rather than discovery. Qualitative and quantitative methods are wrongly thought to be competing with each other whereas in reality they are complimentary to each other and skilful combination of both methods can maximize the quality of research and data and reduce chances of bias.

Definition : Qualitative research can be defined as a research that seeks the answer to the questions in the real world. It has a person centred perspective. Qualitative research is a form of social enquiry that focuses on the way people interpret and make sense of their experiences and the world in which they live.

The characteristics and aims of qualitative research: Different types of qualitative research have common characteristics and use similar procedures while differences in data collection and analysis do exist. The following are part of most qualitative approaches:

- (a) Researcher focuses on the everyday life of people in natural settings
- (b) The data have primacy; the theoretical framework is not predetermined but derives from the data.
- (c) Qualitative research is context bound - this means that the researcher has to be sensitive to the context of the research and immerse himself in the settings and the situation.
- (d) It focuses on the views of the people involved in the research and their perceptions, meanings and interpretations.
- (e) Data collection and analysis generally proceed together and interact with each other.
- (f) It uses open ended methods.
- (g) It involves respondents as active participants rather than subjects

The differences between qualitative and quantitative research are given in Table - 1.

Qualitative Data Collection Techniques

Several methods exist for data collection in qualitative research, however there are three main methods of data collection, namely Participant Observation (Descriptive observations of verbal and non - verbal behaviour), Interactive interviewing (People asked to verbally describe their experiences of phenomenon), and written descriptions by participants (People asked to write descriptions of their experiences of phenomenon). In the succeeding paragraphs, we will discuss only the more important and commonly used techniques (in-depth techniques).

Participant Observation

Observation is one of the strategies in data collection. The researcher as observer looks at places and people in their natural settings. Qualitative researchers use the term ‘participant observation’, a term originally coined by Lindemann (1924).

Participant observation always takes place in community settings, in locations believed to have some relevance to the research questions. The method is distinctive because the researcher approaches participants in their own environment

rather than having the participants come to the researcher. Generally speaking, the researcher engaged in participant observation tries to learn what life is like for an “insider” while remaining, inevitably, an “outsider”. In the community setting, the researcher makes careful, objective notes about what he sees, recording all accounts and observations as field notes in a field notebook. Informal conversation and interaction with members of the study population are also important components of the method and should be recorded in the field notes, in as much detail as possible.

Qualitative Methods	Quantitative Methods
Provides depth of understanding	Measure level of confidence
Ask why?	Ask “how many?” “how often” ?
Study motivations/ intentions/reasons	Study action / manifested behaviour
Are subjective	Are objective
Enable discovery	Provide proof
Are exploratory	Are definite
Interpret	Describe
Instruments use more flexible, iterative style of eliciting and categorizing responses to questions	Instruments use more rigid style of eliciting and categorizing responses to questions
Use semi - structured methods such as in - depth interviews, focus groups, and participant observation	Use highly structured methods such as questionnaires, surveys, and structured observation
Describe and explain relationships	Predict causal relationships
Describe individual exp-eriences. Describe group norms	Describe characteristics of a population
Data format is Textual (obtained from audiotapes, videotapes, and field notes)	Data format is Numerical (obtained by assigning numerical values to responses)
Participant responses affect how and which questions researchers ask next	Participant responses do not influence or determine how and which questions researchers ask next
Study design is iterative, that is, data collection and research questions are adjusted according to what is learned	Study design is subject to statistical assumptions and conditions

It involves establishing a rapport in the community, learning to act so that people go about their work as usual, undisturbed

by the researcher’s presence. To be an efficient participant observer one needs to have the skills of knowing the native language of the researched, having explicit awareness of own behaviour, having a good memory, maintain consciously a naiveté (in order to genuinely know maximum possible about the researched). Refer Table - 2 & 3.

Strengths	Weaknesses
Allows for insight into contexts, relationships, behaviour	Time - consuming
Can provide information previously unknown to researchers that is crucial for project design, data collection, and interpretation of other data	Documentation relies on memory, personal discipline, and diligence of researcher
	Requires conscious effort at objectivity because method is inherently subjective

Questions to be Asked in the Observation

The ‘who’ questions - who all are in the setting, how many people are present ? What are their characteristics and roles?

The ‘what’ questions - what is happening in the setting, what are the actions and rules of behaviour/ what are the variations in the behaviour observed?

The ‘where’ questions - where do interactions occur? Where are people located in the physical space?

The ‘when’ questions - when do conversations and interactions take place? What is the timing of activities?

The ‘why’ questions - why do people in the setting act the way they do? Why are there variations in behaviour?

Participant observation in action, an example : In the early 1990s, sharing needles during injection drug use was a known risk factor for HIV acquisition in the United States. After educational campaigns informed injection drug users about the importance of using clean needles, surveys indicated that needle - sharing had declined. High rates of HIV transmission persisted among this population, however. An anthropologist’s observation of heroin users in one state confirmed that users were not sharing needles. In observing the preparation process leading up to injection, however, the anthropologist noticed numerous opportunities for cross - contamination of the instruments shared in cooking and distributing the heroin (such as cooking pots, cotton, and needles) and of the liquid heroin itself. Discovery of this phenomenon through participant observation, constituted an important contribution to understanding injection drug use behaviour as related to HIV acquisition. The phenomenon itself is now known as “indirect sharing.”

Category	Includes	Observation to make
Appearance	Clothing, age, gender, physical appearance	Anything that might indicate membership in groups or in sub - populations of interest to the study, such as profession, social status, socioeconomic class, religion, or ethnicity
Verbal behaviour and interactions	Who speaks to whom and for how long; who initiates interaction; languages or dialects spoken; tone of voice	Gender, age, ethnicity, and profession of speakers; dynamics of interaction
Physical behaviour and gestures	What people do, who does what, who interacts with whom, who is not interacting	How people use their bodies and voices to communicate different emotions; what individuals' behaviours indicate about their feelings toward one another, their social rank, or their profession
Personal space	How close people stand to one another	What individuals' preferences concerning personal space suggest about their relationships
Human traffic	People who enter, leave, and spend time at the observation site	Where people enter and exit; how long they stay; who they are (ethnicity, age, gender); whether they are alone or accompanied; number of people
People who stand out	Identification of people who receive a lot of attention from others	The characteristics of these individuals; what differentiates them from others; whether people consult them or they approach other people; whether they seem to be strangers or well known by others present

In - depth Interviews

The qualitative in - depth interview is a favoured strategy of data collection in qualitative research and produces rich data. It is a 'conversation with a purpose' in which the interviewer aims to obtain the perspectives, feelings and perceptions from the participants in the research. The in - depth interview is a technique designed to elicit a vivid picture of the participant's perspective on the research topic. During in - depth interviews, the person being interviewed is considered the expert and

the interviewer is considered the student. The researcher's interviewing techniques are motivated by the desire to learn everything the participant can share about the research topic. Researchers engage with participants by posing questions in a neutral manner, listening attentively to participant's responses, and asking follow - up questions and probes based on those responses. They do not lead participants according to any preconceived notions, nor do they encourage participants to provide particular answers by expressing approval or disapproval of what they say. In - depth interviews are usually conducted face - to - face and involve one interviewer and one participant.

The details of conducting interviews have already been covered in detail in an earlier chapter and the readers are advised to go through the same.

Key Informant (KI) Interviews

Key Informant interviews are qualitative, in - depth interviews of 10 to 20 people selected for their first - hand knowledge about a topic of interest. The interviews are loosely structured, relying on a list of issues to be discussed. Key informant interviews resemble a conversation among acquaintances, allowing a free flow of ideas and information. Interviewers frame questions spontaneously, probe for information and takes notes, which are elaborated on later. Key to a KI is selection of the key informant. The KI should be articulate, willing to participate, trustworthy and should have other personal attributes conducive of conducting detailed interviews. The KI is known as key because of his/her unique position in the community by the virtue of which he/she can impart a useful piece of information.

This method is useful in all phases of development activities identification, planning, implementation and evaluation. Specifically, it is useful in the following situations :

- (a) When qualitative, descriptive information is sufficient for decision - making.
- (b) When there is a need to understand motivation, behaviour, and perspectives of our clientele and health partners. For example, In - depth interviews of program planners and managers, service providers, host government officials, and beneficiaries concerning their attitudes and behaviours about a health program activity can help explain its successes and shortcomings.
- (c) When the main purpose is to generate recommendations, Key informants can help formulate recommendations that can improve a program's performance.
- (d) When preliminary information is needed to design a comprehensive quantitative study. Key informant interviews can help frame the issues before the survey is undertaken.

Focus Group Discussions (FGD)

Focus groups discussion is a qualitative data collection method effective in helping researchers learn the social norms of a community or subgroup, as well as the range of perspectives that exist within that community or subgroup. Focus groups seek to illuminate group opinion. This method is especially well suited for socio - behavioural research that will be used to develop and measure health services that meet the needs of a

given population. An FGD requires the following :

- (a) 6 - 12 participants who are willing to talk about the issue under discussion.
- (b) These participants should be as homogenous as possible with respect to their background characteristics.
- (c) There is a moderator conducting the discussion but not leading the discussion.
- (d) There is a recorder who notes down the proceedings and draws the sociogram (a pictorial representation of the way the interactions have occurred between various participants).
- (e) There should be a predetermined FGD guide.
- (f) Recording equipment with a backup should be present.

A focus group discussion is a qualitative data collection method in which one or two researchers and several participants (6 - 12) meet as a group to discuss a given research topic. The discussion is in - depth and is guided by a moderator during which group members talk spontaneously and freely about a certain topic. The aim of the moderator is to use a predetermined pretested line of questioning to stimulate discussion among the participants in order to understand perceptions, interpretations and beliefs of a selected population to gain understanding of a particular issue from the perspective of the group's participants. These sessions are usually tape recorded, and sometimes videotaped. The moderator leads the discussion by asking participants to respond to open - ended questions - that is, questions that require an in - depth response rather than a single phrase or simple "yes" or "no" answer. A second researcher (the note - taker/recorder) takes detailed notes on the discussion. A principal advantage of focus groups is that they yield a large amount of information over a relatively short period of time. They are also effective for accessing a broad range of views on a specific topic, as opposed to achieving group consensus. Focus groups are not the best method for acquiring information on highly personal or socially sensitive topics; one - on - one interviews are better - suited for such topics. Focus groups are commonly used in the following areas :

- (a) Exploratory studies in health issues.
- (b) Testing ideas about acceptances of a new program.
- (c) Solving specific program problems.
- (d) Evaluating health programs.

Specific components of an FGD include *preparation, conduct of the session and decisions regarding number and duration of the sessions.*

Preparation

(a) Recruitment of participants : Participants should be homogenous with respect to the socio - economic group, sex, age and status. It is recommended that one to two FGD be held for each major group of participants.

(b) Physical arrangements : Physical arrangements in terms of a neutral, well lit and a quiet place are very essential for the participants to be able to discuss freely. Sitting arrangement should be semicircular so that each participant is in the view of the others.

(c) Preparation of the FGD guide : It is a written list of the topics that need to be discussed in the group and consists of a series of open ended questions. It should be prepared carefully

ensuring that it covers the most necessary issues and avoids the unnecessary ones. Topics should be arranged in a logical sequence and a thorough familiarisation with the topics is a must for the moderator and helps him/her to anticipate the range of issues that might come up during the FGD.

Conduct of the session : Moderating a focus group discussion is an art. The moderator must be vigilant about covering all the material in the focus group guide, while also ensuring that the entire group participates and that a wide range of perspectives has been solicited and expressed. The role requires you to be fully engaged in the discussion, yet refrain from participating too much in it. You must know how and when to interject and intervene, yet not interfere.

Facilitating group discussion : The following are the general guidelines

- *Open with a general comment* and wait for a response. For example, you might say, "Family planning can be a complex issue ..." or "What do you think about the issue that has brought us here today?" Alternatively, you might address the first question to an individual who seems comfortable speaking in front of the group. The first question in the focus group guide is usually designed to engage participants in discussion and may not actually be intended to yield important data.
- *Invite a wide range of commentary* by asking participants for experiences, thoughts, and definitions. Also ask what others like them or others in their families think, say, or do that may be similar or different. If everyone appears to agree about a particular issue, verify this by inquiring, "Are there any other points of view?" or "Does anyone see it differently?"
- *Use silence to your advantage.* Give participants a chance to think about the questions, and do not be afraid to wait until someone speaks. In some cultures, people are comfortable with silence; in others, they are not. In the latter case, allowing for pauses could be advantageous, because eventually someone would feel compelled to speak to end the silence.
- *Limit your own participation* once the discussion begins. After going through the introductory material, set the stage by posing a question and then letting the participants react to it for a few minutes with limited direction from you. Do not provide commentary on each contribution or take on the role of counsellor or educator. The moderator's role is to elicit information, not dispense it.
- *Covering the material in the guide :* Moderators are responsible for asking all of the questions in the focus group guide. A good way to keep track of the questions addressed is to check them off in the guide. This is especially practical when you ask questions in a different order than they appear in the guide and when a response applies to a different or additional question than the one you initially presented. Checking off the questions also makes it easier to return to questions that were skipped in the natural progression of the discussion. Although the guide is designed to help the discussion flow easily, you usually do not have to follow the exact order of questions. Try to cover each question thoroughly, because each

question is designed to elicit specific information. Probe each topic as necessary to get sufficient information. Make notes in the discussion guide as a reminder to return to a question or address an issue further.

During the focus group discussion, moderators should not correct participants. It is important in qualitative data collection to elicit all the participants' perspectives, including misinformation. If inaccurate information is stated during the focus group, make a note to correct the misinformation but only after the focus group discussion is over. Afterwards, however, the moderator should provide correct factual information.

- **Encouraging maximum participation.** Try to include as many participants as possible in the discussion, keeping track of their participation by marking the seating chart each time individual participants contribute to the discussion. Techniques for encouraging full participation include referring back to a reticent participant's previous comments, if the current conversation relates it. For example, you might say, "What you are describing sounds very similar to (or different from) what Mr X was talking about earlier. What do you think about this, Mr X?" You might also direct one of the questions from the focus group guide to a particular participant. After he or she responds, ask whether others agree or disagree. Also, encourage participants to discuss the questions with each other rather than address the moderator. Finally, remain in charge. Do not allow a pattern to develop in which everyone orients toward one particular participant and his or her comments.

Functions and qualities of a moderator : He introduces the session, he introduces the recorder, participants and puts them at ease, encourages participation, discussion and involvement by all, he builds a rapport amongst all participants, he consciously avoids the role of an expert, ensures that the discussion does not lead away from the topics, he also ensures that no one participant dominates the discussion. At the end of the FGD, he summarizes and thanks all the participants. A good moderator shows flexibility, sensitivity, has a sense of humour, links ideas together and encourages participation from everyone. *A good moderator tries not to dictate* the course of discussion, lose control over the conversation, judge comments or be an "expert", not to inform or educate during the group and does not lead a question and answer session. He ensures that questions are not leading in nature.

Function of the recorder or the note taker : The recorder records the complete proceedings of the FGD, the date, time, place, name and characteristics of the participants, the general group dynamics i.e. level of participation, interest etc. Opinion of participants including their emotional reactions, their language, vocabulary etc. Tape recording and if possible, video recording of the FGD must be ensured.

The number and duration of sessions : A typical FGD should not last for more than an hour and a half. The number of sessions should be decided based on the nature of the project need, resources and whether the information coming is redundant or not. 2 to 3 FGDs are considered enough for each population subgroup.

Sampling in Qualitative Research

In qualitative research, only a sample of a population is selected for any given study. The study's research objectives and the characteristics of the study population (size and diversity) will determine which and how many people to select. Qualitative Research uses non - probability sampling methods. Selection of the respondents is usually flexible and evolves as the study progresses. There are many approaches for selecting samples in qualitative research, the most commonly used is the purposive sampling.

The sample size in qualitative research is relatively small but consists of 'information rich' cases. Generally the chosen sample size is between four and forty participants (large studies may have upto 100). In qualitative research at times, the number of people in the sample is not known before the research starts; the sample undergoes change during the research in respect of size and type. Usually sampling goes on till *saturation* is achieved, that is until no new information is generated and *informational redundancy* occurs. This is the main principle of sampling in qualitative research completeness.

Data Analysis in Qualitative Research

In quantitative analysis, numbers and what they stand for are the material of analysis. By contrast, qualitative analysis deals in words and is guided by fewer universal rules and standardized procedures, rather than statistical analysis.

In Qualitative research, the researcher captures the thoughts and experiences of individual people, and every set of qualitative data collected (from every participant observation event, interview, and focus Group) is distinct. In qualitative evaluation, data collection and data analysis are not temporally discrete stages : as soon as the first pieces of data are collected, the evaluator begins the process of making sense of the information. Qualitative analysis involves examining the assembled relevant data to determine how they answer the evaluation question(s) at hand. Qualitative data most often occur in more embedded and less easily reducible or distillable forms than quantitative data. For example, a relevant "piece" of qualitative data might be interspersed with portions of an interview transcript, multiple excerpts from a set of field notes, or a comment or set of comments from a focus group. Major phases of data analysis are data reduction, data display, and conclusion drawing and verification. Researcher needs to do the following to analyse the data of a qualitative study :

(a) Description of sample population : Qualitative data is derived from small samples, more information is needed to place the data in their context, e.g. who were the KI?, What were the factors that made them qualify as such? Who all took part in the FGDs? How representative were the participants of the population / group they represented? Who all were observed etc.

(b) Data reduction (ordering and coding of data) : Data reduction refers to the process of selecting, focusing, simplifying, abstracting, and transforming the data that appear in written up field notes or transcriptions. Not only do the data need to be condensed for the sake of manageability, they also have to be transformed so they can be made intelligible in terms of the issues being researched. Coding of data should be as per

topics of discussion guide or check list of observation or semi structured interviews.

(c) Data display : Data display goes a step beyond data reduction to provide “an organized, compressed assembly of information that permits conclusion drawing” A display can be an extended piece of text or a diagram, chart, or matrix that provides a new way of arranging and thinking about the more textually embedded data. Data displays, whether in word or diagrammatic form, allow the analyst to extrapolate from the data enough to begin to discern systematic patterns and interrelationships. By displaying data in form of a chart (matrix), a figure (flow chart) or other graphic forms, one is already analysing the data.

(d) Conclusion drawing and verification : Conclusion means what the analyzed data means and to assess the implications for the research issue at hand. Verification is integrally linked to conclusion drawing; it involves revisiting the data as many times as necessary to cross - check or verify the emergent conclusions. The meanings emerging from the data have to be tested for their plausibility, their sturdiness, their validity. Validity means something different in this context than in quantitative evaluation, where it is a technical term that refers quite specifically to whether a given construct measures what it purports to measure. Here validity encompasses a much broader concern for whether the conclusions being drawn from the data are credible, defensible, warranted, and able to withstand alternative explanations.

Unlike quantitative researchers, who need to explain away deviant or exceptional cases, qualitative analysts are also usually delighted when they encounter twists in their data that present fresh analytic insights or challenges. One needs to think about “checking the meaning of outliers” and “using extreme cases.” In qualitative analysis, deviant instances or cases that do not appear to fit the pattern or trend are not treated as outliers, as they would be in statistical, probability - based analysis. Rather, deviant or exceptional cases should be taken as a challenge to further elaboration and verification of an evolving conclusion. Triangulation of data is critical for validity of the study findings.

Software Packages for Qualitative Analysis

Software packages that can be used to aid analysis of qualitative data have been developed in recent years. Most of these packages were reviewed by Weitzman and Miles (1995), who grouped them into six types : word processors, word retrievers, text base managers, code - and - retrieve programs, code - based theory builders, and conceptual network builders. All have strengths and weaknesses. Weitzman and Miles suggested that when selecting a given package, researchers should think about the amount, types, and sources of data to be analyzed and the types of analyses that will be performed.

There are two limitations with softwares used in qualitative research. First, computer software packages for qualitative data analysis essentially aid in the manipulation of relevant segments of text. While helpful in marking, coding and moving data segments more quickly and efficiently than can be done manually, the software cannot determine meaningful categories for coding and analysis or define salient themes or factors.

Software packages cannot and should not be used as a way of evading the hard intellectual labour of qualitative analysis. Second, it takes time and resources to become adept in utilizing a given software package and learning its peculiarities.

Summary

Qualitative research can be defined as a research that seeks the answer to the questions in the real world. Quantitative research is concerned with counting and measuring things, producing estimates of averages and differences between groups whereas Qualitative research has its roots in social science and is more concerned with understanding why people behave as they do: their knowledge, attitudes, beliefs, fears, etc. It has a person centred perspective. It not only provides valuable information to certain research questions in its own right but it is used to complement quantitative research methods either as a vital forerunner or to understand the findings of quantitative research. The skilful combination of both Quantitative and Qualitative methods can maximize the quality of research and data and reduce chances of bias.

The characteristics of the qualitative approaches are : researcher focuses on the everyday life of people in natural settings; the data have primacy; it is context bound; it focuses on the views of the people involved in the research and their perceptions, meanings and interpretations; data collection and analysis generally proceed together and interact with each other; it uses open ended methods and it involves respondents as active participants rather than subjects.

In qualitative research, the three main methods of data collection are Participant Observation (Descriptive observations of verbal and non - verbal behaviour), Interactive interviewing (People asked to verbally describe their experiences of phenomenon), and written descriptions by participants (People asked to write descriptions of their experiences of phenomenon). Key Informant Interview and Focus Group Discussions are important types of interviewing methods. Key Informant interviews are qualitative, in - depth interviews of 10 to 20 people selected for their first - hand knowledge about a topic of interest. Focus group discussion is a qualitative data collection method, effective in helping researchers learn the social norms of a community or subgroup, as well as the range of perspectives that exist within that community or subgroup. Focus groups seek to illuminate group opinion. This method is especially well suited for socio - behavioural research that will be used to develop and measure health services that meet the needs of a given population.

Qualitative Research uses non - probability sampling methods. Selection of the respondents is usually flexible and evolves as the study progresses. There are many approaches for selecting samples in qualitative research, the most commonly used is the purposive sampling. The sample size in qualitative research is relatively small but consists of ‘information rich’ cases.

Qualitative analysis deals in words and is guided by fewer universal rules and standardized procedures, rather than statistical analysis. In Qualitative research, the researcher captures the thoughts and experiences of individual people. In qualitative evaluation, data collection and data analysis go simultaneously. Major phases of data analysis are

data reduction, data display, and conclusion drawing and verification.

Software packages that can be used to aid analysis of qualitative data have been developed in recent years. Most of these packages were reviewed by Weitzman and Miles.

Study Exercises

Short Notes : (1) Differences between Qualitative and Quantitative research (2) Data collection method in Qualitative research (3) Analysis in Qualitative research (4) Focus group discussion.

MCQs :

1. Which of the following is not characteristic of Qualitative research? (a) Provides depth of understanding (b) Study motivations/intentions/reasons (c) Provide proof (d) Study design is iterative.
2. Which of the following is characteristic of Qualitative research? (a) Predict causal relationships (b) Are Objective (c) Measure level of confidence (d) Describe individual experiences.
3. Which of the following is not a method of Data collection in Qualitative research? (a) Participant Observation (b) Interactive interviewing (c) Written descriptions by participants (d) None.

4. The following is false regarding FGD : (a) 6 - 12 participants who are willing to talk (b) These participants should be as homogenous as possible with respect to their background characteristics (c) Moderator leads the discussion (d) There is a recorder who notes down the proceedings and draws the sociogram.
5. The following is false about Qualitative Research (a) Uses non - probability sampling methods (b) Selection of the respondents is usually not flexible and one - time event (c) The most commonly used approach is the purposive sampling (d) The sample size in qualitative research is relatively small.

Answers : (1) c; (2) d; (3) d; (4) c; (5) b.

Seema R. Patrikar

The origin of statistics roots from the Greek word 'Statis' which means state. In the early days the administration of the state required the collection of information regarding the population for the purpose of war. Around 2000 years ago, in India, we had this system of collecting administrative statistics. In the Mauryan regime the system of registration of vital events of births and deaths existed. *Ain-i-Akbari* is a collection of information gathered on various surveys conducted during the reign of Emperor Akbar.

The birth of statistics occurred in mid-17th century. A commoner, named John Graunt, began reviewing a weekly church publication issued by the local parish clerk that listed the number of births, christenings, and deaths in each parish. These so called Bills of Mortality also listed the causes of death. Graunt who was a shopkeeper organized this data, which was published as *Natural and Political Observations* made upon the Bills of Mortality. The seventeenth century contribution of theory of probability laid the foundation of modern statistical methods.

Today, statistics has become increasingly important with passing time. Statistical methods are fruitfully applied to any problem of decision making where the past information is available or can be made available. It helps to weigh the evidences and draw conclusions. Statistics finds its application in almost all the fields of science. We hardly find any science that does not make use of statistics.

Definition of Statistics

Different authors have defined statistics differently. The best definition of statistics is given by Croxton and Cowden according to whom statistics may be defined as the science, which deals with collection, presentation, analysis and interpretation of numerical data.

Definition of Biostatistics

Biostatistics may be defined as application of statistical methods to medical, biological and public health related problems. It is the scientific treatment given to the medical data derived from group of individuals or patients.

Role of Statistics in Clinical Medicine

The main theory of statistics lies in the term variability. No two individuals are same. For example, blood pressure of person may vary from time to time as well as from person to person. We can also have instrumental variability as well as observers variability. Methods of statistical inference provide largely objective means for drawing conclusions from the data about the issue under study. Medical science is full of uncertainties and statistics deals with uncertainties. Statistical methods try to quantify the uncertainties present in medical science. It helps the researcher to arrive at a scientific judgment about a hypothesis. It has been argued that decision making is an integral part of a physician's work. Frequently, decision making is probability based.

Role of Statistics in Public Health and Community Medicine

Statistics finds an extensive use in Public Health and Community Medicine. Statistical methods are foundations for public health administrators to understand what is happening to the population under their care at community level as well as individual level. If reliable information regarding the disease is available, the public health administrator is in a position to:

- Assess community needs
- Understand socio-economic determinants of health
- Plan experiment in health research
- Analyse their results
- Study diagnosis and prognosis of the disease for taking effective action
- Scientifically test the efficacy of new medicines and methods of treatment.

Statistics in public health is critical for calling attention to problems, identifying risk factors, and suggesting solutions, and ultimately for taking credit for our successes. The most important application of statistics in sociology is in the field of demography.

Statistics helps in developing sound methods of collecting data so as to draw valid inferences regarding the hypothesis. It helps us present the data in numerical form after simplifying the complex data by way of classification, tabulation and graphical presentation. Statistics can be used for comparison as well as to study the relationship between two or more factors. The use of such relationship further helps to predict one factor from the other. Statistics helps the researcher come to valid conclusions in answering their research questions.

Despite wide importance of the subject it is looked upon with suspicion. "Lies, damned lies, and statistics" is part of a phrase attributed to Benjamin Disraeli and popularized in the United States by Mark Twain: "There are three kinds of lies: lies, damned lies, and statistics." The semi- ironic statement refers to the persuasive power of numbers, and describes how even accurate statistics can be used to bolster inaccurate arguments. It is human psychology that when facts are supported by figures, they are easily believed. If wrong figures are used they are bound to give wrong conclusions and hence when statistical theories are applied the figures that are used are free of all types of biases and have been properly collected and scientifically analysed.

Broad Categories of Statistics

Statistics can broadly be split into two categories *Descriptive Statistics* and *Inferential Statistics*. Descriptive statistics deals with the meaningful presentation of data such that its characteristics can be effectively observed. It encompasses the tabular, graphical or pictorial display of data, condensation of large data into tables, preparation of summary measures to give a concise description of complex information and also to exhibit pattern that may be found in data sets. Inferential statistics however refers to decisions. Medical research doesn't stop at just describing the characteristic of disease or situation. It tries to determine whether characteristics of a situation are unusual or if they have happened by chance. Because of this desire to generalize, the first step is to statistically analyse the

data.

In order to begin our analysis as to why statistics is necessary we must begin by addressing the nature of science and experimentation. The characteristic method used by researcher when he/she starts his/her experiment is to study a relatively small collection of subjects, as complete population based studies are time consuming, laborious, costly and resource intensive. The researcher draws a subset of the population called as “sample” and studies this sample in depth. But the conclusions drawn after analyzing the sample is not restricted to the sample but is extrapolated to the population i.e. people in general. Thus Statistics is the mathematical method by which the uncertainty inherent in the scientific method is rigorously quantified.

Summary

In recent times, use of Statistics as a tool to describe various phenomena is increasing in biological sciences and health related fields so much so that irrespective of the sphere of investigation, a research worker has to plan his/her experiments in such a manner that the kind of conclusions which he/she intends to draw should become technically valid. Statistics comes to this aid at the stages of planning of experiment, collection of data, analysis and interpretation of measures computed during the analysis. Biostatistics is defined as application of statistical methods to medical, biological and public health related problems. Statistics is broadly categorized into descriptive statistics and inferential statistics. Descriptive statistics describes the data in meaningful tables or graphs so that the hidden pattern is brought out. Condensing the complex data into simple format and describing it with summary measures is part of the descriptive statistics. Inferential statistics on other hand, deals with drawing inferences and taking decision by studying a subset or sample from the population.

Study Exercises

Short Notes : (1) Differentiate between descriptive and inferential statistics (2) Describe briefly various scales of measurement.

MCQs & Exercises

1. An 85 year old man is rushed to the emergency department by ambulance during an episode of chest pain. The preliminary assessment of the condition of the man is performed by a nurse, who reports that the patients pain seems to be ‘severe’. The characterization of pain as ‘severe’ is (a) Dichotomous (b) Nominal (c) Quantitative (d) Qualitative
2. If we ask the patient attending OPD to evaluate his pain on a scale of 0 (no pain) to 5 (the worst pain), then this commonly applied scale is a (a) Dichotomous (b) Ratio scale (c) Continuous (d) Nominal
3. For each of the following variable indicate whether it is quantitative or qualitative and specify the measurement scale for each variable : (a) Blood Pressure (mmHg) (b) Cholesterol (mmol/l) (c) Diabetes (Yes/No) (d) Body Mass Index (Kg/m²) (e) Age (years) (f) Sex (female/male) (g) Employment (paid work/retired/housewife) (h) Smoking Status (smokers/non-smokers, ex-smokers) (i) Exercise (hours per week) (j) Drink alcohol (units per week) (k) Level of pain (mild/moderate/severe)

Answers : (1) d; (2) b; (3) (a) Quantitative continuous; (b) Quantitative continuous; (c) Qualitative dichotomous ; (d) Quantitative continuous; (e) Quantitative continuous; (f) Qualitative dichotomous; (g) Qualitative nominal ; (h) Qualitative nominal; (i) Quantitative discrete; (j) Quantitative discrete; (k) Qualitative ordinal.

Seema R. Patrikar

The observations made on the subjects one after the other is called *raw data*. Raw data are often little more than jumble of numbers and hence very difficult to handle. Data is collected by researcher so that they can give solutions to the research question that they started with. Raw data becomes useful only when they are arranged and organized in a manner that we can extract information from the data and communicate it to others. In other words data should be processed and subjected to further analysis. This is possible through data depiction, data summarization and data transformation.

The first step in handling the data, after it has been collected is to ‘reduce’ and summarise it, so that it can become understandable; then only meaningful conclusions can be drawn from it. Data can be displayed in either tabular form or graphical form. Tables are used to categorize and summarize data while graphs are used to provide an overall visual representation. To develop Graphs and diagrams, we need to first of all, condense the data in a table.

Understanding as to how the Data have been Recorded

Before we start summarizing or further analyzing the data, we should be very clear as on which ‘scale’ it has been recorded (i.e. qualitative or quantitative; and, whether continuous, discrete, ordinal, polychotomous or dichotomous). The details have already been covered earlier in the chapter on variables and scales of measurement (section on epidemiology) and the

readers should quickly revise that chapter before proceeding.

Ordered Data

When the data are organized in order of magnitude from the smallest value to the largest value it is called as ordered array. For example consider the ages of 11 subjects undergoing tobacco cessation programme (in years) 16, 27, 34, 41, 38, 53, 65, 52, 20, 26, 68. When we arrange these ages in increasing order of magnitude we get ordered array as follows: 16, 20, 26, 27, 34, 38, 41, 52, 53, 65, 68. After observing the ordered array we can quickly determine that the youngest person is of 16 years and oldest of 68 years. Also we can easily state that almost 55% of the subjects are below 40 years of age, and that the midway person is aged 38 years.

Grouped Data - Frequency Table

Besides arranging the data in ordered array, grouping of data is yet another useful way of summarizing them. We classify the data in appropriate groups which are called “classes”. The basic purpose behind classification or grouping is to help comparison and also to accommodate a large number of observations into a few classes only, by condensation so that similarities and dissimilarities can be easily brought out. It also highlights important features and pinpoints the most significant ones at glance.

Table 1 shows a set of raw data obtained from a cross-sectional survey of a random sample of 100 children under one year of age for malnutrition status. Information regarding age and sex of the child was also collected. We will use this data to illustrate the construction of various tables. If we show the distribution of children as per age then it is called as simple table as only one variable is considered.

Table - 1 : Raw data on malnutrition status (malnourished and normal) for 100 children below one year of age

Child	Sex	Age (months)	Malnutrition Status
1	f	6	Normal
2	m	4	Malnourished
3	m	2	Malnourished
4	m	5	Normal
5	m	3	Normal
6	f	1	Normal
7	m	5	Normal
8	f	8	Normal
9	f	7	Normal
10	f	9	Normal
11	f	10	Normal
12	f	2	Normal
13	m	4	Malnourished
14	f	6	Normal
15	m	8	Normal
16	f	1	Malnourished

Child	Sex	Age (months)	Malnutrition Status
17	f	2	Normal
18	m	11	Normal
19	m	12	Normal
20	m	11	Malnourished
21	m	10	Normal
22	f	9	Normal
23	f	5	Normal
24	f	6	Normal
25	m	4	Normal
26	f	7	Normal
27	f	11	Normal
28	f	12	Normal
29	m	10	Malnourished
30	m	4	Normal
31	m	6	Normal
32	m	8	Normal
33	m	12	Malnourished
34	m	1	Malnourished
35	m	1	Normal
36	f	3	Normal
37	m	5	Normal
38	f	6	Normal
39	f	8	Normal
40	f	9	Normal
41	f	10	Malnourished
42	m	1	Normal
43	f	12	Malnourished
44	f	2	Malnourished
45	m	1	Normal
46	m	6	Normal
47	m	4	Normal
48	f	9	Normal
49	f	4	Normal
50	m	9	Normal
51	m	7	Normal
52	m	6	Normal
53	m	4	Normal
54	f	2	Normal
55	m	5	Normal
56	m	3	Normal
57	f	1	Normal
58	m	5	Normal

Child	Sex	Age (months)	Malnutrition Status
60	m	7	Malnourished
61	m	9	Normal
62	m	10	Normal
63	f	2	Normal
64	f	4	Normal
65	f	6	Normal
66	f	8	Normal
67	m	1	Normal
68	m	2	Normal
69	m	11	Normal
70	f	12	Normal
71	m	11	Normal
72	m	10	Malnourished
73	f	9	Normal
74	f	5	Normal
75	f	6	Normal
76	m	4	Normal
77	m	7	Normal
78	m	11	Normal
79	f	12	Normal
80	f	10	Normal
81	m	4	Normal
82	m	6	Malnourished
83	m	8	Normal
84	m	12	Normal
85	m	1	Normal
86	m	1	Normal
87	m	3	Normal
88	f	5	Normal
89	m	6	Normal
90	f	8	Normal
91	f	9	Normal
92	f	10	Normal
93	f	1	Normal
94	m	12	Normal
95	m	2	Normal
96	f	1	Normal
97	m	6	Normal
98	f	4	Malnourished
99	f	9	Malnourished
100	m	4	Normal

Steps in Making a Summary Table for the Data

To group a set of observations we select a set of contiguous, non overlapping intervals such that each value in the set of observations can be placed in one and only one of the intervals. These intervals are usually referred to as *class intervals*. For example the above data can be grouped into different age groups of 1-4, 5-8 and 9-12. These are called class intervals. The class interval 1-4 includes the values 1, 2, 3 and 4. The smallest value 1 is called its *lower class limit* whereas the highest value 4 is called its *upper class limit*. The middle value of 1-4 i.e. 2.5 is called the *midpoint or class mark*. The number of subjects falling in the class interval 1-4 is called its class frequency. Such presentation of data in class intervals along with frequency is called frequency distribution. When both the limits are included in the range of values of the interval, the class interval are known as *inclusive type* of class intervals (e.g. 1-4, 5-8, 9-12, etc.) whereas when lower boundary is included but upper limit is excluded from the range of values, such class intervals are known as *exclusive type* of class intervals (e.g. 1-5, 5-9, 9-12 etc.) This type of class intervals is suitable for continuous variable. Tables can be formed for qualitative variables also.

Table - 2 and 3 display tabulation for quantitative as well as qualitative variable.

Age group (months)	Number of children
1-4	36
5-8	33
9-12	31
Total	100

Malnourishment Status	Number of children
Malnourished	17
Normal	83
Total	100

Such type of tabulation which takes only one variable for classification is called one way table. When two variables are involved the table is referred to as cross tabulation or two way table. For example Table - 4 displays age and sex distribution of the children and Table - 5 displays distribution of malnourishment status and sex of children.

Age group (months)	Female	Male	Total
1-4	14	22	36
5-8	15	18	33
9-12	16	15	31
Total	45	55	100

Table - 5 : Malnourishment status and sex distribution of children

Malnourishment Status	Female	Male	Total
Malnourished	6	11	17
Normal	39	44	83
Total	45	55	100

How to Decide on the Number of Class Intervals?

When data are to be grouped it is required to decide upon the number of class intervals to be made. Too few class intervals would result in losing the information. On the other hand too many class intervals would not bring out the hidden pattern. The thumb rule is that we should not have less than 5 class intervals and no more than 15 class intervals. To be specific, experts have suggested a formula for approximate number of class intervals (k) as follows:

$K = 1 + 3.332 \log_{10} N$ rounded to the nearest integer, where N is the number of values or observations under consideration.

For example if $N=25$ we have, $K = 1 + 3.332 \log_{10} 25$ i.e. approximately 5 class intervals.

Having decided the number of class intervals the next step is to decide the width of the class interval. The width of the class interval is taken as :

$$\text{Width} = \frac{\text{Maximum observed value} - \text{Minimum observed value}}{\text{Number of class interval (k)}} \quad (= \text{Range})$$

The class limits should be preferably rounded figures and the class intervals should be non-overlapping and must include range of the observed data. As far as possible the percentages and totals should be calculated column wise.

Graphical Presentation of Data

A tabular presentation discussed above shows distribution of subjects in various groups or classes. This tabular representation of the frequency distribution is useful for further analysis and conclusion. But it is difficult for a layman to understand complex distribution of data in tabular form. Graphical presentation of data is better understood and appreciated by humans. Graphical representation brings out the hidden pattern and trends of the complex data sets.

Thus the reason for displaying data graphically is two fold:

- 1) Investigators can have a better look at the information collected and the distribution of data and,
- 2) To communicate this information to others quickly

We shall discuss in detail some of the commonly used graphical presentations.

Bar Charts : Bar charts are used for qualitative type of variable in which the variable studied is plotted in the form of bar along the X-axis (horizontal) and the height of the bar is equal to the percentage or frequencies which are plotted along the Y-axis (vertical). The width of the bars is kept constant for all the categories and the space between the bars also remains constant throughout. The number of subjects along with

percentages in bracket may be written on the top of each bar. When we draw bar charts with only one variable or a single group it is called as simple bar chart and when two variables or two groups are considered it is called as multiple bar chart. In multiple bar chart the two bars representing two variables are drawn adjacent to each other and equal width of the bars is maintained. Third type of bar chart is the component bar chart wherein we have two qualitative variables which are further segregated into different categories or components. In this the total height of the bar corresponding to one variable is further sub-divided into different components or categories of the other variable. For example consider the following data (Table-6) which shows the findings of a hypothetical research work intended to describe the pattern of blood groups among patients of essential hypertension.

Table - 6 : Distribution of blood group of patients of essential hypertension

Blood Group	Number of patients (frequency)	Percentage
A	232	42.81
B	201	37.05
AB	76	14.02
O	33	6.09
Total	542	100.00

A simple bar chart in respect of the above data on blood groups among patients of essential hypertension is represented as in Fig. - 1.

Similarly a multiple bar chart of the data represented in Table - 5 of the distribution of the malnourishment status among males and females is shown in Fig. - 2.

The same information can also be depicted in the form of component bar chart as in Fig. - 3.

Fig. - 1 : Distribution of blood groups of patients with essential hypertension

Fig. - 2 : Multiple Bar Chart showing the distribution of malnourishment status in males and females

Fig. - 3 : Component Bar Chart showing the distribution of malnourishment status in males and females

Pie Chart : Another interesting method of displaying categorical (qualitative) data is a pie diagram also called as circular diagram. A pie diagram is essentially a circle in which the angle at the center is equal to its proportion multiplied by 360 (or, more easily, its percentage multiplied by 360 and divided by 100). A pie diagram is best when the total categories are between 2 to 6. If there are more than 6 categories, try and reduce them by “clubbing”, otherwise the diagram becomes too overcrowded.

A pie diagram in respect of the data on blood groups among patients of essential hypertension is presented below after calculating the angles for the individual categories as in Fig. - 4 a, b.

Frequency Curve and Polygon : To construct a frequency curve and frequency polygon we plot the variable along the X-axis and the frequencies along the Y-axis. Observed values of the variable or the midpoints of the class intervals are plotted along with the corresponding frequency of that class interval. Then we construct a smooth freehand curve passing through these points. Such a curve is known as frequency curve. If instead of joining the midpoints by smooth curve, we join the consecutive

points by a straight line then it is called as frequency polygon. Conventionally, we consider one imaginary value immediately preceding the first value and one succeeding the last value and plot them with frequency = 0. An example is given in Table - 7 and Fig. - 5.

Fig. - 4a : Distribution of patients according to blood group

Fig. - 4b

$$\begin{aligned} \text{Blood group A} &= \frac{42.81}{100} \times 360 = 154 \text{ degrees} \\ \text{Blood group B} &= \frac{37.08}{100} \times 360 = 134 \text{ degrees} \\ \text{Blood group AB} &= \frac{14.02}{100} \times 360 = 50 \text{ degrees} \\ \text{Blood group O} &= \frac{6.09}{100} \times 360 = 22 \text{ degrees} \end{aligned}$$

Table - 7: Distribution of subjects as per age groups

Age	Midpoints	Number of subjects
20-25	22.5	2
25-30	27.5	3
30-35	32.5	6
35-40	37.5	14
40-45	42.5	7
45-50	47.5	5

Fig. - 5 : Distribution of subjects in different age groups

Stem-and-leaf plots : This presentation is used for quantitative type of data. To construct a stem-and-leaf plot, we divide each value into a stem component and leaf component. The digits in the tens-place becomes stem component and the digits in units-place becomes leaf components. It is of much utility in quickly assessing whether the data is following a “normal” distribution or not, by seeing whether the stem and leaf is showing a bell shape or not. For example consider a sample of 10 values of age in years : 21, 42, 05, 11, 30, 50, 28, 27, 24, 52. Here, 21 has a stem component of 2 and leaf component of 1. Similarly the second value 42 has a stem component of 4 and leaf component of 2 and so on. The stem values are listed in numerical order (ascending or descending) to form a vertical axis. A vertical line is drawn to outline a stem. If the stem value already exists then the leaf is placed on the right side of vertical line (Fig. - 6).

The value of each of the leaf is plotted in its appropriate location on the other side of vertical line as in Fig. - 7.

To describe the central location, spread and shape of the stem plot we rotate the stem plot by 90 degrees just to explain it more clearly as in Fig. - 8.

Roughly we can say that the spread of data is from 5 to 52 and the median value is between 27 and 28. Regarding the shape of the distribution though it will be difficult to make firm statements about shape when n is small, we can always determine (Fig. - 9) :

- Whether data are more or less symmetrical or are extremely skewed
- Whether there is a central cluster or mound
- Whether there are any outliers

Fig. - 8

Fig. - 9

For the given example we notice the mound (heap) in the middle of the distribution. There are no outliers.

Histogram : The stem-and-leaf is a good way to explore distributions. A more traditional approach is to use histogram. A histogram is used for quantitative continuous type of data where, on the X-axis, we plot the quantitative exclusive type of class intervals and on the Y-axis we plot the frequencies. The difference between bar charts and histogram is that since histogram is the best representation for quantitative data measured on continuous scale, there are no gaps between the bars. Consider an example of the data on serum cholesterol of 10 subjects (Table - 8 & Fig. - 10)

Serum cholesterol (mg/dl)	No of subjects	Percentage
175 – 200	3	30
200 – 225	3	30
225 – 250	2	20
250 – 275	1	10
275 – 300	1	10
Total	10	100%

Fig. - 10 : Distribution of subjects according to Serum Cholesterol Levels

Box-and-Whisker plot : A box-and-whisker plot reveals maximum of the information to the audience. A box-and-whisker plot can be useful for handling many data values. They allow people to explore data and to draw informal conclusions when two or more variables are present. It shows only certain statistics rather than all the data. Five-number summary is another name for the visual representations of the box-and-whisker plot. The five-number summary consists of the median, the quartiles (lower quartile and upper quartile), and the smallest and greatest values in the distribution. Thus a box-and-whisker plot displays the center, the spread, and the overall range of distribution (Fig. - 11)

Fig. - 11

Line chart: Line chart is used for quantitative data. It is an excellent method of displaying the changes that occur in disease frequency over time. It thus helps in assessing “temporal trends” and helps displaying data on epidemics or localised outbreaks in the form of epidemic curve. In a line

diagram, the rate of disease are plotted along the vertical (y) axis. However, in localised outbreaks, with a well demarcated population that has been at risk (as sudden outbreaks of food poisoning) the actual numbers can be plotted on Y-axis, during quick investigations. The unit of time, as applicable to the disease in question, is plotted along the “X”-axis (horizontal). This unit of time would be hours-time in food poisoning, days (i.e, as per dates of the month) for cholera, weeks for typhoid, malaria or Hepatitis-A, months for Hepatitis-B and in years (or even decades) for IHD or Lung Cancer.

Scatter Diagram : A scatter diagram gives a quick visual display of the association between two variables, both of which are measured on numerical continuous or numerical discrete scale. An example of scatter plot between age (in months) and body weight (in kg) of infants is given in Fig. - 12.

Fig. - 12 : Scatter Diagram of the association between Age and Body Weight of infants

The scatter diagram in the above figure shows instant finding that weight and age are associated - as age increases, weight increases. Be careful to record the dependent variable along the vertical (Y) axis and the independent variable along the horizontal (X) axis. In this example weight is dependent on age (as age increases weight is likely to increase) but age is not dependent on weight (if weight increases, age will not necessarily increase). Thus, weight is the dependent variable, and has been plotted on Y axis while age is the independent variable, plotted along X axis.

Summary

Raw information, which is just jumble of numbers, collected by the researcher needs to be presented and displayed in a manner that it makes sense and can be further processed. Data presented in an eye-catching way can highlight particular figures and situations, draw attention to specific information, highlight hidden pattern and important information and simplify complex information. Raw information can be presented either in table i.e. tabular presentation or in graphs and charts i.e. graphical presentation. A table consists of rows and columns. The data is condensed in homogenous groups called class intervals and the number of individuals falling in each class interval called frequency is displayed. A table is incomplete without a title. Clear title describing completely the data in concise form is written. Graphical presentation is used when data needs to be displayed in charts and graphs. A chart or diagram should have

a clear title describing the data depicted. The X-axis and the Y-axis should be properly defined along with the scale. Legend in case of more than one variable or group is necessary. An optional footnote giving the source of information may be present. Appropriate graphical presentation should be depicted depending on whether data is quantitative or qualitative. While dealing with quantitative data histograms, line chart, polygon, stem and leaf and box and whisker plots should be used whereas bar charts, pictograms and pie charts should be used when dealing with qualitative data.

Study Exercises

Long Question : Discuss the art of effective presentation in the field of health, in respect of data and information; so as to convince the makers of decision.

Short Notes: (1) Discuss the need for graphical presentation of data (2) Differentiate between inclusive and exclusive type of class intervals (3) Box and Whisker Plot (4) Scatter diagram

MCQs

- Which of the following is used for representing qualitative data (a) Histogram (b) Polygon (c) Pie chart (d) Line chart
- The scatter plot is used to display (a) Causality (b) Correlation (c) Power (d) Type II error
- Five summary plot consists of Quartiles and (a) Median (b) Mode (c) Mean (d) Range
- The appropriate method of displaying the changes that occur in disease frequency over time (a) Line chart (b) Bar chart (c) Histogram (d) Stem and leaf.
- Box and whisker plot is also known as (a) Magical box (b) Four summary plot (c) Five summary plot (d) None of the above
- The type of diagram useful to detect linear relationship between two variables is (a) Histogram (b) Line Chart (c) Scatter Plot (d) Bar Chart
- The following table shows the age distribution of cases of a certain disease reported during a year in a particular state. Which graphical presentation is appropriate to describe this data? (a) Pie chart (b) Line chart (c) Histogram (d) Pictogram

Age	Number of cases
5-14	5
15-24	10
25-34	120
35-44	22
45-54	13
55-64	5

- Which graphical presentation is best to describe the following data? (a) Multiple bar chart (b) Pie chart (c) Histogram (d) Box plot

Year	Exports (crores of rupees)	Imports (crores of rupees)
1960-61	610.3	624.65
1961-62	955.39	742.78
1962-63	660.65	578.36
1963-64	585.25	527.98

- Of the 140 children, 20 lived in owner occupied houses, 70 lived in council houses and 50 lived in private rented accommodation. Type of accommodation is a categorical variable. Appropriate graphical presentation will be (a) Line chart (b) Simple Bar chart (c) Histogram (d) Frequency Polygon
- A study was conducted to assess the awareness of phimosis in young infants and children up to 5 years of age. The awareness level with respect to the family income is as tabulated below. Which graphical presentation is best to describe the following data?

	<2000	2000 – 5000	5000 – 8000	>8000
Aware	50	62	77	70
Unaware	50	28	23	30

- (a) Stem & Leaf (b) Pie Chart (c) Multiple Bar Chart (d) Component Bar Chart
- Following is the frequency distribution of the serum levels of total cholesterol reported in a sample of 71 subjects. Which graphical presentation is best to describe the following data?

Serum cholesterol level	Frequency
< 130	2
130-150	7
150-170	18
170-190	20
190-210	15
210-230	7
>230	2

- (a) Stem & Leaf (b) Pie (c) Histogram (d) Component Bar Chart
- Information from the Sports Committee member on representation in different games at the state level by gender is as given below. Which graphical presentation is best to describe the following data

Different Games	Females	Males
Long Jump	4	6
High Jump	2	4
Shot Put	9	11
Running	15	10
Swimming	5	4

(a) Box plot (b) Histogram (c) Multiple Bar Chart (d) Pie chart

13. Which graphical presentation is best to describe the following data

Grade of malnutrition	Frequency
Normal	60
Grade I	30
Grade II	7
Grade III	2
Grade IV	1

(a) Box Plot (b) Component Bar Chart (c) Histogram (d) Pie chart

Answers : (1) c; (2) b; (3) a; (4) a; (5) c; (6) c; (7) c; (8) a; (9) b; (10) d; (11) c; (12) c; (13) d.

Statistical Exercise

1. Following is the population data in a locality, present the data in tabular form as well as using appropriate graphs.

S. No.	Age	S. No.	Age	S. No.	Age
1	11	11	8	21	16
2	15	12	12	22	17
3	6	13	22	23	19
4	17	14	24	24	8
5	18	15	16	25	9
6	7	16	19	26	10
7	25	17	20	27	24
8	32	18	9	28	31
9	12	19	21	29	32
10	34	20	31	30	37

Summarising the Data: Measures of Central Tendency and Variability

Seema R. Patrikar

The huge raw information gathered by the researcher is organized and condensed in a table or graphical display. Compiling and presenting the data in tabular or graphical form will not give complete information of the data collected. We need to “summarise” the entire data in one figure, looking at which we can get overall idea of the data. Thus, the data set should be meaningfully described using summary measures. Summary measures provide description of data in terms of concentration of data and variability existing in data. Having described our data set we use these summary figures to draw certain conclusions about the reference population from which the sample data has been drawn. Thus data is described by two summary measures namely, measure of central tendency and measure of variability. Before we discuss in detail, the various measures we should understand the distribution of the data set.

Measures of Central Tendency

This gives the centrality measure of the data set i.e. where the observations are concentrated. There are numerous measures of central tendency. These are : Mean; Median; Mode; Geometric Mean; Harmonic Mean.

Mean (Arithmetic Mean) or Average

This is most appropriate measure for data following normal distribution but not for skewed distributions. It is calculated by

summing all the observations and then dividing by number of observations. It is generally denoted by \bar{X} . It is calculated as follows.

$$\text{Mean } (\bar{x}) = \frac{\text{Sum of the values of all observations}}{\text{Total number of observations, that is, the total number of subjects (denoted by "n")}}$$

Mathematically,

$$\bar{x} = \frac{\sum x_i}{n}$$

It is the simplest of the centrality measure but is influenced by extreme values and hence at times may give fallacious results. It depends on all values of the data set but is affected by the fluctuations of sampling.

Example : The serum cholesterol level (mg/dl) of 10 subjects were found to be as follows: 192 242 203 212 175 284 256 218 182 228

We observe that the above data set is of quantitative type.

To calculate mean the first step is to sum all the values. Thus,

$$\sum_i x_i = 192 + 242 + 203 + \dots + 228 = 2192$$

The second step is to divide this sum by total number of observation (n), which are 10 in our example. Thus,

$$\bar{x} = \frac{\sum x_i}{n} = 2192/10 = 219.2$$

Thus the average value of Serum cholesterol among the 10 subjects studied = 219.5 mg/dl. This summary value of mean describes our entire data in one value.

Calculation of mean from grouped data : For calculating the mean from a “grouped data” we should first find out the midpoint (class mark) of each class interval which we denote by x . (Mid point is calculated by adding the upper limit and the lower limit of the respective class intervals and dividing by 2). The next step is to multiply the midpoints by the frequency of that class interval. Summing all these multiplications and then dividing by total sample size yields us the mean value for grouped data.

Consider the following example on 10 subjects on serum cholesterol level (mg/dl), put in class interval (Table - 1).

Serum cholesterol level (mg/dl) (a)	Midpoint (x) (b)	No. of subjects (f) (c)	$x \cdot f$ (bxc)
175-199	187	3	561
200-224	212	3	636
225-249	237	2	474
250-274	262	1	262
275-299	287	1	287
Total		$10 = \sum f$	$2220 = \sum fx$

The mean, then is calculated as

$$\bar{x} = \frac{\sum fx}{\sum f} = \frac{2220}{10} = 222$$

Median

When the data is skewed, another measure of central tendency called median is used. *Median* is a locative measure which is the middlemost observation after all the values are arranged in ascending or descending order. In other words median is that -value which divides the entire data set into 2 equal parts, when the data set is ordered in an ascending (or descending) fashion. In case when there is odd number of observations we have a single most middle value which is the median value. In case when even number of observations is present there are two middle values and the median is calculated by taking the mean of these two middle observations. Thus,

$$\text{Median} = \begin{cases} \frac{n+1}{2} & ; \text{when } n \text{ is odd} \\ \text{mean of } \frac{n}{2}\text{-th \& } (\frac{n}{2}+1)\text{th obs} & ; \text{when } n \text{ is even} \end{cases}$$

Let us work on our example of serum cholesterol considered in calculation of mean for ungrouped data. In the first step, we will order the data set in an ascending order as follows :

175, 182, 192, 203, 212, 218, 228, 242, 256, 284

Since n is 10 (even) we have two middle most observations as 212 and 218 (i.e. the 5th and 6th value)

$$212 + 218$$

$$\text{Therefore, median} = \frac{\quad}{2} = 215$$

Like mean, median is also very easy to calculate. In fact if

the observations are less, median can be calculated by just inspection. Unlike mean, median can be calculated if the extreme observation is missing. It is less affected by fluctuations of sampling than mean.

Mode

Mode is the most common value that repeats itself in the data set. Though mode is easy to calculate, at times it may be impossible to calculate mode if we do not have any value repeating itself in the data set. At other end it may so happen that we come across two or more values repeating themselves same number of times. In such cases the distribution are said to bimodal or multimodal.

Geometric Mean

Geometric mean is defined as the n th root of the product of observations.

Mathematically,

$$\text{Geometric Mean} = \sqrt[n]{x_1 \cdot x_2 \cdot x_3 \cdot \dots \cdot x_n}$$

Thus if there are 3 observations in the data set, the first step would be to calculate the product of all the three observations. The second step would be to take cube root of this product. Similarly the geometric mean of 4 values would be the 4th root of the product of the four observations.

The merits of geometric mean are that it is based on all the observations. It is also not much affected by the fluctuations of sampling. The disadvantage is that it is not easy to calculate and finds limited use in medical research.

Harmonic Mean

Harmonic mean of a set of values is the reciprocal of the arithmetic mean of the reciprocals of the values. Mathematically,

$$\text{Harmonic mean} = \frac{n}{\frac{1}{x_1} + \frac{1}{x_2} + \dots + \frac{1}{x_n}}$$

Thus if there are four values in the data set as 2, 4, 6 and 8, the harmonic mean is

$$\frac{4}{\frac{1}{2} + \frac{1}{4} + \frac{1}{6} + \frac{1}{8}} = 3.84$$

Though harmonic mean is based on all the values, it is not easy to understand and calculate. Like geometric mean this also finds limited use in medical research.

Relationship between the Three Measures of Mean, Median and Mode

1. For symmetric curve
Mean = Median = Mode
2. For symmetric curve
Mean - Mode \approx 3 (Mean - Median)
3. For positively skewed curve
Mean > Median > Mode
4. For negatively skewed curve
Mean < Median < Mode

Choice of Central Tendency

We observe that each central tendency discussed above have some merits and demerits. No one average is good for all types

of research. The choice should depend on the type of information collected and the research question the investigator is trying to answer. If the collected data is of quantitative nature and symmetric or approximately symmetric data, generally the measure used is arithmetic mean. But if the values in the series are such that only one or two observations are very big or very small compared to other observations, arithmetic mean gives fallacious conclusions. In such cases (skewed data) median or mode would give better results. In social and psychological studies which deals with scored observations or data which are not capable of direct quantitative measurements like socio-economic status, intelligence or pain score etc., median or mode is better measure than mean. However, 'mode' is generally not used since it is not amenable to statistical analysis.

Measures of Relative Position (Quantiles)

Quantiles are the values that divide a set numerical data arranged in increasing order into equal number of parts. *Quartiles* divide the numerical data arranged in increasing order into four equal parts of 25% each. Thus there are 3 quartiles Q1, Q2 and Q3 respectively. *Deciles* are values which divide the arranged data into ten equal parts of 10% each. Thus we have 9 deciles which divide the data in ten equal parts. *Percentiles* are the values that divide the arranged data into hundred equal parts of 1% each. Thus there are 99 percentiles. The 50th percentile, 5th decile and 2nd quartile are equal to median.

Measures of Variability

Knowledge of central tendency alone is not sufficient for complete understanding of distribution. For example if we have three series having the same mean, then it alone does not throw light on the composition of the data, hence to supplement it we need a measure which will tell us regarding the spread of the data. In contrast to measures of central tendency which describes the center of the data set, measures of variability describes the variability or spreadness of the observation from the center of the data. Various measures of dispersion are as follows.

- Range
- Interquartile range
- Mean deviation
- Standard deviation
- Coefficient of variation

Range

One of the simplest measures of variability is range. *Range* is the difference between the two extremes i.e. the difference between the maximum and minimum observation.

$$\text{Range} = \text{maximum observation} - \text{minimum observation}$$

One of the drawbacks of range is that it uses only extreme observations and ignores the rest. This variability measure is easy to calculate but it is affected by the fluctuations of sampling. It gives rough idea of the dispersion of the data.

Interquartile Range

As in the case of range difference in extreme observations is found, similarly interquartile range is calculated by taking difference in the values of the two extreme quartiles.

$$\text{Interquartile range} = Q3 - Q1$$

Quartiles divide the total number of observations into 4 equal parts of 25% each. Thus there are three quartiles (Q1, Q2 and Q3) which divide the total observations in four equal parts. The second quartile Q2 is equivalent to the middle value i.e. median. The interquartile range gives the middle 50% values of the data set. Though interquartile range is easy to calculate it suffers from the same defects as that of range.

Mean Deviation

Mean deviation is the mean of the difference from a constant 'A' which can be taken as mean, median, mode or any constant observation from the data. The formula for mean deviation is given as follows:

$$\text{Mean deviation} = \frac{\sum |x_i - A|}{n}$$

where A may be mean, median, mode or a constant; x_i is the value of individual observations; n is the total number of observations; and, $\sum =$ is a sign indicating "sum of". The main drawback of this measure is that it ignores the algebraic signs and hence to overcome this drawback we have another measure of variability called as Variance.

Standard Deviation

Variance is the average of the squared deviations of each of the individual value from the mean (\bar{x}). It is mathematically given as follows:

$$\text{Variance} = \frac{\sum (x_i - \bar{x})^2}{n}$$

Most often we use the square root of the variance called *Standard Deviation* to describe the data as it is devoid of any errors. Variance squares the units and hence standard deviation by taking square root brings the measure back in the same units as original and hence is best measure of variability. It is given as follows:

$$\text{Standard Deviation (SD)} = \sqrt{\frac{\sum (x_i - \bar{x})^2}{n}}$$

The larger the standard deviation the larger is the spread of the distribution.

Note: When n is less than 30, the denominator in variance and standard deviation formula changes to (n-1).

Let us demonstrate its calculations using our hypothetical data set on serum cholesterol (Table - 2).

$$\text{Standard Deviation (SD)} = \sqrt{\frac{\sum (x_i - \bar{x})^2}{n - 1}}; \text{ since } n < 30$$

$$= \sqrt{\frac{(739.84 + 519.84 + \dots + 77.44)}{10 - 1}}$$

$$\text{Thus SD} = \sqrt{\frac{10543.6}{9}} = 34.227$$

Sr. No	Serum cholesterol	$x_i - \bar{x}$ ($\bar{x} = 219.2$)	$(x_i - \bar{x})^2$
1	192	192-219.2 = -27.2	$(-27.2)^2 = 739.84$
2	242	242-219.2 = 22.8	$(22.8)^2 = 519.84$
3	203	-16.2	262.44
4	212	-7.2	51.84
5	175	-44.2	1953.64
6	284	64.8	4199.04
7	256	36.8	1354.24
8	218	-1.2	1.44
9	182	-37.2	1383.84
10	228	8.8	77.44
Total	2192		10543.6

Calculation of Standard deviation in a grouped data : For grouped data the calculation of standard deviation slightly changes. It is given by following formula.

$$SD = \sqrt{\frac{\sum f_i (x_i - \bar{x})^2}{\sum f_i = n}}$$

; replace n by n-1 if observations are less than 30

where f_i is the frequency (i.e. number of subjects in that group) and \bar{x} is the overall mean. Suppose the data on serum cholesterol was grouped, as we had demonstrated earlier in this chapter for calculation of the mean for grouped data. We had calculated the mean as 222. Now in the same table, make more columns as in Table - 3.

Thus,

$$SD = \sqrt{\frac{\sum f_i (x_i - \bar{x})^2}{\sum f_i - 1 = n - 1}} = \sqrt{\frac{10250}{9}} = 33.74$$

Coefficient of Variation

Besides the measures of variability discussed above, we have one more important measure called the *coefficient of variation* which compares the variability in two data sets. It measures the variability relative to the mean and is calculated as follows:

$$\text{Coefficient of Variation (CV)} = \frac{SD}{\text{Mean}} * 100$$

If the coefficient of variation is greater for one data set it suggests that the data set is more variable than the other data set.

Thus, any information that is collected by the researcher needs to be described by measures of central tendency and measures of variability. Both the measures together describe the data. Measures of central tendency alone will not give any idea about the data set without measure of variability. Descriptive Statistics is critical because it often suggests possible hypothesis for future investigation.

Summary

Raw information is organized and condensed by using tabular and graphical presentations, but compiling and presenting the data in tabular or graphical form will not give complete information of the data collected. We need to "summarise" the entire data in one figure, looking at which we can get overall idea of the data. Thus, the data set should be meaningfully described using summary measures. Summary measures provide description of data in terms of concentration of data and variability existing in data. Having described our data set we use these summary figures to draw certain conclusions about the reference population from which the sample data has been drawn. Thus data is described by two summary measures namely, measures of central tendency and measures of variability. Measures of central tendency describe the centrality of the data set. In other words central tendency tells us where the data is concentrated. If the researcher is dealing with quantitative data, mean is the best centrality measure whereas in qualitative data median and mode describes the data appropriately. Measures of variability give the spreadness or the dispersion of the data. In other words it describes the scatter of the individual observations from the central value. The simplest of the variability measure is range which is difference between the two extreme observations. Various measures of dispersion are mean deviation, variance and standard deviation. Standard deviation is the most commonly used variability measure to describe quantitative data and is devoid of any errors. When commenting on the variability while dealing with two or more groups or techniques, special measure of variability called coefficient of variation is used. The group in which coefficient of variation is more is said to be

Serum cholesterol level (mg/dl)	Midpoint (x)	No. of subjects (f)	$x_i - \bar{x}$	$(x_i - \bar{x})^2$	$f_i * (x_i - \bar{x})^2$
175-199	187	3	$(187-222) = -35$	$(-35)^2 = 1225$	$3 * 1225 = 3675$
200-224	212	3	$(212-222) = -10$	100	300
225-249	237	2	15	225	450
250-274	262	1	40	1600	1600
275-299	287	1	65	4225	4225
Total		$10 = \sum f$		7375	10250

more variable than the other. Both measures of central tendency and measures of variability together describe the data set and often suggest possible hypothesis for future investigation.

Study Exercises

Short Notes : (1) Measures of central tendency (2) Measures of Variation

MCQs

- Which of the Statistical average takes into account all the numbers equally? (a) Mean (b) Median (c) Mode (d) None of the above
- Which of the following is a measure of Spread (a) Variance, (b) Mean (c) p value (d) Mode
- Which of the following is a measure of location (a) Variance (b) Mode (c) p value (d) Median
- Which among the following is not a measure of variability: (a) Standard deviation (b) Range (c) Median (d) Coefficient of Variation
- For a positively skewed curve which measure of central tendency is largest (a) Mean (b) Mode (c) Median (d) All are equal
- Most common value that repeats itself in the data set is (a) Mean (b) Mode (c) Median (d) All of the above.
- Variance is square of (a) p value (b) Mean deviation (c) Standard deviation (d) Coefficient of variation.
- Percentiles divides the data into _____ equal parts (a) 100 (b) 50 (c) 10 (d) 25

- 10 babies are born in a hospital on same day. All weigh 2.8 Kg each; What would be the standard deviation (a) 0.28 (b) 1 (c) 2.8 (d) 0
- To compare the variability in two populations we use this measure (a) Range (b) Coefficient of Variation (c) Median (d) Standard deviation

Answers : (1) a; (2) a; (3) d; (4) c; (5) a; (6) b; (7) c; (8) a; (9) d; (10) b.

Statistical Exercises

- A researcher wanted to know the weights in Kg of children of second standard collected the following information on 15 students: 10, 20, 11, 12, 12, 13, 11, 14, 13, 13, 15, 11, 16, 17, 18. What type of data is it? Calculate mean, median and mode from the above data. Calculate mean deviation and standard deviation. (Answer : Mean = 13.7, Median = 13, Mode = 11&13, Mean deviation = 2.34, Standard deviation = 2.9)
- If the height (cm) of the same students is 95, 110, 98, 100, 102, 102, 99, 103,104, 103,106, 99, 108,108,109. What type of data is it? What is the scale of measurement? Calculate mean, median and mode from the above data. Calculate mean deviation and standard deviation. Between height and weigh which is more variable and why? (Answer : Mean = 103.1, Median = 103, Mode = 99,102,103 &108, Mean deviation = 3.55, Standard deviation = 4.4, Coefficient of variation of weight = 21.17, Coefficient of variation of height = 4.27 hence weight is more variable)

Introducing Inferential Statistics : Gaussian Distribution and Central Limit Theorem

Seema R. Patrikar

The Gaussian Distribution or Normal Curve

If we draw a smooth curve passing through the mid points of the bars of histogram and if the curve is bell shaped curve then the data is said to be roughly following a normal distribution. Many different types of data distributions are encountered in medicine. The *Gaussian* or "*normal*" distribution is among the most important. Its importance stems from the fact that the characteristics of this theoretical distribution underline many aspects of both descriptive and inferential statistics (Fig. - 1).

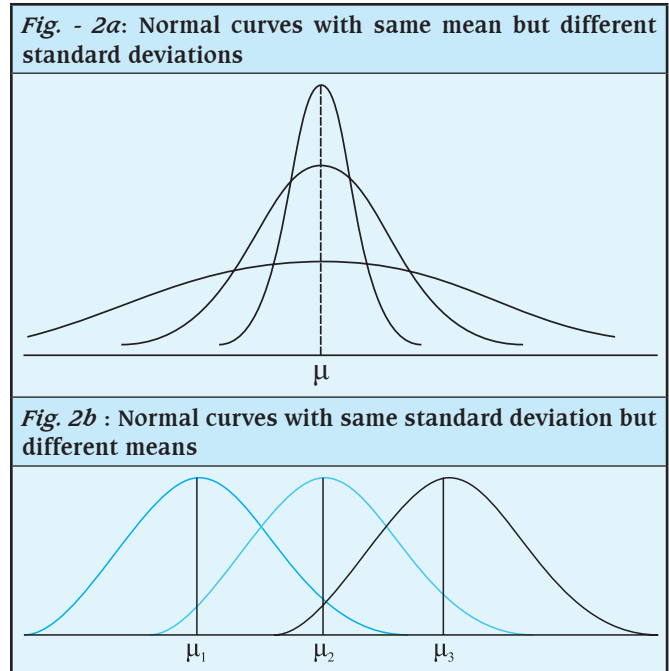

Gaussian distribution is one of the important distributions in statistics. Most of the data relating to social and physical sciences conform to the distribution for sufficiently large observations by virtue of central limit theorem.

Normal distribution was first discovered by mathematician De-Moivre. Karl Gauss and Pierre-Simon Laplace used this distribution to describe error of measurement. Normal distribution is also called as 'Gaussian distribution'.

A normal curve is determined entirely by the mean and the standard deviation. Hence it is possible to have various normal curves with different standard deviations but same mean (Fig. - 2a) and various normal curves with different means but same standard deviation (Fig. - 2b).

The normal curve possesses many important properties and is of extreme importance in the theory of errors. The normal distribution is defined by following characteristics:

- It is a *bell shaped symmetric* (about the mean) curve.
- The curve on either side of the mean is mirror image of the other side.
- The mean, median and mode coincide.

- Highest frequency (frequency means the number of observations for a particular value or in a particular class interval) is in the middle around the mean and lowest at both the extremes and frequency is decreasing smoothly on either side of the mean.
- The total area under the curve is equal to 1 or 100%.
- The most important relationship in the normal curve is the area relationship.

The proportional area enclosed between mean and multiples of SD is constant.

- Mean ± 1 SD -----> 68% of the total area
- Mean ± 2 SD -----> 95% of the total area
- Mean ± 3 SD -----> 99% of the total area

Fig. 3 shows the area enclosed by 1, 2 and 3 SD from mean.

If these criteria are not met, then the distribution is not a Gaussian or normal distribution.

Standard Normal Variate (SNV)

As already specified, a normal frequency curve can be described completely with the mean and standard deviation values. Even the same set of data would provide different value for the mean and SD, depending on the choice of measurement. For example, the same persons height can be expressed as 66 inches or 167.6 cms. An infant's birth weight can be recorded as 2500 gms or 5.5 pounds. Because the units of measurement differ, so do the numbers, although the true height and weight are the same. To eliminate the effect produced by the choice of units of measurement the data can be put in the unit free form or the data can be normalized. The first step to transform the original variable to normalized variable is to calculate the mean and SD. The normalized values are then calculated by subtracting mean from individual values and dividing by SD. These normalized values are also called the z values.

$$z = \frac{x - \mu}{\sigma}$$

(where x is the individual observation, μ = mean and σ = standard deviation)

The distribution of z always follows normal distribution, with mean of 0 and standard deviation of 1. The z values are often called the 'Standard Normal Variate'.

Central Limit Theorem (CLT)

The CLT is responsible for the following remarkable result:

The distribution of an average tends to be Normal, even when the distribution from which the average is computed is non-Normal.

Furthermore, this normal distribution will have the *same mean* as the parent distribution, *AND*, variance equal to the variance of the parent distribution divided by the sample size (σ/n).

The central limit theorem states that given a distribution with a mean μ and variance σ^2 , the sampling *distribution of the mean* approaches a *normal distribution* with a mean (μ) and a variance σ^2/N as N , the *sample size*, increases. The amazing and counter-intuitive thing about the central limit theorem is that no matter what the shape of the original distribution, the sampling distribution of the mean approaches a normal distribution. Furthermore, for most distributions, a normal distribution is approached very quickly as N increases. Thus, the Central Limit theorem is the foundation for many statistical procedures.

To understand the concept of central limit theorem in detail let us consider the following example (Fig. - 4a - g).

Thus we notice that when the sample size approaches a couple dozen, the distribution of the average is very nearly Normal, even though the parent distribution looks anything *but* Normal.

Summary

Normal distribution was first discovered by mathematician De-Moivre. Karl Gauss and Pierre-Simon Laplace used this distribution to describe error of measurement. Normal distribution is also called as 'Gaussian distribution'. When the midpoints of the histograms are joined by smooth curve and if the curve resembles a bell shaped curve, the data is said to be approximately normal. The normal distribution is defined by certain characteristics. It is a bell shaped symmetric (about the mean) curve. The curve on either side of the mean is mirror image of the other side. The mean, median and mode coincide. Highest frequency is in the middle around the mean and lowest at both the extremes and frequency is decreasing smoothly on either side of the mean. The total area under the curve is equal to 1 or 100%. The most important relationship in the normal curve is the area relationship. The proportional area enclosed

between mean and multiples of SD is constant. Mean \pm 1SD, Mean \pm 2SD and Mean \pm 3SD encompass 68%, 95% and 99% of the total area. Central limit theorem is an important theorem by virtue of which the distribution of an average tends to be Normal, even when the distribution from which the average is computed is non-Normal. In other words, the central limit theorem states that given a distribution with a mean μ and variance σ^2 , the sampling distribution of the mean approaches a normal distribution with a mean (μ) and a variance σ^2/N as N , the sample size, increases. This concept is used in most of the statistical analysis.

Study Exercises

Short Notes : (1) Describe Gaussian (normal) distribution (2) Skewness and kurtosis in Gaussian curve (3) Central limit theorem

MCQs

1. Characteristics of normal distribution curve includes all except (a) Bell shaped symmetrical curve (b) Mean, Mode, Median coincides (c) Area under the curve is 1 (d) Mean of all the curves is same.
2. Area enclosed in normal distribution curve between Mean \pm 2 S.D. is (a) 90% (b) 95% (c) 99% (d) 20%
3. Mean of unit normal distribution is (a) One (b) Zero (c) Unknown (d) Hundred
4. Variance of unit normal distribution is (a) Zero (b) Two (c) One (d) Not known
5. Coefficient of kurtosis, β_1 measures (a) Peakedness of distribution (b) Skewness of distribution (c) Spreadness of distribution (d) All of the above
6. All are true regarding Normal distribution curve except (a) One standard deviation includes 95% of values (b) Mean, Median, Mode coincides (c) Median is mid value (d) Area under the curve is one

Answers : (1) d; (2) b; (3) b; (4) c; (5) a; (6) a.

Inferential Statistics: Estimation and Hypothesis Testing

Seema R. Patrikar

Another important broad category for which statistics is used is Statistical Inference. We have already said that research most often is conducted using samples of individuals from larger populations. It is impractical if not impossible to study all people, so we select a sample of people for study. We collect data on these subjects, draw conclusions from the data and make inferences to the larger population. The collected data is of utility to us only if we are in a position to make interpretation and draw inferences. This process of making interpretation and drawing inferences is called as *inferential statistics*. Any researcher collects information with the aim to draw valid conclusions regarding the research question. The information collected is basically with the purpose of two broad things. The researcher is either interested in estimating a population parameter or testing a hypothesis concerned with population parameter.

Estimation : *An estimate is a numerical value which is used to estimate the corresponding population parameter.*

Consider following situation where an investigator is interested in finding out the mean duration of hospital stay by patients undergoing cesarean section. Ideally the investigator should go through the case details of all patients who have undergone cesarean section. But the investigator decides to examine a sample of these patients from which he computes the average

duration of hospital stay.

Consider another situation where an investigator is interested in assessing the proportion of patients recovering from a disease after administration of a new drug. Again ideally the investigator should select all the patients who suffer from that particular disease, but since it would be expensive and time consuming the investigator selects sample of patients having that disease and administer the new drug to assess its effect.

The first situation deals with mean parameter whereas the second situation deals with proportion parameter. In both the examples the investigator is interested in estimating the population mean and population proportion respectively. Similarly there may be situations when an investigator is studying two populations and is interested in estimating the difference between two means or difference between two proportions. For example, an investigator may be interested in estimating difference between the mean serum cholesterol levels in the males living in hot deserts and in temperate climates. Similarly an investigator may be interested in estimating the rate of complications by administration of two different drugs.

Hypothesis Testing: Hypothesis testing as against estimation deals with testing the statements dealing with population parameters. The researcher states a hypothesis to be tested, formulates an analysis plan, analyzes sample data according to the plan, and accepts or rejects the hypothesis, based on results of the analysis. There are two types of hypotheses—null hypothesis and alternate hypothesis. The concept is best understood by an example of a court decision in a crime case. When a case is presented before a court of law by the prosecution, the judge has to start with the presumption of

innocence. The prosecution has to present adequate evidence against the innocence of the person tried. If the evidence is not sufficient the person is acquitted, whether the crime was actually committed or not. Thus, the permutation and combination between the exact reality (or, truth) and our verdict (decision) can be presented in Table - 1 :

Our judgment about Mr. X (based on evidence produced before us)	The reality about Mr.X	
	Is not Guilty	Is Guilty
Found guilty	Type I error Wrong decision	Correct decision
Found Not Guilty	Correct decision	Type II error Wrong decision

When we do medical research, we take a sample of people, representative of the study population we wish to do. For example, we may wish to study the effect of a new drug in reducing cholesterol levels. Any results we get from our research are only estimates of the true effect that medication will have in the population. The participants are our sample. Since we know our results are just estimates, we may be wrong in giving our conclusions. Statistically these are called as 'errors'. The research question is formally converted into a formal scientific hypothesis, which has two parts: the *null hypothesis* (denoted by H_0) and the *alternative hypothesis* (denoted by H_1). In case of statistical decision making, the assumption initially made unbiasedly is that the new medication is not effective in reducing cholesterol levels which is equivalent to the presumption of innocence in the judicial setting. In the settings where two treatments (new drug and placebo) are administered to two different samples, the null hypothesis would be that there is no difference between cholesterol levels in the two groups i.e. "Persons treated with new drug will have same cholesterol levels as persons not treated with new drug". If this null hypothesis gets rejected then the hypothesis that gets accepted is called as 'Alternate hypothesis'. Thus the alternative hypothesis is the assertion accepted when null hypothesis is rejected. The alternate hypothesis would be phrased as, "Persons treated with a new drug have different (higher or lower) cholesterol levels than persons not treated with new drug". This alternative hypothesis is called as a *two-tailed* hypothesis. If the alternative hypothesis would have been stated as "Persons treated with new drug have lower cholesterol levels than the persons not treated with new drug", then such an alternate hypothesis, which considers only one direction or effect (either lower or else higher), is called as '*one-tailed* alternative hypothesis'.

To prove the hypothesis stated by the researcher, he starts accumulating data from the selected sample. The values observed in the sample serve as evidence against H_0 . The error of rejecting the true null hypothesis is equivalent to punishing an innocent person. This is serious type of error and is called as *Type I error*, denoted by α and referred to as 'p-value'. Thus, p-value is probability that a true null hypothesis is wrongly

rejected. The maximum p-value allowed in a research problem is called the 'Level of significance or α -level'. The type I error is the probability that we reject the hypothesis that there is no difference between the cholesterol levels in the two groups (i.e. we conclude that there is a difference), when actually there is no difference. In other words, these are false positive trials; that is, when there is no difference we conclude that there is difference, (An innocent person is hanged). Being serious, this error is kept at a very low level, mostly 5% or 0.05.

There may be other type of error in taking decision called as *Type II error* which is the probability that we accept a false null hypothesis. In other words, this is equivalent to letting a culprit go free. This error is denoted by β . In medical research this is equivalent to false negative trials i.e. though there is significant difference between the drugs we conclude that there is no difference and declare the new drug as ineffective. This error is not as serious as type I error. If today we are not able to prove that the new drug is effective someone else would prove it in some other trial tomorrow. The effect of type-II error is that it may delay the introduction of the new drug, though effective, in the market but not deny it. Type-I error is pre-decided before the research is undertaken. Depending on type-I error and the alternative hypothesis, the type-II error is calculated. Type-II error can occur when our sample size is too small to detect the difference that really exists between those treated and those not treated. This brings us to the concept of power.

Power : The complimentary of Type II error is called 'Power' (Power = $1 - \beta$). Thus, the power of a test is the probability of correctly rejecting H_0 when it is false. In other words, power means that we readily detect true difference when it exists. Power of a test is high if it is able to detect a small difference and thus reject H_0 . Power of the test is kept atleast at 80%. You will get more power with a larger sample size as in Fig. - 1.

Standard Error of Mean : Sampling errors are caused because we observe a sample instead of the whole population. When you take a sample from a population, you only have a subset of the population - a 'piece' of what you're trying to understand.

The SD is the variability within a sample that we select to study. The mean ± 2 SD would give the spread of 95% of the values within a sample. It does not tell us regarding the variability present in the reference population. However theoretically, if we take repeated samples from the same reference population and keep computing the average for each of the sample, then each sample will give us different mean from each other. We consider the set of all such means from all possible samples of specified size (Fig. - 2).

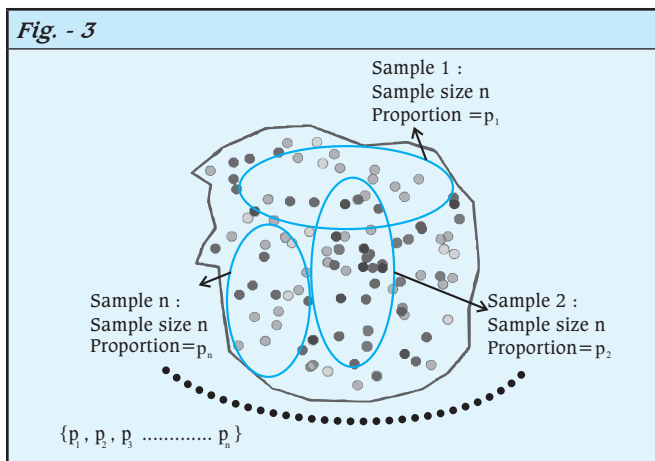

Thus, consider the set of different means from all possible samples.

$$\{\bar{x}_1, \bar{x}_2, \bar{x}_3, \dots, \bar{x}_n\}$$

The mean of these mean would be 'Population mean' and the standard deviation of the sample means is called *standard error of mean* which is given by $\frac{\sigma}{\sqrt{n}}$. The frequency curve of

these means would give us the underlying distribution of these means which is approximately normal and is called *Sampling Distribution of Mean*.

Standard Error of Proportion : The second type of summary statistic besides means which the researcher may be interested in is 'proportion'. It is denoted by 'p'. On the same lines of mean, we consider the set of proportions from all possible samples of specified sample as depicted in Fig. - 3.

Thus we have set of all sample proportions as follows

$$\{p_1, p_2, p_3, \dots, p_n\}$$

The mean of these proportion would be 'Population proportion' and the standard deviation of the sample proportions is called *Standard Error of Proportion* which is given by $\sqrt{\frac{p^*q}{n}}$. The

frequency curve of these proportions would give us the underlying distribution of these proportions which is approximately normal and is called *Sampling Distribution of Proportion*.

p-value : p-value is calculated under the assumption that the null hypothesis is correct. R. A. Fisher first proposed the p-value in the 1920s. Fisher proposed this as an informal index to be used as a measure of discrepancy between the data and the null hypothesis. It is the probability of the test statistic (a function of sample values) as extreme as or more than one actually calculated. Since it is a probability, it lies between 0 and 1 (or, from 0% to 100%). If it is 0%, it implies that the chances of our having gone wrong from our study sample are absolutely nil and on the other hand, if it is 100%, it means that we are absolutely wrong in our conclusions. But how small should we consider the p-value is a difficult question to answer. The answer to this question will vary from one situation to the next, and will depend on many factors. If adopting a new drug would be very expensive, or expose patients to severe side effects, as compared to the already available cheap and low toxicity drugs, then one might demand a very high standard of evidence (that is very small p-value). On the other hand, the shortcoming to adopting the new treatment may be quite low, and may offer advantages over an existing treatment, in which case we may agree to even higher p-value for taking the decision. This could be the situation when we are trying out a vaccine against HIV infection against "no vaccine" against this frightening and potentially fatal condition. Thus, what we need therefore, is a rule to help us decide if a result is likely due to chance alone, meaning it is not statistically significant, or if it is unlikely due to chance alone, meaning it is statistically significant.

- Statistically significant = unlikely due to chance alone
- Not statistically significant = likely due to chance alone

To make a decision, you need a point such that any p-value larger than that point will lead to one conclusion and a p-value smaller than that point will lead to the opposite conclusion. That point is most often set at 0.05 and is called as 'alpha or Type I error'.

When alpha is = 0.05, a p-value of 0.10, for example, indicates the result of the study are not statistically significant and the conclusion will be that chance is a likely explanation for the observed results. The conclusion will be that the observed results are unlikely to represent real treatment differences.

When alpha is = 0.05, a p-value of 0.03, for example, indicates the result of the study are statistically significant and the conclusion will be that chance is an unlikely explanation for the observed results. The conclusion will be that the observed results are likely to represent real treatment differences.

The following provides a reasonable interpretation of p-values:

p-value	Interpretation
$p < 0.01$	Very strong evidence against null hypothesis (H_0)
Between 0.01 to 0.05	Moderate evidence against null hypothesis
Between 0.05 to 0.10	Suggestive evidence against null hypothesis
$p \geq 0.10$	Little or no real evidence against null hypothesis

This interpretation is widely accepted, and many scientific journals routinely publish using such an interpretation for the result of test of hypothesis. However, our readers need to be cautioned at this point. Random error or chance which is estimated by p-value is just one type of error that can occur in research. One needs to be more cautious about the other 3 types of errors in research, i.e. error of basic measurement, systematic error (Bias) and Confounding error, all of which have been discussed in detail in the previous section on Research Methodology. Even the most highly significant p-value is of no avail if the data has flaws of measurement error, systematic error or confounding.

Statistical Procedure in Hypothesis Testing : Hypothesis testing aids the clinician and researcher in reaching a conclusion concerning a population by examining a sample from that population. Hypothesis testing assists the investigator to make decisions. At this point the difference between a statistically significant result and a clinically significant result must be thoroughly understood. Statistical decision should not be interpreted as definitive but it has to balance with the clinical and medical significance. Clinical significance relates to the magnitude of the observed effect while statistical significance answers the question of whether or not the results are due to chance alone or otherwise. The hypothesis testing procedure follows certain steps which are as listed below in the flow chart (Fig. - 4). We will see each step in detail in the next chapter.

Summary

The process of making interpretation and drawing inferences from data is called as *inferential statistics*. The information collected is basically with the purpose of two broad objectives. The researcher is either interested in estimating a population parameter or testing a hypothesis concerned with population parameter. An estimate is a numerical value which is used to estimate the corresponding population parameter. Hence the researcher may be interested in estimating mean, proportion, difference between two means and difference between two proportions. Hypothesis testing as against estimation deals with testing the statements dealing with population parameters. There are two types of hypotheses-*null hypothesis* and *alternate hypothesis*. If the null hypothesis gets rejected then the hypothesis that gets accepted is called as alternate hypothesis which can be *two-tailed* or *one-tailed*. If the information on the direction of the hypothesis is known from review of literature one tailed alternative hypothesis is used whereas when no information is available unbiasedly two tailed hypothesis is considered. Since we deal with sample instead of population,

errors are bound to be present. The error of rejecting the true null hypothesis is called as *Type I error*, denoted by α and referred to as p-value. Thus p-value is probability that a true null hypothesis is wrongly rejected. The maximum p-value allowed in a research problem is called the *Level of significance* or α -level. Accepting a false null hypothesis is called as Type-II error. This error is denoted by β . Type-II error can occur when our sample size is too small to detect the difference that really exists between those treated and those not treated. The complimentary of Type II error is called *power* (Power = $1 - \beta$). The power of a test is the probability of correctly rejecting H_0 when it is false. Power of the test is kept atleast at 80%. Power increases with increasing sample size.

p-value is calculated under the assumption that the null

hypothesis is correct. Whether the results are statistically significant i.e. unlikely due to chance alone is decided by p value. If p value is less than 0.05, than it is said to be statistically significant otherwise the results are said to statistically insignificant.

Study Exercises

Long Question : Discuss the concepts “Hypothesis Testing” and “Estimation” as applied in the field of public health with suitable examples.

Short Notes : (1) Describe type I error and type II error in research (2) p value (3) Null Hypothesis (4) Standard error of mean and proportion

MCQs

- Standard error of mean shows (a) Variation with in samples (b) Variation of sample means from population mean (c) Both of the above (d) None of the above.

- Type-1 error is (a) Rejecting true null hypothesis (b) Rejecting false null hypothesis (c) Accepting true null hypothesis (d) Accepting true null hypothesis
- Type-II error is (a) Rejecting true null hypothesis (b) Rejecting false null hypothesis (c) Accepting true null hypothesis (d) Accepting false null hypothesis
- Power is the ability to (a) Reject true null hypothesis (b) Reject false null hypothesis (c) Accept true null hypothesis (d) Accept false null hypothesis
- Statistically significant results mean that (a) Effect is due to chance (b) Effect is not due to chance alone (c) Findings are clinically significant (d) All of the above
- Type II error and _____ are complimentary (a) Type 1 error (b) p value (c) Power (d) None of the above
- What is the effect of increasing sample size on power? (a) It increases (b) It decreases (c) It remains same (d) None of the above

Answers : (1) b; (2) a; (3) d; (4) b; (5) b; (6) c; (7)a.

Inferences with Single Mean

Seema R. Patrikar

Hypothesis Testing - A Single Population Mean : Here we consider two situations about a population mean (μ)

- When sampling is from *normally distributed population* and *population variance is known*. (Population may not be normally distributed but if sample size ≥ 30 , replace population variance by sample variance)
- When sampling is from *normally distributed population* but with *unknown population variance*.

Situation 1 : When sampling is from *normally distributed population* and *population variance is known*. (Population may not be normally distributed but sample size ≥ 30 , replace population variance by sample variance).

In the first situation the distribution of the test statistic under null hypothesis follows a standard normal distribution. The test statistic value which is a function of null hypothesis and the sampling distribution of the sample means (SE) is calculated as

$$z = \frac{\bar{x} - \mu_0}{\sigma / \sqrt{n}} \dots\dots\dots(\text{Equation 1})$$

If the sample on which we base our hypothesis test about population mean comes from a population that is not normally distributed but if we have large sample drawn ($n \geq 30$), then by virtue of central limit theorem we use the test statistic value as

$$z = \frac{\bar{x} - \mu_0}{s / \sqrt{n}} \dots\dots\dots 2)$$

where s is sample standard deviation, which under null hypothesis follows standard normal distribution.

Let us consider a hypothetical example. Researchers claim that the mean age of population having a certain disease 'A' is 35 years. To prove their claim, a researcher collected information from a random sample of 20 individuals drawn from population of interest. Population variance is known and is equal to $\sigma^2 = 25$ and the study found that the mean age of 20 individuals is as 29.

Hypotheses : Null hypothesis is that the mean age of the population is equal to 35. The alternative hypothesis is that the mean age of the population is not equal to 35.

$$H_0 : \mu = 35 \text{ against } H_1 : \mu \neq 35$$

Data : From the sample the mean age was computed as $\bar{X} = 29$.

Assumptions : It is assumed that the parent population from which the sample is drawn follows a normal distribution. We also assume that $\alpha = 5\%$ and population variance is known and is equal to $\sigma^2 = 25$

Test Statistic : Since we assume that population is normally distributed and since population variance is known, our statistic will be given by equation (1).

Thus,

$$z = \frac{\bar{x} - \mu_0}{\sigma / \sqrt{n}} = \frac{29 - 35}{5 / \sqrt{20}} = -5.36$$

Distribution of test statistic : The test statistic if H_0 is true follows standard normal distribution with mean of 0 and variance of 1.

Decision Rule : The statistical decision is taken by comparing the calculated test statistic value with the table value of standard normal curve against predecided value of α and type of the alternative hypothesis. If the alternative hypothesis is two tailed, then α is divided in the two tails of the standard normal curve into equal parts of $\alpha/2$ each. These areas are called as *Rejection areas*. The decision of rejecting the null hypothesis is taken if the calculated value of absolute test statistic falls in this area i.e. rejects H_0 if calculated value of the absolute test statistic is $\geq Z_{1-\alpha/2}$ or $\leq Z_{\alpha/2}$

From the standard normal table for $\alpha = 0.05$ two tailed, the table value is 1.96. Whereas for one tailed alternative hypothesis, $\alpha = 0.05$, $\mu < \mu_0$ type, the table value is -1.64 and for $\mu > \mu_0$ type, the table value is 1.64. So we may reject H_0 if calculated value of the test statistic is ≥ 1.96 or ≤ -1.96 , otherwise we do not reject H_0 . In the given situation we take the statistical decision to reject the null hypothesis, since absolute value of test statistic (5.36) is greater than the table value (1.96). Tables of normal distribution are provided at the end of the section.

Conclusion : We conclude that the mean age of the population with a specific disease 'A' is not equal to 35 years ($p < 0.05$).

Situation 2 : When sampling is from *normally distributed population* but with *unknown population variance*.

In practice we rarely know the population variance. Quite often we face the situations where the sample size is less than 30 and population variance σ^2 is not known. In such cases, we calculate the sample standard deviation (s) and use this as an estimate of σ . This adds another element of uncertainty to our inference. Z statistics do not consider this additional uncertainty. Therefore, we use a modification of z procedures based on *Student's t distribution*. Student's 't' distribution was discovered by William Gosset who was working for Guinness brewing company. He was not allowed to publish scientific research, so he used the pseudonym "Student" to publish his work. t distributions are similar to z distribution, but have broader tails and less peaked at the center. As 'n' increases, t distribution approaches normal distribution. t tables are set up different than z tables. Each row is for a particular (df) degree of freedom. Columns show cumulative probabilities. (Tables are provided at the end of the section). When sampling is from normally distributed population but unknown population variance, the test statistic for testing $H_0 : \mu = \mu_0$ is given as

$$t = \frac{\bar{x} - \mu_0}{s/\sqrt{n}} \dots\dots\dots(3)$$

which under H_0 follows Student's t test with (n-1) degrees of freedom (df).

Consider a hypothetical situation. Suppose the researcher wants to know as to what extent the diabetics are over weight. He collects information on the body weight in terms of % of ideal body weight in 18 diabetics.

Hypotheses : We convert the claim to null hypothesis. Null hypothesis is that "Diabetics are *not* overweight". (Not overweight = 100% of ideal body weight). Therefore,

$H_0 : \mu = 100$ and alternative hypothesis can be $H_1 : \mu \neq 100$ (*two-sided*)

Data => {107, 119, 99, 114, 120, 104, 88, 114, 124, 116, 101, 121, 152, 100, 125, 114, 95, 117}

We calculate sample mean $\bar{X} = 112.78$ and sample standard deviation (s) = 14.424

Assumptions : It is assumed that the parent population from which the sample is drawn follows approximate normal distribution. We also assume that $\alpha = 5\%$ and population variance is unknown.

Test Statistic: Since the population variance is unknown and $n < 30$, the test statistic is given by equation (3). Thus substituting the values we get the calculated test statistic value as

$$t = \frac{\bar{x} - \mu_0}{s/\sqrt{n}} = \frac{112.78 - 100}{14.424/\sqrt{18}} = 3.76$$

Distribution of test statistic : The test statistic if H_0 is true follows student's t distribution with (n-1) df.

$$t_{n-1, 1-\alpha/2} = t_{18-1, 1-0.05/2} = t_{17, 0.975} = 2.11 \text{ (t table)}$$

Decision Rule : The statistical decision is taken by comparing the calculated test statistic value with the table value of student's 't' distribution. Since our calculated 't' value is more than table value at that particular df (17) and at that particular "two-tailed level of significance" (0.975), we reject the null hypothesis at 5% level of significance.

Conclusion : We have significant evidence against H_0 . Hence we conclude that diabetics are not having the same weight as normals ($p < 0.05$).

Consider another situation. We know from our background knowledge that the mean fasting blood sugar level of non pregnant young adult women is 88 mg/dl. With this background, we conducted a study on a sample of 100 ladies in 2nd / 3rd trimester of pregnancy, attending the obstetric department. We found that the mean fasting blood sugar of this sample of 100 ladies was 102 mg/dl with a standard deviation (SD) of 14. Apparently, our sample shows that the fasting blood sugar, on an average is higher by $(102-88) = 14$ mg/dl among pregnant ladies, as compared to non pregnant ladies. We now want to see, statistically, whether this is a significant finding or simply a matter of chance, i.e, simply due to random (sample to sample) variations. To summarize, this is a situation in which we are studying only one sample and trying to compare the mean from this sample with a known population mean. This is the "single population mean" (or, one sample) situation. The statistical procedure is followed as mentioned

above. The test statistic is

$$t = \frac{\bar{x} - \mu_0}{s/\sqrt{n}} = \frac{102 - 88}{14/\sqrt{100}} = 10$$

The 't' value so calculated is compared with the 't' table value at degrees of freedom = (n-1)

$$df = (n - 1) = (100 - 1) = 99.$$

On looking at the 't' table, we find that the 't' table value at 0.05 level corresponding to df = 99 is approximately 1.98 and at 0.01 level it is 2.62. Since our calculated 't' value (10) is much higher than these values, we say that our results are highly significant ($p < 0.01$); the higher average fasting blood sugar that we have seen among our sample of pregnant ladies is not likely to have come up simply because of "chance" (the probability of its having occurred simply by chance, i.e. random error is less than 1 in 100). We finally conclude, clinically, that pregnancy definitely leads to a rise in fasting blood sugar level.

Summary

The statistical analysis in testing single population mean situation depends on whether the population variance is known or not. If population variance is known, the correct statistical analysis involves 'z' test, whereas when the population variance is unknown, students unpaired t test is used. Student's 't' distribution was discovered by William Gosset who was working for Guinness brewing company. He was not allowed to publish scientific research, so he used the pseudonym "Student" to publish his work. t distributions are similar to z distribution, but have broader tails and less peaked at the center. As 'n' increases, t distribution approaches normal distribution. Comparing the calculated test statistic value and the table value, the statistical decision is taken and accordingly conclusions are drawn. There are various situations which the researcher may be interested in like difference in proportions and means. Sometimes, in medical research, we may have either only one sample which gives us two sets of readings (before and after readings) or else, we may have two different samples which are very similar to each other excepting for the factor which is being studied. The statistical procedure in such situations is the "paired" 't' test where we first calculate the difference between pairs of observation i.e. difference (d_i) between before and after value. The n sample differences then represent a sample from a normally distributed population.

44

Inferences with Single Population Proportion

Seema R. Patrikar

In clinical trials one may count the number of times an event occurs. For example number of successful outcomes, number of failures or number of patients recovered after administration of drug etc. This proportion may be compared with a hypothesized value or we may study a two sample problem in which trials are conducted in two independent study groups. Similarly patients in one group may receive new treatment drug and another independent group may receive existing conventional treatment. We may be interested in comparing the proportion of patients attacked by disease after administration of the treatment in the two populations. The population proportion is denoted by ' π '.

The testing of hypothesis about population proportion is carried out in the same way as means.

Hypothesis Testing : A Single Population Proportion

In testing a single population proportion denoted by π against a hypothesized value of π_0 , approximate normality assumptions holds true if the sample size is large.

The test statistic is given as

$$z = \frac{p - \pi_0}{\sqrt{\frac{\pi_0(1 - \pi_0)}{n}}} \dots\dots\dots 8)$$

Which when the null hypothesis is true follows a standard normal distribution. Here p is the sample proportion and π_0 is the hypothesized population proportion.

Consider a hypothetical example. In clinical studies of an anti-allergy drug, 70 of 781 subjects experienced drowsiness. A competitor claims that 8% of users of his drug experience drowsiness. Use a 0.05 significance level to test this claim.

Hypotheses : $H_0: \pi = \pi_0$ (0.08) against $H_1: \pi \neq \pi_0$ (0.08)

Data : The data obtained on drug says 70 out of 781 subjects experienced drowsiness. Hence,

$$p = 70 / 781 = 0.089$$

Assumptions : The random sample is drawn from a normally distributed population and $\alpha = 5\%$.

Test Statistic: The test statistic is given by equation 8

$$z = \frac{p - \pi_0}{\sqrt{\frac{\pi_0(1 - \pi_0)}{n}}} = \frac{0.089 - 0.08}{\sqrt{\frac{0.08(1 - 0.08)}{781}}} = 0.99$$

Distribution of test statistic : The test statistic, if H_0 is true, follows standard normal distribution with mean of 0 and variance of 1.

Decision Rule : For $\alpha = 0.05$, the standard normal table value is 1.96. Since our calculated test statistic value is less than the

table value, we fail to reject the null hypothesis.

Conclusion : There is not sufficient evidence to warrant rejection of the claim that drowsiness will be less among users of the competitors drug vis-à-vis the drug used by us ($p > 0.05$).

45

Hypothesis Testing: The Difference between Two Population Means

Seema R. Patrikar

One of the commonest situations that a medical researcher faces while testing his/her hypothesis is when his/her interest is to see whether the two samples that he/she has drawn, differ significantly from each other as regards the “mean” of a particular variable of interest. Apparently, the above situation will be possible when we have recorded the data, in respect of that variable, on a “numerical discrete”, or on a “numerical continuous” scale. At this point, it would be worth emphasizing that in case the data has been recorded on a “numerical ordinal” scale (eg, dyspnoea scores, cancer grades etc.), we would NOT do testing for difference between “means”. This is for the simple reason, that though these figures (eg, dyspnoea score 1, 2, 3 etc.) obviously look like mathematical figures, they are not “mathematically meaningful” numbers. In such cases, we should use non-parametric tests for the differences between “medians”. In testing the hypothesis whether the means of the two populations differ significantly or not, we have one of the following hypotheses formulated for our research:

1. $H_0 : \mu_1 = \mu_2$ against $H_1 : \mu_1 \neq \mu_2$ which is equivalent to saying $H_0 : \mu_1 - \mu_2 = 0$ against $H_1 : \mu_1 - \mu_2 \neq 0$
2. $H_0 : \mu_1 - \mu_2 \geq 0$ against $H_1 : \mu_1 - \mu_2 < 0$
3. $H_0 : \mu_1 - \mu_2 \leq 0$ against $H_1 : \mu_1 - \mu_2 > 0$

Again we consider different situations about difference between two population means ($\mu_1 - \mu_2$)

- (1) When sampling is from *normally distributed population* and *population variance is known*. (Population may not be normally distributed but if sample size ≥ 30 , replace population variance by sample variance)
- (2) When sampling is from *normally distributed population* but with *unknown population variance*.

Situation 1 : When sampling is from *normally distributed population* and *population variance is known*. (Population may not be normally distributed but sample size ≥ 30 , replace population variance by sample variance).

In the situation when both the samples follow normal

distribution and population variances are known, the distribution of the test statistic under null hypothesis follows a standard normal distribution. The test statistic in this case is calculated by the following equation.

$$z = \frac{(\bar{x}_1 - \bar{x}_2) - (\mu_1 - \mu_2)}{\sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}} \dots\dots\dots 4)$$

In the situation when the samples do not follow normal distribution but if the samples are large enough (≥ 30), then the distribution of the test statistic under null hypothesis follows a standard normal distribution for assumed α . The test statistic in this case is calculated by the following equation

$$z = \frac{(\bar{x}_1 - \bar{x}_2) - (\mu_1 - \mu_2)}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}} \dots\dots\dots 5)$$

Situation 2 : When sampling is from *normally distributed population* but with *unknown population variance*.

In this situation the test statistic is calculated by first calculating the pooled variance given by s_p^2 . The test statistic is then calculated by the following equation.

$$t = \frac{(\bar{x}_1 - \bar{x}_2) - (\mu_1 - \mu_2)}{\sqrt{\frac{s_p^2}{n_1} + \frac{s_p^2}{n_2}}} \dots\dots\dots 6)$$

$$\text{Where, } s_p^2 = \frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}$$

Under the null hypothesis, the test statistic follows student’s t distribution with $(n_1 + n_2 - 2)$ dfs. Since under null hypotheses that there is no difference, μ_1 and μ_2 are assumed to be the same and hence μ_1 minus μ_2 becomes zero.

The following is a hypothetical data set of a research study to answer the question whether the serum cholesterol of healthy adult males, living in hot desert areas is, on an average, different (ie., significantly higher or lower) from the average serum cholesterol of healthy adult males living in temperate climates. The serum cholesterol values of 12 subjects from the deserts and 14 subjects from temperate climate are presented as :

Serum Cholesterol Values (mg/dl) : Desert group (Total = 12): 254, 218, 176, 242, 184, 239, 225, 256, 218, 182, 210, 191;
Temperate Climate Group (Total = 14):- 210, 176, 194, 250, 219, 207, 162, 154, 258, 166, 219, 200, 176, 182.

Hypotheses : $H_0: \mu_1 = \mu_2$ against $H_1: \mu_1 \neq \mu_2$ which is equivalent to saying

$H_0: \mu_1 - \mu_2 = 0$ against $H_1: \mu_1 - \mu_2 \neq 0$

Data : As given above

Assumptions : Both the populations follow approximate normal distribution with unknown population variances and $\alpha = 5\%$.

Test Statistic : Since population variance is unknown we use equation 6 to calculate the test statistic value.

$$s_p^2 = \frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}$$

$$= \frac{(12 - 1)(28.2)^2 + (14 - 1)(31.5)^2}{12 + 14 - 2} = 901.95$$

$$t = \frac{(\bar{x}_1 - \bar{x}_2) - (\mu_1 - \mu_2)}{\sqrt{\frac{s_p^2}{n_1} + \frac{s_p^2}{n_2}}}$$

$$= \frac{(216.25 - 198.07) - 0}{\sqrt{\frac{901.95}{12} + \frac{901.95}{14}}} = 1.53$$

Distribution of test statistic : If null hypothesis is true then the test statistic will follow student's t distribution with $(n_1 + n_2 - 2)$. From the t table we get the value against $(12 + 14 - 2 = 24)$ dfs as 2.06.

Statistical Decision : Since the calculated test statistic value lies below the table value we do not reject the null hypothesis (accept H_0).

Conclusion : Serum Cholesterol levels of healthy adult males, living in hot desert areas is, on an average, *not different* from the average serum cholesterol of healthy young males living in temperate climates ($p > 0.05$).

Paired Comparisons

The 't' test we have described above deals with situations in which there are two different samples whose means are to be compared. Sometimes, in medical research, we may have either only one sample which gives us two sets of readings (before and after readings) or else, we may have two different samples which are very similar to each other excepting for the factor which is being studied. Let us have a look at the following examples:

1. To study the efficacy of a drug in reducing the Serum Cholesterol level, we took 10 healthy adult males and measured their Serum Cholesterol levels. These 10 subjects are then given the drug for 1 month and the Serum Cholesterol levels were again measured thereafter.
2. For evaluating the skin irritant effect of an industrial chemical, we applied the chemical (in paste form, using paraffin jelly as the medium) on the right forearm of 10

subjects, while on the left forearm, only paraffin jelly was applied to serve as control. After 24 hours, we measured the maximum diameter of hyperaemia in millimeters on both the forearms.

3. For studying the effect of tobacco smoking during pregnancy on the birth weight of the child, we took a sample of 90 pregnant ladies who were tobacco users. For each such lady, we took another pregnant lady of same age, parity, income status and duration of pregnancy but who was a non smoker. In other words, we "pair - matched" each subject (pregnant smoker) with a control (pregnant non-smoker). We then followed up each of the 180 subjects till delivery and recorded the birth weight of the offspring in grams.

All the above three examples have very different objectives and settings; however, they have one thing in common - each data point of the first sample is related to a unique data point of the second sample. These are the situations of "paired samples". Such "paired samples" may represent two sets of measurements on the same subject in a "before and after" fashion (thus, each subject serving as his own control, vide example No. 1 above); or they may be two exactly similar anatomic or physiological points excepting for the factor under study (example No. 2 above); or, measurements on different people who are chosen on an individual basis using "matching criteria", so that they are very similar to each other, except for the factor under study (example No. 3 above).

The statistical procedure in such situations is the "paired" 't' test where we first calculate the difference between pairs of observation i.e. difference (d_i) between before and after value. The n sample differences then represent a sample from a normally distributed population. The test statistic for testing the hypothesis that the mean difference between the before and after value = 0 ($\mu_d = 0$) is as follows:

$$t = \frac{\bar{d} - \mu_d}{\frac{SD(\text{difference})}{\sqrt{n}}} \dots \dots \dots (7)$$

Where \bar{d} is the sample mean difference, μ_d is hypothesized value of the population mean difference and SD is the standard deviation of the sample difference. The test statistic under null hypothesis follows a student's t distribution with $(n-1)$ dfs.

Let us illustrate the calculation by taking following example. The Serum Cholesterol levels of the 10 subjects before giving the drug are mentioned in second column in Table - 1, while the cholesterol values of the same subjects after giving the drug for one month are given in the third column in Table - 1. The differences between these two cholesterol readings in respect of each and every subject are given in the last column.

Hypotheses : $H_0: \mu_d = 0$ against $H_1: \mu_d \neq 0$

Data : Now, the mean of the differences of the 10 observations $(+26 + 12 + \dots - 10)$ comes out to + 9.7 and the standard deviation comes out to 12.96 thus.

$$\bar{d} = 9.7, SD(\text{difference}) = 12.96, n = 10.$$

Subject No.	Serum Cholesterol mg/dl		Difference (d) (= d1 -d2)
	Before therapy d1	After therapy d2	
1	306	280	+ 26
2	254	242	+ 12
3	198	204	- 6
4	242	238	+ 4
5	236	228	+ 8
6	228	202	+ 26
7	286	264	+ 22
8	274	258	+ 16
9	208	209	- 1
10	188	198	- 10

Assumptions : The observed differences constitute a random sample from a normally distributed population and $\alpha = 5\%$.

Test Statistic : Using equation (7) for paired observation we get test statistic value as

$$t = \frac{\bar{d} - \mu_d}{SD(\text{difference})/\sqrt{n}} = \frac{9.7 - 0}{12.96/\sqrt{10}} = 2.37$$

$$df = (n - 1) = (10-1) = 9$$

Statistical Decision : Now, turning to the t table, we find the t table value at p or $\alpha = 0.05$ and $df = 9$ is 2.26. Since our calculated 't' value (2.37) is more than the table value (2.26), we conclude that our results are significant i.e. we reject our null hypothesis.

Conclusion : What we are in fact concluding is our sample of 10 subjects shows that there is a reduction on an average by 9.7 mg/dl due to the drug; and the "probability" that in the large reference population (of millions of persons who would be given the drug), the drug will not lead to a reduction in Serum Cholesterol is less than 5 in 100 chances; thus there are 95 in 100 chances that the drug will lead to a reduction in Serum cholesterol in the large reference population ($p < 0.05$).

Once again, if we are using "numerical-ordinal" scales, then it should not be the "paired t-test" but rather a non parametric test (Wilcoxon's signed rank test) that should be used. For example, if we are comparing the "pain scores" (0,1,2,3 etc) before and after a drug then we should *not* use the paired t test as described above, but the Wilcoxon's signed rank test.

46 Hypothesis Testing: The Difference between Two Population Proportions

Seema R. Patrikar

This is the most common situation in medical research. We test the null hypothesis that the difference between the two proportions is zero or some other value. When the null hypothesis is stated as $\pi_1 = \pi_2$ (two population proportions are same), it means that we are testing the hypothesis that $\pi_1 - \pi_2 = 0$ (difference between two population proportions is zero).

The test statistic is given as

$$z = \frac{(p_1 - p_2) - (\pi_1 - \pi_2)}{SE_{p_1-p_2}}, \dots\dots\dots(9)$$

Where p_1 and p_2 are sample proportion values

$$\text{where } SE_{p_1-p_2} = \sqrt{\frac{\bar{p}(1-\bar{p})}{n_1} + \frac{\bar{p}(1-\bar{p})}{n_2}} \text{ and } \bar{p} = \frac{x_1 + x_2}{n_1 + n_2},$$

x_1 and x_2 are numbers in the first and second samples possessing the characteristic of interest. The test statistic under null hypothesis follows standard normal distribution.

Consider a hypothetical example where we sampled 55 males in their adolescent ages. 24 of them were obese. Another sample of 149 females had 36 obese ladies. Can we conclude that in the sampled populations the proportion of obese males is higher than that of females ?

Hypotheses : $H_0: \pi_1 \leq \pi_2$ or $\pi_1 - \pi_2 \leq 0$ against

$$H_1: \pi_1 > \pi_2 \text{ or } \pi_1 - \pi_2 > 0$$

π_1 and π_2 are proportions of obese in male and female populations respectively.

Data : The data gives the sample proportion values as $p_1 = 24/55 = 0.44$ and $p_2 = 36/149 = 0.24$. $\bar{p} = (24+36)/(55+149)$
 $\bar{p} = 0.29$

Assumptions : The two independent simple random samples are drawn from a normally distributed population and $\alpha = 5\%$.

Test Statistic : The test statistic is given by equation 9

$$z = \frac{(p_1 - p_2) - (\pi_1 - \pi_2)}{SE_{p_1 - p_2}} = \frac{0.44 - 0.24}{\sqrt{\frac{0.29(1-0.29)}{55} + \frac{0.29(1-0.29)}{149}}} = 2.71$$

Distribution of test statistic : The test statistic, if H_0 is true, follows standard normal distribution with mean of 0 and variance of 1.

Decision Rule : For $\alpha = 0.05$, the standard normal table value is 1.645 for one tailed hypothesis. So since the test statistic value is greater than the table value ($2.71 > 1.645$), we reject the null hypothesis.

Conclusion : There is sufficient evidence that proportion of obese in males population is significantly higher than female population ($p < 0.05$)

Study Exercises

Short Notes : (1) Unpaired 't' test (2) 't' test

MCQs

- Twenty-five children are chosen randomly from a school playground. Their heights are measured when they first come into school the next morning, and again just before they go home that same evening. What statistical test could be used to test the hypothesis that their morning heights are no different from their evening heights? (a) Unpaired t-test (b) Paired t-test (c) Z-test (d) Regression
- To label a statistical test definitely significant, the p-value should be (a) Less than 0.05 (b) Less than 0.5 (c) Greater than 0.05 (d) Greater than 0.5
- The basic goal of Hypothesis testing is (a) To confirm the alternative hypothesis (b) To distinguish between random and meaningful differences in outcome (c) To establish the value of alpha (d) To establish the value of beta
- The value of alpha serves as protection against (a) False negative results (b) Inadequate sample size (c) Type I error (d) Type II error
- Six volunteers have gone on a cholesterol lowering diet for six months. The pretrial and the posttrial changes in the cholesterol levels are as given in the table. The appropriate test of statistical significance for this trial is (a) The critical ratio (b) Odds ratio (c) Paired t-test (d) Student's t test
- In the Testing of Hypothesis problems, we reject the null hypothesis. (a) If the Test Statistic value (calculated) is greater than the table value (b) If the Test Statistic value (calculated) is smaller than the table value (c) If the Test Statistic value (calculated) is equal to the table value (d) None of the above
- In comparing the difference between two population means, if value of p is 0.31. Then correct interpretation is (a) There is a significant difference between population means. (b) There is no significant difference between population means. (c) None of the above. (d) All of the above
- In a small sample survey on 7 male and 10 female students, the mean cholesterol levels were found to be 250 mg percent and 260 mg percent respectively. Which one of the following statistical tests is appropriate to find significance of the difference in this case (a) Chi-square test (b) Unpaired 't' test (c) Paired 't' test (d) z-test
- The statistical test used to analyze the difference between the mean values of hemoglobin of two independent samples (of 100 school children in each sample) drawn from normally distributed populations is (a) Paired 't' test (b) Unpaired 't' test (c) Chi-square test (d) z-test
- The minimum power of a study should be (a) 70% (b) 80% (c) 90% (d) None of the above
- Hb of 10 people was measured before and after giving them iron tablets for one month. Statistical test which can be used to measure the effect of iron on Hb is (a) Paired 't' test (b) Unpaired 't' test (c) Sign test (d) Chi-square test
- In hypothesis testing between two population means null hypothesis is (a) $\mu_1 = \mu_2$ (b) $\mu_1 = 0$ (c) $\mu_1 = \mu_2 = 0$ (d) $\mu_1 \neq \mu_2$
- Paired 't' test is used in all the following condition except (a) When only one sample gives two sets of readings (before and after readings) (b) When two different samples are similar to each (paired match) (c) When two different samples are similar to each (frequency match) (d) Independent samples are considered
- If numerical ordinal data for paired samples is used then the statistical test used is (a) Sign test (b) Wilcoxon sign test (c) Paired 't' test (d) Chi-square test
- Researcher's interest is to see whether the two samples that he/she has drawn, differ significantly from each other as regards the "mean" of a particular variable of interest the statistical procedure used is (a) Hypothesis testing of difference between two means (b) Hypothesis testing of single mean (c) Chi-Square test (d) All of the above
- While testing a hypolipidemic drug, serum lipids levels were tested both before and after its use. Which test is best suited for the statistical analysis of the results (a) Paired 't' test (b) Unpaired 't' test (c) Chi-square test

Answers : (1) b; (2) a; (3) b; (4) c; (5) c; (6) a; (7) b; (8) b; (9) d; (10) b; (11) a; (12) a; (13) c; (14) b; (15) a; (16) a.

Statistical Exercises

- A researcher wants to estimate the mean Hb level of adult male population in Pune and studied 100 adult male. Previous studies shows that mean Hb level of Pune population is 12gm%. Average Hb level in 100 adult male is 11.5gm%. (i) Write the null hypothesis and the alternative hypothesis. (ii) What would be the test statistic value and its distribution (iii) Suppose in the above example sample size was 20, then which statistical test would be applied.
- A random sample of 100 subjects with family history of diabetes were selected and their mean fasting blood sugar was measured as 100mg/dl with standard deviation of 0.06mg/dl. It is known from previous study that mean fasting blood sugar level in persons without history of diabetes is 95mg/l. Can you conclude from the following data that mean fasting blood glucose level in subjects with

family history of diabetes is different from that of without family history? let $\alpha = 0.05$. (T.S.=8.33, reject the null hypothesis)

19. A random sample of 52 subjects with family history of IHD were selected and their mean serum cholesterol level with standard deviation were measured as 220mg/dl and 10mg/dl respectively. It is known from the previous study that mean serum cholesterol level in subjects without family history of IHD was 200mg/dl. Can you conclude from these data that the mean serum cholesterol level in subjects with family history of IHD is different from that of without family history of IHD? Let $\alpha = 0.05$. (T.S.=14.4, reject the null hypothesis)

20. A researcher wants to study prevalence of anemia among rural pregnant ladies. Previous studies have shown prevalence to be 50%. She took 100 pregnant ladies from rural areas and took their hemoglobin readings and found 40% as anemic. Which statistical procedure will be used in this method. What would be the null hypothesis and the alternative hypothesis Can researcher conclude that prevalence of anemia in her study is different from previous studies? (T.S.=2, reject the null hypothesis)
21. A survey on 144 women respondents in India shows that 50% females are satisfied with their family life (n=144). Similar survey done globally showed that 45% of females are satisfied with their family life. Can you conclude from the data that females in India are more satisfied than at world level? let $\alpha = 0.05$. (T.S.=1.20, do not reject the null hypothesis)

47

Chisquare Test

Seema R. Patrikar

The previous section of hypothesis testing dealt with situations when we had discrete or continuous, i.e. “quantitative or numerical variables”, which could be measured. Apart from above mentioned situations many times medical research deals with situations involved with comparing two groups with the presence and absence of various diseases. Here the qualitative or categorical variables are measured in terms of “counts”. In other words, the researcher is interested in finding out the association or relationship between two qualitative variables. The statistical tests used for such variables which do not assume normality of the variable are specific and called as *nonparametric tests*. These are also called as *distribution free test*. These tests are weaker than parametric test and require fewer assumptions. For categorical data, the test used is called as chi-square test (χ^2 test). Since information is qualitative, it would be collected in counts. When the information is collected in counts, it is compiled and presented in a table called as *contingency table*. When both the qualitative variables are dichotomous, the tabular presentation takes the form of 2 x 2 contingency table (2 rows and 2 columns). In general we can have r x c contingency table where r is number of rows and c is number of columns. Under the null hypothesis, the test statistic follows a chi-square distribution with (r-1)x(c-1) degrees of freedom. The number of subjects falling in each category from our collected sample is called observed frequencies (O_{ij}) and the numbers of subjects in our sample, that we would expect to observe, if null hypothesis is true are called the expected frequencies (E_{ij}).

Chi-square tests have three applications.

1. χ^2 test for independence to test whether two or more characteristics are associated (independent) to each other.
2. χ^2 test for goodness of fit to study whether two or more independent populations are similar with respect to some characteristic.
3. χ^2 test for homogeneity to study whether two study groups independently drawn from two populations are homogenous with respect to some criteria of classification

In all the three situations, the test statistic takes the same formula given as follows

$$\chi^2 = \frac{\sum (O_{ij} - E_{ij})^2}{E_{ij}}$$

where O_{ij} and E_{ij} are observed and expected frequencies for i^{th} row and j^{th} column. The expected frequencies are calculated as follows

$$\text{Expected frequency} = \frac{(\text{marginal row total}) \times (\text{marginal column total})}{n}$$

The χ^2 test statistic value give details as to how close the observed and expected frequencies lie. When the null hypothesis is true, the test statistics follows a χ^2 distribution with (r-1)*(c-1) degrees of freedom. The calculated χ^2 is compared with the χ^2 table value and the decision to reject H_0 is taken if the calculated test statistic value is greater than the table value for specified value of α .

Let us illustrate the procedure of Chi-square test using the hypothetical example on the association between maternal age and congenital malformations (Table-1). Let us say, we started with the research issue as to whether advanced maternal age (>35 years) is associated with congenital malformations among the children. We took a sample each, say, 500 pregnant ladies

aged > 35 years and another 1000 pregnant ladies aged upto 35 years and followed them till delivery. We found that out of the 500 children born to ladies > 35 years, 50 had congenital malformations, while out of 1000 ladies upto 35 years, there were again 50 children born with congenital malformations. We would thus proceed to test the research hypothesis that the age of mother and congenital malformations are associated. This research hypothesis would be tested against the "Null Hypothesis" which states "There is no association between congenital malformation and age of mother". (Age of mother and congenital malformation are independent to each other). The outcome variable of interest is dichotomous (either malformed child or normal child)

Samples of ladies	Number of Children		Total
	Having Congenital malformations	Not having Congenital malformations	
>35 years	(O ₁₁)50 (10%) (a)	(O ₁₂)450 (90%) (b)	500 (100%) (a+b)
<35 years	(O ₂₁)50 (5%) (c)	(O ₂₂)950 (95%) (d)	1000 (100%) (c+d)
Total	100 (6.67%) (a+b)	1400 (93.33%) (b+d)	1500 (100%) (n)

O₁₁, O₁₂, O₂₁ and O₂₂ (Equivalent to a, b, c and d) are the observed frequencies in our sample. To calculate the chi-square test statistic value, we are first required to calculate the expected frequencies. Expected frequencies are the one that we expect if null hypothesis is true and is given by

$$\text{Expected frequency} = \frac{(\text{marginal row total}) \times (\text{marginal column total})}{n}$$

Thus for the above example we have expected frequencies for each cell as follows:

$$E_{11} = (500 \times 100) / 1500 = 33.33 \quad E_{12} = (500 \times 1400) / 1500 = 466.67$$

$$E_{21} = (1000 \times 100) / 1500 = 66.67 \quad E_{22} = (1000 \times 1400) / 1500 = 933.33$$

Test Statistic: Test Statistic for chi-square tests is given by

$$\chi^2 = \sum \frac{(O_{ij} - E_{ij})^2}{E_{ij}}$$

where O_{ij} and E_{ij} are observed and expected frequencies for ith row and jth column. Substituting the values from the above example we get

$$\chi^2 = \frac{(50 - 33.33)^2}{33.33} + \frac{(450 - 466.67)^2}{466.67} + \frac{(50 - 66.67)^2}{66.67} + \frac{(950 - 933.33)^2}{933.33}$$

$$\chi^2 = 13.39$$

Distribution of the Test Statistic: Under null hypothesis the test statistic follows a chi-square distribution with (row-

1)*(column-1) degrees of freedom. For the above problem we have (2-1)*(2-1) = 1 degree of freedom. For 1 df and assumed α level of significance the chi-square table value is 3.84.

Statistical Decision: If the calculated test statistic value is greater than table value we reject the null hypothesis otherwise accept it. Since our calculated test statistic value = 13.39 > 3.84 we reject null hypothesis.

Conclusion : On the clinical front we conclude that there is a definite relationship between advanced maternal age (> 35 years) and congenital malformations in the offspring.

Shortcut method for 2 x 2 contingency table : When the data is cross tabulated in a 2 x 2 contingency table the χ^2 can be calculated using a shortcut formula given as follows.

$$\chi^2 = \frac{n(ad - bc)^2}{(a + c)(b + d)(a + b)(c + d)}$$

where a, b, c and d are observed frequencies in a 2 x 2 table and the denominator is the product of the marginal totals of the rows and columns. The χ^2 test statistic value always follows χ^2 distribution with 1 degree of freedom.

When 20% of the expected frequencies are less than 5 we apply Yates correction factoring in case of 2 x 2 table. χ^2 corrected formula is given as follows.

$$\chi^2 = \frac{n(|ad - bc| - 0.5n)^2}{(a + c)(b + d)(a + b)(c + d)}$$

where n is the total sample size.

Summary

Many times medical research deals with situations involved with comparing two groups with the presence and absence of various diseases. Here the qualitative or categorical variables are measured in terms of "counts". In other words the researcher is interested in finding out the association or relationship between two qualitative variables. The statistical tests used for such variables which do not assume normality of the variable are specific. These tests are weaker than parametric test and require fewer assumptions. For categorical data the test used is called as chi-square test (χ^2 test). Since information is qualitative it would be collected in counts. When the information is collected in counts it is compiled and presented in a table called as contingency table. The number of subjects falling in each category from our collected sample is called observed frequencies (O_{ij}) and the numbers of subjects in our sample that we would expect to observe if null hypothesis is true are called the expected frequencies (E_{ij}). Under the null hypothesis the chi square test finds the difference between the observed and expected frequencies. Chi-square tests have three applications. χ^2 test for independence to test whether two or more characteristics are associated (independent) to each other. χ^2 test for goodness of fit to study whether two or more independent populations are similar with respect to some characteristic. χ^2 test for homogeneity to study whether two study groups independently drawn from two populations are homogenous with respect to some criteria of classification.

Study Exercises

Long Question : What is test of significance? Discuss Chi-square test in detail.

Short Notes: Chi-square test

MCQs

- In a study to determine relationship between presence of I.H.D and smoking, the appropriate Statistical test is :
(a) z-test (b) Paired 't' test (c) Chi-square test (d) None of the above
- Which of the following is non-parametric test (a) z-test (b) 't' test (c) Chi-square test (d) None of the above
- Under the null hypothesis the test statistic follows a chi-square distribution with _____ degrees of freedom
(a) $(r-1) \times (c-1)$ (b) $r \times c$ (c) n (d) $n-1$
- All are application of chi-square test except (a) χ^2 test for independence (b) χ^2 test for goodness of fit (c) χ^2 test for homogeneity (d) χ^2 test for heterogeneity
- The number of degrees of freedom in a table of (4×4) in Chi-square test is (a) 16 (b) 8 (c) 9 (d) 1.

Answers : (1) c; (2) c; (3) a; (4) d; (5) c.

Statistical Exercises

- A researcher wanted to study association between exercise and survival from myocardial infarction he collected the following data

Exercise	Death	
	Yes	No
No	70	13
Mild	54	45
Moderate	30	50
Rigorous	15	70

Can we conclude from the following data that there is no association between exercise and death due to myocardial infarction? (Answer : T.S. = 80.37, reject null hypothesis)

- A cross sectional survey was carried out among women of age group 20-60 yrs to determine whether there is an association between history of multiple sexual partners and cervical cancer. Can you conclude from the survey results shown below that there is no association between the two?

History of Multiple sexual partner	Cervical cancer	
	Yes	No
Present	538	1125
Absent	112	1425

(Answer : T.S. = 300, reject null hypothesis)

- A cross-sectional survey was carried out to find out the relationship between sex and anemia and following data was collected

Sex	Anemia	
	Present	Absent
Male	15	150
Female	25	115

Can you conclude from the following data that there is no association between sex and anemia

(Answer : T.S. = 5.11, reject null hypothesis).

48

Confidence Interval

Seema R. Patrikar

As we have stated above, if an investigator is interested in estimating population mean (μ) or population proportion (π), he draws a sample from population and compute the sample mean (\bar{X}) or sample proportion (p) as an estimate for population mean or population proportion. Since the investigator is studying a sample instead of population, error would always creep in. Most of the research results rely on the premise that what is true for the randomly selected sample from the population will be true for the population from which the sample is selected. But by all

logic we know that \bar{x} cannot be expected to be exactly equal to μ . It would hence be required to estimate μ by an interval that somehow communicates information regarding the true value of μ . This reliability of the results obtained is addressed by Confidence Intervals (CIs). A CI is the range of values that encompass the actual or true population value. They provide information about how precise the estimate is. Wider CIs indicate lesser precision and narrower CIs indicate greater precision. Also p value and CIs are related to each other. When p value is less than 5%, the 95% confidence interval will exclude the hypothesized null value. Hence confidence intervals can also tell you whether null hypothesis is rejected or not.

Confidence Interval for Population Mean

To calculate confidence interval we make use of the knowledge

of sampling distributions. We have already studied the sampling distribution of mean and proportion in the estimation and hypothesis chapter. From one of the important property of area relationship in a normal curve, we know that approximate 95% of the data value lies within 2 standard deviation from mean ($\mu \pm 2 \sigma_{\bar{x}}$). Now if we consider all possible samples and calculate the mean for each sample we get $\{\bar{x}_1, \bar{x}_2, \bar{x}_3, \dots, \bar{x}_n\}$. From the sampling distribution of mean we know that the mean of these means would be population mean and the standard deviation of the sample means also called standard error of mean is given by $\sigma_{\bar{x}} = \sigma / \sqrt{n}$. If we construct intervals about every possible value of \bar{x} computed from all possible samples of size n we would have a large number of intervals of the form $\bar{x} \pm 2\sigma_{\bar{x}}$. Approximately 95% of these intervals would constitute the population mean value.

Thus a confidence interval gives an estimated range of values which is likely to include an unknown population parameter, the estimated range being calculated from a given set of sample data. It is interpreted as follows.

When sampling is from a normally distributed population with known standard deviation, we are $100(1-\alpha)$ percent confident that the computed interval $\bar{x} \pm z_{1-\alpha/2} \sigma_{\bar{x}}$ contains the population mean μ . This interval is called a confidence interval for μ .

Confidence intervals are usually calculated at 95%, but we can produce 90% or even 99% confidence intervals for the unknown parameter. The width of the confidence interval gives us some idea about how uncertain we are about the unknown parameter. A very wide interval may indicate that more data should be collected before anything very definite can be said about the parameter. Confidence intervals are more informative than the simple results of hypothesis tests (where we decide “reject H_0 ” or “don't reject H_0 ”) since they provide a range of plausible values for the unknown parameter. The confidence level is the probability value $1-\alpha$ associated with a confidence interval. It is often expressed as a percentage. For example, say $\alpha = 0.05 = 5\%$, then the confidence level is equal to $(1-0.05) = 0.95$, i.e. a 95% confidence level.

Example 1 : A dentist wished to estimate with 95% confidence, the mean marginal displacement in the teeth taking place by applying a particular treatment modality. He assumes that the marginal displacement values are normally distributed with a mean of 6.2 units after studying 100 people. The population variance is 9 units. (Population Standard Deviation $= \sqrt{9} = 3$)

Solution: The mean $\bar{x} = 6.2$ with $SD = 3$

The z value corresponding to a confidence limit of 95% is found from normal table which is equal to 1.96.

The standard error $\sigma_{\bar{x}} = \sigma / \sqrt{n} = SD / \sqrt{n} = 3/\sqrt{100} = 0.3$

Thus 95% confidence interval for μ is,

$$\begin{aligned} & \bar{x} \pm z_{1-\alpha/2} \sigma_{\bar{x}} \\ & 6.2 \pm 1.96(0.3) \\ & 5.61, 6.79 \end{aligned}$$

Interpretation : We say that in repeated sampling from the study population, we are 95% confident that the mean marginal displacement for population lies between 5.61 and 6.79.

Example 2 : Suppose a researcher interested in finding the serum TSH in healthy adult females; studied 100 subjects and found that the mean serum TSH was 2 units with a standard deviation (SD) of 0.2. Calculate 95% confidence interval.

Solution : The 95% confidence interval for population mean is given by

$$\bar{x} \pm z_{1-\alpha/2} \sigma_{\bar{x}} = \bar{x} \pm z_{1-\alpha/2} SD / \sqrt{n}$$

where, \bar{x} = the mean from our sample,

SD = standard deviation

n = sample size.

Thus, 95% Confidence interval = $2 \pm (1.96 \times 0.2/\sqrt{100})$

$$= 2 \pm (1.96 \times 0.02)$$

$$= 2 \pm (0.0392)$$

$$= 1.9608 \text{ to } 2.0392$$

Thus, while from our sample under study, the mean serum TSH among healthy females is 2 units, we are 95% confident that the reality or truth that exists in the ‘total population’ (of millions of adult healthy females) would be that mean serum TSH would be between 1.9608 to 2.0392.

Note : In constructing confidence interval knowledge of population variance from which the sample is taken is required. But when sample size is large i.e. greater than 30, we use sample standard deviation as a replacement for the unknown population standard deviation even if it is from non normal distribution by virtue of central limit theorem.

When sample size is small, less than 30, we have alternate procedure of calculating confidence interval. The procedure remains same except that we use t distribution with n degrees of freedom instead of standard normal distribution ‘z’. The confidence interval for population mean in such cases is given by

$$\bar{x} \pm t_{1-\alpha/2} \frac{SD}{\sqrt{n}}$$

Confidence Interval for the Difference between Two Population Means

We have already come across situations when the researcher is interested in estimating difference between two population means. When population variances are known the standard error value is given by

$$\sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}$$

In this case the confidence interval is given by

$$(\bar{x}_1 - \bar{x}_2) \pm z_{1-\alpha/2} \sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}$$

Example : The researcher is interested to find whether waist/hip ratio is different in cases of IHD as compared to healthy adults. For answering the issue the researcher took 100 cases of IHD. Their waist/hip ratio showed a mean of 1.1 with a standard deviation (SD) of 0.05. Another 400 healthy adults of similar age were also examined. Their waist/hip ratio showed an

average of 0.8 with a SD of 0.04. Calculate the 95% confidence interval for difference in means of waist/hip ratio among IHD patients and healthy subjects.

Solution : 95% confidence interval for difference between two population means is given by

$$(\bar{x}_1 - \bar{x}_2) \pm z_{1-\alpha/2} \sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}$$

From the sample we have

$$\bar{x}_1 = 1.1, SD_1 = 0.05, \bar{x}_2 = 0.8, SD_2 = 0.04, n_1 = 100, n_2 = 400$$

Thus the 95% confidence interval is

$$(1.1 - 0.8) \pm 1.96 \sqrt{\frac{0.05^2}{100} + \frac{0.04^2}{400}}$$

$$= (0.289, 0.311)$$

Interpretation : We are 95% confident that the difference between the waist/hip ratio in IHD cases and healthy adults lies in the range of 0.289 and 0.311. Since the 2 limits of the 95% CI are having the same sign (plus), we can also say that our findings are significant at 5% level ($p < 0.05$).

Note : When the sampling is from non-normal population but the sample sizes n_1 and n_2 are large, more than 30, the population variances get replaced by the sample variances by virtue of central limit theorem.

Case 1 : When the population variances are unknown but we assume it to be equal we obtain the pooled estimate of the common variance which is given by

$$s_p^2 = \frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}$$

The standard error in this case is given by

$$s = \sqrt{\frac{s_p^2}{n_1} + \frac{s_p^2}{n_2}}$$

The procedure for calculating the confidence interval remains same except that we use t distribution with $n_1 + n_2 - 2$ degrees of freedom instead of standard normal distribution 'z'. Thus the confidence interval for difference between two population means is given as follows

$$(\bar{x}_1 - \bar{x}_2) \pm t_{1-\alpha/2} \sqrt{\frac{s_p^2}{n_1} + \frac{s_p^2}{n_2}}$$

Case 2 : When the population variances are unknown but we assume it to be unequal the standard error is given by

$$\sqrt{\frac{SD_1^2}{n_1} + \frac{SD_2^2}{n_2}}$$

Again we make use of t distribution. Thus the confidence interval in this case is given by

$$(\bar{x}_1 - \bar{x}_2) \pm t_{1-\alpha/2} \sqrt{\frac{SD_1^2}{n_1} + \frac{SD_2^2}{n_2}}$$

Case 3 : When the observations are paired. In other words when we are dealing with student's paired 't' test situation.

The confidence interval in this case is given by

$$\text{Mean of the differences} \pm t_{1-\alpha/2} \text{SD}(\text{difference})/\sqrt{n}$$

where $t_{1-\alpha/2}$ is the t table value at $(n-1)$ degrees of freedom.

Confidence Interval for Population Proportion

Many times the researcher is interested not in the mean value but a proportion value $[p]$. What is the proportion of patients who survive/recover after administering a particular drug or what is the proportion of side effects and so on. In such cases the researcher proceeds in the same way as when estimating mean value. He selects a sample from the population and compute sample proportion p . The sampling distribution of proportion is normal distribution with standard error as $\sqrt{p(1-p)/n}$. Thus the confidence interval for population proportion is given as

$$p \pm z_{1-\alpha/2} \sqrt{p(1-p)/n}$$

Example : A researcher is interested in knowing the proportion of young men who are seropositive for HIV infection. He took a sample of, say, 1000 young men and did a sero study. He found that out of 1000 young men, 5 were positive. Calculate the 95% confidence interval for population proportion.

Solution : The sample proportion value = $p = 5/1000 = 0.005$; thus, $q = 1-p = (1-0.005) = 0.995$, and $n = \text{total sample} = 1000$. The 95% Confidence interval for population proportion is given by

$$p \pm z_{1-\alpha/2} \sqrt{p(1-p)/n}$$

Thus, 95% CI = $0.005 \pm (1.96 \times \sqrt{0.005(1-0.005)/1000})$

$$= 0.005 \pm 0.0044$$

$$= 0.0006 \text{ to } 0.0094 \text{ (or 6 per 10,000 to 94 per 10,000)}$$

Our interpretation would be that though we are not aware of what exactly the real seropositivity in the entire province would be, we are 95% sure that whatever this reality is, it will be somewhere between 6 per 10,000 to 94 per 10,000 in the total population.

Confidence Interval for Difference between Population Proportions

When the researcher is interested in the difference between two population proportions, the reliability of his results are given by the 95% confidence interval for difference between the two proportions. The standard error is estimated by

$$\sigma_{p_1-p_2} = \sqrt{\frac{p_1(1-p_1)}{n_1} + \frac{p_2(1-p_2)}{n_2}}$$

The confidence interval for difference between population proportions is given by

$$(p_1 - p_2) \pm z_{1-\alpha/2} \sqrt{\frac{p_1(1-p_1)}{n_1} + \frac{p_2(1-p_2)}{n_2}}$$

Example : In a research study, the researcher took a sample of 500 young, married, healthy ladies attending a Family Welfare Clinic. He found that 100 were using oral contraceptives (OC) while remaining 400 were using other temporary methods of

contraceptives. On following up these 2 groups for 1 year we observed that 10 out of the OC group and 20 out of the non OC group developed Thromboembolism (TE). The researcher is interested in estimating 95% confidence interval for difference between the two proportions of occurrence of TE.

Solution : proportion in one group, $p_1 = 10/100 = 0.1$; $q_1 = (1 - p_1)$

proportion in second group, $p_2 = 20/100 = 0.05$; $q_2 = (1 - p_2)$

sample size of first group, $n_1 = 100$

sample size of second group, $n_2 = 400$

Confidence interval for difference between proportions is given by

$$(p_1 - p_2) \pm z_{1-\alpha/2} \sqrt{\frac{p_1(1-p_1)}{n_1} + \frac{p_2(1-p_2)}{n_2}}$$

$$(0.1-0.05) \pm 1.96 \sqrt{\frac{0.1(1-0.1)}{100} + \frac{0.05(1-0.05)}{400}}$$

$$= (-0.012, 0.11)$$

Confidence Interval when we are Working Out the Relative Risk

One important aspect when we are calculating the Relative Risk (RR) or Odds Ratio (OR) is that, while we are testing for the difference between two means or two proportions, the value of “no difference” is zero (For example, if the mean waist/hip ratio in both IHD as well as normal subjects is 1.1, the difference between means is zero and we would say that there is ‘no difference’ between IHD and normal subjects as far as waist/hip ratio is concerned). The value of ‘no difference’ is called the ‘null value’ in research.

The slight difference regarding null value when we are calculating the RR or OR is that the null value in these instances is *one and not zero*. When RR is one, it means that the incidence of the disease among both the groups (having the exposure and not having the exposure) is the same and so the factor does not carry any risk.

95% CI of RR : Let us consider an example of a “prospective” study in which the “outcome” is IHD occurred and not occurred and the “exposure” is smoking present and absent. The 2 X 2 table in this study would look like :

Smoking	IHD		Total
	+	-	
+	150 (10%)	1350	1500
-	175 (5%)	3325	3500
Total	325	4675	5000

We calculate the RR of developing IHD due to smoking as usual which is equal to 2. However, this is a finding from our ‘sample’ of two large “total populations” of millions of smokers and another millions of non smokers. Is it necessary that the “truth” that we are trying to estimate in the total populations, there will be a two fold risk? Can’t it be 3 or 5? Or, it can also be 0.5 in reality. We will therefore, once again, have to work

out the 95% CI around this value of RR, which will give us a range, and we can say that we are 95% confident that the RR in reality, whatever it may be, will be some where in this interval. A rough but simple and reasonably accurate method of calculating the 95% CI of RR or OR is given by

$$95\% \text{ CI of RR} = \text{RR}^{(1 \pm 1.96 / \sqrt{X})}$$

$$95\% \text{ CI of OR} = \text{OR}^{(1 \pm 1.96 / \sqrt{X})}$$

Now in the present example, the χ^2 (chi square) value comes out to 100, thus

$$95\% \text{ CI of RR} = 2^{(1 \pm 1.96 / \sqrt{100})}$$

$$= 2^{(1 \pm 0.196)}$$

$$= 2^{(0.804, 1.196)}$$

$$= (1.79, 3.96)$$

Thus, we would interpret that the estimated RR for IHD due to smoking from our study sample is 2; however we are 95% confident that the truth, whatever it is, lies in the range of 1.79 to 3.96; smoking increases the risk of developing IHD by at least 1.79 times to as much as almost 4 times and we are 95% confident of this statement.

The 95% CI of odds Ratio : Let us say, stimulated by the question of the association between Thromboembolism and Oral Contraceptive use, we conducted a case control study by taking 50 ladies suffering from TE and 200 ladies of similar age and parity who never suffered from TE. We interrogated all these subjects regarding history of OC use during past 2 years. Out of 50 TE cases, 5 (10%) gave history of OC use while out of the 200 healthy ladies, 10 (5%) gave similar history. The data would be presented in the following 2 X 2 table :

History of OC use	TE		Total
	Cases	Controls	
Yes	5 (10%)	10 (5%)	15
No	45	190	235
Total	50 (100%)	200 (100%)	250

In this example, the Odds Ratio (OR) works out to (5×190) divided by $(10 \times 45) = 2.11$. We would conclude that, since OR is a reasonable approximate of the RR, the risk of TE is 2.1 times more if OC have been used during past 2 years. We calculate the 95% CI.

$$\text{Now, } 95\% \text{ CI of OR} = \text{OR}^{(1 \pm 1.96 / \sqrt{X})}$$

Now, X^2 for the given example = 1.77

$$\text{Thus, } 95\% \text{ CI} = 2.11^{(1 \pm 1.96 / \sqrt{1.77})}$$

$$= 2.11^{(1 \pm 1.47)}$$

$$= 2.11^{(-0.47, 2.47)}$$

$$= 0.70 \text{ to } 6.32$$

At this point, note one more surprising thing - the lower limit is less than 1, while the upper limit is more than one. In other words, the null value of 1 is enclosed in this 95% confidence interval. Whenever this happens, i.e. the 95% CI of RR or OR includes 1, we can also conclude that the results are statistically not significant at 5% level ($p > 0.05$). Remember, in the case of 95% CI of the difference between means or proportion this

interpretation is made when zero is included in the interval (i.e. one end is minus and other is having plus sign). The remaining interpretation regarding clinical versus statistical significance has in any case to be made by looking at 95% CI of RR or OR.

Summary

If an investigator is interested in estimating population mean (μ) or population proportion (π) he draws a sample from population and computes the sample mean (\bar{X}) or sample proportion (p) as an estimate for population mean or population proportion. Since the investigator is studying a sample instead of population, error is always present. Most of the research results rely on the premise that what is true for the randomly selected sample from the population will be true for the population from which the sample is selected. But by all logic we know that \bar{X} cannot be expected to be exactly equal to μ . It would hence be required to estimate μ by an interval that somehow communicates information regarding the true value of μ . This reliability of the results obtained is addressed by Confidence Intervals (CIs). A CI is the range of values that encompass the actual or true population value. They provide information about how precise the estimate is. Wider CIs indicate lesser precision and narrower CIs indicate greater precision. Also p value and CIs are related to each other. When p value is less than 5%, the 95% confidence interval will exclude the hypothesized null value. Hence confidence intervals can also tell you whether null hypothesis is rejected or not. While undertaking statistical analysis of any study the estimate values should always be accompanied by the confidence interval.

Study Exercises

Short Notes: Confidence interval

MCQs

- 95% of confidence limits exist between (a) +1SD (b) + 2SD (c) + 3SD (d) + 4SD
- Wider the range of confidence interval (a) more is the precision of estimate (b) precision does not get affected by it (c) less is the precision of estimate (d) none of the above
- Hypothesised null value for confidence interval of relative risk (a) zero (b) one (c) two (d) five

- If confidence interval includes null value then the results are (a) statistically not significant (b) statistically significant (c) clinically significant (d) none of the above.
- 95 % confidence interval means that we are (a) 5% error in our estimation of population parameter (b) 95% close to the estimation of population parameter (c) 95% confident that parameter will lie in this range (d) none of the above.

Answers : (1) b; (2) c; (3) b; (4) a; (5) a.

Statistical Exercises

- A researcher wants to estimate the mean Hb level of adult male population in Pune. He studied 100 adult males. Previous studies shows that mean Hb level of Pune population is 12gm%. Average Hb level in 100 adult males is 11.5gm% with SD 1gm%. Calculate 95% CI of average Hb level of adult male population in Pune and interpret the results.
(Answer : 95% CI = 11.30-11.69, we are 95% confident that average Hb level of adult male population lie in the range of 11.30-11.69 gm%. Also since this range does not contain 12gm% therefore mean Hb level of Pune is different from 12gm%).
- A random sample of 100 subjects with family history of diabetes was selected and their mean fasting blood sugar is 100mg/dl with S.D. of 0.06mg/dl. It is known from previous study that mean fasting blood sugar level in persons without history of diabetes is 95 mg/l. Calculate 95% CI for mean fasting blood sugar with history of diabetes and interpret the results.
(Answer : 95% CI = 98.824-101.176)
- In a prospective study of smoking and IHD following data was collected. Calculate 95% CI of relative risk and interpret the result.

Smoking	IHD	
	Present	Absent
Present	20	80
Absent	12	88

(Answer : 95% CI = 0.87 - 3.20)

Seema R. Patrikar

In the initial chapters, we have highlighted that the major reason for utilizing statistics is because we study a sample instead of complete population. Research studies (surveys, experiments,

observational studies, etc.) are always better when they are carefully planned. Determining sample size is a very important issue and hence must be planned carefully because samples that are too large may waste research time, resources, patient effort and money invested in clinical trial, while samples that are too small may lead to inaccurate results. Also, it may be considered unethical to recruit patients into a study that does not have a large enough sample size for the trial to deliver meaningful information. Thus to ensure that a statistical

test will have adequate power, one usually must perform the exercise of calculating how large an 'n' (sample size) is required. It is not possible to compute a sample size for certain types of experiments because prior information is lacking or because the success of the experiment is highly variable. These studies are called as pilot studies. Pilot experiments are designed to explore a new research area to determine whether variables are measurable with sufficient precision as well as to check the logistics of a proposed experiment. Usually a pilot study is conducted by taking an approximate sample size of 30 or less. In most of the other research designs (for hypothesis testing) the sample size calculation depends upon the four major components viz the power, the level of significance, the effect size or the expected parameter value in the population and the expected size of the treatment effect sought. We have already discussed that power of a study is its ability to detect a true difference in outcome. This is usually chosen to be 80%. If study power is set at 80%, it accepts a likelihood of one in five (that is, 20%) of missing such a real difference i.e. the study will have 20% possibility of a "false-negative" result. Level of significance is predefined before we start the experiment. The chosen level of significance or Type I error is the probability of detecting a treatment effect when no effect exists (leading to a "false-positive" result) and defines the threshold "p value". Results with a p value above the threshold lead to the conclusion that an observed difference may be due to chance alone, while those with a p value below the threshold lead to rejecting chance and concluding that the intervention has a real effect. The type I error is most commonly set at 5% (or, sometimes at 1%). This means the investigator is prepared to accept a 5% (or 1%) chance of erroneously reporting a significant effect. The effect size is the biologically significant difference which is specified from a detailed review of literature, from experts or by conducting a pilot study. This is defined as "minimum detectable RR or OR or Treatment Effect (TE)". The four quantities α , β , sample size, and clinical difference are related to each other. If the three quantities α , β and clinical difference are specified, sample size can be determined. Sample size determination is done for two situations when the researcher is dealing with simple estimation problem or with hypothesis testing problem. We consider below sample size determination in both the situations of estimation and hypothesis testing. In hypothesis testing along with α , power is also considered.

Sample Size Determination for Estimating a Mean

Sample size 'n' is given by

$$n \geq \frac{z_{1-\alpha/2}^2 \sigma^2}{d^2}$$

where,

d ---- is the precision or margin of error. In other words, it is the acceptable deviation between the hypothesized value and the true value of population parameter assuming 95% confidence interval.

σ ---- is the population standard deviation which is estimated from pilot study or from previous similar study.

$Z_{1-\alpha/2}$ - is the table values for alpha error corresponding to the standard normal distribution. This is 1.96 at 5% (i.e. 0.05) and

2.57 at 1% alpha error (two tailed).

Sample Size Determination for Hypothesis Testing for Single Population Mean

Sample size 'n' is given by

$$n \geq \frac{(z_{1-\alpha/2} - z_{\beta})^2 \sigma^2}{d^2}$$

where,

d ---- is the precision or margin of error. In other words it is the acceptable deviation between the hypothesized value and the true value of population parameter assuming 95% confidence interval.

σ ---- is the population standard deviation which is estimated from pilot study or from previous similar study.

$Z_{1-\alpha/2}$ - is the table values for alpha error corresponding to the standard normal distribution. This is 1.96 at 5% (i.e. 0.05) and 2.57 at 1% alpha error (two tailed).

Sample Size Determination for Estimating Proportion

The procedure in estimating sample size for proportion remains same as in case of means. Assuming that population is large we determine the sample size by following equation.

$$n \geq \frac{z_{1-\alpha/2}^2 Pq}{d^2}$$

where,

p --- is the proportion in population possessing the characteristic of interest and q=1-p. This expected proportion in population is estimated from literature or pilot study. If nothing is known of p then it can be assumed to be 0.5.

d ---- is the acceptable deviation and

$Z_{1-\alpha/2}$ --- is the value of two tailed alpha error; this is 1.96 at 5% (i.e. 0.05) and 2.57 at 1% alpha error (two tailed). For one tailed alpha error, this will be 1.64 at 0.05 and 2.33 at 0.01 levels of alpha error.

Sample Size Determination for Hypothesis Testing for Single Population Proportion

Sample size 'n' is given by

$$n \geq \frac{(z_{1-\alpha/2} \sqrt{\pi_0(1-\pi_0)} - z_{\beta} \sqrt{\pi_1(1-\pi_1)})^2}{(\pi_0 - \pi_1)^2}$$

Sample Size Determination for Estimating Difference between Means

For estimating the means in two independent samples the sample size calculation remains similar to single population mean. Here $n_1 = n_2 = n$

$$n \geq \frac{z_{1-\alpha/2}^2 \sigma^2}{d^2}$$

where it is assumed that σ_1 and σ_2 are same and equal to σ . If they are not equal their average can be taken as an estimate of the standard deviation.

Sample Size Determination for Hypothesis Testing for Difference between Two Means

The sample size is given as

$$n \geq \frac{(z_{1-\alpha/2} - z_{\beta})^2 \sigma^2}{(\mu_1 - \mu_2)^2} * 2$$

where it is assumed that σ_1 and σ_2 are same and equal to σ . If they are not equal their average can be taken as an estimate of the standard deviation.

Sample Size Determination for Estimating Difference between Proportions

The method of sample size determination for estimating difference between proportions is slightly tedious than for single population proportion. No estimate of standard deviation from previous work or literature is required but the actual proportions in the two populations must be specified as well as their difference (d).

$$n \geq \frac{z_{1-\alpha/2}^2 (p_1 q_1 + p_2 q_2)}{d^2}$$

where p_1 and p_2 are proportion in population possessing the characteristic of interest and $q_1 = 1 - p_1$ and $q_2 = 1 - p_2$.

Sample Size Determination for Hypothesis Testing for Difference between Two Proportions

For comparing the proportions in two independent samples the sample size is given as

$$n \geq \frac{[z_{1-\alpha/2} \sqrt{2\pi(1-\pi)} - z_{\beta} \sqrt{\pi_1(1-\pi_1) + \pi_2(1-\pi_2)}]^2}{(\pi_1 - \pi_2)^2}$$

where $\pi = \frac{\pi_1 + \pi_2}{2}$

Sample Size Application for Hypothesis Testing in a Case Control and Prospective Studies

In a case control study, besides giving specifications for acceptable alpha error and acceptable beta error, the proportion of the persons without the outcome who are likely to give a history of the exposure (i.e. proportion of controls who are exposed) and the minimum risk (i.e. the minimum Odds Ratio that our study wants to detect), needs to be specified.

In case of a prospective study, besides giving specifications for acceptable alpha error and acceptable beta error, the proportion of subjects those who are not exposed to the exposure but are likely to develop the outcome and the minimum risk (i.e. the minimum Relative Risk that our study wants to detect) needs to be specified.

Once the above specifications have been made, the calculation becomes simple by the following formula :-

$$n = \frac{(z_{1-\alpha/2} + z_{1-\beta})^2 * p * q}{(p_1 - p_0)^2}$$

where, n = minimum sample size for each group; $Z_{1-\alpha/2}$ = value of alpha error; $Z_{1-\beta}$ = value of beta error; For the usual situation when alpha error = 0.05 two tailed, the value is 1.96 and for beta error = 0.20, it is 0.84; P_0 = Proportion of those

“without the exposure” who are likely to develop the “outcome” (in a prospective study) or Proportion of those without the outcome who are likely to have the exposure (in a case control study).

The value of P_0 would have to be specified by us. The methods of obtaining the same are extensive reading into the subject, discussions with experts, or finally, by conducting a pilot study if required. Once P_0 is specified, P_1 is then obtained as follows

In a prospective study,

$$P_1 = \frac{P_0 \times RR}{[1 + P_0 (RR - 1)]}$$

In case-control study,

$$P_1 = \frac{P_0 \times OR}{[1 + P_0 (OR - 1)]}$$

And,

$$P = \frac{P_0 + P_1}{2}$$

$$q = 1 - P$$

(Please note: Sample size determination is discussed in detail with examples in the section on EPI – 2002. Hence it is suggested that the readers also review the details given in that section)

Summary

Determining sample size is a very important issue and hence must be planned carefully because samples that are too large may waste research time, resources, patient effort and money invested in clinical trial, while samples that are too small may lead to inaccurate results. Also, it may be considered unethical to recruit patients into a study that does not have a large enough sample size for the trial to deliver meaningful information. Thus to ensure that a statistical test will have adequate power, one usually must perform the exercise of calculating how large an ‘n’ (sample size) is required. In most of the research designs the sample size calculation depends upon four major components viz the power, the level of significance, the effect size or the expected parameter value in the population and the expected size of the treatment effect sought. Most of the times, the power is chosen to be 80%. Level of significance is predefined before we start the experiment. The chosen level of significance or Type I error is the probability of detecting a treatment effect when no effect exists (leading to a “false-positive” result) and defines the threshold “p value”. Results with a p value above the threshold lead to the conclusion that an observed difference may be due to chance alone, while those with a p value below the threshold lead to rejecting chance and concluding that the intervention has a real effect. The type I error is most commonly set at 5% (or, sometimes at 1%). This means the investigator is prepared to accept a 5% (or 1%) chance of erroneously reporting a significant effect. The effect size is the biologically or clinically significant difference which is specified from a detailed review of literature, from experts or by conducting a pilot study. This is defined as “minimum detectable RR or OR or Treatment Effect (TE)”. The four quantities α , β , sample size and clinical difference are related to each other. If the three quantities α , β and clinical difference are specified sample size can be determined.

Study Exercises

Short Note : Determinants of sample size

MCQs

1. Sample size determinations depends upon all except (a) Type I error (b) Test statistic value (c) Power (d) Expected parameter value
2. In case control study P_0 is proportion of those (a) Without the outcome who are likely to have the exposure (b) With the outcome who are likely to have the exposure (c) Without the outcome who are likely not to have the exposure (d) None of the above
3. Sample size determination for estimating a mean depends upon all except (a) Margin of error (b) Type I error (c) Population standard deviation (d) Population mean
4. In prospective study P_0 is proportion of those (a) Without the exposure who are likely to develop the outcome (b) Without the exposure who are not likely to develop the outcome (c) With the exposure who are likely to develop the outcome (d) None of the above
5. All are true of sample size except (a) It should be representative of population (b) It should be of adequate size (c) It gives exactly the same results as exists in population (d) Sample size should be determined during the planning stage itself

Answers : (1) b; (2) a; (3) d; (4) a; (5) c.

Statistical Exercises

1. An investigator wants to conduct a study to find out whether there is an difference in prevalence of diabetes among adults in town 'A' and 'B'. From previous study it is known that prevalence of diabetes among adults in town 'A' and 'B' are 11% and 8% respectively. How many adults from each of town should be included in a study for testing the null hypothesis that there is no difference in prevalence against the alternative hypothesis that there is difference in prevalence? The investigator wishes to be 90% confident of detecting a difference in prevalence between the towns at 5% level of significance. (Answer : 2004 adults from each town)
2. A researcher wanted to detect relative risk of 2 among smokers developing IHD as compared to nonsmokers. How many smokers and healthy subjects he should take if chances of developing IHD among healthy subjects are 0.03? Let level of significance is 0.05 and power of study to be 80%. (Answer : 335 each of healthy subjects and smokers)

Sampling Methods

Seema R. Patrikar

As already stated, most researchers come to a conclusion of their study by studying a small sample from the huge population or universe. To draw conclusions about population from sample, there are two major requirements for a sample. Firstly, the sample size should be adequately large, an issue which has been discussed in the previous chapter. Secondly, the sample has to be selected appropriately so that it is representative of the population. Sample should have all the characteristics of the population. In other words, a sample is expected to be mirror of the population from which it comes. Sampling techniques is concerned with the selection of representative sample, especially for the purposes of statistical inference. The idea of sampling is very old and from time immemorial, people have used it in day-to-day life. For example, a housewife examines one or two grains of cooked rice to ascertain whether rice is ready to eat or not. When a person goes to market to buy grains, he does not investigate each and every grain from the bag full of grains but just selects a fistfull to ascertain the quality of the grains. Thus, on the basis of a sample study, we

can predict and generalise the behaviour of the population. For sampling purpose, the population has to be divided into smaller units called as sampling unit. Evidently the population must be capable of division such that every element of the population belongs to one and only one sampling unit.

In order to cover the population, there should be a list consisting of all the subjects/units of the population. This list of each and every individual in the population is called as '*Sampling frame*'.

Sampling errors : The errors involved in the collection, processing and analysis of a data, may be classified as sampling errors. In other words, errors arising due to drawing inferences about the population on the basis of few observations is termed as 'Sampling error'. Sampling errors may arise due to bias in selection of sample. It may also occur due to faulty work during the collection and analysis. The sampling error can be reduced by ascertaining that the sample drawn is truly random and by increasing the sample size (See Fig. - 1).

Non Sampling errors : These errors arise at the stages of observations, compilation and analysis of data. They are present in both sample surveys as well as complete population enumeration survey. Thus the sample survey would be subject to both the sampling errors as well as non-sampling errors whereas the population surveys would be having non

sampling errors only. Non sampling errors occur at every stage of planning and execution because of faulty planning, errors in response by the respondents, compilation errors etc.

Methods of sampling : The various methods can be classified into two categories, namely, probability sampling and non-probability sampling. Probability sampling are those where each unit in the population has an equal chance or probability of being chose for the sample. Non probability sampling are those which do not have equal chance to every unit in the population. These methods are also called as Subjective or Purposive sampling. We will discuss few of the important sampling techniques adopted in medical research.

Simple Random Sampling (SRS)

In this method, the individual units constituting the sample are selected at random. Each unit in the population has equal chance or probability to be selected in the sample. For this reason, it is sometimes referred to as a 'Probability Sample'. There are two types of random sampling, simple random sampling with replacement and simple random sampling without replacement. In SRS with replacement, the selected unit is replaced back to the population and again has the chance of getting selected. In SRS without replacement, which is the usual method in medical research, the selected unit is not put back in the population and hence the population size reduces by one at each selection. Random samples can be drawn by lottery method or by using random number tables. In Lottery method, we make small chits of paper for each unit in the population which are folded and then mixed together. From this the required number are picked blindly. For example, if you want to select 10 subjects randomly from a population of 100, you can write their names, fold them up, mix them thoroughly then pick ten. In this case, every name had an equal chance of being picked. The other method of drawing a random sample is by using random number tables. This method is possible only with finite population i.e. when the population size N is known. The technique of selecting random sample with the help of these numbers is very simple. Suppose we have to select a sample (n) of 100 subjects from a population of 500 (N). We first make a serial list of each and every subject of the 500 subjects in the population. This is called the "Sampling frame".

Then from the random number table, random numbers are selected row wise or column wise. Since ' N ' (500) is of 3 digits, the random numbers selected are also 3 digits. If the selected random number is less than N , then the unit corresponding to that random number from population is selected in the sample. However if the random number is greater than N , then the remainder after dividing the random number by N is selected in the sample. For example, if selected random number is 167, then the unit corresponding to this number in the sampling frame is selected in the sample. But if the random number is 641, then the remainder after dividing 641 by 500 is 141. Thus, the unit corresponding to 141 in the sampling frame is taken in the study. The advantage of SRS over other methods is that subjectivity is completely eliminated as each subject has an equal chance of getting selected. Simple random sampling is very scientific but the practical problem is that it may be quite difficult, often impossible to make a complete list of all subjects in the population from which the sample is to be selected.

Stratified Random Sampling

This method is preferred when the population is heterogeneous with respect to characteristic under study. In this method, the complete population is divided into homogenous sub groups called 'Strata' and then a stratified sample is obtained by independently selecting a separate simple random sample from each population stratum. This gives equal chance to the units in each stratum to be selected as sample. The total sample is the addition of samples of each stratum. Population can be divided into different groups based on some characteristic or variable like income or education. The advantage of this sampling procedure is that each subgroup, however small, has representation in the total sample. For example, if we draw a simple random sample from a population, a sample of 100 may contain only 10 to 15 high income groups, 20 to 30 middle income groups and 80 to 90 low income groups. To get adequately large representation for all the three socio economic structures, we can stratify on socioeconomic class and select simple random samples from each of the three strata. The advantage is that minority group is not left out but we require a sampling frame for each stratum separately.

Systematic Random Sampling

Systematic sampling is a commonly employed technique, when complete and up to date list of sampling units is available. A systematic random sample is obtained by selecting one unit on a random basis and then choosing additional units at evenly spaced intervals until the desired number of sample size is obtained. For example, if there are 100 students (N) in a class and we wish to select a sample of 20 students (n) from them by systematic random sampling procedure, than the first step is to write the names of 100 students in alphabetical order or their roll numbers one below the other. In the systematic sampling procedure we divide N by n to get the sampling fraction (k). Thus in the example $k=100/20 = 5$. Next we randomly select any number between 1 to k i.e. between 1 to 5. Suppose the number we select is 4. Then the student number 4 is selected in the sample. Thereafter every k^{th} student is selected in the sample until we reach the last one. Thus the student's corresponding to numbers 4, 9, 14, 19,99 are to be selected in the sample. The advantage of systematic sampling is that it is easier to

draw, but the demerit is that the sample may exhibit a pattern or periodicity.

Cluster Sampling

Cluster sampling is used when the population is heterogeneous. Clusters are formed by grouping units on the basis of their geographical locations. A cluster sample is obtained by selecting clusters from the population on the basis of simple random sampling. From the selected clusters each and every unit is included for study. Cluster sampling is a very useful method for the field epidemiological research and for health administrators. A special form of cluster sampling called the “30 cluster sampling”, has been recommended by the WHO for field studies in assessing vaccination coverage. In this a list of all villages (clusters) for a given geographical area is made. 30 clusters are selected using Probability Proportional to Size (PPS). From each of the selected clusters, 7 subjects are randomly chosen. Thus a total sample of $30 \times 7 = 210$ subjects is chosen. The advantage of cluster sampling is that sampling frame is not required and in practice when complete lists are rarely available, cluster sampling is suitable.

Multistage Sampling

In this method, the whole population is divided in first stage sampling units from which a random sample is selected. The selected first stage is then subdivided into second stage units from which another sample is selected. Third and fourth stage sampling is done in the same manner if necessary. For example, in an urban survey in a state, a sample of towns may be taken first and then in each of the selected towns, a second stage sample of households may be taken. If needed, further from each of the selected household, a third stage sample of individuals may be selected. Since the samples are selected at each stage the method is called ‘Multi stage sampling’.

Randomization (Random allocation) : ‘Randomization’ is different from random sampling. Randomization (or, random allocation) is a method used for allocating selected subjects (already selected by random sampling method) into 2 or more than 2 groups, with a view to ensure that these groups are similar in all respects excepting for the drug or vaccine etc. that we are interested in administering to them. Randomization ensures that the treatment groups are comparable with respect to other factors (such as age, sex, severity of illness) which might be associated with the outcome. Hence if a difference in response between groups is seen, we can be confident that this is due to the treatment, rather than due to other factors.

Random allocation can be done in many ways from tossing a coin to using random number tables. For example, keep tossing a coin and all patients who get ‘heads’ get drug ‘X’ and all patients who get ‘tails’ get ‘Y’. If there are 3 groups (drugs X,Y,Z), toss a dice and all patients who get 1 and 4 go to X, 2 and 5 go to Y and 3 and 6 go to Z; or, more scientifically, we should use a random table and all subjects getting even numbers go to ‘X’ and all getting odd numbers get Y.

Let us say, we are having an experimental study in which we are studying a new drug ‘X’ against an existing drug ‘Y’. Our sample size calculations indicated that we will need 10 subjects in each of the groups ‘X’ and ‘Y’ (total 20 subjects).

Now, the first step is to decide by any “random” (fair play) process, as to which all random members so selected will get treatment ‘X’ and which will get ‘Y’. This we can do by keeping two chits, having written ‘X’ on one and ‘Y’ on the other. Similarly, place another 2 chits (with “even” written on one and “odd” written on the other) in another box. Now, ask any impartial observer to pick up one chit from each box. Let us say that chits drawn were ‘X’ from one box and “even” from the other. Thus, we will give treatment “X” to all even random numbers so selected and “Y” to all odd random numbers. Next, make a table, listing all the 20 patients as shown in Table -1.

Now, select any random starting point from the random numbers table by dropping a pencil. Let us say, out of the 35 rows and 36 columns in our random number table, we picked up the intersection of 29th row and 4th column, i.e. number 9. Now note down this number against patient No. 1. From here we proceed down the 4th column, noting the numbers against the patient’s serial numbers *and ignoring* any zero. Once we come to the end of column 4, we continue with column no. 5.

Patient No.	Random No.	Even or odd	Treatment (X or Y)
1.			
2.			
3.			
...			
...			
20.			

Thus, the next number after 9 is zero, hence we ignore it; we take the next number i.e. 7, and write it against patient No.2. The next random member is 8 and we write it against patient No. 3. We continue this process till a random number has been allocated to each of the 20 patients. Now, in the next column of our above table we write down whether the random number selected for the particular patient is odd (O) or even (E). Thus, the random number given to the first patient is 9, i.e. odd and we write ‘O’ opposite it, similarly we write ‘O’ and ‘E’ respectively for 2nd and 3rd patient and so on. Now, in the fourth column with the heading “treatment X and Y”, write X for all patients getting ‘E’ and ‘Y’ for all patients getting ‘O’. The final layout is given in Table - 2.

Thus, first and second patients will get treatment ‘Y’, third and fourth get ‘X’, next 3 get ‘Y’ and so on, as the patients keep coming to our wards or OPD. We have, thus, “randomized” 20 patients into 2 treatment groups, well in advance.

Patient No.	Random No.	Even or odd	Treatment (X or Y)
1	9	O	Y
2	7	O	Y
3	8	E	X
4	4	E	X
5	1	O	Y
6	1	O	Y
7	7	O	Y
8	8	E	X
9	9	O	Y
10	2	E	X
11	8	E	X
12	7	O	Y
13	1	O	Y
14	8	E	X
15	6	E	X
16	8	E	X
17	8	E	X
18	5	O	Y
19	9	O	Y
20	6	E	X

Summary

Most researchers come to conclusion of their study by studying a small sample from the huge population or universe. To draw conclusions about population from sample, there are two major requirements for a sample. Firstly, the sample size should be adequately large and secondly, the sample has to be selected appropriately so that it is representative of the population. Sample should have all the characteristics of the population. In other words, a sample is expected to be mirror of the population from which it comes. Sampling techniques is concerned with the selection of representative sample, especially for the purposes of statistical inference. For sampling purpose the population has to be divided into smaller units called as 'Sampling unit'. In order to cover the population there should be a list consisting of all the subjects/units of the population.

This list of each and every individual in the population is called as 'Sampling frame'. Errors arising due to drawing inferences about the population on the basis of few observations are termed as 'Sampling error'. Whereas non sampling errors arise at the stages of observations, compilation and analysis of data. They are present in both sample surveys as well as complete population enumeration survey. Various methods of sampling are namely probability sampling and non probability sampling. Probability sampling are those where each unit in the population has an equal chance or probability of being chosen for the sample. Non probability sampling are those which do not have equal chance of selection for every unit in the population. These methods are also called as 'Subjective or Purposive Sampling'. Most commonly used sampling methods are simple random sampling, stratified sampling, systematic random sampling and cluster sampling methods.

Study Exercises

Long Question : (1) What are advantages of sampling over complete enumeration? Describe briefly the SRS technique (2) Discuss various type of sampling method.

Short Notes : (1) Multistage sampling (2) Cluster sampling (3) Define cluster sampling. How will you evaluate the immunization status of children below five years of age from your district by the cluster sampling method.

MCQs

- The list of each and every individual in the population is called as (a) Sampling frame (b) Sampling error (c) Sampling ratio (d) Sampling procedure
- All is true about simple random sample sampling except (a) Impractical if N is very large (b) Minority subgroups are adequately represented (c) Every member has an equal chance of being included (d) Population estimate is easy to calculate
- Probability samplings are all except (a) Simple random sampling (b) Systematic random sampling (c) Cluster sampling (d) Quota sampling.
- In simple random sampling if the subject is replaced back in the population it is termed as (a) Simple Random Sampling with replacement (b) Simple Random Sampling without replacement (c) Systematic sampling (d) None of the above
- Requirements of a sample is that it should be (a) Representative (b) Adequate (c) None of the above (d) Both 'a' and 'b'

Answers : (1) a; (2) b; (3) d; (4) a; (5) d.

Seema R. Patrikar

Regression Techniques

Often in medical research it is desirable to analyse the relationship or association between two quantitative (i.e. continuous, discrete or numerical ordinal) variables. The term 'Correlation' indicates the relationship between two variables in which, with changes in the values of one variable, the values in the other variable also changes. The nature and strength of relationship that exists is examined by regression and correlation analysis. When the objective is to determine association or the strength of relationship between two such variables, we use correlation coefficient (r). If the objective is to quantify and describe the existing relationship with a view of prediction, we use regression analysis. Correlation can either be positive or negative. When the values of the two variables move in the same direction, implying that if one variable increases the other variable also increases may not be in same magnitude or decrease in variable is associated with the decrease in the value of the other variable, the correlation is called 'Positive'. If on the other hand, the values of the two variables move in opposite directions so that with an increase in the value of one variable, the other variable decreases and with a decrease in the value of one variable the value of the other increases, the correlation in such case is called 'Negative'.

Scatter Diagram : Before we develop a mathematical model describing relationship we should first plot the scatter diagram of the variables. A scatter plot is a visual description of the relationship between two continuous variables. It consists of a graph with horizontal axis (x-axis) and vertical axis (y-axis) representing the two variables. Each observation of x and y are represented by dot on the graph at the point (x, y).

Fig. - 1 shows the scatter diagram where the relationship indicates positive correlation, as the values of the two variables move in the same direction. Fig. - 2 shows the scatter diagram where the relationship indicates negative correlation, as the values of the two variables move in the opposite direction. Fig. - 3 and Fig. - 4 shows the scatter diagram where the relationship indicates perfect correlation, as the values of the two variables move in the same direction but in exact magnitude i.e. if one value increase in 5 units the other variable also increase in the same units whereas Fig. - 4 depicts perfect negative correlation where if one value increases in 5 units, the other variable decreases in the same units. Fig. - 5 shows that there is no correlation between the two variables.

Correlation Coefficient (r)

Correlation coefficient is calculated to study the extent or degree of correlation between the two variables. The correlation coefficient ranges between -1 to +1 and is denoted by 'r'. A correlation of zero indicates no association whereas a correlation of 1 indicates perfect association. The sign of correlation coefficient provides information on the type of association between the variables. If it is positive, then the high values of one variable will be associated with high values of

the other variable and if the correlation coefficient is negative, then low values of one variable are associated with high values of other variable. Thus Fig. - 3 & 4 have correlation coefficient value as +1 and -1, whereas the correlation coefficient in Fig. - 5 is zero. Fig. - 1 has r lying in the range of 0 to 1 and Fig. - 2 has r lying between -1 to 0. We have two types of correlation depending on whether the variables are continuous variables and joint distribution is following normal distribution or not.

Fig. - 1

Fig. - 2

Fig. - 3

Fig. - 4

Fig. - 5

Karl Pearson Correlation Coefficient : This correlation coefficient works when variables are continuous variables and joint distribution is following normal distribution. The Karl Pearson's correlation coefficient (r) also called as 'Product moment correlation' is given by the following formula.

$$r = \frac{\sum (x - \bar{x})(y - \bar{y})}{\sqrt{\sum (x - \bar{x})^2 \sum (y - \bar{y})^2}}$$

The numerator is the sum of cross products about the mean whereas the denominator is the square root of the product of the sum of squares of deviation about the mean for each of the two variables. As an example, consider two variables x and y as given below. We find out whether the two variables are correlated to each other or not.

x	6	8	12	15	18	25	24	28	31	20
y	10	12	15	15	18	25	22	26	28	18

Mean of x (\bar{x}) = 18.7 Mean of y (\bar{y}) = 18.9

$$r = \frac{\sum (x - \bar{x})(y - \bar{y})}{\sqrt{\sum (x - \bar{x})^2 \sum (y - \bar{y})^2}}$$

Numerator = $\sum (x - \bar{x})(y - \bar{y}) = 459.7$

Denominator = $\sqrt{\sum (x - \bar{x})^2 \sum (y - \bar{y})^2} = 466.48$

Thus correlation coefficient $r = 459.7/466.48 = 0.98$. There is very good positive correlation between x and y (Fig. - 6).

Fig. - 6 : Scatter diagram of the two variables

Spearman correlation coefficient : Sometimes the variables are not normally distributed but are ranked in order, then the appropriate correlation measure is Spearman rank correlation coefficient. The Spearman correlation coefficient also ranges from -1 to +1 and is interpreted in the same way as the 'Pearson correlation coefficient'. The Spearman correlation coefficient (r) is given as follows.

$$r = 1 - \frac{6(\sum d^2)}{n(n^2 - 1)}$$

Where $\sum d^2$ is the total of the squares of the difference of corresponding ranks and n is the number of pairs of observations.

Example : Suppose a nurse doing a preliminary assessment of the condition of the patients in the ward, ranks the patients as per two variables of socio economic status and IQ. The data is given in Table - 1.

$$\sum d^2 = 68$$

The correlation coefficient is given as

$$r = 1 - \frac{6(\sum d^2)}{n(n^2 - 1)}$$

Thus,

$$r = 1 - \frac{6(68)}{9(81 - 1)} = 1 - 0.567 = +0.433$$

Table - 1

Patient No.	Ranks as per socio-economic class	Rank as per IQ level	Difference in the ranks d	d ²
1	1	4	-3	9
2	2	2	0	0
3	3	3	0	0
4	4	9	-5	25
5	5	5	0	0
6	6	1	5	25
7	7	7	0	0
8	8	8	0	0
9	9	6	3	9

The interpretation of r is shown in Table - 2.

Table - 2 : Interpretation of r

Value of r	Relationship
If $0 < r < \pm 0.25$ Between 0 and ± 0.25	Little or no linear relationship.
If $\pm 0.25 \leq r < \pm 0.50$ Between ± 0.25 and ± 0.5	Fair degree of linear relationship
If $\pm 0.50 \leq r < \pm 0.75$ Between ± 0.5 and ± 0.75	Moderate to good linear relationship.
If $r \geq \pm 0.75$ More than ± 0.75	Very good linear relationship.

Coefficient of determination : Coefficient of determination is defined as square of correlation coefficient. It is the amount of variation in the dependent variable accounted for by the independent variable. In other words, if coefficient of correlation (r) between age and blood pressure is 0.8 then coefficient of determination $r^2 = 0.64$. This is interpreted as 64% of variability in blood pressure is accounted by age whereas the remaining 36% is not by age. Other factors such as weight, diet and exercise may account for the 36% variability in blood pressure.

Hypothesis Testing about Population Correlation Coefficient

The general steps in testing of hypothesis dealing with population correlation coefficient denoted by ρ are same as discussed in hypothesis testing dealing with mean, proportion or difference between means or proportions. The first step is to formulate the null and the alternative hypothesis. In this situation the hypothesis is stated as follows.

$H_0: \rho = 0$ (No relationship between the two variables)

$H_1: \rho \neq 0$ (There exist relationship between the two variables)

In this case the test statistic is given as follows.

$$\text{Test Statistic} = \frac{r\sqrt{(n-2)}}{\sqrt{(1-r^2)}}$$

Where r is sample correlation coefficient and n is sample size.

Under null hypothesis, the test statistic follows student's t distribution with $(n-2)$ degrees of freedom. We compare the calculated test statistic value with the table value at specified α significance level for two tailed hypothesis. If calculated value is smaller than the table value, we accept the null hypothesis otherwise reject it.

Regression Analysis

As stated earlier, if the objective is to quantify and describe the existing relationship with a view of prediction, we use regression analysis. In regression we assume one variable generally y as dependent variable and x as independent variable. Regression analysis determine the form of the relationship by a line which best fits the data. This line is called as 'Regression Equation'. This regression line which is unique is determined by the 'Least Square Method'. The principle of least square method is that the sum of squares of deviations of the observed points about the line is minimum. The deviation is obtained by measuring the distance from observed point to the line.

The equation of the straight line is given by $Y = a + bx$

Where 'a' is the intercept and 'b' is the slope of the line which measures the amount of increase or change in y for unit change in x , whose estimates are found using the normal equations given as follows.

$$\Sigma y = an + b\Sigma x \text{ and } \Sigma xy = a\Sigma x + b\Sigma x^2$$

Solving these two equations we get the estimate of a and b as follows.

$$a = \bar{y} - b\bar{x} \text{ and } b = \frac{\Sigma(x - \bar{x})(y - \bar{y})}{\Sigma(x - \bar{x})^2}$$

Using the values of a and b , the dependent variable y for given x value can be predicted by substituting these values in the regression equation.

Summary

Often in medical research, it is desirable to analyse the relationship or association between two quantitative (i.e. continuous, discrete or numerical ordinal) variables. The nature and strength of relationship that exists is examined by regression and correlation analysis. When the objective is to determine association or the strength of relationship between two such variables, we use correlation coefficient (r). If the objective is to quantify and describe the existing relationship with a view of prediction, we use regression analysis. Before we develop a mathematical model describing relationship we should first plot the scatter diagram of the variables. A scatter plot is a visual description of the relationship between two continuous variables.

Correlation Coefficient (r) : We have two types of correlation depending on whether the variables are continuous variables and joint distribution is following normal distribution or not.

Pearson Correlation Coefficient: This correlation coefficient works when variables are continuous variables and joint distribution is following normal distribution. The correlation coefficient ranges between -1 to $+1$. A correlation of zero indicates no association whereas a correlation of 1 indicates perfect association. The sign of correlation coefficient provides information on the type of association between the variables. If it is positive then high values of one variable will be associated with high values of the other variable and if the correlation coefficient is negative then low values of one variable are associated with high values of other variable.

Spearman correlation coefficient : Sometimes the variables are not normally distributed but are ranked in order then the appropriate correlation measure is Spearman rank correlation coefficient. The Spearman correlation coefficient also ranges from -1 to $+1$ and is interpreted in the same way as the Pearson correlation coefficient.

Coefficient of determination : Coefficient of determination is defined as square of correlation coefficient. It is the amount of variation in the dependent variable accounted for by the independent variable. In other words, if coefficient of correlation (r) between age and blood pressure is 0.8, then coefficient of determination $r^2 = 0.64$. This is interpreted as 64% of variability in blood pressure is accounted by age whereas the remaining 36% is not by age. Other factors such as weight, diet and exercise may account for the 36% variability in blood pressure.

Regression Analysis : If the objective is to quantify and

describe the existing relationship with a view of prediction, we use regression analysis. In regression we assume one variable generally y as dependent variable and x as independent variable. Regression analysis determine the form of the relationship by a line which best fits the data. This line is called as 'Regression Equation'. This regression line which is unique is determined by the least square method.

Study Exercises

Long Question : (1) What is correlation? Distinguish between positive correlation, negative correlation and zero correlation by means of scatter diagrams with suitable examples (2) Describe how relationship between two variables can be found out? Discuss correlation coefficient.

Short Note : Regression and correlation.

MCQs

- The scatter plot is used to display (a) Causality (b) Correlation (c) Power (d) Type II error
- The correct statistical procedure for studying the association between an exposure and an outcome variable when both of them are measured on a continuous scale is (a) Chi square test (b) Pearson's correlation coefficient (c) ANOVA (d) t-test
- In regression equation $Y = a + bx$, b represents (a) Intercept on Y axis (b) Slope of the line (c) Intercept on X axis (d) None of the above
- If correlation coefficient $r = 0$ it implies (a) Perfect positive linear relationship (b) Perfect negative linear relationship (c) No linear relationship (d) None of the above
- When the variables are not normally distributed but are ranked in order then the appropriate correlation measure is (a) Spearman rank correlation coefficients (b) Karl Pearson product moment correlation (c) Wilcoxon sign test (d) None of the above.

Answers : (1) b; (2) b; (3) b; (4) c; (5) a.

Statistical Exercises

- A researcher collected weights (kgs) and heights (cms) of the 15 children of second standard as 10, 20, 11, 12, 12, 13, 11, 14, 13, 13, 15, 11, 16, 17, 18. If the heights of the same students are 95, 110, 98, 100, 102, 102, 99, 103, 104, 103, 106, 99, 108, 108, 109. Can you conclude from the data that there is a significant linear relationship between age and height of children? Let level of significance be 0.05. Estimate the height of the children for weight of 12kg. (Answer : $r = 0.955$, $T.S. = 11.6$ highly significant ,height = 103cm)
- Suppose the heights and weights of a group of people are approximately normally distributed with mean weight of 140lb, $SD = 12lb$, mean ht = 68 inches, $SD = 4$ inches and correlation coefficient $2/3$. If an individual is found to be 66 inches tall. What is his expected weight? (Answer : 136)

Seema R. Patrikar

In the simple regression discussed in the previous chapter, we had considered only two variables one being a dependent variable and the other being the independent variable. From the simple regression equation, we predict the value of the dependent variable on the basis of independent variable. Many times the researcher may come across situations where he/she is dealing with more than one independent variable. For example, the researcher may be interested in finding out as to how much change is likely to occur in serum cholesterol level (outcome or dependent variable) following changes in age, body weight, alcohol intake, calories consumed per day, and calories spent per day in physical exercise. Thus, we have a set of 5 independent variables, all of which are likely to affect the outcome variable by themselves. Such situations where more than one independent variable and one dependent variable are available and the aim is to predict dependent variable on the basis of many independent variables, the technique used for analysis is called as '*Multivariate Regression Analysis*'.

We will consider three types of situation under multiple regression situations. Multiple linear situation, logistic regression and cox regression.

Multiple Linear Regression Model : Multiple regression is the extension of simple linear regression, except that in this regression model, we have more than one independent or explanatory variables, and the outcome (dependent) variable is continuous or discrete numerical scale. When there is one outcome (dependent) variable which is measured on a "Numerical continuous" or else "Numerical discrete" Scale; and there are more than one predictor (independent) variables, this model is used.

In our example on serum cholesterol, there was one outcome variable which was measured on a continuous numerical scale (mg/dl). There were 5 independent variables, with X_1 denoting body weight in Kg, X_2 denoting age in years and so on till the n^{th} (5th variable) viz, exercise energy, denoted by X_5 . Such a situation when there is a single outcome variable which is measured on a numerical continuous or numerical discrete scale, and there are more than one independent variables, is known as "*Multiple Linear Regression Analysis*".

The advantage of multiple linear regression is that the result gives the β coefficient which indicates the change in the

dependent variable for the change in independent variable. For example, if after carrying out multiple linear regression if the beta coefficient for weight is 2.1, it indicates that for every kilogram increase in weight, the serum cholesterol is likely to increase, on an average, by 2.1 mg/dl. Along with the coefficients, the analysis also gives the 95% confidence interval, the significance value for each variable and the regression equation.

Multiple Logistic Regression Model : Another very common situation in epidemiology and medical research is when the outcome variable is measured on a “dichotomous scale”, of “either/or”; for example, the outcome variable could be “either having a disease (cases) or not having that disease (controls)”; or “either developed the disease or did not develop”; or “either survived or died” and so on. In such situations when the outcome variable is measured on a dichotomous scale and the independent (predictor or exposure) variables, which are at least two or more, are measured either on numerical continuous or numerical discrete or categorical dichotomous scale, the regression analysis procedure is “Multiple logistic regression”. Logistic regression is widely used in medical science since the medical researcher many a times is interested in presence or absence of a condition or disease and also the coefficients derived from logistic regression can be interpreted as odds ratio.

The analysis under logistic regression gives the β coefficient along with the odds ratio and 95% confidence interval for odds ratio. The beta coefficients (β) in multiple logistic regression are interpreted differently as compared to beta coefficients in multiple linear regression. In multiple logistic regression, the beta-coefficients represent the “natural logarithm of the risk of the outcome due to that particular independent variable, following one unit change in the independent variable, or else as compared to the baseline category, and this estimate is, of course, adjusted for the confounding effect of all other independent variables that have put into the analysis.

Since the beta coefficients are the natural logarithm of the “risk”, we will have to exponentiate them to get the estimate of risk. This can be very easily done with a “Scientific calculator”. In any case, it is calculated directly in the results under the heading of “Odds Ratio (OR)”. Thus, if the beta coefficient for age is 0.037; then the odds ratio is 1.04, which is written under the column Odds Ratio (OR). The interpretation of OR is that it represents the independent, adjusted estimate of risk of the outcome, due to “particular level” of the independent variable, as compared to its baseline category (and not the immediately lower category).

Cox Regression Model : In the multiple regression and logistic regression models, we have the outcome or the dependent variable as continuous and dichotomous respectively. Apart from this, when the researcher is dealing with situations where the dependent or outcome variable is survival data i.e. time-to-event data or censored data, the regression method applied is called as ‘Cox Regression Model’. It is also called as ‘Proportional Hazard Regression’ as it makes use of the hazard function. The hazard function is defined as a conditional probability that an event will occur at time t , with the condition that the event has not occurred until time t (event free survival). Hazard function

is denoted by $h(t)$, which is the risk to death at time t , given survival up to time t . In other words, it is the probability that an individual dies at time t , conditional on having survived to that time. As in multiple and logistic regression when the analysis is carried out, it gives the regression coefficients, the hazard ratio estimates and the confidence interval.

Summary

Situations where more than one independent variable and one dependent variable are available and the aim is to predict dependent variable on the basis of many independent variables the technique used for analysis is called as Multivariate regression analysis. Various regression models are simple, multiple, logistic and cox proportional models.

Simple Linear Regression : In simple model we have one outcome or dependent variable associated with only one independent variable. The line describes the linear relationship between the variables. We predict the dependent variable by a straight line equation.

Multiple Linear Regression : Multiple regression is the extension of simple linear regression except that in this regression model we have more than one independent or explanatory variables, and the outcome (dependent) variable is continuous or discrete numerical scale.

Multiple Logistic Regression: In logistic regression, the outcome variable or dependent variable is dichotomous (Died/Alive, Yes/No, Present/Absent). Logistic regression is widely used in medical science since the medical researcher many a times is interested in presence or absence of a condition or disease and also the coefficients derived from logistic regression can be interpreted as odds ratio.

Cox Regression Model : When the researcher is dealing with situations where the dependent or outcome variable is survival data i.e. time-to-event data or censored data, the regression method applied is called as Cox Regression model. It is also called as Proportional Hazard regression as it makes use of the hazard function. The hazard function is defined as a conditional probability that an event will occur at time t , with the condition that the event has not occurred until time t (event free survival).

Study Exercises

MCQs

1. Multivariate analysis is appropriate when (a) Bivariate analysis fails to reveal statistical significance (b) More than one independent variable is predicting the dependent variable (c) Multiple hypothesis are being tested (d) None of the above
2. When there is a single outcome variable which is measured on a numerical continuous or numerical discrete scale, and there are more than one independent variables statistical test used is (a) Multiple linear regression analysis (b) Multiple logistic regression analysis (c) Cox regression analysis (d) None of the above
3. β coefficient in multiple linear regression indicates (a) The change in the dependent variable for the change in independent variable (b) The change in independent

- variable (c) Variability amongst independent variability (d) All of the above.
4. In situations when the outcome variable is measured on a dichotomous scale and the independent (predictor or exposure) variables are measured on numerical continuous or numerical discrete, the regression analysis procedure is (a) Multiple linear regression analysis (b) Multiple logistic regression analysis (c) Cox regression analysis (d) None of

- the above
5. When the dependent or outcome variable is survival data, the regression method applied is (a) Multiple linear regression analysis (b) Multiple logistic regression analysis (c) Cox regression analysis (d) None of the above

Answers : (1) b; (2) a; (3) a; (4) b; (5) c.

Life Tables and Survival Analysis

Seema R. Patrikar

A life table is a life history of a hypothetical group or cohort of people as it diminishes gradually by deaths. The concept of life table was first given by John Graunt when he published a elementary life table on his collected data '*Bills of Mortality*'. Edmund Halley in 17th century developed a life table for the city of Breslau.

Life tables find numerous applications like finding the longevity of life, expectancy of life, for calculating the insurance premiums by the insurance companies and actuaries. It is also widely used by demographers and public health workers for studying the mortality patterns because of certain disease and comparing survival patterns of different communities. It is useful in projecting future population growth.

Types of life tables : There are various types of life tables. It is mainly categorized into different types depending on the reference year of the life table. According to the reference year, life tables are of two types *current life table* and *cohort or generation life table*. A current life table is based on the mortality experience of the community for a short period of time such as one year i.e. a hypothetical population is considered and this population is exposed throughout their entire lifetime to the average mortality rate. The cohort life table is based on the mortality experience of a birth cohort. Thus it is constructed

from the mortality records of individuals followed from the birth of the first to the death of the last member of a group. Life tables are also segregated into two different types on the basis of presentation into complete life tables and abridged life tables. In complete life table information is given for every year of age from birth to the last age whereas in abridged life tables information is given for age intervals such as x to $x+5$ years.

Description of life table: Before we discuss the various columns of the life table we will consider certain basic assumptions required for the preparation of a life table. The first basic assumption is that the cohort is closed for migration in or out. Hence the change in the cohort is only due to death. People die at each age according to a fixed schedule. The cohort originates from a standard number of births (such as 1,000, 10,000, 100,000) called 'radix' of the life table. The cohort normally contains members of only one sex. (It is possible to construct life tables for both sexes combined). The various columns of the life table are shown in Table - 1.

The first column gives the age interval x to $x+1$. Column 2 gives the probability of dying between x to $x+1$. It is denoted by q_x . It represents the probability that a person at his x^{th} birthday will die before reaching his $(x+1)^{\text{th}}$ birthday. These q_x values are the basic values from which the other columns of life tables are computed. The complementary event i.e. the probability of survival is $p_x = 1 - q_x$.

Column 3 gives the number alive at the beginning of the age interval which is normally taken as 1000 or 10,000 or 100,000. This starting number is called as the radix of life table.

Table - 1 : Life Table

Age interval (x to $x+1$)	Probability of dying in age interval for those alive at the beginning of the interval (q_x)	Number alive at the beginning of the interval (l_x)	Number dying in the interval (d_x)	Number of persons living in interval (L_x)	Number of persons lived beyond age X (T_x)	Average number of years of life remaining (e^o_x)
(1)	(2)	(3)	(4)	(5)	(6)	(7)

Thus $l_x = l_{x-1} - d_{x-1}$

Column 4 gives the number of deaths d_x in the interval x to $x+1$ which is calculated as the product of number of survivors at age x multiplied by q_x .

i.e. $d_x = l_x * q_x$

Column 5 which gives the number of person years lived between age x to $x+1$ is assumed to be the average of l_x and l_{x+1} . But it is not logical to use average as deaths are not evenly distributed in the complete life. (More deaths in childhood and old age) Thus at young ages L_0 is estimated as follows

$$L_0 = \alpha.l_0 + (1 - \alpha)l_1$$

where α is average age at deaths of those dying below age 1 or half of the proportional post neonatal deaths.

For L_2 and ages greater than 2,

$$L_x = \frac{1}{2}(l_x + l_{x+1})$$

Column 6 depicts the total number of years lived beyond age x . In other words it is the total number of person-years lived from age x onwards. Thus T_x is obtained by summing L_x column from the bottom upwards.

$$T_x = L_x + T_{x+1}$$

Column 7 is the last column of the life table which gives the expectation of life at age. It represents the average number of years lived after the age x . It is calculated by taking the ratio of T_x and l_x

Thus,

$$e^0_x = T_x / l_x$$

Survival Analysis

The various statistical situations that we have considered till now relate to “risk” or to “prognosis” or treatment related outcomes. However, sometimes the research question may be more interesting and somewhat different from the above mentioned situations. For example the question could be “what are the chances that a case of HIV infection acquired due to blood transfusion would be surviving at the end of 6 years?”; or, “what are the chances that a lady who has been diagnosed as cervical cancer by early screening and is treated would be alive at the end of 5 years?” or in general how long people with a life threatening disease survive following treatment. The analytical methods used to draw inferences regarding the chances of surviving/dying/getting cured/getting diseased (in short, the chances of developing the “outcome of interest”), over the various points of time are answered by “survival analysis”. Thus survival analysis deals with situations where the outcome is dichotomous and is a function of time.

Suppose patients suffering from a life threatening disease ‘A’ are treated with two treatment modalities and followed over specific time period say 5 years. The study continues during which any of the following three situations may occur.

1. The event of interest (death of patient due to disease ‘A’) has occurred.
2. The patient is lost to follow up, from death due to cause other than disease ‘A’ or has left the study by moving out of area etc.

3. The event of interest (death of patient) does not occur till the end of study. i.e. the patient is alive when the study is terminated.

The time from enrollment to experiencing one of the above situations is called survival time. In situations 2 and 3 the survival time of patients is called as ‘Censored Survival Time’. Thus all those who achieve the outcome of interest are “uncensored” data while those who do not achieve the outcome are “censored” data (Fig. - 1).

Visual representation of the survival experience of patients against time is represented by ‘Survival Curves’. Thus survival curves show the percentage surviving versus time. The following is a graph depicting survival curve (Fig. - 2).

Most real life survival curves (Fig. - 3) usually are shown as staircase curves with a step down each time there is a death. This is because the survival curve represents the actual experience of a particular group of people. At the moment of each death, the proportion of survivors decreases.

Comparison between two survival curves : The curves may compare results from different treatments as in the graph shown in Fig. - 4. If one curve is continuously “above” the other, as with these curves, the conclusion is that the Treatment A associated with the higher curve was more effective for these patients than Treatment B. The two lines represent the two “survival curves”.

Fig. - 3 : Real Life Survival Curve

Fig. - 4 : Comparison between Two Survival Curves

The vertical (or Y) axis of the graph is the percentage of patients in the group surviving. The horizontal (or X) axis represents time, starting from the time of diagnosis, or the time that treatment starts. As time goes on, some of the patients die and the curve steps down each time this happens. Most of the times these curves flatten out at the ends suggesting that some patients in each of the two groups are cured or at least are long term survivors, though the odds of that are obviously much greater for the upper curve.

There are number of methods of analyzing a survival data. Life table method accounts for differences in follow-up time and also account for changes in survival rate over time. It breaks the follow-up period of the study into intervals and then calculates the proportion of people at risk at the start of each interval who survive until the start of the next interval. There are two methods to calculate life tables viz. *the Actuarial method and the Kaplan-Meier method*. The basic difference between the two methods is the interval classification. The actuarial method adopts fixed class intervals which are most often year following the end of treatment given. The Kaplan-Meier method uses the next death, whenever it occurs, to define the end of the last class interval and the start of the new class interval. In both the methods the statistical test applied to test the null hypothesis that there is no difference in survival rates of the patients treated with two different treatment modalities (comparing two survival curves) is the *Log-Rank Test*. Log-Rank test does not control for confounding. To control for confounding we use

another test called as '*Cox Proportional Hazards Regression*' (which is discussed in chapter on advanced multivariate analysis). The mathematical calculation of the two tests is not discussed in detail but we only need to know that in medical research articles when we see Log-Rank test applied, a crude test for difference in survival curves was conducted whereas when we come across Cox proportional hazard model then the comparison in survival curves was conducted after controlling for confounding. Methods of working out survival curves and statistical testing by statistical software are explained in the EPI INFO section.

Summary

A life table is a life history of a hypothetical group or cohort of people as it diminishes gradually by deaths. The concept of life table was first given by John Graunt when he published a elementary life table on his collected data 'Bills of Mortality'. Edmund Halley in 17th century developed a life table for the city of Breslau. Life tables find numerous applications like finding the longevity of life, expectancy of life, for calculating the insurance premiums by the insurance companies and actuaries. It is also widely used by demographers and public health workers for studying the mortality patterns because of certain disease and comparing survival patterns of different communities. It is useful in projecting future population growth. There are various types of life tables. It is mainly categorized into different types depending on the reference year of the life table. According to the reference year, life tables are of two types current life table and cohort or generation life table. A current life table is based on the mortality experience of the community for a short period of time such as one year i.e. a hypothetical population is considered and this population is exposed throughout their entire lifetime to the average mortality rate. The cohort life table is based on the mortality experience of a birth cohort. The various columns of the life table are age interval, probability of dying in age interval, number of people alive at the beginning of the interval, number of people dying in the interval, number of persons living in the interval, number of persons who lived beyond particular age and average number of years of life remaining.

The analytical methods used to draw inferences regarding the chances of surviving/dying/getting cured/getting diseased (in short, the chances of developing the "outcome of interest"), over the various points of time are answered by "survival analysis". Thus survival analysis deals with situations where the outcome is dichotomous and is a function of time. Survival analysis makes use of the life tables. In survival analysis data is transformed into censored and uncensored data. A patient who is lost to follow up, from death due to cause other than disease 'A' or has left the study by moving out of area etc. and the event of interest (death of patient) does not occur till the end of study. i.e. the patient is alive when the study is terminated are situations of censored data. Patients in whom the event of interest (death of patient due to disease 'A') has occurred are called uncensored data. There are number of methods of analyzing a survival data. Life table method accounts for differences in follow-up time and also account for changes in survival rate over time. It breaks the follow-up period of the study into intervals and then calculates the proportion of people

at risk at the start of each interval who survive until the start of the next interval. There are two methods to calculate life tables like Actuarial method and the Kaplan-Meier method.

Study Exercises

Short Notes : Survival analysis, life table

MCQs

1. The starting numbers in life table is known as (a) Radix (b) Radius (c) Origin (d) Cohort
2. The analytical methods used to draw inferences regarding the chance of developing the "outcome of interest" over the various points of time is (a) Multiple logistic regression (b) Multiple linear regression (c) Survival analysis (d) None of the above
3. In survival analysis all those who achieve the outcome of interest are called as (a) Censored data (b) Uncensored data (c) Survival data (d) None of the above
4. The statistical test applied to test the null hypothesis that there is no difference in survival rates of the patients treated with two different treatment modalities (comparing two survival curves) is (a) Log-Rank Test (b) Cox regression analysis method (c) Kruskal wallis test (d) Multiple logistic regression test.

5. Figure given below shows the survival curves of treatment A and treatment B. From these curves it may be inferred that (a) Treatment A is more effective in prolonging life (b) Treatment A is less effective in prolonging life (c) Both treatment are equally effective in prolonging life (d) None of the above .

Answers : (1) a; (2) c; (3) b; (4) a; (5) a.

RajVir Bhalwar & Seema R. Patrikar

We had mentioned during our discussion on confounding, that one of the methods of making "adjustments" for the potential confounding effect of a variable, during the stage of analysis, is by "standardisation". "Standardisation of rates is sometimes used for controlling the effect of potential confounders during the analysis stage of large scale field research work, though for the usual epidemiological and medical research, such methods as Mantel-Haenszel stratified analysis or multiple regression analysis are definitely preferable.

Let us say, if you were to examine two coloured cards, one having a colour just a marginal shade lighter than "perfect yellow" and the other just a marginal shade darker than perfect yellow, you may find it very difficult to give your opinion as to which is lighter and which is darker of the two. However, your decision would be much better if we interposed, between the two cards, a "standard" card of "perfect yellow colour". This is an every day experience in life that comparison between two characteristics is always better if it is made against a preset, common standard.

On the similar lines, if you were to compare the overall (crude) death rate of a developing country with that of an affluent country, the overall death rate of the developing country would appear to be higher; and, it may be actually higher, or maybe it appears higher because a developing country has a higher proportion of infants and young children as compared to a developed country, and it is a known fact that mortality is much more among infants and young children. Thus, the observed difference as regards the "outcome" (crude death rate) due to the suspected "exposure" (being from developing or from developed country) has been thrown into a "confusion" by a third variable (the "age-structure") which is related to both, the "exposure" (higher proportion of younger persons in developing countries) as well as the "outcome" (higher death rate among younger persons). Thus, for giving a correct verdict in this comparison, we will have to compare the death rates in the two countries against a common standard. This process is called as Standardisation, and, depending on the choice of standard used, the method could be "direct Standardisation" or "indirect Standardisation".

Direct Standardisation

Let us start with a hypothetical example. While comparing the death rate among children up to 15 years age group in a well developed influential province with the death rate among

children up to 15 years in a developing, poor provincial area, we found that the crude (overall) death rates among this age group were 31.3 per 1000 in the developing province and 27.5 in the well developed province. We would thus conclude that the death rate in the developing province is (31.3 / 27.5), i.e. 1.14 times higher. However, to a certain extent, this may be because of the confounding effect of age structure, with the developing province having a higher proportion of infants and toddlers, among whom the death rate, in any case, would be higher.

For removing the confounding effect of age structure, by direct Standardisation, we will, first of all, make suitable “subgroups” according to the confounding variable. Thus, in our example, we will make three groups, i.e. age 0 to 4 years, 5 to 9 years, and 10 to 14 years. These subgroups should be decided after careful medical and epidemiologic consideration of confounding variable. Next, for undertaking direct Standardisation, we must have the information as regards *at least* the following two aspects:-

a) The category - specific mortality rates (or, morbidity, if the outcome is morbidity and not mortality) of the two populations being compared. Thus, in our example, we should have the information as regards the “age group specific mortality rates per 1000 persons” for the age groups 0 to 4, 5 to 9 and 10 to 14 years, preferably for both the populations but *at least* for one of the populations.

b) The “age structure” of a “standard population” (usually the national population, or else, any other populations whose age structure is known)

Let us say, we had information regarding age group specific mortality rates of the provinces and we also knew the national population structure based on the census figure, which we decided to take as a “standard population”. The information which we had, is presented as in Table - 1.

Now, in the direct method of Standardisation, we will calculate the deaths that would be expected to occur in each age group of the “standard population” if the death rate of the two different populations were to apply separately on such standard population. We would add up the deaths so calculated for each subgroup and calculate the overall, standardised death rates, separately for the two populations.

Let us first of all calculate the deaths that would have been expected to occur in the various age groups of the standard population, if the age specific death rates of the developing province were to apply as follows :

Expected death rate

$$0-4 \text{ years} = (60 \div 1000) \times 27000000 = 1620000$$

$$5-9 \text{ years} = (20 \div 1000) \times 25000000 = 500000$$

$$10-14 \text{ years} = (5 \div 1000) \times 24000000 = 120000$$

Thus, total deaths = 1620000+500000+120000 = 2240000 and, age standardised mortality rate for developing province, (as standardised for the standard population).

$$= \frac{\text{Expected total deaths in standard population}}{\text{Total standard population}} \times 1000$$

$$= \frac{2240000}{76000000} \times 1000 = 29.47 \text{ per } 1000$$

Next, we shall calculate the expected deaths in the various age groups of standard population if the death rate of the developed province were to apply as follows :

$$0-4 \text{ years} = (55.6 \div 1000) \times 27000000 = 1501200$$

$$5-9 \text{ years} = (18 \div 1000) \times 25000000 = 450000$$

$$10-14 \text{ years} = (4 \div 1000) \times 24000000 = 96000$$

$$\text{Total deaths} = 2047200$$

Thus age standardised mortality rate for developed province

$$2047200 \div 76000000 \times 1000 = 26.94 \text{ per } 1000$$

Thus, after Standardisation, the mortality in developing province is 29.47 / 26.94 = 1.07 times and not 1.14 times higher as was apparent when crude death rates were being compared.

The Choice of Standard Population

Please note one point - the direct age standardised mortality rates of the two provinces have come out as 29.47 and 26.94 per 1000 respectively. Now, this *does not mean* that mortality rates in the two provinces are actually 29.47 and 26.94 (and not 31.3 and 27.48 as calculated without Standardisation). The age standardised mortality rates so calculated are only for the purpose of comparison, to get an idea of the “comparative mortality” between the two provinces after “adjusting” for the confounding effect of age structure. Thus, these standardised

Table - 1

Age group (Years)	Developing Province			Developed Province			National Population In 1000 (*)
	Total population	Total deaths	Age specific death rate per 1000 [(c/b) X 1000]	Total population	Total deaths	Age specific death rate per 1000 [(f/e) X 1000]	
(a)	(b)	(c)	(d)	(e)	(f)	(g)	(h)
0-4	12000	720	60.0	9000	500	55.6	27000
5-9	10000	200	20.0	8500	153	18.0	25000
10-14	8000	40	5.0	8500	34	4.0	24000
Total	30000	940	31.3	25000	687	27.48	76000

* Multiply by 1000 to get actual value

rates are basically imaginary or hypothetical figures, calculated only to make comparisons between two (or more) populations which may differ according to their age structure. This concept is important in interpreting the results of large scale health statistics. For example, if you find a table showing “age standardised mortality rates in our country for 1990”, it does not mean that these standardised rates represent the ultimate truth; it simply indicates the overall mortality rate that was expected to occur in our national population with a age structure that was there in 1990, if it was subjected to the subgroup mortality rates that are occurring now, at the time of this study. In the words of Sir A B Hill, the eminent biostatistician, standardised rates are more of a “fiction” meant only for making comparisons between two populations and not a reality. With this background, one can use any population as the “standard population”. One more thing that the field epidemiologist must remember is that “standardised” mortality or morbidity rates, whether directly or indirectly, standardised, cannot replace the “specific death/disease rates” (e.g. age - specific or sex specific death/disease rates). Comparisons of these age or sex specific death/disease rates will provide more meaningful information about the distribution and putative risk factors of the diseases.

Indirect Standardisation

From what we discussed in the preceding paragraphs regarding direct Standardisation, a different situation may often arise, in that we may not be knowing the age group specific death rates about any one of the population composition in each age group of both the provinces and the total number of deaths in the 2 provinces as in Table - 2.

Age Group	Total population	
	Developing Province	Developed Province
0-4	14000	8000
5-9	13000	9000
10-14	13000	11000
Total	40000	28000
Total deaths	371	110
Crude death Rate	$(371/40000) \times 1000$ = 9.28 per 1000	$(110/28000) \times 1000$ = 3.95 per 1000

Now, in this case, we will have to find out the “age group specific death rates” of a third, standard population. We can use the “national age group specific death rates” to calculate the overall “expected” deaths in each population. Let us say, hypothetically, the national age specific death rates per 1000 population available to us from census information are 15, 3.5 and 1.5 per 1000 for the age groups 0-4, 5-9 and 10-14 years respectively. The overall expected number of deaths in each population is calculated as

\sum (age specific mortality rate x population in that age group)
Thus, for the developing province, the “expected deaths”

$$[(15 \div 1000) \times 14000] + [(3.5 \div 1000) \times 13000] + [(1.5 \div 1000) \times 13000] = 210 + 45.5 + 19.5 = 275$$

Similarly, for the developed province, the “expected” deaths.

$$[(15 \div 1000) \times 8000] + [(3.5 \div 1000) \times 9000] + [(1.5 \div 900) \times 11000] = 120 + 31.5 + 16.5 = 168$$

Now, the next step is to calculate the “Standardised Mortality Ratio” (SMR) for each population as

$$SMR = \frac{\text{Observed No. of deaths in the population}}{\text{Expected No. of deaths in that population}}$$

Where observed deaths means the total number of deaths that have actually been recorded in that population. Thus, SMR for developing province $371 \div 275 = 1.35$ and SMR for developed province $110 \div 168 = 0.65$.

A SMR of more than one, as has been calculated for the developing province, indicates that the mortality rate is higher than the standard population and vice versa. Thus, in our example, the developing province has a higher, and the developed province has a lower mortality rate, as compared to the “standard population”. Thus, in indirect Standardisation, we make “relative comparisons” (as the example of inserting perfect yellow cards of different shades given earlier in this chapter). On the other hand, direct Standardisation helps us in making “absolute comparisons”. For this reason, some epidemiologists use the term “changing base method” for indirect Standardisation and “fixed base method” for direct Standardisation.

Summary

The crude death rate (CDR) could be different among 2 communities simply because their age structures are different. Hence to scientifically compare the 2 CDRs after removing the confounding effect of age structure on mortality, we use the process called as Standardisation. Standardisation can be done by two methods (i) Direct method and (ii) Indirect method.

This is simple and preferred method to calculate the age adjusted mortality rates. To perform a direct Standardisation, one has to first select a standard population. This population is arbitrary, although conventionally one uses either the World Standard Population produced by the World Health Organization, or a census population for the country in which the work is being conducted. Next, one computes the age-specific rates within the study group. Then, one multiplies these age specific mortality rates by the number of people in that age group in the standard population to get the “expected” number of deaths in each age group in the standard population. These expected counts are summed and divided by the total population size of the standard population to yield the direct standardised rate. In other words the standardised crude death rate in direct method is the crude death rate experienced by standard population if it was exposed to the age specific death rate of the study population.

Indirect Standardisation uses the standard population to provide age-specific rates i.e. the age specific mortality rates of the standard population are applied to the age structure of the study population. Within each age stratum, one multiplies the age specific mortality rates of the standard population by

the number of people in that age group in the study population to determine the “expected” number of deaths that would have been expected in each age group of the study population, had the age specific mortality rates of the standard population been applicable to them. These expected numbers are added up across all age groups. We now divide the observed number of deaths by the expected number of deaths. This ratio is multiplied with the crude death rate of the standard population to yield the Standardised Mortality Rates. In other words in indirect Standardisation, one computes the number of cases of deaths (or disease) that would have been expected if the death (or disease) rates from the standard population had applied in the study population. This is also known as standardised mortality or morbidity rate (SMR) and is quite commonly used in Occupation Health Studies.

Study Exercises

MCQs

- All are true regarding direct Standardisation except
 - Age specific death rate is required for comparison
 - Age composition of the standard population is required
 - Vital statistics are required
 - Without knowledge of the age composition, the two populations can be compared.
- Which method is used for controlling the effect of potential confounders during the analysis stage of large scale field research work
 - Standardisation
 - Matching
 - Restriction
 - All of the above
- Which statement is true
 - Standardised mortality rate are actual rate
 - For indirect Standardisation age specific mortality rate are required
 - Standardised mortality rate are imaginary
 - Standardisation is done in planning stage.
- Standardised mortality ratio is calculated in
 - Indirect standardisation
 - Direct standardisation
 - Both
 - None
- Direct standardisation is also known as
 - Changing base method
 - Fixed base method
 - Hanging base method
 - None of the above

Answers : (1) d; (2) a; (3) c; (4) a; (5) b.

Statistical Exercise

Two populations of cities A and B are shown below. Crude death rate of population A & B is 38.28 and 36.39 per 1000 respectively. Compare the crude death rate using direct Standardisation.

<i>City A</i>			
Age group	Population	Age specific death rate per 1000	Deaths
0-10	20000	58	1160
11-19	18000	50	900
20-29	17000	35	595
30-39	15000	32	480
>40	55000	30	1650
Total	125000		4785

<i>City B</i>			
Age group	Population	Age specific death rate per 1000	Deaths
0-10	18000	62	1116
11-19	20000	43	860
20-29	22000	42	924
30-39	17000	34	578
>40	65000	26	1690
Total	142000		5168

<i>Standard population</i>	
Age group	Population
0-10	50000
11-19	48000
20-29	54000
30-39	45000
>40	125000
Total	322000

Answer : standardised mortality rate in population A and B are 38.44 and 37.925 respectively.

RajVir Bhalwar & Seema R. Patrikar

There are certain issues wherein the public health and community medicine specialist may face situations when the commonly used simple tests may not serve the purpose of analysing the data. A brief overview of these tests is being given in this chapter to orient the readers to the basic terminologies and the situations in which these tests are used. The actual calculations are beyond the scope of this book and interested readers may refer to standard texts referred to at the end of this chapter. In addition, the calculations of these procedures have also been illustrated in the chapter on EPI – 2002.

Non Parametric Tests

The hypothesis testing procedure discussed earlier, whether z test, unpaired t test or paired t test required the population distribution to be normal or approximately normal. In medical research many times we are not sure about the underlying distribution of the population. In such cases we apply non parametric tests which are not based on the assumption of normality of population especially when the sample size is small ($n < 30$). Since they do not assume any distribution they are also called as distribution free tests. Non parametric tests are weaker than parametric tests as they do not have any information on the parameters of the distribution of data. Non parametric test are mainly used when the researcher is dealing with numerical ordinal scale i.e. when the data is scored. For example history of fever in patients may be recorded in terms of categories like no fever, mild fever, moderate fever and high fever. We can further give numerical values to these categories as No Fever=0, Mild Fever =1, Moderate Fever=2 and High Fever=3. These scores of 0, 1, 2 and 3 are not real mathematical numbers. Thus non parametric test are used when the underlying distribution is not known. It is also useful when the sample size is small. Non parametric tests allow us to test the hypothesis which does not deal with parameter values like mean and variance. Few of the commonly encountered non parametric tests are :-

Mann Whitney U Test : This test is the non parametric counterpart of the parametric 't' test. It is used to test whether two independent groups have been drawn from the same population or the two populations have equal median.

Sign Test : This test is a frequently used non parametric test for single population as well as paired samples. The test uses plus and minus signs and hence is named as sign test. For the single population the null hypothesis assumes the median value against an alternative hypothesis of not equal to median value. When data are paired (X, Y), the sign test is used to test the null hypothesis that the median difference is zero.

Wilcoxon Signed Rank Test : As we may have already explained under paired 't' test, there could be paired sample situations, in the form of "before and after readings", or "paired matched" data. The non - parametric counterpart of the paired 't' test is called "Wilcoxon signed rank test". The sign test takes into

consideration the direction of the differences (either negative or positive) whereas a stronger test, the Wilcoxon test considers the direction as well as the magnitude of the differences. This test gives more weight to a large difference between the two pair than to a pair which shows small difference.

Inferences with More than 2 Means : Introduction to ANOVA

In the previous chapters on inferential statistics we have dealt in detail with hypothesis testing in difference between two populations with respect to mean. Many times the researcher is dealing with situations where there are more than 2 groups of interest. In such cases the usual z test and t test fails. The correct technique to compare means in three or more groups is analysis of variance or ANOVA. When one qualitative variable defines the groups, a one way ANOVA is used whereas when the groups are defined by two qualitative variables a two way ANOVA is used. It should be noted that the analysis of variance is not intended for testing the significance of sample variances but its purpose is to test for significance of difference among sample means. This chapter provides detail procedure for one way ANOVA.

When dealing with three or more groups the variability creeps in from two sources. One source is because of the groups itself, i.e. between group variability and the second source is within group variability. One of the basic assumptions of ANOVA is that the variances in the groups being compared are all equal i.e. homogenous. Also the variable of interest in the three groups is measured on either continuous or discrete scale. In case if the variable is measured in ordinal scale we use a non parametric test, the Kruskal-Wallis test where we compare the medians in the groups rather than mean. The assumption regarding homogeneity of variances is tested using Bartlett's test. Consider an example where three groups of Vegetarian, Non vegetarian and egg-etarian are considered. The researcher is interested to find out whether there is difference in the mean BMI value in the three groups. The data is as in Table - 1.

Sr. No.	Group 1 (Egg-etarian)	Group 2 (Vegetarian)	Group 3 (Non vegetarian)
1	15.40	16.28	21.13
2	16.75	17.02	20.47
3	17.97	17.83	23.32
4	19.29	18.24	18.28
5	18.24	20.00	21.05
Mean (\bar{X}_i)	17.53	17.87	20.85
SD (S_i)	1.49	1.41	1.80
n	5	5	5
N= 15 and the grand mean $\bar{X} = 18.75$			

As is already specified the total variability is due to the two sources between groups and within group. If the variation between groups is more than the variation within the groups, it would imply that the groups differ otherwise there would not

have been a difference in the variations between the groups and within the groups. Hence in the analysis of variance we find the relationship of the variation between the groups and the variation within the group. As from the example we find that the individual group means and the grand mean is different as also the group means are different from each other. The between group variance is obtained in the usual way, where the three means \bar{x}_i replace the individual observations (x_i) and the grand mean is subtracted from each value. This between group variance is called as *between group mean square*, or error mean square.

The between group variance is greater than the within group variance which implies that the groups differ significantly. The significance is tested using F test which is based on the ratio of the two variances.

Like the tables of z, t, chi-square distributions, tables of F distribution is also available. F table is based on the degrees of freedom for the two variances i.e. the numerator degree of freedom is (k-1) whereas the denominator degree of freedom is (N-k). The results from analysis of variance are always tabulated in a table called as ANOVA Table. For the example considered above the ANOVA Table is presented as in Table - 2.

Multiple Comparisons : When an F test is significant i.e. when we reject the null hypothesis of equal means in all groups, we only come to know that the means are not equal however it is not clear where the difference lies. To know which mean is differing significantly there is a need for multiple comparisons. There are a number of methods for this purpose, viz, Bonferroni's procedure, Schaffe's method, linear contrasts, 'q' statistic, Newman - Keul's procedure and least significant difference (L.S.D.) method. The L.S.D. procedure is easy and uses less assumptions. The value so calculated for each pair is checked against the 't' table value at p=0.05 and d.f. = (N-K). If our calculated 't' value is higher than the t-table value, we conclude that the 2 groups being compared are significantly different. On the other hand if the calculated value is less than the table value, we would conclude that the two groups being compared are not significantly different.

Inferences with More than 2 Medians : Introduction to Kruskal-Wallis Test

As we have already mentioned if the data in the groups are not quantitative but qualitative ordinal then instead of parametric ANOVA we should use non parametric test called Kruskal Wallis test. Is called as 'H' and follows chi-square with k-1 degree of freedom for specified α . If the calculated value of H (or, H* if there are ties) is more than the table value of chi square then

we conclude that the results are significant and that atleast two or more groups are different amongst each other. If this is so, then we proceed further to do the inter group comparisons, using the Dun's procedure (a counterpart of L.S.D. procedure used for intergroup comparisons after ANOVA).

Stratified Analysis using Mantel Haenszel Procedure for Control of Confounding

We have discussed in the chapter on confounding in the section on epidemiology and research methodology that there are two methods of controlling confounding in research. First method is during the planning and designing phase of the study. The researcher should plan and set up the study in such a way as to eliminate the effect of confounding variable right at the beginning. This can be done by restriction, matching or randomization. The second method is statistical analytical method called stratified analysis carried out during the analysis phase after completing data collection. Stratification means making a separate table of disease by exposure for each possible combination of confounders and analyzing the tables at each level. In the simplest case, this could mean separate tables for males and females, if SEX is the potential confounder. If AGE, SEX, and CITY are confounders, separate tables would be made for each possible combination of age, sex and city. In a case control study or cohort studies the data are in the form of a 2 x 2 table. The first step in stratification is to split the data into strata, a stratum having the confounder and other not having the confounder. The significance test for each along with the adjusted odds ratio or relative risk is estimated. The significance test performed in stratification is called Mantel-Haenszel chi square test. For example if we have a cross sectional analytical study conducted to see whether there is any association between obesity (exposure variable, defined as Body Mass Index (BMI) > 25) and Hypertension (outcome variable defined as BP > 140/90), among middle aged males. A total of 1099 subjects were studied. Results shown in Table-3:

Table - 3 :

Obesity	Hypertension		Total
	Present	Absent	
Present	198 (a)	284 (b)	482 (a+b)
Absent	98 (c)	519 (d)	617 (c+d)
Total	296 (a+c)	803(b+d)	1099 (n)

The crude (unadjusted) OR

$$= [(198 \times 519) \div (284 \times 98)] = 3.69$$

Table - 2 : ANOVA Table

Source of Variation	Sum of Squares	Degrees of freedom	Mean Squares	F ratio
Between groups	$n\sum(x_i - \bar{x})^2 = 33.32$	k-1=2	$S_B^2 = \frac{n\sum(x_i - \bar{x})^2}{k-1} = 16.68$	$\frac{S_B^2}{S_w^2} = 6.70$
Within groups	$\sum S_i^2 = 29.83$	N-k=12	$S_w^2 = \frac{\sum S_i^2}{k} = 2.48$	
Total	$\sum(x_{ij} - \bar{x})^2 = 63.16$	N - 1 = 14		

Thus, the risk of hypertension is 3.7 times higher among obese. Now, it was felt that the above observed association between obesity and hypertension may be confounded by “lack of physical exercise”, since it is known fact that lack of regular physical exercise is associated with obesity (i.e. the exposure), and, irrespective of its relation with obesity, is also associated with hypertension (outcome). Thus, “lack of regular physical exercise” qualifies as a potential confounding factor and stratified analysis was required for control of confounding. Thus, the data was broken up into two strata, as follows:-

STRATUM – I : Not exercising regularly			
Obesity	Hypertension		Total
	<i>Present</i>	<i>Absent</i>	
Present	89 (a ₁)	131 (b ₁)	220 (a ₁ +b ₁)
Absent	56 (c ₁)	326 (d ₁)	382 (c ₁ +d ₁)
Total	145 (a ₁ +c ₁)	457(b ₁ +d ₁)	602 (n ₁)

STRATUM – II : Undertaking regular exercise			
Obesity	Hypertension		Total
	<i>Present</i>	<i>Absent</i>	
Present	109 (a ₂)	153 (b ₂)	262 (a ₂ +b ₂)
Absent	42 (c ₂)	193 (d ₂)	235 (c ₂ +d ₂)
Total	151 (a ₂ +c ₂)	346(b ₂ +d ₂)	497 (n ₂)

Now, we calculate the stratum specific OR using the usual formula :

$$\text{Stratum – I OR} = [(89 \times 326) \div (131 \times 56)] = 3.96$$

$$\text{Stratum – II OR} = [(109 \times 193) \div (153 \times 42)] = 3.27$$

The next step is to compare the stratum specific OR to identify whether the variable can be considered as confounder or whether there is a possibility of interaction. If the stratum ORs are not different we say confounding is present and if the stratum ORs are different from each other, we say interaction is present. In the above considered example since the stratum ORs (3.96 and 3.27) are almost same we say that confounding is present. We compare these ORs with the crude OR (3.69) which is calculated for table without stratifying the tables with respect to potential confounding variable. If these are different we say there is definite confounding effect. In the example it is slightly different from stratum ORs. We conclude that there is definitely slight confounding due to lack of regular physical exercise. Since confounding is present there is requirement of calculating adjusted odds ratio which is calculated by Mantel-Haenszel method denoted by (OR(MH)).

In our example, after calculations the OR (MH) comes to 3.60. Now, this OR (MH) of 3.6 tells us that the risk of hypertension due to obesity, after adjusting for physical exercise, i.e. irrespective of whether a middle aged male exercises regularly or not, is 3.6 times. Since the crude OR (3.69) and adjusted OR (3.60) are not very dissimilar, we can also conclude that there was only slight confounding due to lack of physical exercise. Our next step is to estimate the significance using Mantel-Haenszel chi square test.

The degrees of freedom for MH chi-square are always 1 irrespective of the number of strata. The calculated MH-chi square is compared with the table value of chi-square at specified degrees of freedom. The calculated value is much more than the table value and hence we reject the null hypothesis that there is no relationship between the tables at alpha of 5%.

Tests for Linear Trends in Proportions

When the researcher is dealing with qualitative ordinal variables, the analysis is not simple analyzing proportion in various categories but more powerful test called chi-square for linear trend. The Chi Square for trend tests whether the odds (risk) increase or decrease in each group with respect to the first group, which is taken as the baseline for comparison. Normally the various groups are given an arbitrary numerical value to each category as ‘exposure Score’ (x_i). In general, it is best to give the numbers 1, 2, 3, 4, 5, ----- where 1 is the baseline group with which each of the other groups are compared. The procedure calculates odds ratio for each of the group, and the overall chi square for liner trend in proportions. This calculated chi-square has 1 degree of freedom irrespective of the number of categories or groups.

Let us consider an example of a hypothetical cohort study which was undertaken to assess whether smoking by mothers during pregnancy is a possible determinant of congenital malformations in the foetus. A total of 2462 pregnant ladies were taken up and their average daily cigarette consumption was assessed. 2076 ladies were non smokers. While 172, 143 and 71 were smoking up to 10 cigarettes, 11 to 20 and more than 20 cigarettes per day respectively. It was observed that 81 (i.e. 3.09%) of the non-smoker mothers delivered congenitally malformed children. The proportion of such malformed children increased progressively as the smoking category increased.

Smoking habit	Exposure score (x _i)	Status of delivered child		Total (n _i)
		<i>Had congenital malformations (d_i)</i>	<i>Normal</i>	
Non-smokers	1	81	1995	2076
1-10 cig/day	2	10	162	172
11-20 cig/day	3	28	115	143
>20 cig/day	4	21	50	71

In this example, based on the statistical procedures we calculated that the χ^2 linear trend = 125.50. The calculated chi-square is compared with the table value at 1 d.f. Since the calculated value is more than the table value for specified alpha at 5% we reject the null hypothesis that there is no trend. We thus conclude that the “trend of increasing risk of the outcome (congenital malformations) with increasing dose of exposure (cigarettes smoking) is statistically very highly significant.

Paired Data Analysis

A paired sample is so termed if every individual in one of the groups has a unique match or pair in other group, for

example when the variable value is measured before and after a particular intervention. At times the patient himself acts as self control i.e. the same patient is in both the groups. We have already seen the paired analysis, paired 't' test when the variable measured is quantitative and observations are paired as before and after or pre and post intervention. An alternative to this parametric paired 't' test is the non parametric sign test taking into account only the direction of the differences between pre and post scores and Wilcoxon signed rank test which takes into account the direction as well as the magnitude of the differences between the paired observations. Both these test are discussed in details in the non parametric chapter. Besides these situations the researcher at times deals with data which is dichotomous and are matched paired. Then the proportions in these matched data are analysed using McNemar's chi-square test. The general layout of the McNemar test is as given below.

Group2	Group1	
	+	-
+	a	b
-	c	d

The McNemar's $\chi^2 = \frac{(c - b)^2}{b + c}$ which follows a chi-square distribution with 1 degree of freedom. It is important to note that only the paired or united observations contribute to the test statistic value.

Summary

Most hypothesis testing procedure requires the population distribution to be normal or approximately normal. In medical research many times we are not sure about the underlying distribution of the population. In such cases we apply non parametric tests which are not based on the assumption of normality of population especially when the sample size is small ($n < 30$). Since they do not assume any distribution they are also called as distribution free tests. Non parametric tests are weaker than parametric tests as they do not have any information on the parameters of the distribution of data. Non parametric test are mainly used when the researcher is dealing with numerical ordinal scale i.e. when the data is scored. Non parametric tests allow us to test the hypothesis which does not deal with parameter values like mean and variance.

Many times the researcher is dealing with situations where there are more than 2 groups of interest. In such cases the usual z test and t test fails. The correct technique to compare means in three or more groups is analysis of variance or ANOVA. When one qualitative variable defines the groups, a one way ANOVA is used whereas when the groups are defined by two qualitative variables a two way ANOVA is used. When dealing with three or more groups the variability creeps in from two sources. One source is because of the groups itself, i.e. between group variability and the second source is within group variability. One of the basic assumptions of ANOVA is that the variances in the groups being compared are all equal i.e. homogenous. The assumption regarding homogeneity of variances is tested using Bartlett's test. Also the variable of interest in the three

groups is measured on either continuous or discrete scale. In case if the variable is measured in ordinal scale we use a non parametric test, the Kruskal-Wallis test where we compare the medians in the groups rather than mean.

Confounder is a variable that can distort the true research findings. There are two methods of controlling confounding in research. First method is during the planning and designing phase of the study and the second method is statistical analytical method called stratified analysis carried out during the analysis phase after completing data collection. Stratification means making a separate table of disease by exposure for each possible combination of confounders and analyzing the tables at each level. The first step in stratification is to split the data into strata, a stratum having the confounder and other not having the confounder. The significance test for each along with the adjusted odds ratio or relative risk is estimated. Then stratum odds ratio are compared amongst themselves and with crude ratio. If stratum ORs are not different we say confounding is present and if the stratum ORs are different from each other we say interaction is present. The significance test performed in stratification is called Mantel-Haenszel chi square test. While dealing with qualitative ordinal variables the analysis is not simply analyzing proportion in various categories but more powerful test called chi-square for linear trend. The Chi Square for trend tests whether the odds (risk) increase or decrease in each group with respect to the first group, which is taken as the baseline for comparison. Also when data is dichotomous and are matched paired then the proportions in these matched data are analysed using McNemar's chi-square test.

Study Exercises

Non Parametric Test

Short Note : What are non-parametric tests?

MCQs

1. An obstetrician takes two groups of expectant ladies from her ANC - one group having anemia while the other did not have anemia. She follows them till delivery and notes the APGAR score of baby, to see if anemia in pregnancy was associated with a lower APGAR score in new born. The correct statistical procedure in this study would be: (a) 't' test (b) Mann-Whitney test (c) Odds ratio (d) Correlation coefficient
2. All of the following are non-parametric test except (a) Mann-Whitney test (b) Wilcoxon sign test (c) Chi-square test (d) 't' test
3. All of the following are correct except (a) Non-parametric test are stronger than parametric test (b) Non-parametric test are also known as distribution free test (c) Chi-square is a non-parametric test (d) None of the above
4. For comparing the median of two population statistical test used is (a) z-test (b) 't' test (c) Mann-Whitney test (d) all of the above
5. Wilcoxon signed rank test takes into account (a) Direction of differences (b) Magnitude of differences (c) Both (d) None of the above

Answers : (1) b; (2) d; (3) a; (4) c; (5) c.

ANOVA

Long Question: Discuss the theory and application of ANOVA.

MCQs

1. When more than two treatment groups are present and you wish to test whether the groups differ significantly with respect to a parameter which statistical method would be applied? (a) ANCOVA (b) ANOVA (c) Logistic regression method (d) Multivariate regression
2. The correct technique to compare difference in three or more groups when homogeneity condition fails is (a) z-test (b) 't' test (c) ANOVA (d) Kruskal Wallis test.
3. Assumption that variance in all the group is same is tested by (a) Wilcoxon sign test (b) Bartlett's test (c) Bonferroni's procedure (d) Schaffe's method.
4. All of the following are multiple comparison test except (a) Bonferroni's procedure (b) Schaffe's method (c) Newman - Keul's procedure (d) Wilcoxon sign test.
5. Pair wise comparison between the groups or treatments when F ratio is significant is carried using (a) Paired 't' test (b) Unpaired 't' test (c) Bonferroni's test (d) Duncan's test

Answers : (1) b; (2) d; (3) b; (4) d; (5) c.

Statistical Exercises

A study was conducted among pregnant ladies of age group 20-30 yrs in a community to assess the effect of socioeconomic state on hemoglobin level. The data collected is given below

Lower	Middle	Higher
11, 10, 09, 10.5, 09.5, 10	11, 11.5, 12, 11, 12.5, 13	12, 12.5, 13, 14, 13.5, 14

Can you conclude from the following data that there is no difference in Hemoglobin level in different socioeconomic groups (Answer : $F=24.72$, reject null hypothesis there is a significant difference in blood Haemoglobin level in different socioeconomic status)

Control of Confounding, Linear Trend and Paired Data Analysis

Short Notes: McNemars test, paired 't' test.

MCQs

1. When data is dichotomous and are matched paired what is the correct statistical test (a) Paired 't' test (b) Mantel-Haenszel chi square test (c) McNemar's chi square test (d) Chi square test for linear trend.
2. All are true of confounder variable except (a) It is related to exposure (b) It is related to outcome (c) It is in direct chain of causation from exposure to outcome (d) It is differentially distributed.
3. If stratum odds ratios are different from each other it means (a) Confounding is present (b) Effect modification is there (c) No effect (d) All of the above
4. If stratum odds ratios are different from crude ratio then (a) Confounding is present (b) Effect modification is there (c) No effect (d) All of the above
5. When the researcher is dealing with qualitative ordinal variables the analysis is done by (a) Analyzing proportion in various categories (b) Chi-square for linear trend (c) McNemar's chi-square test (d) sign test

Answers : (1) c; (2) c; (3) b; (4) a; (5) b.

Which Statistical Procedures to Use Depending upon Exposure and Outcome Variable

Seema R. Patrikar & RajVir Bhalwar

The most commonly used statistical procedures in medical research are the "z" test for comparing two means or two proportions, the unpaired and paired 't' tests and the chi-square test, the details of which have been explained in this section. There are certain situations when different statistical techniques are required. The medical researcher should have an orientation to these procedures so that he/she can decide as to which procedure is most appropriate. As regards actual calculations, the same can be easily undertaken with statistical software EPI-2002, details of which are being described in the

next section.

Which test to use : As we said earlier, in the previous section on Research Methodology, the prototype scenario is to study an association between a given exposure variable and an "outcome" variable. (Please refer to detailed discussion on 2 x 2 table in that chapter). Now, we must first decide as to which "scale" have we recorded the exposure and the outcome variable. (i.e. Quantitative - Continuous, Discrete or Ordinal; or, Qualitative- Dichotomous, polychotomous nominal or polychotomous ordinal) Next, depending on the scale on which the exposure and outcome variables have been recorded, the appropriate test can be used as per Table - 1.

1. For testing One to One (Univariate) relationship between exposure and outcome variable
2. One - to - One (Univariate) Situation of Paired (dependent) samples or 'Before and After' situations
For Means : Paired 't' test

		Outcome					
		<i>Continuous</i>	<i>Discrete</i>	<i>Numerical Ordinal</i>	<i>Dichotomous</i>	<i>Polycho-tomous Nominal</i>	<i>Polychotomous Ordinal</i>
Exposure	Continuous	Pearson Correlation & Regression	Pearson Correlation & Regression	Spearman Rank correlation	't' test	ANOVA	ANOVA
	Discrete	- do -	- do -	- do -	- do -	- do -	- do -
	Numerical Ordinal	Spearman Rank correlation	Spearman Rank correlation	Spearman Rank correlation	Mann Whitney U test	Kruskal Wallis test	Kruskal Wallis test
	Dichotomous	't' test	't' test	Mann Whitney U test	Chi square for 2x2 table	Chi square for r x c table	Chi square for linear trend in proportions
	Polychotomous Nominal	ANOVA	ANOVA	Kruskal Wallis	Chi square for r x c table	Chi square for r x c table	Chi square for r x c table
	Polychotomous Ordinal	ANOVA	ANOVA	Kruskal Wallis	Chi square for linear trend in proportions	- do -	- do -

For proportion : McNemar Chi square
 For Medians : Wilcoxon Signed Rank test.

3. *If the outcome variable is dependent on time (as survival)*
 - Use Survival analysis method as Kaplan Meier method
4. *For control of confounding (Bivariate or multivariate analysis)*
 - (a) *For one or two confounding variables and when both the exposure & outcome are recorded on qualitative (usually dichotomous) scale:* Mantel-Haenszel's stratified analysis
 - (b) *For one or two confounding variables and when either exposure or outcome are recorded on quantitative (Continuous, discrete or ordinal) scale :* Two way or Multiple way ANOVA.
 - (c) *When a large number of confounding variables are to be controlled.*
 - (i) If outcome variable is recorded on quantitative (Continuous or discrete numerical) scale: Multiple Linear Regression Model.
 - (ii) If the outcome variable is recorded on dichotomous scale: Use Multiple Logistic Regression
 - (iii) If the outcome variable is a dichotomous variable but dependent on some type of time duration, as survival time: Use Cox Proportional Hazards Regression model.

Fisher Exact Test for 2 x 2 table : Many times we face the situation where the variables of classification are qualitative but the sample size is too small. *Chi-square test fails when the sample size is less than 30*. In such situations instead of using chi-square test we should use Fisher Exact Test.

McNemar Test for related data : In the situation of a chi square test, as described earlier, if "paired matching" has been done then McNemar test should be done instead of ordinary Chi square test.

Median based Non Parametric test : At times when the scale of measurement has been ordinal numerical (as rank achieved, grade of dyspnoea, economic status and so on) we should compare the medians rather than the means, using certain non parametric tests. The following tests are commonly used:-

Mann-Whitney 'U' test : When medians of the two independent samples are to be compared. It is the counterpart of unpaired 't' test.

Wilcoxon Signed Rank test : When the medians of the paired samples are to be compared. It is the counterpart of "paired t test".

Kruskal Wallis test : When medians of three or more samples are to be compared. It is the counterpart of ANOVA.

Table - 1 : Standard Normal Distribution Table

(It gives area included between $Z = 0$ and given positive value of Z)

For example : $P(0 \leq Z \leq 1.96) = 0.4750$, $P(0 \leq Z \leq 2.57) = 0.4949$

Z	0.00	0.01	0.02	0.03	0.04	0.05	0.06	0.07	0.08	0.09

Table - 2 : Student's t Distribution Table (It gives t value for given d.f. and corresponding to two tail areas)

For Example : $P(-2.571 \leq t_5 \leq 2.571) = 0.100$, $P(-2.131 \leq t_{15} \leq 2.131) = 0.05$

D.F.	Probability of greater value, p			
	0.100	0.050	0.010	0.001

20	1.725	2.086	2.845	3.850
21	1.721	2.080	2.831	3.819
22	1.717	2.074	2.819	3.792
23	1.714	2.069	2.807	3.768
24	1.711	2.064	2.797	3.745
25	1.708	2.060	2.787	3.725
26	1.706	2.056	2.779	3.707
27	1.703	2.052	2.771	3.689
28	1.701	2.048	2.763	3.674
29	1.699	2.045	2.756	3.660
30	1.697	2.042	2.750	3.646
40	1.684	2.021	2.704	3.551
50	1.676	2.009	2.678	3.496
60	1.671	2.000	2.660	3.460
80	1.664	1.990	2.639	3.416
100	1.660	1.984	2.626	3.390
120	1.658	1.980	2.617	3.373

For $\alpha = 0.05$ $t_{k, 0.05} = 1.96 + 2.5/k$ and $\alpha=0.01$
 $t_{k, 0.01} = 2.58 + 5.3/k$ where d.f. = k

e.g. k = 45, $\alpha = 0.05$ $t_{k, 0.05} = 1.96 + 2.5/45 = 2.015556$

Table - 3 : Chi-square Distribution Table. (It gives $\chi^2_{k, \alpha}$ value for given k d.f. and corresponding to right one tail area α)

For Example : $\chi^2_{k, \alpha} = 3.841$ is Chi-square Distribution Table for $\alpha = 0.05$ k = 1

D.F.	Probability of greater value, p

Mrs Seema R. Patrikar & Col RajVir Bhalwar

Overview of Epi Info

Epi Info is a package which is most suitable for doctors and researchers. It is a package which suffices for nearly all the usual clinical research and epidemiological settings. Epi Info is a public domain database and statistics program for performing statistical applications in clinical research. Statistics, graphs, tables, and maps can be produced with simple commands. *Epi Info is free, downloadable software provided by the CDC (www.cdc.gov/epiinfo/)* and has been developed as a joint collaboration between WHO and CDC, Atlanta. In our experience Epi-Info 2002 is the best for all the statistical requirements of most clinical researchers and epidemiologists and it would be worthwhile that we master the use of this programme.

A word of caution, however, is required. Statistical software are actually “enlarged calculators”, which make easy your problems of calculation. However, they can never substitute for the essential knowledge of epidemiology, research methodology and bio-statistics. In fact, inadvertent use of statistical software without adequate background of research methodology and biostatistics may create more problems than do good. Secondly, please do remember that no statistical software can substitute for accurate, valid and reliable data. In the field of Information Technology, there is an old saying “Garbage In, garbage Out” (GIGO) !

Installing Epi Info 2002

You will need to uninstall any earlier versions of EPI that may already be on your system.

- On your desktop, click Start, then Programs, then Epi Info 2000 , then Uninstall Epi Info 2000.
- Continue to follow the instructions on your screen.
- When this is complete, install the new Epi Info.

A. Installation from the Internet

Step 1: Log on to CDC’s website at www.cdc.gov/epiinfo/epiinfo.htm

Step 2: Click the *Download* button to perform a Web Install of the latest Epi Info.

Step 3: Save the file to a temporary folder on your hard drive (anywhere except where Epi Info will be stored).

Step 4: Go to this temporary folder and double click the *Setupweb.exe* icon for a complete installation by following the directions on your screen. You *must be* connected to the Internet while this installation occurs. Web Install will NOT result in a copy of setup files after the installation is complete. This means that you will not be able to install the program onto another system with these files. To do so, you must download the Complete Installation Package, then save onto a CD-ROM.

Step 5: Begin using Epi Info

B. Installation from a CD-ROM

Step 1: Insert disc in CD-ROM drive.

Step 2: Open *My Computer*, click on (E:) (CD Drive)

Step 3: Click on *Epi Info* folder and select *Full Version* folder

Step 4: Click on *Setup* icon. The Installation Wizard should begin. Follow the instructions as they appear. Most of your selections should be *OK* and *Next*.

Step 5: Click OK to put Epi Info icon on your desktop. Make sure icon is on your desktop; double click to make sure it works.

Step 6: Begin using Epi Info.

How to Run Epi Info

Once Epi Info is installed on your computer, the easiest way to “run” the software is clicking the Epi Info icon on your desktop. The Epi Info main menu should then appear:

Main Menu

The main programs of Epi Info can be accessed either through the PROGRAMS menu or by clicking on the buttons. The components of the Main Menu of Epi Info 2002 are -

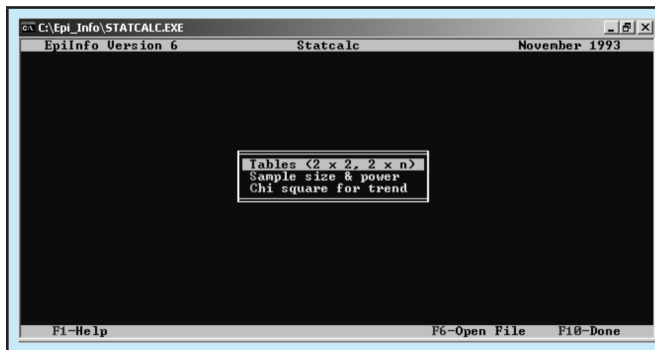

MakeView, Enter Data, Analyze Data, Epi Map, Nutrition, Epi Info Website and Exit

Though all these programs are being mentioned we would concentrate on two major programs- Statcalc (assessed through Utilities) and Analyze Data because these are the major requirements for epidemiologists and clinical researchers.

Statcalc

Statcalc is assessed through the dropdown menu in Utilities on the top of the main menu. Statcalc is an epidemiologic calculator that gives various statistical analysis of the data entered in the table form which appears on the screen. Three types of analysis are offered. Each option can be assessed by pressing <Enter>.

- Tables (2 x 2, 2 x n)
- Sample size and power
- Chi square for trend

Tables

It provides statistical analysis of tables (from 2 x 2 to 2 x 9 tables) along with the exact confidence limits for odds ratios. Stratified analysis of 2 X 2 tables can be carried out to produce odds ratios and risk ratios (relative risks) with confidence limits. Several types of chi-square tests, Fisher exact tests, Mantel Haenszel summary odds ratios and associated p values are provided.

Single 2 X 2 Tables

2 X 2 tables are frequently used in medical research to explore associations between EXPOSURE (to risk factors or the intervention in a clinical trial) and DISEASE (or other outcomes, if the outcome is not a disease but rather improvement from disease as may occur in a clinical trial). The table in STATCALC is set up with EXPOSURE on the left and DISEASE across the top. STATCALC produces results that test for relationships between EXPOSURE and DISEASE. The 2x2 layout is given in Table - 1.

	Disease present (D+)	Disease Absent (D-)	Total
Exposure present(E+)	a	b	a+b
Exposure Absent(E-)	c	d	c+d
Total	a+c	b+d	

When a 2 x 2 table appears on the screen we need to enter four numbers in the table. To do this enter the number in the first cell and press <Enter>, the cursor goes in the next cell. Again enter the next cell entry and press <Enter> to go to the next cell. (If any entry is wrongly entered this option does not allow you to edit hence you have to keep on pressing <Enter> till we are back to the empty 2 x 2 table). After the entry in the 4th cell press <Enter> or <F4> to calculate the single table statistics showing associations between EXPOSURE to the risk factor and DISEASE or other outcomes. Generally an association is suggested by an odds ratio or relative risk. The statistical significance is interpreted by 'p' values for chi square tests.

Pressing <Enter> or <F4> displays the statistical result which gives all the summary statistics i.e. Odds ratio along with the 95% confidence interval, Relative Risk along with 95% confidence interval. Remember that only one of these will be appropriate so don't quote both. You will also get some test statistics, such as χ^2 values. If the computer says that Cornfield not accurate, you can generally ignore this, but take advice from Epidemiologist or Statistician. Depending on the study design (a case-control or a cohort or a cross sectional design) we should select summary statistics (as either OR or RR). Generally, an association is suggested by an odds ratio or relative risk larger or smaller than 1.0. The further the odds ratio or relative risk is from 1.0, the stronger the apparent association. The significance is assessed by the p value. Whenever $p < 0.05$ it is considered to be statistically significant; also when the confidence limits for the odds ratio do not include 1.0 it is significant. Whenever the frequencies entered in the table are very small (<5) the program recommends Fisher Exact Test Results and the Exact confidence limits to be used.

Consider an example where we picked up 100 diagnosed patients of IHD from our Cardiology centre and another 100 subjects from the same centre in whom IHD had been excluded (Total = 200). We took the history from each and every one regarding smoking. Suppose we observed from our data that out of the 100 IHD cases, 80 were smokers and 20 non-smokers; while out of 100 healthy (non-IHD) subjects, there were 20 smokers and 80 non smokers. We would then consolidate our data into a '2 X 2' table. The data is given in Table - 2.

	Disease present (D+)	Disease Absent (D-)	Total
Exposure present(E+)	80	20	100
Exposure Absent(E-)	20	80	100
Total	100	100	200

Once we enter this data, press <Enter> or <F4> to get the table statistics.

On pressing <Enter> or <F4> analysis is provided as given in Table - 3.

The output given by the software includes the odds ratio as well as the RR along with the 95% confidence interval (which is shown in parentheses after the value of OR or RR. Depending on our study design we select between the two estimates. If the study design is a case control study (as was in this example) then select odds ratio (OR) along with 95% confidence limits. If the study design is a cohort study then select RR and if cross sectional then also select the odds ratio which is approximately equal to the prevalence odds ratio. Whether you select the RR or OR, also select the chi square along with the p value for mentioning in your results. To be on the safer side, select Mantel-Haenszel Chi-square along with the p value.

Table - 3 : Analysis of Single Table		
Odds ratio = 16.00 (7.60<OR<34.18)		
Cornfield 95% confidence limits for OR		
Relative Risk = 4.00 (2.67<RR<5.99)		
Taylor Series 95% confidence limits for RR		
Ignore relative risk if case control study.		
	Chi-Squares	P-values
Uncorrected	72.00	0.0000000
Mantel-Haenszel	71.64	0.0000000
Yates corrected	69.62	0.0000000
F2 More Strata; <Enter> No more Strata; F10 Quit		

Stratified Analysis of 2 X 2 tables

Associations between DISEASE and EXPOSURE can be missed or falsely detected if CONFOUNDING is present. A confounding factor is one that is associated with both the DISEASE and the EXPOSURE. Age is a frequent confounder. Any factor other than the main EXPOSURE being considered can be treated as a confounder.

Stratification means making a separate table of DISEASE by EXPOSURE for each possible combination of confounders. In the simplest case, this could mean separate tables for males and females, if SEX is the potential confounder. If AGE, SEX, and CITY are confounders, separate tables would be made for each possible combination of age, sex and city. The Mantel-Haenszel weighted odds ratio, relative risk, summary chi square and p value combines results from different strata to remove confounding caused by the variables. Thus, if tables are entered for males and females, confounding by SEX will be removed. The degree of confounding can be judged by comparing the crude and weighted odds ratios; if they are identical, there was no confounding by SEX. The approximate and exact confidence limits provide additional measures. If the weighted odds ratio or relative risk has confidence limits that do not include 1.0, then there is a significant statistical association between the DISEASE and the EXPOSURE, after controlling for confounding by the stratifying factor.

Table - 4			
History of Alcohol	Oral cancer		
	<i>Present</i>	<i>Absent</i>	<i>Total</i>
Present	80	20	100
Absent	20	80	100
Total	100	100	200

Consider following example. A study was done to see whether consumption of alcohol is a risk factor for oral cancer. 100

cases of oral CA and 100 healthy subjects were asked regarding history of alcohol consumption during past 15 years. The results are shown in Table - 4. Enter the four numbers in the 2 X 2 table on the screen and press <Enter> or <F4>. On pressing <Enter> or <F4> the following output is given (Table - 5).

Table - 5 : Analysis of Single Table		
Odds ratio = 16.00 (7.60<OR<34.18)		
Cornfield 95% confidence limits for OR		
Relative Risk = 4.00 (2.67<RR<5.99)		
Taylor Series 95% confidence limits for RR		
Ignore relative risk if case control study.		
	<i>Chi-Squares</i>	<i>P-values</i>
Uncorrected	72.00	0.0000000
Mantel-Haenszel	71.64	0.0000000
Yates corrected	69.62	0.0000000
F2 More Strata; <Enter> No more Strata; F10 Quit		

Since above is a case control study we select *odds ratio* = 16 which concludes that the risk of getting oral cancer is 16 times higher if a person drinks alcohol.

Now we also know that tobacco use is related to oral cancer. Hence stratifying the data by Tobacco status, we have two tables, one for tobacco users and the other for non-users. This becomes stratified 2 X 2 tables with 2 stratum. In this case enter the four numbers for the first stratum and press <F4> or <Enter> to calculate the related statistics. Press <F2> to enter another stratum. Enter the four numbers for this second stratum and press <F4> or <Enter>. Repeat the process for all the stratum available. Pressing <Enter> when there are no more stratum will present the stratified analysis summary for all strata entered. Pressing <Enter> again will then offer an opportunity to do exact confidence limits. Stratified analysis are not done for tables larger than 2 X 2

In the example considered the stratum for Tobacco users and non-Tobacco users are as follows. Substituting the values for first stratum and pressing <Enter> or <F4> yields the following output

Stratum I : Tobacco users			
History of Alcohol	Oral cancer		
	<i>Present</i>	<i>Absent</i>	<i>Total</i>
Present	60	15	75
Absent	20	5	25
Total	80	20	100

Analysis of Single Table (Stratum I)		
Odds ratio = 1.00 (0.28 < OR < 3.46*)		
Cornfield 95% confidence limits for OR		
*Cornfield not accurate. Exact limits preferred.		
Relative Risk = 1.00 (0.80<RR<1.25)		
Taylor Series 95% confidence limits for RR		
Ignore relative risk if case control study.		
	<i>Chi-Squares</i>	<i>p-values</i>
Uncorrected	0.00	1.0000000
Mantel-Haenszel	0.00	1.0000000
Yates corrected	0.08	0.7728300
F2 More Strata; <Enter> No more Strata; F10 Quit		
Since we have one more stratum of non-Tobacco users we press <F2>.		

On pressing <F2> another 2 X 2 table appears on the screen. Enter all the four cell values for non-Tobacco users and press <Enter>. The following output appears on the screen.

Stratum II : Non users of Tobacco			
History of Alcohol	Oral cancer		
	Present	Absent	Total
Present	5	20	25
Absent	15	60	75
Total	20	80	100

Analysis of Single Table (Stratum II)		
Odds ratio = 1.00 (0.28<OR<3.46*)		
Cornfield 95% confidence limits for OR		
*Cornfield not accurate. Exact limits preferred.		
Relative Risk = 1.00 (0.40<RR<2.47)		
Taylor Series 95% confidence limits for RR		
Ignore relative risk if case control study.		
	<i>Chi-Squares</i>	<i>p-values</i>
Uncorrected	0.00	1.0000000
Mantel-Haenszel	0.00	1.0000000
Yates corrected	0.08	0.7728300
F2 More Strata; <Enter> No more Strata; F10 Quit		

Since no more stratum are available press <Enter>. On pressing <Enter> the stratified analysis or the summary of 2 tables appears on the screen as follows:

Stratified Analysis	
Summary of 2 Tables	
Crude odds ratio for all strata = 3.45	
Mantel-Haenszel Weighted Odds Ratio = 1.00	
Cornfield 95% Confidence Limits	
0.41 < 1.00 < 2.37	
Mantel-Haenszel Summary Chi Square = 0.04	
P Value = 0.83907676	
Crude RR for all strata = 1.86	
Mantel-Haenszel Weighted Relative Risk	
Of Disease, given Exposure = 1.00	
Greenland / Robins Confidence Limits =	
0.77 < MHRR < 1.29	
<Enter> for more; F10 to quit	

The odds ratio for each table is 1.0 and the Mantel-Haenszel summary odds ratio is 1.0. The crude odds ratio and the Mantel – Haenszel summary odds ratio are quite different, leading to the conclusion that use of tobacco was a confounding factor and that there appears to be no risk of cancer due to alcohol after considering the effect of tobacco.

Sample Size & Power

Determining sample size is a very important issue, as already emphasized in the section of biostatistics. In the sample size calculations, an initial screen explains the data items and allows input of a single set of values. Pressing <F4> then shows the results on the second screen. On pressing *Sample size & power* three options are made available

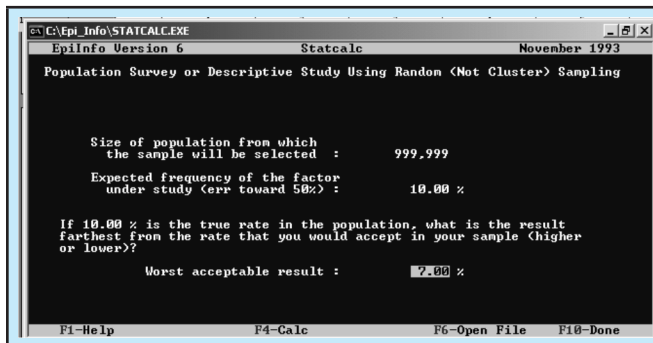

- Population Survey
- Cohort or cross-sectional
- Unmatched case-control

The screen is as follows

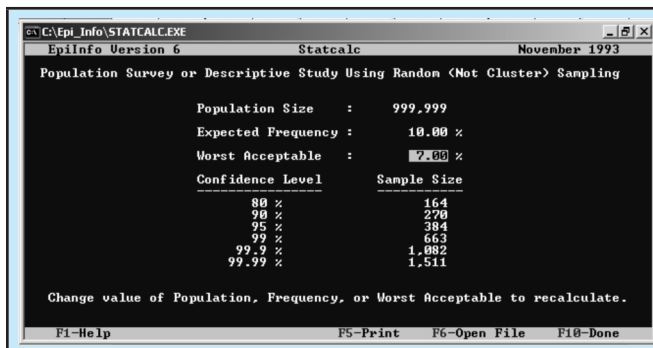

Sample size calculations are possible by both *Statcalc* as well as *EpiTable*. *EpiTable* is separately discussed after the *Epi2002* module. For cohort, cross sectional and unmatched case-control design you can calculate by either *EpiTable* or *Statcalc*. For matched pair case-control design calculate sample size using *EpiTable*.

Population Survey : Let us understand this with an example. Suppose a study on gestational diabetes is undertaken. The expected proportion is $p=10\%$ with the desired precision or acceptable deviation as 7% to 13% i.e. 3% on either side. ($d=0.03$). Alpha error is considered to be 5%. The information required to in this module is the population size from which the sample is selected. If the population size is known the researcher should substitute it, but in case if the total population size is not known then a default value of 999,999 is taken by the software. The prevalence or proportion of the disease or parameter under study should be substituted in percentage. The third requirement is regarding the worst acceptable result by the researcher.

In the above considered example since the population size is unknown we take the default value of 999,999. The proportion of gestational diabetes is 10%. And worst acceptable result as per the researcher varies from 7% to 13%, so we can either put the lower value of 7% or upper value of 13% as worst acceptable result. On pressing <F4> we get 384 as the minimum sample size against 95% confidence interval.

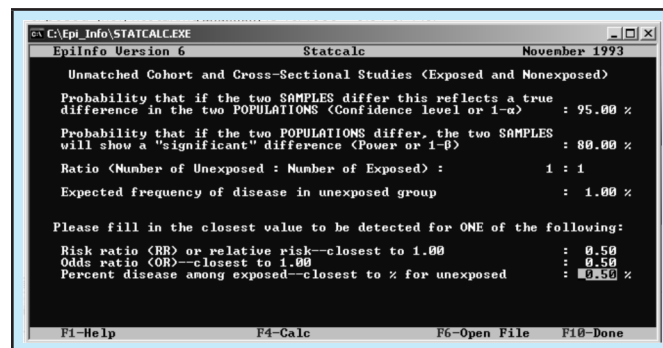

Cohort or Cross-Sectional Studies : For this type of study the proportion of disease in the unexposed group and the relative risk that the study anticipates to detect needs to be specified. Also the confidence interval along with desired power of the study requires to be specified. Once all the specifications are filled up, pressing <F4> calculates the minimum required sample size for our study.

Consider following study. We want to try acetazolamide as a prophylactic therapy against the development of High Altitude Pulmonary Oedema (HAPO). Our background information based on available data tells us that till now people have not been taking Diamox (i.e. are 'not exposed' to Diamox) and 10 out of

every thousand such persons develop HAPO; thus proportion of 'outcome' (HAPO) among those who are 'not exposed' (i.e. not taking Diamox) is $10/1000 = 0.01$ or 1%.

Considering the cost and problems of logistics, we would say that putting this prophylactic therapy into routine preventive use will be worthwhile only if Diamox reduces the load of HAPO by at least 50%; thus the minimum detectable RR = 0.5. We specify an alpha error of 0.05 (two tailed) (i.e. confidence level of 95%) and beta error of 0.20 i.e. power of 80%.

Substituting the values as above, the required minimum sample size is obtained by pressing <F4>. The result screen is as follows.

Thus we would require a total of 10130 subjects to be studied, 5065 subjects who would get Diamox and another 5065 subjects who would not get any drug.

Case-control Study : This option deals with the sample size determination when the study design is case control study. For this type of study the proportion of exposure in the not ill group (control) and the odds ratio that the study anticipates to detect needs to be specified. Also the confidence interval along with desired power of the study requires to be specified. Once all the specification is filled up pressing <F4> calculates the minimum required sample size for our study.

Continuing the same situation of HAPO, a research study wanted to find out whether even a slight physical exertion during first 24 hours of entry into high altitude may be associated with the development of HAPO. To proceed with this question as a case-control study, we want to take up cases of HAPO admitted to the hospital and healthy subjects who did not develop HAPO as a control group. Our background information from pilot study gives an indication that out of the healthy persons who did

not develop HAPO (i.e. in whom outcome is absent), about 10% did engage in physical exertion within 24 hours after entry into high altitude (i.e. had the 'exposure' to physical exertion); thus percentage of exposure among controls is 10% or 0.1. We think that physical exertion during first 24 hours should carry at least 3 times higher risk for developing HAPO; a risk less than this may not have public health significance since the administrators may not agree to "waste" so many man-days in rest if the risk is not really high (3 times). Thus, the minimum detectable OR that we choose is 3.

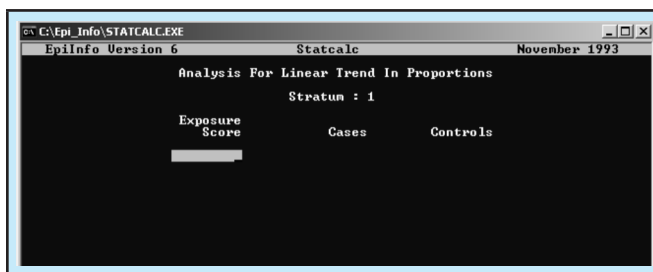

Once all the required information is substituted in the Case-control study screen and press <F4> the required minimum sample size is displayed on the screen as under.

Thus a total of 224 subjects are needed. In other words we will we will need 112 cases of HAPO and another 112 healthy controls to do this study.

Chi Square for Trend

Many times the variables of interest are measured on qualitative polychotomous ordinal scale, i.e. there are more than two exposure categories and these multiple categories have a definite common-sense ordering. In such situations, it is advisable to do the chi-square test for linear trend in proportions and not a simple chi-square test for r X c contingency table. The Chi Square for trend tests whether the odds (risk) increase or decrease in each group with respect to the first group, which is taken as the baseline for comparison. Epi calculates the chi-square for trend if there are at least three or more exposure levels and which have a sensible ordering of categories. For this we have to choose Chi square for trend and press return (<enter>). The screen looks as under

You have to choose an exposure score. The first category should be your unexposed (or least exposed) group. Choose 1 as their exposure score, then go on to fill in the cases and controls columns, which refer to the outcome. Fill in your next group as

the next least exposed. Typically the exposure score would be 2 and for the next group 3 and so on. When all data is entered, press F4 which will calculate the X^2_{trend} . This statistic always has 1 degree of freedom. This is also accompanied with the p value. When finished press F10 to exit.

Consider an example to understand this concept in detail. Suppose we have a hypothetical cohort study, which was undertaken to assess whether smoking by mothers during pregnancy is a possible determinant of congenital malformations in the foetus. Let us assume that a total of 2462 pregnant ladies were taken up and their average daily cigarette consumption was assessed. 2076 ladies were non smokers, while 172, 143 and 71 were smoking upto 10 cigarettes, 11 to 20 and more than 20 cigarettes per day respectively. It was observed that 81 (i.e. 3.09%) of the non-smoker mothers delivered congenitally malformed children. The proportion of such malformed children increased progressively. It was 10, 28 and 21 as the smoking category increased respectively. Putting the following information in a table form we have the following, which is clearly an qualitative, ordinal, polychotomous data :-

Exposure Category (Exposure Score)	Smoking habits during pregnancy (Exposure score)	Status of delivered child	
		Congenital Malformation (cases)	Normal (controls)
1	Non-smokers	81	1995
2	1 to 10 cig/day	10	162
3	11 – 20 cig/day	28	115
4	> 20 cig/day	21	50
Total		140	2322

After entering all the numbers in the table, pressing <F4> gives the following output

Analysis for Linear Trend in Proportions			
Chi Square for linear trend : 128.167			
		Exposure Score	Odds Ratio
p value	0.00000	1.00	1.00
		2.00	1.52
		3.00	6.00
		4.00	10.34

Interpretation : There exist highly significant linear trend in the odds of successive levels of the smoking and congenital malformation. The odds of congenital malformation in ladies who are smoking 11-20 cig/day increases by 6 times and in ladies who smoke > 20 cig/day the odds increases by more than 10 times as compared to non smokers. In addition with a p value of < 0.0001, this overall 'trend' (of increasing risk of congenital malformation with increasing smoking) is statistically very highly significant.

Analyze Data

Let us once again revert back to the main menu of Epi 2002.

One of the most important component of Epi 2002 is Analyze Data. This program allows access to data entered in 20 data formats (e.g. Epi Info data files, Foxpro data base files, Excel files, Access data base files etc.) to perform statistical analysis. Though you can directly enter data in the EPI INFO we strongly recommend that the data be first entered in Excel, Foxpro or Access and then imported to EPI. To understand this option in detail a practice data file named "SAMPLE.dbf" consisting of 200 records is provided. It is suggested that the readers use this file and try out all the options available in the Analyze Data menu of Epi 2002. The description of the data set in "SAMPLE.dbf" is given below.

Description of data set SAMPLE.dbf

Description of the data : SAMPLE.dbf file is a HYPOTHETICAL data given in Table - 5, meant for practicing only. It was a cross sectional study in which 614 healthy army subjects aged more than equal to 35 years were randomly selected from various army units in a very

large cantonment. General particulars included age, rank, native state. History was recorded of details of physical exercise, alcohol consumption and tobacco use. Clinical measurements included measurement of height, weight, waist circumference, hip circumference and systolic & diastolic blood pressure. Biochemical measurements included fasting and 2 hour PP blood sugar, lipid profile and fasting insulin levels. Resting ECG was recorded and assessed for evidence of coronary insufficiency (CI) as per the standard Minnesota code criteria. Syndrome X was defined as per standard international code criteria. A total of 52 persons out of 614 studied were found to have syndrome X as per defined criteria.

In Analyze Data menu following statistical analysis can be carried out.

- It produces tables, epidemiologic statistics and graphs.
- It can also produce lists, frequencies, cross tabulations, and other epidemiologic statistics, such as odds ratios,

Table 5 : SAMPLE data file.

The description of various variables coded in the data sheet is as follows

AGE	Actual age in completed years.
WK_EX_CAL	The number of K-calories spent on an average in one week in structured physical exercise (as Games, Walking, running, etc)
EXCAT	NIL-undertaking no exercise; Similarly MILD, MODERATE & HEAVY INTENSITY EXERCISE.
BMICAT_01	0 means < 25 and 1 ≥ 25
WAIST_HIP	Waist-Hip ratio (WHR)
WHR_CAT	0 = Having normal waist, normal WHR ≤ 0.90; 1= Having central obesity i.e. WHR>0.90
S_CHOL	Serum total cholesterol mg/dl.
HYPERINSUL	1 = Having hyperinsulinemia as per defined criteria of fasting insulin in uppermost quintile; 0 for Normoinsulinemia
HR_CAT_01	0 Heart Rate ≤72 beats/min, 1 for Heart Rate>72 beats/min
SYNDX	1= SyndX present as per defined criteria; 0= SyndX absent
FINAL_IHD	TRUE=evidence of IHD present; FALSE=No evidence (Normal)

relative risks, and p-values.

- Graphing and mapping are also available using this component.

First, to activate the analysis screen, click on the “Analyze Data” button on the main screen of EPI - 2002. The following menu appears on the screen.

Read : By using READ command, located in the left hand column we can tell EPIINFO which file or table to analyze. The Data Formats requires the format in which the data is entered. If the researcher has the data in the form of excel or FoxPro, he should specify the data format accordingly. The Data Source requires the source destination of this file from where it can be extracted to read.

List : List does a line listing of the current dataset. If variable names are given, *List* option will list only these variables whereas *List ** will list all variables of all active records, using several pages across to accommodate all the variables, if necessary. The simplest and sometimes the best way to analyze data are to produce a line listing, using the List command.

Frequencies : The *Freq* command is used to determine the frequency of values for numeric character. The output shows a table of the values for a variable, the number and percent of records having each value, and the confidence intervals for each value as a proportion of the total. For numeric data only, descriptive statistics such as mean and standard deviation are also shown. On selecting the variables and clicking OK the results appear in the browser window. The yellow bars accompany each table to the right indicates the frequencies. Statistics will be displayed below the table if the value of the variable is numeric.

Example: Suppose in the example “SAMPLE” data file we want to find the frequencies of the person with hyperinsulinemia and without hyperinsulinemia. The variable we have used for hyperinsulinemia is HYPERINSUL. Click frequencies and specify HYPERINSUL in the drop down menu of Frequency. Pressing OK yields the Frequencies, Percent, cumulative percent along with 95% confidence intervals for the frequencies in the following manner. The yellow bars also

indicate the frequencies for each category.

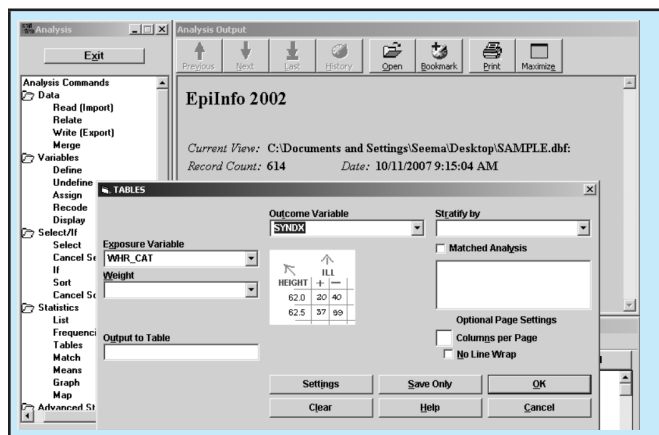

FREQ HYPERINSUL				
HYPER-INSUL	Freq- uency	Percent	Cum Percent	
0	159	79.5%	79.5%	Yellow Bar (YB)
1	41	20.5%	100.0%	(YB)
Total	200	100.0%	100.0%	Yellow Bar (YB)

95% Confidence Limits		
0	73.2%	84.9%
1	15.1%	26.8%

Tables : The *Tables* command is used to create a table of categorical data, often called as cross-tabulation. Two variables can be compared using Tables. This is similar to the ‘*Tables (2 x 2, 2 x n)*’ option of “Statcalc”. In Statcalc when ‘Tables’ option is used either for analyzing a single table or carrying out stratification analysis for confounding effect, we make use of the readymade 2 x 2 tables. The disease status as well as the exposure status cross classification cell values is directly entered by counting them separately from raw data. In the “Tables” option of “Analyze Data” the difference is that we do not count the frequencies manually but the raw data file is accessed through the ‘*Read (Import)*’ command in “*Analyze Data*”. The computer counts the cell frequencies.

On clicking the command *Tables*, we select the Exposure (Independent variable) and the Outcome (Dependent variable) variables. Exposure variable is that variable in the database which is to be considered as the risk factor. Outcome variable is the variable in the database considered as the Disease of consequence. Click on *OK* when done. A single table of 2 or more rows and 2 or more columns can be provided, which is called as an R x C table (Row by Column). In addition to the row and column variables, the user can stratify on additional variables, which is then called as an R x C x S table (Row by Column by Strata). This is used for control of confounding and is equivalent to stratification in Statcalc. The output gives frequency tables accompanied by confidence limits on the proportions and 2x2 tables by odds ratios, risk ratios, and several types of confidence limits on these ratios, as well as chi square and Fisher exact tests. Stratified analyses result in Mantel-Haenszel summary odds ratios and confidence limits.

We will understand the usage of this command by considering our hypothetical data set of “SAMPLE”. Let us say that we are interested in exploring association between SyndromeX and central obesity. Central Obesity (WHR_CAT) is considered to be a risk factor for development of SyndromeX and hence is selected as exposure factor and SyndromeX as our variable of interest as Outcome. We select these variables and then press <OK>.

On pressing OK following single 2 x 2 analysis is provided. The disease measures in terms of Odds ratio and relative risk along with 95% confidence interval and their significance is given in tabular form. This output is almost same as what we get in *Tables (2 x 2, 2 x n)* option of *Statcalc*.

TABLES WHR_CAT SYNDX.

Fisher exact		0.0045192928	

Let us now consider another variable BMI. We now wish to explore whether BMI is a confounding variable in the observed association between central obesity and syndrome X. Hence along with exposure and outcome variable we also give the variable BMI in the Stratify By on the screen.

The procedure is to click on Tables in Analyze Data after the data file is imported through 'Read' command. In the exposure dropdown we select the exposure variable as WHR_CAT and the outcome variable as SYNDX. Along with these we also select the confounding variable (BMICAT_01) from the dropdown list of "Stratify By". This is equivalent to stratification in Statcalc. On pressing <OK> the output is rendered as a single 2 x 2 analysis of WHRCAT and SYNDX but taking into consideration BMICAT_01 as 0 and 1. In other words the cross tabulated frequencies are only for the group having BMICAT as 0 (<25) and another single 2 x 2 analysis for the group having BMICAT_01 as 1 (≥25). A SUMMARY TABLE provides the summary statistics after removing the effect of confounder. The output is given as under.

WHR_CAT : SYNDX, BMICAT_01=0

MH Chi square - uncorrected	4.6013		0.0319
MH Chi square - corrected	3.3752		0.0662
Mid-p exact		0.0141	
Fisher exact		0.0255	

We conclude that BMI_CAT_01 is a confounder variable as the crude odds ratio and adjusted odds ratio differ. Based on Adjusted OR(MH) of 5.86, we conclude that the risk of syndromeX due to high WHR, after controlling (adjusting) for the confounding effect of raised BMI, increase the risk by almost 6 times.

Means : The Means command can compare mean values of a variable between the groups. The Means command can also compare mean group values before and after the event. This method, however, ignores the matching that occurs from using the same student or subject for both tests. A better method is to subtract the before score from the after score to find the difference for each student, and then to see if the average difference is significantly different from zero, using Students t-test. Epi Info performs the t-test every time the Means command is given with a single variable, just in case the variable represents a difference and you would like to know if it differs, on the average, from zero. If there are only two groups, the equivalent of an independent t-test is performed. If there are more than two groups, then a one-way analysis of variance (ANOVA) is computed. Thus Means provides the equivalent of ANOVA for two or more samples. "One way" means that there is only one grouping variable. If there were two grouping variables, then that would be a two-way ANOVA, which Epi Info *does not perform*. The one-way ANOVA can be thought of as an extension of the independent t-test to more than two groups. Because the ANOVA test requires certain assumptions about the data and the underlying population, another test (Kruskal-Wallis, also known as the Mann Whitney/Wilcoxon test if there are only two groups) is also provided. This is a non-parametric test, meaning that it does not require assumptions about the underlying population. We will discuss in detail each of the output section separately.

Consider again the example of "SAMPLE.dbf". One of the numeric variables considered is age of the person. If we wish to test whether there is any significant difference between the three ranks of the personnel as regards to the age parameter, we use one way ANOVA. For carrying out this analysis we first click on Means. The following screen will appear.

In the *Means of* we substitute the continuous numeric age variable and in the *Cross Tabulate by values of* substitute groups which is given in the column of Rank i.e. press Rank and then Press OK. The output is provided in 5 different sections:

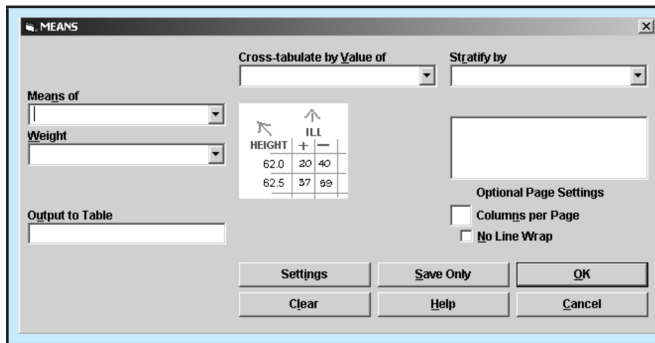

Single Table Analysis			
	Point	95% Confidence Interval

Crude Risk Ratio (RR)	1.1255	1.0488	1.2079
Adjusted RR (MH)	1.0936	1.0152	1.1779
(T= Taylor series; R=RGB; M=Exact mid-P; F=Fisher exact)			

1. A table of the two variables with the continuous variable forming the rows and the grouping variable forming the columns.
2. Descriptive information of the continuous variable by each group such as number of observations, mean, variance, and standard deviation; minimum and maximum values; the 25th, 50th (median), and 75th percentiles; and the mode values are described.
3. An Analysis of Variance (ANOVA) table and a p-value for whether or not the means are equal.
4. A test to determine whether the variances in each group are similar (Bartlett's test for homogeneity of variance).
5. A non-parametric equivalent, Kruskal-Wallis test instead of the independent t-test and one-way ANOVA is also provided.

For the example considered from SAMPLE.dbf following output is given on the screen.

Descriptive Statistics for Each Value of Crosstab Variable					
	Obs	Total	Mean	Variance	Std Dev
Heavy	65	2513.0000	38.6615	14.8524	3.8539
Mild	30	1242.0000	41.4000	38.7310	6.2234
Moderate	64	2430.0000	37.9688	17.8720	4.2275
Nil	41	1608.0000	39.2195	17.6256	4.1983

	Minimum	25%	Median	75%	Maximum	Mode
Heavy	35.0000	36.0000	37.0000	41.0000	50.0000	35.0000
Mild	35.0000	36.0000	37.5000	47.0000	54.0000	36.0000
Moderate	35.0000	35.0000	36.0000	38.5000	55.0000	35.0000
Nil	35.0000	36.0000	37.0000	41.0000	49.0000	37.0000

ANOVA, a Parametric Test for Inequality of Population Means (For normally distributed data only)

Variation	SS	df	MS	F statistic
Between	250.0393	3	83.3464	4.1836
Within	3904.7157	196	19.9220	
Total	4154.7550	199		
p-value = 0.0067				

Bartlett's Test for Inequality of Population Variances

Bartlett's chi square= 11.1485	df=3	p-value=0.0110
--------------------------------	------	----------------

A small p-value (e.g. less than 0.05 suggests that the variances are not homogeneous and that the ANOVA may not be appropriate.

Mann-Whitney/Wilcoxon Two-Sample Test (Kruskal-Wallis test for two groups)

Kruskal-Wallis H (equivalent to Chi square) = 7.6873
Degrees of freedom = 3
P value = 0.0429

The overall one-way ANOVA results are said to be significant ($p= 0.0000$) so we conclude that the mean age in the exercise groups are not same.

Note : *All statistical methods require assumptions.*

ANOVA requires *distributional assumptions* of

- Independence
- Normality
- Equal variance

Bartlett's Test for Inequality of Population Variances test for the assumption of equal variances. It also advises you as to whether ANOVA results are appropriate or Non-parametric test are more appropriate.

Kruskal-Wallis Test

The Kruskal-Wallis test is the nonparametric analogue to one-way ANOVA. It can be viewed as ANOVA based on *rank-transformed data*. The initial data are transformed to their ranks before submitted to ANOVA. The p-value suggests the significance. The null and alternative hypotheses for the K-W test may be stated in several different ways. We choose to state:

H_0 : the population medians are equal

H_1 : the population medians differ

In case when the ANOVA results are significant ($p<0.05$), multiple comparisons between two groups at a time should be carried out. Since in our case results are significant ($p<0.05$) we now compare two means at a time. This is a *post hoc (after-the-fact) comparison*. In other words it means that after rejecting H_0 we conduct the following six tests:

Test 1: H_0 : Group 1 = Group 2 vs. H_1 Group 1 \neq Group 2

Test 2: H_0 : Group 1 = Group 3 vs. H_1 Group 1 \neq Group 3

Test 3: H_0 : Group 1 = Group 4 vs. H_1 Group 1 \neq Group 4

Test 4: H_0 : Group 2 = Group 3 vs. H_1 Group 2 \neq Group 3

Test 5: H_0 : Group 2 = Group 4 vs. H_1 Group 2 \neq Group 4

Test 6: H_0 : Group 3 = Group 4 vs. H_1 Group 3 \neq Group 4

This is carried out by the procedure explained in EPITABLE section of COMPARE.

Match

MATCH performs a matched analysis of the specified exposure and outcome variables, which are assumed to be yes/no variables. One table is produced for each number of cases in a match group. The first variable will appear on the left margin

and will contain values from zero to the number of cases in the match group. The second variable will appear on the top margin and will contain values from zero to the number of cases in the match group. The cells contain the number of match groups showing the combination of positive exposures and positive outcomes shown in the margins. The output table produced by the command is similar to that produced by TABLES.

Graph

The GRAPH command in Analysis offers many types of charts for displaying the values of one or more fields in a data table. A toolbar within the graphing module can be activated to allow customization of the resulting graphs. Settings can be saved as templates and used again from Analysis.

Advanced Statistics

Linear regression : Regression analysis deals with developing a mathematical relationship between two variables of interest. Regression is used when the primary interest is to predict one dependent variable (y) from one or more independent variables (x_1, \dots, x_k). When only one independent variable is used to predict the dependent variable then it is termed as simple linear regression. When multiple independent variables are used to predict the dependent variable it is defined as multiple linear regression and for quantifying the relationship between two variables we calculate correlation. To analyse the relationship between the independent and dependent variables we click on Linear Regression. From the dropdown menu in Outcome Variable select the outcome or dependent variable. In the Other Variables select the multiple independent variables and press OK. On pressing OK the output is visible on the screen.

Consider the SAMPLE data file. Suppose the outcome variable is diastolic blood pressure (DIA_BP). Let the independent variables or predictors be BMI (BMICAT_01), Waist-hip ratio (WAIST_HIP), serum cholesterol level (S_CHOL) and heart rate (HR_CAT_0_1). Follow the instructions given above and arrive at the solution.

Linear Regression				
Variable	Coefficient	Std Error	F-test	P-Value
BMICAT_01	6.340	1.624	15.2339	0.000131
HR_CAT_0_1	2.891	1.461	3.9177	0.049196
S_CHOL	0.029	0.025	1.3625	0.244546
WAIST_HIP	18.3	13.839	0.1339	0.714821
CONSTANT	82.277	12.640	42.3677	0.000000
Correlation Coefficient : $r^2 = 0.11$				

Source	df	Sum of Squares	Mean Square	F-statistic
Regression	4	2200.351	550.088	5.969
Residuals	195	17970.844	92.158	
Total	199	20171.195		

Thus in the above example, the regression line is:

$$DIA_BP = a + b_1x_1 + b_2x_2 + b_3x_3 + b_4x_4$$

$$DIA_BP = 82.277 + 6.340(BMICAT_01) + 2.891(HR_CAT_0_1) + 0.029(S_CHOL) + 18.3(WAIST_HIP)$$

For any given value of independent variables, diastolic blood pressure (DIA_BP) value can be predicted.

Logistic Regression : Logistic regression shows the relationship between an outcome variable with two values (i.e. dichotomous) and explanatory variables that can be categorical or continuous. In Epi Info 2002, either the TABLES command or logistic regression (LOGISTIC command) can be used when the outcome variable is dichotomous (for example, disease/no disease). Analysis with the TABLES command in Epi Info is possible if there is only one "risk factor." Logistic regression is needed when the number of explanatory variables ("risk factors") is more than one. The method is often called "multivariate logistic regression." A model might predict the probability of occurrence of a myocardial infarction (MI) over a 5-year period, given a patient's age, sex, race, blood pressure, cholesterol level, and smoking status. Please note that the outcome variable has to be of YES/NO type or logical (TRUE/FALSE). The latest version of EPI2002 can take the outcome variable in logical form as 0 and 1. Epi Info 2002 uses a process called "maximum likelihood estimation" to arrive at the best estimate of the relationships based (usually) on a follow-up study. The results include values for the beta coefficients ' β ' but more important for epidemiologists, can produce an odds ratio (OR) for each value of a risk factor compared with its baseline ("absent" or "normal") state.

Consider in SAMPLE data file the dependent outcome variable as having IHD (which is coded separately as FINAL_IHD and is logical type) given the different risk factors as BMICAT_01(categorized 0 for BMI < 25 and 1 for BMI \geq 25), weekly exercise (WK_EX_CAT categorized 0 for no exercise and 1 for exercise), waist-hip ratio, (WHR_CAT categorized 0 for having normal waist i.e. \leq 0.90 and 1 for having central obesity i.e. $>$ 0.90), heart rate (HR_CAT_01 categorized 0 for heart rate \leq 72 beats/min and 1 for $>$ 72 beats/min) and SyndromeX (categorized 0 for all those who did not qualify as having syndrome X and 1 for all those who qualified as having or presence of syndrome X). Follow the instructions given above and arrive at the solution.

Survival Analysis

Survival Analysis deals with situations where the outcome variable is dichotomous and is a *function of time*. The analytical methods used to draw inferences regarding the chances of surviving/dying/getting cured/getting diseased (in short, the chances of developing the "outcome of interest"), over the various points of time are answered by "survival analysis". Consider a HYPOTHETICAL data of a new drug which was being tried out for treatment of Leukemia. 100 patients of confirmed leukemia were randomized into two groups. One group of 50 subjects which continued with the existing standard therapy (Group1) and another 50 subjects (Group 2) were given the trial modality. All subjects were followed up for maximum period of 7 years (84 months) from the point of starting treatment or else till they died due to leukemia or lost to follow up or died due to some other disease. Subject who died because of leukemia are called as uncensored data (0) whereas subjects who died of

some other cause and not leukemia or were lost to follow up or were still alive by the end of 7 years are called as censored data (1). The defined outcome of interest was the subject who was living at the end of followup. (This includes those who were lost to followup assuming that they would have lived).

There are three columns. The first column named "Time_since" represents the time in months of the event (death) taking place. The second column, named "Outcome" represents the status of the patient, whether the patient is alive or has died, and the third column, named "Group" represents the group to which the patient belongs, with 1 = existing treatment given and 2 = new trial treatment given.

Firstly read the file through Analyze Data and Import Data option. Once the data is imported press Kaplan-Meier Survival from Advanced Statistics and give input of all the required variables. The Censored Variable is the Outcome variable, Time Variable is Time_Since and Group Variable is Group respectively in our example. Value of uncensored is 0 whereas Time Unit is taken as months. Once you press OK the survival curve along with statistical difference between the two survival curves are provided. (The details on Survival Analysis are given in the section of Biostatistics). Following the instructions given above we arrive at the solution.

KMSURVIVAL TIME_SINCE = GROUP * OUTCOME (0)
TIMEUNIT="Months"

Test	Statistic	D.F.	P-Value
Log-Rank	1.2764	1	0.2586
Wilcoxon	2.3399	1	0.1261

Study Exercise

Using SAMPLE data file answer the following questions:

- Write the scales of measurement for all the variables considered in the SAMPLE file.
- If the investigator is interested in assessing whether there exist any association between the occurrence of IHD and systolic blood pressure as risk factor. How will the investigator proceed to test this association?
- In the above situation how will the investigator check whether age is a confounder variable or not?
- Describe the following variables along with the 95% confidence interval. (a) Heart Rate (b) Serum Cholesterol Level (c) Tobacco consumption (d) Age.
- Test whether there is any difference in the proportion of subjects consuming tobacco in the two groups with presence of IHD and absence of IHD.
- To test whether there is any correlation between Waist Hip Ratio and BMI (taking both as dichotomous variables) what type of statistical analysis will be carried out?
- Taking Fasting Insulin as a continuous variable and age as dichotomous variable (0 for ≤ 35 years of age and 1 as > 35 years of age) test whether there is any difference between the insulin levels in the two age groups.
- Carry out analysis to find out whether there is any association between the exposure variables WK_EX_CAL and the outcome variable FINAL_IHD with and without considering the confounder variable BMI.
- If we wish to test whether there is any significant difference in the proportion of people of different ranks (RANK) with outcome of "SyndromeX" using EPITABLE and ANALYZE DATA, what would be the difference?
- Which statistics will be used to predict the outcome of SyndromeX in subjects, considering the risk factors as Age, Exercise (WKEXCAT01), TOBACCO consumption (categorized as 0 and 1)?
- Correlate Fasting Insulin and Fasting Sugar using 'Graph' from "Analyze Data".

EPITABLE is statistical calculator with many statistical functions and graphs which you should become acquainted with to carry out various research analysis. EPITABLE is a module which is available in the previous version *EPI6* which is again a freely downloadable software from internet. This programme can be accessed by first pressing on the EPI6 icon and then subsequently pressing EPITABLE calculator through Programs. The EPITABLE appears as below.

The components of Epitable are: (a) Describe (b) Compare (c) Study (d) Sample (e) Probability (f) Setup

Describe

This option calculates confidence intervals around an estimate of a proportion, a mean or a median.

Proportion : Confidence interval is calculated for proportions estimated from simple random samples or cluster samples. Three methods for calculating confidence intervals of a proportion are presented. These are Fleiss quadratic, exact binomial and mid-p.

Ex : Suppose in a survey we wish to detect the seropositivity for HIV in blood donors. Total of 997 cases are considered. Out of these 12 are found to be positive. In the describe dropdown menu select the proportion option and then select Simple random sampling. Substitute 12 in the numerator and 997 in the denominator. On pressing calculate, the following output is given.

Simple Random Sampling	
Numerator	12
Total observations	997
Proportion	1.2036%
Fleiss quadratic 95% CI	[0.6534 – 2.1552]
Exact binomial 95% CI	[0.6234 – 2.0930]
Mid-p 95% CI	[0.6538 – 2.0372]
Select the Exact binomial 95% CI	

Mean : This command provides the confidence interval of a mean using the alpha risk specified in the setup option. The

inputs required are the mean and the standard deviation values for the given data. If the size of the population from which the sample is taken is not known, we should use the default maximum value of 999999999.

Let us consider a hypothetical example where 10 volunteers are weighed in a consistent manner before they start consuming an experimental diet. Weights in kg for these 10 volunteers are as follows, 81, 79, 92, 112, 76, 126, 80, 75, 68, 78. We calculate the mean in the usual manner by adding all the observations (weights) and then dividing by 10 to give us the mean weight as 86.7. Similarly we calculate the standard deviation which is equal to 18.33. Now if we wish to calculate the 95% confidence interval for mean we select 'Mean' and substitute the requisite information, i.e. value of mean as 86.7, Sample standard deviation as 18.33 along with the sample size as 10. On pressing calculate following output renders the 95% confidence interval.

Median : This option gives the confidence interval of a median using the alpha risk specified in the setup option. The inputs required are the median and the sample size for the given data. For example we ask the 10 patients attending OPD to evaluate his pain on a scale of 0 (no pain) to 10 (the worst pain). The scores given by the patients are 3,4,2,6,1,8,1,9,3,6.

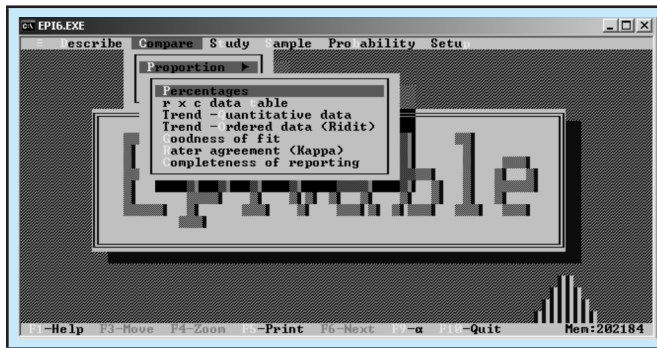

Note that the package gives the median position along with 95% confidence interval for median position and not the median value.

The median score of pain after arranging the patients in ascending order is 3.5 which is the middle most position i.e. 5.5.

Compare

This menu compares the *proportions, means* and *variances* using various statistical methods. Under proportion menu following components are available:

Proportion : This option compares several proportion expressed either as percentages, rows or columns, quantitative or qualitative manner using the chi square test. The various options available are as follows.

Percentages : When we have the percentages in the two groups which we are interested to compare we use this option. The program requires the percentage values along with the sample sizes for each group. On analyzing it gives the chi-square statistics along with the significance value i.e. p-value. Consider a hypothetical example where we sampled 55 males in their adolescent ages. 44% of them were obese. Another sample of 149 females had 24% obese ladies. To test whether from the sampled populations the proportion of obese males was comparatively higher than that of females, we use the Percentage option of Proportion in EpiTable.

Chi ²	7.34
Degrees of freedom	1
p value	0.006748

Since $p < 0.05$ we reject the hypothesis i.e. we can conclude that there is significant difference in proportion of obese. In other words we say that the percentage of obese males is greater than percentage of obese females in the sampled population.

Chi square for r x c data table : This is applicable when we have qualitative data in terms of counts which can be compiled in terms of rows and columns. The procedure is as follows. First indicate the number of rows and the number of columns. Then enter the data for each cell. Chi square calculation will be performed when the calculate button is selected. The percentage of cells with an expected value < 5 is returned if any such cells are found. When more than 10% of the cells have expected values < 5 , chi square calculation is no longer recommended. The chi square calculation is not valid if there are expected cells with values < 1 . In this case, an error message is displayed.

Let us illustrate the procedure of Chi-square for r x c table using the hypothetical example on the association between maternal age and congenital malformations. Let us say, we started with the research issue by taking two groups of mothers, one group upto 35 years of age and other above 35 years of age. We took a sample each, 500 pregnant ladies aged > 35 years and another 1000 pregnant ladies aged upto 35 years and followed them till delivery. We found that out of the 500 children born to ladies > 35 years, 50 had congenital malformations, while out of 1000 ladies upto 35 years, there were again 50 children born with congenital malformations. Converting it into a 2 x 2 table.

Mothers	Status of delivered child	
	<i>Congenital Malformation</i>	<i>Normal</i>
Upto 35 years of age	50	950
> 35 years	50	450

Substitute all the observed frequencies and press calculate. The following output is displayed.

Chi square calculation	
Chi ²	13.39
Degrees of freedom	1
p value	0.000253

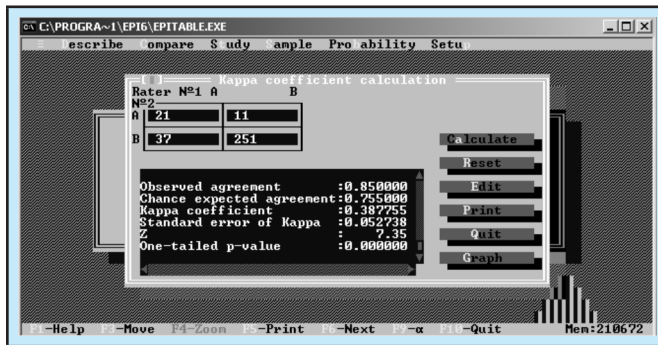

Since $p < 0.05$ we can conclude that there is statistically significant association or that there is a definite relationship between advanced maternal age (> 35 years) and congenital malformations in the offspring.

Trend - Quantitative data : This is same as discussed under chi square for trend in 'Statcalc' and hence is not repeated here.

Two Rater Agreement (Kappa) : This allows us to measure the inter observer reliability. The consistency of measurement by different observers is assessed by kappa coefficient. This measure is carried out only for categorical data upto 6 categories. Each cell of the table corresponds to the count of observation classified by rater 1 and rater 2. For example we may be desirous of undertaking a study on Pulmonary TB, with AFB on sputum smear as the method of measurement. Let us say we are using Laboratory technicians to examine the sputum slides after training given to them by microbiologist. For doing an inter observer reliability assessment (between the microbiologist and Lab technician) we took 320 stained slides and each slide was examined by both of them. The results are as follows:

Lab Technician's Diagnosis	Microbiologist's Diagnosis		
	<i>Positive</i>	<i>Negative</i>	<i>Total</i>
Positive	21	11	32
Negative	37	251	288
Total	58	262	320

On pressing Rater Agreement (Kappa) and substituting the values as given above the following output is rendered.

The Kappa coefficient of 0.38 is interpreted as moderate agreement.

Means : This option performs a test (F test), which is equivalent to a student's t test for 2 samples. This test is not valid if all samples come from normally distributed populations with variances not statistically different.

Consider a hypothetical data of a research study to answer the question whether the serum cholesterol of healthy adult males, living in hot desert areas is, on an average, different (i.e. significantly higher or lower) from the average serum cholesterol of healthy young males living in temperate climates. The serum cholesterol values of 12 subjects from the deserts yielded a mean value of 216.25 mg/dl with variance of 795.24 mg/dl. Similarly 14 subjects from temperate climate yielded a mean value of 198.07 mg/dl with variance of 992.25 mg/dl.

The details of the two population means along with variance (SD^2) and sample size are substituted to give us following output.

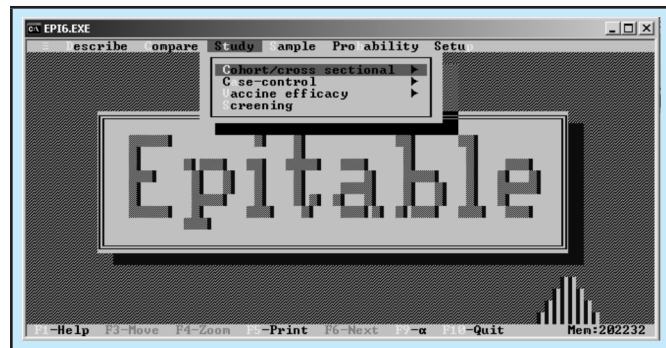

Variance between samples	2135.62
Residual variance	901.95
F Statistic	2.37
p value	0.135090

Since $p > 0.05$ we accept the null hypothesis i.e. we can conclude that Serum Cholesterol levels of healthy adult males, living in hot desert areas is, on an average, *not different* from the average serum cholesterol of healthy young males living in temperate climates.

Study

This option gives methods of measuring association for cohort and case control studies. Different methods for measuring vaccine efficacy are also presented. There are various methods available. The control method uses the *proportion of population vaccinated* and the *proportion of cases vaccinated*. Methods based on the estimation of attack rates in cohort study, estimation of odds ratio in case control and matched case-control study is given. Also measures of parameters in screening studies are performed using this module. Examples are not carried out for each sub option. It is expected that students solve few modules on their own with real life data set.

The screen appears as given below.

Cohort / cross sectional : Cohort/cross sectional (In cohort study, associations are measured for data tables with cumulative incidence and incidence density). In stratified cohort studies, after specifying the number of strata, associations are measured on cumulative incidence and incidence density

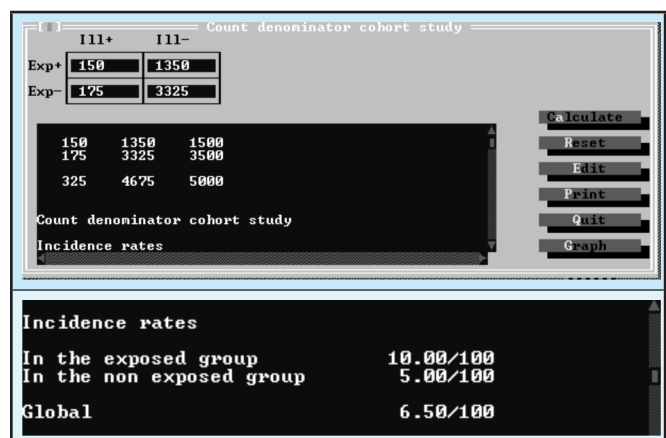

- Cumulative incidence
- Incidence density
- Stratified, cumulative
- Stratified, density

For example, if we take 5000 healthy adult males in whom IHD was excluded based on history of smoking and resting/exercise ECG. Then, on asking them about history of smoking we found that 1500 were smokers and 3500 non-smokers. We followed up these 2 groups (1500 smokers and 3500 non-smokers) for 20 years and observed that during this period there were 150 cases of IHD among smokers and 175 cases of IHD among non-smokers.

Thus substituting the values of this 2x2 table on the screen as

	Ill+	Ill-
Exp+	150	1350
Exp-	175	3325

On pressing Calculate following output is given. Again depending on the type of study carried out the correct statistics is selected

Test of significance		
One-tailed p-value(Fisher):		p:0.000000
Two-tailed p-value(Fisher):		p:0.000000
Pearson'chi square	$\chi^2:43.19$	p:0.000000
Yates'chi square	$\chi^2:42.37$	p:0.000000

Measure of association and 95% confidence interval		
Relative risk	2.00	1.62, 2.47
Risk difference	5.00/100	3.32, 6.68
Attributable fraction	50.0%	38.3, 59.5
Population risk dif.	1.5/100	1.0, 2.0
Population attr. fraction	23.1%	17.7, 27.4
Odds ratio	2.11	1.68, 2.65

The information gathered is set in the form of a 2 x 2 table.

Exposure	Outcome		
	Developed TB	Did not develop TB	Total
Given isoniazid (intervention group)	3	42	45
Not given isoniazid (Control group)	9	36	45
Total	12	78	90

Please compare the results as they are shown in the above screen with the calculations of RR, AR and PAR% which were calculated for the same example in the chapter on "Measurement of Risk" in the section of epidemiology.

Case-control

(1) Unmatched (2) Matched 1:1(3) Matched 1: 2 (4) Stratified

Depending whether the cases and controls are unmatched or matched in the ratio of 1:1 or 1:2 (1:2 means number of controls will be twice the number of cases) we select that particular option

Please refer to our example on odds ratio in the chapter on "Measurement of Risk". We observed from our data that out of the 100 IHD cases, 80 were smokers and 20 non-smokers; while out of 100 healthy (non-IHD) subjects; there were 20 smokers and 80 non smokers. Substituting the values in a 2 x 2 table and pressing calculate gives the following output on the screen

Vaccine efficacy Cohort study			
Uac+	3	42	
Uac-	9	36	
Pearson'chi square	$\chi^2:3.46$		p:0.062812
Yates'chi square	$\chi^2:2.40$		p:0.121037
Measure of association and 95% confidence interval			
Relative risk	0.33	0.10, 1.15	
Vaccine efficacy	66.7%	-15.1, 90.4	
Population vaccine effica	16.7%	22.6, -9.8	
Odds ratio	0.29	0.07, 1.14	

Output : Measures of association and 95% confidence interval		
Odds ratio	16.00	8.00, 31.99
Attributable fraction	93.8%	87.5, 96.9
Exact confidence limits of the odds ratio		
Fisher	7.6013	34.0195
Mid-p	7.9638	32.1333

Substituting all the four cell values of the cohort study with the aim to find beneficial effect of the drug or vaccine we press Calculate. This yields us the efficacy of 66.7% and hence we conclude that isoniazid chemoprophylaxis reduces the occurrence of TB in close contacts by 66.7%.

Screening : This option is used to evaluate the performance of a diagnostic test. On substituting the true+ and true- values (Gold standard + and - values) and the test+ and test- values the option gives the sensitivity, specificity along with the Predictive value positive and predictive value negative.

Consider an example on evaluating the performance of ELISA as a diagnostic test for HIV infection as compared to the gold standard as PCR. We took 1,00,000 subjects and subjected each and every one of them to both, the ELISA as well as the PCR tests. After substituting the values of a=990, b=9900, c=10 and d=89100 in the table the following output is given.

Vaccine efficacy

(1) Control method (2) Cohort study (3) Case-control study (4) Matched case control study 1:1(5) Matched case control study 1:2

Vaccine efficacy is measured by comparing Attack Rates among Vaccinated and Attack Rate among Non vaccinated people. There are four different methods presented which corresponds to different approaches for measuring or estimating Attack Rates among Vaccinated and Attack Rate among Non vaccinated people. The first method i.e. control method is not very precise method. Also confidence interval cannot be calculated unless denominators are known for calculation of various proportions. Other methods are used depending on the study design.

Let us take a hypothetical example where isoniazid chemoprophylaxis and development of tuberculosis is studied.

Screening		
Measures of association and 95% confidence interval		
Sensitivity	99.0%	98.1, 99.5
Specificity	90.0%	89.8, 90.2
Predictive Value Positive	9.1%	8.6, 9.7
Predictive Value Negative	00%	100.0, 100.0

The interpretation of each of the parameters listed in the table is explained in detail in the section on Research Methodology.

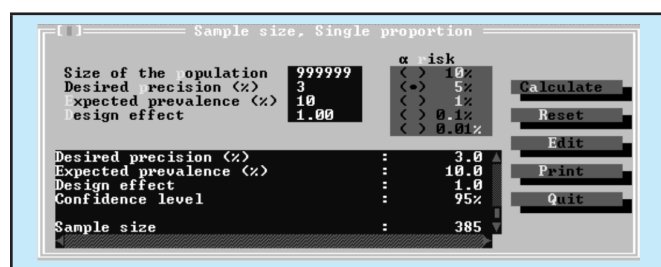

Sample

On pressing sample following options are made available.

- Sample size
- Power Calculation
- Random number table
- Random number list

Sample size: The first option gives the desired number of *minimum* sample size required for the various studies. The parameter under consideration can be single proportion or two proportions. Also sample size can be calculated for cohort and case-control studies.

Single proportion : Let us understand this with an example. Suppose a study on gestational diabetes is undertaken. The expected proportion is $p=10\%$ with the desired precision or acceptable deviation as 7% to 13% i.e. 3% on either side. ($d=0.03$). We specify the alpha error as 5%. To estimate the minimum sample size for the above proposed study we first have to press *sample* and then select the first option *single proportion* which displays the screen requesting the information on the size of the population, desired precision (%), expected prevalence (%) and design effect.

Design effect is a bias introduced in the sampling design and is taken as 1 which means that there is no design effect. (Note: In case of cluster sampling the design effect is taken as 2). After substituting the required information press *calculate*. The required minimum sample size is calculated as 385. It is noted that the sample size is same as was calculated by the Population Survey from Statcalc option of EPI2002.

Two proportions : This option is used when we are interested in comparing two groups with respect to variable of interest. The specifications required are the anticipated or expected proportions in both the groups along with the alpha error and power of the test. Let us calculate the sample size for the following situation. Suppose the proportions of patients who develop complications after a particular type of surgery is 5% while the proportion of patients who develop complications after another type of surgery is 15%. We wish to test whether the second surgery has more complication rate than the first type of surgery with a power of 90%. The level of significance or type I error is assumed to be 5%. In this given situation to arrive at the number of patients that would be required in each group we first press *sample size* from the menu sample. From the sample size select *Two Proportions*. After specifying the requirements as given above and then pressing Calculate the

results on the screen appear are as follows:

Thus a total of 414 i.e. 207 patients in each group are required to study.

Cohort study : Refer back to the example on HAPO which was considered for sample size determination using Statcalc. Substitute the required values of attack rate among non exposed as 1% and the detectable RR as 0.5. Also substitute the alpha error and power as 5% and 80% respectively. After pressing Calculate the minimum required sample size is 10134. In other words we would require to study 5067 subjects who would get Diamox and another 5067 subjects who would not get any drug.

Case control study : Refer back to the example on HAPO which was considered for sample size determination using Statcalc. Substitute the required values of percentage of exposure among controls as 10% the OR worth detectable as 3. Also substitute the alpha error and power as 5% and 80% respectively. After pressing Calculate the minimum required sample size rendered is 226. In other words we will need 113 cases OF HAPO and another 113 healthy controls to do this study. (Note that the sample size determined are almost same when calculated by sample size option of Statcalc)

Power calculation : The power calculation option calculates the power of the study. It is the complement of the beta error. In other words it is the probability of making the correct decision. It can be calculated in both the cohort studies and case-control studies. The specifications required in both the situations are as seen in subsequent figure.

Substitute the sample size along with alpha error and other information of the study. Pressing *Calculate* reveals the power of the study.

Consider the two examples that we have discussed above in the sample size determination option for cohort and case-control study. If we substitute retrospectively all the specification (except power) taken into consideration including sample size which was calculated. On pressing *Calculate* the power of the study is detected as 80% for cohort study and 84% for case-control study.

Please note that the calculations for sample size and power by the package differ from the manual way of calculations by slight margin. Hence it is recommended that for calculation of sample size and power the reader preferably uses the ready tables from WHO manual.

Random Number Table : This option generates a table of random numbers with a specified number of digits. Available options include the number of digits of generated numbers, as well as the total number of random numbers generated.

Ex : Let us consider a hypothetical study where we require selecting 25 subjects by simple random sampling technique using random number method. Thus we want to generate 25 random numbers. On the screen we specify the number of random numbers as 25 and the digits per number as 2 (Since we have population which consists of subjects numbered in two digits). Pressing calculate gives a list of 25 two digit random numbers as follows.

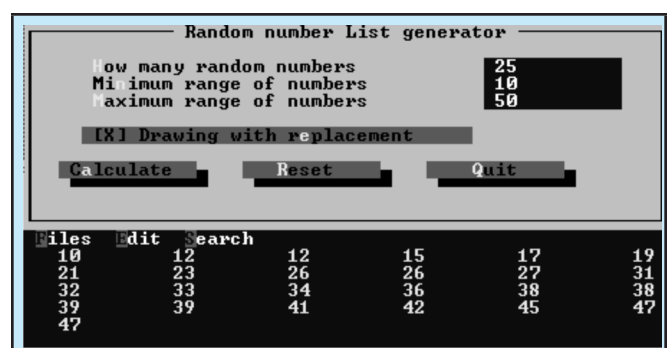

Thus, from the population we will choose the subjects with numbers 12, 58, 73 and so on, to form our study sample.

Random number list : This option generates a list of random numbers ranging from a minimum to a maximum value. These random numbers can be drawn with or without replacement. In without replacement duplicates are not allowed whereas in with replacement duplicates are allowed. The random numbers generated are presented in sorted order.

The difference between random number table and random number list is that the random number table generates the specified number of random numbers from all the available digit number that we have specified. For example in the above example the 25 random numbers are generated from 01 to 99. Whereas the random number list gives us a list of numbers where the range can be specified by us. For example if we want a list of 25 random numbers from 10 to 50 without replacement then the output is as follows

Note that none of the random number repeats itself in the list. Let us draw the same number of random numbers (25) but now if we specify with replacement then the output is as given below.

Note that the random number 12, 26 38 and 47 are repeated in the study.

LS Vaz

Medical informatics is the application of computers, communications and information technology and systems to all fields of medicine - medical care, medical education and medical research. Medical informatics is the rapidly developing scientific field that deals with resources, devices and formalized methods for optimizing the storage, retrieval and management of biomedical information for problem solving and decision making. It is the branch of science concerned with the use of computers and communication technology to acquire, store, analyze, communicate and display medical information and knowledge to facilitate understanding and improve the accuracy, timeliness and reliability of decision-making. Medical Informatics (MI) provides a comprehensive survey of current work performed to develop information technology for the clinical workplace. It deals with the acquisition of data from patients, processing and storage of data in computers and the transformation from data into information data. Some topics pertain to methodological aspects of medical informatics and others are intended to be used for more advanced or specialised education. They contain the methodology for information systems and their processing. The future of MI as a profession is very promising. The international standards on Health informatics are covered by ICS 35.240.80 in which ISO 27799:2008 is one of the core components.

The earliest use of computation for medicine was for dental projects in the 1950s at the United States National Bureau of Standards by Robert Ledley. The next step in the mid 1950s were the development of expert systems such as MYCIN and INTERNIST-I. In 1965, the National Library of Medicine started to use MEDLINE and MEDLARS. MUMPS (Massachusetts General Hospital Utility Multi-Programming System) was developed at Massachusetts General Hospital in Boston. The largest enterprise-wide health information system that includes an electronic medical record is known as the Veterans Health Information Systems and Technology Architecture or VistA. A graphical user interface known as the Computerized Patient Record System (CPRS) allows health care providers to review and update a patient's electronic medical record at any of the VA's over 1,000 health care facilities. Since then, Internet-based communications are evolving at a tremendous speed. Searching medical literature: The information technology has made searching the medical literature easier and more readily accessible. The United States National Library of Medicine (NLM) maintains several comprehensive, cross-referenced medical literature databases.

In the 1970's a growing number of commercial vendors began to market practice management and electronic medical records systems. Although many products exist only a small number of health practitioners use fully featured electronic health care records systems. The NHS in England has also contracted out to several vendors for a National Medical Informatics system 'NPFIT' that divides the country into five regions and is to be

united by a central electronic medical record system nicknamed "the spine". 60% of residents in England and Wales have more or less extensive clinical records and their prescriptions generated on 4000 installations of one system (EMIS) written in 'M' similar to MUMPS. The other 40% predominantly have records stored on assorted SQL or file-based systems. Scotland has the GPASS system whose source code is owned by the State and controlled and developed by NHS Scotland. It has been provided free to all GPs in Scotland. The European Commission's preference is for Free/Libre and Open Source Software (FLOSS) for healthcare. In Hong Kong a computerized patient record system called the Clinical Management System (CMS) has been developed by the Hospital Authority since 1994. This system has been deployed at all the sites of the Authority (40 hospitals and 120 clinics) and is used by all 30,000 clinical staff on a daily basis, with a daily transaction of up to 2 millions. The comprehensive records of 7 million patients are available on-line in the Electronic Patient Record (ePR), with data integrated from all sites. Radiology image viewing has been added to the ePR, with radiography images

The hospital management and information system consists of not only information of the hospital and clinical information of a patient but also includes telemedicine, computer-assisted instructions to patient as well as doctors and may even cover computer-assisted imaging and surgery. Surgical simulations and virtual environment are educational tools not only for doctors but also for patients. It is the era of convergence with the computer screen.

Uses of Medical Informatics : Informatics Use in Health Care can be in the following fields:

- 1) Communication : This includes Telemedicine, Tele-radiology, Patient e-mail and Presentations
- 2) Knowledge management : Including Journals, Consumer Health information and Evidence-based medical information
- 3) Decision Support : Including Reminder systems, Diagnostic Expert Systems and Drug Interaction
- 4) Information Management : Examples are Electronic Medical Records, Billing transactions and Ordering Systems

Hospital management and information system : Hospitals are the main providers of medical and health care. Significant progress has been made in improving their efficiency and operations. Effective computerised systems and procedures need to be implemented to ensure proper utilisation of limited resources toward cost-effective quality health care and the patient satisfaction. Before deciding to go for such system one should have some insight to the implementation of the different modules and evolving user-friendly computerised systems, which are loved and cared by all. The various parts of the Hospital information systems are

- a) Electronic medical records & medical vocabularies
- b) Laboratory information systems
- c) Pharmaceutical information systems
- d) Radiological (imaging) information systems
- e) Patient monitoring systems

Computer-based patient record: Physicians and health administrators can efficiently retrieve data for consequent research from the computerised medical records. Good clinical

research needs accurate and detailed clinical information and they significantly improve the medical care. This detailed information can even be used for other processes in the business of medical and health care. The knowledge of advantages and disadvantages of different systems available for recording and codifying are important.

Knowledge-based and expert systems: The rapid evolution of technology and clinical research makes it difficult even for the specialist to keep up. In the light of this 'information explosion', it has been demonstrated that physicians do not always make optimal decisions. A computer-assisted diagnostic support system generates diagnostic hypothesis from a set of patient data. It can be used simultaneously with the doctor-patient consultation.

The knowledge-based system (KBS) is designed to meet the knowledge gaps of the individual physician with specific patient problems. KBS and such other expert systems (ES) can be a boon to the rural health centres because even the general medical practitioners can operate the systems. Computer-assisted medical decision making and knowledge-based systems are ideal examples of artificial intelligence.

Clinical decision-support systems help the physician in Diagnosis/Interpretation and then further in Therapy/Management. The software for such Diagnosis/Interpretation could have a broad scope as in Internist-I/QMR which deals with internal medicine. Others include softwares like Dx; DxPlain; Iliad; EON for guideline-based therapy. Softwares with Narrow scope include de Dombal's system for diagnosis of acute abdominal pain; MYCIN for infectious diseases ; ECG interpretation systems; ONCOCIN support application of oncology protocols. Specific softwares like MYCIN, QMR are useful for human-initiated consultation; while data-driven reminders are provided by MLMs. Some closed loop systems help which help in certain specific activities e.g. ICU ventilator control

Telemedicine : With the advancement in information technology, telemedicine has become an important part of medical practice. This method of distance management in medical and health care not only benefits patients but also medical practitioners. How to use the electronic transmission of medical data to enhance patient care and empower the physician is the hotly discussed topic among the health providers. Telemedicine is set to revolutionise health care system. The advances and convergence of IT and telecommunication can bring the entire health care services to the patient's doorstep. Telemedicine is delivery of health care information across distances using telecom technology. This includes transfer of images like X-rays, CT, MRI, ECG etc. from patient to expert doctors seamlessly, apart from the live video conferencing between the patient at remote hospital with the specialists at the super speciality hospital for tele-consultation and treatment.

Telemedicine has been successful in reaching masses and telemedicine is set to revolutionise the health care system because it is one of the innovative methods of connecting two distant hospitals through Satcom-based communication link. It may be noted that generally 90 per cent of the patients do not require surgery and if so the doctor generally need not touch

the patient and in that case both need not to be at the same place. They can be at different locations and still the patient can be treated. Telemedicine makes an ordinary doctor in rural area do extraordinary work since the doctor is advised by the specialist in handling the medical problems including emergencies. Further, the needy patient need not undertake long and difficult journey to towns and cities, especially when the condition of the patient is serious like in case of heart attack or trauma. There will be cost-saving in terms of reduced necessity to travel for the patient and the family when telemedicine facility is used.

ISRO has initiated a number of telemedicine pilot projects which are very specific to the needs of development of our society. The projects consist of linking hospitals in remote and inaccessible areas with superspeciality hospital located in the city through Indian National Satellite (INSAT). Remote areas covered are J&K and Ladakh in North, offshore islands of Andaman and Lakshadweep, interior parts of Orissa, north-eastern states of country and some tribal districts in the mainland states. Telemedicine is most effective for India which is vast and has different regions like the mountain region of J&K and Ladakh, far-flung areas of North East and offshore islands of Andaman and Lakshadweep. With a majority of our population living in rural area and majority of doctors living in urban areas, telemedicine can be a solution for providing improved health care for benefits like improved access, reduced cost, reduced isolation of doctors and finally improved quality of health care.

The telemedicine has good potential to grow since it provides speciality health care to the remote hospitals. The growth could be the connectivity between (a) district hospitals/ health centres and super-speciality hospitals in the cities (b) Community Health Centres (CHC) at block level and district hospital (c) Primary Health Centre (PHC) at village level and community health centres for health care and delivery of medical advice. Further, there could be a network of super-speciality hospitals providing telemedicine consultation to any of the regions.

Physician Education : Computer-assisted learning is rapidly evolving and provides several advantages over traditional approaches. The biomedical knowledge base can no longer be taught in its entirety; therefore, one must depend on his learning skills. Self-directed learning and lifelong learning skills can enhance and accelerate the application of the application of an expanding knowledge base to patient care. The impact of computers on the continuing medical education (CME) programmes is immense.

Patient Education : On the Internet, patients can quickly obtain the latest information on support groups, therapeutic modalities, late-breaking research and individual coping strategies. If clinicians incorporate some sort of Computer-assisted patient education in their practice that can empower their patients to make the right individual decisions. Informatics applications will have their greatest impact on the quality of patient care and patient safety when in the future applications are merged into one seamless system. Evidence that this trend has begun can be seen in the latest clinical information systems that include communications and decision support as well as

knowledge management.

More recently, hospitals are installing or planning to install computerized physician order entry systems. Research has shown that these systems as well as telemedicine, computerized reminder systems and broader based decision support systems can enhance clinician's performance and improve patient care.

Order entry systems reduce medication errors and detect potential drug interactions while clinical decision support systems improve drug dosing, improve preventive care but not diagnosis.

Barriers to Progress : Five categories of barriers to technology integration: time, expertise, access, resources and support.

The lack of time is at the top of their list as the obstacle most often mentioned. This includes time to plan, collaborate with peers, prepare lessons and materials, explore, practice and evaluate, as well as develop, maintain and expand skills. Other articles also identify time as an important barrier. Expertise is another potential barrier to technology integration. Technology training for teachers must be available. Effective technology training must be hands-on, systematic and ongoing. Additionally, a variety of models and approaches should be available to accommodate different needs, schedules and learning styles. Teachers must have uninterrupted, on-demand access to the technologies they intend to use, both while inside and outside of the classroom. Hardware and software availability is a potential barrier.

The fourth category is resources. This includes resources to purchase, maintain and upgrade hardware and software; to provide training and support; and for auxiliary costs, such as coordinating technology access and continuing costs, such as purchasing printer ink. They also note a relationship where time, expertise and access are dependent on resources.

Support is their fifth barrier category, both administrative and technical. Administrative leadership and support may be the most critical factor. In addition to providing the needed financial resources, the administration can set expectations, develop a vision and plan for technology integration and provide incentives and encouragement. Technical support not only includes the personnel for maintaining the technology, but it also includes personnel who are knowledgeable about pedagogical issues, such as appropriate instructional methods or media. Growth of Medical Informatics has also been stifled due to lack of:

- Universally agreed-on medical vocabulary
- Principled and standard formats for laboratory data, medical images, medical record...
- Standardization of medical literature formats--structured abstracts
- Health care standards -- treatment guidelines
- Standards for health data exchange

The Future

So let's see what it is like to be a student of medical informatics or a doctor living in the 21st century. Here is a typical basic sciences classroom. Students who normally have a microscope in front of them now have a wireless laptop computer and PDAs. These would be loaded with Microsoft Office Professional, Stedman's Medical Spellchecker, Endnotes, Adobe Photoshop Elements and Medical References InfoRetriever. The students would be capable of Evidence Based Ref., Disease Reference, Medical Calculator, Drug Reference and Medical Dictionary. The Computer Lab is being used for Student teaching and Faculty development. The faculty would be assisted with programs like Anatomy lab video enabled, digital BacusLabs web-slide program, Gold Standard Multimedia, Cross Sectional Anatomy. The students test themselves with LXR Testing Program which has Question bank, Computer-based testing and Item analysis/grading. The United Streaming Videos in Anatomy and

Histology provide an insight into aspects difficult to visualize earlier. The internet provides the students with guides for Knowledge management through eJournals , Consumer Health information and Evidence-based medical information.

Summary

Medical informatics is the application of computers, communications and information technology and systems to all fields of medicine - medical care, medical education and medical research. It is the branch of science concerned with the use of computers and communication technology to acquire, store, analyze, communicate and display medical information and knowledge to facilitate understanding and improve the accuracy, timeliness and reliability of decision-making. It deals with the acquisition of data from patients, processing and storage of data in computers and the transformation from data into information data. Informatics Medical informatics is used in Health Care can as Communication (Telemedicine, Tele-radiology, Patient e-mail and Presentations), Knowledge management (Journals, Consumer Health information and Evidence-based medical information), Decision Support (Reminder systems, Diagnostic Expert Systems and Drug Interaction), Information Management (Electronic Medical Records, Billing transactions and Ordering Systems).

Various health information systems like MEDLINE, MEDLARS, MUMPS (Massachusetts General Hospital Utility Multi-Programming System), VISTA (Veterans Health Information Systems and Technology Architecture) CPRS (Computerized Patient Record System) were developed in various nations. The NHS in England has also contracted out to several vendors for a National Medical Informatics system 'NPFIT' and Scotland has the GPASS system. The various parts of the Hospital information systems are Electronic medical records & medical vocabularies, laboratory information systems, pharmaceutical information systems, radiological (imaging) information systems and Patient monitoring systems.

The Knowledge-Based System (KBS) is designed to meet the knowledge gaps of the individual physician with specific patient problems. KBS and such other Expert Systems (ES) can be a boon to the rural health centres because even the general medical practitioners can operate the systems.

Clinical decision-support systems help the physician in Diagnosis/interpretation and then further in Therapy/management. The software for such Diagnosis/interpretation could have a broad scope as in Internist-I/QMR which deals with internal medicine .Others include softwares like Dx; DxPlain; Iliad; EON for guideline-based therapy. Softwares with Narrow scope include de Dombal's system for diagnosis of acute abdominal pain; MYCIN for infectious diseases ;

ECG interpretation systems; ONCOCIN support application of oncology protocols. Specific softwares like MYCIN, QMR are useful for human-initiated consultation ; while data-driven reminders are provided by MLMs. Some closed loop systems help which help in certain specific activities e.g. ICU ventilator control.

Telemedicine is a method of distance management in medical and health care not only benefits patients but also medical practitioners. Telemedicine is delivery of health care information across distances using telecom technology. This includes transfer of images like X-rays, CT, MRI, ECG, etc. from patient to expert doctors seamlessly, apart from the live video conferencing between the patient at remote hospital with the specialists at the super speciality hospital for tele-consultation and treatment.

Five categories of barriers to technology integration are time, expertise, access, resources and support. Time to plan, collaborate with peers, prepare lessons and materials, explore, practice and evaluate, as well as develop, maintain and expand skills. Effective technology training must be hands-on, systematic and ongoing. Teachers must have uninterrupted, on-demand access to the technologies they intend to use, both while inside and outside of the classroom. Resources to purchase, maintain and upgrade hardware and software; to provide training and support; and for auxiliary costs are required. Administrative leadership and support may be the most critical factor.

Study Exercises

Long Question : Describe various parts of the Hospital information systems. How is it used in a Health care system?

Short Notes : (1) Uses of Medical Informatics (2) Hospital information system (3) Telemedicine (4) Clinical decision-support systems

MCQs

1. NPFIT is a Hospital information system in (a) UK (b) Scotland (c) India (d) USA
2. Dx software is a (a) Knowledge-based system (b) Clinical decision-support systems (c) Hospital information system (d) None
3. The transfer of images like X-rays, CT, MRI, ECG etc. from patient or doctor to expert doctors/specialists at speciality hospital for consultation and treatment is known as (a) Hospital information system (b) Telemedicine (c) knowledge-based system (d) Clinical decision-support systems

Answers : (1) a; (2) b; (3) b.

3

Health Policy & Health Care Systems

- 3a) Management Process in Health Care
- 3b) Health Systems and Policies
- 3c) Public Health Administration & Community Health Care in India

Anuj Bhatnagar

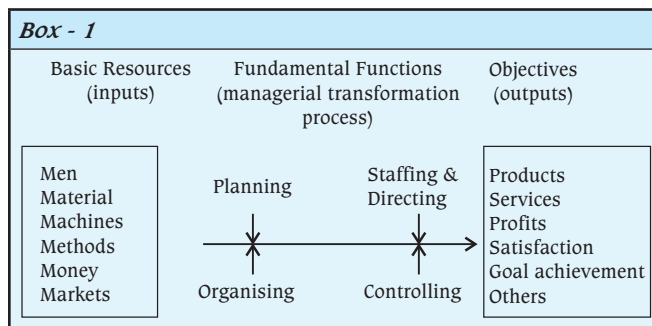

The key issue which forms the basis of any organisation or group of people is a common objective or a goal, which may be winning the match, prevent thefts in the neighborhood, deliver good quality health care to community or earn maximum profits. It is thus natural that without a common goal or objective, there would be no need for people to form groups or organisations. Since achievement of a common goal forms the basis for forming groups, each organisation must then also have some plans to achieve the common goals and every organisation must also procure and dedicate certain resources (in the form of money, material and men) for achieving the common goals.

Definition of Management

The shortest definition of 'Management' is "*Management is getting things done through and with people*". However, two of the most widely quoted definitions are :

"Management is the art of getting things done through and with people in formally organized groups. It is the art of creating the environment in which people can perform and individuals can cooperate towards attainment of organisational goals. It is the art of removing blocks to such performance and a way of optimizing efficiency in reaching goals." (Harold Koontz)

"Management is a distinct process consisting of planning, organizing, actuating and controlling, performed to determine and accomplish stated objectives, by the use of human beings and other resources." (George R Terry). Box - 1 represents this often quoted definition of management :

Basic Principles of Management

Henry Fayol (1881-1925), generally considered as the founder of classical management theory, laid down certain basic principles of management. Prior to Fayol, it was believed that good managers were born, not made. Fayol proposed that management, like any other skill, could be taught and mastered once its basic underlying principles, as under, were understood. These principles are :

1. Division of work according to the ability, capacity and aptitude of the workers is essential in any organisation for optimal utilization of scarce human resource and to maximize productivity in any form.

2. Well-defined responsibility leads to accountability and thus enhances performance of individuals. However responsibility can only be effective when it is combined with delegation of authority.
3. Discipline in any organisation is essential and a hallmark of compliance and mutual cooperation between various functionaries. Discipline within any organisation directly depends on good supervision, fair codes of conduct and judiciously implemented rewards & punishments.
4. An employee should ideally receive his/her orders only from one superior since multiple commanding authorities would lead to confusion and chaos. This principle is well entrenched in the armed forces, where the unity of command is practiced.
5. Organisational goals should receive preference and are more important than individual goals.
6. Remuneration in form of pay and allowances should be pre-determined for all personnel, to avoid uncertainty.
7. Centralization of important policy decisions and key matters is essential in any organisation to provide a well defined direction to efforts of individuals.
8. Employees should function in well defined functional chain of senior-subordinate relationships, called scalar chains, ideally depicted by a line organisation (explained subsequently).
9. Unity of direction, which means that directions for the entire organisation should flow downwards from the head of the organisation to all other functionaries.
10. An order in an organisation ensures stability & efficiency.
11. Equity in an organisation removes conflicts and ensures compliance & cooperation.
12. Stability of working period (tenure) ensures certainty in minds of workers and enhances performance by inculcating a sense of belonging & responsibility among individuals.
13. Initiative among employees gives them a chance to utilize their skills and hence results in better employee satisfaction, besides enhancing performance.
14. Team spirit (spirit-de-corps) is essential for any organisational work.

Why must you study management as a medical doctor?:

It is sometimes said that doctors are poor managers. The unwillingness to study management sciences has led to a large number of brilliant doctors being failures when it comes to leading. Like any other team, any medical team also consists of various individuals who perform their respective tasks in order to meet the common goal - of providing best health care with optimum utilization of scarce medical resources. All aspects of management are equally, in fact more, applicable to a health team, be it at a PHC or a highly specialized team of a multi-speciality tertiary care centre in a metropolis. As a medical doctor, you are expected to lead a highly professional team of trained health care workers. All your activities, be it a vaccination drive in a village or a highly complicated surgery has to be planned well in advance. You will have to carefully select your team members & motivate them to perform. In short, any health team with you as its leader is just like any other organisation with its unique organisational objectives, which have to be attained through sustained efforts of all the members.

In addition, we must also remember that all medical personnel are highly trained and intellectual, posing a challenge to any leader of such capability. Medical logistics and resources, like in any other field are always in short supply and hence have to be optimally deployed and utilized to ensure maximum benefit. For example, a MRI scan machine worth a few crores must give adequate returns in the form of adequate patient load. Investing heavily in such equipment at a location where only one or two MRI scans are done in a month would be waste of vital resources which could be better utilized elsewhere. Thus, medical profession today is no more isolated and has to extensively draw upon all managerial sciences of human resource development, financial and material management for smooth functioning of the health team. Hospitals today are complex organisations and hospital management, as a sub-specialty of management, has gained grounds rapidly. It is now being increasingly felt that basic management skills are essential for every medical doctor for him/her to function effectively as a team leader.

Management Vs Administration

Some ambiguity exists regarding 'management' and 'administration', with some writers thinking them to be distinct activities whereas others feel they are different aspects of management itself. Having defined management, administration can be defined as 'those functions in an organisation, which are concerned with policy formulation, finance, production, distribution and ultimately control all key activities for meeting the organisational objectives' (Sheldon). It can thus be assumed that policy-making, planning and decision making are the basic components of administration whereas supervision, implementation and operational aspects are considered components of management. Thus the top management such as Director or Dean of a teaching hospital is more concerned with policy and decision making and lesser of day-to-day supervision & control, whereas lower management levels (Heads of Departments and Registrar) are concerned more with effective supervision & control of daily activities being carried out. Fig - 1 depicts the difference between Administration (administrative management) and Management (operative management).

The Management Processes

A medical officer, in many ways is like any other leader and manager and has to daily meet some objectives, which may range from implementing a health program in a district to undertaking a complicated surgery with his surgical team. To successfully attain the objectives with optimum resources, requires a series of managerial processes, which are as shown in Fig. 2 :

Planning

Planning is the fundamental and initial process in any activity and success of any project or activity depends on how well it has been planned. If any team effort has to be successful, all team members must know in advance what they are expected to accomplish (objectives). Thus setting the objectives is a major function of planning. Planning consists of deciding in advance what to do, how to do, when to do and who is to do it, and thus it bridges the gap between where we are presently and where we have to reach. Planning consists of taking conscious and well thought out decisions about which course of action to take out of the many available and most suitable method to achieve these objectives. Planning ensures that pre-determined objectives and goals are identified so that all resources can be allocated and dedicated in achieving these goals in the most optimal manner. In short, it can be said that the process of planning answers the following questions for the manager :

- What will be done – identifying short and long term objectives and goals.
- What resources will be used – identifying the available & potential resources required for achieving the objectives and filling the gaps in resources, if any.
- How will it be done - determining the specific activities required for attaining the goals and formulating strategies, policies, procedures, methods, standards & budgets.
- Who will do what – delegating responsibilities to various individuals for attaining the organisational goals.
- When will it be done – assigning the time frame and sequence for completing each activity.

The Planning Process in Health Sector

As a leader of medical professionals, a doctor is often faced with a situation where he has to plan various health activities. The basics of planning process in the health sector can be remembered by answering the following key questions :

- Where are we at present (situational analysis)
- Where do we finally want to reach (objectives & goals)
- How do we get there (resources & constraints)
- How effectively we have performed the required activities (evaluation, monitoring & feedback)
- What new problems do we face and how do we overcome them (re-planning)

Steps Involved in Planning a Health Program

This aspect has been deliberated in detail in an exclusive chapter in the section on epidemiology. You are advised to go through the same.

General Terms used in Relation to Plans : As a leader of the health team, it is important for a medical officer to know about the various types of plans and the distinction between them. As discussed earlier, all organizational plans are formulated with the instinct to achieve the pre-determined objectives in the

most efficient manner. Various types of plans can be classified as under :

(a) Mission : The mission of an organization is described as the very reason why that organization exists. It is always described in terms of the benefit (direct or indirect) provided to users by the organization and not in terms of the product or services rendered. It is of utmost importance for any organization to clearly define its mission, since that will determine all efforts of that organization. The organization must ask the question “what is our business” and answer it from the users' viewpoint. The mission of an organization is described in its ‘mission statement’. For example the ‘mission statement’ of Department of Community Medicine of a medical college would be “To provide comprehensive training in community medicine to medical graduates and post graduates, with the aim to make them better public health specialists.” The mission of an organization is dynamic and must adapt to the environmental changes and requirements. The organization has to decide how it would like to define what its business would be. Formulating the mission is of utmost importance and never easy; it must balance between the present & the future. A narrow definition of ‘mission’ will limit the activities of the organization to the immediate present & prevent its growth and utilization of newer opportunities & technologies, whereas too broad a definition of mission will not enable the organization to concentrate on any workable activity and opportunities at present. For example, a doctor at PHC would most likely describe his mission as “providing timely and expert primary care to villagers in his jurisdiction” whereas a cardiothoracic surgeon at a large multispeciality metropolitan hospital would describe his mission as “providing highly specialized cardio-thoracic surgery to all those who are brought to the cardiothoracic department of the hospital”.

(b) Objectives : Having first formulated the ‘Mission’ of the organization, which answers the question ‘what is our business’, the next step would be to translate this relatively abstract mission into smaller, tangible, measurable & achievable ‘objectives’ for managers at lower levels. Thus objectives are the ‘action orientation of the mission’ and form the basis for taking action in appropriate direction and for measuring the performance. For example, let us assume that the mission statement of a measles immunization program is ‘to immunize children below 2 yrs with measles vaccine to protect them against measles’. The objective in this case would be ‘immunization of 90% of all children in any given village’, which would form the basis of action to be taken by the health workers and would also act as a measurement of performance. However, it must be remembered that objectives remain statements of expected outcomes and not the actual performance or outcome.

(c) Goals : Goals can be described as intermediate time-bound and specific targets which are necessary for achievement of objectives in the organization. Being derived from objectives, goals are very specific (quantitatively or qualitatively). ‘Goals’ would broadly have four characteristics as under:

- (i) Goals are derived from the objective which they seek to fulfill.
- (ii) Goals form the benchmark and standards for measuring performances & progress towards achieving the larger

organizational objectives.

- (iii) Goals often represent a target to be achieved or a hurdle to be overcome.
- (iv) Achievement of goals has to be within a specific time frame.

Thus we have seen that goals are action-oriented, provide a means for converting plans into smaller achievable tasks and are time bound. Goals also play a major role in motivating people towards working in a coordinated fashion towards the larger organizational objectives.

(d) Strategies : Strategy is any decision, plan or action which takes into consideration the actions of competitors and other factors in external environment, with the aim of achieving the objectives. For example, when as a doctor, you would plan your IEC campaign for promoting condom usage among community, keeping in mind the reaction and resistance of a particular section of community, it would be called a strategy. The strategist would thus consider the reaction of external environment and plans of his ‘rivals’ (anyone who could delay or derail the achievement of his goals & objectives), while planning his course of action. As a health strategist, one would select strategies (plans) that would help in achieving the objectives and which would create an advantageous position for the entire health team in dealing with the external (socio-economic & socio demographic) environment in which the health team has to operate.

(e) Policies : It is important to understand the difference between strategies and policies, since both are often confused and used interchangeably. Whereas strategies focus of the best course of action (among alternatives) after considering external environment and possible actions of competitors / rivals, policies on the other hand, provide guidelines for decisions and actions. For example, it is the policy of a state government to immunize all children against Hepatitis B, which is thus the guideline for the health directorate of that state to procure vaccines and implement Hepatitis B vaccination at all its health centers & hospitals. Policies do not tell a manager what he should or should not do in a given situation. Policies tell a manager what he can do by setting a limit within which a manager must operate. Well formulated policies in any organization help in achieving the pre-determined objectives by channelising all managerial decisions in the right direction, providing tangible and measurable criteria for evaluation of decisions taken and by ensuring uniformity in decisions throughout the entire organization.

(f) Rules : As compared to policies (which are guide to decisions), rules are guides to action and prescribe a type of behavior / actions which are permissible. Rules define what should or should not be done. For example, the attendance rule of PHC staff states that if any health worker is late for three days in a month, he shall lose one day's casual leave. Rules are effective only when they carry a penalty / punishment for non-compliance and thus regulate employee behavior, though at the same time restricting their initiative and innovativeness. Policies by and large, define a broad sphere within which a leader has to act using his discretion. Rules on the other hand, leave no scope for any discretion by clearly defining the acceptable behaviour/actions.

<i>General principles to be followed for formulating organizational policies</i>	
1.	Policies should always assist in achieving the organizational objectives.
2.	Policies should be well defined and should be in writing.
3.	Policies at each level should be derived from and should support the policies of the next higher level.
4.	Policies of a department in the organization should be well coordinated with policies of other departments, and should not pose a hindrance / obstacle to policies of other departments.
5.	Policies should be just, unbiased and equitable towards all sections of employees.
6.	To incorporate the changing needs and changing organizational environment, policies should be periodically reviewed and revised.

(g) Procedures : We have seen that policies are guides to decisions and rules are guides to action. Procedures are chronological steps involved in performing any action or taking any decision. For example, the procedure of administering an intra muscular injection to a patient can be broken down into distinct sequence of actions as under :

- (i) Disinfection of site with spirit.
- (ii) Assemble the syringe & needle.
- (iii) Break the injection vial.
- (iv) Fill the syringe with injectable drug (say Inj Voveran).
- (v) Insert the needle into the muscle (deltoid or gluteal region)
- (vi) Partly withdraw the plunger to ensure that needle is not in a blood vessel.
- (vii) Depress the plunger to inject the drug.
- (viii) Withdraw the needle out of the skin without shaking/bending .
- (ix) Swab the injection site with cotton.

Thus, procedures are sequence of activities that have to be performed in order to achieve a certain objective (e.g. giving an intramuscular injection). All medical officers are well conversant with many surgical or nursing procedures which have to be performed sequentially to complete a task, such as 'Hand washing procedure' in operation theatre, procedure for starting an intravenous lifeline in intensive care unit etc.

(h) Programs : As a doctor, one is often required to manage and implement various health programs in our respective areas, which makes it important for every doctor to understand the concept of a program as a plan at the national level. A program is a set of those activities which have a specific time schedule and a distinct mission. Thus programs are a series of actions performed for achieving the organizational objectives '*within the scheduled time*'. In our example, when a medical officer of a PHC undertakes specific actions with the objective of attaining the 90% vaccination mark for measles among children below 2 years by the end of the year 2010, it is a health program. All medical students are also well aware of several National Health Programs (described in detail elsewhere in this book),

which aim at achieving certain health related objectives within a stipulated time-frame through a series of actions.

Organising

As a function of management, organizing deals with identifying and grouping various activities, delegating authority and command to managers and coordination of various activities and hierarchies in the organization. The process of organizing can be described as a series of steps as under :

(i) Detailed description of various activities to be performed for achieving organizational goals : For achieving the pre-determined organizational goals, we must know in detail what activities are to be performed. For example, before a hospital team can actually start treating the sick (organizational goal), they must know what equipment to buy, how many doctors, nurses and paramedical workers to hire, where to locate the hospital, how to construct and how many departments to create in the hospital.

(ii) Grouping of various activities in some meaningful manner : An organization invariably functions better when activities of a similar nature are grouped together, based on their essential similarity & difference from other activities. This would be best exemplified in creation of various departments in a large hospital. For example, all patients requiring surgical intervention (which may be for hernia, burst abdomen, gun shot wound or a simple abscess requiring incision & drainage) are referred to & attended in the surgery department (which itself may be further divided into cardio-thoracic surgery, gastrointestinal surgery, neurosurgery or vascular surgery depending on the detailed type of surgeries performed).

(iii) Delegation (comprising of authority, responsibility and accountability) : Consists of assigning each group of activities (departments) to a manager with authority to supervise its functioning (head of the department). Delegation, thus, is the most important part of organizing since any manager due to limited individual capabilities, can not carry out all organizational activities alone and has to delegate work to his subordinates. Successful delegation of work is accompanied by delegation of authority to take decisions & actions of accountability.

(iv) Coordination (horizontal and vertical) : Makes the organizing process complete. In any organization, every individual or group of individuals very often start concentrating on performing only their specific assigned task, often relegating the overall organizational goals to the background and generating conflicts. For example, in a large multispeciality hospital, the medicine department may be unwilling to part with their assigned vacant bed in ICU in anticipation of a case even when the surgery department needs it urgently for a patient of burst abdomen. The medical stores may be refusing to issue costly medicines prescribed by a junior doctor with the aim to curb wasteful expenditure, not realizing that the medicine is urgently required by the patient. Such occurrences are quite common in medical practice and this is where the role of the medical superintendent as a manager is of utmost importance. Coordination between departments and between various hierarchies in organization is thus an essential requirement to channelise energies towards achieving the

overall organizational goals and look beyond individual or departmental goals.

Principles of organizing : Some important principles of organizing are enumerated below :

(i) Unity of direction : One leader & one plan for a group of activities having the same objectives.

(ii) Unity of command : A subordinate reports only one boss to avoid conflict of orders.

(iii) Authority : Every individual in an organization has some responsibility commensurate with his authority.

(iv) Span of control : Number of subordinates supervised by a leader should not be too many for better control.

(v) Flexibility : Organisational staffing pattern & structure should be able to accommodate changes in internal & external environments.

(vi) Management by exception : All routine decisions should be taken by subordinates & only policy decisions and unusual matters should be referred to the leader.

(vii) Scalar principle : Clear lines of authority in hierarchical structure ensures more effective performance.

Formal and Informal Organisations : The organizing process results in a deliberately designed and thought out organizational structure where it is specified who will do what, with whom and under whose supervision. Such an organization is said to have a *formal organization* where hierarchies and levels of authority are formally laid down and observed. For example, a large corporate hospital, with its clearly and formally defined departments and its rigid hierarchy with the CEO at the top is a formal organization. On the other hand, a volunteer group of specialists who undertake charity work every weekend at a nearby charitable hospital for the poor would have emerged spontaneously due to their common likes and dislikes. Such an organization, which was not 'planned' to come into existence and which has no formal departments or hierarchies, is an informal organization. As a doctor, one is faced everyday with informal groups, like the village elders, a village self help group, a youth club etc and we must remember that informal organizations, with expressed shared values and sentiments of a large majority, can be very effectively utilized for achieving the organizational goals. The effort to include religious leaders & volunteer groups such as Rotary Club in the Pulse Polio Immunization in India is an example where such informal groups are often more successful in achieving organizational goals than the highly formal organization of the government.

Staffing

The concept of 'span of control' : Depending on the type of organization and objectives to be achieved, every manager must decide how many subordinates he/she can effectively supervise. Consequently, a wider span of control (generally found in highly technical organization with highly motivated subordinates) will result in lesser 'levels of management' than a narrow span of control (where one subordinate is controlled only by one superior). A 'flat organisation' (with lesser levels of management) has faster flow of information and greater satisfaction levels for individual subordinates. Such type of organization, where subordinates are highly motivated and

responsible is ideal for research and development such as in groups developing new drugs, vaccines or conceptualizing newer & better methods of health care delivery in remote villages.

Factors determining an effective span of control : Though there is no laid down limit of the optimum number of subordinates a manager can supervise effectively, the most important factor is the managers ability to reduce the time he spends with each subordinate in order to gain the maximum output from him. Seven important factors which determine the frequency and duration of superior-subordinate interaction (time spent by a superior with each subordinate, hence the span of control of each manager) are as under :

(a) Training levels of subordinates : Well trained subordinates require less frequency and duration of contact with superiors & result in wider span of control for the superiors.

(b) Clear delegation of authority : If a subordinate's task is not clearly defined or if he is not given enough authority, he would be spending disproportionate time seeking clarifications, thereby reducing his span of control.

(c) Clarity of plans : A superior would need to spend considerable time supervising & guiding the decisions of subordinates wherever subordinates have to do much of their own planning. This usually occurs whenever organizational plans are not clearly laid down.

(d) Objectivity in standards : Use of tangible and measurable standards against which actual performance of subordinates is to be measured enables the manager to avoid time-consuming procedures to ascertain if his subordinates are actually following the plans.

(e) Rate of organizational change : Narrow span of control becomes necessary wherever the rate of change in the organization is fast; which determines the stability of policies. Organizations with slow rate of changes (or relatively stable organizations in stable environment) would do better to have a broader span of control.

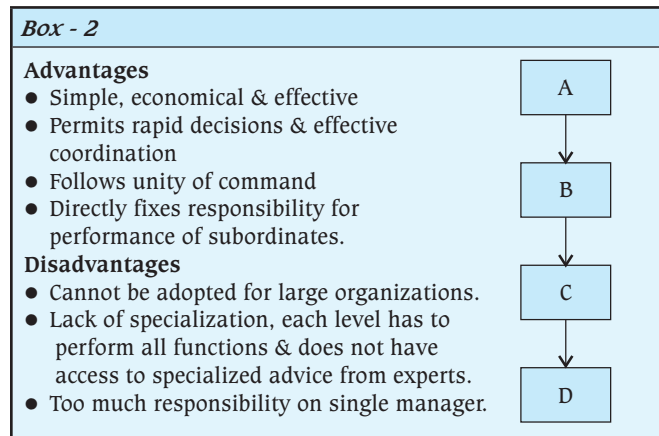

(f) Communication techniques : If instructions have to be personally delivered by a superior to his subordinates and repeated clarifications have to be sought, naturally there will be an added burden on the managers time, reducing his span of control.

(g) Amount of personal contact required : Under many circumstances, face to face meetings or conferences with subordinates are essential, which draw upon the time of a manager resulting in narrower span of control.

The concept of line and staff relationships : Traditionally, it has been held that line functions & personnel are those that are directly responsible for achieving an organization's primary objectives, while staff functions and personnel are those that assist line managers to function more effectively. Conceptually, it is important to note that in line relationship, there is a direct relationship of command between superior and subordinate, whereas staff functions are advisory nature to line managers whom they support. It is essential for any medical manager to know in what capacity (for example, an orthopedic consultant to a tertiary care hospital) their job is to advise and not command,

but when in line capacity (such as a medical superintendent of a large government hospital), they must make decisions and issue instructions for others to follow.

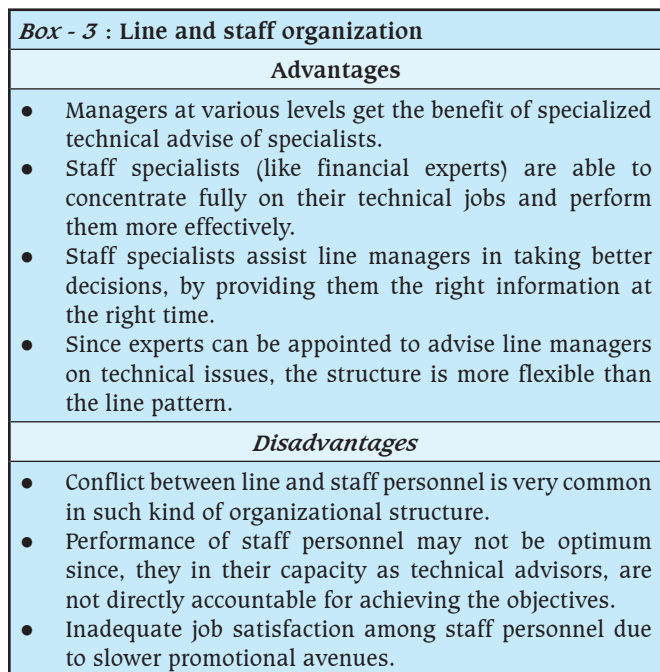

Line organization : A line organization consists of line personnel, where each position has direct authority over all lower positions. No subordinate is under more than one superior, and the scalar principle and principle of unity of command are strictly adhered to. The flow of authority in line organisation is depicted in Box - 2.

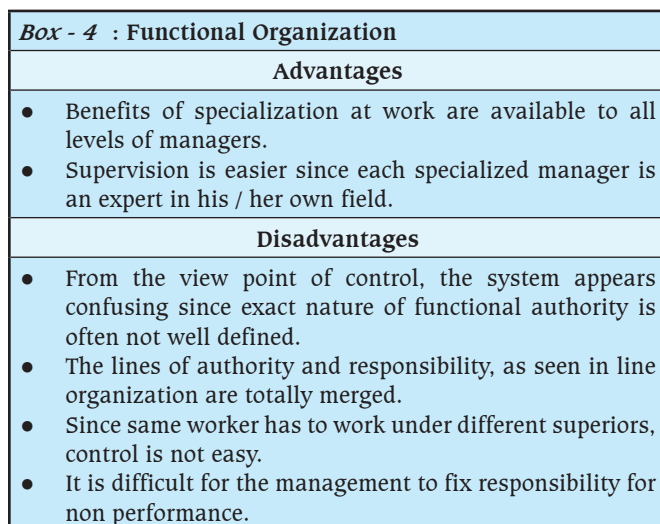

Line and staff organization : When in addition to the line authority of managers, there are specialists and experts to advise various levels on specialized issues, it is called the line and staff organization . In the figure below, A, C and D managers are in direct line relationship as discussed earlier; but B is in staff relationship and advises A and C on important issues. B may have lower status than A and higher status than C in the organization, but is not in direct line of command. Generally in any organization, those personnel who develop new ideas, undertake research and advise on technical matters and fall outside the direct chain of command are staff personnel. It is important to remember however that even in a staff department (for example, finance department of a large corporate hospital), the departmental head would still have line control over all subordinate financial experts. The flow of authority in line and staff organization is depicted in Fig. - 3.

The advantages and disadvantages of Line and Staff Organization are as in Box - 3.

Functional organization : In the large and complex organizations of the present day, the traditional principle of one boss and one subordinate (unity of command) is not possible. In such organizations, different superiors performing different functions (finance, human resource, inventory control etc) exercise control over a subordinate in respect of their respective functions. Thus a functional organization is one wherein a worker is accountable to two or more different executives for a given specific and specialized function. For example a radiographer in a large corporate hospital may be providing specialized services (radiotherapy) in three different wards and thus would be accountable or advising their respective Medical Officers in-charge in addition to being accountable to the Head of Department of Radiology Services. The advantages and disadvantages are as in Box - 4.

The Matrix Organisation : A combination of the product and functional structures, the matrix structures are the choice for large and complicated projects where the skills of a functional man (manager) and specialized (technical) knowledge (e.g. finance consultant) are both required. Under the matrix structure, an employee is accountable & takes orders from two different superiors at the same time. For example, a ward nurse is accountable to the Head Nurse of the Hospital as well as to the ward MO in which she is working. An example of the matrix organization in a large hospital is as represented in Box - 5.

Box - 5			
	Ward MO	ICU i/c	Anesthesiologist
Head Nurse	Ward Nurse	ICU Nurse	OT Nurse
Chief Sanitary Supervisor	Ward sweeper	ICU Sweeper	OT Sweeper
Chief Pharmacist	Ward Pharmacist	ICU Nurse	OT Storekeeper

Directing (Leading)

Leadership can be described as the activity of influencing people to strive *willingly* to achieve the group objectives. This ability may be *formal* (as in form of formal authority vested with an individual) or *informal* (as in form of power and ability to influence people outside the formal structure of an organization).

Leadership styles : This refers to the way in which a leader would influence the followers. Some of the leadership styles are described below :

(a) **Iowa leadership studies** : Lewin, Lippitt and White, in 1939, studied different styles of leadership among 10 year old boys in three groups. Three main types of leadership which emerged from their studies were :

(i) **Authoritarian leader** : Where the leader was directive and did not permit any participation from team members. Concern for completing the task was of prime importance and each member of the team was told what to do and how to do.

(ii) **Democratic leader** : One who encouraged participation and discussions by group members, he involved all group members in planning and completing the task.

(iii) **Laissez-faire leader** : Such a leader give complete freedom to the group members, did not provide any leadership, did not establish policies or procedures to complete the job. Under such scenario, no member of the group influenced another member.

(b) The Managerial Grid Theory

The Managerial Grid Theory proposed by Black and Mouton in 1978 indicates that leaders can be oriented towards both tasks and persons. The managerial grid, based on the interaction between person-orientation and task orientation of a leader, is depicted in Box - 6 :

The Managerial Grid shown here is characterized by the following qualities among the leaders :

- The (9, 1) leader is only concerned with task and has least concern for welfare of his subordinates. Such a leader is

called a 'task-management leader'.

- The (1, 9) leader, called the 'Country Club' management leader, is only concerned with people, to establish good relationship with and among his subordinates such leaders has least concern for tasks.
- The (1, 1) leader (impoverished leader) is neither concerned with welfare of his subordinates nor with the task. Such a leader does not take any decision and stays out of the way.
- The (9, 9) leader (Team Management leader) has maximum concern both for people and for task. Though an ideal situation, such a leader wants to achieve the goals through committed people.
- The (5, 5) leader (middle-of-the-road leader) attempts to compromise between high production and satisfaction of the subordinates.

Summary

Management is the art of getting things done through and with people in formally organized groups. It is the art of creating the environment in which people can perform and individuals can cooperate towards attainment of organisational goals. It is the art of removing blocks to such performance and a way of optimizing efficiency in reaching goals. It is a process consisting of planning, organizing, actuating and controlling, performed to determine and accomplish stated objectives, by the use of resources like men, material, machines, methods, money and markets. The basic principles of management are Division of work according to the ability, capacity and aptitude of the workers; Well-defined responsibility; Discipline; Orders only from one superior; Preference of Organisational goals to individual goals; Pre-determination of remuneration in form of pay and allowances for all personnel; Centralization of important policy decisions and key matters; Functioning in well defined functional chain of senior-subordinate relationships (scalar chains); Unity of direction; Equity; Stability of working

period (tenure); Initiative among employees; and the Team spirit. Administration can be defined as 'those functions in an organisation, which are concerned with policy formulation, finance, production, distribution and ultimately control all key activities for meeting the organisational objectives'. It can thus be assumed that policy-making, planning and decision making are the basic components of administration whereas supervision, implementation and operational aspects are considered components of management.

To successfully attain the objectives with optimum resources, requires a series of Managerial processes which are Planning, Organising, Staffing & directing, Decision making, Controlling and Feedback. Planning is the fundamental and initial process in any activity. Setting the objectives is a major function of planning. The basics of planning process in the health sector consists of deciding Where are we at present (situational analysis), Where do we finally want to reach (objectives & goals), How do we get there (resources & constraints), How effectively we have performed the required activities (evaluation, monitoring & feedback), what new problems do we face and how do we overcome them (re- planning). Various types of plans can be classified as Mission of an organization (described as the very reason why that organization exists), Strategy (any decision, plan or action which takes into consideration the actions of competitors and other factors in external environment, with the aim of achieving the objectives), Policies (guide to decisions), Rules (guides to action), Procedures (chronological steps involved in performing any action or taking any decision), Program (a series of actions performed for achieving the organizational objectives within the scheduled time).

As a function of management, organizing deals with identifying and grouping various activities, delegating authority and command to managers, and coordination of various activities and hierarchies in the organization. The process of organizing can be described as a series of steps which include Detailed description of various activities to be performed for achieving organizational goals, Grouping of various activities in some meaningful manner, Delegation (comprising of authority, responsibility and accountability), and Coordination (horizontal and vertical). Some important principles of organizing are Unity of direction, Unity of command, Authority, Span of control, Flexibility, Management by exception and Scalar principle. Depending on the type of organization and objectives to be achieved, every manager must decide how many subordinates he/she can effectively supervise. Consequently, a wider span of control will result in lesser 'levels of management'. Seven important factors which determine the frequency and duration of superior-subordinate interaction are Training levels of subordinates, Clear delegation of authority, Clarity of plans, Objectivity in standards, Rate of organizational change, Communication techniques and amount of personal contact required.

In line and staff relationship, there is a direct relationship of command between superior and subordinate, whereas staff

functions are advisory nature to line managers whom they support. A line organization consists of line personnel, where each position has direct authority over all lower positions. No subordinate is under more than one superior, and the scalar principle and principle of unity of command are strictly adhered to. A functional organization is one wherein a worker is accountable to two or more different executives for a given specific and specialized function. A combination of the product and functional structures, the matrix structures are the choice for large and complicated projects where the skills of a functional man (manager) and specialized (technical) knowledge (e.g. finance consultant) are both required. Under the matrix structure, an employee is accountable & takes orders from two different superiors at the same time. Leadership can be described as the activity of influencing people to strive willingly to achieve the group objectives. This ability may be formal (as in form of formal authority vested with an individual) or informal (as in form of power and ability to influence people outside the formal structure of an organization).

Study Exercises

Long Question : Enumerate the basic principles of Management and describe the steps involved in Planning process.

Short Notes : (1) Management and administration (2) Line and staff relationship (3) Steps in planning process (4) Concepts of strategy, policy and program.

MCQs :

1. Following is a guide to Action (a) Policy (b) Rule (c) Program (d) Objective.
2. A series of actions performed for achieving the organizational objectives within the scheduled time is known as (a) Policy (b) Rule (c) Program (d) Procedure.
3. The following are basic components of "Administration" *Except* (a) Policy-making (b) Planning (c) Implementation (d) Decision making.
4. Unity of direction and Unity of command are some of the important principles of (a) Planning (b) Organising (c) Staffing (d) None.
5. A wider span of control will result in (a) Lesser levels of management (b) Wider levels of management (c) Independent of each other (d) None.
6. The type of organization in which worker is accountable to two or more different executives for a given specific and specialized function is (a) Line (b) Functional (c) Matrix (d) None of the above.
7. The type of organization in which no subordinate is under more than one superior, and the scalar principle and principle of unity of command are strictly adhered to is (a) Line (b) Functional (c) Matrix (d) None of the above.
8. The type of organization in which an employee is accountable & takes orders from two different superiors at the same time is (a) Line (b) Functional (c) Matrix (d) None of the above.

Answers : (1) b; (2) c; (3) c; (4) b; (5) a; (6) b; (7) a; (8) c.

Anuj Bhatnagar

Any organization is entirely dependent on the people who work there, for its success, i.e. for achieving the organizational goals. Broadly, four competency requirements have been identified for any organisation; Technical, Managerial, Human and Conceptual. Human resources, unlike all others, have to be nurtured and have almost unlimited potential. Since all organisations are made up of 'people', acquiring their services, developing skills, motivating people for high levels of performance and maintaining their commitment towards organizational goals are essential in achieving these goals. Human Resource Development (HRD) system uses various mechanisms, as under, with the view to achieve these objectives.

- (i) Recruitment & training
- (ii) Potential appraisal & development
- (iii) Performance appraisal
- (iv) Career planning
- (v) Organisational Development (OD)
- (vi) Rewards & compensation
- (vii) Employee welfare
- (viii) Human Resources Information

Personnel Management

Personnel management (also known by several other terms such as personnel administration, labour management, industrial relations, employee relations) is the functional front of HRD in any organisation. Thus, personnel management :

- (a) Is concerned with employees as individuals as well as groups.
- (b) Covers all levels of employees including senior managers, clerks, technical workers as well as the 'blue collar' workers.
- (c) Aims to help employees to develop their potential to the maximum.
- (d) Is an inherent and continuous process in any organisation.
- (e) Attempts to obtain willing cooperation of all employees to achieve the organizational goals.

Objectives of Personnel Management

- (a) Achieve optimal utilization of human resources with the aim to achieve organizational goals.
- (b) Maintain adequate organizational structure among members of the organisation.
- (c) Develop a feeling of involvement, commitment & loyalty towards the organisation among the members.
- (d) Personal growth & development of individual workers through opportunities for advancement.
- (e) Satisfy the individual needs through optimal remuneration.
- (f) Develop high morale and better human relationships.

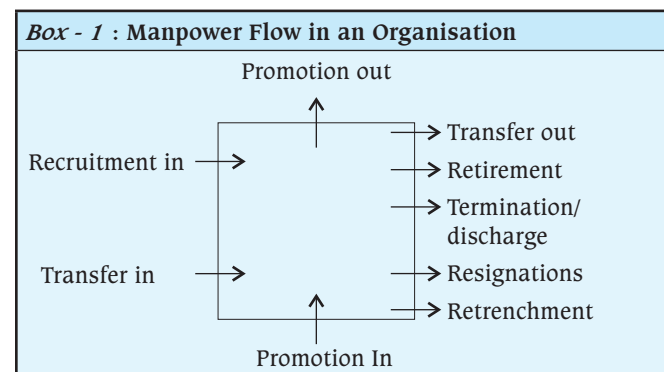

Functions of Personnel Management

The functions of personnel management include the following : Planning of the manpower requirement; Recruitment; Organising manpower resources; Selection; Classification of employees; Staffing; Transfer & promotion; Manpower development; Training; Motivation; Recreation; Communication; Collective bargaining; Employee discipline; Performance evaluation; Employee counseling.

Manpower Planning : Manpower planning is an essential and integral part of any organisation which has to survive in future. It can be defined as the 'Strategy for the acquisition, utilization, improvement and presentation of human resource of an organisation. It is aimed at meeting the future requirements and assessing the availability of different types of human resource available to an organisation and ensures that the organisation always has the right kind of the people for the right job, at the right time. For example, as a Medical Officer in-charge of a hospital, it would be essential for you to keep in mind, if your pharmacist is retiring next year, to start the process of recruiting another pharmacist for your hospital before the present one retires. This is essential to ensure the smooth functioning of your hospital.

Broadly, manpower planning consists of *Forecasting* (estimating future manpower requirement), *Inventorying* (analyzing the present manpower available and the extent to which they are employed optimally), *Anticipating* (projection of the present resources for the future and assessing their adequacy) and *Planning* (drawing up plans for recruitment, selection, training, development etc. to meet the future requirements).

Manpower planning for any organisation is a vital activity to ensure optimal utilization of presently available human resource. At the same time, it also forecasts the future requirements of trained manpower and ensures that right type of manpower is available when needed. Human resource being the most important resource in any organisation, manpower planning directly affects future of the organisation by anticipating and catering for the redundancies and recruitment levels. It indicates the optimum training needs and infrastructure like accommodation, office space, recreational facilities etc based on the manpower projections. Manpower flow in an organisation is as shown in Box - 1.

Recruitment of Personnel : The success of any organisation naturally depends entirely on its workforce and the people

who work for the organisation. Recruitment, thus, naturally assumes great importance to ensure that the right person is selected and employed. This section would deal with the issues of recruitment, selection, placement and induction.

Recruitment : It is defined as the “process of identifying prospective employees, stimulating and encouraging them to apply for a particular job in an organisation”. The aim of recruitment is to have an inventory of eligible and qualified people from whom most eligible will be selected by the organisation to work for it.

Selection : This is the process of “examining a large number of applicants for their suitability for a given job and selecting the best suited & qualified candidate(s) and rejecting the others”.

Placement : It is the “determination of the job for which a selected candidate is best suited and assigning that job to him”. Proper employee placement improves productivity, motivation & output by reducing absenteeism, accidents & turnover of employees.

Induction : This can be defined as “introducing the new employee to the job and to the organisation with the view to ‘sell’ the organisation to him so that he takes pride in his new job and association with the organisation”. This is also called ‘*indoctrination*’.

Before we actually start ‘recruiting’ people, we have to clearly know what job is required to be done. For example, before advertising for an anesthesiologist for a hospital, we must know that he would be required to provide anesthesia in OT during surgeries and would also be required to manage seriously ill patients in ICU. Only then can we plan our recruitment effectively. This process is carried out by *job analysis*. It can be defined as “a systemic compiling of detailed description of tasks, determination of relationship of the job to technology and to other jobs and examination of knowledge, qualifications and employment standards, accountability and other requirements”. Simply put, job analysis indicates the activities and accountabilities associated with any job. It is the process of examining a job to identify its various components and the circumstances in which it is performed. The information gathered from job analysis is used to make vital decisions about organizational design & planning, recruitment and selection of personnel and all other managerial functions. Ideally, all jobs in an organisation need to be analyzed, but the complexity of the process will depend on the complexity of the job. For example, the job analysis of a safai worker’s job in a corporate hospital can be simple description of the steps required to be taken to sweep an OPD. However, job analysis of a cardio-thoracic surgeon in the same hospital (including his position in the hospital hierarchy) is very complex.

The step-wise process of recruitment : These include the following steps

1. Preparation for recruitment : Identifying the ‘job specifications’ (based on job description) to decide what type of people, with what characteristics should be invited to apply for the job. These will include specifications of physical, medical, mental, social and behavioural attributes for the job.

2. Identifying the sources of manpower : These could be following :

- (i) Internal sources are personnel already employed, (including past employees who quit voluntarily or on production lay off, whom the organisation could retire for the new posts.
- (ii) External sources that are not associated with the organisation, selecting internal candidates for new posts improves morale of the workforce and promotes loyalty for the organisation. External sources on the other hand provide wide choice and bring in new ideas and enthusiasm. However larger investments in training & induction have to be made in case of external candidates.

Selection of Personnel : Selection of personnel can be defined as the ‘process of acquiring the relevant information about an applicant, evaluation his qualifications & experience in order to match these to the job requirements’ and is thus the process of picking out the best suited individual for the organisation. The ‘*successive hurdles technique*’ is often used for selection process in organisation, which is depicted in Fig - 1.

Training & Development of Personnel : We have seen that after an individual is selected & inducted into an organisation, he/she has to learn how the assigned work can be done most efficiently and effectively. This is done through training programs. Training is defined as a “short term process utilizing a systematic and organized procedure by which non-managerial personnel acquire technical knowledge and skills for definite purpose.” Designed primarily for non-managerial personnel, training is essentially of *short duration* and for a *specific job related* purpose. *Development*, on the other hand is a “long term educational process utilizing a systemic and organized procedure by which managerial personnel get conceptual and theoretical knowledge. Thus, development pertains not only to technical knowledge and skill, but also to theoretical and conceptual concepts; and involves education and long-term development. Training of personnel is undertaken by both “on the job” as well as “off the job” training methods.

Performance Appraisal as an Element of HRD

Performance Appraisal (PA) is an important managerial tool by which an employee’s performance, accomplishments and

behavior are evaluated for a given period of time. This becomes important for any organisation to achieve the maximum possible utilization of human resources available. Thus performance Appraisal is an important managerial tool for monitoring and measuring the performance of employees, with the overall aim to improve performance and enhance individual efficiency to benefit the organisation. PA is therefore an important method for collecting, reviewing, analyzing and recording information about performance of an employee.

Methods of Performance Appraisal

As managers and leaders of men, all doctors should be able to objectively and successfully assess the performance of their subordinates, whether in a PHC or in a tertiary health care centre. Ideally, all performance appraisals should be based on pre-determined and objective performance standards; should lead to improvement of the subordinate by means of a joint performance review and should be based on more than one channel/ method of assessment, as explained subsequently.

Performance appraisal becomes more important where work performed can not be directly measured in terms of tangible goods and where individual characteristics affecting productivity and performance must be determined. It is important to specify the job performance criteria to be measured. The following methods are used for PA in most organisations.

- (a) *Global Assays & Rating* where the assessor, in an essay form, provides an overall impression of the performance of the ratee during a specified time period. This method may have serious disadvantages in the absence of specific performance criteria derived from a job analysis procedure undertaken well in advance.
- (b) *Trait Rating Scales* usually include a list of personal traits of an individual, such as loyalty, leadership qualities, sincerity, courage of conviction etc, which are required to be rated on a numerical scale. Trait Rating Scales tend to be unreliable if elements of halo effect, leniency/ strictness or central tendency creep into the evaluation process.
- (c) *Ranking Procedures* involves an overall assessment of performance and classifying the employees into categories (such as Top 10%, Bottom 10%, Exceptional, Unsatisfactory etc). This procedure, even though it prevents rating-errors like central tendency, but is not based on specific and objective rating criteria.
- (d) *Behavioural Anchored Rating Scales (BARS)* are based on objective parameters on which the behaviour of an employee is assessed. Although the performance appraisal in such a case tends to be more job oriented, it still faces the problem of identifying which actual behaviour matches with which (objectively determined) performance scale.
- (e) *Objective and Goal-setting procedures* focus on the outcomes and the output of an employee, as a measure of performance appraisal. Goals and targets are previously set, most often by the manager and the performance appraisal of a subordinate is undertaken based on the extent to which these objective have been achieved.

Important Issues in Employee Compensation

Employee compensation and wages paid to employees are the foremost issues for any manager. Over a period, these issues have become more complicated with the involvement of legislature, issues of equity and justice and also national economy. The wages for employees, which was initially only an issue decided by the employer, is now an inescapable component of the socio-economic texture of a country.

Basic Wage and Dearness Allowance

Basic wage is the stable wage paid to employee, which is based on the statutory minimum wage and is aimed at providing not only basic sustenance for family of four, but also provide for social amenities like education, health, recreation etc. *Dearness allowance* was first conceptualized after First World War subsequent to the steep and uncontrolled increase in cost of essential household commodities, the basic idea being to offset the rising cost of living by giving some additional monetary relief over and above the basic wage.

The flat rate system of DA administration provides a one-time standard payment to the employee to offset the inflation. On the other hand, the *consumer price-linked system*, though complex is more realistic because it attempts to offset the actual increase in cost of living. In one form of DA based on consumer price-linked index, a specified rate of DA is determined for every point increase in consumer price index, irrespective of the income, and thus employees of all pay-scales get the same amount of DA, thereby giving higher proportion of basic wage as DA to the lower paid employees. The other system is based on income groups where the actual DA admissible (as a proportion of basic pay) steadily reduces with each higher income group.

The Concept of Social Security

Social security programs are essentially instruments of social and economic justice and forms one of the major pillars of a welfare state such as ours. The International Labour Organisation (ILO) has defined social security as “the protection which society provides for its members through a series of public measures, against the economic and social distress that otherwise would be caused by the stoppage or substantial reduction of earnings resulting from sickness, maternity, employment injury, unemployment, invalidity, old age and death, the provision of medical care, and the provision of subsidies for families with children”.

In India, a number of legislative measures such as ‘The Workmen’s Compensation Act 1923’, ‘The Employees’ State Insurance Act 1948’ etc have been passed as social security measures, which are described in the section of occupational health.

Motivation

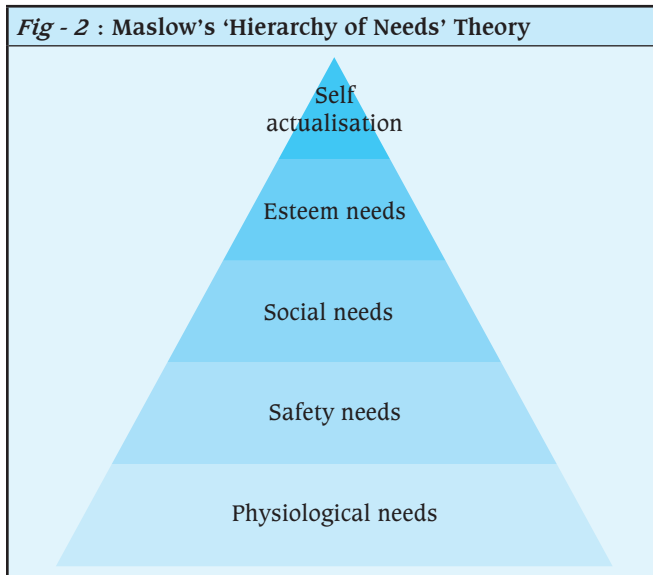

As a doctor and manager of men, you are often faced with a situation where one wonders about “what is motivation” ? We may erroneously label people who have no motivation as ‘lazy’. Today we know that motivation is the result of interaction between the individual and the situation. We may get easily bored reading a textbook but may finish an interesting novel in

a single sitting. Motivation can be defined as the willingness on the part of an individual to exert extra effort for attaining organizational goals, which is determined by such an effort's ability to satisfy some individual need (tangible or intangible). In short, when an individual is motivated, he 'tries hard'. But this effort has to be also channelised in the direction that would benefit the organization. Therefore, motivation is dependent both on the intensity and quality of the effort. In addition, there is also a component that satisfies some tangible or intangible 'need' in the individual. The motivation process can be summarized as :

Theories of Motivation

1. Maslow's 'Hierarchy of Needs' Theory : Abraham Maslow postulated that a hierarchy of five needs exists inside every human being, which are (Fig - 2) :

- (a) *Physiological needs* such as hunger, thirst, sex, shelter & other bodily needs.
- (b) *Safety needs* like protection from physical & emotional harm.
- (c) *Social needs* like needs for affection, belonging & acceptance etc.
- (d) *Esteem needs* including internal needs (self respect, autonomy & achievement) and external needs (status, recognition and attention).
- (e) *Needs for self actualization* i.e. to become what the individual is capable of becoming, achieving one's full potential & self fulfillment.

According to Abraham Maslow, from motivational viewpoint, if a need is substantially satisfied, it ceases to motivate a person and he moves on to the next plane of hierarchical need. Maslow's theory of hierarchy of need was widely accepted initially but has not been validated by research, which has

shown that need structures are not necessarily organized as proposed by Maslow and that satisfied needs at a particular level may not necessitate movement to the next level.

2. Theory X and Theory Y : Proposed by Douglas McGregor, this theory broadly divides human being into inherently negative (Theory X) and inherently positive (Theory Y) individuals. Under 'Theory X' the basic assumptions are that individuals are inherently dislike work, will attempt to avoid it whenever possible and hence must be coerced or threatened with punishment to achieve organizational goals, since they inherently dislike work. 'Theory Y' in contrast, proposes that the individuals would inherently consider work to be as natural as rest or recreation and will naturally exercise self control if they are committed to the organisational goals.

When McGregor's theory is superimposed on Maslow's Hierarchy of Needs theory, it is evident that Theory X assumes that lower-order needs such as physiological needs and safety needs dominates individuals whereas Theory Y assumes that higher order needs dominate individuals.

3. Herzberg's Motivation-Hygiene Theory : Fredrick Herzberg, after asking workers for situations when they felt exceptionally good or bad about their jobs, came to the conclusion that certain variables (intrinsic factors like achievement, recognition, responsibility & growth) are always related to job satisfaction and certain variables (extrinsic factors like company policies, administration, interpersonal relations and working conditions) are always related to job dissatisfaction. According to him, factors responsible for job satisfaction are distinctly different from those that are responsible for job dissatisfaction. Hence, when managers remove the factors responsible for job dissatisfaction, workers are merely placated rather than motivated in the true sense. Herzberg emphasized that if we want to truly motivate individuals, focus should be on achievement, recognition, responsibility and growth, which individuals find inherently rewarding and motivating.

Summary

Since all organisations are made up of 'people', acquiring their services, developing skills, motivating people for high levels of performance and maintaining their commitment towards organizational goals are essential in achieving these goals. Personnel management is the functional front of Human Resource Development HRD in any organisation. Thus, personnel management is concerned with employees as individuals as well as groups, covers all levels of employees, aims to help employees to develop their potential to the maximum, inherent and continuous process in any organization, and attempts to obtain willing cooperation of all employees to achieve the organizational goals. The functions of personnel management include the following : Planning of the manpower requirement; Recruitment; Organising manpower resources; Selection; Classification of employees; Staffing; Transfer & promotion; Manpower development; Training; Motivation; Recreation; Communication; Collective bargaining; Employee discipline; Performance evaluation; Employee counseling. Employee compensation and wages paid to employees are the foremost issues for any manager. Over a period, these issues have become more complicated with the involvement of legislature,

issues of equity and justice and also national economy. The wages for employees, which was initially only an issue decided by the employer, is now an inescapable component of the socio-economic texture of a country.

Social security programs are essentially instruments of social and economic justice. The International Labour Organisation (ILO) has defined social security as “the protection which society provides for its members through a series of public measures, against the economic and social distress that otherwise would be caused by the stoppage or substantial reduction of earnings resulting from sickness, maternity, employment injury, unemployment, invalidity, old age and death, the provision of medical care, and the provision of subsidies for families with children”. In India, a number of legislative measures such as ‘The Workmen’s Compensation Act 1923’, ‘The Employees’ State Insurance Act 1948’ etc have been passed as social security measures.

Motivation can be defined as the willingness on the part of an individual to exert extra effort for attaining organizational goals, which is determined by such an effort’s ability to satisfy some individual need (tangible or intangible). In short, when an individual is motivated, he ‘tries hard’. But this effort has to be also channelised in the direction that would benefit the

organization. Therefore motivation is dependent both on the intensity and quality of the effort. In addition, there is also a component that satisfies some tangible or intangible ‘need’ in the individual. The Theories of Motivation which explain the concept are Maslow’s ‘Hierarchy of Needs’ Theory, Douglas McGregor’s Theory X and Theory Y, Herzberg’s Motivation–Hygiene Theory.

Study Exercises :

Short Notes : (1) Personnel management (2) Human Resource Development (3) Motivation (4) Social security.

MCQs

1. Strategy for the acquisition, utilization, improvement and presentation of human resource of an organization is (a) Manpower Planning (b) Recruitment (c) Employee counseling (d) Collective bargaining.
2. According to which theory, from motivational viewpoint, if a need is substantially satisfied, it ceases to motivate a person and he moves on to the next plane of hierarchical need (a) Abraham Maslow (b) Mc Gregor (c) Herzberg (d) None.

Answers : (1) a; (2) a.

Anuj Bhatnagar

Accounting is defined as the “art of recording, classifying and summarizing in a significant manner and in terms of money, transactions and events which are financial in nature, and interpreting the result there of”. Accounting can also be described as “the process of identifying, measuring and communicating economic information to permit informed judgments and decisions by the user”.

Concepts of Costs

‘Cost’ can be described as the amount of expenditure (actual or notional) incurred on a thing. For example if a printer prints a book by spending Rs 1000/- on paper, Rs. 500/- on printing ink and Rs. 100/- on its binding, the cost to the printer is said to be Rs. 1600/-. The elements of a cost are :-

Fixed Cost

Fixed costs (Fig - 1) are the costs which remain constant and do not depend of the amount of output for example, if a hospital pays Rs.1.5 lac per month as rent for the premises, this amount is constant and has to be paid even if no patient is admitted in the hospital in the entire month.

Fig - 1

Fixed costs can be broadly divided further into :

- (i) **Committed Fixed Costs** which are fixed costs that result from the possession of infrastructure such as building and equipment or services to be rendered. For example, once a hospital has been set up, the management has committed itself to paying property tax, salaries of health care providers, depreciation of value of equipment etc.
- (ii) **Discretionary Fixed Costs** also called ‘managed’ or ‘programmed’ fixed costs, are costs that are fixed for a specified period by management through their budgeting

process. For example, costs involved in Research & Development, social donations etc have no link with the quantum of output, can be even abolished completely and reflect the policies of the top management.

Variable Costs

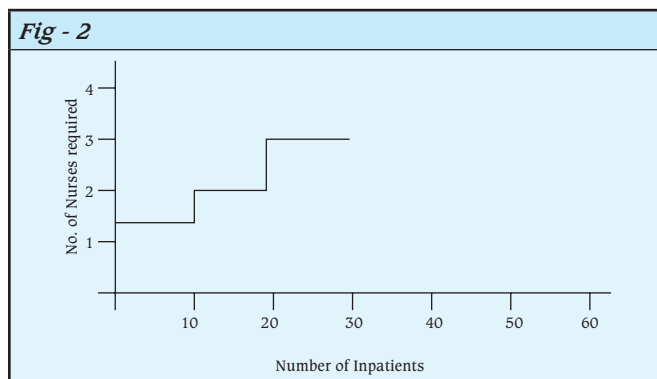

Variable costs are costs which are directly dependent on the quantity of output, such as cost of direct labour, direct material etc. For example, if Rs 200/- are required for a film by a Radiologist to undertake one X ray, Rs 4000/- would be required for 20 films to undertake 20 radiographs by the same radiologist. This type of direct proportionate variation in cost is constant per unit of output

Semi Variable Costs

Semi variable costs are the cost which vary with the quantum of output but not in direct proportion, such as electricity bill, telephone bill etc.

Step Costs

Under some circumstances, the cost remains fixed for a range of time period or for certain quantum of output and then steps up to the next level of cost. For example, it may take one nurse to provide nursing care to 10 indoor patients. However, as soon as the number of in-patients rise to beyond 10, a second nurse is required to be employed, as depicted in Fig - 2 :

Shut Down Costs

Shut down costs are the fixed costs that are incurred by the organisation even when it is shut down and no production / service is produced / rendered. For example, even if a MRI centre is temporarily shut down for a period of one month due to any reason, it would still have to pay the rent for the premises, insurance for the equipment etc.

Sunk Costs

Sunk costs are the costs incurred in the past due to past decisions, which can not be reversed or recovered by any subsequent decisions. For example let us assume that a hospital invests an amount of Rs. 10 lac in an X Ray machine with the expectation of earning an income of Rs. 9 lac over a period of next 10 years. However, immediately after procurement of the machine, it was realized that the machine should not have been bought in the first place and it can be immediately re-sold for Rs. 9.5 lac. When the hospital administrators have to take a decision whether to sell the machine or not, the original cost of Rs. 10 lac would not be considered since it is 'sunk cost'. Hence

the hospital should sell the machine immediately and recover at least Rs. 9.5 lac.

Controllable Cost

Controllable cost is the cost which can be influenced (controlled) by the intervention of any member of the organisation. For example, the cost of expired medicines can be controlled in a hospital if the pharmacist is careful in inventory control and issues the medicines well before their expiry date.

Uncontrollable Costs

Uncontrollable costs are those that can not be controlled by the initiative of an individual. For example, the pharmacist may be able to control cost of expired medicines but he shall have no control over the unwanted medicines prescribed by an overzealous medical officer. Thus controllable costs are controllable at a particular level of management while being uncontrollable at other levels.

Differential Cost

Differential cost is used for assessing the suitability of an alternative out of many alternatives, since it indicates the difference in total cost involved between two or more alternatives. When an alternative option results in an increase in total cost involved, it is called '*incremental cost*' and when it involves a decrease in total cost, it is called '*decremented cost*' and is used to assess the profitability of an option out of many alternatives available.

Out-of-Pocket Cost

Out-of-pocket cost are the cash expenditures which would be incurred or saved, based on a decision. Let us assume that a hospital decides to shut down its own MRI centre and decides to out-source it to a nearby existing private MRI centre. The hospital management should ideally take into consideration the cost of electricity, salary of its own operators, rent for premises that the hospital would be saving if it decides to out-source. However, the initial cost of the MRI machine (sunk cost) and depreciation of the machinery would not be considered in this case.

Opportunity Cost

Opportunity cost can be described as the cost of foregoing an opportunity in favour of another alternative. For example, if a building originally planned and constructed for a PHC is used as a community centre, the planners must consider the 'opportunity cost' of not providing primary health care to an entire village, the disease burden and morbidity/mortality resulting from the lack of primary health centre (PHC) in the area.

The Concept of Marginal Cost

The "traditional" Costing Technique (also called "Absorption" or "full cost" method) is a method of ascertaining the cost of a product or service (to the manufacture / provider) by identifying and taking into account both the *variable costs* (direct labour & materials etc) (which are directly attributed to each unit of finished product) and the *fixed costs*, (which are allocated proportionately to different products produced during the given time period). A certain amount of 'profit' is added to this total cost (variable cost + fixed cost) to arrive at the '*price*' (fixed

cost + variable cost + profit) of a product/service. However, absorption costing technique has the disadvantages that prices are assumed to be dependent only on costs, only past costs are considered which may not be appropriate for deciding the price currently and demand is not taken into consideration which fixes the price of a commodity/service (in other words the amount that the community members are willing to spend on that item) in a community. In order to overcome these disadvantages, 'marginal costing technique' is adopted.

Marginal cost can be defined as "the amount at any given volume of output by which aggregate costs are changed if the volume of output is increased or decreased by one unit". This would entail an increase (or decrease) in the cost when the output increases (or decreases) by a single unit. Ordinarily, marginal cost is considered to be equal to the increase/decrease in total variable cost only because within the existing capacity, increase or decrease of a single unit of output would have a negligible or no impact on the fixed cost and any change in cost would only be due to variable cost such as direct labour & material used to produce that single unit.

Break Even Analysis

Break Even Analysis is an important financial tool to determine the level of production (output) where the total cost to producer equals the total revenue from sales. This is important for any organisation because it would indicate the probable profit at any given level of output. Thus, break even analysis is used by financial experts to establish the relationship between cost of production incurred by the producer, volume of production and profit and sales volume.

Break Even Point (BEP)

BEP refers to the level of output where the revenue from the business would exactly equal its expenditure (cost to the producer). Thus, when the output reaches the BEP, it is a point of 'No profit, No loss'. If the production is now increased to beyond this level, profit would be accrued and if the production level is reduced beyond this BEP, loss shall be incurred.

Budgeting

The word 'budget' derives its origin from a leather 'pouch' or leather bag in which the Chancellor of exchequer of Great Britain carried the government's statement of anticipated financial needs & available resources, to be presented to the Parliament. A 'budget' is thus the anticipated receipts and available resources of an organisation during the given year, and is the basis of all financial decisions during the year.

A budget can be defined as a statement of future plans described in quantitative and monetary terms, for a specific period of time, which is usually one year in case of financial budgets. It can also be defined as a financial statement, prepared and approved by the management in advance for a period of time, which determines all future actions of the organisation.

Like any other organisation, a systematic approach to financial planning is required to manage any health care establishment and budget is an important tool in the hands of a trained health professional. Financing in health care sector is presently in its nascent stage in India and it is imperative that all health care professionals and those associated with health have a sound

knowledge of budgeting and health care financing. It must be realized that a budget for health care establishment has to be also prepared and approved in advance, has to be based on the long term strategy, has to focus on future and is expressed in monetary term. Advantages of budgeting are as in Box - 1.

Box - 1 : Advantages of budgeting	
Every healthcare professional should also be aware of advantages of budgeting, which are as under:-	
(a)	Budgets are effective means of communicating the future organizational plans to all people, in monetary and financial terms.
(b)	A pre-decided and approved budget serves as an effective benchmark for monitoring the ongoing operations.
(c)	Budgeting reduces wastage and losses by identifying wasteful expenditures well in advance and rectifying them.
(d)	Budgets, when drawn up through participation, encourage, and develop team spirit and collective responsibility towards excellence.
(e)	Budgets form the basis for assessing the performance of senior managers in any organisation.

Types of Budgets

Budgets are broadly classified on the basis of time, function and flexibility, as under :

Time-based Budgets

- (i) Long term budgets which are financial estimates and planning for more than five year duration.
- (ii) Short term budgets which pertain to financial planning for up to one year duration.
- (iii) Current budgets pertain to very short term periods.
- (iv) Rolling (Progressive) budgets wherein some duration of advance budget will always remain. In this scheme after a quarter passes, the financial figures for that period are dropped and a new budget is prepared for the next 12 month period.

Function-based budgets

- (i) Sales (Revenue) budgets are the basis for developing most other budgets, especially in commercial and profit-based organisations. Sales budgets are developed based on the anticipated sales volume that are to be achieved in a given time period.
- (ii) Production (Expenditure) budgets are based on the expected expenditure under various heads such as materials requirement, material procurement, labour, overheads and research.
- (iii) Capital based (Planned) budgets have to be drawn up for earmarking financial resources for new proposed projects, such as setting up of a new ICU or a Cobalt Therapy Unit for a hospital.
- (iv) Operation budgets (Non-Plan budgets) are the financial outlays for routine and operational running of an organisation, and are generally short term in nature.
- (v) Cash budgets are financial plans which indicate the expected cash inflow and cash outflow over a given period

of time, in an organisation. These are comparisons of income in cash and cash disbursement undertaken by an organisation and are helpful by preventing unwanted accumulation of large amounts of cash, determining future cash requirements and providing better control over liquidity of an organisation during the budget period.

- (vi) Research budgets are financial plans for undertaking research and development activities & allocation of financial resources for innovation, developing new products and services. Unlike budgets allocated for fixed costs, research budgets reflects the mindset of a top management and may be increased or decreased depending on the policies of top management.
- (vii) Master budget is an amalgamation of all organizational budgets and indicates in detail the planned working of all departments in financial terms. The master or the final budget may be presented in the form of a balance sheet, fund flow statement or a profit & loss statement at the end of the budget period.

Flexibility-based budgets

- (i) Fixed budgets are prepared in advance based on a standard level of output or activity and do not change mid-way with a change in level of output. Let us assume that a budget for a PHC has been drawn up to provide primary health services to a population of five lakh people in that area. This kind of fixed budget will then be unable to accommodate any changes if it is realized that the population is seven lakh instead of five lakh and hence performance of the health care facilities can not be accurately measured since the actual services rendered will not match the budgeted quantum of services to be rendered.
- (ii) Flexible budgets are the financial outlays which are planned in such a way that they can change with the level of output/activity. In this, the fixed cost and variable costs are taken into account and a flexible budget drawn up. Let us assume that a hospital has to draw out a financial budget for maintaining an ICU, assuming the following :

Fixed cost for maintaining the ICU = Rs 5,00,000 per month

Thus, it is seen that to maintain an ICU of 10 beds, it would need Rs 15, 00,000/- whereas to maintain an ICU with 5 beds, the hospital would need Rs 10,00,000/-.

Flexible budgets are better indicators of actual performance since the actual and proposed levels of activity are matched beforehand while preparing the financial outlay and finances are allocated accordingly. Procedure for budgeting is outlined in Box - 2.

Approaches to Budgeting

Incremental approach : It is a process of budgeting where the previous year's expenditure is applied to the next year with additional components of increased salaries and cost of materials. Though widely followed for most public health expenditures being simple to understand, incremental budgeting however assumes that all activities carried out in the last year are essential, were most cost-effectively carried out and still remain more important than the new proposed activities. Thus under this scheme, only the increment over the previous year's budget is actually justified for the present duration.

Incremental budgets have been often described as “an elephant with muscles of a mouse and brains of an amoeba” since it does not promote operational efficiency due to following major disadvantages :-

- (i) Wasteful expenditures of previous years are again included for drawing up financial outlays of the next year.
- (ii) Alternative better options for achieving the same objectives are not even considered since it is assumed that previous year's actions are still essential and most cost-effective.
- (iii) Main problem areas, wasteful expenditures and priorities are not ascertained before drawing up the budget.
- (iv) Decisions taken regarding the amount of financial outlays for any given year are arbitrary and not based on any justifiable reasoning.
- (v) There is no linkage between inputs and outputs and it is assumed that cost efficiency of all past activities would remain same in future years.
- (vi) Administrators of various departments often tend to inflate their proposed individual budgets, since no detailed justification is sought along with the proposal.

Performance budgeting (Program budgeting) : It is defined as “the process of analyzing, identifying, simplifying and crystallizing specific performance objectives of a job to be achieved over a period of time”. Developed and adopted in 1949 in USA, it lays more stress on precise detailment of a job to be done or services to be rendered. A performance budget thus presents the actual operations undertaken by an organisation, department-wise, in terms of functions, activities, projects and programs. In order to undertake performance budgeting, it is essential that objectives should be clearly defined and financially feasible & activity classification should be done logically into distinct department. Such budgeting procedure is better than the traditional system; it involves the evaluation of actual performance of the organisation in terms of departmental and organizational objectives, provides a definite direction to efforts of every employee and is a useful control tool for higher managers. It is upto the departmental head usually to prepare the periodic performance reports (required for performance budgeting) which compare the budgeted actual performance (in terms of output, production or services rendered) with the aim to detect any deviations at the earliest possible.

Zero Based Budgeting (ZBB) : With both traditional (incremental) budgeting and performance (program) budgeting, it was increasingly realized that scarce resources were not being optimally utilized, wasteful expenditures were not being identified, decision making was often irrational, budgets tended to be over inflated by managers and there was very little relationship between the expenditure and the results obtained. Thus, need was felt to further improve the budgeting procedure with the view to utilize the scarce financial resources in the best possible manner. Zero Based Budgeting (ZBB) is defined as “the planning and budgeting process which requires each manager to justify the entire budget in detail from ‘scratch’ (‘zero base’) thereby making it the responsibility of each manager to justify why he should spend any money at all during the budget period.” Under zero based budgeting, an organisation should not only decide about financial allocation to new programs & plans but must also review the existing & old programs, especially which involve a high degree of discretionary costs such as research & development programs, newer vaccine initiatives etc. Under ZBB, therefore, the proposer of an activity must justify before each budget that the activity proposed is essential, cost effective and must detail the output levels expected. No activity or action is financed simply because it was done in the past and the entire program must be justified each time a budget is being drawn up. Advantages and limitations of ZBB are given in Box - 3.

Box - 3 : Advantages and limitations of ZBB
Advantages
Based on cost benefit analysis. No arbitrary decisions are taken.
Allocation of scarce financial resources is strictly based on priority of programs/ actions.
Links the budgets to organizational objectives & performance by not financing those activities which though carried out in the past, now do not contribute to the overall objectives or are not carried out cost effectively.
Complements the concept of ‘Management By Objectives.’ (MBO)
Ensures that only essential projects and activities are undertaken by the managers.
Identifies areas of wasteful expenditure, problem areas and key result areas for an organisation.
Limitations
Initial planning stage before each budget requires greater effort and time by all departmental heads.
Less applicable for those activities which do not have a direct and tangible cost-benefit relationship such as immunization programs or public health programs for supplying safe water and sanitation to villages.
Identification of decision variables in case of non-tangible benefits such as public health programs invariably require complicated managerial processes.

Financial Control in Health Settings

Financial control is as important in health care settings as in any other field. In addition, the issue is complicated by the intangibility and often non-measurability of the product (ie health care rendered and the result thereof). Financial control in a health setup would include a proper accounting system for funds, equipment and expendables; laid down standards of performance against which actual performance would be measured and regular audits of performance. Some important tools used for exercising financial control are as under :-

Budgets

Budgets are an important tool in the hands of a health manager because they lay down the expected standards of performance against which the actual performance is measured to identify the variations. Operational control in any organisation can only be exercised when actual performance is compared and evaluated with some pre-decided standards and remedial actions instituted to correct any deviations from the expected & pre-determined standards.

Hospital Statistics and Cost Control

The most important hospital statistic from the point of view of financial control is ‘patient day’ which is defined as ‘the number of patients to whom in-patient services have been provided in a healthcare setup between two successive census’. The performance of the hospital as a whole and that of individual departments can be ascertained by calculating the ‘cost per patient-day’ as under :

$$\text{Cost per patient day} = \frac{\text{Total expenditure by hospital}}{\text{Total number of patient-days}}$$

Similarly, department-wise or bed-wise cost per patient-day can also be worked out, which indicates the performance of the department or a ward.

Other indicators which may be used as financial control tools in a health care set up are :

- (i) *Hospital census* : The total number of in-patients occupying beds in the hospital at a particular time.
- (ii) *Bed occupancy* : is calculated by patient days divided by bed-days multiplied by 100 and indicates the future expansion needs of a hospital.
- (iii) *Average length of hospital stay* : indicates the average time spent by a patient in a hospital and when compared with other similar hospitals, is an indicator of performance of that hospital.

Financial Statement Analysis and Control

They are important tools for financial control in any organisation and are broadly of the following variety :-

(i) *Balance sheet* : indicates the financial state on a given date (which may be the last date of the month) and by showing ‘assets’ and ‘liabilities’ the organisation, it shows what the organisation owns (assets) and what it has to give to others (liabilities). In case of a health care establishment, the assets may be ‘fixed assets’ (such as buildings, land, furniture, ambulances, medical equipment etc) or ‘current assets’ (such as cash in bank, hospital bills receivable from patients, medicines and expendables in current stock etc). On the other hand,

the liabilities in case of a hospital may be 'current liabilities' (like electricity/telephone/property bills payable), 'long term liabilities' (such as loan taken from bank initially to set up the hospital/buy equipment) and 'special funds' such as funds earmarked for training or disaster management.

(ii) **Income and expenditure statement** : In contrast to balance sheet (which is the financial state on a given single day), income and expenditure statement of an organisation is the record of all financial transactions of the organisation over a given period of time. In case of a health care setup, the inflow of finances (income) may be in form of payment by the patients for various medical and support services, grants and charity donations, interest on bank deposits and other investments. On the other hand, expenditures would be in the form of salaries of health care providers and ancillary staff, inventory costs, payment for amenities such as electricity, water, telephones etc.

Income statement vs Balance sheet

The income statement is a record of all financial transactions of an organisation over a period of time (which may be taken as a year or a month) whereas the balance sheet depicts the final assets and liabilities of an organisation at the end of a period of time (which may be on the last day of the month or year at a point of time).

(iii) **Cash flow statement** : is also a type of financial statement used for financial control by managers, wherein cash inflow from the three major activities (operations, investments and financing) are summarized.

(iv) **Funds flow analysis** : records the various sources of funds available to an organisation and the usage of these funds over a given period of time. For the survival of any organisation, it is important to be able to finance the various operations and assets through appropriate sources and hence the importance of identifying and recording all possible sources from where funds are obtained.

(v) **Liquidity ratios** : are a form of financial analysis which indicates the utilization of cash and the ready availability of cash for future payments in an organisation. Current ratio is a ratio of current assets to current liabilities and indicates proper management of cash (current ratio of more than one) or possible shortage of cash for payments in the near future (current ratio less than one). The current ratio can be made more accurate by excluding the inventories (which are not considered 'liquid' or easily available in terms of cash) so as to provide the Quick Ratio (Acid test ratio)

$$\text{Quick ratio} = \frac{\text{Current assets} - \text{Inventories}}{\text{Current liabilities}}$$

The Concept of Audit

Auditing is a financial process undertaken as a *verification process based on past records, assessed against a set of predetermined rules, regulations and standards*. Thus, audit is undertaken to ascertain that all financial transactions during a given past period were undertaken as per the rules and regulations. *Auditing* has been defined as "An examination of

accounts and records undertaken with a view to ascertain if they completely and correctly reflect the transactions to which they relate and to ascertain that the transactions themselves are supported by the competent authority wherever required" (Lawrence R Dicksee). Box - 4 lists out the special issues involved in audit of a healthcare establishment.

Box - 4 : Special issues involved in audit of a health care establishment

It must be remembered that the financial audit of a health care establishment differs from a routine audit of any other organisation, primarily since hospital activities are fundamentally different from any other commodity or service based activity. Hospitals do not produce or sell a commodity, but render medical care which is highly personalized and varies from patient to patient. Any auditor therefore should keep in mind the following aspects while auditing services of a hospital :

- Essential documents governing the policies of a hospital like the constitution of the hospital, the rules and regulations regarding employing health care professionals and ancillary staff, the policy regarding admission of patient and their treatment etc should be examined in detail.
- Comparison of figures of corresponding periods of two years can not be relied upon to detect internal discrepancies, since the services rendered by a hospital are highly unique & not standardized.
- It must be ensured through hospital records (like bed occupancy report, daily admissions/ discharge summary etc) that all services rendered have been correctly billed and recorded.
- Transactions must be recorded and completed promptly because after a patient is discharged from the hospital, the charges against services not recorded remain un-recovered.
- Procedures for recording and taking 'on charge' any gifts, grants and donations to the hospital should be in place and should be followed.
- Authority to allow discounts to patients should not be vested with the people concerned with billing and all discounts should be properly recorded.

Audit can thus be said to be financial tool undertaken to check the arithmetic accuracy of account records, check the relevant supporting documents like vouchers, sanction noting, invoices, bills etc.; check the balance sheets prepared by verifying all entries and assets & liabilities recorded with the aim to appraise the management of any discrepancies noted. Even though audit is carried out for ensuring completeness, correctness and honesty in financial transactions, an auditor's ultimate aim remains to detect clerical errors in accounts by checking the past records of accounts. Audits are based entirely on past documents and the actual circumstances under which the financial documents had taken place are not known to the auditors.

Summary

Accounting is defined as the "art of recording, classifying and summarizing in a significant manner and in terms of money, transactions and events which are financial in nature, and

interpreting the result there of". 'Cost' can be described as the amount of expenditure (actual or notional) incurred on a thing. The elements of a cost are Fixed costs (remain constant and do not depend of the amount of output); Variable costs (directly dependent on the quantity of output); Semi variable costs (vary with the quantum of output but not in direct proportion); Step costs (remains fixed for a range of time period or for certain quantum of output and then steps up to the next level of cost.); Shut down costs (fixed costs that are incurred by the organisation even when it is shut down and no production / service is produced /rendered); Sunk costs (incurred in the past due to past decisions, which can not be reversed or recovered by any subsequent decisions); Controllable cost (influenced by the intervention of any member of the organization); Uncontrollable costs (can not be controlled by the initiative of an individual); Differential cost (indicates the difference in total cost involved between two or more alternatives); Out-of-pocket cost (incurred or saved, based on a decision) Opportunity cost (the cost of foregoing an opportunity in favour of another alternative).

Marginal cost can be defined as "the amount at any given volume of output by which aggregate costs are changed if the volume of output is increased or decreased by one unit". This would entail an increase (or decrease) in the cost when the output increases (or decreases) by a single unit. Ordinarily, marginal cost is considered to be equal to the increase/decrease in total variable cost only.

Break Even Analysis is an important financial tool to determine the level of production (output) where the total cost to producer equals the total revenue from sales. It is used by financial experts to establish the relationship between cost of production incurred by the producer, volume of production and profit and sales volume. Break Even Point (BEP) refers to the level of output where the revenue from the business would exactly equal its expenditure (cost to the producer). Thus, when the output reaches the BEP, it is a point of 'No profit, No loss'.

A budget can be defined as a statement of future plans described in quantitative and monetary terms, for a specific period of time, which is usually one year in case of financial budgets. It can also be defined as a financial statement, prepared and approved by the management in advance for a period of time, which determines all future actions of the organisation. Like any other organisation, a systematic approach to financial planning is required to manage any health care establishment and budget is an important tool in the hands of a trained health professional. Budgets are broadly classified as Time-based Budgets (Long term, Short term, Current, Rolling/Progressive budgets); Function-based budgets (Sales /Revenue, Production /Expenditure, Capital based/Planned, Operation/Non-Plan budgets, Cash, Research, Master Budgets); Flexibility-based budgets (Fixed and Flexible). The approaches to Budgeting are Incremental approach, Performance budgeting (Program budgeting) and Zero Based Budgeting (ZBB).

Financial control is important in health care settings as in any other field. Financial control in a health setup would include a proper accounting system for funds, equipment and expendables; laid down standards of performance against which actual performance would be measured and regular audits of performance. Some important tools used for exercising financial control are Budgets, Hospital statistics and cost control (like Cost per patient day, Hospital census, Bed occupancy, Average length of hospital stay), Financial Statement Analysis and Control (like Balance sheet, Income and expenditure statement, Cash flow statement, Funds flow analysis, Liquidity ratios). Auditing is a financial process undertaken as a verification process based on past records, assessed against a set of predetermined rules, regulations and standards. The financial audit of a health care establishment differs from a routine audit of any other organisation, primarily since hospital activities are fundamentally different from any other commodity or service based activity and render medical care which is highly personalized and varies from patient to patient.

Study Exercises

Short Notes : (1) Types of costs (2) Break Even Analysis (3) Medical Audit (4) Tools for financial control in Health care setting.

MCQs

- The cost incurred in the past due to past decisions, which can not be reversed or recovered by any subsequent decisions is (a) Semi variable costs (b) Step costs (c) Sunk costs (d) Uncontrollable cost.
- The process of analyzing, identifying, simplifying and crystallizing specific performance objectives of a job to be achieved over a period of time is (a) Incremental approach of budgeting (b) Program budgeting (c) Zero based budgeting (d) Flexible budgeting.
- The planning and budgeting process which requires each manager to justify the entire budget in detail from 'scratch' is (a) Incremental approach of budgeting (b) Program budgeting (c) Zero based budgeting (d) Flexible budgeting.
- The record of all financial transactions of the organisation over a given period of time is (a) Balance sheet (b) Income and expenditure statement (c) Cash flow statement (d) Funds flow analysis.
- A financial process undertaken as a verification process based on past records, assessed against a set of predetermined rules, regulations and standards is (a) Budgeting (b) Accounting (c) Auditing (d) Analysis.

Answers : (1) c; (2) b; (3) c; (4) b; (5) c.

Logistics Management

Logistics management is defined as “*the systematic and scientific process of planning, implementing and controlling the efficient and effective flow and storage of resources (goods & services) from point of origin to the point of consumption in order to meet the customer's requirements*”. Logistics management in a health care set up becomes essential to ensure procurement and provisioning of vital medical supplies at the correct cost, consistency in quality, low storage cost and high turnover of items. In addition, logistics management also ensures proper forecasting & standardization of medical supplies and assists the manager in deciding whether ‘to make’ or ‘to buy’ a facility such as MRI facility to the patients.

One of the important components of logistics management is *materials management* which aims to “coordinate, supervise and execute the tasks of flow of materials to, through and out of an organisation”. It thus ensures a continuous supply of good quality material at the lowest possible price, at the same time keeping the inventory level to minimum so that working capital is not blocked in inventory but without compromising the operations due to shortage of inventory.

Logistics Management in a Health Care Setup

Any healthcare establishment is heavily dependent on material, equipments and medicines and hence logistics management assumes great importance since availability of the right item, at right time, right place and in the hands of the right person can often make the difference between life and death in a hospital. Broadly, Logistics and materials management involve a large number of activities, which are more sensitive in a hospital because each activity influences & is influenced by other activities. These are listed below and are explained subsequently :

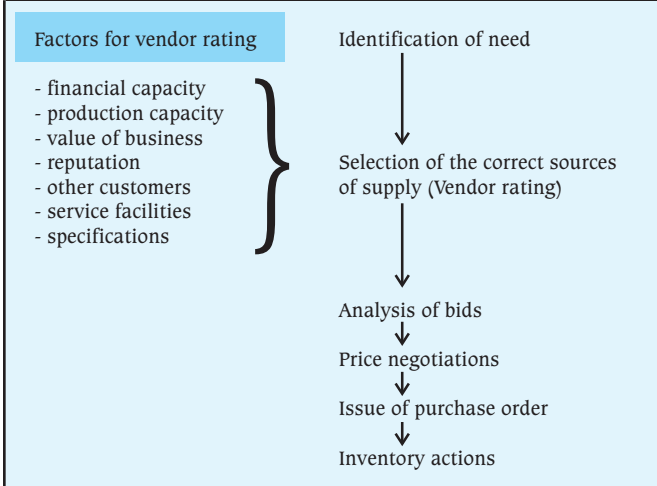

- (a) Tendering, procurement & inspection
- (b) Storage, standardization, codification & classification
- (c) Materials accounting & physical distribution
- (d) Transportation
- (e) Security of materials
- (f) Condemnation and disposal of stores

(a) Tendering, procurement & inspection : Any organisation has to resort to purchasing of goods or services (process of actual buying of materials for services) to ensure an uninterrupted flow of materials, a minimum inventory investment and to buy materials / services at a reasonable cost .

Broadly, the steps involved in purchasing are summarized as in Fig-1.

Concept of Tenders : Tender buying is resorted to by all govt./ public sector organisations wherein enquiries are floated to various short-listed vendors, for purchases to be done. Tenders may be Open tenders (through advertisement in media) Limited tenders (where bids are called for only from reputed / pre-qualified parties); Simple tenders (where only one firm is asked

Fig. - 1

to submit its rates in writing) and Global tenders (in case of large purchases tenders are often invited from within India and abroad). All govt and public sector undertakings should follow the following steps in the tendering system while undertaking purchases :

1. Specifications of the item to be purchased are established carefully.
2. A vendor list is identified which should have as many vendors as possible.
3. Competitive bids are invited from vendors through an open advertisement, which should also mention the technical specifications of the item, modalities of payment and any other terms & conditions.
4. Bids received are opened in front of representatives of vendors on a pre-notified date and time.
5. Comparative statement is drawn up of the quality, price & support services of those bids which meet the qualifying requirements.
6. Bids are evaluated. Contract is awarded to lowest responsible bidder, who meets the specifications which are pre-determined.
7. Price negotiation with the selected vendor.
8. Issue of purchase order.
9. Supply of items within the stipulated time frame.
10. Inventory action (including inspection and issue to concerned department)

Types of purchase processes

- (1) Rate contract is the purchase system wherein the rate of an item is determined through a tender system, without specifying the quantity to be purchased. Under running contract system, the minimum quantity to be purchased is specified. Followed by all Govt./ PSU through DG S&D, the system reduces the lead time for the organisation, since purchases are made at pre-determined rates (centrally carried out by the DG S&D).
- (2) Blanket ordering is a contract with a vendor to periodically supply low cost items only on receipt of an authorized release order from the organisation.
- (3) Cash purchases (Imprest purchases) are the purchases made from the open market on strictly need basis and are

usually confined to urgently required but low priced items, required in small quantities.

- (4) System contracting is a form of purchasing which does not involve maintenance of any stocks and inventory by the organisation and where authorized individuals from the organisation can draw low priced materials needed in high quantity directly from a supplier's store.
- (5) Reciprocal purchases involve a policy where two contracting parties purchase their specialized items from each other on a mutual basis.

Storage, Standardization, Codification & Classification

(a) **The storage system** : The main function of a storage system is to receive material, check it for quality and quantity, prepare the receipt vouchers, accept the inspected and passed material, undertake documentation for payment of bills, store the accepted material properly and safely, issue required material to various departments on requisition from them, prepare issue vouchers and account for them. Broadly any storage system in an organisation consists of the following sub- systems which work together to cater to the existing demands and also the further growth potential of an organisation :

- (i) Receipt system
- (ii) Maintenance & upkeep system
- (iii) Issue system

(b) **Codification of goods** : One of the basic requirements of an efficient stocking and logistics management system is an effective and scientific system of coding the items, to ensure quick tracing & retrieval and early identification of dead / duplicate stocks. In a health care setting, this task is more complicated since detailed characteristics and nature of large number of drugs available are required to be known for their coding and classification. Ideally, all health care stores should be classified in broad categories (such as pharmacy, X-rays, chemicals, laboratory items, waste disposal, ancillary items etc) and then grouped and sub-grouped logically according to functions and usage. Various systems presently in vogue for codification are described as under :

- (i) *Alphabetical system* (Table - 1)

Class	Group	Code
Patient bed (PB)	Iron(I), Hydraulic(H)	PB-I-H

- (ii) *Numerical system* (Table - 2)

Class	System	Generic name with strength	Family of drug	Condition
Drug (01)	Musculo-skeletal (38)	Ibuprofen IP 400mg (08/4)	Tablet (1)	New (1)

In this example, the Code would be : 01-38-08/4-1-1.

- (iii) *Combined alphabetical and numerical system* (Table - 3)

Class	Sub group I	Sub group II	Code
Ibuprofen	IP-400	08/4	IP400-08/4

- (iv) *Other Systems* : These include the "*Brisch system*", which is a complex and detailed system wherein a 7-digit unique number is allotted to each item based on its position and value; "*Kodak system*" which is based on numerical system and grouping done based on purchase category of the particular item, with 10-digits. Thus, the code allotted to an item may be depicted as 301-1234-123.

Accounting of Stores

Accounting of materials : It is essential that in order to demand the optimal material, the stock held with the stores must be accurately known and maintained. This is important to prevent over-ordering of material and is absolutely essential to avoid 'stock- outs', both of which are detrimental to functioning of an organisation. Thus, in order to continuously keep a track of the material available in stock, the following systems are adopted :-

- (i) *Bin Cards* show the daily receipt, issue and balance in hand in the form of cards attached to each bin / shelf containing the particular item. Bin cards can also be suitably and effectively modified to indicate the maximum / minimum permissible stocks and the re-order levels.
- (ii) *Stock identification cards* are identification cards for each item, with details such as material code number, description, ledger folio number etc, kept next to the bin/rack in order to identify the item completely.
- (iii) *Material requisition slip* is a requisition for the type and quantity of material required by any department from issue counter. When maintained properly it accurately indicates the exact quantity and type of material issued to various departments for various purposes.
- (iv) *Material received note* is a document through which the material received from a supplier is taken on ledger charge. Subsequently the accounts department, based on this document makes the payment to the suppliers.
- (v) *Stores ledger* is a complete record of materials indicating the details such as suppliers' details, price of the item, invoice / bill number and stock levels.
- (vi) *Material return note* : Surplus material lying with various departments are returned to the stores through a 'material return note' which enables the stores to take this surplus material on ledger charge once again and to adjust their stock levels.
- (vii) *Material transfer note* : Surplus material lying with one department may be transferred directly to another department in need of the same material through such a note, by informing the stores.

Concept of Flow of Goods and Stores Accounting

Flow of goods (issue of stock) is of utmost importance in any health care setup since the problems of obsolete items, expired medicines and old stocks are faced by every store keeper in a hospital. Such avoidable wastages not only increase the cost of managing a hospital but may also occasionally result in a fatality due to issue of expired and out of date medicine to a

critical patient. The following are some of the methods followed for flow of goods and stores accounting :-

(a) **First In, First Out (FIFO)** : Material from the oldest stock is issued first with the view to turnover the stock.

(b) **Last In, First Out (LIFO)** : Materials which are received last are issued first in this case, but it usually results in poor inventory management and hence is generally not recommended in health care establishments.

(c) **Specific cost method** : Provides the most realistic valuation of inventory stock and physical stock-taking of stores can be done any time of the year. Under this method, values of the material charged off / taken on charge are identical to the material issued / received and hence is the most suitable method of maintaining stocks in commercial organisations.

(d) **Average cost method** : Average cost of each item issued from stores/ received at stores is assessed and this value is taken for maintaining the cost of inventory held by the organisation. Though easy to follow, this method often leads to inaccurate values of inventory in the organisation.

Inventory Control

Inventory may be defined as “usable but idle resource having an economic value”. It can also be described in financial terms as the sum total value of raw materials; semi processed and finished goods at any given time. When we deal with tangible items such as materials, it is called ‘stock’. The basic issue involved in inventory management is to ensure that adequate amount of raw materials are available to meet the demand of the organisation, while at the same time ensuring that too much inventory is not accumulated and also that there are no ‘stock-outs’ in the organisation. Thus, a well managed organisation would necessarily have a higher inventory turn-over rate and lesser cash would be blocked as inventory/stocks. In order to manage any organisation without affecting its outputs, some amount of ‘inventory’ is necessary so that raw materials are available in correct quantity at correct time. Similarly, in a health care establishment some inventory of essential drugs and supplies has to be maintained to ensure that health care to patients does not suffer.

In any hospital, high quantities of inventory in form of large number of costly drugs and supplies would be detrimental to profitability and smooth running of the hospital due to blocking of cash in form of idle stores, requirement of large storage space for medical stores, substantial handling and transportation charges, pilferage and cost of expired medical stores. The ultimate aim of inventory control in a healthcare setting is to ensure that adequate and optimal essential items are properly stored, controlled, are easily retrievable and distributed to points of uses so that patient care does not suffer due to lack of these essential medical supplies.

Some Important Economic Terms in Inventory Control

(a) **Purchase cost** is the actual cost paid for the purchase of materials & stores, and the aim should be to reduce this as far as possible without compromising on the quality and quantity of items purchased.

(b) **Inventory carrying cost** are the hidden costs and pertain to maintenance of a large inventory/stock, which lies idle and which blocks the finances of the organisation. Special efforts are required by a manager to identify these carrying costs, since they are often hidden and not easily decipherable. Some such inventory carrying cost are the (i) **Cost of borrowed money** which is the interest paid to a financier or the interest lost which could have been earned, had a large amount of money not been used for purchasing the stock presently held as inventory; (ii) **Cost of space** : which needs to be hired for storage; (iii) **Cost of additional manpower** : by incurring additional expenditure on salaries etc of manpower required to manage the stocks; (iv) **Cost of obsolescence** : All materials, especially hospital supplies, become obsolete, leading to financial loss; (v) **Cost of deterioration** : Supplies when stored for a very long time tend to deteriorate with time, especially crucial hospital supplies like injections, medicines and intravenous medicines etc; and; (vi) **Cost of pilferage** : A large and unmanageable inventory is bound to lead to pilferage and loss to the organisation.

(c) **Ordering Costs** are costs incurred by an organisation in placing an order for some material with a supplier. In case of large orders and government orders, the ordering costs can be substantial if we also include the salaries and time of personnel involved in the purchase procedures, besides the ancillary like paper, stationery etc. At times, a professional expert may also have to be called from abroad or the manager may be required to visit a foreign country to place an order, in which case the ordering cost would also include the travel cost etc.

(d) **Shortage costs** are the ‘direct’ and ‘indirect’ costs paid by an organisation for not having a particular item in ready stock. The impact of this shortage would depend on the criticality of that item and its importance for functioning of the organisation. In a hospital set up, let us assume that there is a sudden shortage of life saving drugs like Digoxin. The **direct cost of this shortage** would be in form of the expenditure incurred by the hospital in procuring these drugs urgently from the open market at a premium. The **‘indirect cost’** would be in the form of adverse publicity, suspended healthcare in form of refusal of admissions and may be a few avoidable deaths due to shortage of those critical drugs.

Types of Inventory Control

Pareto, a German economist found that in any given city, 20% of the people controlled 80% of the income & 80% of the other people controlled only 20% of the finances of the city. This ‘**Pareto’s law**’ also forms the basis for inventory control, wherein it is theorized that a few items in the inventory will account for a large proportion of total cost whereas bulk of the items will account for only a small percentage of the cost or importance of total inventory. Thus, basic principle of inventory control is based on the effort to closely control costly / critical items in inventory all the time, while other, less important / less costly items could enjoy less stringent controls. Various selective inventory control measures are as under :-

- (a) ABC : Inventory control based on annual total cost of items and not on unit cost of an item. This type of inventory control is described in detail subsequently.
- (b) VED : Based on criticality and importance of consumables, items are classified as Vital (V), Essential (E) and Desirable (D).
- (c) HML : Items are classified based on cost of individual item as High cost (H), Medium cost (M) and Low cost (L). This classification does not depend on consumption of items.
- (d) SDE system is based on the ease of availability of items and items are classified as Scarce (S), Difficult to obtain (D) and Easy to obtain (E).
- (e) GOLF system is based on the source of supply & include Governmental sources (G), Ordinary (O), Local (L) and Foreign (F).
- (f) FSN : Items are classified based on the rate of issue from the stores into Fast- moving (F), Slow moving (S) and Non-moving (N) items.
- (g) SOS is the classification of items based on Seasonal (S) and Off-seasonal (OS) availability.
- (h) XYZ is the classification based on the value of stocks of items held.

An ideal inventory control mechanism would ensure the optimal quantity of resources at all times at all places where they are required for smooth & unhindered operations and would prevent stock- outs and under-stocking. At the same time, a good inventory control system would also prevent over-stocking and blockage of vital finances in form of idle stocked stores. In a health care setup, a good inventory control systems would improve the service delivery and enhance patient satisfaction, reduce the operating (functional) costs of the hospital, increase efficiency and liquidity (cash availability), thereby improving the return on investment (ROI).

ABC Analysis

ABC Analysis is based on the principle that generally a small proportion of items account for a large proportion of cost and vice versa (Pareto's Law) and under this system, inventory items are classified based on the total annual cost of the different items. It is usually seen that 10% of the stores would cost 70% of the total resources (Group A items); 20% of the items would cost around 20% of total resources (Group B items) and remaining 70% of items would cost only 10% of the total resources (Group C items).

Steps Involved in ABC Analysis in a Hospital

- (a) Consumption cost of each medicine/ item is worked out for the whole year.
- (b) The medical store items are arranged in descending value of their annual cost, the most expensive being at the top and item which is least costly being placed at the bottom.
- (c) The cumulative cost is then calculated and a table is prepared (Table - 4) .
- (d) From Table - 4 above it is seen that about 10 % of items would cost 70 % of total annual cost. These are termed as group 'A' items. The next 20 % items would cost 20 % of total annual cost and these are termed as group 'B' items. The rest of 70 % items account for only 10 % of the total annual cost of all hospital items and these are the group 'C' items. Same is depicted in Fig - 2.

Table - 4

S. No.	Name of drug /Item	Annual consumption cost (Rs)	Cumulative cost (Rs)	% of total cost
01	Inj Ciprofloxacin	9000	9000	9 %
02	Tab Ciprofloxacin	8500	17500	17.5 %
03	Inj Dexamethasone	8300	25800	25.8 %
04	Inj Ampicillin	8000	33800	33.8 %
.....				
10	Inj Streptokinase	5000	70000	70%
.....				
30	Oint Soframycin	1000	90000	90%
.....				
100	Gauze	100	100000	100%

It is thus derived that group A items, which are the costliest should be kept under strict control and should be monitored closely for turnover and expiry. If such costly items accumulate in large quantities in a hospital, they would block scarce finances and lead to high cost of operating the hospital. ABC analysis of inventory leads to certain benefits in form of guidance to the manager about level of control for each type of item, which are summarized in Table - 5.

VED Analysis

VED analysis is based on the 'criticality' and importance of an item and not merely on the annual cost of consumption of items. Often it is seen, especially in health care settings that a medicine of low cost and low consumption is critical in saving lives and the hospital can not ignore such drugs simply because they fall in group 'C' category (if classified as per their annual cost). For example, Inj Rabipur or Anti snake venom may be used only once or twice in a month and thus have very low annual cost and usage, but these drugs are vital & life saving drugs and have to be available in every hospital at all times.

Activity	Group A	Group B	Group C
Monitoring	Very strict	Strict	Moderate
Safety stock to be kept	Low	Medium	High
Level of control for issue	Tight	Moderate	Low
Estimates of requirements	Very accurate	Moderately accurate	May be low
Frequency of purchase	Most frequent	Less frequent	Least frequent
Turnover	Maximum	Medium turnover	Least turnover
Management involvement	Top level	Middle level	Lower level

VED analysis of inventory classifies various items into three categories of *Vital (V)*, *Essential (E)* and *Desirable (D)*.

- Vital items (V)* are items like Oxygen which are vital for functioning of a health care establishment and whose shortage will have serious adverse effects on routine functioning of the organisation. Such vital items should be monitored by top management, irrespective of their cost and their availability should be ensured with sufficient stocks available in medical stores.
- Essential items (E)* are the items whose shortage or non-availability can only be afforded for a short time (such as intravenous sets & IV fluids in a hospital) and if their shortage continues for anything more than the shortest time, the functioning would be affected seriously and adversely.
- Desirable items (D)* are those items whose shortage would not affect the routine functioning of an organisation even if the shortage is for a long time (such as Vit E capsules or sun screen lotions in a hospital's medical store).

As highlighted earlier, hospital and medical stores can not be only classified on the basis of their annual cost and annual consumption, since some items may be vital life saving stores even though they are of low cost and low usage. If a hospital inventory is classified only by 'ABC system' based on cost and usage, such vital drugs would invariably fall in group 'C' and would be given least importance. Thus it is felt that in a hospital setting, a combination of ABC analysis (based on annual cost) and VED analysis (based on the criticality of the item) is to be adopted, as under :

- Category I* contains all the vital and costly items, whose shortage may adversely affect the functioning of the hospital or whose over stocking /pilferage may lead to financial loss to the hospital. These items such as Inj Rabipur, Anti snake venom or costly medicines and vaccines should be monitored by a senior manager himself.
- Category II* items are essential but are less costly and can have lesser stringent controls.
- Category III* items are the stores and medicines which are desirable but would not affect the functioning of the hospital

even if they are not available for a long time. In addition this category would also include least costly medical stores which need not be kept under strict control.

Summary

Logistics management is defined as "the systematic and scientific process of planning, implementing and controlling the efficient and effective flow and storage of resources (goods & services) from point of origin to the point of consumption in order to meet the customer's requirements". Logistics management in a health care set up becomes essential to ensure procurement and provisioning of vital medical supplies at the correct cost, consistency in quality, low storage cost and high turnover of items. Any healthcare establishment is heavily dependent on material, equipment and medicines and hence logistics management assumes great importance since availability of the right item, at right time, right place and in the hands of the right person can often make the difference between life and death in a hospital.

Broadly, Logistics Management in a health care establishment would encompass the activities like Tendering, procurement & inspection; Storage, standardization, codification & classification; Materials accounting & physical distribution; Transportation; Security of materials; Condemnation and disposal of stores. The process of Tendering and Procurement involves Vendor rating, Analysis of bids, Price negotiations, Issue of purchase order and Purchasing. The storage system is to receive material, check it for quality and quantity, prepare the receipt vouchers, accept the inspected and passed material, undertake documentation for payment of bills, store the accepted material properly and safely, issue required material to various departments on requisition from them, prepare issue vouchers and account for them. Codification of goods is to ensure quick tracing & retrieval and early identification of dead / duplicate stocks. It is done by various methods like Alphabetical system, Numerical system, Combined alphabetical and numerical system, Brisch system, Kodak system etc. Accounting of materials is essential that in order to demand the optimal material, the stock held with the stores must be accurately known and maintained. This is important to prevent over-ordering of material and is absolutely essential to avoid 'stock-outs', both of which are detrimental to functioning of an organisation.

Inventory may be defined as "usable but idle resource having an economic value". It can also be described in financial terms as the sum total value of raw materials; semi processed and finished goods at any given time. In any hospital, high quantities of inventory in form of large number of costly drugs and supplies would be detrimental to profitability and smooth running of the hospital due to blocking of cash in form of idle stores, requirement of large storage space for medical stores, substantial handling and transportation charges, pilferage and cost of expired medical stores. The ultimate aim of inventory control in a healthcare setting is to ensure that adequate and optimal essential items are properly stored, controlled, are easily retrievable and distributed to points of uses so that patient care does not suffer due to lack of these essential medical supplies. Various selective inventory control measures

are ABC (Inventory control based on annual total cost of items and not on unit cost of an item); VED (Based on criticality and importance of consumables, items are classified as Vital, Essential and Desirable); HML (Items are classified based on cost of individual item as High cost, Medium cost, and Low cost); SDE system (based on the ease of availability of items and items are classified as Scarce, Difficult to obtain and Easy to obtain); GOLF system (based on the source of supply & include Governmental sources, Ordinary, Local and Foreign); FSN (based on the rate of issue from the stores into Fast-moving, Slow moving, and Non-moving items); SOS (based on Seasonal and Off-seasonal availability); XYZ (based on the value of stocks of items held). ABC Analysis is based on the principle that generally a small proportion of items account for a large proportion of cost and vice versa (Pareto's Law). VED analysis is based on the 'criticality' and importance of an item and not merely on the annual cost of consumption of items.

Study Exercises

Short Notes : (1) Tendering and procurement of medical stores. (2) ABC Analysis (3) VED analysis.

MCQs

1. The analysis which is based on the principle that generally a small proportion of items account for a large proportion of cost and vice versa is a) ABC analysis b) VED analysis c) HML d) SOS.
2. The analysis which is based on the 'criticality' and importance of an item and not merely on the annual cost of consumption of items is a) ABC analysis b) VED analysis c) HML d) SOS.
3. A contract with a vendor to periodically supply low cost items only on receipt of an authorized release order from the organization is called a) Rate contract b) Blanket ordering c) Cash purchases d) System contracting.

Answers : (1) a; (2) b; (3) b.

Anuj Bhatnagar

It has been increasingly realized that with increasing complexities of activities and projects being planned and undertaken, the conventional methods of management are no longer adequate to meet the demand of today's projects. With larger and complicated organisations with their own unique organisational and structural issues a need has been felt for better, more effective and innovative managerial methods, some of which are discussed in this chapter.

Network Analysis

Network analysis is a means of planning and controlling processes. In this, a project is broken up into small operations which are arranged into logical sequence. Thereafter, the order in which these actions are to be performed is decided and a network diagram shows the relationship between the various operations involved. Thus, any network analysis indicates the relationship between various operations involved and also points out which activities are to be completed before the others are begun. For example, the simple process of making tea and snacks may be interlinked with each other by common resource (gas stove). Also the activity of serving tea can not be completed till the time the activity of preparing tea has been completed. This is a highly simplified example of network analysis, which indicates interdependence between two or more activities and the time-schedule between such activities in a large project. Time management of a project, an important managerial control technique, can be done through Critical

Path Method (CPM) and Project Evaluation & Review Technique (PERT), which are discussed subsequently.

Critical Path Method (CPM) : Here, it is assumed that durations of individual activities in a project are known with certainty. The method thus helps to determine the earliest possible start time & latest possible start time for each activity. CPM also identifies the critical activities, which are critical because if any of these activities are delayed by even a short period, the entire project will be delayed. CPM requires greater planning but this is justified by concentrating on critical path only and avoiding expense on strict supervision & control on non-critical activities or on whole project. Besides ascertaining the time schedule of a project, CPM is also the standard method of communicating project plans, progress and costs.

Project Evaluation & Review Technique (PERT) : PERT involves planning, monitoring and controlling of projects where time taken for each activity in the project is not known. It uses probability to estimate the timings of various activities in the project and linear programming for maximizing the achievement of objectives. PERT is classically used in long-term projects like construction of hospitals, ships, roadways and buildings, in planning & launching of new health programs, products & services, in publication of books etc where exact time for each phase is not known with certainty. PERT uses probabilistic and linear programming methods to assist a manager in planning schedules & costs, determining time & cost status, forecasting skill requirements, predicting schedule slippages & cost overruns, developing alternate time cost plans & committing resources to various tasks. Under PERT, three time-estimates are made, as under :

- (a) *Most Likely Time* is the time taken most frequently in completing a particular activity.

- (b) *Optimistic Time* is time in which an activity can be completed, if all goes as per the pre-determined plan.
- (c) *Pessimistic Time* is the time taken to complete an activity under most adverse conditions. This is thus the longest possible time taken to complete a project.

From the above estimates, expected time for completion of an activity is computed as :

$$\text{Expected Time for an activity} = \frac{\text{Optimistic Time} + (4 \times \text{Most Likely Time}) + \text{Pessimistic Time}}{6}$$

Unlike in CPM (where time taken for completion of each activity is known & certain), PERT is used when time taken for various activities is uncertain and hence time of completion of the entire project itself is also uncertain. Hence the expected time of completion & variance of project completion time are estimated. The expected completion time can be estimated as in case of length of critical path in CPM method, by replacing activity times by the expected time of various activities. An illustration of critical path method is shown in Box - 1.

Box - 1 : Critical Path Method : An illustration

Let us depict a project by breaking it up into individual activities (A to G) as under :-

Let us assume that activities A, B, B1, C, D, E, F & G take 4, 2, 1, 2, 2, 7, 3 & 2 weeks respectively in the entire project of Step No 1 to 7. Here we see that A, B & C can be started simultaneously since they do not have any preceding activity. Activities A, E & F for steps 1, 4, 6 & 7 take a total of 14 weeks (4+7+3). This is the critical path since any delay in this sequence will result in delay for entire project. For the sequence 1-2-5-6 (6 weeks), we have a lead time of 5 weeks since sequence 1-4-6 will take minimum of 11 weeks. Similarly sequence 1-3-4 (3 weeks) has a lead time of 1 week over activity A which will take minimum of 4 weeks.

This way, CPM not only helps in planning & sequencing of activities, it also indicates the critical activities (which when delayed, will lead to delay in entire project), thereby concentrating on strict control & supervision of such critical activities.

CPM is an effective managerial control technique where time taken for various activities are known with certainty. However, very often, for long projects, esp in Research & Development, time duration for various activities can not be predicted. Here, we use the Project Evaluation & Review Technique (PERT)

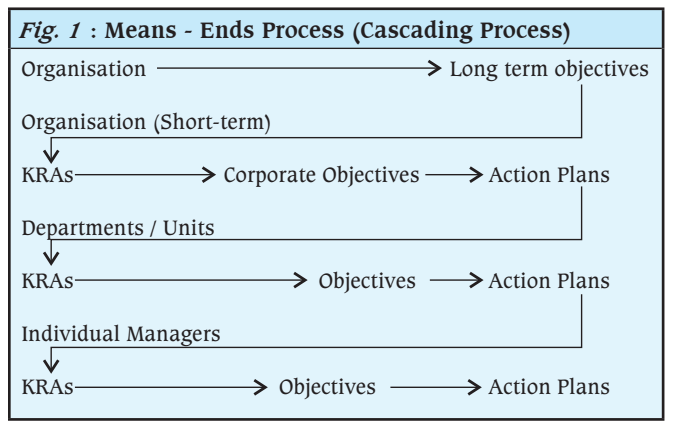

Management by Objectives (MBO)

MBO is a modern managerial tool by which managers can improve their performance and their overall effectiveness. The concept of MBO can be, in a way, considered an extension of normal management functions of planning, control &

motivation. The term MBO was first used by Peter Drucker more than 25 years ago in a very broad sense as an approach to or philosophy of management. John Humble of United Kingdom described MBO as “a system which integrates an organisation’s need to achieve its objectives with the managers’ need to contribute and develop himself”. Thus, MBO can be defined as a managerial approach which uses objectives as a focal point to improve managerial performance & effectiveness at individual and organisational levels. The important feature of MBO which distinguishes it from other planning and control processes is the *emphasis on results (objectives) rather than on activities & processes*. In MBO, the emphasis is on outputs and not on inputs. MBO, being based on behavioural approach to management, is based on concepts as under :

- (a) Emphasis on results rather than activities.
- (b) Defining objectives (expected results) for specific positions.
- (c) Participatory or Joint objective setting.
- (d) Identification of Key Result Areas (KRAs)
- (e) Establishing a Periodic Review System.

MBO also emphasizes the concept of “means-ends” sequence. Results at one echelon in an organisation are the means to results at the next higher level and results for a given span of time are the means to results for a longer time-span (Shown as in Fig - 1). MBO leaves detailed methods & actions to the concerned managers by focusing on attaining objectives, and therefore, results in better delegation, decision-making & job satisfaction at all levels.

The MBO Process

There are broadly four steps involved in MBO process, as under:

- (a) **Identifying the Key Result Areas (KRAs)** : KRAs delineate the broad areas on which the organisation must focus its attention. They are based on the concept that a smaller part of manager’s activities yield larger proportion of his results. Here, it is worthwhile to mention the *20 : 80 concept*, which implies that 20% of a manager’s activities/efforts/time (which are thus critical & important) account for 80% of his results/output and as much as 80% of his activities/efforts/time (which are thus not important) lead to only 20% of results/output. KRAs help to identify those 20% activities/efforts/time which will yield 80% of the results/output, thereby focusing on them and improving

effectiveness. Once KRAs have been correctly identified, it is easy to concentrate on important aspects and give lower priority to less important activities, thereby conserving vital resources. A KRA is an area where results are important, where success would lead to significant gains and where failure would be disastrous. Although the emphasis is on objectives in MBO, it is even more important to identify KRAs. There are several ways to identify KRAs, including data analysis and brain storming, wherein all possible KRAs are listed and a short list is thereafter selected. The process of identifying KRAs by the top management consists of the following broad steps :-

- (i) SWOT Analysis : Analysis of Strengths, Weaknesses, Opportunities and Threats.
- (ii) Brainstorming exercise to identify all possible KRAs.
- (iii) Discussion, analysis & classification to arrive at an agreed list of KRAs.
- (iv) Establishment of specific objectives in each KRA.
- (v) Preparation of Action Plans, including assignment of responsibilities for results to be achieved.

(b) Setting up Objectives : Having identified KRAs, the next step is to set up objectives within these KRAs, which have to be measurable and quantifiable. The broad organisational objectives define the purpose & mission of the organisation and generally answer the question “what is our business?” Long-term and short-term objectives emanate from organisational objectives. Strategic objectives are related to choice of product, technology or market. Choice of objectives (statement of expected result) is the starting point for management process in MBO. Hence under MBO, all inputs and processes are modified to meet the requirements of objectives. No doubt that activities are essential to obtain results, but it is well known that all activities do not contribute to achievement of objectives. In addition, objectives should be stated in terms of expected results and not merely in terms of planning activities or activities. It is well established that specific, quantifiable, measurable and concrete objectives result in higher levels of performance as compared to when managers are merely told to perform their best. An objective is a statement of expected results, which provides guidelines for decisions and actions at lower level & provides standards against which performance is assessed.

Any objective thus, should have the following four elements, which are also determinants of improved performance, viz., Quantity, Quality, Cost and Time. Objectives are successful as guidelines only if they are quantifiable & measurable. If you can not count, can not describe, can not measure what you want, you probably do not know what you want, and hence can not use it as an objective in your plan of action.

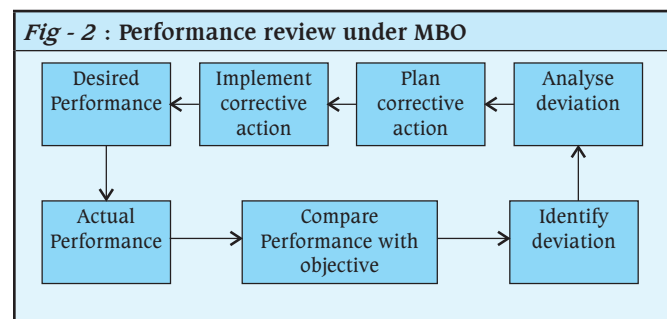

(c) Action Planning : Action plans are the means to convert objectives into reality. Objectives describe what is to be achieved, whereas action plans describe how these objectives are to be achieved. Every objective has to be achieved only through converting them into specific action plans, which specify what activities will

be performed and the specific time when each activity will be performed. The four broad steps essential in all action plans are:

- (i) Choice of strategies which are essential for achieving objectives.
- (ii) Fixing the responsibility for achieving each objective.
- (iii) Resource allocation for achieving the objectives.
- (iv) Scheduling specific activities in specific sequence for maximum utilization of resources.

Activities (series of acts) have to be done in a particular sequence for attaining the objectives. Thus, all activities have to be arranged sequentially in most logical manner & each activity has to be completed within a stipulated time frame. This is called scheduling, which converts plans into action plans. An example of Action Plan is given below. Let us assume that as the District Health Officer, you, after SWOT analysis and brain storming session with your peers and colleagues, have identified two of your KRAs as “upgradation of infrastructure” at all hospitals/PHCs and “printing of new health education material on HIV/AIDS prevention” for the district. With these KRAs, an action plan would be drawn out as in Box - 2.

(d) Performance Review : Performance review, in the MBO process, focuses on performance appraisal, improvement, future corrective action, frequency of reviews & self appraisal. The main purpose of performance review in MBO process is to provide corrective feedback to the concerned person. A system of Performance Review under MBO is shown in Fig - 2 :

Advantages & Disadvantages of MBO are shown in Box-3

Box - 3 : Advantages & Disadvantages of MBO	
Advantages	<ul style="list-style-type: none"> • Greater role clarity, job satisfaction and better measurement of performance. • No wastage of scarce resources. • Single-minded dedication to achievement of objectives. • Motivating factor & weeds out non-performers. • Increases productivity through role clarity & increasing job satisfaction. • Provides objective appraisal method. • Strengthens superior-subordinate relationship. • Based on concept of participation
Disadvantages	<ul style="list-style-type: none"> • Problem of joint setting of objectives among unequals in the organisation. • MBO may not always percolate to the lowest level in the organisation • Difficult to implement in situation of change.

Box - 2 : Action Plan												
KRA's	Objectives	Action Plans

Total Quality Management (TQM)

Quality can be defined as “the totality of features and characteristics of a product / service which have the ability to satisfy the clients felt / implied needs”. Total Quality Management (TQM) as a management tool, focuses on continuous improvement of procedures and processes involved in any activity or any services. The entire focus in TQM is to continuously improve the way things are done in an organisation, for which each member of the organisation must know what is the right thing to do, how to do these right things and how to measure the current level of quality and improvement in this level. The basic principles of TQM, on which all activities in TQM are carried out are described as under :

(a) **Satisfy the consumer** : TQM involves satisfying the felt or perceived needs of the customer, which tend to change with time and circumstances. Managers need to be sensitive to these changes in expectations of clients since being able to always satisfy the customer in an integral part of TQM.

(b) **Management based on facts** : Every manager needs to have access to correct facts about the product or services being offered by the organisation. Based on these facts, improvements can be initiated in the product / services. TQM also involves apprising the client of the correct facts about the product.

(c) **People-centric management** : It has been seen that people tend to take responsibility for their actions and are willing to improve upon the processes once they understand what to do and how to do. By themselves, mere procedures, standards and technology can not ensure quality without the commitment of people involved in producing the product / rendering the service. By involving the stakeholders, especially the workers, commitment to quality (and customer satisfaction) can be enhanced significantly.

(d) **Ongoing improvement** : TQM is not a short term or one-time activity which would end once the target has been achieved. It is an ongoing process which aims to improve the every day routine procedures & processes involved in product /

service. Under TQM, improvement is viewed as an incremental change over the previously existing level of quality rather than any major breakthrough in the manufacturing process.

Various TQM Methods and their Role in Management

TQM methods are aimed at bringing about a change in the organisational culture wherein customer satisfaction is the over-riding concern in the mind of each and every member of the organisation, irrespective of the importance or status of his or her job. The introduction of TQM in an organisation invariably begins with setting up of teams to solve problems and by educating and training team members.

Some important TQM methods are as under

- (i) *Acceptable Quality Level (AQL)* provides a set of pre-determined rules and standards for acceptance or rejection of a product, so that each item inspected for its 'quality' is classified as acceptable or unacceptable. This is used to ensure that the supplier provides at least the minimum quality mutually agreed upon by both the customer and the supplier of the product/services.
- (ii) *Affinity diagrams* provide some type of relationship to groups within an organisation. Such methods are useful when a team attempts to translate the customer requirements into an organisational structure, which requires to highlight the associations rather than only the logical sequence & connections of client needs.
- (iii) *Arrow diagram* is used to depict the time required to solve a problem in the organisation. This can be used for planning routine daily projects where depiction of time required for completing each step is essential.
- (iv) *Benchmarking* provides comparison with pre-determined standard of quality of product/service, thereby focusing on overall mission of the organisation and is a process which compares the performance (quality) with that of others, thereby ensuring better performance through comparison.
- (v) *Consensus* reaching is a way of examining alternatives so that an organisation can collectively reach a conclusion which is acceptable to all members of the organisation.

- (vi) *Contingency planning* is the process of planning for unforeseen circumstances to ensure least wastage of resources and to avoid 'fire-fighting' at the last moment.
- (vii) *Cost benefit analysis* involves the analysis of real cost and benefit involved in the project. It is used to assess if the solution is practical and achievable in terms of the cost incurred by the organisation.
- (viii) *Criteria testing* is the process of listing the various criteria and evaluating an alternative course of action against these pre-determined & pre-decided criteria.
- (ix) *Deming Wheel (PDCA)* is a graphical representation of essential requirements to satisfy a customer's requirements, namely, plan (P), do (D), check (C) & action (A). Such a managerial tool is used extensively to develop new products & services based on the felt needs of the clients.
- (x) *Error proofing (pokayoke)* is the managerial process of designing and conducting an operation in such a manner so as to eliminate specific errors which cause major disruption of process / services, thereby causing dissatisfaction to customers.
- (xi) *Force analysis* is used while developing the contingency plan for identifying the various issues (forces) and problems and their effect on the organisation.
- (xii) *Gantt Charts* are graphical representation of the essential steps for completing a project. Thus the entire project is broken down into smaller component steps and a graph is created to depict the time scheduling of each step (as shown under "action plan" earlier under MBO). Gantt charts make it easier to identify the various steps involved and also easily indicate (visually) when the deadline for particular step in the project has been missed.
- (xiii) *Kaizen* (change for the better) is a Japanese concept which implies an on-going and continuous improvement in all activities in an organisation and at all levels. It is a people-centric concept which depends on their commitment and participation for effective implementation, which may be for products or for services. Quality circles & suggestion schemes in organisations are important methods to implement the concept of Kaizen.
- (xiv) *Pareto analysis* (proposed by Wilfredo Pareto) is used extensively and effectively to identify the important causes for poor performance (or quality) which need to be addressed on priority. This is also called the 80/20 rule which states that 80% of the problems are caused by 20% of the activities and hence the organisation should ideally concentrate on these 20% activities which determine the large proportion of problems in manufacturing a product or delivery of a service.
- (xv) *Quality Circles (QC)* are small groups of individuals who regularly meet voluntarily during duty time and attempt to solve problems faced by the workers in the organisation. QCs provide a direction and aim to individuals to identify their own problems and solve them.

Quality assurance in health care is rendered difficult due to the fact that the output (health care) is most often intangible, highly personalized and can not be standardized in most cases. However, it must be remembered that patients perceive quality of health care provided not only by the end result, but also

through small routine procedures and facilities provided by a hospital. Quality can be described as "doing the right thing the first time and doing it better the next time". Quality in health care has to be patient-centric and should meet the expectations of a patient (client) in the most cost-effective manner. The need and importance of quality in health care settings imply that Total Quality Management (TQM) in health care has vast scope.

Summary

With larger and complicated organisations with their own unique organisational and structural issues a need has been felt for better, more effective and innovative managerial methods, some of which are Network Analysis, Management By Objectives (MBO) and Total Quality Management (TQM). Network analysis is a means of planning and controlling processes. In this, a project is broken up into small operations which are arranged into logical sequence. Thereafter, the order in which these actions are to be performed is decided and a network diagram shows the relationship between the various operations involved. Time management of a project, an important managerial control technique, can be done through Critical Path Method (CPM) and Project Evaluation & Review Technique (PERT). In CPM it is assumed that durations of individual activities in a project are known with certainty. The method thus helps to determine the earliest possible start time & latest possible start time for each activity. CPM also identifies the critical activities, which are critical because if any of these activities are delayed by even a short period, the entire project will be delayed. PERT involves planning, monitoring and controlling of projects where time taken for each activity in the project is not known. It uses probability to estimate the timings of various activities in the project and linear programming for maximizing the achievement of objectives. It is classically used in long-term projects and uses probabilistic and linear programming methods to assist a manager in planning schedules & costs, determining time & cost status, forecasting skill requirements, predicting schedule slippages & cost overruns, developing alternate time cost plans & committing resources to various tasks.

Management By Objectives (MBO) is a modern managerial tool by which managers can improve their performance and their overall effectiveness. It is a system which integrates an organisation's need to achieve its objectives with the managers' need to contribute and develop himself. It can be defined as a managerial approach which uses objectives as a focal point to improve managerial performance & effectiveness at individual and organisational levels. The important feature of MBO which distinguishes it from other planning and control processes is the emphasis on results (objectives) rather than on activities & processes. It also emphasizes the concept of "means-ends" sequence. There are broadly four steps involved in MBO process which are (a) Identifying the Key Result Areas (KRAs), which in turn include SWOT Analysis, Brainstorming exercises, Discussion, analysis & classification, Establishment of specific objectives in each KRA, Preparation of Action Plans, including assignment of responsibilities for results to be achieved; (b) Setting up Objectives within these KRAs, which have to be measurable and quantifiable. Any objective should have the

four elements, which are Quantity, Quality, Cost and Time. (c) Action Planning: Action plans are the means to convert objectives into reality. The four broad steps essential in all action plans are choosing strategies, fixing the responsibility, allocation of resources and scheduling specific activities in specific sequence. (d) Performance Review: It focuses on performance appraisal, improvement, future corrective action, frequency of reviews & self appraisal.

Total Quality Management (TQM) focuses on continuous improvement of procedures and processes involved in any activity or any services. The basic principles of TQM, on which all activities in TQM are carried out, are Satisfy the consumer, Management based on facts, People-centric management and Ongoing improvement. Some important TQM methods are Acceptable quality level (AQL), Affinity diagrams, Arrow diagram, Benchmarking, Consensus reaching, Contingency planning, Cost benefit analysis, Criteria testing, Deming Wheel (PDCA), Quality Circles (QC) etc.

Study Exercises

Long Questions : (1) Enumerate some modern management techniques. Describe Network Analysis. (2) Enumerate some modern management techniques. Describe Management by Objective.

Short Notes : (1) Critical Path Method (CPM) (2) Project Evaluation & Review Technique (PERT) (3) Management By Objectives (MBO) (4) Total Quality Management (TQM).

MCQs

1. Planning, monitoring and controlling of projects where time taken for each activity in the project is not known is (a) CPM (b) PERT (c) MBO (d) TQM.
2. Emphasis is on results rather than on activities & processes in (a) CPM (b) PERT (c) MBO (d) TQM.
3. Identifying the Key Result Areas (KRAs) is first step in (a) CPM (b) PERT (c) MBO (d) TQM.
4. Cost benefit analysis is an example of (a) CPM (b) PERT (c) MBO (d) TQM.

Answers : (1) b; (2) c; (3) c; (4) d.

Rajvir Bhalwar

Today the importance of planning and evaluation needs no further emphasis. What is relevant to note, at this point is that epidemiology is central to the successful execution of these key managerial functions. The reason is simple – the indispensable requirement for any planning or evaluation process is “valid and reliable data” and epidemiology is the science which deals with valid and reliable data collection, collation, analysis and interpretation (1).

The Planning Process

Planning is a very scientific and systematic process which essentially visualizes as to where we are at present (*present situation or baseline*), where do we want to go (*the future or “outcome”*), why do we want to go there (*logic*) and how do we get there (*process*). It consists of a series of steps and we need accurate data at each of these steps (2).

Step 1 - Laying down the premises (scope) : This defines the general perimeters or “boundaries”, in terms of place, time, population and disease condition(s), within which the health program being planned, will be restricted to (3).

Step 2 - Situational analysis : Relevant Demographic (age, sex, population distribution etc.), socio-economic (literacy, occupation, economic status etc.) and disease data (mortality and morbidity) is obtained and analysed.

Step 3 - Resource analysis : Data on available resources (health manpower, money and material) is obtained and analysed.

Data for steps – 2 and 3 is either obtained as a secondary data, from various sources as already described in detail in the chapter on sources of data in epidemiology or else obtained as primary data by a survey, as per details given in a subsequent chapter.

Step 4 - SWOT Analysis : The Strengths (S), Weaknesses (W), Opportunities (O) and Threats (T) are identified in context of the proposed programme. S and W are permanent phenomena that exist within the organization or community; O and T are temporary, often fleeting, phenomena that exist in the external environment. For example, in a proposed programme for prevention and control of HIV in our country, the organizational and constitutional philosophy and political will of the country to prevent HIV / AIDS is a “strength” which should be utilized to the maximum. At the same time, the common social tendency not to encourage talking about sexual health is a weakness pitched against us, and we need to either neutralise it or circumvent it. The fact that recently funds have been made available for developing health educational material and that the new Mayor of the city is strongly in favour of educating the public as well as high risk groups for HIV / AIDS, is an opportunity and we should grab this opportunity. However, if there has been some recent resistance and objection from parents against sex education of children, it is a threat and we need to either negotiate it or else bypass it.

Step 5 - Ensure Community participation : Identify the community leaders, peers and voluntary groups and involve

Step 13 - Undertake a “Pilot Run” : This is another very important step. Do a small scale trial run of your procedures and rectify any defects that are observed.

Step 14 - Conduct the Programme : Launch the programme in a full fledged manner. Ensure that you or your dependable deputies are there always at the sites where the services are being delivered. Make it a point to regularly obtain and analyze data on various aspects as the programme progresses, making changes if required.

Step 15 - Evaluate the programme : Evaluation is the process of assessing the extent to which our results are commensurate with our pre-decided objectives. Evaluation should be a continuous process as the programme progresses (concurrent evaluation) and not simply an exercise to be undertaken at the end of the programme (terminal evaluation). For evaluation, we again need valid and reliable data in the same way that we obtained in the planning stage. Broadly, evaluation is undertaken for six different facets, as follows :

- **Evaluation of Relevance** : This evaluates whether we need to continue it as such or in some modified manner (concurrent evaluation) or, at the end when we do terminal evaluation, to find out whether the programme was required at all. This requires obtaining and reviewing the data / intelligence about situational analysis, resources and community needs.
- **Evaluation of Adequacy** : Whether the required amount of manpower, equipment, expendables, logistics, other type of material and finances have been provided? Have they been suitably placed?
- **Evaluation of Process** : How are / were the services/ activities undertaken? What has been the quality of services? Were the services accessible to or provided to all the beneficiaries or only few segments? For example, are the targeted number of children being vaccinated, have some areas been left out, the scheduled number of patients being seen and the planned number of health education sessions being taken, and so on?
- **Evaluation of Efficacy, Effectiveness and Efficiency**: Efficacy answers the question “can the programme or procedure work” (maybe in ideal or controlled situations); Effectiveness addresses the question “Does it work” (i.e., in the real life situations); Efficiency answers the issue “Is it the most economical way (in terms of time or money)”. For example the conventional combination regime of Streptomycin, INH and Thioacetazone may still give good results for curing pulmonary tuberculosis if we were to treat patients admitted into the sanatoria for 18 months (i.e., is efficacious), but in the real domiciliary settings, bring about only about 30% cure (is not effective), while MDT would cure 70 to 80% patients in real life domiciliary settings (is effective). Finally, comparison between the total costs of the two regimen (drugs, duration of treatment, requirement of doctors, paramedics and hospital buildings, commuted cost of reduction in human suffering due to earlier cure, etc) vis-à-vis the overall cure rate may finally indicate that short term MDT may be more “efficient”. We have already had a detailed discussion on these aspects in the chapter on studies on economic evaluation, in this section.

Summary Box: Steps in Planning The Health Programme

- Laying down the premises (scope)
- Situational analysis
- Resource analysis
- SWOT analysis
- Enunciation of the “Community Needs”
- Setting the Priorities
- Identify the “High Risk” Groups
- Enunciate the Goal (Aim), Objectives, Indicators and Targets of the Programme
- Choose a Strategy
- Draw an Action Plan
- Work out where are your high risk persons are located and how will you address accessibility and coverage
- Ensure Community participation
- Organise the manpower, material, and finances
- Undertake a “Pilot Run
- Conduct the Programme
- Evaluate the programme
 - Relevance
 - Adequacy
 - Process
 - Efficacy, Effectiveness and Efficiency

Summary

Planning is a very scientific and systematic process which essentially visualizes the present situation or baseline, the future or “outcome”, the logic of doing so and the process therein. It consists of a series of steps, each of which necessitates accurate data. The first step in planning & evaluation of a health programme involves laying down the premises or scope of the programme i.e., the general perimeters or “boundaries”, within which the health program being planned, will be restricted to. Thereafter, a Situational analysis is undertaken, in which relevant demographic, socio-economic and disease data is obtained and analysed.

The next step would be an analysis of resources available; health manpower, money and material is assessed at this step. After this, we proceed to perform a SWOT analysis, wherein Strengths, Weaknesses, Opportunities & Threats are assessed. S and W are permanent phenomena that exist within the organization or community; O and T are temporary, often flitting, phenomena that exist in the external environment. Ensuring community participation and enunciation of the “Community Needs” (vis-à-vis the “professionally assessed needs”) would be the next step in the process. Setting the Priorities i.e. addressing the most important requirements given the available (and expected) resources, would be the next step. An epidemiological method for according priorities is to consider Importance of disease, Effectiveness of Interventions and Cost of interventions and give marks (as numerals 1, 2 or 3) to each heading.

The next step would be identification of “High Risk” Groups i.e. those persons, who due to some characteristics, have a much higher chance of being affected by the disease or it’s adverse consequences- this would differ according to the health issue being addressed. Subsequently, we proceed to enunciate the

them fully in the planning process.

Step 6 - Enunciation of the “Community Needs” : We now carefully evaluate our findings of situational, resource and SWOT analyses and decide as to what are the major issues (within the boundaries defined by our scope) which need to be addressed and which can be feasibly addressed by us. We should also work out an optimum trade-off between ‘normative’ or ‘professionally assessed needs’ (what we, as Doctors or public health care managers, feel that the community requires) and the “felt needs” of the community (what the community members feel is their need). By way of community participation, educate and convince the community if, in your perception, their felt needs are unscientific or cannot be addressed within the resources (4 - 7).

Step 7 - Setting the Priorities : On the basis of our adjudged community needs and the resources, work out the “priority” areas within the proposed programme, which are the most important requirements and we, given our available (and expected) resources, can feasibly address them. An epidemiological method for according priorities is to consider the following three headings and give marks (as numerals 1, 2 or 3) to each heading as per following description. Disease which gets the highest score (max possible will be a score of 9) would get the highest priority while the lowest scoring disease (minimum possible score will be 3) gets lowest priority.

- **Importance of disease (based on mortality, morbidity, suffering, cost of treatment and loss of productivity)**: 3 marks if high importance, 2 if moderate, 1 if low importance.
- **Effectiveness of Interventions** : 3 marks if interventions known to be very effective, 2 if moderately effective, 1 if low or non effective.
- **Cost of interventions** : 3 marks if cost is low, 2 if moderate cost and 1 if cost is high (Intervention could be a treatment or preventive modality).

Step 8 - Identify the “High Risk” Groups : High Risk groups are those persons, who due to some characteristics, have a much higher chance of being affected by the disease or it’s adverse consequences. It is important, at this stage, to identify who are the high risk persons, based on our situational analysis and identification of community needs, so that extra efforts may be directed towards them. Young children, women of child bearing age, the elderly, people living in slums or inaccessible area are some of the usual examples of high risk groups. However, it depends on the disease or condition being addressed. For example, in an educational programme to obtain favourable change in sexual lifestyle, truck drivers may be identified as high risk group. The importance of identifying these groups lies in the fact that while we shall direct our activities to all members of the community but more focused and elaborate (targeted) actions will be directed towards these special groups. Consequently, large amount of benefit will occur from the programme if these groups are addressed.

Step 9 - Enunciate the Goal (Aim), Objectives, Indicators and Targets of the Programme : Once the community needs have been identified within the context of the proposed programme, we enunciate the Aim or the Goal. This is a broad statement of the overall end-point which the programme

intends to achieve. Objectives, on the other hand, are specific statements, through which the overall goal would be achieved. Objectives are thus specific, quantifiable and usually relate to a time-plan. Indicators are parameters and targets are numerical quantities written in conjunction with the indicators, which actually quantify the end points which the objectives are to achieve. For example in a program directed towards healthy lifestyle, the statement “to bring about healthy improvement in various aspects of lifestyle and a reduction of lifestyle diseases so that they are no more a significant health problem” is the broad goal or aim. The statement “To ensure that by 31 Dec 2008, at least 80% of the adults undertake 45 minutes of brisk walk, daily, on at least 5 days a week” is an objective, in which “community members who are undertaking regular aerobic exercise as per defined criteria of 45 min a day on at least 5 days a week” is an indicator and “80% achievement by 31 Dec 2008” is the qualifying target.

One of the most crucial steps in planning process is to intelligently enunciate the goal, objectives, indicators and targets. A lot of thought process and expert evaluation should go in at this stage. They should be realistically set, should be do-able, neither too ambitious nor too under-achieving.

Step 10 - Choose a Strategy and Draw an Action Plan : With the background of the enunciated goal, objectives, targets and indicators, and duly considering the resources (step - 3), select out as to what overall strategy you will use in the proposed programme. For instance, in a proposed programme for prevention of HIV, the strategy could be to only have health educational efforts, or else it could be a comprehensive strategy of combination of health education, blood safety, diagnosis and treatment, surveillance and PPTCT. Obviously the choice of strategy will be strongly guided by the programme objectives and your available / expected resources. If you do not have lot of resources, naturally you would select a strategy of limited activities which are likely to give you the best results. Now, having decided the strategy, write down a detailed action plan as to how the programme will be executed, as has been already explained in the previous chapter. Do ensure that a “time-line” has been given for each objective, target and indicator, giving the date of each end point.

Step 11 - Address the Issues of Accessibility and Coverage : Get detailed spot maps of your areas and work out the aspects of population distribution, roads, communications and transportation. Do remember that very often, those who would benefit most from your programme, are also the ones who are living far off, do not have access to your services, are often thought to be not really in need of the proposed preventive or curative services. Hence at this point, work out where are your high risk persons located and how will you ensure that they are covered adequately.

Step 12 - Organise the manpower, material, and finances : Place the required manpower, equipment, material and other logistics at the required places. If some more resources are expected, make a plan as to where they will be relocated and how. Make out detailed, written “operations manual” including the operative procedures for each activity, i.e. “who will do what to whom and in what manner”. Ensure that your personnel have been centrally trained and tested for undertaking the procedures.

Goal (Aim), Objectives, Indicators and Targets of the Programme. They should be realistically set, should be do-able, neither too ambitious nor too under-achieving.

Thereafter, the Strategy to be followed will have to be chosen- the choice of strategy will be strongly guided by the programme objectives and your available / expected resources. After this is done, we proceed to draw an Action plan as to how the programme will be executed, giving a time-frame for each activity. The next action would be to work out where the high risk persons are located and how the issues of accessibility and coverage are to be addressed- this may be achieved by getting detailed spot maps of the relevant areas and working out the aspects of population distribution, roads, communications and transportation. At this point, a vital component would be to ensure community participation, without which the entire programme will be laid to waste.

Organizing the manpower, material, and finances forms the next step, wherein a detailed "Operations Manual" needs to be prepared, that would indicate who would do what, to whom and in what manner. Subsequently, a "Pilot Run" needs to be undertaken. Thereafter, the programme is launched in full swing – a pertinent point at this juncture would be to regularly obtain and analyze data on various aspects as the programme progresses, making changes if required.

The final step in this series of events would be to Evaluate the programme- this is done on various parameters, which include Relevance i.e. whether we need to conduct the program at all; this can be done by concurrent or terminal evaluation. The next parameter to be assessed for would be Adequacy i.e. to assess whether the required resources have been provided and suitably placed. Thereafter, the process itself would be assessed- quality, accessibility etc. The final parameters to be evaluated in conduct of a health care programme would be Efficacy (can the programme work in ideal / controlled settings), Effectiveness (does it work in real-life situations) and Efficiency (is this the most economical way- in terms of time or money).

Study Exercises

Long Question : Epidemiology is an essential requirement at each step of planning and evaluating. Critically analyse this statement.

Short Notes : (1) SWOT analysis (2) Aim, objectives, targets and indicators (3) Planning cycle (4) Parameters on which evaluation is undertaken.

Exercises and MCQs

1. The first step in the process of planning a health programme would be (a) SWOT analysis (b) resource analysis (c) Situational Analysis (d) Laying down the premises (scope).
2. Strengths are permanent phenomena that exist within the organization or community. Yes/ No.
3. Arrange the following steps in planning a health programme, in the sequential & ideal order : (a) Setting priorities (b) SWOT analysis (c) Evaluation of the programme (d) Enunciation of community needs (e) Identifying of "high-risk" groups.
4. Specific statements, through which the overall goal would be achieved, are known as (a) Objectives (b) Targets (c) Aims (d) Indicators.
5. In estimating the effectiveness of interventions, the number

of marks that would be given if interventions known to be very effective is (a) 1 (b) 2 (c) 3 (d) 4.

6. What the community members feel are their needs, are known as (a) Felt needs (b) Assessed needs (c) Professionally assessed needs (d) Minimum needs.
7. The conventional combination regime of Streptomycin, INH and Thioacetazone may give pretty good results for curing pulmonary tuberculosis if we were to treat patients admitted into the sanatoria for 18 months (say 90% cure), but in the real domiciliary settings, bring about only about 30% cure. This means that the regimen is (a) Both efficacious and effective (b) Efficacious but not effective (c) Effective but not efficacious (d) Neither efficacious nor effective.
8. Broadly, evaluation of a health care programme is undertaken for how many different facets? (a) 4 (b) 5 (c) 6 (d) 7.
9. During preparation of which particular document in the process of planning a health programme, it is to incorporate a time line i.e. a time frame for each objective, target and indicator, giving the date of each end point : (a) Operation manual (b) High-risk group register (c) Pilot run (d) Action plan.
10. The maximum possible score that can be given to a disease/ health event in according of priorities for purposes of planning and evaluation is (a) 09 (b) 10 (c) 11 (d) 12.
11. All of the following subset of data is analysed while doing a situational analysis, except (a) Demographic data (b) Socio- economic data (c) Disease data (d) Resource data.
12. "Threats" are permanent, mostly long-lasting, phenomena that exist in the external environment. Yes/ No.
13. A broad statement of the overall end-point which the programme intends to achieve is known as (a) Target (b) Indicator (c) Aim (d) Objective.
14. All of the following headings are taken into consideration for according priorities (through scoring system) in conduct of a health care programme, except (a) Importance of disease (b) Effectiveness of interventions (c) Cost of interventions (d) High risk groups.

Answers : (1) d; (2) Yes; (3) b-d-a-e-c; (4) a; (5) c; (6) a; (7) b; (8) c; (9) d; (10) a; (11) d; (12) No; (13) c; (14) d

Kunal Chatterjee

Health has been at the centre of human concern since ancient times. Civilisations developed and perished due to wars, conflicts and raging diseases, which left none untouched, save those whose health was taken care of by an organised system. Ancient civilisations that developed in Indus valley, Greece, Rome and Mesopotamia had fairly advanced health systems for their times and the medical practitioners enjoyed a high status in the society due to their practice.

Two renowned medical systems developed in India in ancient times; Ayurveda and Siddha, which were quite similar in concept and practice. Indian systems sought knowledge by which life could be prolonged and some of the popular medical treatises of those times were the Charaka Samhita and the Sushruta Samhita. Medicine practiced in China was based on 'Yang' and 'Yin' principle and claimed to be the first organised body of medical knowledge. One of the oldest civilisations of the world developed on the banks of river Nile in Egypt. Ancient Egyptian medicine mingled with religion and enjoyed great patronage under their rulers. Nearby in the land between Tigris and Euphrates rivers, the Mesopotamian civilisation emerged, which was called the 'Cradle of the World'. Medical practice in this land was remarkable for a code of medical ethics created by the King Hammurabi, which though drastic was nevertheless the first of its kind. Greeks and Romans gave the world of medicine its modernity. They taught medical practitioners to think of 'why' and 'how' and raised medicine to the status of science.

The practice of medicine has come a long way since the time of magic, religion and supernatural thoughts to a modern science following evidence-based practice with a range of services extending from preventive, promotive, curative to rehabilitative offered to the individual and community.

What is a Health System?

Health system covers a whole gamut of health activities, health programmes, institutions providing medical care such as hospitals, clinics and primary health care centres and the policies enunciated by governments to provide optimal health care for its citizens. A health system as described by WHO is the "sum total of all the organisations, institutions and resources whose primary purpose is to improve health." A health system needs staff, funds, information, supplies, transport, communications and overall guidance and direction. And it needs to provide services that are responsive and financially fair, while treating people decently. The government is ultimately responsible for the overall performance of a country's health system, however individual institutions, municipalities and regions need also to play an important role in its propagation and maintenance. Health systems affect the socio-economic status of a community in any region and in turn are affected by its poverty, development and stability.

Health systems usually include the following :

- Development of health policies, plan for their implementation and development of a system of regulation of health services.
- Define and develop the institutional framework to deliver the health services within the purview of this system.
- Allocate and mobilise financial and human resources for its functioning.
- Plan, manage and deliver the health services.

Health systems should be accessible, efficient, affordable and of a good quality. They should ultimately aim to improve, maintain and restore the health status of the community at a cost that an individual and the community can afford to spend without substantial change in their financial status.

Goals of a Health System

A health system has to provide for much more than routine delivery of services. It has to protect the health of its community, treat them with dignity and ensure that it responds fairly to the expectations of the population. The WHO has thus identified three overall goals for the health systems to be effective, responsive and fair :

- Effective in contributing to better health throughout the entire population.
- Responsive to people's expectations, including safeguarding patient's dignity, confidentiality and autonomy and being sensitive to the specific needs and vulnerabilities of all population groups.
- Fair in how individuals contribute to funding the system so that everyone has access to the services available and is protected against potentially impoverishing levels of spending.

Historical Evolution

The oldest known health system, since the time humans settled down to community living, is the family. Families came together since ancient times to care for the pregnant women, young and elderly and for basic survival needs such as nutrition, safety and care during sickness. The oldest known organised health efforts date back to the time when religion was identified with healing and deities were worshipped for seeking cure of a disease in the community. Some civilisations proffered sacrifices to appease the Gods. Worship, herbal medicines, medicines from animal sources and disciplined lifestyle were integral to the ancient medical systems. Thereafter, in the era when Buddhism and Christianity spread across countries, the first hospitals were constructed for the sick, destitute, old, orphans and lepers. Notable among them were the early sanatoria built by Emperor Ashoka in Indian subcontinent in 2nd century BC. Hospitals remained the domain of religious institutions such as churches till well into the 16th century in most parts of the world. State supported institutions developed subsequently when Europe awoke from the dark ages and superstition and dogma in medicine were challenged. Monarchs also lent their support to health care activities as a pious duty towards their people. In India modern hospitals were started by missionaries and later supported by the colonial government. Industrial revolution in Europe created conditions of overcrowding, rapid urbanisation and even rapid decline in the health of community. It brought

about an appreciation of the losses incurred by the state due to ill-health, especially of the workforce. This motivated them to work systematically towards improvement of health systems. Health was now perceived as a citizens' basic right.

The Rise of Modern System of Medicine

In the second half of 19th century, several revolutionary breakthroughs were witnessed in the medical science. They heralded the coming of age of medicine making it one of the most researched sciences. Advances in the medical field continue unabated even today. Newer drugs, modalities of treatment, health systems and research have improved the quality of life of people. Life expectancy has risen, many diseases, which in early days caused significant morbidity and mortality have been controlled and some eradicated. Countries have witnessed an improvement in the health and quality of life indicators, which have added onto the rising economic prosperity.

This rise has however been associated with increase in the cost of newer technologies. Newer and deadlier diseases have emerged throughout the World. Microorganisms are increasingly showing resistance to the routine drug regimes and disease vectors have developed ability to survive in the environment despite using physical, chemical and biological methods to control them. Lifestyles of the human population are found to be associated with various chronic diseases and rising expectations of a relatively healthy and prosperous population have created the demand for immediate relief of illnesses often at the cost of rational drug policies and evidence based interventions. This milieu has created the impression of profitability of health care industry with health care providers, medical equipment manufacturers, insurance and pharmaceutical industry and the corporate world staking its claim of the pie. As a result there is a widening disparity in the quality of medical care being provided to different social status of population in the countries. The cost of medical care is growing out of the reach of common man.

Financing the Modern Health Care System

The modern health care systems need funding from the state or citizen sources to create financial viability and enhance responsiveness, efficiency, equality and fairness in the delivery of health care. The following questions need to be asked to describe the financing of health care systems :

- Who is financing – Government, finance companies or employees?
- What are the services covered by this payment?
- Which financier pays for how much of the service provided?
- Who are the organisations or individuals receiving this funding?
- What is the basis for this payment – whether it is fee for service, capitation charges or both?

The primary source of funds is from the public, whether by direct cash for service or indirectly through the government contribution. There are generally five primary methods of financing health care systems as enumerated below.

- Direct or out-of-pocket payments
- General taxation

- Social health insurance
- Voluntary or private health insurance
- Donations or community health insurance

Private out-of-pocket Funds

In most of the low-income countries, people pay a high proportion of their health costs directly to the health care providers out of their own pockets. While in the wealthiest countries in the world, few health care costs are paid by the individuals directly to providers. This system exposes the family in a poor country to exploitation and catastrophe in case of sickness. Some people are deterred from using health services or from continuing treatment because of unaffordability. The people who use these services have to cut expenditure on the more important needs of the family such as nutrition, clothing, housing and education. As per WHO, each year approximately 150 million people in the world are obliged to spend more than 40% of the income available to them on health care, after meeting their basic needs, which drives most of them below poverty line. To this scenario, market forces are added, which move the focus of health care from user benefit to vendor profitability. The formal health systems are thus seriously damaged and perception of effectiveness of a system gets linked to its cost. Traditional and cheaper alternatives are also pushed out. Though the system provides choices and control to the customers and also accelerates competition and research, most often all these efforts are oriented towards increased profitability.

General Taxation

It is the responsibility of the governments to facilitate healthy and prosperous life for its citizens. A variety of functions are included to achieve this goal such as improvement of security, infrastructure, enforcement of laws and spending on education, health and nutrition. The health sector thus needs to compete with the others for resources out of the common government kitty. Governments of different countries have installed mechanisms to tax its citizens in various commodities and services, to fill the treasury from which it allocates a percentage share to develop health of its citizens. It is generally observed that in almost all the developed nations and some underdeveloped nations, governments spend heavily on health, even though a majority of its citizens are in a position to pay for health services. In the rest of the world, government spending is extremely low on healthcare and is unable to meet health needs, even though it remains the largest organised resource pool for health systems.

Health Insurance

Here the basic tenet is that a large group of people are made to share the risk that they may need health care at any point of time, thus creating a 'risk pool'. The funds dedicated for health care are collected through prepayment and managed in such a way as to ensure that the risk of having to pay for health care is borne by all the members of the pool and not by each contributor individually.

Social Health Insurance

In this finance scheme contributions targeted specifically for health care are collected from workers, self-employed people, businesses and the government. A pool of funds is thus created

and health care is financed through this source. The successful implementation of this scheme depends on the contributions of each member of the population. Often the government ends up contributing on behalf of people who cannot afford to pay themselves to this fund. An example of this type of insurance is the Employees State Insurance in India.

Private Insurance

Private insurance companies operate in fairly big numbers in the developed countries such as USA. These collect contributions from its members and work for high profit margins due to the high insurance coverage amount and incentives that they create to increase appeal of their schemes. As a result the premiums paid for these schemes are also high and hence the private insurance players are more interested in the high income groups. In most countries part of the population is covered directly through general taxes, while others are required to make contributions to a social health insurance fund or another type of health insurance, which may be private.

Donations

Donations play a very important role in the health systems such as during calamities and such emergencies in the affected areas. There is a lack of authentic data regarding the type and source of funds received during these situations especially when such catastrophes occur in lesser-developed countries. Similarly the availability of these funds are unpredictable and depends on the mobilisation and involvement of governments, non governmental organisations, corporate world and private donors.

Health Care System Models

The health care systems in different countries are either purely private enterprises following the so called capitalistic model or the public insurance systems which enshrine the fact that health care is a fundamental right of every citizen and a basic responsibility of the government. Most often a country has a mix of the two systems to ensure equitable distribution of quality medical care.

Private Systems

The purely private enterprises are relatively rare. In some countries where such systems exist, they cater to the requirements of a comparatively economically well-off population subgroup in a developing country. In such places the overall standard of health care is poor and private enterprises in the form of private clinics or nursing homes meet the requirements of wealthy expatriates. In most countries where the government health care system functions to provide health care, a parallel private system is also allowed to operate.

Public Systems

The other model is the public insurance system where in the state covers the risks involved substantially. Here the citizens do not pay from their pockets to finance their treatment and mostly insurance is the medium of payment for health care. Among the methods of funding enumerated above, governments use taxation, social security measures and donations to fund this method of health care. Public insurance systems include social security model, publicly funded health care model and

the social health insurance models. In the social security model, workers and their families are insured by the state, while the residents of a country are insured by the state in a publicly funded health care model. Social health insurance scheme has been discussed before and includes a system where the population is a member of a sickness company. In India, the Employees State Insurance Corporation is an amalgamation of the social security model and social health insurance scheme. Some of the other social security models are practised in organisations such as Defence and Railways. A publicly health care model works in high-income countries and the small countries where government sources are mobilised to fund for the health care of its population such as in Cuba. A fall out of this model is that the quality of health care is compromised when the governments do not devote adequate resources for health care and private players take over.

Planning & Development of Health Systems

Planning

The earliest developed planning is where each individual or organisation makes decisions for definition and selection of relevant health problems, establishment of priorities among problems and allocate resources accordingly, establish coordination with other health system personnel and chose daily activities in the use and financing of health services. This is known as the *dispersed health planning*. Thus each physician selects his patients, area of practice, referral system, standard of performance and relationship with other health care workers and establishments. Similarly the consumer defines his health problem, which needs more priority and investment in time and money and ties up services of medical workers and laboratories and pharmacies he would utilise. A financing organisation also priorities the services, facilities and disabilities for distribution of funds. Thus each individual or organisation balances its own self-interest with the self-interest of other individuals and organisations whose help and cooperation are required. While some important goals and standards are achieved with this planning, it results in creation of gaps and inconsistencies in distribution of health care especially among minority and disadvantaged who have not been able to participate in the planning process. Similarly each provider or consumer needs external help to solve all relevant health problems in the era of specialisation, population expansion, social mobility and rising expectations.

There have thus developed voluntary associations of persons and organisations to solve common problems and collectively attain goals, which were difficult to achieve individually. Such form of planning is known as *focused health planning*. These associations are established solely for purpose of organising voluntary efforts of persons interested in planning together to solve problems in organisation and financing of health care such as the health and welfare councils or comprehensive health planning councils in certain countries. These do not themselves provide health care nor allocate resources or engage in funding but facilitate the dispersed planning by individuals and organisations. The lack of control of resources, disagreements with those who control finances, domination by self-interest groups have limited the ability of these

organisations to implement recommendations arising out of planning processes.

The limitations of focused and dispersed planning to deal with certain kinds of issues, have resulted in development of another type of planning called as *central health planning*. Central health planning refers to the planned use of power controlled by an individual or organisation to force other individuals and organisations to use their own resources in accordance with their plans. Central health planning may be based on the legal or professional authority for health care, such as a physician in a clinical practice, or a health care financing organisation such as the medicare programme or state governments exercising their authority, which requires the hospitals to perform certain activities to improve these institutions.

Development

The health systems need to respond to a variety of disease conditions, which have themselves been influenced by the social, demographic and epidemiological transition of communities. They require the financial means, organisation and procedures to efficiently manage the diversity of health conditions. Thus for development of health system in a country, the following key issues must be kept in mind that it should aim in :

- Improving health status.
- Reducing health inequalities.
- Enhancing responsiveness to legitimate expectations.
- Increasing efficiency.
- Protecting individuals, families and communities from financial loss.
- Enhancing fairness in the financing and delivery of health care.

A health system must aim at ensuring *universal coverage* of all the citizens of its country. To achieve this, the poorest, underprivileged and the sickest have to be reached by health promotion and prevention programmes. They have to be able to reach the nearest health post or clinic for treatment of locally prevalent and common health conditions. It also means that irrespective of the source of funds, the health care system must function like a national health insurance system, prepaid either through tax revenues or through social insurance. In this connection a historic WHO conference in Alma-Ata in 1978 established the goal of Health for All by the year 2000 defining the goal as 'attainment by all peoples of the world a level of health that permits them to lead a socially and economically productive life'. It suggested the achievement of this level by the extension of basic primary health care services to everyone as the major route to attain this goal.

Efficiency of a health system would vary with the amount of resources allocated to its development out of the total health budget of a country. The health status achieved with this kind of allocation would define efficiency in the macroeconomic terms. Most of the developed countries devote upto 9 percent of Gross Domestic Product for health care, which is considered optimal in view of the fact that the World Bank suggests US \$12 be allocated by a country for a combined package of per capita basic preventive and curative interventions. In most of the developing countries such as Cameroon, Sudan, Nigeria the percentage of GDP share for health is upto 2 percent, which

is grossly inadequate. Some countries such as USA spend upto 14 percent of GDP on health, which conversely could be an indicator of inefficiency. The scope of achieving greater efficiency out of the existing resources defines microeconomic efficiency. This includes issues such as overstaffing, spending large amount on health needs of diseases, which are absolutely preventable and so on.

Establishment of priorities in spending health resources is essential to ensure universal access to affordable and effective health care. Clear definition of priorities facilitates planning, training, monitoring and supervision of services in districts with inputs to build capacities at this level. In developed countries guidelines on priorities are debated and while several categories of priority are defined they differ among countries based on the need. In developing countries the debate on establishment of priorities is mostly led by the international agencies such as the focus on malaria control, diarrhoeal diseases or poliomyelitis. In such settings once the common conditions, with the maximum disease burden, are covered then the health facilities could be reorganised for improving patient waiting times, standardised dispensing of drugs and better communication with service users. Thus limited resources could be focused to have the greatest impact on service quality and health outcomes.

Lastly, *service quality* of a health system is influenced in the way service providers are paid. It is seen that when the providers are paid in the fee-for-service manner, it results in overspending, extravagant and wasteful care due to over-prescription, overuse of diagnostic services and excessive surgical interventions. This leads to an unproductive growth in health expenditure, hence a control on utilisation volume or quality of service is required. This control includes an arrangement between the funding agency, provider and the user. Referral process, profile of the health care personnel, performance and quality of care audit are such important measures to check the economic efficiency of health care. Appropriate incentive-disincentive process should be utilised for supervision of health care providers both in public and private sectors.

Health Care Systems in the World

France

The health care system in France is one of the best in the World. It permits all citizens access to treatment irrespective of their payment capacity, social class or any other disposition. The health care system is a combination of public, private (not for profit) and private profit making system. The doctor-population ratio at 3 : 1000 is among the highest in the world. The social security with regard to health care consists of several public organisations, with separate budgets that refund patients for health care. These budgets are generated by direct and indirect taxes such as that on tobacco and alcohol and contributions. Upto 70 percent of health care costs in most patients and 100 percent in long-term ailments is refunded by the social security. Supplementary insurance is also taken by the citizens, either from their employers or private organisations, mostly non-profit insurers. Insurance is compulsory for all employed and self-employed adults, besides which, social security also protects against economic losses incurred due to sickness and

provides maternal and child care services at home for women with new-born babies.

United Kingdom

The United Kingdom established National Health Service (NHS) under the auspices of Department of Health in 1948 with the basic purpose of providing all British nationals with free physician and hospital services. Most health care facilities are owned by the state and the people working in NHS are employed by the state either directly or as independent contractors. The General Practitioners (GPs) are the mainstay of NHS and every patient has to be routed through them. They are paid by a nationally agreed contract, according to the number of patients registered with them and the range of additional services offered. The GPs refer the patients to specialists or secondary or tertiary level trust hospitals. Hospital staff are salaried employees according to nationally agreed contracts. Financing of health care is mainly through taxes and insurance. Private health care continues parallel to NHS, funded by private insurance and utilised by those who can afford it. The NHS has received its own share of criticism due to poor allocation of funds and long waiting lists despite being considered as the most cost effective health system in Europe.

United States of America

The health care system of USA is alone among developed nations with the absence of universal coverage. It is a mix of public, private and charity hospitals and clinics. Majority of the health care expenses of its citizens are met by health insurance. Yet the US Census Bureau estimates that 16 percent of US population are uninsured, which mostly includes people less than 30 years of age who don't believe in the need to purchase health care and some eligible people who have not applied for insurance due to escalating costs. Some of the health insurance is provided by the government and includes Medicare covering people aged 65 years and above and those below that age with disabilities, Medicaid for low income groups mostly covering the dependant population and the State Children's Health Insurance Program (SCHIP) for all children upto 19 years of age. These state insurance schemes and those for serving or retired military personnel cover about 27 percent of population by government financed insurance. Besides this there are almost 50 private insurance companies, which offer medical insurance products to the citizens. The insurance systems in USA follow Diagnosis-Related Group (DRG) concept, that groups patients according to diagnosis, type of treatment, age and other relevant criteria. The health care establishments are paid a set fee for treating patients in a single DRG category, regardless of the actual cost of treatment for the individual.

India

Health is a state subject in India, though the Centre plays an important role as a regulator, advisor and resource provider. The government is obligated to provide health care to every citizen of India. The total share of health costs of the government towards provision of free health care in India today is 17.6 percent, which is a quarter of what a country like USA spends on its citizens. As a result of this dismal spending on health, the government hospitals and primary care institutions are ailing.

There is a large and diverse private health care system including corporate hospitals, nursing homes and private clinics, which exist around urban areas and are utilised by people who can afford the out-of-pocket expenses. Medical insurance in India is in nascent stages and unavailable to majority of population. As a result majority of the lower economic groups cannot afford private health care and depend on government institutions or practitioners of indigenous or alternative health systems.

Alternate systems of health care in India : There is a large share of health practice in the country based on alternate systems of medicines, some indigenous and some, which were brought by the different invaders over the centuries. The scientific basis of these systems have been debated time and again, however it goes without saying that a vast majority of these systems are supporting health care in remote areas, for the disadvantaged groups and the poor who cannot afford the increase in health care costs in the country. Government of India has established a separate Department of AYUSH (Ayurveda, Yoga and Naturopathy, Unani, Siddha and Homeopathy) under the Ministry of Health & Family Welfare, to promote and regulate the practice of alternative medicine in the country. The more common ones are mentioned in the next paragraph.

The term Ayurveda means 'Science of Life', which is conceived as the union of body, senses, mind and soul. The living man is considered as a matrix of three humors; *Vata*, *Pitta* and *Kapha*, seven basic tissues and the waste products of the body. Besides this the body is considered to be composed of five basic elements namely earth, fire, water, air and vacuum (ether). Any disturbance in the balance in the matrix or the elements is considered to cause sickness and the aim of Ayurveda is to restore the balance. It employs treatment modalities such as purification treatment, palliative treatment, prescription of various diets, exercises, avoidance of disease causing factors and the use of psychotherapy and ayurvedic medicines. Siddha system of medicine is another ancient Indian system, which takes into account the patient, his surroundings, age, sex, race, habitat, diet, appetite, physical condition etc to arrive at the diagnosis. It uses minerals, metals & alloys and drugs & inorganic compounds to treat the patients. Unani medicine is another alternative system, which was introduced by the Greeks in ancient India. It considers that the body is made up of four basic elements, earth, air, water and fire which in turn form humors, blood, phlegm, yellow bile and black bile. Health is a state of equilibrium among these humors and when this is disturbed a person falls sick. The system treats a patient with diet, pharmacotherapy, exercise, massages and surgery somewhat similar to Ayurveda. Yoga is a tradition evolved over thousands of years by saints and sages. According to yoga, most of the diseases originate through wrong way of thinking, living and eating and its basic approach is to correct the lifestyle by cultivating a rational, positive and spiritual attitude towards all life situations. Among the other alternate systems practised in India is homeopathy, which was created by Dr Hahnemann in Germany and found great popularity in this country. It considers that symptoms are the best possible reaction of body's defence mechanism to a disease and aims to strengthen these reactions. It tries to find out the best possible

remedy that would be effective and uses minimum doses of drugs to cure diseases against the principles of dose-response effect.

Summary

A health system as described by WHO is the “sum total of all the organisations, institutions and resources whose primary purpose is to improve health.” Health systems affect the socio-economic status of a community in any region and in turn are affected by its poverty, development and stability. Health systems usually include - Development of health policies, plan for implementation and regulation of health services; Define and develop the institutional framework to deliver the health services within the purview of this system; Allocate and mobilise financial and human resources for its functioning; Plan, manage and deliver the health services. Health systems should be accessible, efficient, affordable and of a good quality. They should ultimately aim to improve, maintain and restore the health status of the community at a cost that an individual and the community can afford. The WHO has identified three overall goals for the health systems to be effective in contributing to better health; responsive to people’s expectations, fair in how individuals contribute to funding the system.

Most often a country has a mix of the two health care systems, Public and Private, to ensure equitable distribution of quality medical care. The governments use taxation, social security measures and donations to fund public health care system. Public insurance systems include social security model, publicly funded health care model and the social health insurance models. Health insurance is also provided through Private insurance companies.

Health planning is of three types - Dispersed, Focused and Central. Central health planning refers to the planned use of power controlled by an individual or organisation to force other individuals and organisations to use their own resources in accordance with their plans. Planning efforts in a country shift from one type of planning to another as decisions made in one planning context create the need for other types of planning. For development of health system in a country key issues to be considered are improving health status; reducing health inequalities; enhancing responsiveness to legitimate

expectations; increasing efficiency; protecting individuals, families and communities from financial loss; and enhancing fairness in the financing and delivery of health care.

In India Health is a state subject, though the Centre plays an important role as a regulator, advisor and resource provider. The government is obligated to provide health care to every citizen of India. The total share of health costs of the government towards provision of free health care in India today is only 17.6 percent. There is a large and diverse private health care system including corporate hospitals, nursing homes and private clinics, which exist around urban areas and are utilised by people who can afford the out-of-pocket expenses. Medical insurance in India is in nascent stages and unavailable to majority of population. As a result majority of the lower economic groups cannot afford private health care and depend on government institutions or practitioners of indigenous or alternative health systems like Ayurveda, Yoga and Naturopathy, Unani, Siddha and Homeopathy. In India, the Employees State Insurance corporation is an amalgamation of the social security model and social health insurance scheme. Some of the other social security models are practised in organisations such as Defence and Railways.

Study Exercises

Long Question : Describe the health care system in India

Short Notes : (1) Health Insurance (2) Social security measures (3) Goals of a Health care system

MCQs :

1. The total share of health costs of the government towards provision of free health care in India today is (a) 17% (b) 7% (c) 37% (d) 50%
2. The following is not a method of financing health care systems (a) Direct or out-of-pocket payments (b) General taxation (c) Social health insurance (d) None of the above
3. The type of health planning which refers to the planned use of power controlled by an individual or organisation to force other individuals and organisations to use their own resources in accordance with their plans is (a) dispersed (b) focused (c) central (d) none

Answers : (1) a; (2) d; (3) c.

Amitava Datta

Assessing “Health Status”

Assessing the health of a population is a fundamental part of many public health activities. Performing the assessment correctly is a challenging process as there are usually problems in obtaining the necessary data and in balancing alternative approaches.

Reasons for Assessing Health Status

The usual circumstances under which assessing of health status of a community is conducted are as follows :

- To conduct a “health needs” assessment to establish whether particular health problems exist in a given population, describing the problems and identifying the magnitude of mortality and morbidity due to the problem.
- To conduct an audit into equitable distribution of resources, namely provision of health services by establishing the quantitative difference between “need” and “supply” for a defined population/service and bringing about necessary interventions.
- To assist in conducting a review of existing policy or plans to assist policy making decisions by decision-makers either directly or by informing the public, professional groups and other interested parties about the nature and distribution of health challenges and the definition of the problem; this may include a health impact assessment.
- To enable setting of targets for achievement and decide on quantum of resource allocation that is for better planning and implementation of health programs, improving resource allocation, target setting and helping targeting of health and other services.
- To conduct an evaluation of existing / proposed health services /interventions
- For research purposes by assisting in prioritizing the areas where research is needed.

Steps in Assessing the Health Status of a Community/ Population

As indicated above, there may be many reasons for conduct of assessment of the health status of a community / population. The methodology varies depending on the objective. However the usual steps in performing a health status assessment are as follows :

- Define the purpose of the assessment.
- Define the population concerned including the populations which will be compared.
- Define the aspect / aspects of health to be considered.
- Identify and review existing data sources from which information can be obtained. In case good local data is already available or reliable local or national statistics already available or relevant published or unpublished surveys already available, there may be no need to conduct a fresh health assessment survey. The various sources of

secondary data are discussed in detail in the section of epidemiology.

- Determine the most appropriate existing data which can be used.
- Use of the available data, statistics or survey reports to appropriately analyze the aspects needed which includes adjusting for population composition, deriving suitable measures and modeling future trends if required.
- Determine if any issues / aspects require data to be specially collected in which case a special survey may need to be undertaken. Details of undertaking a survey are dealt with in the section on epidemiology.
- Determine the aspects of comparators which will be considered.
- If so needed issues of confidentiality of information and disclosure by the subjects will need consideration besides any ethical issues.
- Interpret and communicate the results of the assessment.
- Evaluate the results and efforts undertaken

Step 1 - Clarity of purpose : The starting point of the health assessment, defining the purpose, is very important. Many a times, a tendency to have an extensive unfocused list of objectives as well as the temptation to examine interesting but irrelevant issues may arise. These must be resisted.

Step 2 - Define the population : Defining the population to be assessed is extremely important. Population size, structure and the period of observation can have major effects on the numbers of cases of disease or disability observed. The data is therefore usually expressed as proportions (e.g. the number of children aged under five per thousand population at a particular point of time) or rates (the number of new cases of tuberculosis per thousand population per year). Adjustment for potential confounding variables (e.g. age, sex, socio-economic status, etc) to allow valid comparison with other populations will be needed. Often geographic locations are used to frame the population studied, for example district boundaries. Problems can arise with population estimates for small areas, especially those projected from a data source that is relatively distant in time. The smaller the areas being studied, the bigger the chance of errors in estimates of population numbers and composition which can result in dramatic but erroneous findings.

Step 3 - Define the aspect / aspects of health to be considered : Health as indicated above can have a variety of meanings which can range from the lofty definition of World Health Organization having physical, emotional and social dimensions. In practice a more restrictive definition should be used which can be easily measured, for example a particular group of diseases or certain summary measures of population health.

Step 4 - Review the available data : Comprehensive population health assessments are based on a wide range of data of different types. While local data are required for assessing the health of the local population, they may not be available and so national (or indeed international) data may be used if the local population is felt to be typical of the nation as a whole. Data from similar localities (e.g. from different developing countries sharing common boundaries) or national data may be used for comparative purposes.

Many data are collected routinely by periodic national census, health service providers, local and central government and others. In addition, some of the many ad hoc studies that have been carried out locally or elsewhere may be relevant to a particular issue. Weaknesses of routine data collection systems include non-standard or inconsistent approaches to coding and data collection and limited availability due to cost and privacy policies. Data can be Quantitative, which usually answer questions such as 'How many people have a particular condition?' or Qualitative, when exploring such issues as what it is like to be afflicted with a chronic disease like diabetes, or perceptions about the effects and tolerability of risks from industrial pollutants. Strengths and weaknesses of various data sources are discussed in the section on epidemiology

Step 5 - Select data carefully : At first sight there may seem to be so many data available that assessing health should not be much of a challenge. However, in this connection Finagle's law is usually proved correct in public health work, which can be roughly stated as, 'The information you have is not what you want; the information you want is not what you need; the information you need is not what you can get; the information you can get costs more than you want to pay'. Relevant, detailed and accurate data are seldom available directly and so data collected for other purposes have to be used appropriately to give an indirect assessment. In considering the use of any data, one must consider how they have been obtained. People often assume that the quality and relevance of the data is satisfactory for the intended purpose. While recording data consistent terms or criteria may not be used and this can have a major impact. The use of international data needs great care as different countries may use different definitions and data collection processes.

When the data source proposed to be used has been identified the following aspects of the data should be considered before utilizing it :

Validity of data for the assessment : The data must be relevant to the issue, the data items should have been defined, there should be no conceptual biases in the data source (e.g. data collection should not have been structured to benefit the organization that has produced the data), the data should still be relevant as per time and the data should be relevant to the defined population so that the findings can be generalizable.

Technical quality of data : The data should have been properly recorded according to the specified definitions, complete in all aspects (preferably all subjects included or a representative adequate random sample used), be free from classification or selection biases and appropriate for the assessment planned

Quality of the analytic methods : The data should be adjusted for the population structure, e.g. age, sex, social group or ethnic composition and the numbers should be big enough to allow a statistically adequate and precise estimate of the aspects being considered

Other aspects : The relevant use of the data should be possible in spite of confidentiality policies, whether the data is available in computer analyzable form and what the likely cost of obtaining the data is.

Step 6 - Make good use of the existing data - Analyze and interpret the existing data : In progressing from data to information, the purpose of the assessment will determine the nature of the analyses chosen. The results of the health assessment need to be communicated to the concerned people for who the assessment has been designed and executed. The usual aspects which may be planned to be communicated include :

- Comparison of findings on health aspects of the population with other similar populations or larger populations, or comparing health status observed with that expected for the type of population.
- Describing the relative health of groups of the population (based on defined areas or social groups) and identifying inequalities.
- Comparing the health trends over time.
- Estimating the extent of potentially preventable health problems or conditions.
- Describing the likely health impact of environmental and social factors.
- Describing the impact of health problems in terms of people's experience of health problems.

Step 7 - Carry out a local study, if necessary : The health aspect planned to be assessed can be sufficiently important and the available local data so limited that a case may exist for conducting a fresh data collection. At national or state level, this situation arises relatively frequently in the field of public health. Conduct of special survey is however usually constrained by the cost involved. At the local level, a special survey or longitudinal study should only be carried out if time is available and the value of the data likely to be provided justifies the cost. The purpose of the assessment must be clear. Attempting to answer too many interesting questions or record too many findings may become unnecessarily expensive, besides reducing the response rate, if a questionnaire is used which appears too complex. The key features of a successful survey are described in an exclusive chapter in the section on epidemiology.

Step 8 - Consider the use of comparators : Assessing the health of a population may be undertaken to assess what is the actual extent of a health problem and also to determine how it compares with previous years, other areas and other social groupings. For example in examining the need for initiatives to reduce smoking, all that may be required is the number of deaths and extent of ill health associated with smoking locally. Information that locally this data is 10% lower or higher than the national average may well be redundant and indeed may divert attention from the principal data. However on other occasions comparative data will be required to highlight problems that are becoming more important with the passage of time or are particularly acute locally and need to be addressed in ways that are different from those required for most other areas. For example, the proportion of school children smoking in the town surveyed has increased since the previous survey or is more as compared to national average. Comparisons are of particular relevance when considering inequalities and inequities.

Step 9 - Address issues of confidentiality and disclosure : Assessing the health status of a population, especially at a small

area level, increases the risk of inappropriate and unnecessary disclosure of personal data. For example, the assessment of the HIV positive status of commercial sex workers in a particular area. Social and other discrimination besides loss of clients may result from the publication of the survey results. This is a highly complex and evolving area, as there are both technical and ethical issues, concerning balancing the benefits to society being weighed with the risks to individuals. Informed consent of the participating subjects is an essential pre-requisite to their inclusion in the assessment process.

Step 10 - Communicate results effectively : Occasionally a large set of data is to be produced for reference purposes, for subsequent expert analysis. But usually the information is used to inform the process of identifying opportunities to improve health and while experts may be involved, the information usually needs to be communicated to a general audience. When communicating results, a full description of the analytic methods used together with their limitation and assumptions may well be inappropriate. If so the assessor must take great care to provide a fair assessment and ensure that the typical audience will gain the right impression. The assessor must, however, be prepared and able to justify the methods in detail if requested.

Key points about health status analyses to consider in a written or oral communication are :

- Think through its purpose.
- Don't leave it to the reader to relevant points from a mass of data—quote specific data to make a point.
- Ensure confidentiality for participants in survey and ensure this is made clear to everyone.
- Don't be too sophisticated—many people in the target audience will not have that much background knowledge of the issue.

Step 11 - Evaluate your health status assessment : Those who are engaged in public health need to emphasize the importance of assessment to others. This should begin at home. It is important that our work is assessed using correct tools such as audit.

Assessing Health “Needs”

Definition

“Health needs assessment” is a systematic method of identifying the unmet health and health-care needs of a population and making changes to meet these unmet needs. Health needs assessment is used to improve health and other service planning, priority setting and policy development. Most doctors are familiar with assessing the health needs of individual patients. Professional training and clinical experience imparts a systematic approach to this assessment before starting treatment that the health professional believes to be effective. Such a systematic approach has often been missing in assessing the health needs of local or practice populations. Case studies have revealed the importance of conducting scientific “health needs assessment” before planning appropriate interventions in society.

Defining Need

An understanding of health needs assessment requires a

clear definition of need. Need, implies the capacity to benefit from an intervention. ‘To speak of a need is to imply a goal, a measurable deficiency from the goal and a means of achieving the goal.’

Health needs assessment is not the same as population health status assessment. It incorporates the concept of a capacity to benefit from an intervention. It therefore introduces an assessment of the effectiveness of relevant interventions to supplement the identification of health problems. Health needs assessment should also make explicit what benefits are being pursued by identifying particular interventions.

Health needs may be of two broad categories, viz. normative or professionally assessed needs, which are the needs which the expert health care providers think should be addressed, based on their professional assessment of the community. The second is the “felt needs” which the community feels to be important. Both the view points are important and need to be considered when assessing the health needs of a community.

Approaches to Needs Assessment

Varied approaches to needs assessment have been suggested, which include ‘epidemiologically based’ needs assessment – thereby combining epidemiologic approaches (like specific health status assessments) with assessment of the effectiveness and possibly the cost-effectiveness of the potential interventions. It can also be a comparison of the levels of service receipt between different populations. Determining the demands and wishes of professionals, patients, politicians and other interested parties can also be an effective approach to needs assessment.

The epidemiologic and qualitative approach in determining priorities incorporates aspects of clinical effectiveness, cost-effectiveness and patients’ perspectives. Comparisons of health service usage are commonly used as indicators of need. However, often for unexplained reasons, population-based usage rates typically vary markedly between areas. The relation between usage rates and improved health outcomes is also often hard to demonstrate.

The distinction between individual needs and the wider needs of the community is important to consider when assessing needs. If individual needs are ignored then there is a danger of a top-down approach to providing health and other services, reflecting what a few people perceive to be the needs of the population, rather than what they actually are. In India, the present concept of decentralization through decision making by the panchayati raj institutions and implementation of National Rural Health Mission are clear examples of this concept.

It is important to appreciate that health needs assessment involves the active, explicit and systematic identification of needs rather than a passive, ad hoc, implicit response to demand. For example, evaluation of the pattern of referrals for specialist care from a health centre and then base the recommendation for posting of a particular specialist based on work load, rather than base the recommendation simply based on “demand” of the local politician. The assessment of health needs can be made clearer by classifying the issues into needs, demands and supply, considering that health needs is not restricted to health-care needs. Health needs include wider social and environmental determinants of health

such as social and economic deprivation, housing, nutrition, education and employment. Health needs should ideally be appropriately addressed ('met'), but these needs are too often unmet (e.g. waiting lists, undiagnosed anemia, ignored needs of contraception) or 'over met' (e.g. prescribing antibiotics for all diarrhea cases).

Assessing of health needs provides the opportunity for :

- Assessing the population's health status in terms of the patterns of disease or disorders in the local population and the differences from district, regional, or national disease patterns.
- Learning more about the needs and priorities of patients and the local population.
- Highlighting areas of unmet needs and working towards meeting these needs.
- Deciding rationally and appropriately how to use scarce resources to improve the health of the local population in the most effective and efficient way.
- Influencing government policy, inter-sector collaboration, as well as research and development priorities.
- It also provides a method of monitoring and promoting equity in the provision and use of health services and addressing inequalities in health.

Framework for Assessing the Health Needs of a Population

There are eight steps involved in a formal health needs assessment project. However every assessment need not follow a simple linear progress through all the steps. Health needs assessment can be approached in much the same way as doing a jigsaw, so that different pieces are put together to give a complete picture of local health problem and thus the "need". The various steps involved are as follows :

Step 1 : Identify the health problem to be addressed in the defined population.

Step 2 : Carry out a health status assessment for the population, covering the relevant areas of ill-health and/or potential health to determine what is the size and nature of the problem.

Step 3 : Identify the existing services and interventions being delivered, including, where relevant, the service targeting, quality, effectiveness and efficiency.

Step 4 : Identify the interventions by determining what patients, professionals and other stakeholders want.

Step 5 : Identify interventions by reviewing the scientific knowledge and determine the most appropriate and cost-effective solutions.

Step 6 : Determine the resource implications. It may require to choose between competing ways of meeting needs (competing interventions) and decide on competing priorities – resources are always limited.

Step 7 : Enunciate the recommendations and the plan for implementation.

Step 8 : Determine whether assessing need is likely to lead to appropriate change by identifying expected health gains.

Needs Assessment Requires Careful Preparation

The process of needs assessment involves identifying the right

issues, using the right technical methods and managing the process effectively. The task needs to be defined right in the beginning with the objectives as clear, simple and focused as possible. The right project team should be assembled and all relevant stakeholders included, which may include representatives from the likely funding agency, clinicians and the users. Good leadership is important besides providing a clear and effective communication during the project. This aspect is especially important if there are multiple agencies involved in the assessment process. Access to relevant available information and informants should be sought at an early stage.

Identify the Health Problem or Issue

The health problem on which to focus the needs assessment exercise should be clearly identified. A health problem may come to attention from many sources, including the results of a population health status assessment, media reports, input from patients or stakeholders, government priority setting, or the scientific and professional literature.

The definition of the problem may involve a search of the health and social science databases besides review of the published health literature, which will provide a national and international perspective about the health topic and may provide already known methods, case definitions, disease incidence and prevalence, current provision of health services, etc, which may be applicable to the local population. In the absence of reliable published professional literature, a search of unpublished literature sources, for example reports of public health professional bodies and government health department databases, can also provide useful information. After initial analysis, it should become apparent whether the problem justifies a full and systematic needs assessment.

Dimension of the Problem

With a working definition of the health problems in mind, relevant health data can then be collected by selected methodology – study of records or special survey. Although it would be desirable to be able to estimate the likely number of beneficiaries of the planned interventions, the assessment process should be able to establish the following :

- How many people in the studied population are likely to be suffering from the target condition or conditions ?
- What their socio-demographic and other characteristics are?
- To what extent they are already receiving appropriate interventions.

Availability of Services

There are several sources of data on health care in a locality. Hospital data can provide information on OPD attendance and hospital admissions, diagnoses, length of stay, operations performed and patient characteristics to some extent. Clinical indicators can provide information on the comparative performance of hospitals and health authorities. Health-care provision indicators (e.g. number of doctors and nurses per capita, number of operations per capita) are often compared with national or international norms. There is however rarely evidence of a direct link between provision of health services and positive health outcome.

What do Professionals, Patients and other Stake Holders want

A wide range of stakeholders can be consulted to describe local health needs. Local health professionals – both private practitioners as well as those in government run health care facilities will have valuable contributions to make about the health needs of their local community. Other stakeholders such as health administrators, local government agencies, local politicians and voluntary groups also provide important contributions. This not only obtains views on their knowledge and beliefs but also engages them in the assessment process and encourages ownership and eventual implementation of the results. It is important to include the general public in decision-making about local health care. With increasing recognition of the importance of obtaining greater public involvement, various methods have been used, including use of panchayati raj institutions in India.

Determining the most Appropriate and Cost-Effective Interventions

An essential part of a health needs assessment is the review of the clinical effectiveness and cost-effectiveness of interventions that can address the identified health needs. Evidence about the effectiveness of health interventions or services can be found in databases of good-quality systematic reviews such as the Cochrane Library, or peer reviewed publications. Where there is a limited evidence of effectiveness of interventions then professional consensus about best practice may have to be relied on.

Resource Implications

If needs are to be matched to the usually limited available resources so that as much need as possible is met, then economic appraisal, including cost-effectiveness or cost-benefit information, must be considered. This involves :

- Determining how resources are currently being spent (programme budgeting)
- Defining options for change by suggesting alternatives :
 - (a) identify potential services which require more resources
 - (b) identify services which could be provided at the same level of effectiveness but at reduced cost.
 - (c) identify services which are less cost-effective than those identified.
- Assessing the costs and benefits of the principal options.
- Decide on the best option, aiming to increase investment in (a) and reduce investment in services identified in (b) and (c).

Implementation of Recommendations

In a needs assessment program, the collected information should be collated, analyzed and presented, usually in a report form. A summary of key findings is very useful in communicating the results to the decision-makers and those who will be affected by the decisions. Reporting results, however, is not an end in itself. Building agreement to a practical implementation plan for meeting the unmet needs is an essential part of needs assessment.

The Demarcation Between Health Needs Assessment (HNA) and Health Impact Assessment (HIA) : Health needs

assessment starts from the health of a defined population and result in proposals (for policy, programmes, strategy, plans or other developments). Health impact assessments (HIAs) and Integrated Impact Assessment (IIA) start from proposals and compare how they may impact on health. HIA has been dealt with in detail in a subsequent chapter in this section.

Summary

Assessing health status of a community is a challenging process but is required for numerous reasons viz- to conduct a health needs assessment; to audit equitable distribution of resources; to assist in conducting review of existing policy; to enable setting of targets for achievement; to evaluate existing / proposed health services / intervention and for research purpose as well. The methodology varies depending on objective; however mentioned steps could be followed to achieve the same. Needs implies the capacity to benefit from an intervention. The concept of felt needs- what people consider and/or say they need, expressed needs - needs expressed by action and normative needs-what health professionals define as need are very important to understand and apply. Health Needs Assessment is a systematic method of identifying the unmet health and health care needs of a population and making changes to meet these unmet needs. Approaches used commonly for need assessment are epidemiological and qualitative in nature. Health needs are not static and therefore any assessment will only provide snapshot of current needs of population concerned. Thus health need assessment is a continuous process which is to be reviewed, updated and evaluate concurrently.

Study Exercises

Exercises

- (1) Give WHO's definition of health and its drawback.
- (2) Enumerate the limitations of hospital based data.
- (3) What is Finagle's law in public health work?
- (4) Name a difficulty with use of international data.
- (5) What are the aims of health need assessment?
- (6) Name approaches utilized for needs assessment.
- (7) State the ethos of health needs assessment.

Answers

1. WHO has defined Health as a state of complete physical, mental and social well being and not merely absence of disease. This is an idealistic definition which does not lend itself easy measurement.
2. (a) Although voluminous, needs to be evaluated with care as not all people with a disease/ disability receive treatment. (b) Data is recorded for clinical purpose rather for analytic purpose. (c) Definition of a condition vary substantially from clinician to clinician, from clinician to researcher. (d) Issues related to patient confidentiality.
3. "The information you have is not what you want; the information you want is not what you need; the information you need is not what you get; the information you get costs more than you want to pay".
4. The use of international data needs great care as different countries may use different definition and data collection processes.
5. (a) To identify unmet health and health care needs of

a population. (b) To improve health and other service planning, priority setting and policy development.

6. (a) Epidemiologic method. (b) Qualitative method.
7. Health needs assessment starts from the health of a defined population and result in proposals- for policy, programmes, strategy, plans or other developments.

Assessing the “Health Impact”

Amitava Datta

Definition, Scope and Need for HIA

The word “Impact” in public health parlance means the overall, totalistic effect of an intervention. It does not restrict itself to specific outcomes. For example, the specific outcome measure in the case of an intervention like polio vaccination is reduction in the incidence of paralytic polio cases. However assessment of “impact” will go much beyond this and include wider range of outcomes both positive like, improvements in quality of life, increase in productivity as well as negative outcomes like community apprehensions, misconceptions, etc. Health impact assessment is a combination of procedures, methods and tools by which a policy, programme or project may be judged as to its potential effects on the health of a population and the distribution of those effects within the population. Health impact assessment may focus on projects such as new industry, hospital or health centre, programmes such as women’s empowerment or immunization of children, or policies such as ban on advertisement on tobacco in movies. On an international level, HIA can be employed to assess global public policies in areas such as international trade, war and human rights.

Health Impact Assessment (HIA) is based on four values-Democracy, Equity, Sustainable development and Ethical use of evidence. These values provide the foundation based on which the benefits of HIA can be derived and link HIA to the policy environment in which HIA is being undertaken.

Elucidation of these values explains the concept of HIA. By democracy is meant allowing people to participate in the development and implementation of policies, programmes or projects that may impact on their lives. By assessing the distribution of impact from a proposal or policy on the whole population, with a particular reference to how the proposal will affect vulnerable people (in terms of age, gender, ethnic background and socio-economic status), equity is ensured. By assessing short and long term impacts, sustainable development is ensured. The ethical use of evidence ensures the best available quantitative and qualitative evidence must be identified and used in the assessment. A wide variety of

evidence should be collected using the best possible methods.

Health impact assessment builds on the fact that a wide range of economic, social, psychological, environmental and organizational influences determines a community’s health. It is important to try to estimate these influences on health prospectively and so HIA should precede the start of the project, programme, or policy concerned.

The aims of prospective HIA are :

- To systematically assess the potential health impacts, both positive and negative, of projects, programmes and policies.
- To improve the quality of public policy decisions by making recommendations that are likely to enhance predicted positive health impacts and minimize negative ones.

The key output of a HIA is a set of recommendations for beneficially modifying a proposal so that its overall health impacts are enhanced and any potential health inequalities are minimized.

The Importance of Health Impact Assessment

Health impact assessment is an important public health method because of the following reasons :

- It promotes equity, sustainability and healthy public policies in a world which has unequal and different levels and perceptions of health.
- The quality of decision-making in health sector and of its partner organizations is improved by incorporating into the planning and policy-making process the need to address health issues.
- It emphasizes social and environmental justice as the disadvantaged sections of society and the world suffer the most from negative health impacts.
- It involves a multidisciplinary approach.
- Participation by the public is encouraged in debates about public health, planning and other public policy issues.
- Gives equal status to qualitative and quantitative assessment methods.
- Makes values and politics explicit and opens all issues to scrutiny.
- Demonstrates that health is a subject which is far broader than only health-care issues.
- Health impact assessment is used in public policy decision-making in a wide and rapidly increasing range of developed and less developed countries throughout the world.

Methods for Assessing Health Impacts

There are a wide range of methods used for HIAs which clearly reflect the nature and complexity of the subject. It is very important to use all methods and involve all disciplines that may contribute to the overall tasks. The methods commonly used are :

- Analysis of policies.
- Assessing the health profiles of affected areas/populations.
- Identification of potential positive and negative health impacts.
- Assessment of perceived health risks.
- Quantification and valuation of health impacts.
- Ranking the most important impacts.
- Consideration of alternative options and recommendations for management of desired impacts.

Participation in HIAs

The process of HIA requires broad participation of all disciplines and all stake holders to enable obtaining of a comprehensive picture of potential health impacts. Public participation throughout the HIA is essential, both to ensure that local concerns are addressed and for ethical reasons of social justice. The commonly sought participation includes :

- Those involved at all levels in the project.
- Those likely to be directly affected by the project.
- Others who have knowledge or information of relevance to the project and its outcomes
- Local or outside experts whose knowledge is relevant to the project.
- Relevant professionals including medical and paramedical workers, social workers or community workers.
- Voluntary organizations working in the field under assessment.
- Community participation adds value and credibility to HIA recommendations. The experiences of the local community are more important than routinely collected statistics. Undue reliance on quantitative methods may oversimplify the complexity of real life situations.

Reasons to Use HIA

Promotes cross-sectoral working : The health and wellbeing of people is determined by a wide range of economic, social and environmental influences. Activities in many sectors beyond the health sector influence these determinants of health. HIA is a participatory approach that helps people from multiple sectors to work together. HIA participants consider the impacts of the proposed action on their individual sector and other related sectors – and the potential impact on health from any change. Overlaps with other policy and project initiatives are often identified, providing a more integrated approach to policy making.

A participatory approach that values the views of the community : An initial stage within the HIA process is to identify the relevant stakeholders to the HIA. This process usually produces a large number of relevant people, groups and organisations. The HIA can be used as a framework to consult meaningfully with stakeholders, allowing their messages to be heard. The common stakeholders besides those who

commissioned the HIA are network of people and organisations who will carry out the HIA include the local community / public, specially the vulnerable groups, developers, planners, local/national government officials, voluntary agencies / NGOs, health workers at local, national or international levels, employers and representatives of workers' unions and representatives of other sectors that are affected by the proposal.

The best available evidence provided to decision makers:

The purpose of an HIA is to provide decision makers with a set of evidence-based recommendations about the proposal. The decision makers can then make decisions about accepting, rejecting, or amending the proposal secure in the knowledge that they have the best available evidence before them. HIA should consider a range of different types of evidence – going beyond published reviews and research papers, to include the views and opinions of key players who are involved or affected by a proposal. Often, evidence of the quality and quantity demanded by decision makers is not available, this is noted within the HIA and the best available evidence is provided.

Improves health and reduces inequalities : Addressing inequalities and improving the health of its community or population is a goal for many organisations and all Governments. One way of contributing to the planning of policies to improve health and overcome inequalities is through the use of HIA. It also ensures that proposals do not inadvertently damage health or reinforce inequalities. HIA provides a systematic approach for assessing how any new proposal can affect a population - specially, the distribution of those effects among the different subgroups of the population. Recommendations can specifically target improvement of health, particularly for vulnerable groups.

Appropriate for policies, programmes and projects : HIA is suitable for use at many different levels. HIA can be used on projects, programmes and policies, though it has most commonly been used on projects. The flexibility of HIA allows these projects, programmes and policies to be assessed at either a local, regional, national or international level – making HIA suitable for almost any proposal. Therefore, choosing when to carry out an HIA is important.

Timeliness : In order to be able to influence the decision making process, the HIA recommendations must reach the decision makers well before any decisions about the proposal will be made. This basic principle of HIA highlights the practical nature of the approach. Experienced HIA practitioners can work with most timeframes, undertaking comprehensive HIAs, which may take a longer time or a rapid HIAs.

Links with sustainable development and resource management : When HIA is undertaken early in the development process of a proposal it can be used as a key tool for sustainable development. For example, for an HIA on road building, it enables the inclusion of health and other sustainability aspects to be built in from the very beginning, such as cycle lanes, noise and speed reduction interventions, crossings, pedestrian over bridges, etc rather than solving the health impacts like accidents at a later date. This enables health objectives to be considered on a par with socio-economic and environmental objectives, bringing sustainable development closer.

Many people can use HIA : HIA because of being participatory in approach, has many potential users which include decision makers who may use the information for making decisions; Commissioners of the HIA, who use it to consult widely and gather differing views to build capacity and develop strong partnerships; HIA workers, who actually carry out the individual components of the HIA, which may include consultants, local staff from a wide variety of organisations and the community and finally the Stakeholders, who want their views to be considered by decision makers.

The HIA Procedure

1. Identifying if an HIA should occur – Screening : It is not possible to carry out an HIA on every project, policy or programme. Therefore screening is used to systematically decide when to do an HIA. Although ideally screening of each planned proposal should be conducted to assess whether an HIA should be conducted, in practice it is usually not followed due to resource and organisational issues. Screening only works when there is organisational commitment to HIA – where management allows the time and resource to screen each project, policy or programme. Typically, the decision to carry out an HIA occurs because a significant project is occurring and someone (the developer, the public, local public health, planners, etc) thinks an HIA would be a good idea. At other times funding is received for carrying out an HIA and a single topic is chosen.

2. Identifying what to do and how to do it - Scoping : Scoping sets the boundaries for and considers how the HIA appraisal stage should be undertaken. Some typical scoping issues which need to be considered are :

- Who will do the HIA and who will be in charge.
- Are there any specialists or practitioners who could be involved ?
- What monitoring and evaluation of the HIA will occur.
- When does the HIA have to be done by, to influence key decision makers (often influencing the choice of whether a rapid or comprehensive HIA is undertaken).
- Setting and agreeing the aims and objectives of the HIA

The terms of reference for the HIA are often drawn up at this stage to clarify exactly what is expected from whom. The HIA may be conducted as a Rapid HIA where the appraisal stage is carried out quickly (often only in days/weeks) with a limited amount of resource, or else a Comprehensive HIA, in which an extensive appraisal is conducted, where new information is generated, significant literature reviews undertaken and comprehensive involvement of stakeholders often occurs. This may take several months or longer.

3. Identifying the health hazards and considering the evidence of impact - Appraisal : This is where a large amount of HIA work is carried out. The work usually begins with a panel of experts to guide the assessment process who examine the proposal in detail. The panel can draw on a variety of documents that may include information on a number of determinants of health including social and economic issues, besides other relevant issues. Specific health hazards and diseases in the defined area would also need to be listed. The relationships between the determinants of health and key elements of the

proposal are then investigated (often laid out in a table/grid like fashion for clarity). Normal procedures for collecting field data may not be used at all times and improvisations conducted to suit the specific requirements. Normally within an HIA the best available qualitative and quantitative evidence would be collated using a range of methods, including interviews, focus groups, surveys and community profiling. However, if these are not possible for various reasons or constraints, secondary analysis of existing data to estimate the likely number of deaths per year from the most important health and safety risks can be conducted to rank important health risks. Identification and description of the type and size of health impacts (both positive and negative) is typical of the appraisal stage of HIA.

4. Developing recommendations to reduce hazards and / or improvement of health- Reporting : A key output of HIA is the set of recommended changes to the proposal. Recommendations are provided in a formal report to the decision-maker and delivered in good time. The stakeholders' views are clearly set out within the recommendations made. Decision makers are provided with recommendations that cover all of the possible decisions that could have been taken. If there are any conflicting impacts, these are acknowledged. Consideration is also given to provide a feed back of the outcome of the HIA to the community.

5. Evaluation and monitoring - Monitoring : Evaluating whether the HIA has influenced the decision making process (and the subsequent proposal) is an important component of HIA. As with any intervention, evaluation is required to see if it has worked. Monitoring the implementation of the proposal is critical to ensure that any recommendations that decision-makers agreed to, actually occur. Longer term monitoring of the health of populations is sometimes a component of larger proposals. This long term monitoring can be used to see if the predictions made during the appraisal were accurate and to see if the health, or health promoting behaviours, of the community have improved.

The Impact of HIA

Health impact assessment has now been carried out on a number of major policies, programmes and projects and has had significant influence on policy-making and planning. Examples include the Greater London Assembly's HIA programme, the Fintongley airport study conducted by Doncaster Health Authority (which for the first time in the UK incorporated the establishment of an independent airport health impact group into the regulatory framework for an airport) and the St Helens and Knowsley PFI study which was instrumental in attracting significant additional financial investment in the scheme at reduced interest rates from the European Investment Bank. At a global level, the World Health Organisation has appointed a HIA adviser at its Geneva Headquarters and has published a special issue of its Bulletin on HIA. The WHO has also played a major role in promoting the consideration of health within Strategic Environmental Assessment (SEA). These actions reflect the importance ascribed to HIA in health care management by the world body.

Health impact assessment is also increasingly used by global agencies such as the World Bank and by multinational corporations.

Even in developing countries, poverty reduction strategies are among the most structured ways of developing investment policies and HIA has been recommended to be an ideal way to support these strategies and integrate economic and social activities with health concerns.

Summary

'Impact' in public health refers to overall totalistic effect of an intervention. Assessment of health impact combines procedures, methods and tools by which a policy, programme or project may be judged as to its potential effects on the health of a population. HIA is based on 4 values - Democracy, Equity, Sustainable development and Ethical use of evidence. Ideally, HIA should precede start of project, programme or policy concerned. The aims of prospective HIA are to systematically assess potential health impacts and to improve quality of public policy decisions by making suitable recommendations. The methods commonly employed for HIA are- analysis of policies, assessing the health profiles of affected population, identification of potential positive and negative health impacts, assessment of perceived health risks, quantification & valuation of health impacts, ranking impacts and consideration of alternative options. HIA requires broad participation of all disciplines concerned to obtain comprehensive picture of potential health impacts. HIA has now been carried out on number of major policies, program and projects and has had significant influence on policy making and planning. It is being increasingly used by global agencies viz WHO, World Bank and by multinational corporations. HIA has been recommended to be ideal way to support strategies used by most of them.

Study Exercises

MCQs and Exercises

1. Which are the four values on which health impact assessment is based ?
2. Enumerate the aims of prospective HIA.

3. What are the possible methods of assessing health impacts?
4. Health Impact assessment is a _____ approach.
5. Potential users of HIA includes _____
(a) Decision makers (b) Commissioners of HIA (c) HIA workers (d) Stake holders (e) All the above
6. Highlight the difference between Rapid HIA and Comprehensive HIA
7. Strategic environmental assessment is a concept of HIA implemented by which international organization?

Answers

1. Democracy, Equity, Sustainable development and Ethical use of evidence.
2. (I) Systematic Assessment of potential health impacts
(II) Improve quality of public policy decisions by making suitable recommendations
3. Methods commonly used are : Analysis of policies; Assessing the health profiles of affected areas/ populations; Identification of potential positive and negative health impacts; Assessment of perceived health risks; Quantification and valuation of health impacts; Ranking the most important impacts; Consideration of alternative options; Recommendations for management of desired impacts.
4. Participatory
5. e.
6. Rapid HIA is one in which appraisal stage is carried out quickly- in days and weeks with limited resources where as comprehensive HIA is the one in which extensive appraisal is conducted, new information is generated, significant literature reviews are undertaken and there is comprehensive involvement of stakeholders.
7. WHO.

Further Suggested Reading

1. Assessing health impacts on a population. Alex Scott-Samuel, Kate Ardern and Martin Birley in Oxford Handbook of Public Health Practice. 2nd ed, 2007. 42-55

Amitava Datta

The definition of a community can have many interpretations such as a neighbourhood, or a collection of people in similar geographical circumstances. A community also refers to a group of people who share the same stakes and common interests. Epidemiological methods can be used to assess the condition of the people living in a community or defined geographical area. Indices can be produced of the health and wellbeing and

the character and dimensions of the problems can be charted. The process of diagnosing the health, health related problems and their determinants, in a community is called community diagnosis. In some contexts it has also been considered to be the methods which enable communities in developing a consensus about the priority health problems in their individual communities and developing strategies to address the issues identified. The completion of the *Community Diagnosis process* should answer the following questions for the community :

- Where is the community now?
- Where does it want to be?
- How will it get there?

There are several ways to obtain information for the diagnosis of communities including routine health facility reporting, screening, surveillance, special large scale surveys, contact tracing and population census. These methods vary depending on the objectives, investment and utilities available.

The overall objective of community diagnosis is to estimate the magnitude of the health problems and the determinants as well as to analyse trends and changing paradigms of these problems and determinants. Because the community consists of heterogeneous groups, the overall objective may need to be expanded to include many value laden issues such as health needs and determinants, equity, responsiveness to expectation, efficacy, protection of individuals and fairness. The diagnosis of the state of health of a community must also be dynamic as there are continuous changes happening. The results of the community diagnosis process can then be used as evidence for discussion among the stakeholders in the community, balancing the views of the stakeholders in setting priorities and making decisions for resource allocation which are acceptable to the community. The priorities and decisions for control should take into account not only the current status but also the impact that controls may have on health of future generations. The priorities and decisions for control depend not only on the indicators used for the diagnosis but also on the expressed values of a health system.

Types of Health Information Needed for Planning Health Care

Health situations and needs : Planning of health care of any community will need to start from simple descriptions of the state of health of the community or presence of illnesses. The socio- demographic distribution of the diseases and conditions will help assess the “needs”.

Availability of resources to deal with those needs including the various approaches to organizing and financing of the resources : The availability of health resources determines the relative ability to cope with the requirement and “needs” of the community and setting of priorities for allocation of resources.

The accessibility and utilization of existing health resources: This is important to determine the type of services which will be most appropriate for the community and therefore can be considered for provision.

Impact on health outcomes : The planned outcome will play an important role in determining what health services or facilities need to be provisioned.

Consequences of health care financing on politics, economy and society as well as on the welfare of the entire population: Health is central to the overall development of any community. The outcomes in the non – health field in a community which can be also expected because of improved health can provide additional bargaining support while requesting for resources for the planned health interventions.

General Framework for Community Diagnosis

Defining the community : The first task to be considered when it is planned to define health and disease in a community is to define the target community – country, province, district, or

state but might be a more defined geographical region such as urban inner city or a socially defined group such as poor communities, women in reproductive group, pregnant mothers, infants, young adults, elderly, etc. If not properly defined there may be a chance of over representation of sub groups from who it is easy to obtain data.

Health indicators : Definition of indicators is a pre-requisite for the development of an effective information system in community diagnosis. They should reflect both the positive (as SMPH) and negative (as IMR) aspects of health status. Positive health measures have been less used in developing countries as these populations are more likely to be satisfied with poorer health. Concept of burden of risk can be brought to the notice of public health officers. Mostly the health indicators are oriented to the negative aspect of health because of ease of measurement. Details of various indicators in community health practice are dealt with in another chapter on “measures of health and disease in community health”.

Sources of information and the methods that can be used for community diagnosis : A variety of information regarding the health status of a community is available from existing health system records. Depending on the type of information required specific surveys may need to be conducted to gain the desired information if not available from existing health system records. Some of the sources which can be considered for obtaining information about the community are as follows:

- Routine reporting from health facilities
- Surveillance – active and passive and sentinel surveillance
- Screening of the community
- Surveys
- Vital registration of events
- Combination of several methods

Trend analysis : Information regarding various health parameters can be obtained and analysed regarding changes over a period of time. Various aspects like demographic transition, urbanization, economic transformation, politics, globalization, etc may impact on the health status of a community. Trend analysis can be conducted to assess the changes in a community of the health situation, burden of illness, prevalence of risk factors and many other factors.

Characteristics of community diagnosis : Basis of Community Diagnosis is to assess the health situation in the community including its dimensions and determinants besides whether the community has achieved the objectives proposed by the health policies and programmes in use. There are several desirable characteristics in the Community Diagnosis process which are enumerated as follows :

- Ability to address important community problems which are amenable to practical control.
- Ability to identify most of the targeted health events.
- Adequacy in reflecting changes in distribution of events over time, place and person.
- Having a clearly defined population, data collection, data flow, analysis, interpretation and feedback.
- Orientation towards appropriate action.
- Being participatory, uncomplicated, sensitive, timely and inexpensive.

Sources of Information and Methods for Community Diagnosis

The various important sources of obtaining information have been enumerated above and have been dealt with in detail in an exclusive chapter on “sources of information in epidemiology”. Readers are advised to go through the same.

Steps in Conduct of Community Diagnosis

There are no clearly laid down chronological steps in the conduct of a community diagnosis program. Several short cuts can be easily taken to achieve the desired results. However, when time and resources permit a thorough study, the various steps involved may be considered to be as follows :

Step 1 - Establishing a Community Diagnosis Team : The first step is to establish a Community Diagnosis Team who will lead the assessment process. This group should consist of motivated individuals who can act as advocates for a broad range of community members and can represent appropriately the concerns of various populations within the community.

Step 2 - Analyzing the existing Health Data : The Community Diagnosis Team will compare the community’s health statistics with those of the district, state or national figures to identify possible health problems in the community.

Step 3 - Collecting Community Data : Data will be collected from the community on health issues of interest, especially those that go beyond the information available in the existing community or health system records. The necessary data can be conducted using specially devised Community Health and Opinion Survey Questionnaire, conducting Focus Group Discussions with community members and obtaining data from the Health Resources Inventory (if it exists). Community surveys take a lot of time and it may not be possible to implement all of these data collection efforts before the reporting deadlines. These tools may be employed at any time, since community health assessment should be an ongoing process.

Step 4 - Combining existing Health Statistics With Community Data : The Community Diagnosis Team will review the data from Steps 2 and 3 in detail. By the end of this phase, one will have a basic understanding of the community’s major health issues including comparison with other communities.

Step 5 - Choosing Health Priorities : Community Diagnosis Team will determine the priority health issues which will need to be addressed in the community based on the data collected and analysed.

Step 6 - Developing the Community Health Action Plan : Community Diagnosis Team will develop a plan of action for addressing the health issues deemed as priorities in Step 5. Developing of appropriate and effective health interventions and prevention activities is the basic idea behind the community diagnosis exercise.

Step 7 - Measuring Environmental and Policy Changes : The Community Diagnosis Team will do some advance planning about evaluating the success of the interventions developed in Step 6. A particular focus of this step is on collecting community-level indicator data to document the extent to which the community is making changes to improve health.

Step 8 - Creating the Community Diagnosis Document : Community Diagnosis Team will develop a stand-alone report to document the process as well as the findings of the entire assessment effort. The purpose of this report is to share the assessment results and plans with the entire community and other interested stakeholders. At the end of this step, the community will be ready to move from assessment to action by implementing the Community Health Action Plan developed in Step 6.

Limitations of Community Diagnosis

The process of community diagnosis as a solution to assessing the problems of the community and instituting appropriate interventions based on the findings has its limitation in ability to provide valid inputs to enable prioritizing health care facilities and interventions. The effects of health problems of individuals on their relatives cannot be assessed so simply. For example, all deaths are not equal in effect. Death of a person who is the sole earning member in the family has catastrophic effects which cannot be compared with the death of any other member of the family. The community will need to be consulted regarding their perceptions of values to assess the correctness of community diagnosis in these circumstances. The principles of community diagnosis are however valid in laying the foundation for appropriate public health interventions specially in the settings of developing countries where multiple health problems are vying for attention of politicians and health administrators for allocation of scarce resources.

Summary

The process of diagnosing the health and health related problems of a community is called community diagnosis. The overall objective of community diagnosis is to estimate the magnitude of health problems and the determinants as well as to analyze changing trends of these problems and determinants. There are several ways to obtain information for the diagnosis of communities including routine health facility reporting, screening, surveillance, special large scale surveys, contact tracing and population census. The health information required for planning health care includes information on health situations and needs, available resources, organizational capacity, impact on health outcomes and consequences of health care financing on politics, economy and society as well as on the welfare of entire population. Various sources of information commonly utilized are routine reporting from health facilities, active and passive surveillance, screening of community, special and rapid surveys conducted to obtain same. The priorities for policy decisions should take into account not only the current status but also the impact that policies may have on health of future generations.

Study Exercises

Exercises

1. The process of diagnosing the health, health related problems and their determinants, in a community is called _____ .
2. The overall objective of community diagnosis is to estimate the magnitude of the health problems and the determinants as well as to analyse trends and changing paradigms of

- these problems and determinants. True/False
- The diagnosis of the state of health of a community is static as there are no changes happening. True/False
 - Positive health measures have been less used in developing countries as these populations are more likely to be satisfied with poorer health. True/False
 - Information regarding various health parameters can be obtained and analysed regarding changes over a period of time, this is referred to as

Answers : (1) Community diagnosis; (2) True; (3) False; (4) True; (5) Trend analysis

Ethics in Public Health, Health and Human Rights

Amitava Datta

Ethics has been defined as “a set of principles of right conduct”. In the medical sense, it has also been defined as “the principles and norms of proper professional conduct concerning the rights and duties of health care professionals themselves and their conduct toward patients and fellow practitioners, including the actions taken in the care of patients and family members”.

The ethical practice of health dates back to ancient times. The Hippocrates oath administered to all practitioners of medicine was the start of the formalization of ethical medical practice. The concept of “bioethics” however took birth due to the experiences of the Second World War and the atrocities conducted in the name of medical research by Nazis among inmates of concentration camps. The vulnerability of human beings to being subjected to medical research against their wishes was highlighted by the experiences of the inmates and findings of the Allies after Germany surrendered in 1945. A code of conduct for human research, namely the Nuremberg Code was established. In 1964, the World Medical Association Declaration of Helsinki took this process a step further and underscored 12 basic principles for the conduct of human biomedical research (Details are given in Box-1 towards the end of this chapter). However, these principles were largely physician oriented and did not directly address the issue of research in developing countries. The issue of research in developing countries was eventually taken up by the Council for International Organization of Medical Sciences (CIOMS), which in collaboration with WHO, proposed guidelines for international research. The guidelines were further amended in 1993 as the International Ethical Guidelines for Biomedical Research involving human subjects. The rapid advances in medicine, including reproductive health, organ transplantation and genetics, raised questions about the purpose and limits of medical technology. In recent years, there have been efforts to broaden the scope of ethical analysis in health care to focus more directly on public-health issues.

What is Public Health Ethics

Public health ethics can be subdivided into a field of study and a field of practice. As a field of study, public health ethics seeks to understand and clarify principles and values which guide public health actions. Principles and values provide a framework for decision making and a means of justifying decisions. Because public health actions are often undertaken by governments and are directed at the population level, the principles and values which guide public health can differ from those which guide actions in biology and clinical medicine (bioethics and medical ethics) which are more patient or individual-centered.

As a field of practice, public health ethics is the application of relevant principles and values to public health decision making. In applying an ethics framework, public health ethics inquiry carries out three core functions :

- Identifying and clarifying the ethical dilemma posed.
- Analyzing it in terms of alternative courses of action and their consequences.
- Resolving the dilemma by deciding which course of action best incorporates and balances the guiding principles and values.

Public health ethics thus focuses on the design and implementation of measures to monitor and improve the health of populations. This is in contrast to the traditional emphasis of bio-ethicists on the physician–patient relationship. Public-health ethics also looks beyond health care to consider the structural conditions that promote or inhibit the development of healthy societies.

Issues in Public Health Ethics

Who is Responsible for Health?

The conflicting views on ethics in the field of public health arise due to differing perceptions regarding responsibility for health. The wide spectrum of views has at one end the view, that it could be purely a matter of individual choice. On the other extreme, responsibility for health could be completely delegated to government. The central dilemma, therefore in public health is to balance respect for individual freedom and liberty with the responsibility of governments to provide their citizens with some degree of protection in relation to health.

The role of the government has been evolving over a period of time. Today, very few would argue against state sponsored fortification of bread or pasteurization of milk. However many of the interventions to prevent the so called “lifestyle choices” leading to arising of risk factors of killer diseases like ischemic heart disease, lung cancer, chronic obstructive pulmonary disease and diabetes mellitus are still contentious depending on the country involved. It is common knowledge that the so called “choices of lifestyle” are often constrained by actions of others like industry and government as well as socio-economic, environmental and genetic factors. In traditional bioethics, much emphasis is placed on the freedom of the individual. However, in public health policy, some measures might constitute minor infringements of a person's freedom but bring about significant benefit for a large number of people. The western world with democratic traditions would recommend that governments should not coerce their people or restrict their freedom unnecessarily. However, these same governments are also expected to provide the conditions under which people can lead healthy lives. “Tobacco smoking” lends itself easily as an example. By banning advertisements by tobacco companies and restricting the availability to children, the governments are discharging their role in harm reduction to vulnerable citizens while still permitting their citizens their right to smoke tobacco.

Disparities in Health Status in Different Parts of the World

It is an accepted fact that resource allocation depends in part on value judgments about the relative importance of small improvements in quality of life for a large portion of the population as compared with a life-saving intervention that would benefit only a few people. Most of the developing countries have very poor state of health of their citizens. They look towards the affluent nations and philanthropic agencies for economic and technological aid to alleviate the sufferings of their citizens. Most inter governmental economic aid is however conditional to the use of services provided through companies of the donor country, which may exploit the situation for economic gain rather than philanthropy. The astronomical and unjustifiable gains of some pharmaceutical companies, from sale of life saving drugs, are well documented. Governmental health policies may become dictated by the donor of funds rather than from perceived need.

Disparities in Access to Quality Health Care and the Benefits of Medical Research

Many of the clinical researches being conducted in the world have used subjects who may have nothing to gain from the research. Medical research is one of the most contentious issues in public health today. Even in the developed world, discriminations against the deprived communities have been documented in literature and have raised ethical concerns. The existing ethical norms need to be guided more by the need and circumstances of individual nations (especially developing countries) rather than be exceedingly idealistic and moralistic in their approach. The Global Forum for Health Research has pointed out that less than 10% of the world's research resources are earmarked for 90% of the health problems. If a country's

health research system could be regarded as the “brain” of its health system, then ethics would constitute its “conscience”. It is imperative that health research systems function to the highest aspirations of ethics and distributive justice.

Responding to the Threat of Infectious Diseases

Efforts to contain the spread of infectious diseases raise difficult questions about the appropriateness of restricting individual choices to safeguard other people's welfare. Examples include the use of isolation and quarantine for tuberculosis, yellow fever, SARS and pandemic influenza.

International Co-operation in Health-Monitoring and Surveillance

The international context also matters in the case of infectious diseases, since infections do not respect national borders. Countries also differ in their capacities to monitor and respond to outbreaks. Therefore, developed countries have obligations to assist developing ones, for example in terms of enhancing surveillance capacity. At the same time, developing countries have obligations to cooperate with international surveillance and control efforts. The implementation of the International Health Regulations reflects the commitment of countries to collective action in the face of public-health emergencies. Defining the scope of countries' obligations to act collectively and determining how those obligations should be enforced, will inevitably raise difficult ethical dilemmas.

Exploitation of Individuals in Low-Income Countries

Current practices in medical research, for example, may expose participants to significant risks without a benefit for themselves or their communities. Defining and enforcing foreign research sponsors' obligations to local participants is therefore a critical ethical issue. In the area of organ transplantation, the growing practice of “transplant tourism” exposes individuals living in poverty to significant health risks while also raising broader questions about the commodification of the human body.

Participation, Transparency and Accountability

As an ethical matter, the process by which decisions are made is as important as the outcome of the decisions. In the area of medical research, much attention has been devoted in recent years to strengthening systems for informed consent and community oversight. Once such systems are in place, the next step will be to develop mechanisms for evaluating their effectiveness.

Medical Research in Developing Countries

The ethical issues in conduct of medical research on public health in developing countries need special attention. This aspect is deliberated in detail in the section on epidemiology and research methodology.

The recent landmark trial in Gadchiroli, India, makes an interesting case in point which clearly elucidates the above concerns. The trial evaluated domiciliary neonatal care with community-based health workers administering oral trimethoprim-sulfamethoxazole and twice-daily gentamicin to newborn infants with suspected sepsis. A control population was used for comparison and the researchers were able to demonstrate a 72% reduction in neonatal mortality using this

approach. This study would have raised ethical questions by most existing standards, since it involved a control population and also used an experimental protocol, when the “national standard of care” for suspected neonatal sepsis was intravenous antibiotics and supportive care. The authors, Bang et al, went through an elaborate scientific and ethical review process prior to the study, involving national experts and the Indian Council for Medical Research. The researchers were also able to get community concurrence to participate in this study, in a situation where even the national “standard of care” was not available to the participants. The benefits of the study for the local people (in terms of improved neonatal survival) and its impact on national and global programmes for neonatal care have been enormous. Taking an extreme position on the “standards of care” would have required that the study only be conducted with a control arm that received neonatal intensive care and expensive intravenous antibiotics, neither of which are sustainable even in urban settings in India. Thus, the study could not have taken place. The Gadchiroli trial vindicates the position of public health researchers that each developing country deserves the chance to develop health care interventions that suit local socio-cultural and economic means.

Principles of Ethical Public Health Practice

The Public Health Leadership Society in 2002 has published a code of ethics for the ethical practice of public health based on the definition of health as advocated by WHO. The salient features which explicitly enunciate the current basic understanding of the ethical practice of public health are as follows. The detailed elaboration of each of these principles is being given in detail subsequently.

1. Public health should address principally the fundamental causes of disease and requirements for health, aiming to prevent adverse health outcomes.
2. Public health should achieve community health in a way that respects the rights of individuals in the community.
3. Public health policies, programs and priorities should be developed and evaluated through processes that ensure an opportunity for input from community members.
4. Public health should advocate and work for the empowerment of disenfranchised community members, aiming to ensure that the basic resources and conditions necessary for health are accessible to all.
5. Public health should seek the information needed to implement effective policies and programs that protect and promote health.
6. Public health institutions should provide communities with the information they have that is needed for decisions on policies or programs and should obtain the community’s consent for their implementation.
7. Public health institutions should act in a timely manner on the information they have within the resources and the mandate given to them by the public.
8. Public health programs and policies should incorporate a variety of approaches that anticipate and respect diverse values, beliefs and cultures in the community.
9. Public health programs and policies should be implemented in a manner that most enhances the physical and social

environment.

10. Public health institutions should protect the confidentiality of information that can bring harm to an individual or community if made public. Exceptions must be justified on the basis of the high likelihood of significant harm to the individual or others.
11. Public health institutions should ensure the professional competence of their employees.
12. Public health institutions and their employees should engage in collaborations and affiliations in ways that build the public’s trust and the institution’s effectiveness.

Notes on the Individual Ethical Principles

1. This principle gives priority not only to prevention of disease or promotion of health, but also at the most fundamental levels. Yet the principle acknowledges that public health will also concern itself with some immediate causes and some curative roles. For example, the treatment of curable infections is important to the prevention of transmission of infection to others. The term “public health” is used here and elsewhere in the Code to represent the entire field of public health, including but not limited to government institutions and schools of public health.
2. This principle identifies the common need in public health to weigh the concerns of both the individual and the community. There is no ethical principle that can provide a solution to this perennial tension in public health. We can highlight, however, that the interest of the community is part of the equation and for public health it is the starting place in the equation; it is the primary interest of public health. Still, there remains the need to pay attention to the rights of individuals when exercising the police powers of public health.
3. A process for input can be direct or representative. In either case, it involves processes that work to establish a consensus. While democratic processes can be cumbersome, once a policy is established, public health institutions have the mandate to respond quickly to urgent situations. Input from the community should not end once a policy or program is implemented. There remains a need for the community to evaluate whether the institution is implementing the program as planned and whether it is having the intended effect. The ability for the public to provide this input and sense that it is being heard is critical in the development and maintenance of public trust in the institution.
4. This principle speaks to two issues : Ensuring that all in a community have a voice; and underscoring that public health has a particular interest in those members of a community that are underserved or marginalized. While a society cannot provide resources for health at a level enjoyed by the wealthy, it can ensure a decent minimum standard of resources. The Code cannot prescribe action when it comes to ensuring the health of those who are marginalized because of illegal behaviors. It can only underscore the principle of ensuring the resources necessary for health to all. Each institution must decide for itself what risks it will take to achieve that.
5. This principle is a mandate to seek information to inform

actions. The importance of information to evaluate programs is also implied.

6. This principle is linked to the third one about democratic processes. Such processes depend upon an informed community. The information obtained by public health institutions is to be considered public property and made available to the public. This statement is also the community-level corollary of the individual-level ethical principle of informed consent. Particularly when a program has not been duly developed with evaluation, the community should be informed of the potential risks and benefits and implementation of the program should be premised on the consent of the community (though this principle does not specify how that consent should be obtained).
7. Public health is active rather than passive and information is not to be gathered for idle interest. Yet the ability to act is conditioned by available resources and opportunities and by competing needs. Moreover, the ability to respond to urgent situations depends on having established a mandate to do so through the democratic processes of Ethical Principle number three.
8. Public health programs should have built into them a flexibility that anticipates diversity in those needs and perspectives having a significant impact on the effectiveness of the program. Types of diversity, such as culture and gender, were intentionally not mentioned. Any list would be arbitrary and inadequate.
9. This principle stems from the assumptions of interdependence among people and between people and their physical environment. It is like the ethical principle from medicine, "do no harm", but it is worded in a positive way.
10. This statement begs the question of which information needs to be protected and what the criteria are for making the information public. The aims of this statement are modest : to state explicitly the responsibility inherent to the "possession" of information. It is the complement to Ethical Principles 6 and 7, about acting on and sharing information.
11. The criteria for professional competence would have to be specified by individual professions, such as epidemiology and health education.
12. This statement underscores the collaborative nature of public health while also stating in a positive way the need to avoid any conflicts of interest that would undermine the trust of the public or the effectiveness of a program.

Summary

Ethics has been defined as a 'set of principles of right conduct'. The landmarks in ethical practice of health dates back to the Hippocratic oath, 'Concept of Bioethics' arising out of atrocities of Nazi doctors and Germans during Second World War in the name of medical research, setting up of Nuremberg code for human research, followed by Declaration of Helsinki adopted at World Medical Assembly, Finland, 1964. The Council of International Organization of Medical Sciences (CIOMS) in collaboration with WHO established International Ethical Guidelines for Biomedical Research last amended in

1993. There are 3 core functions of public health ethics viz identifying the ethical dilemma posed, analyzing it in terms of alternative course of action and deciding best course of action. The Public Health Leadership Society in 2002 has published a code of ethics for ethical practice of public health based on definition of health as advocated by WHO constituting the 12 basic principles of ethical public health practice. Ethics has also been at the heart of WHO mission to protect & promote global community health. WHO's General Dr. Gro Harlem Brundtland created an 'Ethics and Intelligence Initiative', which has since served as a focal point for ethics activities throughout the organization.

Study Exercises

MCQs and Exercises

1. The Code of conduct for human research is called the ___.
2. The World Medical association Declaration of Helsinki took place in : (a)1954 (b) 1964 (c) 1974 (d) 1984.
3. The Global forum for health research has pointed out that < _____ % of the world's research resources are earmarked for _____ % of the health problems.
4. Clinical research cannot be legitimately carried out unless the importance of the objective is in proportion to the inherent risk to the subject. True/False.
5. The responsibility for clinical research is both for the researcher & the subject once the consent has been obtained from the subject. True/False.

Answers : (1) Nuremberg Code; (2) b; (3) <10%, 90%; (4) True; (5) False.

Box - 1 : Declaration of Helsinki

Recommendations Guiding Doctors in Clinical Research

Adopted by the 18th World Medical Assembly, Helsinki, Finland, June 1964

It is the mission of the doctor to safeguard the health of the people. His knowledge and conscience are dedicated to the fulfillment of this mission. The Declaration of Geneva of The World Medical Association binds the doctor with the words : "The health of my patient will be my first consideration" and the International Code of Medical Ethics declares that "Any act or advice which could weaken physical or mental resistance of a human being may be used only in his interest. "

Because it is essential that the results of laboratory experiments be applied to human beings to further scientific knowledge and to help suffering humanity, The World Medical Association has prepared the following recommendations as a guide to each doctor in clinical research. It must be stressed that the standards as drafted are only a guide to physicians all over the world. Doctors are not relieved from criminal, civil and ethical responsibilities under the laws of their own countries.

In the field of clinical research a fundamental distinction must be recognized between clinical research in which the aim is essentially therapeutic for a patient and the clinical research, the essential object of which is purely scientific and without therapeutic value to the person subjected to the research.

I. Basic Principles

1. Clinical research must conform to the moral and scientific principles that justify medical research; and should be based on laboratory and animal experiments or other scientifically established facts.
2. Clinical research should be conducted only by scientifically qualified persons and under the supervision of a qualified medical man.
3. Clinical research cannot legitimately be carried out unless the importance of the objective is out of proportion to the inherent risk to the subject.
4. Every clinical research project should be preceded by careful assessment of inherent risks in comparison to foreseeable benefits to the subject or to others.
5. Special caution should be exercised by the doctor in performing clinical research in which the personality of the subject is liable to be altered by drugs or experimental procedure.

II. Clinical Research Combined with Professional Care

1. In the treatment of the sick person, the doctor must be free to use a new therapeutic measure, if in his judgment it offers hope of saving life, reestablishing health, or alleviating suffering.
If at all possible, consistent with patient psychology, the doctor should obtain the patient's freely given consent after the patient has been given a full explanation. In case of legal incapacity, consent should also be procured from the legal guardian; in case of physical incapacity the permission of the legal guardian replaces that of the patient.
2. The doctor can combine clinical research with professional care, the objective being the acquisition of new medical knowledge, only to the extent that clinical research is justified by its therapeutic value for the patient.

III. Non-Therapeutic Clinical Research

1. In the purely scientific application of clinical research carried out on a human being, it is the duty of the doctor to remain the protector of the life and health of that person on whom clinical research is being carried out.
2. The nature, the purpose and the risk of clinical research must be explained to the subject by the doctor.
- 3a. Clinical research on a human being cannot be undertaken without his free consent after he has been informed; if he is legally incompetent, the consent of the legal guardian should be procured.
- 3b. The subject of clinical research should be in such a mental, physical and legal state as to be able to exercise fully his power of choice.
- 3c. Consent should, as a rule, be obtained in writing. However, the responsibility for clinical research always remains with the research worker; it never falls on the subject even after consent is obtained.
- 4a. The investigator must respect the right of each individual to safeguard his personal integrity, especially if the subject is in a dependent relationship to the investigator.
- 4b. At any time during the course of clinical research the subject or his guardian should be free to withdraw permission for research to be continued.
The investigator or the investigating team should discontinue the research if in his or their judgment, it may, if continued, be harmful to the individual.

Amitava Datta

Information is the basis for all planning processes and planning of public health measures for a community is no exception. Health information is generated both at the individual level (patient records from hospitals) as well as at the community level (surveillance systems, population surveys, outbreak reports, etc). The clinician requires detailed information about limited number of persons for clinical follow up. The needs of the public health analyst differs from that of his clinical colleague in that he needs information from large number of persons or patients but comparatively limited information about each person or patient. By the word data, we usually mean numerical information that is collected routinely and that is used to monitor health of the populations (surveillance data) or the activity of health-related services. In general, data tends to refer to numerical information which expresses information in terms of 'how many' and 'how much'. However epidemiology has clearly taught us that simply 'counts' do not allow meaningful comparisons. Public health data invariably has a numerator and a denominator besides preferably having a time dimension and is expressed as rates to enable comparisons with other communities or periods of time. Information can be considered to be the outcome of processing and evaluating raw data. The degree of processing required to turn data into information may depend on the level of expertise of the recipient.

The term evidence is used mainly in legal terms where it is used to describe the material which shows beyond a reasonable doubt that something has occurred. In public health, it is applied to knowledge obtained from research. It can be used for providing support to theory regarding etiology; for example, does iodine deficiency produce hypothyroidism or to what extent does the absence of fluorine in drinking water lead to dental caries. It can also be providing support for some planned or existing intervention; for example does the fortification of salt with iodine lead to reduction in number of mentally retarded children in a community. Evidence can be a mixture of numbers and words as compared to data which has only numbers. Evidence comes from many sources, is of variable quality and requires interpretation. This is also the case when considering empirical evidence, arising from observation or experiment.

Public health policy makers and health care managers require timely, useful and balanced information which is quantifiable and tangible for the diagnosis of health needs of a community, their trends and determinants with a view to achieve effective planning and monitoring of health care interventions. This information can be of three types - derived from research, that is evidence; derived from routinely collected data, that is statistics or derived from experience either from patients or of fellow professionals or other partner organizations.

Components of Information Systems for Planning Health Care

The major components of health care which will need systematic information for planning activities include information about health situations and needs, availability of resources to deal with those needs, organization and capacity to take those resources and convert them into services (that is conduction of system efficacy, effectiveness, efficiency, quality and decision analysis), variation of use and practice with their implication on equity to access and coverage, impact on health outcome and consequences of health care financing on politics, economy and society as well as on the welfare of the entire population. The users and contributors of information for health planning can be policy analysts, health care providers, epidemiologists, social scientists, economists, etc. Those who provide health services and have the task of being accountable for the services they provide should be involved with the development of information system. There are differences in the emphasis shown to the different components of health information system between developing and developed countries as well as depending upon the political system in the respective country.

Important Considerations in Providing Data and Evidence for Policy Makers

It is common knowledge that in the field of public health, as in other planning processes, there had been many occasions when there has been a mismatch between the generation of evidence and data and their communication to the right people in the right way at the right time. The many known reasons for this incongruity can be overcome with careful organization and preparation.

In the field of public health when we attempt to solve serious problems there is often a wealth of descriptive data about a population (like data obtained from routine surveillance system, data from special survey as well as anecdotal evidence from practitioners or professional bodies). However some times, (especially when a new disease appears), there may be too little information available, for example during the initial stages of the AIDS epidemic. In both circumstances however, rarely is information made available in a way that makes it easy for policy makers to take effective action. Some of the problems which have been identified in providing data and evidence for policy makers and needs consideration are as follows :

Availability of many types of knowledge : Data, evidence and best practice (obtained from professional bodies) often leads to confusion. The present confusion to decide which drugs to use in prevention of parent to child transmission of HIV is clearly an apt example. It is necessary to develop an organized approach to considering problems and suggesting solutions using a combination of 'content' and 'process'. Although there can be different sorts of knowledge, all of which can help in different ways, however, these must be critically evaluated before they are assembled and articulated in a clear balanced way. Anecdotes are powerful ways to raise issues but they need to be validated by data and evidence before they can be used to direct significant policy and action.

Information is not available in time : To be able to plan and implement public health policies information is required within

stipulated time frame. Most policy makers are constrained by time schedule beyond which the policy making cannot be kept pending. In India for example, wherever governmental funds are to be committed, the information required to formulate policy and commit funds has to start several months before the start of a financial year and in case of major fund requirement, as much as five years before – in case the policy decision is required to be funded through the five year planning system. In the present age of computers, it is sometimes expected that simply on the click of a button, data and evidence will be generated. Unfortunately, this is far from reality except to generate data regarding some highly prevalent communicable diseases. Most public health data are expensive to collect but expense must not be made an excuse not to collect, analyse and present required data.

Lack of consistency in information definitions : The field of public health is extremely dynamic. The common examples are definitions for hypertension and diabetes mellitus. With better understanding of the risk posed, the definition of what is to be considered “hypertension” and “diabetes” needing therapeutic or other interventions has changed over the last decade. What may have been a mild problem in several geographical areas like states has suddenly become a “burning public health issue” once the new definition is applied. Similarly, there are debates and disagreements among professional bodies to arrive at consensus definitions. .

Lack of meaningful comparators : Many public health problems do not have adequate or appropriate comparators or indicators which allow comparison of the state of health due to the condition under consideration. This may be due to basic problems of ethnicity. The lack of protective effect due to BCG vaccine among Indians as compared with the demonstrated protective effect in other countries is based on evidence. The continued use of BCG in the national immunization program based on evidence of “reasonable” protection from childhood forms of tuberculosis provided by certain surveys does not allow for meaningful comparisons as there is paucity of data on this aspect. Comparators can be the crux of any analysis. The presentation of data should clearly indicate whether we need to be increasingly concerned, whether the magnitude of the problem is less or more than other comparable places, whether time trends are available, whether the change if any or rate of change is satisfactory, etc.

Solution-focused approach of knowledge : There are at times attempts to stress the ‘solution’ rather than the ‘problem’ while presenting analysis of data. For example in a bid to introduce Pneumococcal immunization in the national immunization schedule in India, the protective efficacy of one or more vaccines only is projected without assessing the magnitude and determinants of pneumonia in the country. The initiation of debate should have been with an assessment whether Pneumococcal pneumonia is indeed a problem in our country.

Lack of common language to describe domains : Concern for the health of their citizens is common among practitioners of public health as well as policy makers. However they may have different ideas of the relative importance of different health related problems as well as the means of overcoming them. It would be helpful if all concerned could be aligned in a similar

manner to address the public health problems. Communication of the information therefore has to be consistent in various presentations.

Communication of evidence in unhelpful ways : Even the most committed policy makers will be unable to generate the required policy change if problems are provided to them in a manner which is not conducive to easy understanding of the seriousness of the problem as well as the quantification of the improvement likely. Technical epidemiological terminology, like ‘absolute risk reduction’ though appropriate when used among professionals may be counter productive if used among not so knowledgeable professionals or non- medical persons. Use of simple terms like ‘how many children out of 1000 immunized with the proposed vaccine will be saved’ is likely to be as effective or even more than use of terminology like ‘risk reduction’. An inappropriate stress on evidence can be as damaging to a desired policy outcome as the wrong dose of a drug to a patient. The full range of available evidence (statistics, charts, meta-analyses, etc.) does not always need to be marshaled while communicating the seriousness of the public health problem and its suggested solution. The timing of the presentation of evidence is also very important. Provision of ‘exhaustive evidence’ after the negative policy making decision has occurred is of lesser use as compared to ‘adequate evidence’ before the decision making process. It would be appropriate to present the latter form in time rather than wait too long for the ‘perfect evidence’. It will also be pertinent to know who will receive the evidence- a public health specialist, a clinician, non-medical official or politician before deciding how to package and communicate the evidence. This will ensure a better appreciation of the problem at hand by the receiver of evidence.

Poor communication of information : The ability to convert data into evidence and subsequently convey it in an acceptable manner depends on many factors including capability, training, motivation and other interests of the persons responsible. Even though a problem may be considered to be requiring continued communication, there is a real danger of ‘over exposure’. The danger of military commanders becoming immune to the repeated pleas for attention to curb the STD and malaria incidence among soldiers, as documented to have happened during second world war are apt examples of this aspect needing consideration. Unforeseen reactions like some sub-sections of society rebelling and actually increasing their tobacco use only as an expression of their rebellion is also to be warded against. When economic considerations are likely to play an important role in the policy making process, it may be wiser to have fewer experts propounding the issues at regular intervals rather than attempting to rope in as many and diverse personalities. The use of cinema personalities, sports persons, politicians, etc in the campaign against tobacco use can be considered in this light.

Inability to balance harm, benefit and cost explicitly : The method of communicating data, information or evidence needs to be able to clearly elucidate the harm caused by an element, the benefit on removal of the element from society and the costs involved - direct and indirect in the intervention proposed. The most apt example is the continued debate on tobacco use over

a period of nearly half a century throughout the world. Tobacco does not cause immediate harm and hence users, lay public and policy makers need to have evidence of the cause and effect relationship of tobacco leading to harm, the gains from cessation of use of tobacco as well as stopping the initiation of tobacco use, besides the costs involved in implementing a policy for stopping the use of tobacco which needs to consider the losses to industry, the tobacco farmers, related industry as well as government (in terms of easy taxes). Similarly charging a token sum for the purchase of highly subsidized condoms in the family planning program needs to be considered before implementation. There is evidence that introducing user charges may reduce inappropriate attendance, but it might lead to an adverse impact on the most disadvantaged. At the clinical level, the well known example of suppressing ventricular ectopics in post myocardial infarction period actually increased the risk of sudden death rather than decreasing it. This was established only after careful research and stressed the importance of considering all potential harm as compared to benefits in any intervention.

Inadequate listening to the users : Many a times, information is provided in a sensational manner which attracts the attention of important community persons as well as policy makers. The discussion of HIV / AIDS among the women of a community who are more concerned about the problem of inadequate child health care facilities in the community is hardly likely to succeed. Similarly discussing the problem of child labour in an area with abject poverty may make for good media coverage to identify industries which employ child labour. This may in fact result in the denial of employment to a child but does nothing to take care of his need for this employment as a means of earning money for his and possibly also his family's needs. In the absence of organized social security, implementation of such public policies may only harm the individuals concerned and provide for exploitation of needy children. The key issue with data is to choose the right data (with the right comparators) that will change the particular minds (and hearts) of the people to whom we communicate. Before planning any health related communication, it is almost always a good investment of time and effort to seek to understand the perspective, anxieties and motivations of the people who are the targeted beneficiaries.

Policy makers often don't want evidence : In the field of public health especially, evidence may be unwelcome. It would be politically inappropriate for some evidences in the public health domain to be overlooked. However, constraints of funds may not permit allocations and hence delays in even consideration of needed policies. There are various organisations and individuals who focus their research and other activities only on certain fields of public health. The problems of lobbying activities are well established in western countries. Even in India, lobbies for assisted reproductive therapy vie for funds from policy makers in a country where the problem due to too many births is well recognized. However, good-quality evidence, well generated and explicitly disseminated, can make an issue less political as there may be less debate in the face of scientifically generated information. In case the available evidence is clearly against the known beliefs of the policy maker, then it will need careful planning by the public health

specialists about how you change the belief. However, in no case must spurious or biased evidence be fabricated to merely satisfy a policy position.

Evidence and data are usually, though not exclusively, provided to change and improve the quality of decision-making. A public health professional armed with good data and evidence and presenting in a well organized, skillful and confident fashion to raise and debate issues opportunistically, without the need to berate, harangue, or sermonize the audience, can be very effective in bringing about policy change. In the absence of good evidence on how best the available evidence can best be used to effect policy change, it is one of the major challenges in public health.

Summary

Information is the basis for all planning processes including public health. Health information is generated at the individual & the community level. The Public health analyst needs information from large number of persons, but needs limited information. Data refers to numerical information but to enable comparisons, information can be considered to be the outcome of processing & evaluation of raw data. Evidence refers to knowledge obtained from research, which can be used to provide support to theory regarding etiology or to some planned or existing intervention. It can be a mixture of numbers & words, come from many sources, is of variable quality & requires interpretation. Public health policy makers & health care managers require quantifiable & tangible information in the form of evidence, statistics or experience.

The components of information systems for planning health care need systematic information about health situations & needs, resources, organization, capacity to convert resources into services, impact on health outcome & consequences of health care financing.

In the field of Public health, rarely is information available in a way that it is easy for policy makers to take effective action. The problems that need consideration are :

- Availability of many types of knowledge
- Information not available in time
- Lack of consistency in information definitions
- Lack of meaningful comparators
- Solution – focused approach of knowledge
- Lack of common language to describe domains
- Communication of evidence in unhelpful ways
- Poor communication of information
- Inability to balance harm, benefit & cost explicitly
- Inadequate listening to the users
- Policy makers often don't want evidence

Evidence & data are usually provided to change & improve the quality of decision making. One of the major challenges in public health is to effect policy change in the absence of good evidence.

Study Exercises

MCQs & Exercises

1. Patient records from the hospitals is health information generation at community level : True/False

2. Health information generation at community level includes all except : (a) Surveillance system (b) Population surveys (c) Outbreak reports (d) None
3. Numerical information which expresses information in terms of 'how many' & 'how much' is referred to as _____
4. The outcome of processing & evaluating raw data is referred to as _____
5. The knowledge obtained from research is referred to as _____
6. Information can be in the form of : (a) Evidence (b) Statistics (c) Experience (d) All of the above
7. Information is rarely made available in a way that makes it easy for policy makers to take effective action : True/False
8. Which of the following are powerful ways to raise issues but aren't valid on their own : (a) Data (b) Evidence (c) Anecdotes (d) Policy
9. Spurious or biased evidence may be fabricated to satisfy a policy position : True/False
10. Policy makers often don't want evidence : True/False
11. 'Solution-focused' approach to knowledge is better than 'Problem-focused' approach : True/False

Answers

- (1) False; (2) d; (3) Data; (4) Information; (5) Evidence; (6) d; (7) True; (8) c; (9) False; (10) True; (11) False.

72 Making Public Health Policies

Amitava Datta

A policy is a deliberate plan of action to guide decisions and achieve rational outcomes. The term may apply to government, private sector organizations and groups and individuals. According to the Oxford English Dictionary, policy is 'a course of action or principle adopted or proposed by a government, party, individual, etc. , or any course of action adopted as advantageous or expedient'. Policy or policy study may also refer to the process of making important organizational decisions, including the identification of different alternatives such as programs or spending priorities and choosing among them on the basis of the impact they will have. Policies can thus be understood as political, management, financial and administrative mechanisms arranged to reach explicit goals.

Policy differs from rules or law. While law can compel or prohibit behaviors (e.g. a law requiring the payment of taxes on income) policy merely guides actions toward those that are most likely to achieve a desired outcome. Science and logic may help to identify public health problems and potential solutions, but emotion and power relationships determine whether anything is done about them.

Public policy-making is accepted to be 'political' and seldom driven by public health evidence. To achieve healthy public policy, it is necessary that timing and the relevance of evidence to policy are crucial. Evidence needs to support a practical programme of actions, but much public health research can be criticized for providing elaborate descriptions of problems rather than possible solutions. There is need for public servants who are equipped with critical appraisal skills to use evidence in policy development. The methodology of presenting evidence

for health policy use has been discussed in a different chapter. Many of the public debate on health issues is converted by the media into simplified notions of what each issue is really about. For example, to public health practitioners in USA, gun control is about saving lives, but to the gun lobby, opposing gun control is about limiting the power of the state and preserving the freedom of the individual. Framing of issues in the media is critical to how they are dealt with and understanding this process and responding directly to an adverse framing of an issue, can be critical to influencing policy and politicians.

Multi-national companies and global organizations can now have major influences on 'local' public health problems and public health practitioners must now both think and act locally and globally. Appreciating the full international picture behind modern public health challenges can help us focus on cause rather than symptoms.

Globally, public opinion and the media can be critical to getting public health issues onto the policy agenda and keeping them there. The importance of recognizing the task of influencing policy as a specific challenge of public health practice, as a challenge that requires an understanding of the policy-making process and the adoption of specific attitudes and skills are important considerations in framing public health policy. At most levels, getting public health issues into the mainstream of public debate and influencing public opinion is seen as a major challenge to public health practitioners.

Policy Making Process

Intended Effects : The goals of policy may vary widely according to the organization and the context in which they are made. Broadly, policies are typically instituted in order to avoid some negative effect that has been noticed in the organization, or to seek some positive benefit.

Policies frequently have side effects or unintended

consequences. Because the environments that policies seek to influence or manipulate are typically complex adaptive systems (e.g. Governments, societies, large companies), making a policy change can have counter-intuitive results. For example, a government may make a policy decision to raise taxes, in hopes of increasing overall tax revenue. Depending on the size of the tax increase, this may have the overall effect of reducing tax revenue by causing capital flight or by creating a rate so high; citizens may lose incentive to earn the money that is taxed.

The policy formulation process typically includes an attempt to assess as many areas of potential policy impact as possible, to lessen the chances that a given policy will have unexpected or unintended consequences. Because of the nature of some complex adaptive systems such as societies and governments, it may not be possible to assess all possible impacts of a given policy.

Policy cycle : In political science the policy cycle is a tool used for the analyzing of the development of a policy item. It usually includes the following stages :

- Agenda setting (Problem identification)
- Policy formulation
- Decision-making
- Policy implementation
- Policy analysis and evaluation (continue or terminate)

Agenda setting : Agenda setting, the most crucial step in initiation of new policy, occurs when policy makers identify a problem and develop broad goals to address it. In health care, examples of potential problems include rising health expenditures, an unexpected increase in problems include rising health expenditures, an unexpected increase in infant mortality, or an unexpected increase in the prevalence of a disease (e.g. AIDS). Health-care issues such as these must compete against other policy issues (such as national defence) to become national priorities and specific health issues must compete for attention with other health issues. Policy makers can focus on only a limited number of problems at any one time.

A considerable amount of effort is required to place an issue at the forefront of the policy-making agenda. Although different issues may be influenced by different ways and means, however in general, factors known to help place an issue on the political agenda are the following :

- Large number of people perceiving the existence of the problem.
- Perception of the severity of the problem by many.
- If the problem has occurred recently and is very unique or novel.
- Likely to affect individuals personally.
